Adhesion molecules [12, 13], either on the cell or in the extracellular matrix (see Chs 2 and 7), may also play an important role in neurite outgrowth, since they mediate neurite–neurite and neurite–glia interactions. The probability of outgrowth initiation, rate of elongation and degree of branching of neurites is strongly influenced by the adhesive quality of the substrate. Adhesion of growth cone structures may stabilize extensions. Growth cones may follow the path of greatest adhesiveness, leading to directional control over neurite outgrowth. The glycoprotein laminin, found in the extracellular matrix and on the surface of Schwann cells, can accelerate neurite outgrowth.

Neuron-glia interactions [14] may also be involved in outgrowth and synapse formation. Sympathetic neurons grown in the absence of Schwann cells extend unbranched, axon-like neurites; in the presence of glial cells, however, process outgrowth is extensively branched and dendrite-like in form. In CNS preparations, this interaction is further characterized by the specificity of the astrocytic environment: glia from local homotypic regions give rise to branched neurites and glia from heterotopic regions induce unbranched neurites.

Intracellular pathways are involved in the regulation of neurite outgrowth. Cyclic AMP (see CREB, Ch. 26) and inositol phospholipids have been implicated as intracellular regulators (see Chs 20 and 21). Work on the control of Ca^{2+} influx has helped to establish a causal relationship with neurite outgrowth: Ca^{2+} influx can regulate both neurite elongation and growth cone movements (see Ch. 22). Studies of invertebrate neurons and isolated growth cones suggest that, in the presence of various agents that inhibit neurite outgrowth, for example serotonin and electrical activity, the amount of free cytoplasmic Ca^{2+} is closely correlated with neurite outgrowth. Further support of Ca^{2+}-mediated control of neurite growth has been obtained from studies under conditions in which neurite outgrowth and Ca^{2+} influx could be directly manipulated. Data suggest that specific levels of Ca^{2+} influx promote normal neurite elongation and growth cone movements.

The basic cytoarchitecture of the cortex is the result of a plastic process of neurite outgrowth, as discussed above, relying on adhesion factors and control of terminal arborization, which can be dependent on neuronal activity (see also Ch. 30). The final lattice-like pattern of complex cortical circuitry and its computational capacity arise from a combination of selective and nonselective process outgrowth and synapse formation events coupled to regressive events, including selective cell death, process elimination and synapse elimination. These events can be activity-dependent or -independent processes. For example, the vertical connections in the cortex arise with little dependence on neuronal activity during development, whereas the horizontal connecting outgrowth is clearly regulated by evoked or spontaneous neural activity. Thus, the formation of cortical clusters is dependent on patterned visual activity; binocular deprivation can eliminate the clustered organization of the horizontal connections.

In the case of cortical cluster organization, selective elimination of collaterals, and not cell death, is the essential molding parameter.

In summary, a number of parameters of outgrowth initiation, elongation, branching and cessation combine to generate axonal or dendritic geometry. These components can be modulated *in vitro* by a variety of soluble and substrate-bound factors, suggesting that, *in vivo,* control over morphological differentiation is multifactorial.

MOLECULAR MECHANISMS OF DEVELOPMENT

Environmental factors control developmental decisions made by cells of each lineage. Diffusible growth factors (see Ch. 27) control the processes of proliferation and differentiation [1, 5, 9]. The discovery of NGF in the early 1950s began an era of remarkable success in developmental neurochemistry. Physiological effects of NGF can be classified as (1) an essential neurotrophic or nourishing influence during early development, resulting in selective neuronal survival; (2) a potent influence on neuronal differentiation; or (3) a strong neurotropic or guiding influence on direction of neurite growth. The main experimental strategy employed over the years to demonstrate the presence of the different activities of NGF has been to either block, via specific antibodies or drugs, or enhance, via addition of exogenous NGF, its actions. The survival and differentiation influences of neurotrophins are not unique. Since the mid-1980s, the existence of many other such factors has been reported (see Ch. 27). The sections of this chapter on cell lineages illustrate the rapidly growing understanding of the importance of growth factors and cytokines in neural cell development.

Genetic networks function in neural development. One of the most fascinating fields of research is the elucidation of the complex network of genetic information that controls development. The immense phenotypic diversity of the nervous system reflects the coordination of the numerous genetic programs that regulate cell-type-specific gene expression. How does a cell become responsive to a given set of environmental signals, encode this information into specific channels of intracellular transduction and regulate differential gene expression? The answer lies, in part, in the complex world of transcriptional regulators (see Ch. 26). It is estimated that 5% of the mammalian genome, about 5,000 genes, encode for transcription factors (Fig. 25-3). Of these, up to half are anticipated to have expression restricted to the nervous system. The large number of transcription factors can be subdivided into families whose members share a conserved amino acid sequence responsible for DNA-binding and dimerization. At present, 12 distinct motifs have been identified. Four classes are illustrated in Figure 25-4. Research demonstrates that members of these and other classes can function as transcriptional regulators exerting control over the developmental processes of proliferation and differentiation [15] (see also Ch. 26).

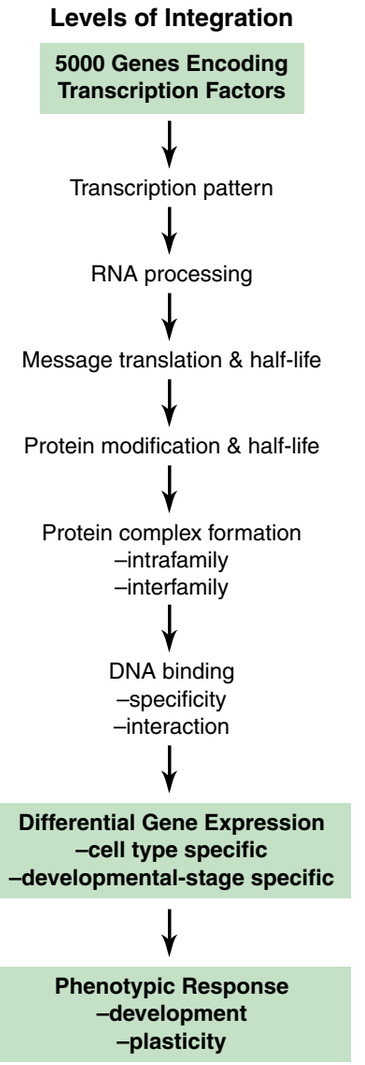

FIGURE 25-3 Levels of integration within the transcription factor network. Of the estimated 5,000 genes in the human genome encoding for transcription factors, perhaps half will exhibit expression specific to the nervous system. This predicted restriction in expression is considered to reflect the need to generate the combinatorial control mechanisms necessary to create the enormous phenotypic diversity unique to neural development. Listed are the various levels of processing whereby complex interactions among many factors and many events are integrated to carry out the critical task of differential gene expression that determines the unique phenotypic response during development and adult plasticity.

There are multiple levels of integration within the transcriptional regulator network. Part of the complexity of control lies in the large number of different factors available to generate cell-type-specific transcriptional regulation. More importantly, control over the expression and functional state of these numerous transcription factors is a source of considerable complexity and opportunity for

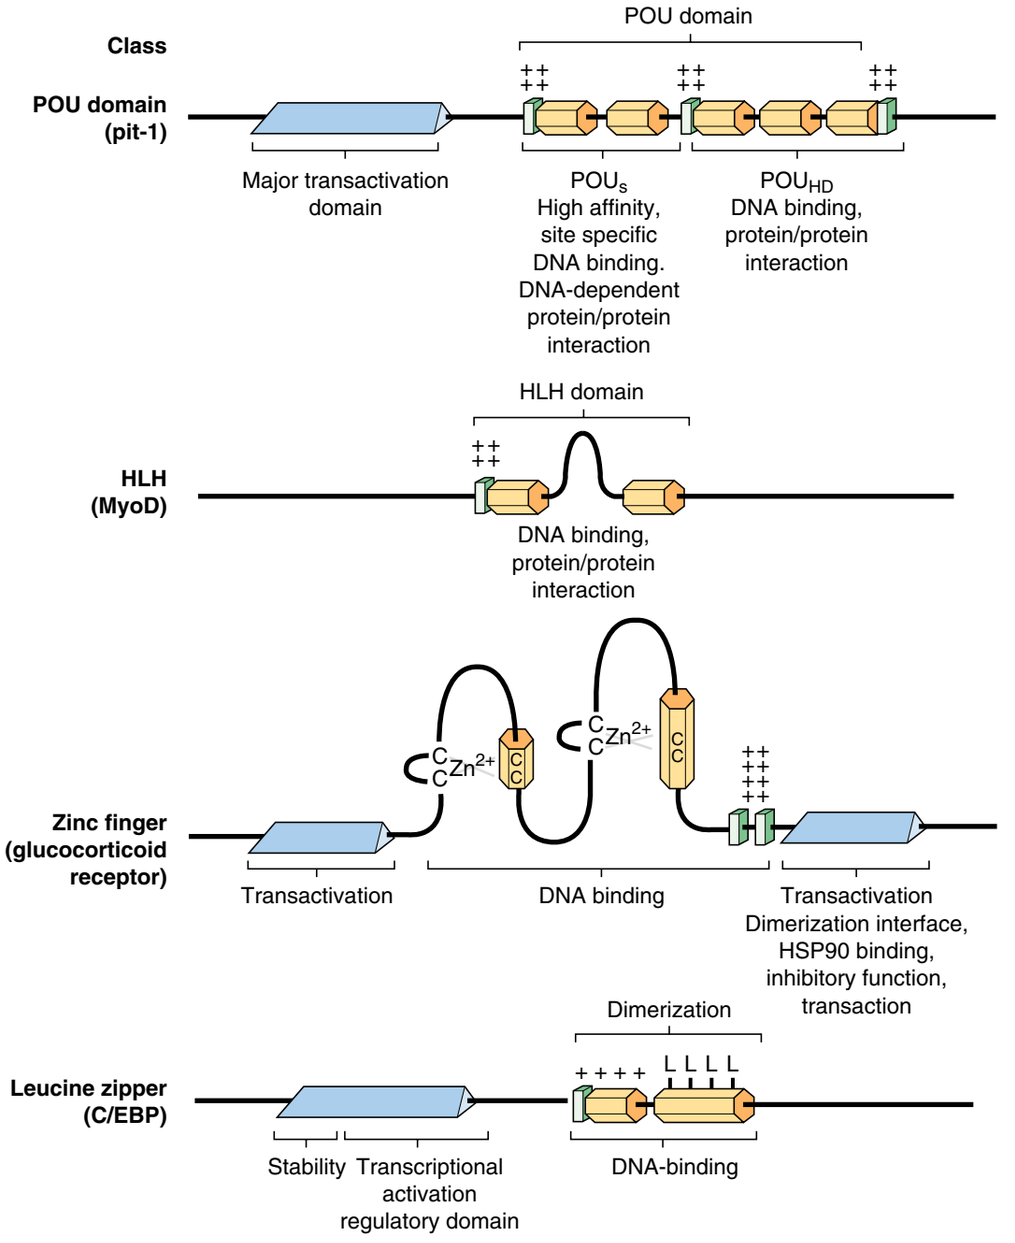

FIGURE 25-4 Major classes of transcription factors. Twelve distinct families of transcription factors have been classified by their DNA-binding motifs. Four examples of these transcription factors implicated in the control of cell proliferation and differentiation are depicted here. Conserved regions unique to each family include regions of basic amino acids functioning as DNA-binding sites (*solid rectangles*) and putative helical regions associated with DNA binding or dimerization (*cylinders*) are shown. Transcriptional activation domains (*solid triangles*) are generally not conserved even within a family, generating considerable diversity of functional transactivation among interacting family members. Each family has at present more than half a dozen members. The classes shown possess a POU domain (pituitary-1, *pit-1*), a basic helix–loop–helix domain (*HLH*, *MyoD*), a nuclear receptor type of zinc-finger domain (glucocorticoid receptors) or the basic region/leucine zipper domain (bZIP; CCAAT enhancer binding proteins, *C/EBP*). (Modified with permission from reference [15].)

combinatorial integration. Figure 25-3 illustrates the many points or levels of control that can be exerted over these developmental regulators. For example, the ability to alter the transcriptional expression of these factors is an initial and key point of control. As shown, other classical points of control, such as translation, are expected to add levels of complexity. Because the activity of most of these transcriptional regulators can be controlled by phosphorylation and dimerization, the number of permutations of interactive modes increases rapidly. Heterodimer formation can determine whether a transcriptional regulator is functionally active or not (discussed in detail in Chapter 26).

Thus, at any point of time in the life of a given cell, the sum total of activity at all levels of integration will be reflected by the nature of the genetic program that is read. This program not only creates the new cell phenotype but also sets the stage for the next round of developmental decisions, in part due to the alteration in the pattern of expression of transcriptional regulators now unleashed to reverberate in the cell physiology.

Early response genes function as development-control signals. How do epigenetic influences participate in decision making? Environmental influences come in the form of growth factors, neurotransmitters and other ligands that are linked to changes in membrane receptors and intracellular signaling pathways, as well as agents or fields capable of altering membrane electrical properties. Most extracellular signals trigger a change in cell physiology that can last for several days. How do these changes come about? In particular, how can environmental factors 'start the ball rolling' and trigger a new wave of genomic activity? Researchers have found that ligand-induced changes result in a very rapid gene expression that is independent of any protein synthesis [16]. This large class of genes can be expressed within minutes of cell activation. Because of the very rapid onset of expression, these genes are referred to as early response genes (ERGs), or primary response genes (Fig. 25-5) (ERGs are discussed further in Ch. 26).

Ligand-activated intracellular signaling pathways induce the transcription of ERGs that encode for four categories of cell proteins: (1) transcription factors, (2) cytoplasm enzymes and structural components, (3) secreted cytokines and (4) membrane proteins. Each category represents developmentally important factors, such as interleukin (IL)-6 and the NGF receptors. Most of the known transcription factors, including members of the families illustrated in Figure 25-4, are ERGs. Therefore, transcriptional regulation of many transcriptional regulators is under tight and rapid control by environmental agents. In addition, since a developing cell is normally exposed to many different signals at a given movement,

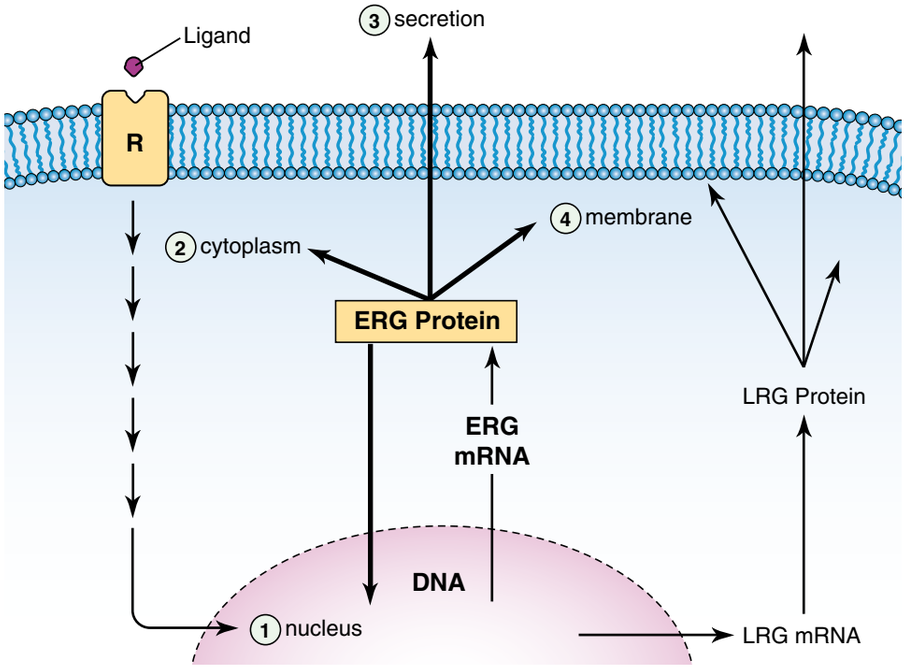

FIGURE 25-5 Early response genes. This figure illustrates the four major classes of early response gene (*ERG*) products serving as either nuclear transcription factors, such as Fos and Jun; cytoplasmic enzymes, such as nitric oxide synthetase and prostaglandin synthetase II or structural components, such as actin; secreted factors, such as interleukin 6 and other cytokines; or membrane receptors such as nerve growth factor receptor. All of these ligand-inducible ERGs are considered to play a role in regulating developmental events. Of particular importance are the ERGs encoding transcription factors, which have the ability to regulate the genomic response of neural cells to extracellular signals. The characteristic rapid and transient induction of this class of ERG mRNAs and proteins represents a self-referral loop of genetic control, whereby genetic information is rapidly expressed only to return to the nucleus and directly participate in the subsequent combinatorial control of late response gene (*LRG*) transcription and phenotypic alterations. Thus, the cell-type-specific, differential control of ERG and LRG expression may be closely coupled. (Modified with permission from reference [36].)

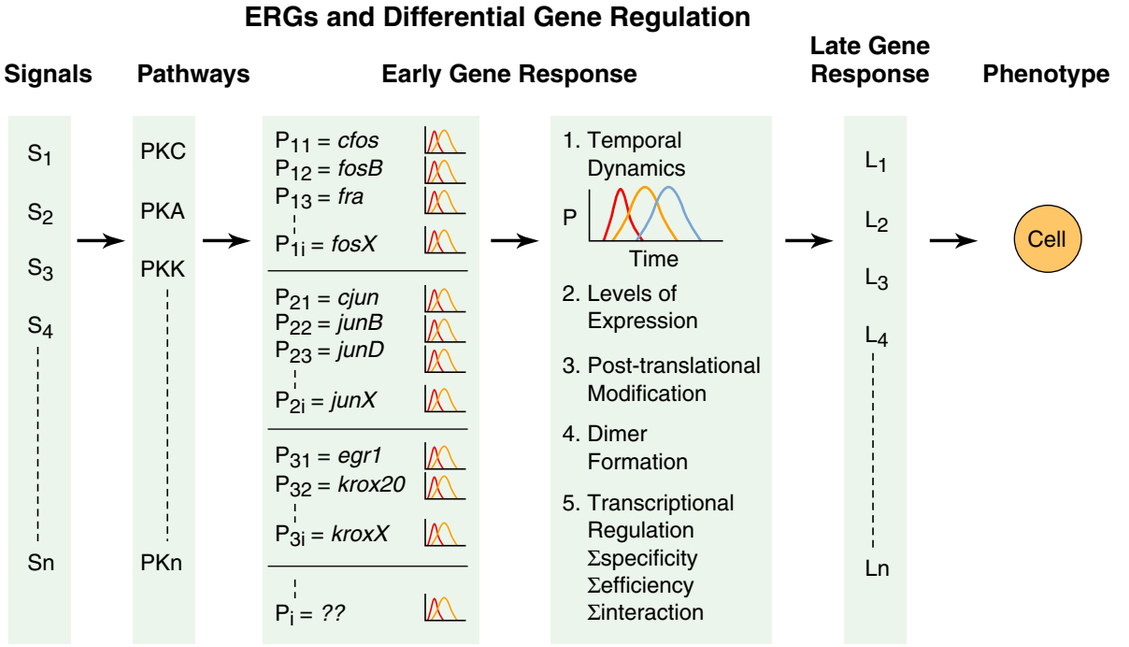

FIGURE 25-6 The early response gene (*ERG*) network and phenotypic diversity. This figure emphasizes the complexity of ERG transcription factor interaction during neural development. The level and kinetics of expression of ERG mRNAs and the subsequent dynamics of interaction among ERG proteins are shown. A wide range of environmental signals (S_1, S_2…*Sn*) can influence a cell by activating intracellular pathways, indicated here by specific protein kinases (*PKs*), such as protein kinases C (*PKC*) and A (*PKA*),…(*PKn*). These kinases are considered to activate target transcription factors capable of inducing the expression of a constellation of ERG families (P_1, P_2…P_i) with family members such as *c-fos* (P_{11}), *fosB* (P_{12}), *fra1* (P_{13})... *fosX* (P_{1i}, hypothetical). The total number of ERGs is equal to $(i) \times (j) = P_{ij}$, estimated to be several hundred. Each pathway induces a largely overlapping subset of ERGs, displaying its own characteristic kinetics and levels of mRNA accumulation, denoted by the small generic graphic symbol inserted to the right of each ERG. The next level of potential complexity is evident in the five main properties summarized for ERG protein synthesis, modification and interaction, which together orchestrate the late gene response (L_1…*Ln*). The concept of combinatorial control suggests that, in addition to the complexity of both ligand-receptor coupling and interaction among signaling pathways responsible for transcriptional activation, the various members of different families of ERG transcription factors extensively interact during the process of transcriptional control of late response genes, exerting a primary role in determining phenotypic diversity.

the ligand-mediated, rapid and transient induction of ERGs represents a tightly controllable, complex mode of encoding environmental information to carry out developmental decisions (Fig. 25-6).

A number of ERG transcription factors have already been shown to play important roles in regulating cell proliferation and differentiation. For example, combinatorial activity of the leucine zipper transcription factors superfamily, including members of the *fos* and *jun* families, is necessary for a cell to respond to a mitogen and enter the cell cycle. Thus, neural phenotypic diversity can be explained in terms of the history of expression of transcriptional regulators, some members changing rapidly (ERGs), some slowly. Together, they exert a combinatorial hold on the genetic programs and physiology of the cell and determine cell fate.

Transcriptional regulator networks function in invertebrate development. Our understanding of the genetic network orchestrating neural development in mammals is rapidly increasing, in large part as a result of the considerable advancement in developmental research of the fly. As part of the genetic network in *Drosophila*, a large number of genes encoding transcription factors and proteins for cell–cell communication help define cell lineages. Most transcription factors perform more than one function during development. For example, many participate during early segmental processes as well as in the later development of the neural, sexual and bristle components. Figure 25-7 illustrates how four major groups of genes interact during development to create the primary body axis and segmentation pattern of the embryo. For example, four maternal-effect proteins, such as bicoid and dorsal, are active in the unfertilized egg. Upon fertilization, these genes establish anterior–posterior concentration gradients that lead to differential effects on the expression of a variety of other genes encoding transcription factors, such as gap genes, which in turn organize the anterior posterior axis of the embryo. Thus, a maternal-effect mutant has no head and two caudal regions. Gap genes, for example, *Krüppel*, help to define the middle segment and to activate the expression of pair-rule genes including *hairy* and *fushi tarazu*, segment polarity genes such as *engrailed* and homeotic genes (see below). Mutations of gap genes produce embryos with deleted middle segments. Homeotic genes, named for the homeobox DNA-binding sequence, specify the identity of each segment. For example, mutation of the *antennapedia* gene

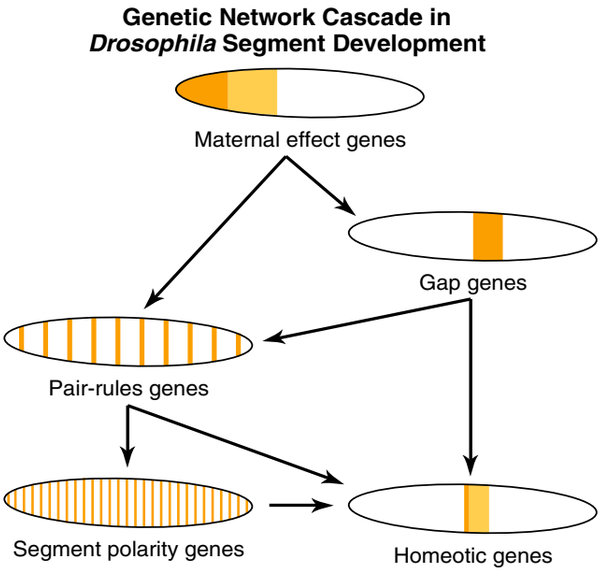

FIGURE 25-7 Genetic network cascade in early *Drosophila* development. Body segmentation in the *Drosophila* embryo results from the sequential and spatially localized expression of specific genes. During early development, maternal-effect genes set up the anterior-posterior orientation of the oblong embryo. Within a very short time, four different groups of genes, depicted here, that encode for transcription factors are expressed and function to regulate not only each other's expression but also many other genes whose products are necessary for proper sequential transformation of linear positional information into a periodic pattern. Note the alternating patterns of gene expression (*orange* vs. *white* areas) that establish boundaries necessary for proper segmentation.

results in the antenna on the head being replaced by a leg! A similar regulatory cascade of transcription factors organizes the dorsal ventral axis (Fig. 25-8).

Our understanding of gene regulation of neural development in *Drosophila* is most complete for the embryonic sensory nervous system [19]. The entire sensory system appears within 5–9 hours of fertilization and is known in detail. Five sets of genes have been described that progressively determine the structure and function of this system. The first set of genes is known as the prepattern genes, described above, which set up the anterior posterior and dorsal ventral body axis and segmentation. Many of these genes contain homeodomains and serve multiple roles during different developmental events; for example, the pair-rule gene *fushi tarazu* later controls the development of the fly CNS. Following the establishment of the body coordinates, proneural gene expression makes cells competent to become neural precursors. All the proneural genes encode helix–loop–helix (HLH) transcriptional regulators. The *achaete–scute* complex (AS-C) is a set of four proneural genes required for sensory organ formation. Mutations lead to no or very few neuronal precursors. Daughterless (da) expression is necessary for sensory organ precursors to appear. Because AS-C and da genes code for basic HLH transcription factors, these two gene products can interact to form heterodimers capable of regulating specific target genes. Two additional HLH proteins interact to expand and further refine the complexity of combinatorial control exerted by these transcription

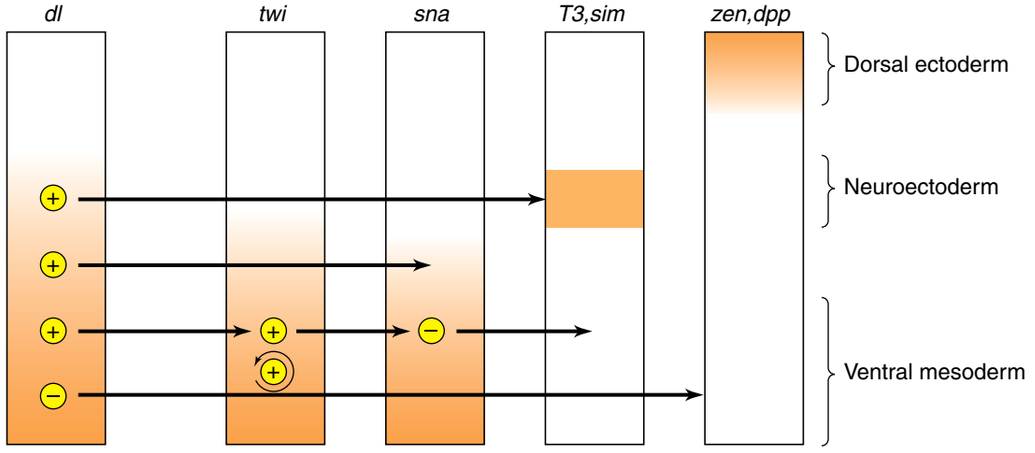

FIGURE 25-8 Dorsal–ventral morphogenesis in *Drosophila*: transcription factor regulatory cascade. The generation of the dorsal–ventral axis is dependent upon a network of transcription factors. The key nuclear morphogen is *dorsal* (*dl*), a member of the *rel/NFκB* family, whose shallow gradient in early embryo nuclei (**left box:** a schematic side view section representation of the embryo, dorsal is at top, ventral at bottom) is based upon a gradient in nuclear translocation: nuclear localization of transcription factors in ventral nuclei (*dark orange*), both nuclear and cytoplasmic localization in lateral regions (*light orange*) and only cytoplasmic localization in dorsal regions (*white*), where it remains inactive. *dl* creates, in turn, the expression gradient of at least six other transcription factors (see **four boxes to right**). *dl* activates the expression of *twist* (*twi*), a helix–loop–helix (HLH) transcription factor and *snail* (*sna*), a zinc-finger transcription factor. The combined expression of *twi* and *sna* leads to induction of the ventral mesoderm. In addition, the combination of *twi*-positive autoregulation (*small circular arrow*) and the ability of *dl* to activate *sna* along with *twi* creates a relatively steep gradient of *sna* expression that creates, in turn, a sharply bound domain of inhibition of *T3,* one of the members of the *AS-C* HLH transcription factor family and *single-minded* (*sim*), an HLH. Thus, the activation of *T3* and *sim* by *dl* (*top long arrow*) is limited to a narrow lateral band of nuclei that become cells of the neuroectoderm that form the nervous system. The dorsal ectoderm cells arise from the control of *zerknült* (*zen*) and *decapentaplegic* (*dpp*), both homeobox transcription factors. Since *dl* exerts a strong inhibitory influence over *zen* and *dpp* (*bottom long arrow*), the gradient of these (**last box**) is the inverse of *dl.*

factors. Hairy (h), named for mutants with ectopic bristles, and extramacrochaete (emc) can interact to form heterodimers with AS-C and da, but since h and emc are HLH proteins lacking functional basic DNA-binding domains, the heterodimers formed are inactive. In this way, h and emc negatively regulate AS-C and da with the resulting loss of neural tissue. Neuronal precursors then express the third set of genes, neurogenic genes, represented by HLH transcription factors such as the enhancer of split (E[spl]) complex and membrane proteins such as mastermind (mam). This set of genes mediates lateral inhibition among cells in proneural cell clusters. Mutations lead to lack of suppression, causing all cells in a cluster to enter the neural lineage. The fourth set are neuronal type-selector genes, controlling the type of sensory neuron that a precursor becomes and, hence, the type of sensory organ that forms. The cut gene product is a homeodomain transcription factor that controls cell-type-specific gene expression and organ type. Finally, cells express cell lineage genes that determine the phenotypic makeup of the cells in the sensory organ. Two genes in particular decide the identity of the final cell phenotypes and, hence, how many neurons and glia will be in each organ. In *numb* mutations, involving loss of a zinc-finger transcription factor, all progeny become socket or hair cells with the loss of neuronal and glial cells. Another gene, *oversensitive*, has the opposite effect: all neurons and glia and no socket or hair cells. Thus, PNS development relies on the sequential expression of HLH, homeobox and zinc-finger classes of transcription factors, which participate in a complex combinatorial network to progressively determine neural cell fate.

Transcriptional regulator networks determine vertebrate development. Vertebrates also rely on networks of transcription regulators to establish body plan and regional identity. However, the remarkably similar mechanisms of genetic and developmental control found in both invertebrates and vertebrates stand in contrast to the timing and form of development in phylogenetically distinct species. Genetic similarities include the existence of highly conserved families of HLH and homeobox transcriptional regulators specifying cell fate. In mammalian development, a genetic regulatory network analogous to that described for *Drosophila* seems to function [17]. In particular, homologous sets of genes are expressed in the rhombomeres of the developing hindbrain, representing a genetic network regulating development of this part of the CNS. Additional studies have implicated other transcriptional regulators in regional pattern formation in more anterior parts of the CNS and in the spinal cord.

The development of the mammalian hindbrain shows strong physical and genetic similarities to invertebrate development. Segmentation is apparent through the transient appearance of rhombomeres, which appear as morphologically distinct 'bumps' in the floor of the fourth ventricle during early development. Rhombomere organization is reiterated through the segmentally repeated

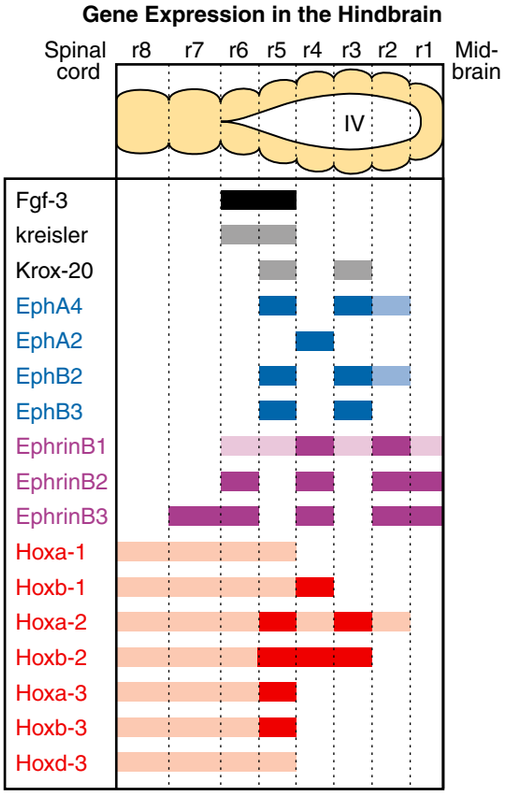

FIGURE 25-9 Segmentally restricted hindbrain gene expression. Vertebrate rhombomeres (*r1–r8*) are analogous to *Drosophila* body segments and are shown in this schematic of the hindbrain and IVth ventricle (IV). The expression pattern of individual genes is indicated below the hindbrain (*black or dark colors*, strong expression; *gray or light colors*, weak expression; *no bar*, no expression). These genes include signaling molecules such as fibroblast growth factor 3 (*Fgf-3*), early-expressed transcription factors such as kreisler and Krox-20, Eph family tyrosine kinase receptors and their ephrin ligands; and the Hox homeobox genes. Note that each of the genes is expressed in a spatially restricted manner that reflects the position of segmental boundaries. These overlapping expression domains create unique combinations of transcription factors within each rhombomere that are considered, in turn, to regulate the phenotype of the cells in each hindbrain region.

reticular formation and branchiomotor neurons found in the hindbrain. A number of genes are expressed in accord with rhombomere boundaries. Figure 25-9 shows the expression pattern of several classes of genes in the vertebrate hindbrain, including early expressed transcription factors such as *kreisler* and *krox-20*, Eph family tyrosine kinase receptors and their ephrin ligands, Hox genes, and genes coding for signaling molecules such as *fgf-3*. Together, these genes may be responsible for creating positional value and establishing segmental identity along the length of the hindbrain [18]. Rhombomeres are cell-lineage-restriction units, similar to the compartments seen in *Drosophila*. Cell mixing across rhombomere boundaries may be inhibited by the complementary expression of Eph receptors and ephrins. Positional value or segmental

identity may be determined by expression of Hox genes. Hox gene expression precedes the formation of the rhombomeres and establishes the location of boundaries between adjacent rhombomeres. Inactivation of Hox genes alters rhombomere identity, suggesting that these genes serve a function akin to that exhibited by homeotic genes in invertebrates. Hox gene expression may be activated by other transcriptional regulators, including *krox-20* and *kreisler*, which are expressed prior to Hox gene expression. Disruption of *krox-20* and *kreisler* activity also disrupts the pattern of Hox gene expression and rhombomere formation, suggesting that these two genes act upstream of the Hox genes. Detection of *krox-20*-dependent enhancers up-stream of Hox genes further supports this hypothesis [19].

The development of other regions of the CNS is not likely to rely on an overt pattern of segmentation such as is seen in the hindbrain, although the genetic mechanisms at play may be shared between vertebrates and invertebrates. Pattern and spatial position in the midbrain may stem from signals provided by the isthmus, a constriction separating the developing midbrain from the hindbrain. Early in development, the midbrain and hindbrain are differentiated from each other by the expression of the transcription factors Otx2 rostral to the isthmus and Gbx2 caudal to this boundary. Two secreted signaling molecules, Fgf8 and Wnt-1 are then expressed at the border between Otx2 and Gbx2 expression. These signaling molecules in turn regulate the expression of the transcription factors engrailed-1 and engrailed-2 in gradients rostral and caudal to the isthmus. Engrailed gene expression is required for the development of mesencephalic structures rostral to the isthmus and for the development of the cerebellum more caudally. Similar interactions are seen in *Drosophila*, with signaling by the Wnt-1 homolog *wingless* required for maintaining *engrailed* expression in neighboring cells.

In the forebrain, a number of transcriptional regulators are expressed in specific longitudinally arrayed domains. These genes include members of the *pax*, *emx*, *otx*, *dlx* and *nkx* homeobox gene families, and other transcription factors such as *bf1* and *tbr-1* [20]. Descriptive expression studies using these genes have suggested that segmentation may act in developing the telencephalon and diencephalon, although the segments identified by gene expression patterns are not restricted lineage units as seen in the hindbrain. For example, GABAergic cortical interneurons arise from the medial and lateral ganglionic eminences, whose territories are initially defined by the expression of *dlx1* and *dlx2*. These cells then migrate tangentially to enter a neocortical domain defined by the expression of *gli3* and *neurogenin1/2* [21]. Inactivation of *dlx1* and *dlx2* does not affect the production of these neurons, but does affect their ability to migrate into the neocortex. The nested expression pattern shown by the *emx* and *otx* genes is similar to the pattern created by Hox gene expression, but the lack of linkage between the four members of this family suggests that a different mechanism is used to establish domains within the forebrain. Some of these genes are expressed in the ventricular zone, suggesting a role in initial patterning of the neuraxis, while others are expressed in the mantle layer suggesting a role in differentiation.

Spinal cord development and regionalization may also be under the control of transcriptional regulators [22]. Regional diversity may be imparted by expression of more distal Hox genes, which continue to be expressed in accord with 'segmental' boundaries within the spinal cord. One inherent difference is that the regional distinctions visible in the spinal cord are imparted by signals from the surrounding mesoderm and not by intrinsic factors within the spinal cord [23]. Thus, external signals may establish the pattern of transcription factor expression along the length of the spinal cord. In addition to patterning along the rostrocaudal axis, the spinal cord, along with all other regions of the developing CNS, is also patterned along the dorsoventral axis. The dorsal–ventral axis of the spinal cord is likely to form through the concurrent action of two signaling systems. A ventralizing signal initially comes from the notochord; transplantation of a second notochord adjacent to the spinal cord results in differentiation of a second set of ventral spinal cord cells. This signal is carried by a molecule called sonic hedgehog, which is secreted by the notochord during early development. The neuroepithelium responds to this signal by developing the floorplate, the most ventral portion of the spinal cord. Once floorplate formation has been induced, the floorplate itself begins to secrete sonic hedgehog in a gradient. The gradient of sonic hedgehog expression in turn establishes distinct progenitor domains within the ventral spinal cord by inducing the expression of homeodomain proteins including Pax, Nkx, Dbx and Irx family members.

These proteins have been divided into two classes based on their differential response to sonic hedgehog signaling. Class I protein expression is repressed by sonic hedgehog, while Class II proteins are activated by sonic hedgehog signaling. Each of these proteins is activated or repressed at a distinct level of sonic hedgehog signaling, allowing each protein to be expressed in a domain that reflects a specific sensitivity to the signal. Expression of these transcription factors then defines five progenitor domains in the ventral spinal cord, each of which generates a specific class of ventral spinal cord neurons. Dorsal spinal cord development relies on a second set of signals emanating from the roof plate, the most dorsal part of the spinal cord. Many factors, including bone morphogenetic proteins, Wnt signaling molecules and fibroblast growth factors, are secreted by the roof plate. Rather than differential responses to a single graded signal as is seen in ventral spinal cord development, the dorsal neural tube appears to be patterned by the combinatorial activity of several different signaling molecules. These signals establish six different classes of progenitor domains that give rise to at least eight different types of neurons.

CELL LINEAGES OF THE NERVOUS SYSTEM

The neural crest lineage is progressively restricted to specific sublineages. The developmental fate of most cells is not fixed initially but becomes progressively restricted by epigenetic and genetic interactions[1, 22]. We have considerable information about the multipotent NC cells and how they become progressively restricted to specific sublineages [11, 24, 25]. NC cells migrate from the neural tube along specific pathways to their peripheral destinations. At these target sites, they differentiate into a diverse number of cell types, including Schwann cells and neuronal cells of the PNS, pigment cells, endocrine cells and cells forming connective tissue of the face and neck (Fig. 25-10).

A basic property of differentiated neuronal cells is the expression of one classical neurotransmitter and several neuropeptides. *In vivo* studies with NC cells first demonstrated that the choice of neurotransmitter phenotype could be altered by the environment. In these studies, NC cells were examined by means of chimera transplantation. Two of the final NC cell phenotypes are sympathetic, mainly adrenergic cells and parasympathetic, cholinergic cells. Presumptive adrenergic neurons transferred to the presumptive cholinergic region of young embryos migrated along the path of vagal NC cells and became cholinergic instead of sympathetic. The nature of the environment could thus switch neurotransmitter phenotype. The inverse experiment also worked: presumptive cholinergic cells become adrenergic when transferred to the adrenergic region. Thus, premigratory NC cells from different axial levels share some common developmental potential and differentiate in a manner appropriate for their final position. These transplantation experiments using heterogeneous cell populations, however, could be interpreted as evidence for selective or instructive processes: selective cell elimination of an inappropriate phenotype or environmental instructions of appropriate cell phenotype.

Environmental factors control lineage decisions of neural crest cells. Several experimental approaches have shown that environmental factors are critical in determining neurotransmitter phenotype by altering existing cell properties and not by selecting different hypothetical subpopulations of NC cells. For example, during normal

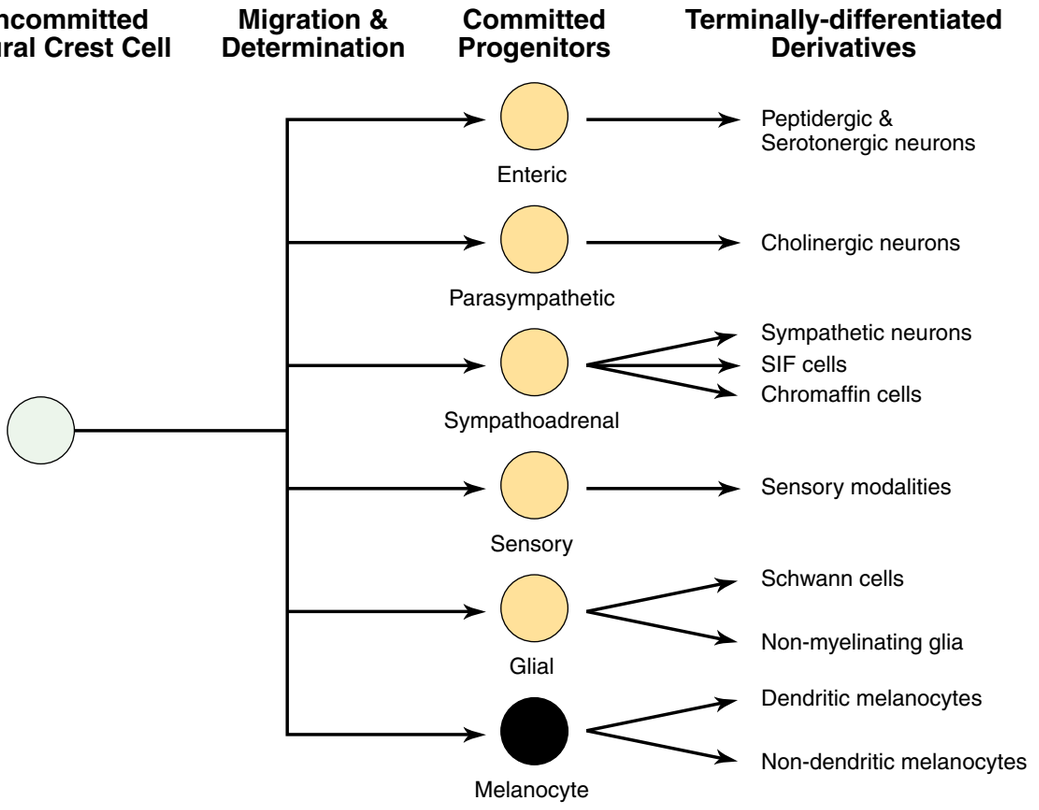

FIGURE 25-10 Neuropoietic model of neural crest cell lineage. Analogous to the process of hemopoiesis, early multipotent neuropoietic stem cells undergo extensive migration along complex pathways to different embryonic environments. Committed progenitor cells, including enteric, parasympathetic and others as listed, generate restricted sublineages under the influence of environmental growth factors. These cell populations expand in number and undergo terminal differentiation to the final adult phenotypes. *SIF*, small, intensely fluorescent cells. (Modified with permission from reference [24].)

postnatal development, the innervation of the sweat glands of the foot pads of cats and rats switches from noradrenergic to cholinergic. Research shows that environmental cues of the target tissue specify both early and late neurotransmitter phenotypes. Cross-innervation studies provide further evidence that the target can retrogradely specify neurotransmitter properties of the neuron that innervates it. Neurons that ordinarily provide noradrenergic innervation of hairy skin become cholinergic and peptidergic when induced to innervate sweat glands. Converse experiments give expected results.

The cellular and molecular mechanisms that specify neurotransmitter phenotype have been described by culture experiments (Fig. 25-11). Polypeptide growth factors such as NGF, bFGF and IL-6 appear to be the primary controllers of neuronal differentiation of the sympathoadrenal progenitor cells. Research findings demonstrate that bFGF promotes the proliferation and initial differentiation of the sympatho-adrenal precursor. For example, bFGF leads to increased neurite outgrowth and upregulation of neuron-specific genes. The survival of these committed neuronal precursor cells, however, ultimately depends upon NGF responsiveness and availability. bFGF can upregulate the low-affinity neurotrophin as receptor ($p75^{NT}$), and cell depolarization induces *trk* genes, which together can produce high-affinity, functional NGF receptors, providing trophic responsiveness.

A number of cytokines appear to control the final stage of differentiation of the sympathetic neuronal lineage. Long ago, it was found that individual sympathetic neurons grown on heart cell monolayers modify their biochemical, pharmacological and electrical properties and shift from adrenergic to cholinergic phenotypes. Growing the neurons in heart-cell-conditioned medium produces similar results, suggesting that non-neuronal cells, for example heart myoblasts or glial cells, release a soluble factor, now termed cholinergic differentiation factor (CDF), also known as leukemia inhibitory factor (LIF), that is responsible for the developmental switch. Ciliary neurotrophic factor (CNTF), belonging to the same cytokine subfamily as IL-6 and LIF, also increases cholinergic and decreases noradrenergic properties. While promoting the cholinergic phenotype, CNTF and LIF also inhibit sympathetic neuroblast proliferation. Thus, non-neuronal cells are a source of many molecules that can influence the choice of neurotransmitter and neuropeptide in cultured sympathetic neurons, suggesting that the spatiotemporal differential expression of a variety of cytokines helps determine the diversity of cell fate.

One more key player is known to participate in sympathoadrenal lineage fate. The presence and concentrations of glucocorticoid strongly influence lineage decisions (see discussions of endocrine regulation of transcription in Chs 26 and 52). Since sympathetic ganglia cells normally grow *in vivo* in the presence of glial cells and become predominantly adrenergic, a second factor was sought in order to explain the discrepancy with the *in vitro* switch studies that showed the appearance of the cholinergic phenotype. Studies showed that physiological levels of glucocorticoid can modulate biochemical differentiation by blocking the shift from adrenergic to cholinergic phenotype. LIF effects can also be blocked by conditions that mimic neuronal activity, such as elevated potassium concentrations. In addition, the concentration of glucocorticoid is an important determinant of the path of the sympathoadrenal precursor: low concentrations generate small, intensely fluorescent (SIF) cells and high concentrations generate chromaffin cells.

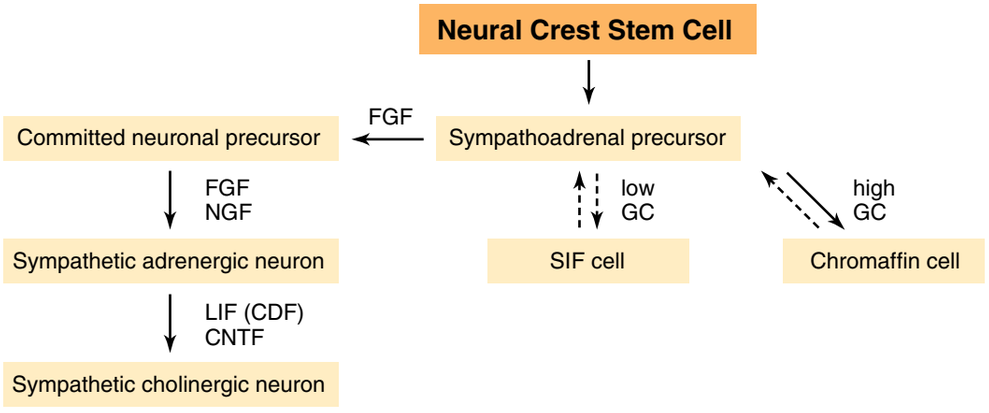

FIGURE 25-11 Growth factor control of neural crest lineage decisions. Regional and temporal differences in environmental factors influence the final phenotype of neural crest progeny. A number of environmental factors influence the committed precursors that give rise to the final four mature phenotypes of the sympathoadrenal lineage. Under conditions of low or high concentrations of glucocorticoids (*GC*), the sympathoadrenal precursors become either small, intensely fluorescent (*SIF*) cells of the sympathetic ganglia or chromaffin cells of the adrenal medulla, respectively. In environments containing high concentrations of fibroblast growth factor (*FGF*) and nerve growth factor (*NGF*) and little or no glucocorticoid, committed neuronal precursors appear, which terminally differentiate into either sympathetic adrenergic neuronal cells or, under the influence of cholinergic differentiation factor (*CDF*), also known as leukemia inhibitory factor (*LIF*), and ciliary neurotrophic factor (*CNTF*) switch neurotransmitter phenotype and become sympathetic cholinergic neuronal cells.

Research has begun to identify the intracellular signaling pathways activated by environmental factors that lead to the induction of developmental control genes in NC cells and their derivatives. For example, developmental restriction of melanogenesis normally occurs before embryonic day 5 in the quail. This process can be altered by treating embryonic day 9 dorsal root ganglion cells with phorbol ester, which activates protein kinase C (PKC) (see Ch. 23). Schwann cell precursors, which normally lack melanogenic activity, undergo a metaplastic transformation into melanocytes when PKC activity is reduced. This suggests that environmental signals capable of altering levels of PKC regulate lineage decisions in NC cells.

Neural crest lineage is transcriptionally regulated. A number of candidate control genes have been characterized that could give rise to progressive restriction in migrating behavior and control over proliferation and differentiation. Several newly discovered genes appear to underlie cell lineage commitment, while other genes appear important as mediators of the ligand-dependent switch of neurotransmitter phenotype in committed neuronal cells. In mammalian development, a gene analogous with the *AS-C* genes in *Drosophila,* which determine whether a cell becomes a neuronal precursor, has been described. The mammalian achaete-scute homolog-1 (*MASH1*) gene is transiently expressed by spatially restricted subsets of early CNS neuroepithelial and PNS NC cells. The precursors of sympathetic and enteric neurons express this bHLH transcription factor just prior to the onset of cell-type-specific gene expression, such as tyrosine hydroxylase (TH), suggesting that *MASH1* is a marker of cells as they enter the sympathoadrenal lineage. It is likely that *MASH1* is an NC control gene determining the commitment step of lineage development. It is expected that *MASH1,* like the activity of *AS-C* genes, will be regulated by a number of other HLH gene families homologous to *da* (E12), *emc* (Id) or *h* (HES) by way of alternative HLH pairing, or heterodimerization, leading to either enhanced or inhibited function in the differentiating mammalian NC cells and CNS.

Once the cells are committed to the sympathoadrenal lineage, a choice of neurotransmitter phenotype must take place. The developmental switch between chromaffin and neuronal phenotype is associated with changes in cell-type-specific gene expression, which require the differential control of NC genetic programs. The molecular mechanism integrating the influences of these two types of environmental signals, peptide growth factors and glucocorticoids, involves, in part, the antagonistic interaction of transcription factors (see Ch. 26). Culture work demonstrates that FGF and NGF are antagonistic to glucocorticoid in their ability to upregulate chromaffin-specific genes. The opposite control is also true. Two classes of transcription factors, Fos, as part of the peptide-inducible AP-1 complex, and glucocorticoid receptors (Fig. 25-4), have been shown to interact in a similar, reciprocal inhibitory fashion. This suggests that, as part of the combinatorial control process, interaction between these different families of transcription factors represents a probable molecular mechanism of reciprocal inhibition exerted by environmental factors.

Glial cell development is critical to nervous system development. Our understanding of glial cell development in the CNS has advanced rapidly since the mid-1980s [1]. The discovery and initial characterization of the oligodendrocyte-type 2 astrocyte (O-2A) cell lineage was the most extensively characterized cell lineage system available to study nervous system development. A variety of cellular and molecular approaches have provided us with an understanding of the environmental signals and the phenotypic responses that are of importance *in vitro.* During the last decade this work has been largely validated *in vivo.* This has led to a rapid increase in our understanding of the key environmental agents that regulate the rate and direction of glial cell differentiation along specific lineage pathways.

The oligodendrocyte and astrocyte lineages have been studied *in vitro*. Oligodendrocytes (OLs) are generated perinatally and pass through a series of cell phenotypes from undifferentiated stem cells to mature myelin-forming cells. This sequential process of maturation of OLs can be reproduced in culture (Fig. 25-12). In the rat, four main stages of development *in vitro* have been delineated. The oligodendrocyte progenitor (OLP) or oligodendroblast, also referred to as the O-2A bipotential progenitor cell, is a proliferating, bipolar cell. These cells, when cultured in chemically defined medium containing 0.5% (low) serum to enhance survival, rapidly differentiate in a relatively synchronous manner into mature oligodendrocytes over a 3–5-day period. In contrast, under high serum conditions or in the presence of CNTF, many cells become positive for glial fibrillary acidic protein (GFAP) and A2B5 and negative for OL markers. These $GFAP^+/A2B5^+$ cells are called type 2 astrocytes (AIIs). This cell type has not been observed *in vivo* and can be considered a plasticity artifact of tissue culture [26]. As bipolar OLPs differentiate to simple multipolar, termed $O4^+$ 'pre-OL' cells, they still proliferate, but at a slower rate than OLPs. When these $O4^+$ cells express the glycolipid galactocerebroside, cyclic nucleotide phosphohydrolase (CNP) and glycerol phosphate dehydrogenase (GPDH) they are called 'immature OLs'. The 'mature OL' phenotype is identified by the appearance of myelin-specific antigens, proteolipid protein (PLP), myelin basic protein (MBP) and myelin-associated glycoprotein (MAG). Thus, immunostaining with glia-specific markers defines six phenotypically distinct cell types *in vitro*, five of which relate to the OL lineage: OLPs, pre-OL cells, immature OL cells, mature OL cells, multipolar AII cells ($A2B5^+/GFAP^+$) and flat AI cells ($A2B5^+/GFAP^+$). This classification scheme can be used to monitor the rate, direction and extent of OL cell differentiation.

Oligodendrocyte lineage *in vivo* resembles that seen *in vitro*. Descriptions of the patterns of gliogenesis in the

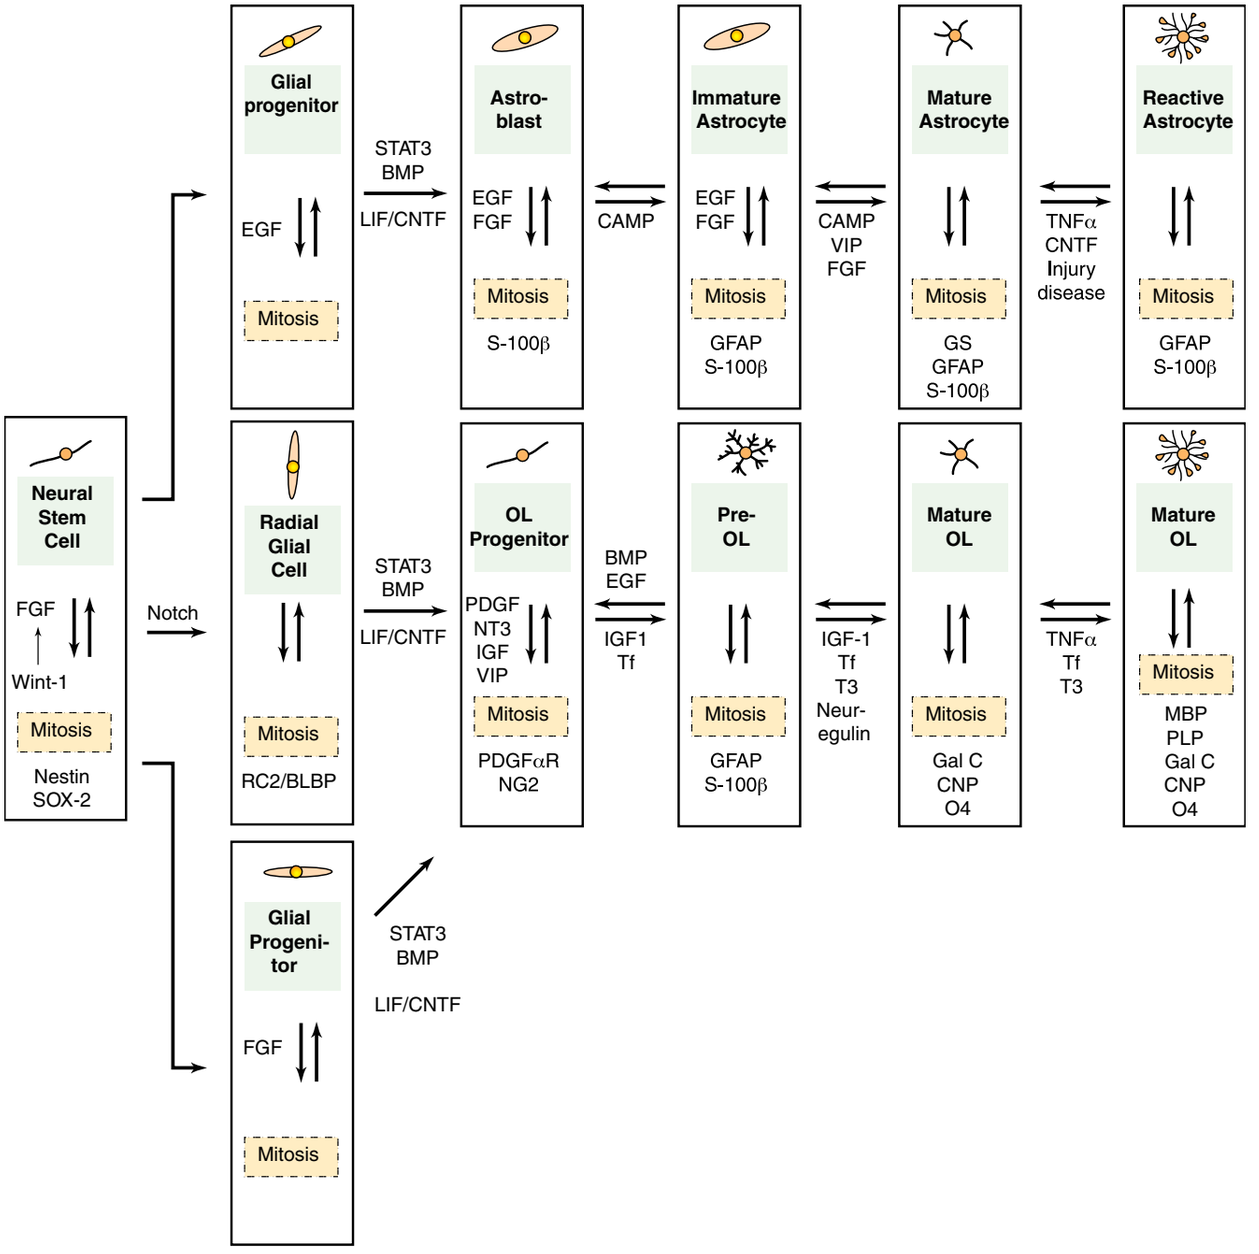

FIGURE 25-12 The oligodendrocyte (*OL*) and astrocyte lineages. The figure illustrates the characteristics that accompany the sequential differentiation within the oligodendrocyte lineage beginning from very early stem cells to the mature phenotypes. This version depicts six cell phenotypes for each lineage based on morphology, proliferative regulation and immunological determinants defined primarily from *in vitro* data. The various growth factors listed have been shown to regulate cell proliferation and/or differentiation. *Dashed arrows* indicate a possible particular direction, though without clear experimental support. The time course of expression of cell-type-specific markers is shown at the bottom. Note that each main stage of lineage development displays not only a different morphology but also a unique antigen profile. Growth factors include basic fibroblast growth factor (*bFGF*), cAMP, ciliary neurotrophic factor (*CNTF*), hydrocortisone (*HC*), insulin-like growth factor (*IGF*), interleukin 2 (*IL-2*), platelet-poor plasma (*PPP*), platelet-derived growth factor (*PDGF*), transferrin (*Tf*), transforming growth factor β(*TGF*β) and triiodothyronine (*T3*). Cell markers (dotted lines indicate unresolved expression pattern): ganglioside (*A2B5*), 2,3-cyclic nucleotide-3-phosphohydrolase (*CNP*), ganglioside (*GD3*), glycerolphosphate dehydrogenase (*GPDH*), galactocerebroside glycolipid (*GC*), ganglioside (*O4*), glutamine synthetase (*GS*), proteolipid protein (*PLP*), myelin basic protein (*MBP*), sulfatide (*SULF*) and vimentin (*VIM*).

forebrain using immunocytochemical probes and lineage tracers closely resemble the *in vitro* data. Similar findings have been reported for the cerebellum and the spinal cord. The ventral subventricular zones (SVZ) covering portions of the lateral ventricles and spinal cord are considered to be the origin of progenitor cells that multiply in the SVZ and as they migrate to and differentiate within the overlying white and gray matter. The separation of OL and AI lineage is considered to occur during embryonic development based on retroviral studies and double labeling, ultrastructural localization and cell morphology. Astrocytes principally originate from radial glia and the SVZ [27]. Immature astrocytes, particularly S100B$^+$ cells, retain the capacity to proliferate and, therefore, do not need to derive from neural stem cells. However, since stem cells are found in many regions of the adult CNS (see Ch. 29), the potential still exists.

A number of glial markers provide static yet overlapping information concerning OL lineage development. Small, proliferating progenitor cells that are positive for ganglioside GD3, NG2 proteoglycan and platelet-derived growth factor (PDGFα) receptor (PDGFR) are observed in the embryonic SVZ. Starting at embryonic day 16 and continuing to 7–10 postnatal days, OLPs proliferate in the SVZ and are similar to the OLPs/O2A cells described *in vitro* above. These cells migrate into the overlying subcortical white matter. By the end of the first postnatal week, the GD3$^+$/PDGFR$^+$ cells diminish in number while O4$^+$ and galactocerebroside$^+$/CNP$^+$/GPDH$^+$ cells rapidly increase in number in the white matter tracts. Thus, early stages of OL differentiation appear to occur in the SVZ, which contains a heterogeneous population of 'progenitor' phenotypes. The subsequent development of O4$^+$ progenitors into galactocerebroside-positive 'immature' OLs and MBP-positive 'mature' OLs occurs in the white and gray matter and not in the SVZ or neighboring subcortical regions.

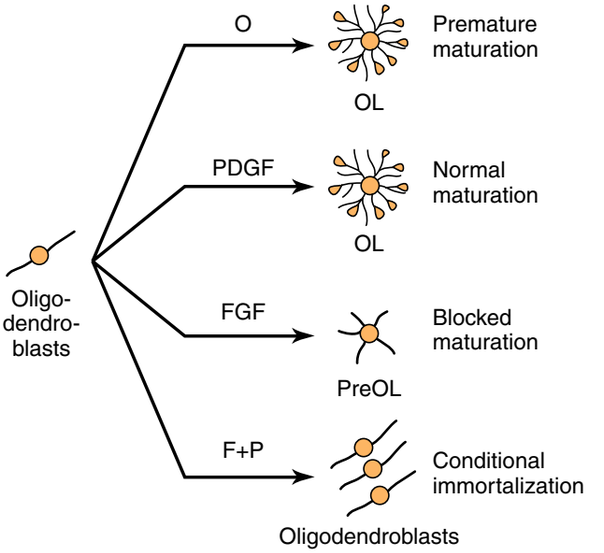

FIGURE 25-13 Growth factor control of oligodendrocyte (*OL*) lineage decisions. *In vitro* studies have demonstrated that the developmental fate of O-2A progenitor cells in culture can be regulated by environmental factors. Progenitor cells cultured in the absence of either basic fibroblast growth factor (*FGF*) or platelet-derived growth factor (*PDGF*) develop to mature OLs but do so on a timetable more rapid than *in vivo*. The addition of PDGF stimulates several rounds of cell division, slowing/delaying the time of development to mature OLs so that it more closely resembles the normal *in vivo* time course. In contrast, FGF stimulates continual proliferation while blocking phenotypic development at the pre-OL (O4$^+$/galactocerebroside glycolipid$^-$) cell stage. Evidence suggests that FGF can lead to downregulation of cell surface galactocerebroside glycolipid and simplification of morphology, indicating possible 'dedifferentiation' or plasticity of the galactocerebroside glycolipid$^+$ cell phenotype. The combination of both factors leads to a stable condition of the immature O-2A phenotype exhibiting continual proliferation. Upon removal of either FGF or both factors, cells leave the state of 'conditional' immortalization and proceed to differentiate normally.

Growth factors regulate oligodendrocyte development. The OL cell lineage culture is an excellent system to study the influence of growth factors on cell lineage development. Each of the four main stages of OL lineage progression can be identified by its characteristic markers and, through the use of growth factors, experiments can be designed to increase or decrease the degree of proliferation and/or block, delay or accelerate maturation of developing precursor cells. Although research shows that OL differentiation is a 'default' pathway, occurring in serum-free medium, in the absence of environmental signals, a number of studies demonstrate that OL development is more complex and is responsive to numerous environmental signals. For example, OL lineage cells continue to proliferate for extended periods *in vivo*, in contrast to *in vitro*. In addition, treatment of OL progenitor cells with growth factors known to be present in the developing CNS yields a complex set of ligand-dependent, phenotypic responses. bFGF, PDGF, NT3, IGF-I [28, 29] and PACAP [30] are key molecular signals controlling OL cell development (Fig. 25-13). In the presence of PDGF, OL progenitor cells are stimulated to divide with a short cell cycle length of 18 hours; are highly motile and bipolar; and differentiate in a synchronous, symmetrical, clonal fashion with a time course similar to that *in vivo*. In the presence of bFGF, however, progenitor cells are stimulated to divide with a longer cell cycle length of 45 hours, become nonmotile pre-OLs with a multipolar shape and are inhibited from expressing galactocerebroside glycolipid, PLP or MBP. Progenitor cells treated with both bFGF and PDGF exhibit a third phenotypic response, remaining motile, bipolar progenitor cells that divide indefinitely and do not differentiate. This ligand-dependent, conditional 'immortalization' can greatly expand the OL progenitor cell population over extended periods of time. Upon removal of bFGF or both mitogens, the progenitor cells differentiate along the OL lineage.

The source of PDGF *in vitro* appears to be AI cells, but *in vivo* PDGF is produced by neurons in the brain and

spinal cord, except in the optic nerve where astrocytes perform this function. From *in situ* hybridization data, the PDGFα receptor is expressed only in galactocerebroside glycolipid/OL lineage cells and not in identifiable astrocytes or neuronal cells. In addition, bFGF appears to upregulate the PDGFα receptor in OL progenitor cells. By altering the responsiveness of these cells to PDGF, bFGF and PDGF together maintain the 'proliferative' state. Members of the transforming growth factor (TGF)β family, such as bone morphogenetic proteins (BMP)2 and 4 inhibit generation of OL and promote astrocyte generation. CNTF and LIF act primarily as survival factors, in contrast to IGF-I, which acts to commit neural stem cells to the OL lineage and then stimulate proliferation, survival and differentiation of OLPs both *in vivo* and *in vitro* [28,29]. The neuropeptide family comprising VIP and PACAP and their receptors was recently shown to play a major role in neural embryogenesis. PACAP stimulates OL proliferation and can delay myelination [30].

Transferrin is an iron carrier protein that acts as a trophic survival factor for neurons, astrocytes and OLs. As the blood–brain barrier becomes established during development, neural cells become dependent on transferrin produced by OLs and choroid plexus epithelial cells (Fig. 25-14). OLs are the major source of transferrin in the CNS. This suggests an important function for OLs in addition to myelination of axonal tracts. Transferrin concentration in CSF is highest at the time of peak myelination. Oligodendrocytes, myelin and several areas of the brain contain higher concentrations of iron than the liver, presumably in the form of ferritin-bound iron. Transferrin seems to play a unique role in OL by regulating the transcription of the *MBP* gene and because its action synergizes with IGF-I to enhance myelin formation and repair [31].

The Schwann cell lineage is also characterized by sequential and overlapping expression of many stage-specific markers. The Schwann cell lineage arises from NC cells. Expression patterns of antigens have allowed the precise delineation of three distinct developmental stages, both *in vivo* and *in vitro,* that give rise to two types of Schwann cells in the adult, myelinating and nonmyelinating cells (Figs 25-15 **and** 25-16). First is the appearance of the Schwann cell precursor, a short-lived population of highly motile cells that depend on two axonal signals, neuroregulin-1 and endothelin, for survival and rapid proliferation. Two transcription factors, Krox -20 and Sox-10, respectively needed for myelination and for the establishment of the Schwann cell lineage, are also required for lineage progression to the second stage, the so called immature Schwann cells [32]. The molecular phenotype

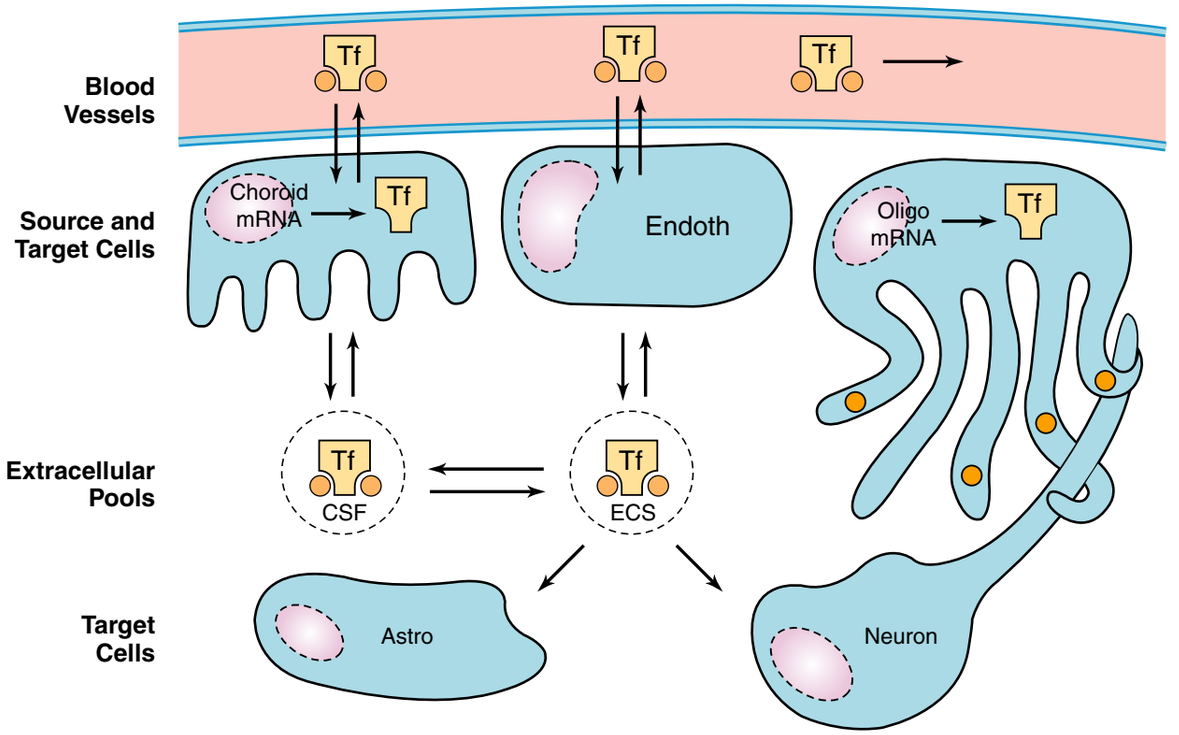

FIGURE 25-14 Regulation of transferrin (*Tf*) in the CNS. Tf is an important molecule regulating the movement and storage of iron in the nervous system. Although blood-borne Tf is exchanged by choroid epithelial cells and the endothelial cells of the capillary beds in the brain, only the oligodendrocytes and choroid cells in the brain can produce Tf *in vivo*. Each Tf molecule can bind two atoms of iron (*dark orange balls*) that in the brain are distributed between the two large pools, the cerebrospinal fluid (*CSF*) and the extracellular space (*ECS*). Astrocytes and neurons are considered to be completely dependent upon these pools and, in turn, upon the oligodendrocytes, choroidal cells and the body for Tf.

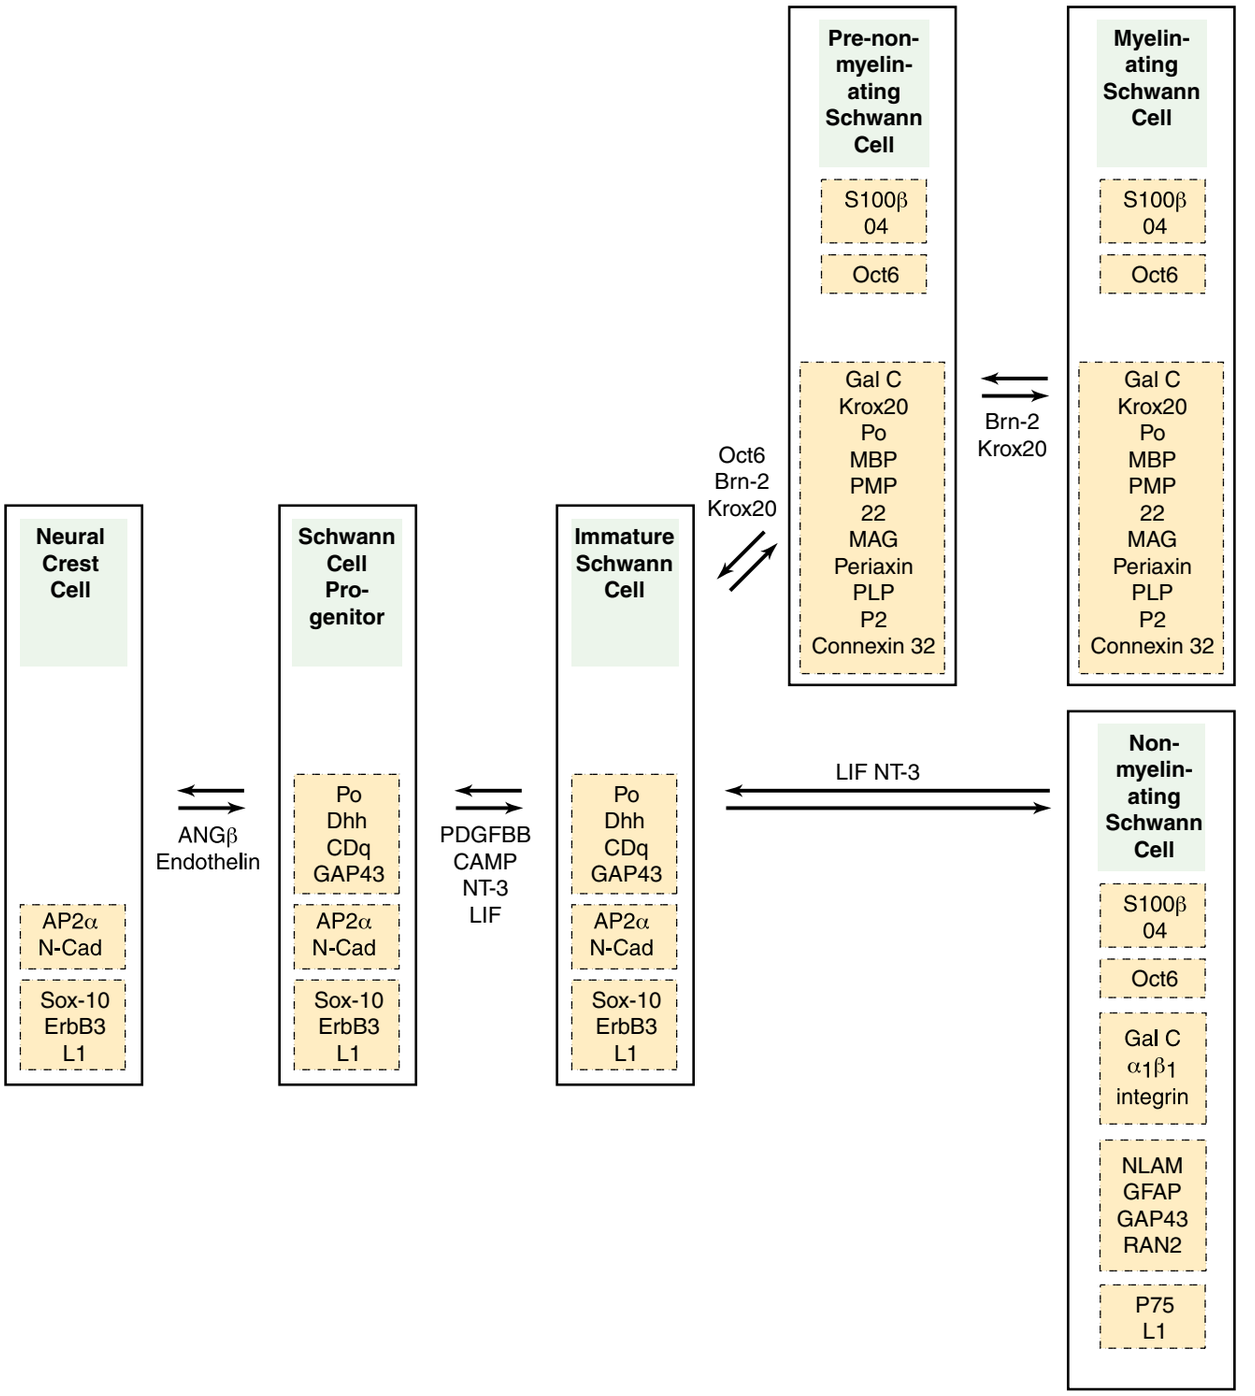

FIGURE 25-15 The Schwann cell lineage. The Schwann cell is the axon-ensheathing cell of the PNS and, thus, displays many properties and developmental processes similar to CNS oligodendrocytes. The figure illustrates the sequential differentiation of Schwann cells from early, uncharacterized neural crest stem cells to the final two mature phenotypes, surrounded by *boxes:* the nonmyelinating and the myelinating Schwann cells of the adult, based on the size of the axons they ensheathe. See Figure 25-16 for the developmental anatomy of these two mature phenotypes. Unlike CNS oligodendrocytes, the vast majority of Schwann cells do not become myelin-producing. This six-stage version of Schwann cell development is based upon cell morphology, proliferative potential and, most importantly, the expression of stage-specific antigens, that is, the appearance and/or disappearance of specific markers, derived from both *in vivo* and *in vitro* data. It appears that upon reaching the nonmyelinating phenotype (**box 4 from left**), cells are fated either to remain in this state and represent the adult population of nonmyelinating cells or to differentiate further, expressing myelin-associated genes. The premyelinating phenotypes then become myelinating cells of the PNS (stage 6).

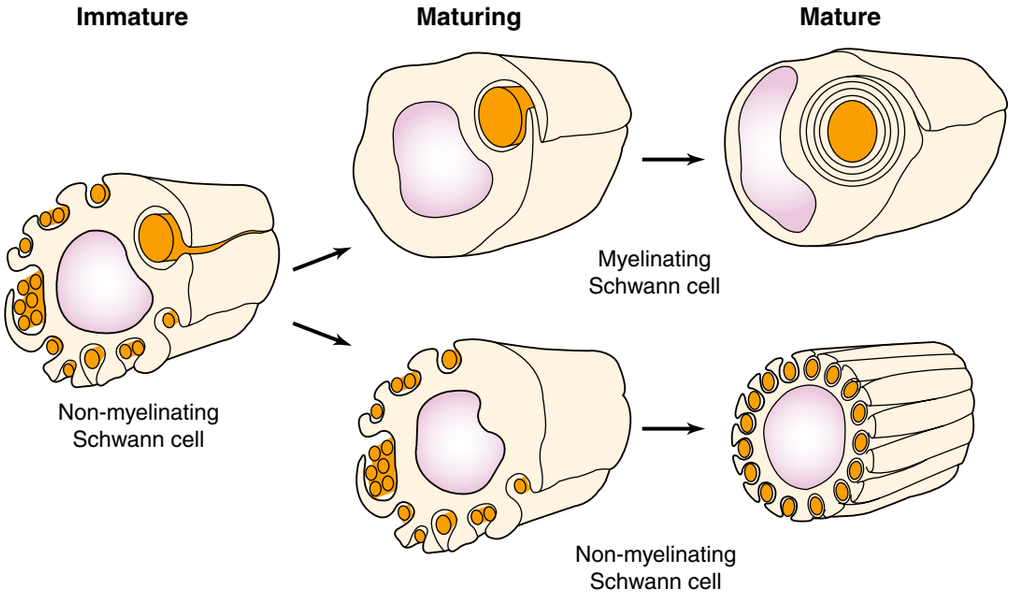

FIGURE 25-16 Schwann cell development and axonal sorting. Immature O4-positive Schwann cells can be found to take one of two paths of differentiation. Initially, both large- and small caliber axons, usually less than 1 μm in diameter, are found embedded in furrows along the surface of a chain of immature Schwann cells. This illustration shows a cross-section through a single cell. During the period of cell proliferation and axonal sorting, large axons that require myelin laminar ensheathment separate, by some undefined process of axonal/Schwann cell interaction, from smaller-caliber axons that require only a simple, nonmyelin ensheathment. In maturing, myelinating Schwann cells, single axons are enveloped by the lip of the trough on the cell surface, one of which elongates to create the myelin wrapping as the number of turns of membrane increase, and the lamellae become more compact as the cytoplasmic content is lost. In maturing, nonmyelinating Schwann cells, no myelin membrane is formed but many small-caliber axons remain completely embedded within separate furrows in each cell. Thus, the adult nerve contains two Schwann cell phenotypes, nomyelinating and myelinating.

of Schwann precursors is complex (Fig. 25-15). It includes markers conserved from NC cells, such as AP-2α and N-cadherin, which are downregulated by the immature Schwann cell stage, and markers from more mature Schwann cell stages, such as Po, the major myelin glycoprotein, Desert Hedgehog, GP 43, PMP22, CD9 and PLP. The appearance of S100, GFAP, O4 and Oct6 define the immature Schwann cell stage. When cells exit this stage, they stop proliferating to give rise to a nonmyelinating Schwann cell type defined by the appearance of galactocerebroside, $\alpha_1\beta_1$ integrin and association with axons. They also retain the immature Schwann cell markers, neural cell adhesion molecule (NCAM), L1 recognition molecule and those mentioned above. Note the curious combination of antigens in the nonmyelinating Schwann cell: O4 and galactocerebroside glycolipid indicative of the CNS OL phenotype, and GFAP and S100 found in CNS astrocytes.

In the PNS, the ensheathing Schwann cells, depending upon the size of the axons with which they are associated, either remain at the nonmyelinating stage (small axons) or begin to produce myelin-associated proteins and myelin-ensheathing large axons (Fig. 25-16). The latter developmental path involves the appearance of proliferative, premyelinating Schwann cells that express myelin genes, such as P_0, *MBP*, *MAG*, P_2, *connexin 32*, *PMP22*, *krox-20* and *periaxin*. These cells then lose GFAP, p75 NTR/NGF receptor, N-CAM, L1, GFAP, Gap 43, RAN-2 and A5E3 while producing myelin membrane as myelinating Schwann cells. Krox is highly expressed in myelinating Schwann cells while Oct6/SCIP is downregulated [32].

cAMP in culture can mimic most of the effects of axons on immature Schwann cells, including expression of early progenitor antigens, suggesting that a cAMP trigger drives most Schwann cell development *in vivo*. For example, cell proliferation by bFGF or PDGF requires the presence of high concentrations of intracellular cAMP. The role of cAMP may be to upregulate mitogen membrane receptors. Thus, in the developing nerve, axon-associated factors elevate cAMP, which is responsible for inducing two key events. The first event is the expression of O4 antigen and the responsiveness to mitogens in immature progenitors and nonmyelinating Schwann cells. The second event is the further differentiation into premyelinating and myelinating Schwann cells, if the suppression of proliferation takes place owing to some secondary permissive signal associated with the ensheathed large-caliber axons.

Of great interest is the expression pattern of suppressed cAMP-inducible POU domain protein (SCIP). SCIP is a member of the POU family of transcription factors, with characteristics of an early response gene, originally defined by the presence of a homology domain between the four transcription factors, Pit-1, Oct-1, Oct-2 and Unc-86. POU proteins are usually considered to function as transcriptional activators of cell-type-specific genes and determine cell fate. In CNS and PNS myelinating cells, SCIP is

expressed at high levels only during a very narrow window of development and acts as a repressor of myelin-specific genes. In Schwann cells, SCIP is expressed in the progenitors but not in the more mature, myelinating Schwann cells (Fig. 25-15). In these proliferating nonmyelinating and premyelinating Schwann cells, SCIP acts on promoters of myelin-associated genes, such as P_0 and *MBP*, as a repressor. Thus, SCIP expression is found in cells with elevated concentrations of cAMP to be correlated with rapid downregulation of the ERG c-Jun transcription factor and the onset of rapid proliferation and repression of myelin genes. In response to denervation, SCIP is rapidly and transiently re-expressed during the period of rapid cell proliferation of premyelinating Schwann cells and its absence is considered to delay the expression of myelin-specific genes.

CONCLUSIONS

Most development focuses on the formation of the complexity of neural tissue during embryonic and postnatal development. These changes provide a basis for later juvenile and adult stages of growth, in which the dynamic interaction between the genes and the environment continues. Although development is now less dramatic, environmental signals continue to produce lasting changes in neural structure and function in the adult nervous system. Genetic epigenetic interaction is now associated with physiological and behavioral learning (Ch. 53). It is likely that the main elements employed during early development that allow a cell to 'learn' to participate in the system are the same elements used during the continual process of learning and corresponding plastic modification of the nervous system across the life-span of the organism. Learning during the life of the organism is correlated with changes at every level of the hierarchy of information flow (Fig. 25-1) leading to the continued expression and refinement of neuronal/glial networks. External and internal events continue to regulate gene expression, and neuronal and glial cells continue to interact metabolically[3]. In its broadest sense, development continues during adulthood [33]. Since neural plasticity can be defined as the long-lasting changes in neural structure and function following environmental perturbation, the term is applicable to adult development. The molecular and cellular basis of adult neural plasticity has focused on environment-induced changes in neurotransmitter metabolism, synaptic structure and function and local circuits. Three experimental models have proved to be most successful in helping to delineate the molecular basis of plasticity: environmental control over catecholamine biosynthesis, long-term potentiation [33] and experience-dependent alterations in brain structure and function [34, 35].

In the future, advances in neuroscience will further our understanding of how the abstract genetic intelligence becomes progressively and continually transformed into the hierarchically organized dynamic networks of information and structure. Throughout the life-span of an organism, environmental perturbation leads to alterations in neural structure and function. Therefore, development can be viewed as a continual process of short- and long-term information storage whereby genetic and epigenetic interaction, at every step of development, is represented in the evolving structural and functional design of the nervous system. The nervous system is always adapting and we are always learning.

TRANSCRIPTION AS A TARGET FOR DRUG DEVELOPMENT 469

The functioning of the CNS requires regulated communication between neurons that are in contact with one another. Generally, this can be viewed as presynaptic neurons modulating the activity of postsynaptic neurons. While the propagation of action potentials is the most rapid form of neuron–neuron communication, there is a slower form of communication where the neurotransmitters and neuromodulators released into the synaptic cleft from presynaptic axons bind to postsynaptic neuronal membranes, inducing the postsynaptic cell to respond. This postsynaptic response can be a cascade of events, often resulting in regulation of the production of mRNA and proteins within cells. This direct cell–cell communication can be modulated by factors that diffuse over long distances and, consequently, do not require specific secretion into the synaptic cleft, yet these factors can also function in selected cell types to again alter transcription and post-transcriptional events. In this chapter, the regulation of transcription in neurons will be discussed first by presenting some basic background concerning transcription and then by highlighting two important classes of modulators of transcription, namely, those associated with glucocorticoid and cAMP regulation of transcription. Finally, given the complexities of transcriptional regulation, a brief discussion of possible sites for pharmacological intervention in the transcriptional process will be presented.

THE TRANSCRIPTIONAL PROCESS

To understand regulation of transcription, it is necessary to categorize the molecules involved. Transcription is the process by which RNA is made from genomic DNA. DNA is a linear polymer composed of four nucleotides, deoxyadenosine, deoxyguanosine, deoxycytosine and thymidine, which are linked in a linear sequence via phosphate linkages. Genomic DNA is double-stranded, oriented in an antiparallel arrangement such that base pairing of adenosine with thymidine and of guanosine with cytosine will stabilize the structure. The linear sequence of the nucleotides contains sequences known as genes that are the regions of genomic DNA that can be copied into RNA. This arrangement suggests that the functional structure of the DNA sequences giving rise to RNAs is modular, with an RNA-encoding region as well as regulatory regions of sequence both 5′ and 3′ to the transcription

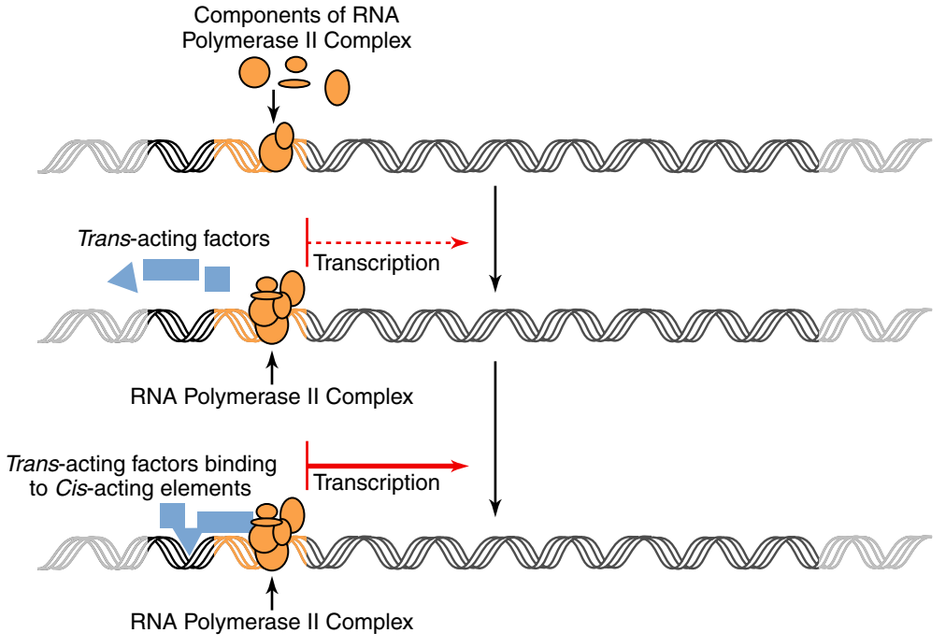

FIGURE 26-1 Formation and regulation of the transcriptional complex. The transcribed region of a gene is indicated in *black*. Immediately to the **right** of this box, on the 5′-side, is an *orange helix*, indicating the TATA box sequence. These are *cis*-regulatory sequences. The transcription complex binds to the TATA box and can initiate transcription when stimulated. Transcription can be regulated by binding of various *trans*-acting factors to the enhancers (*black shapes*) adjacent to the TATA box. The positioning of these sequences permits a direct interaction between *trans*-acting factors and the RNA polymerase II complex.

unit (Fig. 26-1). The transcription process giving rise to mRNA requires the binding of proteins responsible for RNA synthesis to the DNA template immediately 5′ to the start of transcription. Indeed the recent sequencing of multiple genomes has revealed that the transcriptional machinery is largely conserved between different species ranging from yeast to human, reflecting the fundamental nature of the transcriptional process. These studies have revealed good sequence conservation of over 100 proteins known to be involved in the transcriptional process. The protein that synthesizes mRNA is known as RNA polymerase II. RNA polymerase II is a large protein complex composed of multiple subunits. This protein binds to a DNA sequence, which is known as the TATA box because of the linear arrangement of the DNA sequence and its proximity to the start of transcription. However, RNA polymerase II does not bind to the TATA box without the prior association of several other proteins, including transcription factors TFIID, TFIIA and others, with this DNA region [1]. These proteins interact with one another, forming a complex to which RNA polymerase II can bind. This scaffolding of protein interactions at the TATA box forms the transcriptional apparatus. This basic transcriptional complex is probably the same for all genes in all cells of an organism, yet it is clear that transcription of selective genes can be on or off, as well as differentially regulated, in distinct cell types to yield different amounts of mRNA. This process of transcriptional regulation is multifaceted and involves the association of several additional proteins in particular arrangements with the transcriptional complex. The arrangement and identity of transcriptional accessory proteins, also called transcription factors, can be unique for individual genes.

Finally, and perhaps most importantly, transcription is the starting point for a series of biological amplifications necessary for cellular functioning. To illustrate this point, a single gene can be transcribed into multiple mRNAs, in some cases, giving rise to thousands of mRNA molecules (Fig. 26-2). Next, each of these mRNAs may be translated into hundreds of protein molecules, hence providing the quantities required for cellular viability. Cells could not function without this amplification of genetic information. Transcription of selective genes in selective cell types

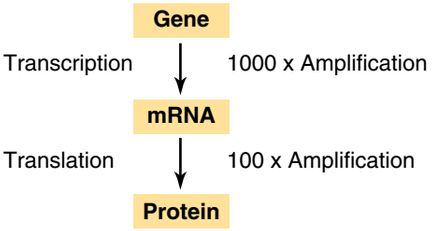

FIGURE 26-2 Gene expression as a biological amplifier. Transcription is an amplification step, giving rise to thousands of mRNA molecules from a single gene. Translation is a second amplification process, producing hundreds of protein molecules from a single mRNA molecule.

and the resultant cell-specific abundances of the transcribed RNAs, provides the opportunity for other biological processes to modulate protein production. The involvement of transcription factors in regulating the first biological amplification step is the subject of the remainder of this chapter

Co-regulators of transcription – histone acetylases modulate chromatin structure. An important feature of a gene's transcriptional response that has been slow to be appreciated is the chromatin structure of the gene. Co-regulators of transcription fall into two classes, co-activators and co-repressors, and are usually proteins that modulate RNA polymerase activity, often at the level of modulating chromatin structure [2]. Eucaryotic DNA exists in the nucleus as a long, double-stranded molecule that wraps around a core protein complex composed of histone proteins. This structure is called a nucleosome. Nucleosomes are packed into a tight bundle that forms the chromatin structure of the gene and genome. Transcription occurs at genes where the promoter is accessible such that RNA polymerase and the modulatory transcription factors can bind. The polymerase moves from the promoter across the gene making RNA as it progresses; this occurs through the activity of the core transcriptional complex displacing the DNA from the nucleosome such that it can be copied into RNA. While the nucleosome doesn't necessarily hinder RNA elongation, the ability of nucleosome to block RNA polymerase binding to the promoter is now well documented. The blocking activity of the nucleosome is mediated in large part through the regulated activity of the histone proteins. Acetylation of the histones tends to facilitate transcription of the gene while deacetylation usually blocks access of the polymerase to the promoter. Often the acetylation state of the promoter-associated histones is modulated by transcription factors that act as histone acetyltransferases. These co-regulators associate with the RNA polymerase core and are often recruited through the binding of transcription factors to the core transcriptional complex.

REGULATION OF TRANSCRIPTION BY TRANSCRIPTION FACTORS

Transcription factors are co-activators or co-repressors that are categorized as *trans*-acting factors because they are regulatory agents that are not part of the regulated gene(s). These *trans*-acting factors regulate gene transcription by binding directly or through an intermediate protein to the gene at a particular DNA sequence, called a *cis*-regulatory region. This *cis*-regulatory region is usually located in the 5′-flanking promoter region of the gene and is composed of a specific nucleotide sequence, for example the cAMP response element (consensus sequence TGACGTCA). There is also a class of *cis*-regulatory elements called enhancers, which can be positioned anywhere in a gene and, consequently, are not restricted to the promoter region, which bind, for example, the glucocorticoid receptor. Binding of the *trans*-acting factor to the *cis*-regulatory region alters the initiation of transcription, probably through a direct interaction of the *trans*-acting factor with the RNA polymerase complex. This binding probably occurs through the secondary and tertiary structures of the genomic DNA–protein complexes. Usually, transcription factors bind as dimers to the DNA, suggesting that there are dimerization sites on transcription factors, as well as DNA-binding sites. There are several types of transcription factors, which are grouped by virtue of sequence similarities in their protein interaction and/or DNA-binding domains (Fig. 26-3). Similarities in protein–protein interaction sites suggest that monomers of different transcription factors can interact to form heterodimers. An individual heterodimer may bind to multiple *cis*-acting elements or, alternatively, interact with differing affinity for the same *cis*-acting element as compared to the homodimer. Indeed, these types of protein interaction do occur and provide a major source of regulatory complexity.

A particular *cis*-acting element may be present in multiple genes so that activation of a single transcription factor has potential for altering the expression of multiple target genes. Furthermore, an individual transcription factor may increase transcription of one gene while decreasing the transcription of another gene. This difference is partly due to the positioning of the *cis*-acting element relative to the start of transcription as well as to the identity of the protein partners in the heterodimer complex. It is important to note that, with the increase in sequence information being generated by the Human Genome Project, *cis*-acting elements can be found in genes, suggesting potential gene regulatory mechanisms without any biological information. While *cis*-acting element sequence identification in a gene is indeed predictive and necessary, this is often not sufficient to fully characterize the transcriptional regulation of that gene. *cis*-acting elements for a particular gene are commonly nonfunctional in all tissues and, even more often, silent in one tissue and active in another because of the differential distribution of transcription factors.

Technology that has hastened the study of transcription. Promoter characterization by filter binding assays and UV-crosslinking and various genetic assays such as knockout and regulated overexpression cellular and animal models have been invaluable in assessing translational regulatory mechanisms. However, the cellular complexity of the CNS makes use of these standard biochemical analysis problematic. Recently two methodologies have been developed that facilitate a more specific analysis of gene transcriptional mechanisms in the CNS and other tissues.

The chromatin immuno-precipitation assay (ChIP) is a procedure that is employed to determine which genes are

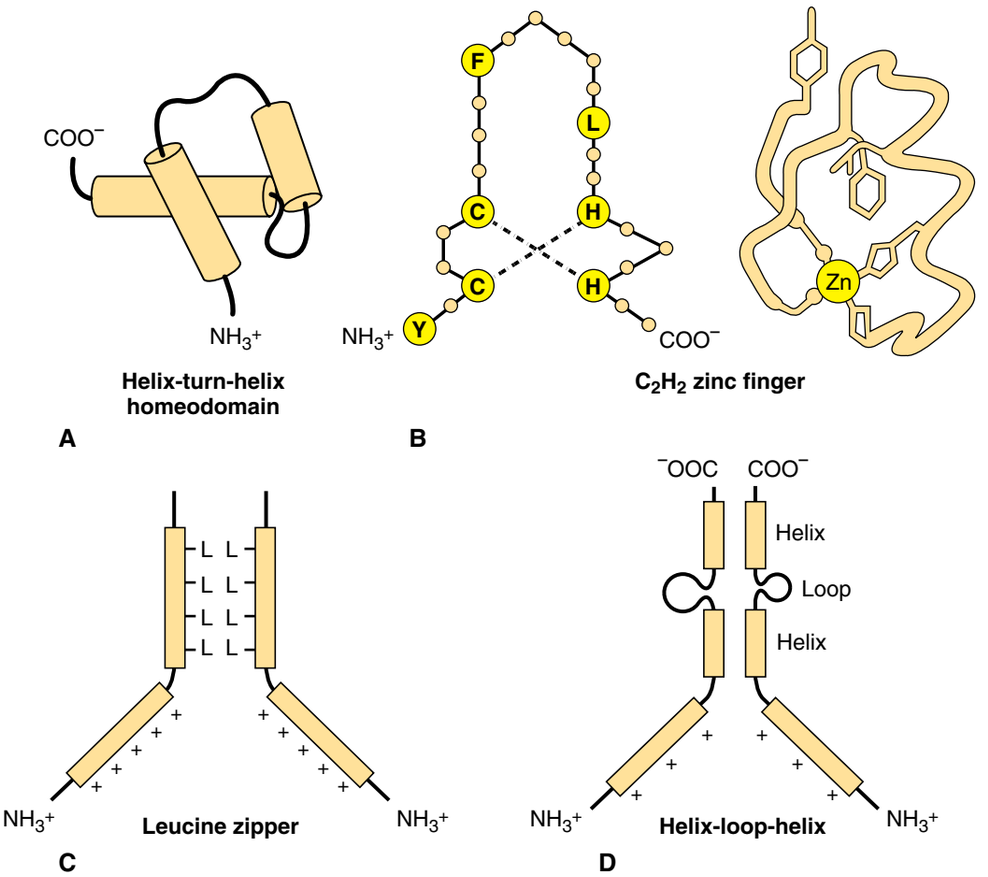

FIGURE 26-3 Structure of transcription factors from different families.

being transcriptionally regulated by a particular transcription factor, co-activator or co-repressor or any protein that affects gene activity. Biochemical analysis of transcription requires the isolation of cellular lysates and, when the cell is lysed, charged proteins, such as many transcription factors, often bind indiscriminately to DNA. The ChIP assay has the advantage of providing *in vivo* targets for analysis (Fig. 26-4). The assay works by first cross-linking DNA-binding proteins to chromatin DNA *in vivo*, using formaldehyde. This cross-linking freezes the protein of interest to the DNA to which it is bound. The chromatin is then isolated and sheared to small fragments. Antibodies to the protein of interest (e.g. transcription factor) are used to immunoprecipitate the specific protein and any DNA that is cross-linked to the protein. The immunoprecipitated protein-bound DNA is then amplified by polymerase chain reaction (PCR) and sequenced to identify the genes to which the protein was bound. The disadvantage is that the specificity of the reaction can be limited by the number of proteins cross-linked to a particular protein–DNA complex. Nonspecific results can easily be generated so great attention must be paid to secondary screens to confirm the ChIP-generated data.

Traditionally the analysis of genes that are regulated by particular transcription factors has proceeded one candidate gene at a time. With the advent of microarrays it is now possible to assess the abundance of thousands of mRNAs simultaneously. Microarrays have been used to determine the target genes for various transcription factors through the specific activation or repression of the biological activity of the transcription factor followed by RNA isolation, probe generation and microarray screening (Fig. 26-4). Since transcription can be a very rapid event, effort is made to isolate the RNA quickly after experimental manipulation of the experimental system. While such data can be quite useful, various cautionary notes must be kept in mind when assessing these data. The static RNA abundances assessed using this procedure reflects a balance between the transcriptional activity of the gene and the degradation of the RNA product. Little is known about the regulation of RNA degradation but, presuming that it can be a regulated and rapid event, then microarray data will inform the investigator of genes that are transcription- and degradation-regulated. Large-scale microarray analysis has been referred to as genomics and the resultant data as the transcriptome, i.e. the transcribed

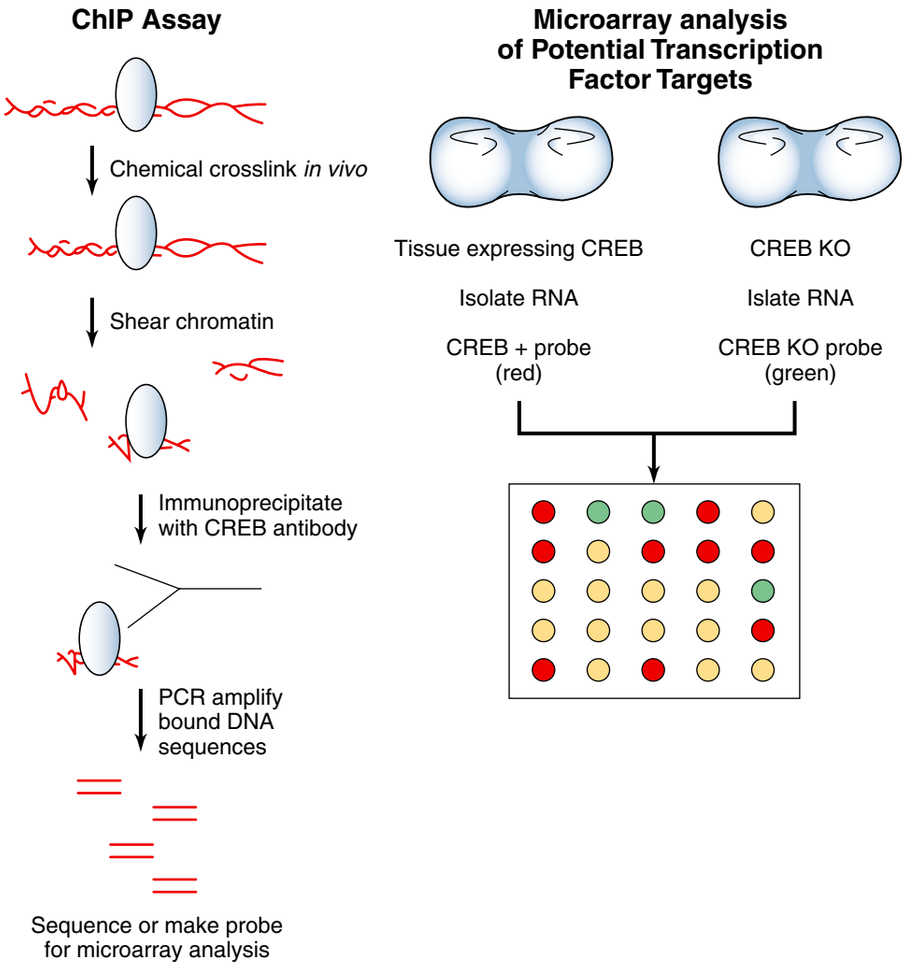

FIGURE 26-4 ChIP and microarray analysis of transcription. The chromatin immunoprecipitation assay is depicted in (**A**). Each of the steps leading to characterization of the DNA sequence associated with selected transcription factors is illustrated for the cAMP response element-binding protein (*CREB*) transcription factor. (**B**) A schematic of one method for selecting putative CREB-responsive genes. Brain tissues from a normal mouse and a CREB knockout (*CREB KO*) mouse are dissected, RNA is isolated and probes are made from each tissue with the $CREB^+$ probe giving rise to red fluorescence while the KO probe gives rise to green fluorescence. When simultaneously hybridized to an array containing thousands of immobilized clones, any RNA that is more abundant in CREB-containing tissue would be *red*, any RNA that is less abundant in CREB-containing tissue (knockout mouse) would be *green* and those RNAs that are present in nearly equal abundances appear as the *yellow* overlapped signal. The *red* fluorescing clones correspond to candidate genes whose transcription is stimulated by CREB while those that are *green* represent candidate genes whose transcription is inhibited by CREB. PCR, polymerase chain reaction.

genes in a particular cell or tissue. The regulated transcriptome for any particular type of stimulation would produce a subset of regulated genes that are good candidates for being associated with the function of particular transcription factors.

GLUCOCORTICOID AND MINERALOCORTICOID RECEPTORS AS TRANSCRIPTION FACTORS

The steroid hormones known as mineralocorticoids and glucocorticoids are synthesized in the adrenal cortex of mammals [3]. The physiological mineralocorticoid is aldosterone, and it is involved in regulating unidirectional Na^+ transport across the epithelium. The physiological glucocorticoid in most mammalian species is cortisol; however, in rats and mice, it is corticosterone (CORT). Initially, glucocorticoids were characterized by their ability to stimulate glycogen deposition and by their release into the circulation in response to stress. Glucocorticoids regulate a wide range of responses, including aspects of immunosuppression and inflammation (see Ch. 49). Glucocorticoids are released in response to increases in circulating adrenocorticotrophic hormones.

Two distinct classes of mineralocorticoid-binding sites were first described in the rat kidney. High-affinity cytosolic aldosterone-binding sites are termed mineralocorticoid receptors [4]. Lower-affinity aldosterone-binding sites

are termed glucocorticoid receptors. Glucocorticoid receptors are the same as dexamethasone-binding receptors [5].

While the affinity of mineralocorticoid receptors for aldosterone is higher than that for CORT, circulating concentrations of CORT are several orders of magnitude higher than aldosterone. CORT is effectively blocked from binding to the mineralocorticoid receptors by plasma proteins such as transcortin, which bind preferentially to CORT. Another mechanism that serves to alter the balance of CORT and aldosterone binding to receptors is the activity of 11β-hydroxysteroid dehydrogenase, which, in the rat kidney, rapidly oxidizes CORT to inactive metabolites. This facilitates binding of aldosterone to mineralocorticoid receptors in the presence of high concentrations of CORT [6].

Corticosteroid receptors regulate transcription in the nervous system. Intracellular binding sites selective for [^{3}H]-CORT were first identified in various brain regions, in particular the hippocampus, of adrenalectomized rats. A similar autoradiographic pattern was obtained using [^{3}H]-aldosterone as a ligand, suggesting that these receptors were mineralocorticoid receptors. The [^{3}H]-dexamethasone-binding pattern shows selective differences in the pattern of binding compared to the CORT and aldosterone patterns, suggesting the existence of multiple corticosteroid receptors. [^{3}H]-CORT binding performed in the presence of unlabeled dexamethasone or aldosterone reveals that CORT binds to at least two receptor types in the brain.

Two high-affinity intracellular corticosteroid receptors have been characterized and are distinguished on the basis of binding properties, amino acid sequence, neuroanatomical distribution and physiological function. The type I corticosteroid receptor, or mineralocorticoid receptor, is localized in various brain regions, including the septum and hippocampus [7]. The type I receptor binds CORT and aldosterone with high affinity, ≈0.5 nmol/l. The relative steroid binding affinity of the type I receptor for CORT is greater than or equal to that for aldosterone, which is greater than that for dexamethasone. The type I receptor is present in all subregions of the hippocampus, i.e. in the CA1, CA2, CA3 and the granular cells of the dentate gyrus (Fig. 26-5).

The type II corticosteroid receptor, also called the glucocorticoid receptor, is widely distributed in the brain and exhibits high-affinity binding to dexamethasone. The type II receptor binds with tenfold lower affinity to corticosterone, 5 nmol/l, as compared with the type I receptor. The relative binding affinities for steroid interaction with the glucocorticoid receptor are such that dexamethasone binding is greater than corticosterone binding, which is much greater than aldosterone binding. Glucocorticoids are present at high concentrations in all regions of the hippocampus, with the exception of the CA3 region, where concentrations are exceedingly low [8].

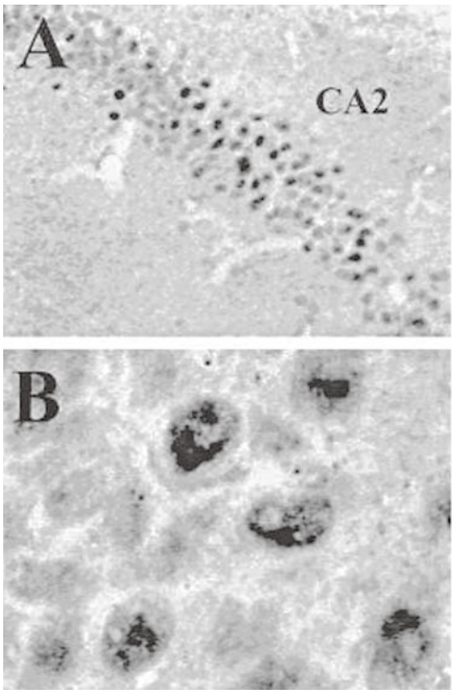

FIGURE 26-5 Immunohistochemical localization of type I corticosteroid receptor (mineralocorticoid receptor) in the rat hippocampus. (**A**) Mineralocorticoid immunoreactivity is concentrated in pyramidal cell fields of the cornu ammonis (*CA2*). (**B**) High-power photomicrograph shows that steroid-bound mineralocorticoid receptors are primarily localized to neuronal cell nuclei. (Courtesy of Dr James P. Herman, Department of Anatomy and Neurobiology, University of Kentucky.)

Mineralocorticoid and glucocorticoid receptors can coexist in the same neurons, as evident from their demonstrated colocalization in the CA1 region of the hippocampus [9]. These CA1 neurons are exquisitely sensitive to the whole range of glucocorticoid concentrations. Because of their high affinity for corticosteroids, the type I receptors are approximately 80% occupied, suggesting that the number of type I receptors is likely to be the rate-limiting factor in mineralocorticoid receptor functioning. However, glucocorticoid receptor functions are most dependent on the extent of glucocorticoid receptor occupancy and are likely to be regulated by the concentration of the available steroid. The presence of multiple binding sites for corticosteroids and their differing concentrations in different cell types forms the molecular basis for their differential actions in the rat brain [10].

The mechanisms of corticosteroid receptor regulation of transcription have been elucidated. Both type I and type II corticosteroid receptors are members of a superfamily of ligand-activated transcription factors defined by protein sequence similarity. Included in this superfamily are various other steroid receptors, such as the estrogen receptor, as well as members of the retinoic acid receptor

family and thyroid hormone receptors. The ligand-activated transcription factor superfamily is estimated to contain several hundred members. Mineralocorticoid and glucocorticoid receptors are each composed of four distinct protein regions, including an N-terminal region, a DNA-binding domain, a nuclear localization signal and a C-terminal hormone-binding region. The N-terminal region is associated with activation of transcription through an as yet unknown mechanism. The DNA-binding domain is a charged protein sequence, known as a zinc-finger. In this case, there are two fingers, each composed of the sequence Cys-X2-Cys-X13-Cys-X2-Cys. The C-terminal region binds glucocorticoids, which, when bound, initiate the conformational change of the receptor which facilitates its translocation.

In the cytoplasm, the mineralocorticoid and glucocorticoid receptors are associated with a large multiprotein complex that contains the heat shock proteins (HSP) HSP70 and HSP90 (Fig. 26-6). This complex maintains unbound corticosteroid receptors in a ligand-accessible but inactive protein conformation. Binding of ligand causes dissociation of receptors from the heat shock proteins, followed by translocation of the activated receptors to the nucleus. In the nucleus, ligand-bound corticosteroid receptors bind to a *cis*-acting element called glucocorticoid response element (GRE). The GRE is a 15-base sequence, TGGTACAAATGTTCT, and is also called an enhancer element because it generally functions to enhance transcription. The GRE can be positioned anywhere within the gene, not just in the promoter region. Modulation of corticosteroid-responsive genes occurs through interactions of the type I or II receptors, bound to the enhancer sequence, with the transcriptional complex.

Ligand-bound corticosteroid receptors have been shown to interact to form heterodimers with other transcription factors, such as the *jun* protein. Such interactions are responsible for transactivation of the *cis*-regulatory sites known as AP-1 sites and for the glucocorticoid-mediated suppression of transcription, such as that seen in the pro-opiomelanocortin gene. A number of such specific protein interactions have been reported; these interactions and their locations relative to other transcription factors transform a ubiquitous steroid hormone signal into a tissue-specific, graded cellular response.

More recently, the protein–protein coimmunoprecipitation assay coupled with the ChIP assay has highlighted particular genes whose promoters bind to steroid receptors and whose transcription can be modulated by these receptor-associated proteins [11, 12]. Among these co-activators are various acetyltransferases such as CBP and p300 and the ATP-coupled chromatin remodeling SWI/SNF complex, as well as the protein methylase CARM-1 [13]. Each of these proteins has the capacity to modulate chromatin structure through post-translational modification of the chromatin. Co-repressors of steroid receptor-mediated gene transcription have also been

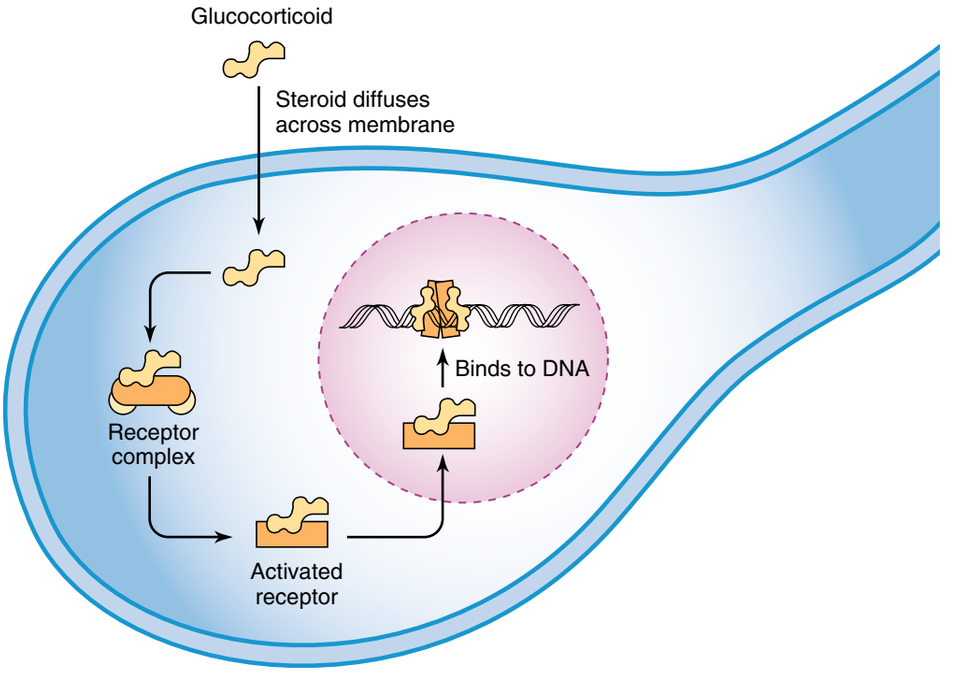

FIGURE 26-6 Activation of glucocorticoid receptors. Glucocorticoids diffuse across the plasma membrane and bind to the glucocorticoid receptor. Upon glucocorticoid receptor binding to the steroid, the receptor undergoes a conformational change which permits it to dissociate from the chaperone heat shock proteins (*light orange circles*). The activated glucocorticoid receptor translocates across the nuclear membrane and binds as a homo- or heterodimer to glucocorticoid response element sequences to regulate gene transcription.

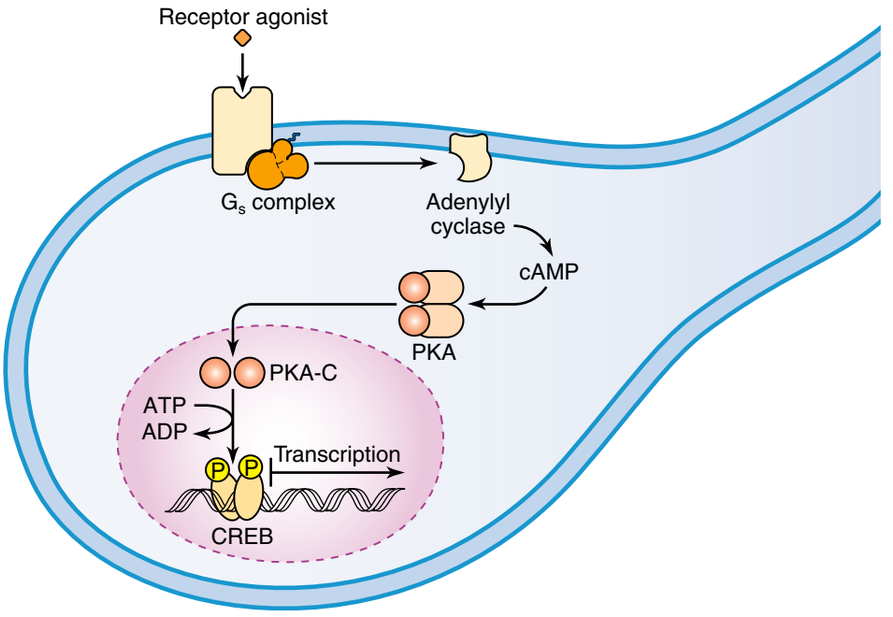

FIGURE 26-7 Activation of cAMP-regulated genes. When agonists bind to G-protein-coupled receptors that activate dissociation of G_s from the G_s complex, G_s will interact with the enzyme adenylyl cyclase, resulting in synthesis and increase of intracellular cAMP. cAMP binds to the regulatory subunits (*orange ovals*) of protein kinase A (*PKA*). This binding facilitates the dissociation of the catalytic subunits (*gray circles*) from the PKA complex, which then translocate across the nuclear membrane and phosphorylate cAMP response element-binding protein (*CREB*) and CREB-related proteins. Phosphorylated CREB increases gene transcription (*right arrow*).

characterized using similar methodologies [12]. At least some steroid receptor co-repressors can function through chromatin deacetylation through the mediation of Sin3 and histone deacetylase. The characterization of co-regulators of gene expression promises to highlight mechanisms for the coordinate regulation of multiple genes by a specific modulator as well as mechanisms for cell specific responses to regulatory signals.

A compendium of genes that are good candidates for being regulated by glucocorticoids has been generated using microarray technology. For example, the glucocorticoid-regulated abundances of RNAs encoded by various genes have been characterized in lymphoid cells during apoptosis. In support of the selectivity of the glucocorticoid responsiveness of these genes, data were generated showing that many of these genes are nonresponsive to glucocorticoids when glucocorticoid receptors are blocked by a glucocorticoid receptor antagonist. Data such as these highlighting potential multiple targets of steroid hormone receptor regulation may provide therapeutic targets to modulate unwanted 'side effects' of glucocorticoid receptor therapeutics.

CYCLIC AMP REGULATION OF TRANSCRIPTION

Cyclic AMP controls phosphorylation of the cAMP response element binding protein. Activation of a transcription factor known as the cAMP response element binding protein (CREB) is the final step in a signal-transduction pathway that is initiated by the binding of a specific class of cell-surface receptors [14] (Fig. 26-7). Binding of a ligand to a G_s protein-coupled receptor, such as the D_1 dopamine receptor or the 5-hydroxytryptamine-1 receptor, liberates G_s protein from the G-protein complex (see Ch. 20). Subsequently, G_s activates adenylyl cyclase, which in turn stimulates cAMP production. The increase in intracellular cAMP induces the dissociation of protein kinase A (PKA) catalytic subunits from their regulatory subunits (see Ch. 22). The catalytic subunits move into the nucleus, where they phosphorylate a number of proteins, including the CREB transcription factor. This phosphorylation event activates CREB protein and transcription is stimulated [15]. The genes which are activated by CREB are those that have the *cis*-acting palindromic CRE consensus sequence (TGACGTCA) in the promoter region. This is distinct from the enhancer activity of the previously discussed GREs, which can function at sites distinct from the promoter region of a given gene. CREB protein appears to be ubiquitously expressed in the brain, with high concentrations in the hippocampus (Fig. 26-8) and cortex. As seen in Figure 26-8, it is apparent that much of the CREB immunoreactivity is present in the nucleus of CA1 pyramidal cells.

The critical feature of CREB protein activation is phosphorylation, which is required for CREB-mediated stimulation of transcription [16]. PKA phosphorylates CREB on a serine positioned at amino acid 133 in the CREB protein sequence. How phosphorylation activates

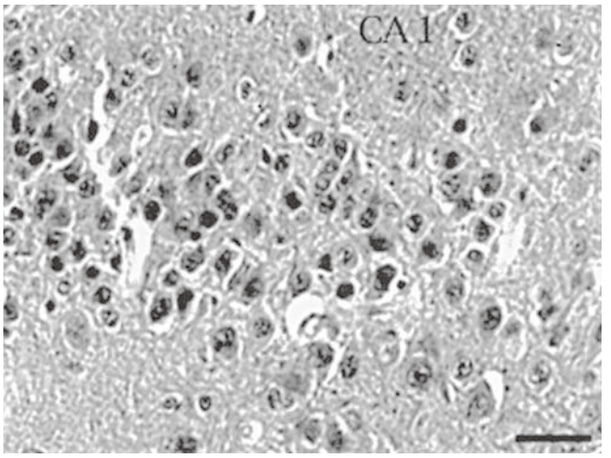

FIGURE 26-8 Immunohistochemical localization of cAMP response element-binding protein (*CREB*) in rat hippocampal neurons. Using a polyclonal antibody which recognizes both CREB and phospho-CREB protein, it is apparent that CREB protein is enriched in the nucleus of pyramidal cells of the CA1 region of the hippocampus. Scale bar is 30 μm. (Courtesy of Dr Stephen Ginsberg, Department of Pathology, University of Pennsylvania.)

CREB-mediated transcription is unclear. Some investigators believe that phospho-CREB has a slightly higher affinity for CRE binding and others believe that transcription factor interaction with the transcriptional complex is stimulated by phosphorylation. The time course for CREB stimulation of transcription is relatively rapid, peaking at approximately 30 minutes after cAMP stimulation, followed by a gradual decrease to basal levels of activation over the course of several hours. This decrease in activation occurs through the activity of protein phosphatase 1 and other phosphatases, which remove the phosphate group from CREB protein. It is important to note that there is increasing evidence that CREB phosphorylation can be induced by factors other than an increase in intracellular cAMP concentrations. The relative contribution of these other stimulators, including an increase in intracellular Ca^{2+}, to the transcriptional activation exhibited by phospho-CREB is under active investigation.

Numerous studies have shown that once CREB is phosphorylated it recruits the histone acetyltransferase CBP to activate gene transcription and that this activation can be ameliorated through the activity of histone deacetylase [17]. While this consensus model does appear to account for the bulk of CREB-mediated transcription, more recent data using a constitutively active CREB mutant and microarray analysis of neuronal gene expression have highlighted the plethora of CREB-regulated genes [18, 19]. Examination of a subset of these genes upon CREB activation in the presence of a histone deacetylase inhibitor has show that not only are the RNA abundances for some of the CREB-responsive genes enhanced, a subset of the genes is inhibited by this treatment. ChIP assays have shown that the differential roles of histone deacetylases in CREB-mediated transcription are evident at the level of preinitiation complex recruitment. These data suggest a complexity of CREB-responsive gene expression that probably involves several co-regulators beyond the simple acetyltransferase mediators.

In large part, the modulation of CREB-regulated genes represents the intracellular balance of active kinases and phosphatases, which is a reflection of cellular activation. This is one of the major differences between CREB and glucocorticoid-receptor-regulated transcription: CREB is an integrator of intracellular homeostasis, while the glucocorticoid receptor integrates whole-body homeostasis.

The cAMP response element binding protein is a member of a family containing interacting proteins. After the mRNA encoding CREB protein was cloned and sequenced, several other members of the CREB family of transcription factors were identified. Using homology screens, the PCR and interaction screening assays, a protein called cAMP response element modulator (CREM) was isolated. CREM can both stimulate and inhibit cAMP-mediated gene transcription. Transcriptional inhibition can occur as a result of generation of modified CREM proteins because of alternative splicing of the CREM mRNA (Fig. 26-9). Among these different proteins are the α, β and γ forms of CREM, which lack the glutamine-rich region present in the activator forms of both CREM and CREB that is required for stimulation of transcription [20]. Inhibition occurs due to heterodimer formation between this inactivating form of CREM and either CREM or CREB [21]. The alternatively spliced forms of CREM, as well as those recently discovered for CREB, which can also act as transcriptional inhibitors, occur in a tissue- and cell-type-specific manner. Additionally, recent data have shown that CREB can interact with other leucine-zipper-containing transcription factors to produce heterodimers that can interact with *cis*-acting elements distinct from the CRE, as previously discussed with regard to the corticosteroid receptors [22]. These findings provide a mechanism for generation of tissue- and cell-type differences in cAMP responsiveness [23].

The function of the cAMP response element binding protein has been modeled in transgenic organisms. The observation that serotonin stimulates learning and memory in the *Aplysia* system with the subsequent discovery that cAMP will mimic this effect suggested that cAMP was involved in this physiological process (see Ch. 50). Recently, direct evidence for the involvement of CREB in learning and memory was presented in the *Drosophila* system (see below). *Drosophila* as an experimental system has several advantages over mammalian systems, including the ease of generation of mutant as well as transgenic flies.

The role of CREB in learning and memory was first anticipated by screening *Drosophila* mutants in a learning and memory task in which flies were behaviorally tested

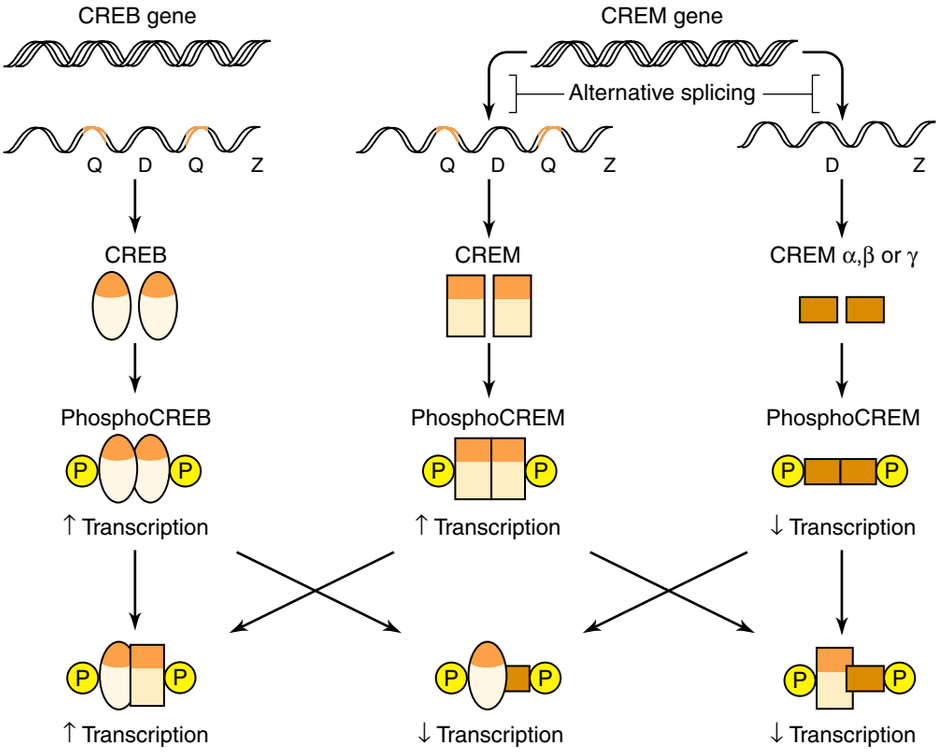

FIGURE 26-9 Mechanism for generation of activators and repressors of cAMP-stimulated transcription. The cAMP response element binding protein (*CREB*) and the cAMP response element modulator (*CREM*) genes can give rise to alternatively spliced mRNAs, which give rise to distinct protein products. While CREB and CREM can stimulate CRE-mediated gene expression, generation of the α, β or γ forms of CREM will produce proteins that can heterodimerize with activated CREB and CREM subunits, inhibiting their stimulatory capacity. The symbols used to highlight functional regions of CREB and CREM protein are *Q* for the polyglutamine tract, which stimulates transcription; *D* for the DNA-binding region; and *Z* for the leucine zipper region, which is involved in dimerization.

in an odorant-association task, where an odorant was paired with an electric shock. Flies with 'normal' phenotype learn that the odorant is associated with an electric shock and will learn to avoid the odorant. Two fly mutants were discovered that could not learn this association: *dunce* and *rutabaga*. The *dunce* mutant was deficient in cAMP phosphodiesterase, which breaks down cAMP, and the *rutabaga* mutant had a mutation in adenylyl cyclase, which synthesizes cAMP. These data combined with the prior *Aplysia* work suggested that CREB was involved in acquisition of learning and memory [24].

More recently, with the same odorant-association behavioral test, the specific role of CREB in learning and memory was assessed by using a dominant-negative CREB (dCREB) protein expressed in transgenic flies [25]. This dCREB complexes with normal CREB through a functional leucine zipper region, yet inhibits the transcriptional activation mediated by normal CREB protein. The experiment was designed so that dCREB was controlled by a heat shock promoter and could be activated in the adult animal. This experimental paradigm allows for the assessment of the role of CREB in the adult animal by using heat shock to induce dCREB expression rather than by examining the behavioral consequences of CREB deficiency during development. Heat shock does not, in and of itself, alter learning and memory [26]. Data from these experiments show that the form of memory requiring protein synthesis, called long-term memory (see Ch. 50), was inhibited by expression of dCREB. This inhibition was not observed when a mutant dCREB, in which the leucine zipper was inactivated by site-directed mutagenesis, was expressed in flies. This leucine zipper mutant precludes dCREB dimerization with normal CREB. These data show that the relative concentrations of activating and inhibiting CREB monomers are critical to the development of long-term memory.

The dissection of CREB involvement in various physiological or behavioral paradigms in the mammalian system has been much slower than in *Drosophila*. In the mammalian system, targeted gene disruption has been used in attempts to inhibit CREB function. In one set of experiments, the exon of the gene containing the initiator methionine was deleted in hopes of blocking CREB production. However, the targeting of this region facilitated an alternative splicing event so that a previously undiscovered spliced variant mRNA of the CREB gene was produced and was, in fact, upregulated. In the other targeted disruption experiments, the DNA-binding region

was disrupted and, indeed, CREB protein production was inhibited. Unfortunately, this disruption resulted in perinatal lethality, so no adult animals could be generated. The problem with the design of these experiments is that targeted disruption of CREB production would result in a developmental deficit, making it difficult to attribute any particular modification of behavior in the adult to a direct deficiency of CREB.

What is needed to directly assess the involvement of CREB in adult mammalian neurons is the production of a conditional knockout mouse in which the knockout could be activated in the adult animal in a tissue-specific manner. This mutant could be similar to the production of a dominant-negative mutant, as was done in the *Drosophila* system, or potentially through induction of genetic recombination in adult neurons using an inducible system similar to that being used to produce conditional knockouts for other genes (see Ch. 40). Such a model system would be very useful in understanding the potential involvement of CREB in long-term memory in the mammalian system as well as in other physiological conditions associated with CREB functioning, such as opiate tolerance and withdrawal (see Ch. 53) or aspects of behavioral aggressiveness (see Ch. 49).

TRANSCRIPTION AS A TARGET FOR DRUG DEVELOPMENT

It should be clear from this brief discussion of transcription factors that disruption of transcription factor function may have dire consequences for neuronal functioning. Because of their pivotal role in the regulation of multiple genes, they are potential targets for pharmacological intervention in the control of disease processes [27]. Indeed, the multigenic regulatory role of transcription factors suggests one mechanism by which multigenic diseases can exhibit multiple physiological characteristics. The combinatorial nature of transcription factor activity implies that, should the activity of a transcription factor be modulated then multiple downstream genes will likewise be regulated. This suggests that the problem with development of drugs targeted to transcription factors is that there are several hundred estimated *trans*-acting factors in the nucleus, many of which can heterodimerize to produce distinct transcriptional responses. The strategies being investigated to modulate transcription factor function focus on antisense knockout of expression and modulators targeted toward post-translational modifiers of transcription factors. Such modifiers include protein kinases and phosphatases.

Often, it is desirable to block expression of particular genes that are activated by transcription factors. The antisense knockout experiments are directed toward this end and require the addition of an antisense oligonucleotide, which will anneal to the *cis*-acting regulatory element for a particular transcription factor in a specific gene. The hope is that a triple helical structure will form around this oligonucleotide-binding site, inhibiting the expression of the downstream gene.

This same strategy can be attempted at the mRNA level to inhibit the translation of individual mRNAs. These experiments are almost never 100% efficient; hence, the problem becomes how much neutralization is necessary to elicit the desired effect. If the antisense oligonucleotide is targeted toward the mRNA for a particular transcription factor or splice form of a transcription factor, then it may be possible to knock down or reduce the expression of that particular protein. The result of such a knockdown will be a new balance of transcription factor subunits in the cell, probably resulting in alteration of the relative amounts of particular homo- and heterodimers.

Finally, development of drugs targeted toward modification of kinases and phosphatases required for activation or inhibition of particular transcription factors is a promising therapeutic approach. The problem with this paradigm is the specificity of the kinases and phosphatases, since they will often act enzymatically on multiple proteins (see Chs 24 and 25). Furthermore, such drugs often lack specificity and may interact with multiple kinases or phosphatases.

Clearly, transcription is a critical regulatory nexus in neuronal function. More information is being generated about the biology of transcription factors, including how many transcription factor genes exist, which proteins dimerize, identification of the *cis*-acting elements to which they bind and how transcription is modulated by these proteins. From these studies, significant insight into the mechanisms of transcriptional responses to the local environment and to pharmacological agents in the normal and abnormal nervous system will be gained.

GROWTH FACTORS ACT COMBINATORIALLY AND SEQUENTIALLY TO REGULATE NERVOUS SYSTEM DEVELOPMENT 483

GROWTH FACTORS ARE ESSENTIAL FOR NERVOUS SYSTEM DEVELOPMENT AND FUNCTION

Growth factors have been defined as proteins that stimulate cellular proliferation and promote cellular survival. The number of molecules considered to have growth factor activity has been substantially expanded with the discovery of the diverse and complex roles these molecules play both in the developing animal and in the adult. Historically, the first growth factor to be identified was nerve growth factor (NGF) by Rita Levi-Montalcini [1]. This molecule has been termed a neurotrophic factor, since its actions are largely restricted to the nervous system. NGF has now been shown to have an extraordinarily wide array of activities and has forced a substantial reevaluation of how growth factors are defined. The nervous system exhibits remarkable cellular heterogeneity and one of the major challenges is to elucidate how a relatively small number of growth factors act to direct the development of the nervous system and sustain these cells in the mature animal [2]. Some growth factors act only during restricted periods during development while others function throughout the life of the animal. In the past, attempts have been made to distinguish between 'neurotrophic factors' and growth factors; however, this has not proved to be a useful distinction given our current appreciation of the broad range of actions of these molecules.

At very early developmental stages, growth factors play critical roles in determining cell fate throughout the organism. Stem cell populations that give rise to the nervous system are influenced by growth factors that direct the cell toward either a neuronal or glial fate (see Ch. 29). Subsequent decisions on the phenotypic commitment to become a specific cell type and subclass are also governed by the combinatorial actions of several growth factors.

The nervous system is subject to a unique set of constraints during development. Many more neurons are generated during development than are required in the mature nervous system. Importantly, after their last mitotic division neurons are unable to re-enter the cell cycle and can no longer proliferate. As development proceeds there is a period during which as many as half of all neurons die, a process known as normal or programmed cell death that occurs by apoptosis of the cell (see Ch. 35).

Basic Neurochemistry: Molecular, Cellular and Medical Aspects
0-12-088397-X

Programmed cell death typically occurs at the time that the axonal processes of the innervating neurons arrive at and invade their peripheral target tissues. The selective survival of only a fraction of the initial number of neurons is accomplished by the competition of the innervating processes for a limited amount of trophic factor elaborated by the target tissue. Those neurons that fail to obtain the target-derived trophic factor then die. This concept forms the basis of what is now known as the 'neurotrophic factor hypothesis'. This mechanism can largely account for the tailoring of the number of neurons that connect with their targets in the periphery to the size of the target field, resulting in a stable neuronal population whose size is essentially determined at birth. Trophic factors are then continuously supplied by the target to those neurons that establish functional connections. The trophic factor is internalized at the nerve ending and then retrogradely transported to the cell body (Fig. 27-1). While much of the data supporting this hypothesis has been gathered through the study of the peripheral nervous system, it is clear that analogous mechanisms also operate in the central nervous system [3].

Trophic factors can also be supplied through less specific mechanisms. Growth factors are synthesized by a wide variety of cell types, including neurons and glial cells. The factors are secreted into the extracellular milieu where they diffuse and then act in a paracrine fashion on other cells (Fig. 27-1). Indeed, there is evidence that this type of paracrine support is necessary to sustain neurons as they extend their processes over long distances in the developing nervous system [2]. An analogous process, autocrine stimulation, occurs when a cell synthesizes and secretes a growth factor to which the cell itself is responsive. In this case, the cell provides its own trophic support.

Individual neurons and glial cells are responsive to a number of different growth factors. Growth factors play both unique and overlapping roles in the development and sustenance of these cells. Perhaps the most dramatic example of this is the elaborate array of trophic factors that have evolved to support spinal motor neurons. There are presently at least 15 different factors that are known to influence the survival of these cells [4].

Recently, it has been appreciated that some of these growth factors serve a much wider role. For example, nerve growth factor has been shown to acutely regulate aspects of neurotransmitter synthesis and release, as well as mediating both synaptic plasticity and the stabilization of synaptic contacts. It is likely that in subsequent years we will discover additional novel actions of these molecules.

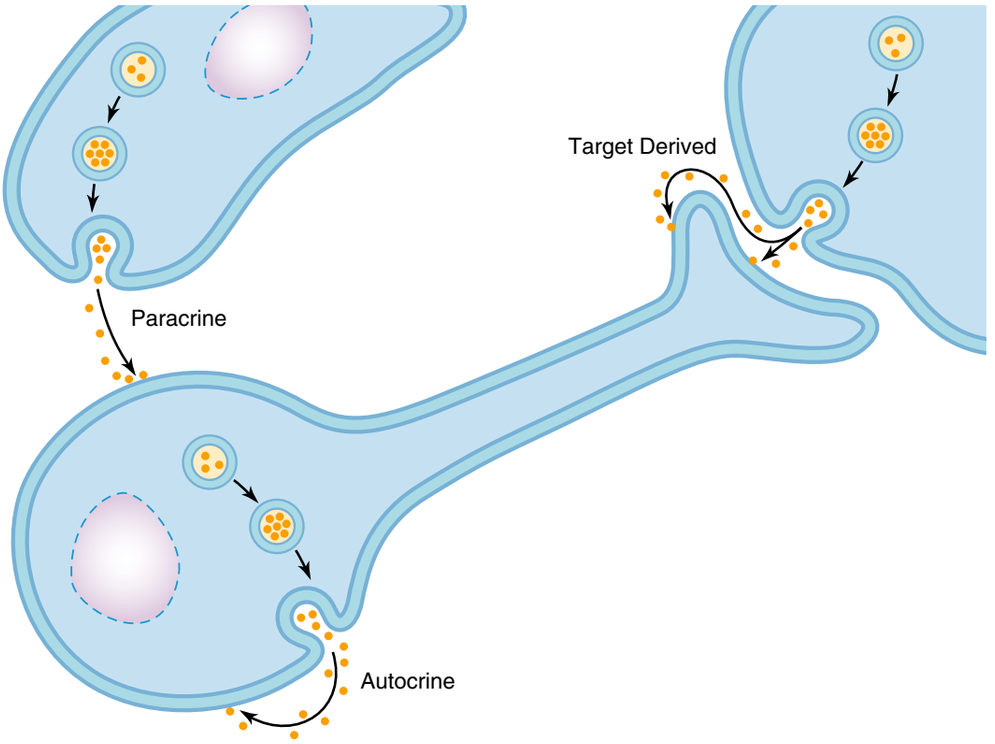

FIGURE 27-1 Mechanisms of growth factor/trophic factor support. Growth factors can be provided to cells through autocrine mechanisms in which the cell secretes growth factors to which itself responds while paracrine support is mediated by secretion of factors which then act upon neighboring cells. Target-derived support of neurons is mediated by the growth of fibers into their target tissues. The target tissue synthesizes the growth factor and provides it to the innervating neurons.

Cells respond to growth factors as a consequence of the binding of the factors to specific cell-surface receptors. The association of the growth factors with their receptors leads to activation of extraordinarily complex signal transduction pathways, leading to biochemical changes in the cells that mediate cellular survival as well as the acquisition and maintenance of the cellular phenotype. The responsiveness of a cell to any particular growth factor is dependent upon expression of specific receptors on the plasma membrane. The regulated expression of such receptors is a well documented feature of development and temporally regulates the sensitivity of the cells to growth factors in their environment. It is noteworthy that the receptors for many of the growth factors are themselves protein kinases whose enzymatic activity is stimulated upon association with their specific ligand, thereby initiating intracellular signaling events [5, 6]. Other growth factor receptors also employ protein kinases to initiate their action but do so through the incorporation of these enzymes within large signaling complexes that are assembled subsequent to growth factor binding. The specificity of growth factor action is governed by the intrinsic structure of the receptor; the extracellular domain imparts ligand binding specificity while the intracellular domain specifies the intracellular signaling pathways that are activated upon ligand binding.

Growth factors activate multiple signal transduction pathways required for survival and differentiation. The signal transduction pathways that mediate the actions of growth factors have been examined in detail. Multiple signaling pathways are activated in parallel following receptor binding that result in cellular survival and direct the acquisition and maintenance of the cellular phenotype [5, 6]. The principal signaling pathway that is responsible or sustaining for cellular viability involves the activation of phosphotidylinositol 3-kinase (PI3K) [7]. The binding of growth factors to their receptors result in the formation of large receptor-associated complexes comprised of a diverse array of signaling elements on the inner face of the plasma membrane. PI3K is recruited to the receptor and is then enzymatically activated. The enzymatic product of PI3K is phosphatidylinositol trisphosphate, which is a bioactive lipid species that is responsible for the formation of stable signaling complexes and the activation of the serine/threonine kinase Akt. Akt activation, in turn, stimulates a signaling cascade that results in the synthesis of proteins that protect the cell from death, inactivates proapoptotic signaling proteins and stimulates the basic metabolism of the cell, such as protein synthesis. The activation of a second major signaling pathway, the MAP kinases or extracellular signal regulated kinases (ERKs) is a common effect of cellular stimulation by all growth factors. ERK activation is linked to a large number of growth factor actions. In neurons, ERK activity is required for the initiation and extension of neuritic processes and the morphological differentiation of these cells [8]. The individual growth factors elicit specific effects and the signaling events that subserve these actions are the subject of intense investigation. A more detailed description of intracellular signaling pathways can be found in Chapters 23 and 24.

CLASSES OF GROWTH FACTORS ACTING IN THE NERVOUS SYSTEM

There are several major classes of growth factors that act within the nervous system (Table 27-1). Some of these, such as the neurotrophins, act almost exclusively in the nervous system, while others, for example fibroblast growth factors and insulin-like growth factor I, act on a number of cell types throughout the body in addition to the nervous system. Unexpectedly, it has been discovered that a subset of growth factors whose actions where thought to be restricted to the immune system have important actions on both neurons and glial cells. The determination of which molecules can legitimately be termed growth factors has thus become less clear. There are a growing number of factors that act to regulate

TABLE 27-1 Growth factors acting in the nervous system

Growth factor	Receptor
Neurotrophins	
Nerve growth factor	TrkA
Brain-derived neurotrophic factor	TrkB
Neurotrophin 3	TrkC
Neurotrophin 4/5	TrkB
Neurokines	
Ciliary neurotrophic factor	CNTFRα, LIFRβ + gp130
Leukemia inhibitory factor	LIFRβ, gp130
IL6	IL6Rα, gp130
Cardiotrophin 1	LIFRβ, gp130 + ?
Fibroblast growth factors	
FGF-1 (acidic FGF)	FGFR1–4
FGF-2 (basic FGF)	FGFR1–3
Transforming growth factor β superfamily	
Transforming growth factors β	TGFβRI and TGFβRII
Bone morphogenetic factors	BMPR I and BMPRII
Glial-derived neurotrophic factor family	
Glial-derived growth factor	c-Ret, GDNFRα-1
Neurturin	c-Ret, GDNFRα-2
Artemin	c-Ret, GDNFRα-3
Persephin	c-Ret, GDNFRα-4
Epidermal growth factor superfamily	
Epidermal growth factor	EGFR
Transforming growth factor α	EGFR
Neuregulins [GGF, ARIA, SMDF, etc.)	ErbB2, ErbB3, ErbB4
Other growth factors	
Platelet derived growth factor	PDGFRα and β
Insulin-like growth factor I	IGFR-I
Hepatocyte growth factor	c-Met
Macrophage-stimulating protein	c-Ron

TABLE 27-2 Neurotrophin targets

	Peripheral	Central
Nerve growth factor	Sympathetic neurons Sensory neurons:dorsal root ganglia	Basal forebrain cholinergic neurons Striatal cholinergic neurons Purkinje cells
Brain-derived neurotrophic factor	Sensory neurons: nodose dorsal root neurons	Spinal motor neurons Basal forebrain cholinergic neurons Substantia nigra dopaminergic neurons Facial motor neurons Retinal ganglion cells
Neurotrophin 3	Sympathetic neurons Sensory neurons	Basal forebrain cholinergic neurons Locus ceruleus neurons
Neurotrophin 4/5	Sympathetic neurons Sensory neurons: nodose dorsal root ganglia	Basal forebrain cholinergic neurons Locus coeruleus neurons Motor neurons Retinal ganglion cells

specific aspects of development and are unlikely to play significant roles or have currently unappreciated roles in the nervous system of the mature animal.

The neurotrophins comprise a family of highly related molecules that act to support the survival and phenotypic specificity of select subsets of neurons. The neurotrophins (Table 27-2) are small highly basic proteins of approximately 13 kDa that dimerize to form the biologically active species [5]. The neurotrophins have a highly conserved structure. This family includes five distinct members: NGF, brain-derived neurotrophic factor (BDNF), neurotrophin 3 (NT3), neurotrophin 4/5 (NT4/5) and neurotrophin 6 (NT6). NT6 is found only in fish and will not be discussed further.

The neurotrophins interact with two distinct cell surface receptor species [5, 6, 9] (Fig. 27-2). The neurotrophins bind to the Trk family of receptors, which serve as the principal signal transducer for this class of growth factors. The Trk receptors comprise a small, highly related family of molecules that possess an extracellular ligand binding domain that selectively interacts with the individual neurotrophin species. Trk A specifically binds NGF, TrkB interacts with BDNF and NT4/5, and TrkC preferentially binds NT3. Importantly, the Trk receptors have an intracellular tyrosine kinase domain that is activated upon neurotrophin binding. The kinase domains of the Trk family members are highly conserved and the Trks differ mainly in the structure of their extracellular domains. Trk receptor expression is limited to neurons and the

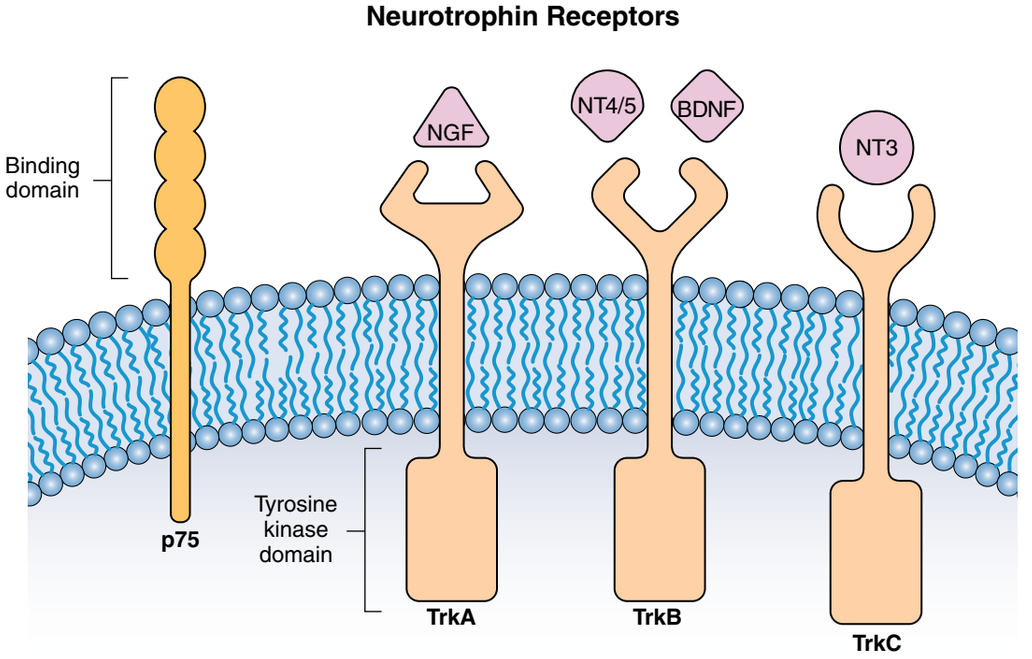

FIGURE 27-2 Neurotrophin receptors. Neurotrophin family members bind specifically to cognate Trk receptors. The low affinity neurotrophin receptor, p75, promiscuously binds all neurotrophins. *BDNF*, brain-derived neurotrophic factor; *NGF*, nerve growth factor; *NT*, neurotrophin.

responsiveness of subpopulations of neurons to the neurotrophins is due to the restricted and selective expression of the individual Trk receptor species. The neurotrophins also bind to another receptor, termed p75 or the low affinity neurotrophin receptor. p75 is promiscuous and binds all mature neurotrophin species with low affinity. It has recently been shown to also bind to the longer unprocessed precursor forms of NGF. p75 can interact with the Trks to participate in a heteromeric receptor complex to transduce neurotrophin signals. It has recently been discovered that p75 binds the immature pro-forms of the neurotrophins with high affinity, and this interaction may play a role in nervous system responses to injury. The p75 receptor has also been shown to be a co-receptor for other cell surface receptors. It is clear that the p75 receptor plays more diverse and complex roles that previously appreciated and that its actions are not restricted to neurotrophin biology [10].

The specific actions of the individual neurotrophins have been the subject of intense interest (Table 27-2). It is now evident, through analysis of animals in which the individual neurotrophin genes or their receptors have been knocked out, that the family members have unique actions acting exclusively to support some neuronal subpopulations [11]. However, in some neuronal populations, the action of several of the neurotrophins overlap. For example, in the peripheral sensory ganglia, individual neurons are responsive to more than one neurotrophin.

Nerve growth factor is the prototypic member of the neurotrophin family [9]. It was discovered on the basis of its ability to stimulate the dramatic outgrowth of processes from sympathetic ganglia. NGF is absolutely required for the survival of sympathetic and a subset of sensory neurons during development. NGF is synthesized within the tissues that receive innervation by these neurons and sustains those neurons whose processes extend into these tissues during the period when programmed cell death occurs. The ability of the target organs to provide trophic support underlies the neurotrophic hypothesis, and much of the action of NGF and other neurotrophins can be explained on this basis. NGF is required for sympathetic neuron survival not only during development but also throughout their life. Sensory neurons are also dependent on NGF during development but become independent of this factor for their survival in the mature animal. It should be pointed out that NGF regulates cell number not by supporting the proliferation of neuronal precursors but by permitting the selective survival of neurons that are protected from programmed cell death. NGF has not been shown to directly stimulate cell division of neurons or their precursors. NGF, like other classical growth factors, acts to stimulate cellular metabolism by positively regulating a wide array of biosynthetic processes. It promotes the morphological differentiation of its target cells, promoting extensive outgrowth of axonal and dendritic processes. Indeed, there is evidence that NGF not only acts in a permissive fashion to facilitate the morphological and biochemical differentiation of the neurons and process outgrowth but is also instructive and plays a role in specifying the phenotype of the neuron [9].

NGF also has actions within the CNS, although it is not particularly abundant in the CNS. Its synthesis appears to be largely restricted to the hippocampus and neocortex, and even in these regions it is present at relatively low concentrations relative to the other neurotrophins. The most prominent population of NGF-responsive neurons expressing TrkA are the basal forebrain cholinergic neurons. The principal projections of these neurons are to the hippocampus and cortex, which conforms with the concept that NGF acts as a target-derived trophic factor in the CNS, just as it does in the peripheral nervous system (PNS). NGF also acts on a subpopulation of cholinergic neurons within the striatum. These interneurons express the NGF receptor, TrkA, and respond to NGF. However, they do not appear to rely entirely on NGF for their survival, and the specific actions of NGF on this neuronal population have not been clearly defined. NGF may also have autocrine actions in the CNS, as some neuronal populations have been identified that express both TrkA and NGF.

NGF has effects on the physiological responses of mature neurons. NGF acts as a target-derived trophic factor for pain neurons, which innervate peripheral tissues such as the skin. Inflammation of these peripheral tissues leads to local elevation of NGF synthesis and abundance. Elevated concentartions of NGF are responsible for the enhanced sensitivity to pain that accompanies inflammation. This is due to the ability of NGF to lower the sensory threshold of the pain fibers, leading to hyperalgesia. Nocioceptive sensory neurons mediating pain sensation are entirely dependent upon NGF for their survival as these cells are selectively lost in animal in which either the NGF or TrkA genes have been knocked out. These animals are insensitive to pain and live only a few weeks.

The receptor for NGF is TrkA, a 140 kDa cell surface protein that specifically binds NGF, but not other neurotrophins [5, 6, 9]. TrkA is expressed on the neuronal cell body and on neuronal processes. In its action as a target-derived trophic factor, NGF is secreted within the target organ and it then binds to TrkA receptors present on the growing neuronal process or synapse. The NGF-TrkA complex is then internalized and subsequently translocated to the cell body by retrograde axonal transport. In those cells that respond to NGF through autocrine or paracrine mechanisms, the growth factor can bind to any of the widely distributed TrkA molecules on the neuronal membrane.

Brain-derived neurotrophic factor was identified on the basis of its ability to stimulate process outgrowth from peripheral sensory neurons. It was isolated from brain and, upon analysis of its structure, discovered to be highly homologous to NGF [3]. BDNF has a different spectrum

of targets from NGF and acts on both peripheral sensory ganglionic neurons and parasympathetic neurons of the nodose ganglia, but not sympathetic neurons. In the CNS, BDNF supports the survival and process outgrowth of basal forebrain cholinergic neurons, dopaminergic neurons in the striatum, retinal ganglion cells and some motor neurons. Analysis of mice in which the BDNF gene was knocked out revealed that the vesibulocochlear neurons were completely lost, accounting for the inability of these mice to maintain their balance. BDNF knockout mice die within 1–2 weeks of birth. Analysis of the specific actions of BDNF is significantly complicated because NT4/5 also binds and activates the TrkB receptor. Interestingly, animals in which the *trkB* gene has been inactivated die within 1–2 days of birth, but the basis of this is not understood given the modest phenotype of the NT4/5 knockout mice.

The discovery that sensory neurons themselves synthesize BDNF has led to the suggestion that its secretion from these neurons results in both autocrine and paracrine actions. It is thought that, during development, some neurons, for example sensory neurons of the dorsal root ganglia, may rely on target-derived factors while, during later periods, the neurons synthesize growth factors that support themselves through autocrine stimulation and from cells in their immediate environment. These mechanisms serve to lessen the dependency on targets for trophic support. This view is supported by the finding that axotomy, or target removal, has much diminished effect in older animals. In the PNS, neurotrophins, including BDNF, are also synthesized by glial cells. Glial cells proliferate at later stages of development, largely after all neurons have been born and have passed through the period of normal cell death. Thus, glia are likely to play a role in providing trophic support in the mature nervous system through paracrine mechanisms.

Neurotrophin 3 is the most abundantly distributed of the neurotrophins and appears to have a wider range of action than other members of this family, particularly in the CNS. It is expressed throughout the CNS. In the mature brain, NT3 is found at high levels in the cortex, hippocampus, thalamus and cerebellum. NT3 also acts on subpopulations of spinal motor neurons and on cochlear neurons. It exerts its actions principally through binding to another member of the Trk family, TrkC.

In the periphery, NT3 uniquely supports proprioceptive neurons in sensory ganglia. These neurons and their peripheral targets, the muscle sensory organs, are lost in NT3 knockout mice. Mice in which the NT3 receptor TrkC has been knocked out do not live long and have abnormal movements as a consequence of their loss of proprioception.

NT3 plays an earlier role in development than other neurotrophin family members. It sustains progenitor cells of the neural crest, which then give rise to sympathetic and sensory ganglia, as well as a number of other structures. It is also likely that NT3 functions to regulate the period of time these precursor cells remain mitotically active and, thus, it acts indirectly to regulate cell number. In NT3 knockout mice, approximately 70% of neurons within the sensory ganglia are lost, indicating an absolute requirement for NT3 for the survival of neuronal subpopulations. Analysis of the pattern of NT3 expression has shown that it is highly expressed during periods of rapid process extension in regions adjacent to the developing ganglionic neurons. It is therefore likely that these neurons are supported during this period principally through autocrine and paracrine mechanisms. As the cells differentiate and extend processes to their target, NT3 expression is found in these end organs. Importantly, there is a coincident dramatic reduction in NT3 synthesis in the regions within and adjacent to the developing ganglia, rendering the neurons wholly dependent on target-derived trophic support.

NT3 is also critical for glial development. There is good evidence that NT3 acts to stimulate the proliferation of oligodendrocyte precursor cells, probably in concert with platelet derived growth factor (PDGF) (see below).

Neurotrophin 4/5 is not as well characterized as other members of the neurotrophin family. Much of what is known is derived from analysis of NT4/5 and TrkB knockout mice. Elucidating the actions of NT4/5 is complicated by virtue of the fact that both NT4/5 and BDNF exert their effects via the TrkB receptor. It appears that NT4/5 functions largely overlap with those of other neurotrophin family members, particularly BDNF. NT4/5 knockout mice are essentially normal, in contrast to BDNF knockout mice, which do not live long. NT4/5 is likely to have unique actions on a subpopulation of neurons in the nodose and geniculate ganglia, which are not supported by BDNF. Like BDNF, NT4/5 acts on sensory neurons and retinal ganglion cells, supporting their survival.

NT4/5 is expressed in muscle and this neurotrophin can support facial motor neurons as well as other populations of motor neurons. Interestingly, NT4/5 expression is regulated by the activity of the muscle and this neurotrophin stimulates axonal sprouting, suggesting that it acts as a muscle-derived trophic factor for motor neurons.

Neurotrophins influence neurotransmission and synaptic plasticity. The discovery that the neurotrophins have acute effects in the mature nervous system and can modulate synaptic efficiency has forced a substantial reevaluation of the role of these molecules in modulating the dynamic behavior of the nervous system [12].

Direct application of neurotrophins to the brain of animals results in the rapid initiation of dramatic seizure activity, reflecting the coordinated discharge of large populations of neurons. This effect is the result of neurotrophin-stimulated release of neurotransmitters and enhanced synaptic efficiency. BDNF and NT3 cause

an increase in neurotransmitter release from presynaptic nerve terminals. An analogous effect in the PNS is the ability of NGF to enhance painful sensations. Thus, neurotrophins can act over short intervals to regulate synaptic transmission, a role not previously attributed to these molecules.

Synaptic activity can also provoke the release of neurotrophins and acutely regulate the synthesis of these factors [13]. It is likely that the normal physiological levels of neurotrophins in the CNS are regulated by ongoing neuronal activity in the brain. There are a number of examples showing that the synthesis of neurotrophins, most prominently BDNF, is stimulated following neurotransmitter release. In an extreme example, induction of seizure activity in the brain results in the stimulation of NGF and BDNF synthesis, but not NT3. A growing body of evidence suggests that there is a intricate interplay between the ability of the neurotrophins to regulate synaptic activity in the brain and the effect of such activity on neurotrophin synthesis and secretion. The enhanced synaptic stimulation of neurons then positively regulates the synthesis of neurotrophins. Insights into these events have come from examination of complex phenomena like long term potentiation in the hippocampus using neurotrophin knockout mice.

The ability of the neurotrophins to regulate the structural organization of the peripheral nervous system during development is well documented. The capacity of these molecules to affect the anatomical organization of the CNS is less well studied. Perhaps the most striking example of the ability of neurotrophins to affect neuronal connectivity in the CNS is the development and maturation of visual cortex. In this system, the axons of lateral geniculate neurons normally invade visual cortex and have a broad and diffuse projection pattern. However, as development proceeds the axonal projection fields of these neurons become progressively smaller and more refined, eventually becoming restricted to innervate defined linear columns of cortical neurons, termed *ocular dominance columns*, that are sensitive to the input from a single eye. Neurotrophins regulate the process by which the restriction and segregation of axonal projections occur. Administration of neurotrophins can block the formation of dominance columns by inhibiting the loss of synapses within the broad projection area. These data suggest that normally the visual neurons may compete for a limited supply of neurotrophins elaborated by the cortical neurons and the neurotrophins may act to stabilize synaptic contacts. Thus, neurotrophins appear to play a critical role in the activity-dependent development of cortical connectivity and function.

Neurotrophic cytokines are a small group of cytokine-like molecules that act in the nervous system. The terms neurotrophic cytokines, neurokines or neuropoietins have been applied to a small group of molecules which are most highly related to cytokines and share both structural similarity and employ common effector mechanisms in their target cells [14]. These factors include ciliary neurotrophic factor (CNTF), interleukin 6 (IL-6), leukemia inhibitory factor (LIF), cardiotrophin 1 (CT-1), and oncostatin-M. Some of these molecules act as *bona fide* growth factors while others appear to have more restricted roles and dictate the differentiated phenotype of subpopulations of neurons. Recently, this class of molecules has been shown to regulate the proliferation and differentiation of neural stem cells, both during development and in the mature nervous system.

The cell surface receptors for the neurotrophic cytokines are multisubunit complexes that employ a common receptor subunit, gp130 (Fig. 27-3). gp130 forms a receptor complex, with itself or the LIFβ receptor. In the case of CNTF and IL-6 (and possibly CT-1) the ligand binds to an additional receptor alpha subunit, which imparts ligand-specific binding properties to the receptor, forming an active trimeric receptor complex. The receptor complex transduces signals through its interaction with cytoplasmic tyrosine kinases of the JAK family. Ligand binding to the receptor leads to activation of their intrinsic tyrosine kinase activity of the receptor-associated JAKs, leading to the stimulation of diverse intracellular signaling pathways.

Ciliary neurotrophic factor was discovered through its ability to sustain parasympathetic neurons of the ciliary ganglia. It exhibits an extremely broad range of activity, acting on a number of neuronal populations [15]. CNTF promotes the survival of parasympathetic ganglionic neurons as well as sensory and sympathetic neurons in the PNS. In the CNS, CNTF acts on neurons in the hippocampus, as well as both cholinergic and GABAergic neurons in the basal forebrain. CNTF, like the neurotrophins, can regulate neurotransmitter release and directly affect ion channel function.

Substantial interest in the biological actions of CNTF has arisen as a result of its actions on motor neurons. CNTF is synthesized in muscle and can be actively taken up by motor neurons and then retrogradely transported to the cell body. Application of CNTF to the nerve after injury prevents motor neuron death and can partially reverse the progressive loss of motor function in animal models of neuromuscular disease. On this basis, CNTF appears to act as a target-derived trophic factor for these neurons. However, this view is complicated by the fact that CNTF does not possess a signal sequence which is necessary for its secretion and it is not known how it is released from its sites of synthesis, primarily in muscle and glial cells in both the CNS and PNS. Of particular interest, injury to the nervous system results in the induction of CNTF synthesis by astrocytes and Schwann cells, suggesting it plays a role in the response to traumatic injury. In addition to its actions on neurons, it appears that CNTF acts to promote the differentiation of glial precursor cells into astrocytes and myelin-forming oligodendrocytes.

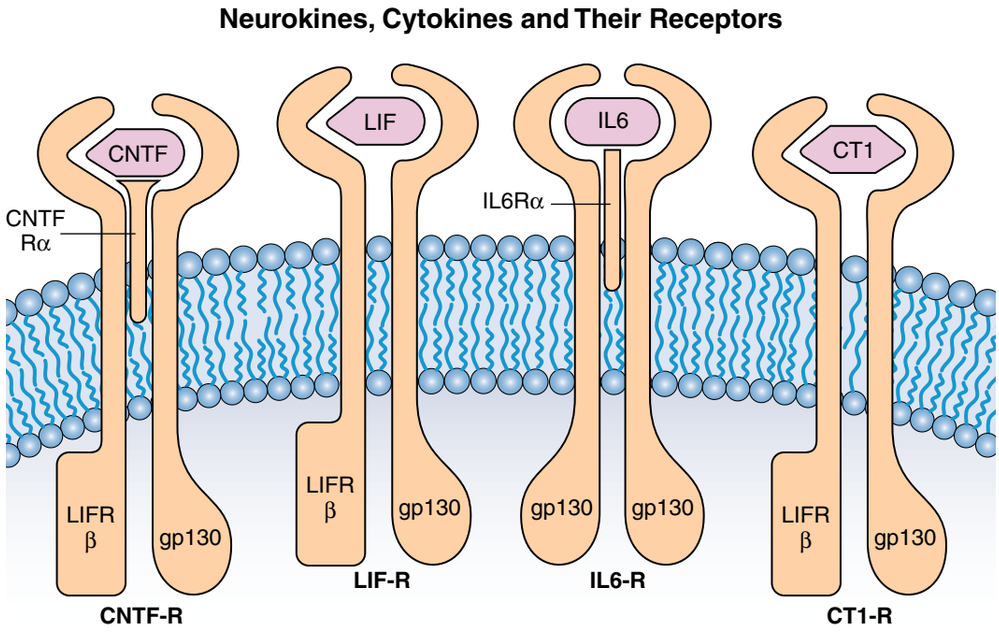

FIGURE 27-3 Neurotrophic cytokines and their receptors. Neurotrophic cytokines are related to IL6 and bind to cell surface receptor complexes that share a common structural organization. The four ligands interchangeably employ two distinct receptor subunits, leukemia inhibitory factor receptor β (*LIF-Rβ*) and gp130, and some employ a ligand-specific α subunit. *CNTF-R*, ciliary neurotrophic factor; *CT-1R*, cardiotrophin 1 receptor; *IL6-R*, interleukin-6 receptor.

In humans and mice, mutations in the CNTF gene have no obvious effect, suggesting that other molecules can mediate all of the significant physiological actions of CNTF. Indeed, about 2% of the Japanese population do not have an active CNTF gene. However, knockout of the CNTF receptor gene has much more dramatic effects with significant loss of all motor neurons. These data suggest that there must be other as yet undiscovered factors that utilize the CNTF receptor and play a more critical role in development than CNTF itself.

Leukemia inhibitory factor (LIF) has well described actions in the immune system. The recognition that this factor also acts in the nervous system followed the discovery that it acts on cultured sympathetic neurons to direct a change in neurotransmitter expression from a noradrenergic to a cholinergic phenotype and regulates the expression of neuropeptide transmitters in these cells. LIF exhibits a similar activity toward spinal motor neurons through its ability to stimulate the biosynthesis of acetylcholine. LIF also functions as a trophic factor for peripheral sensory neurons and spinal motor neurons *in vitro*, supporting their survival. LIF is a trophic factor for oligodendrocytes and promotes astrocytic survival and differentiation. It has recently been recognized that it plays an important role in neurogenesis in the adult nervous system by promoting the proliferation of neural stem cells. LIF has functionally critical roles in responses to nervous system injury, promoting neuronal survival, injury-induced neuropeptide synthesis and astrocyte differentiation following damage to the mature nervous system.

Interleukin 6 (IL-6) actions in the nervous system are not well studied, nor is this cytokine particularly abundant. IL-6 has been shown to sustain cultured hippocampal neurons as well as basal forebrain cholinergic and mesencephalic catecholaminergic neurons. IL-6 is likely to be synthesized in the CNS principally by astrocytes, although microglia are also a source for this cytokine. Microglial-derived IL-6 inhibits neural stem cell generation. IL-6 is synthesized by neurons and has recently been shown to be an important regulator of neurogenesis in the adult nervous system. IL-6 has been shown to promote the differentiation of neural stem cells into astrocytes while inhibiting them from acquiring a neuronal phenotype in the developing cortex.

Cardiotrophin 1 acts as a survival factor for spinal motor neurons. CT-1 is synthesized by both skeletal muscle and myotubes and has been shown to be secreted from the latter, suggesting that it acts as a target-derived trophic factor. Indeed, in CT-1 knockout mice there is a loss of motor neurons in the spinal cord and brainstem [16]. CT-1 also promotes the survival of dopaminergic neurons and ciliary neurons.

Other Cytokines including interleukins 1β, 2, 3, 4, 5, 7, 9, 11 and 12 have been reported to exhibit neurotrophic activities [17]. The concentrations of these cytokines in

nervous tissue are not high and their effects are not particularly well documented. For many of the cytokines, their significance in nervous system development and function is not clear. These molecules play central roles in immune system function and many of their described actions follow injury to the nervous system and in disease states. In this regard, the microglia are the principal immune effector cell in the brain and function as macrophages. As such, the microglia are the likely sources of many of the cytokines that have been reported to be present in the CNS. Astrocytes also synthesize a number of cytokines and are responsive to some of these molecules.

The fibroblast growth factors comprise a gene family of nine members that share substantial sequence homology and have diverse effects in the nervous system. Fibroblast growth factors (FGFs) were initially identified on the basis of their ability to stimulate the proliferation of fibroblasts, it was subsequently been found that they have an extremely broad distribution in the body and act on a host of different cell types. FGFs stimulate the proliferation of neurons in the developing nervous system and glial cells throughout the life of the organism. FGFs act on a large number of neuronal populations and all glial cell subtypes [18]. In the mature nervous system only two members of this family, FGF-1 (also known as acidic FGF) and FGF-2 (also known as basic FGF), are present at significant levels. In the adult brain the FGFs represent the major mitogenic species. They are present at significantly higher levels than the neurotrophins, FGF-1 levels are estimated to be approximately 500-fold and FGF-2 up to 50 times greater than that of NGF. FGF-1 is found to be expressed at high levels in ganglionic sensory neurons in the PNS. In the mature CNS, FGF-1 is detected at highest levels in motor, basal forebrain cholinergic and substantia nigra neurons, and in neurons of other subcortical nuclei. FGF-2 is expressed abundantly by astrocytes, although hippocampal pyramidal cells have also been shown to express this growth factor. FGF2 has trophic effects on most neurons derived from the CNS. There is evidence that the FGFs may play a role in facilitating axonal regeneration in the PNS and provide trophic support to neurons following trauma or injury.

The FGFs stimulate the proliferation of mesodermally and ectodermally-derived cells and play central roles in mammalian development. Members of the FGF family are expressed in the embryonic period and are required for several critical events in neural development and specifically for neural induction. FGF-8 is necessary for positional identity required for axial specification and patterning of limb development. FGF-2 stimulates the proliferation of multipotential stem cells that subsequently give rise to neurons of the cortex and other brain regions.

The complexity of FGF action is compounded by the existence of at least four receptors for FGF (FGFR1–4). Three FGFRs are expressed in the CNS where they exist as multiple alternatively spliced products. The FGF receptors are all ligand-activated tyrosine kinases and comprise a distinct subfamily of the receptor tyrosine kinases. The interaction of the various FGFs with the four FGF receptors and their multiple splice products is bewilderingly complex and is incompletely understood. The FGFR1 receptors appear to be expressed exclusively in neurons, while FGFR2 and FGFR3 are expressed principally by glial cells. Interestingly, neurons of the substantia nigra and some motor neurons appear to express both FGF-1 and its receptor FGFR1, suggesting that FGF-1 may act in an autocrine fashion to support these cells. FGFR1 and FGFR2 appear to play a role in development as both receptors are expressed at a time prior to that of their ligands, FGF-1 and FGF-2. These data support the view that other FGF family members are the functionally relevant species during embryogenesis. FGFR1 is expressed in the primitive neuroepithelium. A novel aspect of FGF biology is the ability of these growth factors to bind to cell surface proteoglycans, specifically heparan sulfate proteoglycans. Indeed, it appears that these proteoglycans can act as low affinity receptors for the FGFs. It is thought that FGFs bind to the proteoglycans that effectively immobilize them and induces or stabilizes an active conformation, facilitating binding to the FGFR.

Transforming growth factors β are the prototypic members of a large family of related factors that have a diverse roles both in development and in the mature animal. There are over 50 members of this extended family that have been assigned to five distinct subfamilies [19]. The actions of most transforming growth factor β (TFGβ) superfamily members are best described in other organ systems. However, the TGFβ-related factors have important roles in the nervous system where they are thought to act principally through autocrine and paracrine mechanisms. This family of growth factors employs a unique receptor complex involving two distinct subunits, both of which are serine/threonine kinases (see Ch. 23). The ligand first binds to the type II subunit and this dimeric complex then associates with the type I subunit. The hetero-oligomeric receptor complex then phosphorylates downstream signaling transduction elements, which then initiate intracellular signaling events leading to the activation of a specific group of transcription factors, termed SMADs.

TGFβ subfamily in mammals comprises three subfamily members, $TGF\beta_1$, $TGF\beta_2$ and $TGF\beta_3$. $TGF\beta_1$ is expressed principally by glial cells and is not present in significant amounts in the mature nervous system. $TGF\beta_1$ is thought to function principally following injury to the nervous system, where its expression is dramatically induced in microglial cells [20]. It is synthesized, albeit at lower levels, by astrocytes. In some neurons TFGβ1 is a component of the response to neurodegeneration or trauma and its synthesis and secretion are elevated in these settings.

The synthesis of TGFβ$_1$ following injury in the nervous system is consistent with its effects on inflammatory responses in other organ systems. Although this factor is not particularly well studied in the developing nervous system, it has been reported to play an instructive role in specifying cellular phenotype.

TGFβ$_2$ and TGFβ$_3$ are widely expressed in both the peripheral and central nervous systems [19]. Early in development TGFβ$_2$ is found associated with developing fiber tracts and later in development it is found in astrocytes. TGFβ$_3$ acts as a mitogen for amacine cells in the developing retina. In the adult TGFβ$_2$ and TGFβ$_3$ are found in many neuronal populations and in both astrocytes and Schwann cells.

The TGFβ family has diverse effects that are likely to be cell-type-specific and it is presently impossible to make general statements about their functions. It has been documented that TGFβ$_2$, in contrast to many growth factors, can inhibit cellular proliferation and is growth inhibitory towards neurons. It has antimitotic effects on astrocytes and also acts to arrest the proliferation of oligodendrocytes and subsequently promotes their differentiation. There is now evidence that the TGFβs act principally to modulate that actions of other growth factors. For example, TGFβ enhances the survival promoting properties of CNTF, FGF and the neurotrophins on ciliary ganglionic neurons. Whereas TGFβ$_2$ and TGFβ$_3$, acting alone, have also been reported to exhibit frank negative effects on the survival of these neurons. Similarly, TGFβs augment the actions of the glial-derived neurotrophic factor (GDNF). TGFβ$_2$ and TGFβ$_3$ act as survival and trophic factors for dopaminergic neurons in the striatum and midbrain in concert with GDNF, both during development and in the mature animal. These factors are expressed principally within the projection fields of these neurons, thus these findings have been interpreted to support the view that members of the TGFβ family act as target-derived trophic factors for dopaminergic neurons.

Bone morphogenetic protein subfamily comprises a TGFβ subfamily of factors that are most highly related to the *Drosophila* decapentaplegic gene product, a critical regulator of morphogenesis and axial specification. These factors, as their name indicates, were first identified on the basis of their effect on bone formation. The focus of most studies of these factors has been on their role in inductive events in development. These factors have important roles early in development of the nervous system. BMP2 has been shown to act to influence the differentiation of multipotential cells of the neural crest into a neuronal phenotype. The BMPs also have significant roles as trophic factors. BMP4 acts in the cerebellum to promote the differentiation of both neurons and astrocytes. BMP6 and 7 have been shown to enhance cerebellar granule cell survival. Sensory neurons in the PNS are responsive to BMPs produced in target tissues and serve to regulate their differentiation. There is a growing literature suggesting that these BMP family members may act in concert with other factors to regulate neuronal differentiation and survival.

The glial-derived neurotrophic factor family represents a newly recognized family of target-derived neurotrophic factors. The GDNF-family ligands (GFLs) include GDNF, neurturin, artemin and persephin [21]. These factors are synthesized by a number of tissues and support the survival of the innervating neurons [22]. The GFLs exist as homodimers and share general structural features with the TGFβ family but have little sequence homology.

GFLs bind to a related family of four cell surface receptors termed GDNF receptor-α (GFRα), which are attached to the membrane through a glycosyl phosphatidylinoisitol anchor (Fig. 27-4). The individual GFLs bind specifically to GFRα species; GDNF binds to GFRα-1, neurturin to GFRα-2, artemin to GFRα-3 and persephin to GFRα-4. The ligand-bound GFRα receptors then interact with c-Ret, a receptor tyrosine kinase. The formation of the GFRα-Ret complex results in activation of the tyrosine kinase activity of Ret and stimulation of downstream signaling pathways [23].

Glial-derived neurotrophic factor as its name suggests, is synthesized by glial cells; in the CNS by astrocytes and in the PNS by Schwann cells. GDNF was first characterized as a trophic factor which supported the survival and differentiation of dopaminergic cells of the midbrain and striatum. It is this latter cell population that is selectively lost in Parkinson's disease. GDNF has been shown to selectively support these cells after physical or chemical insults, suggesting this factor may have utility as a therapeutic agent in this disease. GDNF acts as a target-derived trophic factor as it is synthesized in areas receiving dopaminergic innervation and the factor is retrogradely transported to the cell bodies of the dopaminergic neurons.

In the periphery, GDNF acts as a trophic factor for both sympathetic and parasympathetic neurons as well as several distinct subpopulations of sensory neurons. Consistent with its role as a target-derived trophic factor, it is highly expressed in a variety of tissues receiving sympathetic and sensory innervation. GDNF is essential for the development of enteric neurons and thus the innervation of the gut. Importantly, GDNF is a potent trophic factor for spinal motor neurons and can rescue these cells from programmed cell death during development, as well as prevent their death following injury. GDNF is synthesized by skeletal muscle and is retrogradely transported suggesting that it acts as a target-derived trophic factor for the innervating spinal motor neurons.

Neurturin (NRTN) plays a critical role in supporting parasympathic neurons innervating peripheral target tissues. NRTN is required for the survival and function of enteric neurons and a subset of ganglionic sensory neurons, particularly those mediating temperature sensation.

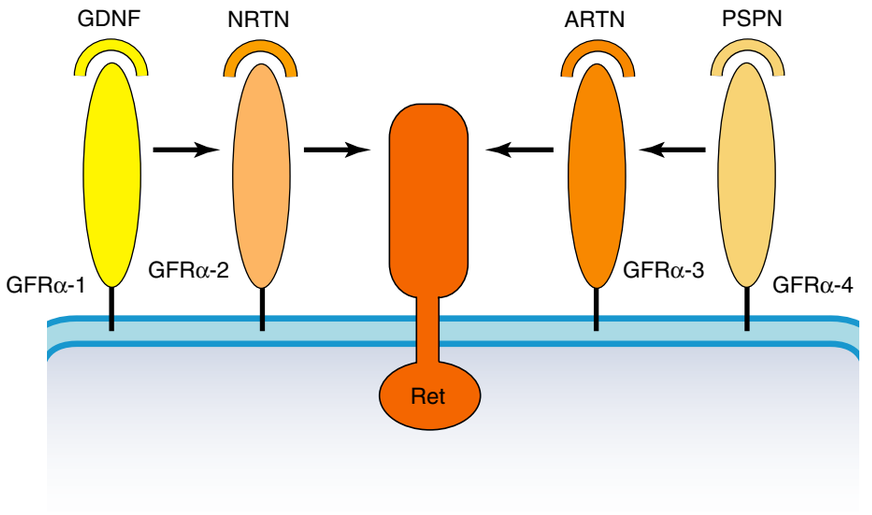

FIGURE 27-4 Glial-derived neurotrophic factors and their receptors. The glial-derived neurotrophic factors, GDNF, neurturin, artemin and persephin bind to specific GFRα subunits. The GFRα-ligand complex then associates the Ret and activates its intrinsic tyrosine kinase activity, stimulating downstream signal transduction pathways. *ARTN*, artemin; *GDNF*, glial-derived neurotrophic factor; *GFRα*, glial-derived neurotrophic factor receptor alpha.; *NTRN*, neurturin; *PNSN*, persephin.

The most dramatic phenotype in NRTN knockout mice is a breathing defect due to loss of about half of the neurons in the petrosal ganglia. NRTN can support both dopaminergic neurons and spinal motor neurons *in vitro*.

Artemin The biological actions of artemin (ARTN) have been elucidated largely through examination of $GFR\alpha_3$ knockout animals. These animals exhibit defects in the proliferation, migration and axonal outgrowth of superior cervical ganglia neurons. Loss of ARTN function results in the loss of most neurons in this ganglia in older animals. ARTN is expressed along blood vessels and it has been postulated to act in a chemotactic manner to guide sympathetic fibers along blood vessels. ARTN is reported to reduce pain following nerve injury, although the basis of this effect is unknown.

Persephin (PSPN) has been shown to promote the survival of basal forebrain neurons including both cholinergic neurons. Moreover, it supports midbrain dopaminergic neurons. PSPN is expressed in the striatum, consistent with its role as a target-derived trophic factor for these cells.

Epidermal growth factor and related factors have a diverse range of actions in the nervous system.

Epidermal growth factor (EGF), is the most prominent member of a family of growth factors and was originally identified by its mitogenic actions on ectodermally derived cell types. In the nervous system, EGF's best documented actions are related to neural stem cell survival and proliferation. Some populations of neural precursor cells respond to EGF, allowing their expansion and transition to a multipotent stem cell. EGF acts in concert with FGF2 to support proliferation and the initial commitment of neural stem cells to neuronal and glial lineages. EGF is not likely to play a major role in the mature nervous system. A structurally related growth factor, *transforming growth factor* α (TGFα), is widely expressed throughout the developing embryo including the nervous system. TGFα binds to and activates EGF receptors and may be the physiologically relevant ligand for these receptors during development. Little is known about the specific actions of TGFα in the nervous system, but it is likely to act principally through autocrine or paracrine mechanisms.

Neuregulins are a large and unique family of growth and differentiation factors that arise from the alternative splicing of mRNAs derived from the NRG1 gene and possess an EGF-like motif [24, 25]. There are three additional neuregulin genes whose functions are unknown. There are currently about a dozen recognized neuregulin isoforms derived from the NRG1 gene and include molecules originally termed glial growth factor (GGF), heregulin, neu differentiation factor (NDF), sensory and motor-neuron-derived factor (SMDF) and acetylcholine-receptor-inducing activity (ARIA). These molecules are important intermediates subserving neuronal–glial interactions. Neuregulins are both membrane bound and secreted proteins. The secreted forms have been shown to act by both paracrine and autocrine mechanisms. The membrane bound isoforms are responsible for direct cellular interactions leading to contract-dependent neuregulin signaling, for example the axonal membrane-dependent proliferation of Schwann cells.

Neuregulins bind to a family of receptor tyrosine kinases that are homologous to the EGF receptor, termed

ErbB (or HER in the human). There are four ErbB receptors that form homo- or heterodimers in various combinations upon ligand binding. Specific NRG isoforms preferentially interact with different ErbB dimers. The ErbB receptors are ligand-activated tyrosine kinases structurally similar to the EGF receptor.

Neuregulins are highly expressed in the nervous system by neuroblasts, cortical neurons, peripheral sensory ganglionic cells and spinal motor neurons as well as myelin-forming glia.

In mice in which the NRG1 gene has been inactivated, Schwann cells and cranial ganglia fail to develop. Neuregulins have been shown to be critical in mediating the differentiation of neural crest cells into glial phenotypes and the subsequent proliferation of Schwann cell precursors. Neuregulins have similar effects in the CNS and promote oligodendrocyte precursor mitogenesis.

Neuregulins are likely to act principally in a paracrine manner on adjacent glial cells and on non-neuronal targets tissues innervated by neuregulin-expressing neurons (such as muscle).

The neuregulins also act on Schwann cells to stimulate motility and migratory activity. It is postulated that this interaction provides a mechanism by which neurons can influence glial metabolism and behavior, which are important both in development and for peripheral nerve regeneration.

An important insight into the function of neuregulins was gained by the observation that they are synthesized by motor neurons and are released at the neuromuscular junction where they interact with the erbB receptors expressed on the muscle cell membrane. Interestingly, in this context the neuregulins were first detected as an activity that stimulated the expression and aggregation of acetylcholine receptors at sites of nerve contact and was dubbed acetylcholine receptor inducing activity, or ARIA. Neuregulin/ARIA acts as a synaptic signal that regulates muscle gene expression, most prominently the acetylcholine receptor genes.

A number of other growth factors act in the nervous system.

Platelet-derived growth factor (PDGF) is synthesized by neurons and astrocytes throughout the central nervous system and by Schwann cells in the PNS. These various cell types also express PDGF receptors, and it is thought that this growth factor acts in an autocrine and paracrine fashion. The best described action of PDGF is on oligodendrocyte progenitor cells stimulating the proliferation of these cells and subsequently promoting their differentiation into mature oligodendrocytes.

Insulin-like growth factor I (IGF-I) has a well recognized role as a trophic and survival factor for nervous system cells in tissue culture [26]. However, its specific functions in the developing and mature nervous system have been difficult to define largely because its actions as a trophic factor overlap extensively those of other growth factors. IGF I is expressed in nervous tissue only late in development and at highest levels in neurons of the olfactory bulb, hippocampus, thalamus, cerebellum and retina. IGF I and insulin enter the brain from the systemic circulation, thus it is unclear to what degree the endogenously synthesized proteins contribute to the levels of IGF-I and insulin in the brain. IGF-I and insulin sustain many nervous-system-derived cell types in tissue culture; however, the amount of insulin required to elicit biological effects in most of these cells is quite high, suggesting that many of the reported effects of insulin on cells of the nervous system *in vitro* are mediated through insulin acting on the IGF I receptor. The IGF I receptor possesses a ligand-stimulated tyrosine kinase domain whose structure is quite similar to that of the insulin receptor. The IGF I receptor is ubiquitously expressed throughout the nervous system and is found at higher levels in the developing brain than in the adult, in contrast to IGF I expression. *In vitro* studies have shown that IGF-I is likely to act principally through autocrine or paracrine mechanisms to promote the proliferation of neuronal and glial precursors and facilitate their subsequent differentiation and survival. Interestingly, mice overexpressing of IGF-I possess larger brains owing to larger numbers of neurons. Conversely, inactivation of the IGF-I gene or its receptor in mice and humans results in reduced brain size, diminished numbers of neurons and hypomyelination, suggesting that IGF-I plays an important role in neuronal proliferation and maintenance. Recent studies have demonstrated that IGF-I stimulates the proliferation of neural progenitor cells in the hippocampus and drives the induction of a neuronal phenotype from progenitor cells in adult mice. These effects may underlie the dramatic effects of IGF-I on overall brain size.

IGF I has recently been the focus of considerable interest due to its actions on motor neurons. It can prevent normal motor neuron cell death during development, reduce the loss of these cells following nerve injury and enhance axonal regeneration. In the adult, injection of IGF I results in sprouting of motor neuron terminals and increases the size of the neuromuscular junction. These and other studies suggest potential therapeutic applications of IGF I in several neurological diseases including amyotrophic lateral sclerosis and peripheral neuropathies.

Hepatocyte growth factor (HGF), also known as scatter factor, has been shown to support the survival of sympathetic neuroblasts and subpopulations of spinal motor neurons. In the former case this is apparently an autocrine effect since these cells have been shown to synthesize HGF.

HGF serves as an attractant for developing spinal motor neurons and thalamic axons *in vitro*. HGF was shown to protect cerebellar granule neurons against excitotoxicity.

Macrophage stimulating protein (MSP) is structurally related to HGF and signals through the Ron tyrosine

kinase receptor. MSP is a target-derived neurotrophic factor for subsets of sensory and sympathetic neurons at different times during their development. Moreover, MSP appears to act on a restricted subset of motor neurons innervating the tongue.

GROWTH FACTORS ACT COMBINATORIALLY AND SEQUENTIALLY TO REGULATE NERVOUS SYSTEM DEVELOPMENT

One of the primary outcomes of the investigation of growth factor action has been the recognition that there are a relatively small number of growth factors that must act in concert to orchestrate the survival and differentiation of a diverse population of neuronal and non-neuronal cell types. The foregoing review has detailed the broad spectrum of actions of some classes of growth factor while other growth factors have more restricted roles. It is apparent that most cells are dependent upon more than one growth factor through embryogenesis and in the mature nervous system [3]. One of the most significant outcomes from analysis of neurotrophin (and their receptors) knockout mice is that these mice show very modest phenotypic changes in the CNS. This reflects the extensive interconnectivity of neurons in the brain, providing a wide range of cellular contacts from which trophic support may arise. In the PNS, the phenotypes are more dramatic, with significant cell loss, indicating the more restricted source of trophic factors available to these cells. There is ample evidence that both neurons and glial cells express receptors for a number of growth factors that allow the cells to respond to multiple sources of trophic support. Moreover, responsiveness to several factors also serves to broaden cellular sensitivity to changes in the environment during development and in the mature nervous system and may subserve a dynamic response to changing rates of activity or to injury. Also, trophic support for neurons is delivered at different cellular loci. For example, adult sensory neurons express multiple members of the Trk family; however, NGF appears to be delivered to the neurons through axonal transport, while BDNF and other factors are supplied by paracrine mechanisms to the cell body.

Motor neurons provide a compelling example of how a single class of neurons can be supported by an extraordinarily wide range of factors. More than 15 growth factors have been shown *in vitro* or *in vivo* to sustain these cells. Some of these are derived from the muscle target, while others are elaborated by ensheathing Schwann cells and by cells resident within the spinal cord. It is likely that motor neurons rely upon multiple factors for their survival and different subpopulations of motor neurons may exhibit unique combinations of trophic factor dependence [4].

Detailed study of the actions of growth factors has revealed that they act in concert to mediate developmental events and, further, that they act sequentially [15]. The ability of a neuron to respond to a given trophic factor is frequently dependent on its developmental stage. The complexity of trophic factor dependence exhibited by some populations of neurons is a consequence of both the developmentally regulated expression of growth factor receptors and the spatiotemporal pattern of growth factor expression. For example, pluripotent neural crest cells giving rise to sensory neurons are dependent upon NT3 for proliferation during early periods in development. The cells lose their responsiveness to NT3 and become NGF-dependent during the period when they establish their contacts with their peripheral targets [2]. Similarly, neuroblasts of the cortex and hippocampus are stimulated to proliferate in response to FGF-2, and subsequently, they become responsive to NT3 that then promotes their survival and differentiation. These examples illustrate the serial dependence of neurons upon different factors for mitotic expansion, acquisition of a differentiated phenotype and their sustenance in the mature nervous system.

One of the most significant conclusions to be derived from the study of growth factors in the nervous system is that we surely have discovered only a fraction of the growth/trophic factors that are responsible for the generation of the cellular complexity and the specific and extensive interconnections between populations of cells. In the last few years, largely through the power of molecular biology and molecular genetics, we have identified a number of novel factors. This process of discovery will undoubtedly continue at an accelerating pace.

AXONAL TRANSPORT AND NEUROPATHOLOGY 499

CONCLUSION 499

NEURONAL ORGANELLES IN MOTION

The axon comprises a major portion of the total volume and surface area in most neurons and may extend several thousand cell body diameters. Since the genetic material and nearly all the protein synthesis machinery are localized to the cell body, a supply line is maintained to provide structural and functional materials to sites all along the length of the axon. Insights as to how neurons accomplish this task can be obtained by real-time imaging of living axons with video-enhanced light microscopy [1] (Fig. 28-1).

Such video images reveal an array of organelles moving down the axon toward the nerve terminal (anterograde direction) as well as returning to the cell body (retrograde direction). The movements create patterns as engrossing as the ant farms of our childhood and initially appear as chaotic. Some organelles glide smoothly, while others move in fits and starts. On closer examination, an underlying order emerges: the organelles moving in the anterograde direction are typically fainter and smaller but more numerous than those moving in the retrograde direction, and all organelles appear to travel along gently curving fibrils. Occasionally, two organelles are seen to travel in opposite directions along the same fibril, appearing destined for a head-on collision but seeming to pass through each other; other organelles hop from one fibril to another. The images imply, and other studies confirm, that the

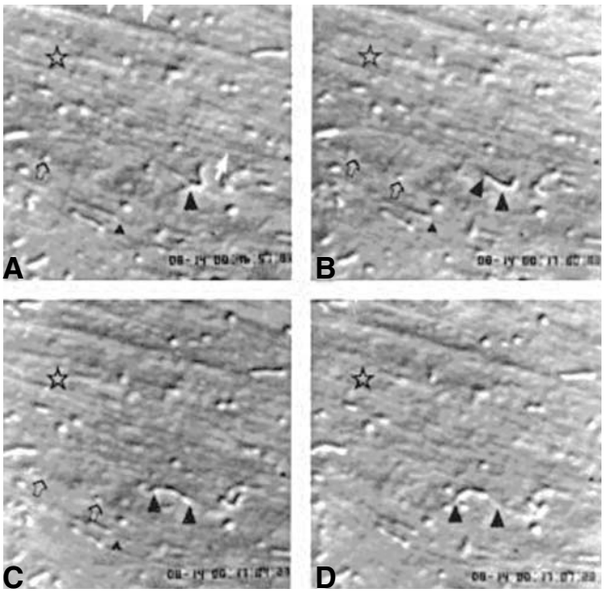

FIGURE 28-1 Sequential video images of fast axonal transport in isolated axoplasm from the squid giant axon. In this preparation, anterograde axonal transport proceeds in the direction from upper left to lower right (from 10 o'clock toward 4 o'clock). The field of view in these stills is approximately 20 µm, and the images were recorded in real time on videotape. The large, sausage-shaped structures (*filled triangles*) are mitochondria. Medium-sized particles (open arrows) most often move in the retrograde (right to left) direction. Most structures of this size are lysosomal or prelysosomal organelles. The majority of moving particles in these images are faint and moving rapidly (2 µm/s), so they are difficult to catch in still images; however, in the region above the star, a number of these organelles can be visualized in each panel. The entire field contains faint parallel striations (such as those indicated by the white arrows in (**A**)) that correspond to the cytoskeleton of the axoplasm, primarily microtubules. The movement of membranous organelles is along these structures, although organelles can occasionally be seen to switch tracks as they move (see the mitochondrion indicated by *large triangles*). (With permission from Brady, S. T., Lasek, R. J. and Allen, R. D. Fast axonal transport in extruded axoplasm from squid giant axon. *Science* 218: 1129–1131, 1982.)

organelles represent membrane-bound packets of materials *en route* to a variety of intraneuronal destinations. Unseen in these images because their movements and changes occur orders of magnitude more slowly, structural elements of the axon, the cytoskeleton, are equally dynamic.

The life cycle of these organelles, their kinetics and molecular cargo, the molecular motors driving their transport and the substrates along which these movements track constitute interrelated aspects of what is broadly termed axonal transport. A primary aim of this chapter is to provide an understanding of this form of intraneuronal traffic. Achieving this goal requires an appreciation of the dynamics and structure of the relevant neuronal components and structures. Studies of how cellular structures and components move from where they are synthesized to where they are utilized comprise an area of intensive research in cellular and molecular neurobiology. To encompass this topic, we examine how our concepts of axonal transport evolved to our present understanding of this complex and dynamic field.

DISCOVERY AND CONCEPTUAL DEVELOPMENT OF FAST AND SLOW AXONAL TRANSPORT

The size and extent of many neurons presents a special set of challenges. Since protein synthesis for the entire neuron takes place in the cell body, which may represent only 0.1% of the total cell volume, growth and maintenance of neuronal processes requires timely, efficient delivery of material to axonal and dendritic domains. The idea that materials must be transferred from cell body to axon was suggested by Ramon y Cajal and other pioneers during the early part of this century. For many years, the existence of such transport processes could only be inferred.

The first experimental evidence for axonal transport resulted from studies on peripheral nerve regeneration, which were stimulated by the desire to improve treatment of limb injuries sustained during World War II. In the classic work of Weiss and Hiscoe [2], surgical constriction of a sciatic nerve branch led to morphological changes in the nerve that directly implicated the cell body as the source of materials for axon regrowth. After several weeks, the axon appeared swollen proximal to the constriction but shriveled on the distal side. Following removal of the constriction, a bolus of accumulated axoplasm slowly moved down the nerve at 1–2 mm/day, very nearly the rate observed for outgrowth of a regenerating nerve. Weiss and Hiscoe concluded that the cell body supplies a bulk flow of material to the axon. This view dominated the field for two decades, but the characteristics of this slow 'flow' of material did not seem adequate to explain some aspects of nerve growth and function.

Cell biologists subsequently provided convincing arguments for the necessity of this intracellular transport. Neuronal protein synthesis was almost completely restricted to the cytoplasm surrounding the nucleus (translational cytoplasm, which includes polysomes, rough endoplasmic reticulum and the Golgi complex) and ribosomes were undetectable in the axon [3]. If proteins cannot be synthesized in the axon, then materials necessary for axonal function have to be supplied by transport from the cell body. Thus, axonal transport must be a normal, ongoing process in neurons. By the mid-1960s, the use of radioactive tracers confirmed the existence of a slow 'bulk flow' component of transport. Using autoradiography, Droz and Leblond [4] elegantly showed that systemically injected ^{3}H-amino acids were incorporated into nerve cell proteins and transported along the sciatic nerve as a wavefront of radioactivity. These methods demonstrated that newly synthesized proteins were transported,

TABLE 28-1 Major rate components of axonal transports

Rate component	Rate (mm/day)	Structures and composition
Fast transport		
Anterograde	200–400	Small vesiculotubular structures, neurotransmitters, membrane proteins and lipids
Mitochondria	50–100	Mitochondria
Retrograde	200–300	Lysosomal vesicles and enzymes
Slow transport		
SCb	2–8	Microfilaments, metabolic enzymes, clathrin complex
SCa	0.2–1	Neurofilaments and microtubules

but some responses of the neuron occurred too rapidly to be readily explained solely by a slow 'flow'.

Shortly thereafter radiolabeling and histochemical studies demonstrated that faster rates of transport occur [5]. Unlike slow transport, the faster components move material bidirectionally, both toward and away from the cell body. Both endogenous proteins and exogenously applied labels were detected moving at fast transport rates. These findings expanded the concept that axonal transport materials move in both anterograde and retrograde directions and that rates vary by as much as three orders of magnitude (Table 28-1).

At first, emphasis was placed on the characterization of fast and slow axonal transport. The kinetics of axonal transport were analyzed by injection of radiolabeled amino acids into the vitreous of the eye or the dorsal root ganglia (to 'label' sensory neurons) or ventral spinal cord (motor neurons). In the case of fast transport, a wavefront of labeled protein was detected traveling away from the cell body at 250–400 mm/day in mammals. Using this same approach, slow transport rates were shown to approximate 1 mm/day. Rates for fast transport were also determined by measuring the amount of a transported substance, such as acetylcholinesterase or norepinephrine, accumulating at a nerve constriction over a few hours, well before bulk accumulation of axoplasm is detectable. These two approaches for studying axonal transport – locating a radiolabeled wavefront by analysis of successive nerve segments and monitoring the accumulation of materials at a constriction with time (Fig. 28-2) – generated considerable information on the kinetics and on the metabolic and ionic requirements of axonal transport [5]. Such findings formed the basis for more detailed characterization of the axonally transported materials and for studies of the underlying molecular mechanisms.

Fast and slow components of axonal transport differ in both their constituents and their rates. Fast transport is bidirectional: many proteins that are distributed by fast

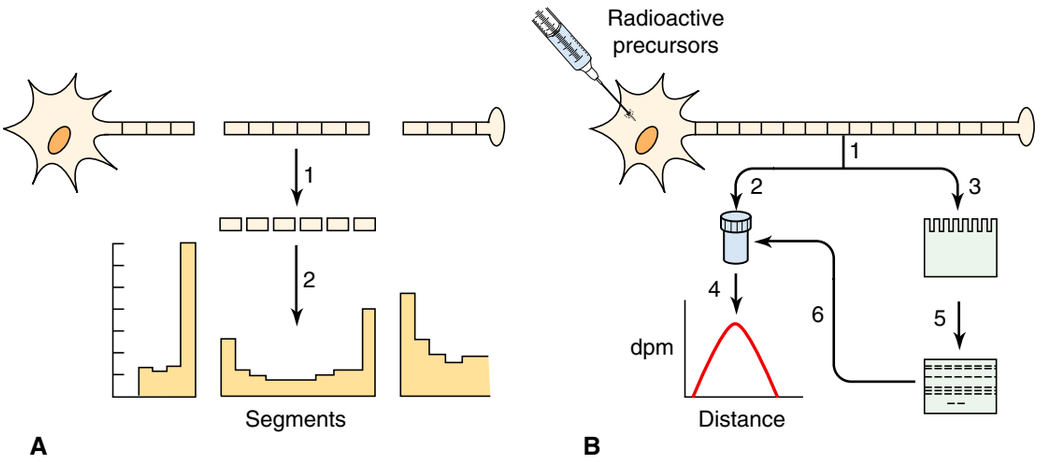

FIGURE 28-2 Schematic diagram of two common methods for analyzing the component rates of axonal transport. (**A**) Accumulation of transported material can be studied at a focal block of axonal transport caused by a cut, a crush, a cold block or a ligature. This approach is a variation of that employed by Weiss and Hiscoe and has been used often in studies of fast axonal transport. In this example, two cuts have been made in order to detect both anterograde and retrograde transport. After time for accumulation at the ends, the nerve segments are cut into uniform segments for analysis (*step 1*). Each segment is analyzed either for radioactivity in labeled nerves or for enzyme activity, and the rate of accumulation is estimated (*step 2*). (**B**) With segmental analysis, the nerve must be pulse-labeled, usually with radioactive precursors. After an appropriate injection-sacrifice interval to label the rate component of interest, the nerve is also cut into segments (*step 1*). In some cases, only a single segment is used as a 'window' onto the transport process. Each segment is analyzed both by counting the radioactivity in an aliquot (*step 2*) and by gel electrophoresis (*step 3*), where each lane corresponds to a different segment. The amount of radioactivity in different polypeptides can be visualized with fluorography (*step 5*) and individual bands cut out of the gel (*step 6*) for analysis by liquid scintillation counting. The distribution of either total radioactivity or radioactivity associated with a specific polypeptide can then be plotted (*step 4*); *dpm*, disintegrations per minute. (Adapted with permission from Brady, S. T. Axonal transport methods and applications. In A. Boulton and G. Baker (eds), *Neuromethods*, vol. 1: *General Neurochemical Techniques*. Clifton, NJ: Humana Press, 1986, pp. 419–476.)

anterograde transport also return in the retrograde direction. In contrast, proteins transported at slow rates are degraded when they reach their destination and are not detected in the retrograde component. Biochemical fractionation studies have shown that proteins moved by fast anterograde and retrograde transport are predominantly membrane-associated, whereas proteins moved in the slow axonal transport component are recovered in soluble fractions or in cytoskeletal pellets.

When labeled polypeptides traveling down the axon are analyzed by SDS polyacrylamide gel electrophoresis, materials traveling in the axon can be grouped into five distinct rate components [6]. Each rate component is characterized by a unique set of polypeptides moving coherently down the axon (Fig. 28-3). As specific polypeptides associated with each rate class were identified, most were seen to move only within a single rate component. Moreover, proteins that have common functions or interact with each other tend to be moved together. These observations led to a new view of axonal transport, the structural hypothesis [7]. This model can be stated simply: proteins and other molecules move down the axon as component parts of discrete subcellular structures rather than as individual molecules (Table 28-1).

The structural hypothesis, which was formulated in response to observations that axonal transport rate components move as discrete waves, each with a characteristic rate and a distinctive composition, can explain the coherent transport of functionally related proteins and is consistent with the relatively small numbers of motor molecules in neurons. The only assumption is that the number of elements that can interact with transport motor complexes is limited, and this requires appropriate packaging of the transported material. Different rate components result from packaging of transported material into different, cytologically identifiable, structures. In fact, the faster rates reflect the transport of proteins preassembled as membranous organelles, including vesicles and mitochondria, or of proteins contained in the lumen of these organelles (Fig. 28-4) whereas the slower rate components contain the cytoskeletal proteins. Thus tubulin and MAPs move as microtubules, and neurofilaments move as neurofilaments. Cytoplasmic proteins that are not integral components of a cytoskeletal element may be linked in some manner to those structures (Fig. 28-5). While disputes regarding the size and composition of the transported package for cytoskeletal and cytoplasmic proteins (i.e. polymer, oligomer, macromolecular complex, etc.) continue, the idea that complexes of proteins, rather than individual polypeptides, are moved has gained general currency.

Although five distinct major rate components have been identified, the original categories of fast and slow transport remain useful. All membrane-associated proteins move in one of the fast rate components, while cytoplasmic proteins move as part of the slow components. Current studies indicate that the various organelles transported anterogradely are moved along the axon by one or more motor molecules (see below). The differing rates of fast anterograde transport appear to result from the varying sizes of organelles, with increased drag on larger structures resulting in a slower net movement (Fig. 28-1). Less is known about molecular mechanisms of slow transport.

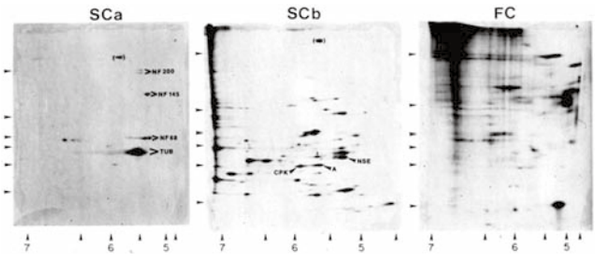

FIGURE 28-3 Two-dimensional fluorographs showing the 35S methionine-labeled polypeptides in the three major anterograde rate components of axonal transport: *SCa*, slow component a; *SCb*, slow component b; *FC*, fast component. Note that rate component not only has a characteristic rate but a characteristic polypeptide composition. The discovery that each rate component has a different polypeptide composition led to the structural hypothesis. (With permission from Tytell, M. *et al. Science* 214: 179–181, 1981 [6]; illustration provided by Dr. Michael Tytell.)

Features of fast axonal transport demonstrated by biochemical and pharmacological approaches are apparent from video images. Video microscopy of axoplasm, as described briefly at the beginning of this chapter, directly confirmed the bidirectionality of fast transport, which had been inferred from the accumulation of radiolabeled materials on both sides of a crush, and established that the populations of organelles moving in each direction are different. Inhibition of transport by agents that disrupt microtubules (MTs) is consistent with movement of organelles along fibrils identified as MTs by correlated video and electron microscopy. Video microscopy also reveals that organelle movement can continue in an apparently normal fashion in axons isolated from their cell bodies and divested of a plasma membrane. The implication is that transport must be driven by local energy-generating mechanisms, as predicted from observations that application of a cold block or metabolic poison (dinitrophenol or cyanide) to a discrete region of a nerve inhibits transport locally [5].

FAST AXONAL TRANSPORT

Newly synthesized membrane and secretory proteins destined for the axon travel by fast anterograde transport. However, not all membrane-bounded organelles (MBOs) are destined for the axon. As a result, the first stage of transport must be synthesis, sorting and packaging of organelles (see Ch. 9). Once assembled, the organelle must then be committed to the transport

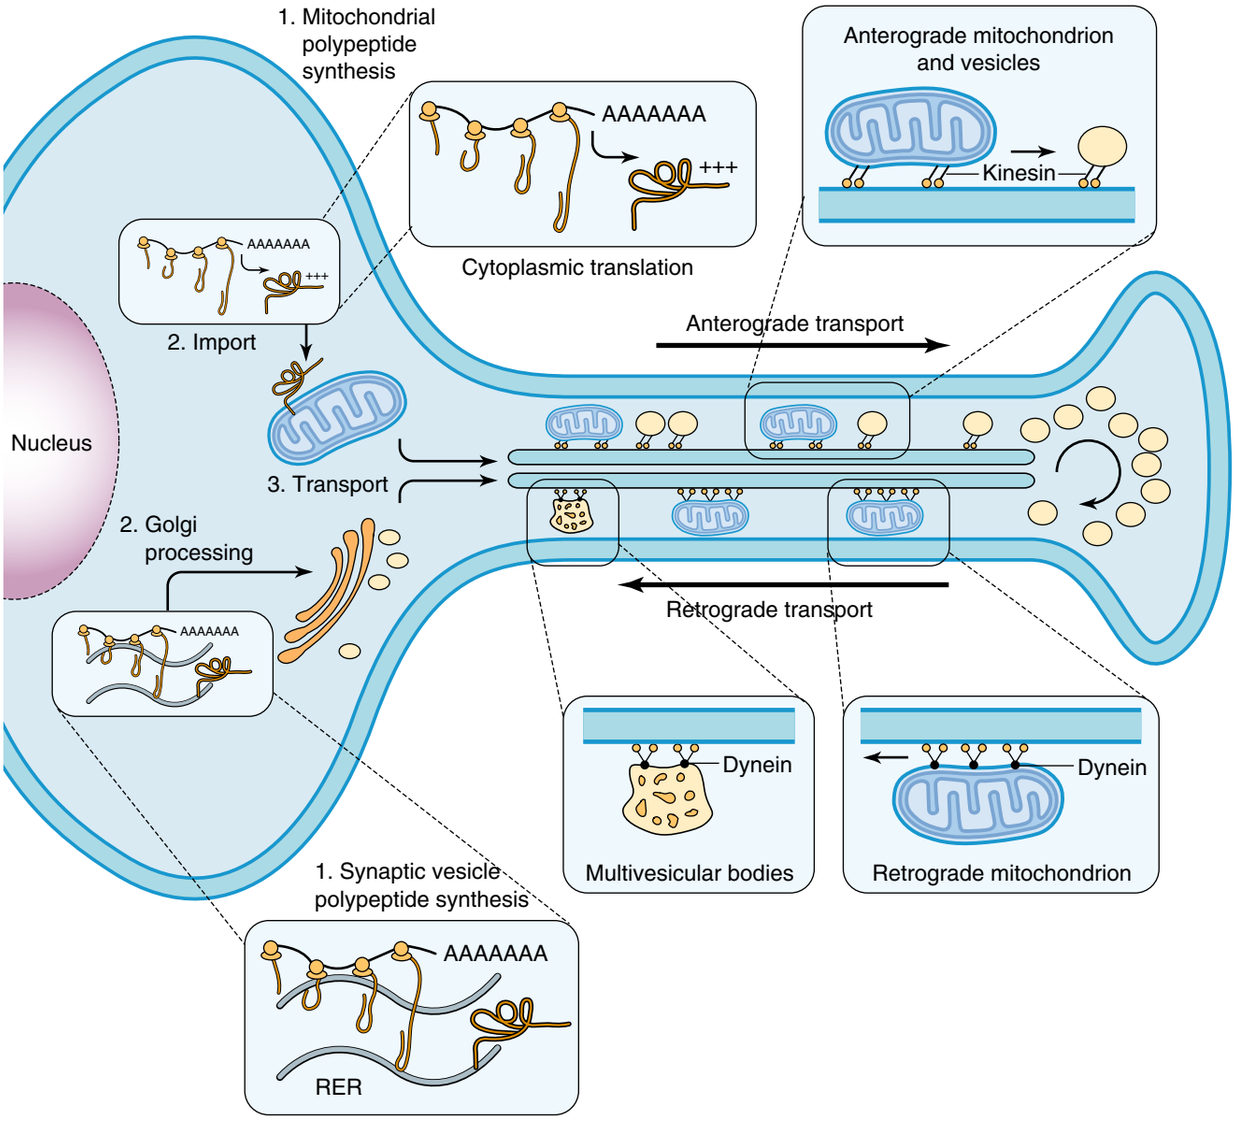

FIGURE 28-4 Schematic illustration of the movement of membrane-associated material in fast axonal transport. Fast axonal transport represents the movement of membrane-bounded organelles along axonal microtubules in both the anterograde and retrograde directions. Two major classes of membrane-bounded organelles that are synthesized and packaged by different pathways are depicted. Synaptic vesicle polypeptides are translated on endoplasmic reticulum-bound ribosomes at which time membrane proteins become properly oriented within the lipid bilayer and secretory polypeptides enter into the lumen of the endoplasmic reticulum. These polypeptides are further processed within the Golgi apparatus where the appropriate post-translational modifications and sorting of polypeptides destined for the axon occur. Once these polypeptides are packaged into vesicular organelles and the appropriate motor molecules are present, the organelles are transported down the axon utilizing axonal microtubules as 'tracks' at rates of 200–400 mm/day. Movement in the anterograde direction is thought to be mediated by the molecular motor kinesin, while the force necessary to move retrograde organelles is thought to be generated by cytoplasmic dynein. Unlike the synthesis of vesicular polypeptides, mitochondrial polypeptides that are supplied by the host cell are synthesized on cytoplasmic ribosomes and contain a targeting sequence that directs the polypeptides to the mitochondria. Following assembly and the association of motor molecules, the mitochondria move down the axon at rates of 50–100 mm/day. Mitochondria can also be detected moving back toward the cell body in the retrograde direction. The morphology of retrogradely transported mitochondria is distinctly different from that of mitochondria moving in the anterograde direction and is believed to represent degenerating organelles that are not metabolically active.

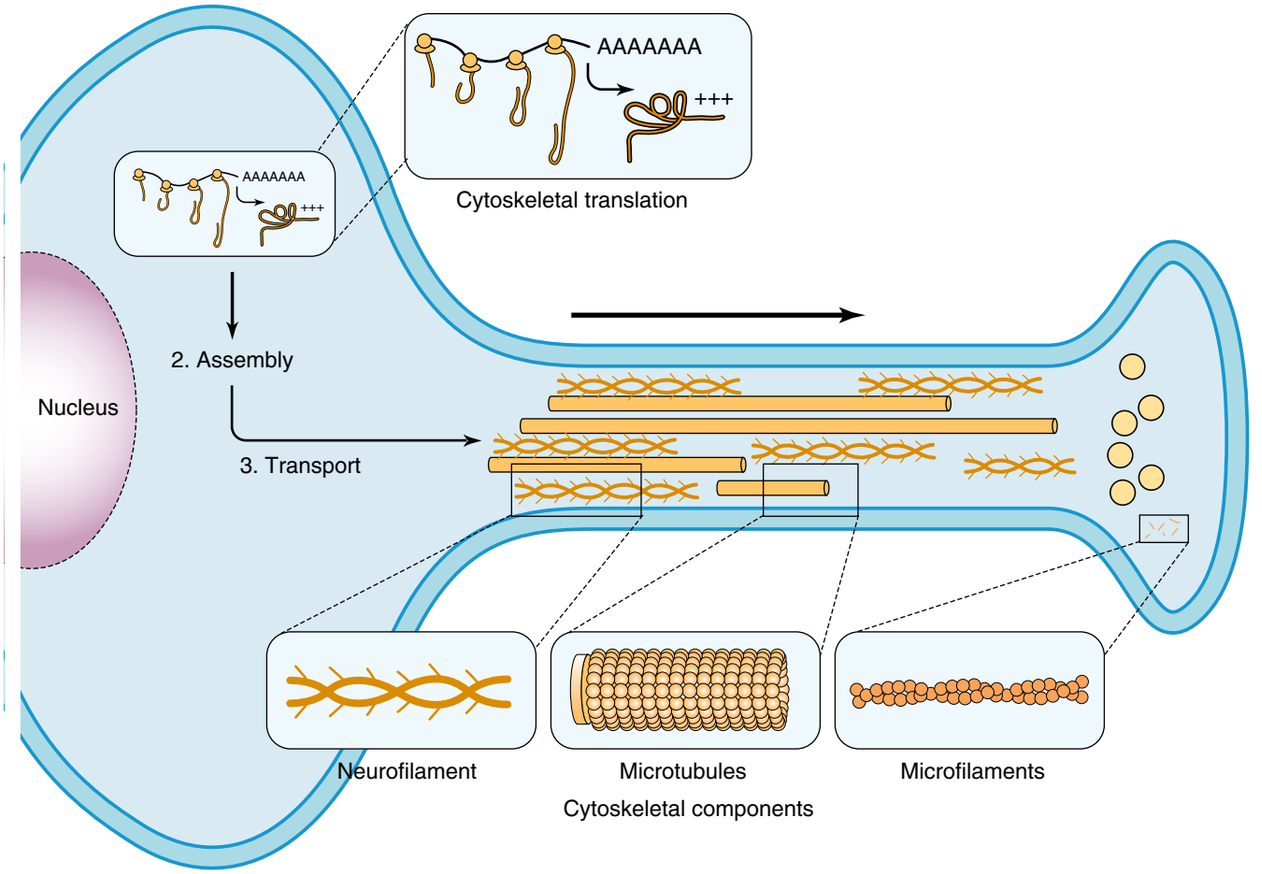

FIGURE 28-5 Schematic illustration of the movement of cytoskeletal elements in slow axonal transport. Slow axonal transport represents the movement of cytoplasmic constituents including cytoskeletal elements and soluble enzymes of intermediary metabolism at rates of 0.2–2 mm/day which are at least two orders of magnitude slower than those observed in fast axonal transport. As proposed in the structural hypothesis and supported by experimental evidence, cytoskeletal components are believed to be transported down the axon in their polymeric forms, not as individual subunit polypeptides. Cytoskeletal polypeptides are translated on cytoplasmic polysomes and then are assembled into polymers prior to transport down the axon in the anterograde direction. In contrast to fast axonal transport, no constituents of slow transport appear to be transported in the retrograde direction. Although the polypeptide composition of slow axonal transport has been extensively characterized, the motor molecule(s) responsible for the movement of these cytoplasmic constituents has not yet been identified.

machinery and moved down the axon. Finally, organelles must be targeted and delivered to specific domains in the axon (presynaptic terminals, axolemma, nodes of Ranvier, etc.). Axonal constituents include integral membrane proteins, secretory products, membrane phospholipids, cholesterol and gangliosides. As predicted by the structural hypothesis and as apparent in video microscopy, rapid transport is achieved after packaging materials into MBOs (Figs 28-4, 28-6). Clearly, an understanding of how MBOs are formed in the cell body and routed to the fast-transport system in axons is essential.

Passage through the Golgi apparatus is obligatory for most proteins destined for fast transport. In all cell types, secretory and integral membrane proteins are synthesized on polysomes bound to the endoplasmic reticulum. Secretory proteins enter the lumen of the reticulum, whereas membrane proteins become oriented within the membrane bilayer. In contrast, components of the cytoskeleton and enzymes of intermediary metabolism are synthesized on so-called free polysomes, which are actually associated with the cytoskeleton. As reviewed in Chapter 9, fast-transported proteins leave the endoplasmic reticulum in association with transfer vesicles that bud off and undergo Ca^{2+}-dependent fusion with the Golgi apparatus. Newly formed membrane-associated proteins must be transferred to the Golgi apparatus for processing and post-translational modification, including glycosylation, sulfation and proteolytic cleavage, as well as for sorting [8].

Drug studies demonstrated a requirement that most proteins destined for fast axonal transport traverse the Golgi stacks, where membrane proteins are post-translationally modified, sorted and packaged [9] (Fig. 28-7). This suggests that proteins in fast axonal transport must either pass through the Golgi complex or associate with

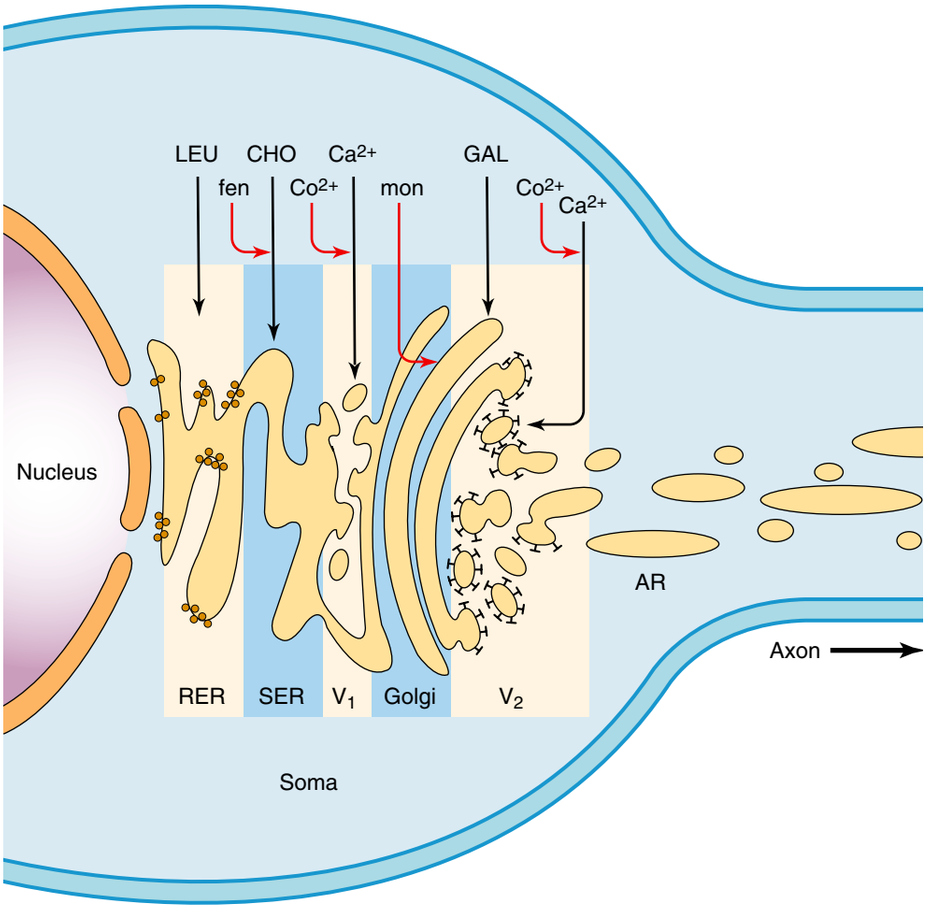

FIGURE 28-6 Summary of pharmacological evidence indicating that newly synthesized membrane and secretory proteins in neurons reach the axons by a pathway similar to that utilized for intracellular transport in non-neuronal cells. Incorporation sites are indicated for several precursors of materials in fast axonal transport: leucine (*LEU*) for proteins, choline (*CHO*) for phospholipids and galactose (*GAL*) for glycoproteins and glycolipids. Sites of action for several inhibitors are also indicated, including fenfluramine (*fen*), monensin (*mon*) and Co^{2+}. One possible site for Ca^{2+}-mediated vesicle fusion is at the transition from rough endoplasmic reticulum (*RER*) and smooth endoplasmic reticulum (*SER*) to the Golgi apparatus via one type of transition vesicle (*V1*). The subsequent budding of vesicles (*V2*) off the Golgi apparatus, presumably mediated by clathrin-coated vesicles, is a second site for Ca^{2+} involvement. The microtubule guides for the axonal tubulovesicular structures in transport and the axoplasmic reticulum (*AR*) are not shown.

proteins that do. Clathrin-coated vesicles mediate transfer from the Golgi apparatus to fast axonal transport system [10] (Fig. 28-6). Coated vesicles, however, are rarely observed in axons, and clathrin, the major coat protein, is primarily a slow transport protein [3]. Thus, Golgi-derived coated vesicles shed their coats prior to undergoing fast transport and travel down the axon either as individual uncoated vesicles or other membrane-bounded structures (Fig. 28-6).

Transport of MBOs to their various destinations is typically mediated by MTs and motor molecules. Membrane and secretory proteins become associated with membranes either during or immediately following their synthesis, and then maintain this association throughout their lifetime in the cell. For example, inhibiting synthesis of either protein or phospholipid leads to a proportional decrease in the amount of both protein and phospholipid in fast-transport, whereas application of these inhibitors to axons has no effect on transport. This suggests that fast axonal transport depends on *de novo* synthesis and assembly of membrane components.

Anterograde transport moves synaptic vesicles, axolemmal precursors and mitochondria down the axon. Fast anterograde transport represents movement of MBOs along MTs away from the cell body at rates ranging in mammals from 200–400 mm/day or 2–5 μm/second [11]. Anterograde transport provides newly synthesized components essential for neuronal membrane function and maintenance. Ultrastructural studies have demonstrated that the material moving in fast anterograde transport includes many small vesicles and tubulovesicular structures as well as mitochondria and dense-core vesicles [12, 13]. Material in fast anterograde transport

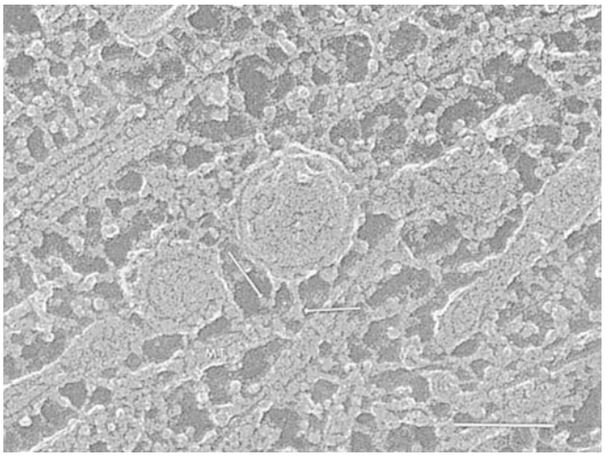

FIGURE 28-7 Axonally transported vesicles and the axonal cytoskeleton in longitudinal section. Quick-freeze, deep etch electron micrograph of a region of rat spinal cord neurite rich in membrane-bounded organelles and microtubules. Arrows point to rod-shaped structures that appear as cross bridges between organelles and microtubules. The bar at the lower right indicates 100 nm. (From Hirokawa *et al.*, Cell 56: 867–878, 1989 [47].)

is needed for supply and turnover of intracellular membrane compartments (i.e. mitochondria and endoplasmic reticulum), secretory products and proteins required for the maintenance of axonal metabolism. The net rate appears to be largely determined by size with the smallest MBOs in almost constant motion, while mitochondria and larger structures frequently pause giving a lower average rate [14].

A variety of materials move in fast anterograde transport including membrane-associated enzymes, neurotransmitters, neuropeptides and membrane lipids. Most are synthesized in the cell body and transported intact, but some processing events occur in transit. For example, neuropeptides may be generated by proteolytic degradation of propeptides. This biochemical heterogeneity extends to the MBOs themselves. The population of small organelles is particularly varied in function and composition. Some correspond to synaptic vesicle precursors and contain neurotransmitters and associated proteins, while others may contain channel proteins or other materials destined for the axolemma. Biochemical and morphological studies have provided a description of the materials transported in fast transport but are not as well suited for identifying the underlying molecular mechanisms involved in translocation.

Video microscopy allows study of molecular mechanisms through direct observation of organelle movements while precise control of experimental conditions is maintained. Fast axonal transport continues unabated in isolated axoplasm from giant axons of the squid *Loligo pealeii* for hours [14]. Video microscopy applied to isolated axoplasm permits a more rigorous dissection of the molecular mechanisms for fast axonal transport through biochemical and pharmacological approaches, because isolated axoplasm has no plasma membrane or other permeability barriers. Such studies have extended earlier observations on properties of fast anterograde transport and demonstrated the existence of new motor proteins that are responsible for axoplasmic transport of MBOs (see below).

Retrograde transport returns trophic factors, exogenous material and old membrane constituents to the cell body. MBOs moving in retrograde transport are structurally heterogeneous and, on average, larger than the structures observed in anterograde transport, which are commonly tubulovesicular [12, 13]. Multivesicular or multilamellar bodies are common in retrograde transport and these are thought to represent materials to be delivered to lysosomes in the cell body. The larger size of these retrograde vectors affects the rate of transport by increasing drag due to interactions with cytoplasmic structures [14].

Both morphological and biochemical studies indicate that MBOs returning in retrograde transport differ from those in anterograde transport. Repackaging of membrane components apparently accompanies turnaround or conversion from anterograde to retrograde transport. The mechanisms of repackaging are incompletely understood, but certain protease inhibitors and neurotoxic agents will inhibit turnaround without affecting either anterograde or retrograde movement. Experiments involving the use of specific protease inhibitors implicate a thiol protease, but the identity of the responsible enzyme is unknown [15, 16]. Consistent with this proposal, protease treatment of purified synaptic vesicles affects directionality of their movements in axoplasm and presynaptic terminals. Exogenously injected fluorescent synaptic vesicles normally move in the anterograde direction, but protease pretreatment of these vesicles results in retrograde transport [17].

Uptake of exogenous materials by endocytosis in distal regions of the axon results in the return of trophic substances and growth factors to the cell body [18]. These factors assure survival of the neuron and modulate neuronal gene expression. Changes in the return of trophic substances play critical roles during development and regeneration of neurites. Retrograde transport of exogenous substances also provides a pathway for viral agents to enter the CNS. Once retrogradely transported material reaches the cell body, the cargo may be delivered to the lysosomal system for degradation, to nuclear compartments for regulation of gene expression, or to the Golgi complex for repackaging.

Molecular sorting mechanisms ensure delivery of proteins to discrete membrane compartments. While pathways by which selected membrane-associated proteins are delivered to the correct destination have been established in general terms, many intriguing questions

regarding the selection process itself remain. How is it that certain membrane proteins remain in the cell body (for example, glycosyltransferases of the Golgi) while others are packaged for delivery to the axon? Among transported proteins, how do some reach the axolemma (i.e. sodium and potassium channels) while others travel the length of the axon to the nerve terminal (a presynaptic receptor or synaptic vesicle) or enter the synaptic cleft (a secreted neuropeptide)? Finally, how are organelles such as the synaptic vesicle directed toward axons and presynaptic terminals but not into dendritic arbors? This question becomes particularly compelling for dorsal root ganglion sensory neurons, where the central branch of its single axon has presynaptic terminals while the peripheral branch of that same axon has none.

The answers to these questions remain incomplete, but some mechanisms have begun to emerge. Some information comes from studies on polarized epithelial cells where the identity of destination signals to deliver newly synthesized proteins selectively to basolateral or apical membranes can be assayed. These mechanisms are relevant to the neuron, because viral proteins that normally go to epithelial basolateral membranes end up in neuronal dendritic compartments, while those targeted to apical compartments may be moved into the axon [19]. However, the underlying mechanisms appear to be complex. Signals may be 'added on', as post-translational modifications including glycosylation, acylation or phosphorylation or 'built in', in the form of discrete amino acid sequences. Both mechanisms appear to operate in cells. For example, addition of mannose-6-phosphate to proteins directs them to lysosomes, while amino acid sequences have been identified that direct proteins into the nucleus or into mitochondria. In general, the targeting signals are likely to direct proteins to specific organelles, whereas other mechanisms direct organelles to appropriate final destinations.

Specific membrane components must be delivered to their sites of utilization and not left at inappropriate sites [3]. Synaptic vesicles and other materials needed for neurotransmitter release should go to presynaptic terminals because they serve no function in an axon or cell body. The problem is compounded because many presynaptic terminals are not at the end of an axon. Often, numerous terminals occur sequentially along a single axon, making en passant contacts with multiple targets. Thus, synaptic vesicles cannot merely move to the end of axonal MTs. Targeting of synaptic vesicles thus becomes a more complex problem. Similar complexities arise with membrane proteins destined for the axolemma or a nodal membrane.

One proposed mechanism for targeting of organelles to terminals might have general implications. The synapsin family of phosphoproteins [20], which is concentrated in the presynaptic terminal, may be involved in targeting synaptic vesicles. Dephosphorylated synapsin binds tightly to both synaptic vesicles and actin microfilaments (MFs), while phosphorylation releases both of them. Dephosphorylated synapsin inhibits axonal transport of MBOs in isolated axoplasm, while phosphorylated synapsin at similar concentrations has no effect [21]. When a synaptic vesicle passes through a region rich in dephosphorylated synapsin, it may be cross-linked to the available MF matrix by synapsin. Such cross-linked vesicles would be removed from fast axonal transport and are effectively targeted to a synapsin- and MF-rich domain, the presynaptic terminal.

More recent studies have begun to map additional pathways for regulation of fast axonal transport based on selective, localized activation of kinase and phosphatase activities within neurons. Some of these phosphotransferase activities have been shown to target specific molecular motors and to regulate some aspect of their functional activities [22]. For example, activation of the GSK-3 kinase in axons leads to phosphorylation of the motor protein kinesin (see below) and this event results in detachment of kinesin from its transported cargo [23]. Other phosphotransferases and phosphotransferase-associated proteins appear to modulate fast axonal transport indirectly, by regulating the activities of enzymes, which in turn modify molecular motors. In this way, molecular pathways leading to the regulation of fast axonal transport have started to be identified [24].

Finally, this section has focused almost entirely on axonal transport, but dendritic transport also occurs [25]. Since dendrites usually include postsynaptic regions while most axons terminate in presynaptic elements, the dendritic and axonal transport each receive a number of unique proteins. An added level of complexity for intraneuronal transport phenomena is the intriguing observation that mRNA is routed into dendrites where it is implicated in local protein synthesis at postsynaptic sites, but ribosomal components and mRNA are largely excluded from axonal domains [26]. Regulation of protein synthesis in dendritic compartments is an important mechanism is synaptic plasticity [27, 28]. The importance of dendritic mRNA transport and local protein synthesis is underscored by the demonstration that the mutation associated with Fragile X syndrome affects a protein important for transport and localization of mRNA in dendrites [27, 29]. Similar processes of mRNA transport have been described in glial cells [30].

SLOW AXONAL TRANSPORT

Cytoplasmic and cytoskeletal elements move coherently at slow transport rates. Two major rate components have been described for slow axonal transport, representing movement of cytoplasmic constituents including cytoskeletal elements and soluble enzymes of intermediary metabolism [3]. Cytoplasmic and cytoskeletal elements in axonal transport move with rates at least two orders of magnitude slower than fast transport.

In favorable systems, the coherent movement of neurofilaments and microtubule proteins provides strong evidence for the structural hypothesis. Striking evidence was provided by pulse-labeling experiments in which NF proteins moved over periods of weeks as a bell-shaped wave with little or no trailing of NF protein. Similarly, coordinated transport of tubulin and MAPs makes sense only if MTs are being moved, since MAPs do not interact with unpolymerized tubulin [31].

Slow component a (SCa) comprises largely the cytoskeletal proteins that form NFs and MTs. Rates of transport for SCa proteins in mammalian nerve range from 0.2–0.5 mm/day in optic axons to1 mm/day in motor neurons of the sciatic nerve, and can be even slower in poikilotherms such as goldfish. Although the polypeptide composition of SCa is relatively simple, the relative contribution of SCa to slow transport varies considerably. For large axons (e.g. alpha motor neurons in the sciatic nerve), SCa is a large fraction of the total protein in slow transport, while the amount of material in SCa is relatively reduced for smaller axons (i.e. optic axons) [32]. The amount and phosphorylation state of SCa protein in axons is the major determinant of axonal diameter.

Slow component b (SCb) represents a complex and heterogeneous rate component, including hundreds of distinct polypeptides ranging from cytoskeletal proteins such as actin (and tubulin in some nerves, see [32]) to soluble enzymes of intermediary metabolism (such as the glycolytic enzymes). The structural correlate of SCb is not as easily identified as the MTs and NFs of SCa. Actin is presumed to form MFs, but actin represents only 5–10% of the protein in SCb and a significant fraction of axonally transport actin is deposited in the membrane cytoskeleton of the axon. Most proteins in SCb may be assembled into labile aggregates that can interact transiently with the cytoskeleton. One possibility is that scaffolding polypeptides such as HSC70, a constitutively expressed member of the heat shock family, may serve to organize these complexes during transport [3].

Although these two rate components can be identified in all nerves examined to date, the rates and the precise compositions varies among nerve populations. For example, SCa and SCb are readily resolved as discrete waves moving down optic axons, but differences in rate are smaller in the motor axons of sciatic nerve so the two peaks overlap. Moreover, virtually all tubulin moves as a single peak in SCa in optic axons, but significant amounts of tubulin move at both SCa and SCb rates in sciatic motor axons [32]. In each nerve, certain polypeptides may be used to define the kinetics for a given slow component of axonal transport. For SCa, those signature polypeptides are the NF triplet proteins, while actin, clathrin and calmodulin serve a similar role for SCb.

Axonal growth and regeneration are limited by rates of slow axonal transport. The rate of axonal growth during development and regeneration of a nerve is roughly equivalent to the rate of SCb in that neuron [3]. This suggests that critical roles are played by the slow axonal transport in growth and regeneration. During development, SCb proteins are prominent and relatively little NF protein is detectable. Tubulin can be detected moving at both SCb and SCa rates. Once an appropriate target is reached and synaptogenesis begins, there is upregulation of NF protein synthesis and a gradual slowing of slow transport.

Axonal regeneration involves a complex set of cell body and axonal responses to a lesion. Downregulation of NF triplet and upregulation of specific tubulin isotypes are hallmarks of cell body responses to a lesion. In CNS neurons that fail to regenerate, changes in NF and tubulin expression are reduced or absent. Since changes in protein expression do not alter axonal cytoskeletal composition until after a regenerating growth cone has formed and extended for some distance, such changes in expression do not affect neurite growth, but may reflect activation of a cellular program for neurite growth. Axonal MTs must be disassembled as part of reorganizing the cytoskeleton for growth, and then reassembled for neurite extension. During axonal growth or regeneration specific tubulin genes are upregulated; during development and in regeneration MAPs are differentially expressed. Finally, in growth and regeneration there are characteristic changes in the axonal transport of tubulin with an increase in the fraction of tubulin moving at SCb rates.

Properties of slow transport suggest molecular mechanisms. Information about mechanisms of slow axonal transport is relatively limited. They are energy-dependent and require an intact axonal cytoskeleton. Indirect evidence suggests that MTs play a critical role, because transport of NFs can be pharmacologically uncoupled from MT transport without eliminating slow transport [33]. In contrast, all agents that disrupt MTs appear to block slow transport of all components. While this does not rule out a role for the MF cytoskeleton in slow transport movements, MTs appear to provide motive force for other elements of the cytoskeleton.

The macroscopic rates measured by radiolabel experiments should not be taken to reflect maximum rates of the motors involved. As with mitochondrial transport, the net rate of slow component proteins reflects both the rate of actual movement and the fraction of a time interval that a structure is moving. The elongate shape of cytoskeletal structures and their potential for many interactions means that net displacements are discontinuous. If a structure is moving at a speed of 2 μm/s, but on average only moves at that rate for one second out of every 100 seconds, then the average rate for the structure will translate to a net rate of only 0.02 μm/s [31].

Recently, methods for direct visualization of fluorescently tagged MTs and NFs in cultured neurons have been developed [34]. In such studies, relatively short MT or NF segments can be seen to move as rapidly as MBOs moving

in fast axonal transport, although they move much less frequently. Integration of these infrequent rapid movements of MTs and NFs over time gives a net rate of approximately 1–2 mm/day instead of the 200–400 mm/day seen for MBOs in mammalian nerve. Other studies permitted visualization of microtubules nucleated at the microtubule organizing center and being translocated toward the cell periphery. The combination of studies of axonal transport using radiolabels and direct observations of individual MTs or NFs with video microscopy provides strong experimental evidence that MTs and NFs can and do move in the axon as intact cytoskeletal structures. As discussed below, there are still questions about the specific motors and mechanisms underlying these movements.

As with membrane proteins, cytoplasmic and cytoskeletal proteins are differentially distributed in neurons and glia. Progress has been made toward identification of targeting mechanisms and some general principles have begun to emerge. Since cytoplasmic constituents move only in the anterograde direction, a key mechanism for targeting of cytoplasmic and cytoskeletal proteins appears to be differential metabolism [3]. Concentration of actin and other proteins in presynaptic terminals can be explained by slower turnover in the presynaptic terminal relative to NF proteins and tubulin. Proteins with slow degradative rates in the terminal accumulate and reach a higher steady-state concentration. Alteration of degradation rates for a protein can change the rate of accumulation for that protein. For example, some protease inhibitors cause the appearance of neurofilament rings in affected presynaptic terminals [35].

Although slow axonal transport of cytoskeletal proteins has received the most attention, all other cytoplasmic proteins must be delivered to distal regions of the neuron as well. Many of these are classical proteins of the 'cytosol' that become solubilized during biochemical fractionation. These include the enzymes of glycolysis and regulatory proteins such as calmodulin and HSC70 [3]. However, in pulse chase radiolabel studies, soluble proteins move down the axon as regularly and systematically as cytoskeletal proteins. This coherent transport of hundreds of different polypeptides indicates a higher level of organization of cytoplasmic proteins than has been traditionally assumed. Such organization is probably necessary to facilitate interactions with motor proteins and targeting mechanisms and to assure a reliable delivery of all required proteins to the axon.

MOLECULAR MOTORS: KINESIN, DYNEIN AND MYOSIN

Prior to 1985, the only molecular motors characterized in vertebrate cells were muscle myosins and flagellar dyneins. Myosins had been purified from nervous tissue, but no clear functions were established. Given evidence that fast axonal transport was microtubule-based, many investigators looked for dynein in the cytoplasm with equivocal success. Moreover, the biochemical properties of fast transport were inconsistent with both myosin and dynein [11, 14]. The pharmacology and biochemistry of fast axonal transport created a picture of organelle transport distinct from muscle contraction or flagellar beating.

The characteristic properties of different molecular motors aided in their identification. One striking difference between fast axonal transport and myosin- or dynein-based motility emerged from studies with ATP analogs. Adenylyl-imidodiphosphate (AMP-PNP), a nonhydrolyzable analog of ATP, is a weak competitive inhibitor of both myosin and dynein. However, when AMP-PNP is perfused into axoplasm, bidirectional transport stops within minutes [1, 36]. Both anterograde and retrograde moving organelles freeze in place on microtubules, and 'pearls on a string' structures became apparent. Inhibition of fast axonal transport by AMP-PNP indicated that fast axonal transport involved a new class of motors and suggested that this new motor should have a high affinity for microtubules in the presence of AMP-PNP. The polypeptide composition of this new motor molecule was soon defined and it was christened kinesin [37, 38]. This discovery raised the possibility of other novel motor molecules and soon additional classes of molecular motors began to be identified. The proliferation of motor types has transformed our understanding of cellular motility.

All three classes of molecular motor proteins are now known to be large protein families with diverse cellular functions [39]. Both the kinesin family (reviewed in [39]) and the myosin family [40, 41] have been defined and proteins grouped into subfamilies. Finally, the elusive cytoplasmic version of dynein was identified and a multigene family of flagellar and cytoplasmic dyneins defined [42]. Members of a given motor protein family share significant homology in their motor domains with the defining member (kinesin, dynein or myosin), but they also contain unique protein domains that are specialized for interaction with different cargoes or differential regulation [43]. This large number of motor proteins may reflect the number of cellular functions that require force generation or movement, ranging from mitosis to morphogenesis to transport of vesicles. Here we focus on motor proteins that are thought to be important for axonal transport or neuronal function, starting with kinesin.

Kinesins mediate anterograde transport in a variety of organisms and tissues. Since its discovery, much has been learned about the biochemical, pharmacological and molecular properties of kinesin [44, 45]. Kinesin is the most abundant member of the kinesin family in vertebrates and is widely distributed in neuronal and non-neuronal cells. The holoenzyme is a heterotetramer comprising two heavy chains (115–130 kDa) and two light

chains (62–70 kDa). Structural studies have shown that kinesin is a rod-shaped protein approximately 80 nm in length, with two globular heads connected to a fan-like tail by a long stalk. High-resolution electron microscopic immunolocalization of kinesin subunits and molecular genetic studies both indicate that kinesin heavy chains are arranged in parallel with their amino terminals forming the heads and much of the stalk. The kinesin heavy chain heads comprise the motor domains, containing both ATP and MT binding motifs. This motor domain is the most highly conserved region within the kinesin family. Binding of kinesin to MTs is stabilized by AMP-PNP and this property remains a hallmark of kinesins. Kinesin light chains localize to the fan-like tail and may also contribute to part of the stalk. The α-helical coil-coiled domains that are present in both heavy and light chains form the stalk itself. Kinesin light chains appear to be unique to conventional kinesin but are highly conserved across species. Light chains are thought to be involved in organelle binding and may also play a role in targeting of kinesin isoforms to different types of MBO [46].

Considerable evidence implicates kinesin as a motor molecule for fast axonal transport. Kinesin is an MT-activated ATPase with minimal basal activity. MTs will glide across kinesin-coated glass surfaces with motor movement toward the MT-plus end. Since axonal MTs have a uniform polarity with their plus ends distal, the directionality of kinesin is consistent with an anterograde transport motor. Immunofluorescence and electron microscopy showed that kinesin is associated with MBOs that are, in turn, associated with MTs [47, 48] (Fig. 28-7). While these properties of kinesin are consistent with a role in axonal transport of MBOs, they are insufficient to prove the hypothesis that kinesin is the fast axonal transport motor. Such proof came from inhibition of kinesin function by antibodies against both heavy and light chains of kinesin. Since kinesin light chains are only associated with conventional kinesin, the ability of kinesin light chain antibodies to inhibit transport is compelling evidence that kinesin is involved in fast axonal transport. Finally, reduction of kinesin levels using antisense oligonucleotides and gene deletion also implicates kinesin in axonal transport processes [46].

In neurons and non-neuronal cells, kinesin is associated with a variety of MBOs, ranging from synaptic vesicles to mitochondria to lysosomes. In addition to its role in fast axonal transport and related phenomena in non-neuronal cells, kinesin appears to be involved in constitutive cycling of membranes between the Golgi and endoplasmic reticulum. However, kinesin is not associated with all cellular membranes. For example, the nucleus, membranes of the Golgi complex and the plasma membrane all appear to lack kinesin. Kinesin interactions with membranes are thought to involve the light chains and carboxyl termini of heavy chains. However, neither this selectivity nor the molecular basis for binding of kinesin and other motors to membranes is well understood.

Cloning and immunochemical studies of kinesin subunits have demonstrated that multiple isoforms of kinesin heavy and light chains occur in brain. Three kinesin heavy chain genes are expressed in mammals, including a ubiquitous kinesin heavy chain gene expressed in all tissues and a neuronal specific heavy chain gene that is expressed only in brain [49]. At least two different genes exist for the kinesin light chains as well and differential splicing for one of these light chain genes generates three different isoforms [50]. These are differentially expressed in tissues. Heterogeneity in kinesin heavy and light chains may regulate the transport of different MBO types and ensure that organelles reach their correct destinations in the axon. Radiolabeled, specific isoforms of the kinesin heavy chains move down the axon at different net rates that correlate with different MBO types, such as synaptic vesicles and mitochondria [51]. These observations suggest that different kinesin isoforms exist to transport different types of organelle.

Multiple members of the kinesin superfamily are expressed in the nervous system. Kinesin has been purified and then cloned from many species including *Drosophila*, squid, sea urchin, chicken, rat and human. Both heavy and light chains of conventional kinesin are highly conserved throughout. However, once the sequence of the kinesin motor domain was available, related proteins with homology only in the motor domain began to be identified. Kinesin related proteins (KRPs) were first identified in yeast and fungal mutants with defective cell division, but many others are now known [39], with more than 40 different genes expressed in mouse and human [52]. A careful analysis of kinesin superfamily sequences from many species led to the definition of a standardized kinesin nomenclature for 14 defined families of kinesins [53]; conventional kinesin is now known as kinesin-1.

Motor proteins of the large kinesin family all have well conserved motor domains, but KRPs are highly variable in sequence and structure. Even the position of the motor domain varies. Kinesin-1 and many other family members have amino terminal motor domains, but other KRPs have motor domains at their carboxyl termini and some have centrally located motor domains. This variation in structure has functional significance. To date, all tested amino and central motor domain proteins have been found to move toward the MT^{+} end, while carboxyl motor domain proteins move toward the MT^{-} end. Many KRPs are known only from their sequences and expression, but a few have been examined for function. Many KRPs are involved in various steps of cell division, but precise cellular functions are still being defined for many of motors.

Systematic cloning strategies based on the conserved motor domain sequences have identified a remarkable number of KRPs expressed in brain. Members of several KRP families expressed in brain have been implicated in forms of MBO transport. Kinesin-2 family members have been implicated in assembly and maintenance of cilia and

flagella and mutations in these motors can lead to sensory defects and polycystic kidney disease [54]. Kinesin-2 motors are heterotrimers with two related KRP motor subunits and a larger accessory subunit. Kinesin-3 family members were proposed as a synaptic vesicle motor because kinesin-3 mutants in the nematode *Caenorhabditis elegans* had defects in synaptic vesicle localization. Subsequently, two distinct kinesin-3 family members were cloned from mouse brain and their distributions examined: one (KIF1A) was neuron-specific and appeared to be associated with synaptic vesicles, whereas the other (KIF1B) was ubiquitously expressed and reported to be associated with mitochondria. Since kinesin has also been localized on mitochondria, some MBOs may have multiple motor types or there may be subsets of MBOs with specific motors. Various other kinesin family members expressed in nervous tissue have been implicated in the transport of other MBO classes [55]. The extent to which these kinesins reflect unique transport mechanisms rather than functional redundancy within the kinesin family is not known.

Curiously, functions proposed for some brain KRPs [55] are very different from functions proposed for similar or identical KRPs in no-neuronal cells. For example, members of the kinesin-13 family have been implicated in both mitotic spindle function and in axonal membrane transport. Similarly, a mouse kinesin-4 was reported to associate with unidentified MBOs in neurites, but its chicken homolog bound to chromosomal DNA and mediates chromosome movements in the mitotic spindle. Finally, a kinesin-6 was originally found to have a role in mitotic spindle function, but members of the kinesin-6 family were also implicated in the transport of MTs into dendrites [56].

Although the last family of motor proteins to be discovered, the kinesins have proved to be remarkably diverse. So far, there are at least 14 distinct subfamilies in the kinesin family and more are likely to emerge, all with homology in their motor domain [53]. Within a subfamily, however, the more extensive sequence similarities are presumed to reflect related functions. At present, many questions remain about the function of these various motors in the nervous system.

Cytoplasmic dyneins may have multiple roles in the neuron. The identification of kinesin as a plus-end directed microtubule motor suggested that it is involved in anterograde transport but left the identity of the retrograde motor an open question. Since flagellar dynein was known to be a minus-end-directed motor, interest in cytoplasmic dyneins was renewed. Identification of the cytoplasmic form of dynein in nervous tissue came as an indirect result of the discovery of kinesin.

Although dynein binding to MTs is not stabilized by AMP-PNP, both cytoplasmic dynein and kinesin associate with microtubules in nucleotide-depleted extracts and both are released by addition of ATP. Early studies with ATP-free MT extracts showed that they are substantially enriched in a minor high-molecular-weight microtubule-associated protein that was called MAP1c. Biochemical analysis showed that MAP1c was not in fact related to the well defined microtubule-associated proteins MAP1a and MAP1b but instead was closely related to flagellar dynein heavy chains. This discovery led to purification and characterization of brain cytoplasmic dynein [57]. Like flagellar dyneins, cytoplasmic dynein is a high-molecular-weight protein complex comprising two heavy chains and multiple light and intermediate chains that form a complex of more than 1,200 kDa.

As with the kinesins, dynein heavy chains are a multigene family with multiple flagellar and cytoplasmic dynein genes [42]. The 530 kDa dynein heavy chain contains the ATPase activity and MT binding domains of dynein. There may be 10–15 dynein heavy chain genes in an organism, but the large size of the dynein heavy chain primary sequence slowed genetic analyses. At present, dynein genes are grouped as members of either flagellar or cytoplasmic dynein subfamilies. The three intermediate (74 kDa), four light intermediate (55 kDa) and a variable number of light chains present in dyneins may also have flagellar and cytoplasmic forms.

The two or more cytoplasmic dynein heavy chain genes could be involved in different cellular functions, but much dynein functional diversity may be due to its many associated polypeptides [58]. The intermediate and light chains of cytoplasmic dynein are thought to be important both for regulation and for interactions with other cellular structures. In addition, a second protein complex known as dynactin copurifies with cytoplasmic dynein under some conditions [59]. The dynactin complex is similar in size to dynein and contains 10 subunits that include $p150^{Glued}$, dynamitin, an actin related protein, and two actin capping polypeptides among others. The $p150^{Glued}$ polypeptide interacts with both dynein intermediate chains and the actin related subunits. Dynamitin may play a role in the binding of cytoplasmic dynein to different types of cargo. Finally, the actin-related protein (Arp1) forms a short filament that may include actin as well as the capping proteins. This short filament may interact with both $p150^{Glued}$ and components of the membrane cytoskeleton such as spectrin. Dynactin may mediate cytoplasmic dynein binding to selected cargoes including the Golgi complex and the membrane cytoskeleton. The wide range of functions associated with cytoplasmic dynein is matched by its complexity and its ability to interact with accessory factors. Additional proposed functions include a role in mitosis and in anchoring and localizing the Golgi complex.

A number of studies have implicated cytoplasmic dynein as playing a role in retrograde axonal transport [11, 39]. *In vitro* motility studies demonstrate that cytoplasmic dynein generates force towards the minus ends of MTs consistent with a retrograde motor. Dynein immunoreactivities have been associated with MBOs and

cytoplasmic dynein accumulates on the distal side of a nerve ligation coincident with retrogradely transported MBOs. Finally, retrograde transport has been reported to be more sensitive than anterograde transport to UV-vanadate treatment. Since exposure of dynein to UV irradiation in the presence of vanadate and ADP cleaves the dynein heavy chain, this has been a signature of dyneins although other ATP binding proteins may be affected as well.

In the nervous system, the most frequent role proposed for dynein is a motor for retrograde axonal transport, but its properties are also consistent with a motor for slow axonal transport [11]. Consistent with this possibility, studies on the axonal transport of radiolabeled cytoplasmic dynein indicated that most cytoplasmic dynein and dynactin moved with SCb [60]. The ability of dynactin to interact with both cytoplasmic dynein and the membrane cytoskeleton suggests a model in which dynactin links dynein to the membrane cytoskeleton, providing an anchor for dynein-mediated movement of axonal microtubules [61]. Some role for the membrane cytoskeleton in the mechanisms of slow axonal transport is likely, since neurons require interaction with a solid substrate for neurite growth. Taken together, these studies suggest that cytoplasmic dynein has a wide variety of functions in the nervous system from anchoring the Golgi to retrograde transport to transport of MTs. Cytoplasmic dynein appears to have adapted to fulfill many cellular functions that require minus-end-directed MT movements.

Different classes of myosin are important for neuronal function. Myosins are remarkably diverse in structure and function. To date, 15 subfamilies of myosin have been defined by sequence homologies [41]. The brain is an abundant source of nonmuscle myosins and one of the earliest studied. Despite their abundance and variety, the roles of myosins in neural tissues have only recently begun to be defined [40].

Myosin II is in the same subfamily as the myosins in muscle thick filaments and it forms large, two-headed myosins with two light chains per heavy chain. Although myosin II is abundantly expressed in brain, little is known about its function in the nervous system. In other nonmuscle cells, myosin II has been implicated in many types of cellular contractility and may serve a similar function in developing neurons. However, myosin II remains abundant in the mature nervous system, where examples of cell contractility are less common.

The second myosin type identified in nervous tissue was the myosin I family. It was first described in protists and subsequently purified from brain. Myosin I is a single-headed myosin with a short tail that uses calmodulin as a light chain [41]. In many cell types it has been implicated in both endocytosis and exocytosis, so it may play an important role in delivery and recycling of receptors. Myosin I is enriched in microvilli and may also be involved in some aspects of growth cone motility along with myosins from other subfamilies. In both cases, it may link MF bundles to the plasma membrane through a membrane-binding domain. Recently, the myosin I family has been implicated in mechanotransduction by the stereocilia of hair cells in the inner ear and vestibular apparatus. A myosin I isoform, myosin Iβ, has been localized to the tips of stereocilia where it appears to mediate sensory adaptation by opening and closing the stretch-activated calcium channel (see Chapter 51).

Two other myosin types have been implicated in hearing and vestibular function [62]. The defect in the Snell's *waltzer* mouse was found to be a mutation in a myosin VI gene that produces degeneration of the cochlea and vestibular apparatus. Myosin VI is localized to the cuticular plate of the hair cell under stereocilia. Similarly, mutations in a myosin VII gene are responsible for the *shaker-1* mouse and several human genetic deafness disorders. This myosin, myosin VIIa, is found in a band near the base of the stereocilia distinct from distributions of myosin Iβ and myosin VI.

Another myosin type that plays a role in nervous tissue is myosin V [41]. Of the myosins identified in brain, myosin I and V are the strongest candidates to act as an organelle motor and myosin V has been reported in association with vesicles purified from squid axoplasm. Myosin V is the product of the mouse *dilute* locus. Mice carrying the mutant *dilute* allele show defects in pigment granule movement that results in a dilution of the coat color. These mice also exhibit complex neurological defects that may be due to altered endoplasmic reticulum localization in dendrites. In addition, an interaction between kinesin and myosin V has also been reported. Curiously, a form of myosin V found in yeast complements mutation in a KRP gene, suggesting an interaction between these two motor molecules. Finally, there is evidence that myosin V plays a role in growth cone motility where it is enriched in filopodia.

Matching motors to physiological functions may be difficult. The three classes of motors are similar in their biochemical and pharmacological sensitivities in many respects [11]. However, some hallmark features can be used to identify a motor. In the case of kinesin, the most distinctive characteristic is stabilization of binding to MTs by AMP-PNP. The affinities of myosin for MFs and dynein for MTs are weakened by treatment with either ATP or AMP-PNP. As a result, if a process is frozen in place by AMP-PNP, then kinesins are likely to be involved. If kinesin is not involved in a process that requires MTs then dyneins are likely to be involved. Similarly, processes requiring MFs suggest that myosins are required. In the case of fast axonal transport, we know that MTs are required and this process is completely inhibited by AMP-PNP, thus implicating the kinesin family. The development of new pharmacological and immunochemical probes specific for different motors will facilitate future studies.

Although many motor proteins are found in nervous tissue, there are few instances in which we fully understand their cellular functions. The proliferation of different motor molecules and the existence of numerous isoforms raises the possibility that some physiological activities require multiple motors. There may be cases in which motors serve a redundant role to ensure that the physiological activity is maintained in the event of a loss of one motor protein. Finally, the existence of so many different types of motor molecule suggests that novel physiological activities requiring molecular motors may be as yet unrecognized.

AXONAL TRANSPORT AND NEUROPATHOLOGY

Inhibition of axonal transport leads rapidly to loss of function in the distal axon and 'dying back' neuropathies are frequently associated with chronic exposure to neurotoxins that inhibit axonal transport. Some of these neurotoxins may act directly on the motor molecules that underlie axonal transport. For example, the neurotoxicant acrylamide has been found to inhibit kinesin function directly. Recently, more direct evidence has emerged directly implicating fast axonal transport defects in neurodegeneration [63, 64]. For example, a loss-of-function mutation in the kinesin I member KIF5A results in a hereditary form of spastic paraplegia. Remarkably, in many cases, mutant proteins are expressed in many neuronal and non-neuronal cells, but specific neuronal populations suffer. For example, genetic analysis showed that mutations in both the ubiquitously expressed dynein heavy chain and $p150^{Glued}$ can lead to motoneuron deficits in mammals [65, 66]. Other disease-related proteins may deregulate fast axonal transport indirectly by affecting the delivery of materials by transport through effects on energy metabolism or by blocking conversion from anterograde to retrograde transport.

A variety of other neurological diseases are also thought to involve axonal transport [45]. For example, motor neuron diseases like amyotrophic lateral sclerosis (ALS) appear to interfere with both fast and slow axonal transport. Analysis of axonal transport in an animal model of ALS documented deficits in both the transport of NFs by slow transport and the delivery of mitochondria to the axon by fast transport [67]. While ALS-like diseases may be caused by a number of different pathogenic mechanisms, all forms feature accumulations of NFs and a dying back neuropathy in motor neurons characteristic of axonal transport deficits [68]. Similar arguments can be made for a variety of neurodegenerative diseases including polyglutamine expansion diseases [64] and Alzheimer's disease [69]. Even when the primary pathogenic pathway has only indirect effects on transport, any cellular event that compromises the timely and efficient delivery of material by axonal transport processes might result in some form of neuronal degeneration.

CONCLUSION

The functional architecture of neurons is comprised of many specializations in cytoskeletal and membranous components. Each of these specializations is dynamic, constantly changing and being renewed at a rate determined by the local environment and cellular metabolism. The processes of axonal transport represent the key to neuronal dynamics. Recent advances have provided important insights into the molecular mechanisms underlying axonal transport, although many questions remain. Continued exploration of these phenomena will improve our understanding of neuronal dynamics in development, regeneration and neuropathology.

COMMON STEM CELL THERAPY CHALLENGES 514

CONCLUSIONS 514

How the complex interconnected neurons and glia in the adult nervous system are generated from neuroectodermal precursors in the embryo remains a fundamental problem for developmental biologists. The mature vertebrate CNS is characterized by distinct stereotyped cytoarchitecture in different anatomical regions. This regional specificity appears to be established by patterning cues during early development that direct precursor cell differentiation. That this broad array of different cells is largely derived from multipotent stem cells is remarkable but perhaps even more remarkable is that cells with characteristics of stem cells are retained during the subsequent development of the CNS and even into the adult. The presence of multipotent stem cells as well as more fate-restricted but highly proliferative 'progenitor cells' in the developing nervous system leads us to ask how environmental signals such as growth factors regulate proliferation, survival and cell fate determination in normal development. It is the enormous potential of stem cells to repair damage or disease in the adult nervous system, however, that has focused intense interest on these cells as potential resources for regenerative medicine.

STEM CELLS ARE MULTIPOTENT AND SELF-RENEWING

During development many cells undergo multiple cell divisions and generate numerous progeny. The majority of these cells are not stem cells but rather are progenitor or precursor cells. A stem cell differs from other precursor or progenitor cells in two essential ways; stem cells are *multipotent* with the ability to give rise to multiple cell types, and *self-renewing* with the virtually unlimited ability to make more of themselves. Within this broad functional definition, there are various types of stem cell that differ in terms of their temporal or tissue-specific

Basic Neurochemistry: Molecular, Cellular and Medical Aspects

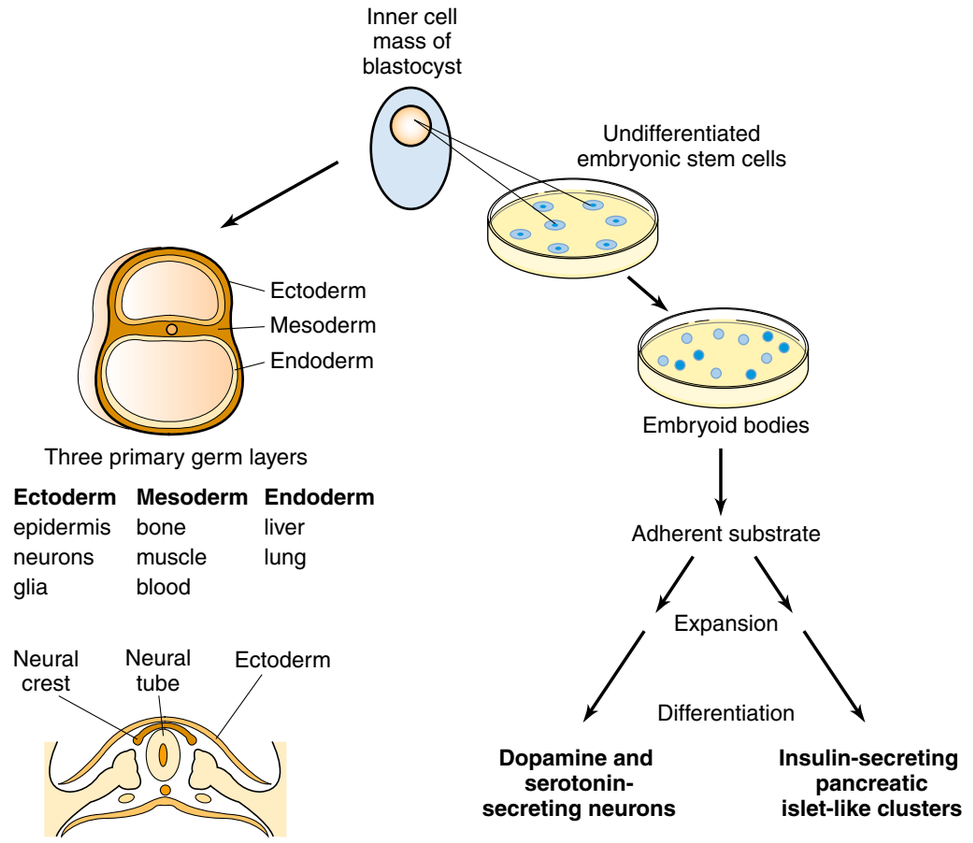

FIGURE 29-1 Embryonic stem cells self-renew and give rise to multipotent progeny. (**Left side**) In normal development, three primary germ layers are established at gastrulation, and these layers give rise to specific derivatives. For example, the outermost ectoderm gives rise to skin epidermis and the neurons and glial cells of the nervous system. Later, after neurulation, the initially sheet-like ectoderm layer gives rise to the neural tube that is the primordium of the central nervous system, and to the neural crest that gives rise to the peripheral nervous system. (**Right side**) Embryonic stem cells derived from the inner cell mass can be grown in culture as adherent, undifferentiated cells. When dissociated and grown as floating embryoid bodies, differentiated cell progeny including neurons and glia can be enriched with specific factors.

locations. For example, embryonic stem (ES) cells are derived from the inner cell mass of embryos generally at 32 cells or fewer and have the broadest range of cellular derivatives. In fact all embryonic tissues originate from ES cells *in vivo* through characteristic primary germ cell lineages (Fig. 29-1). During development, many embryonic tissues are generated from tissue-restricted fetal stem cells and progenitor cells. Once assembled, however, only a few tissues undergo cell turnover in adulthood and rely on a continued source of precursors. The best understood example of an adult tissue that continues to harbor stem cells is the blood (or hematopoietic) system. Here stem cells in bone marrow continuously produce a variety of blood and immune system cells. In other tissues, epithelial stem cells produce new skin cells throughout life, crypt cells produce intestinal lining, and mesenchymal stem cells give rise to bone, cartilage and connective tissue cells. These stem cells are found in different tissue locations, and have distinct properties. One unresolved issue is whether the different types of stem cells have similar potential to generate cells that can be utilized for neural repair.

Stem cells give rise to committed progenitors. In a tissue that depends on the continuous replacement of stem cell-derived progeny, the self renewal of stem cells and the generation of committed progenitor cells must be balanced in order not to deplete the stem cell pool and thus, the entire cell lineage over time. Retention of a stem cell pool might be accomplished in several ways. Stem cells may undergo symmetric divisions to produce two stem cell daughters, or asymmetric divisions to produce a stem cell and one of a variety of committed progenitor cells (Fig. 29-2). Committed progenitor cells typically produce particular lineages of cells and thus are considered to have a restricted cell fate, although this has recently been called into question. Likewise, committed progenitor cells may differentiate immediately into mature cells, or more likely become expanded by selective mitogens to produce many mature cells.

An important controversy remains about which factors, intrinsic or extrinsic, control the stem cell's decision to self-renew or develop into one of several committed progenitor cells. Two distinct models have been proposed to

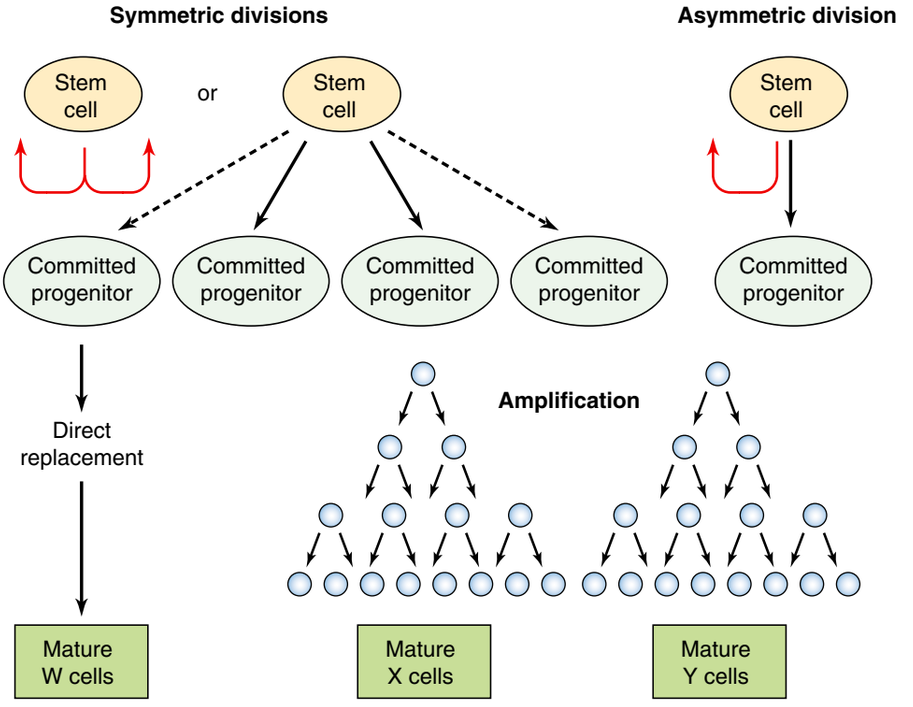

FIGURE 29-2 Stem cells undergo symmetric divisions to increase the pool size of stem cells, or asymmetric divisions to give rise to a committed progenitor cell and another stem cell. Committed progenitor cells may go on to differentiate immediately to directly replace mature cells lost in response to injury or disease. Alternatively, expansion factors may stimulate extensive division of a specific progenitor cell, and produce large numbers of a mature cell type.

describe cell commitment from a stem cell (1) in response to intrinsic molecular events, stem cells *stochastically* produce various committed progenitor cells, and growth factors act upon a particular committed cell to affect its survival or proliferation or (2) growth factors act on stem cells to *induce* the production of particular committed progenitor cells. The ability to control the generation of distinct precursor cells from stem cells is of critical importance if these cells are to be useful for various therapies and it is possible that cell commitment in the nervous system involves features of both mechanisms.

Lessons from the hematopoietic stem cell. In healthy individuals, circulating red and white cells in the blood are replaced every few weeks and new cells are generated from stem cells in the bone marrow. This turnover process suggests there are sufficient stem cells and stem cell proliferation to continue to make differentiated cells for some 90 years, and that the specific growth and differentiation signals required to produce appropriate mature cells are present throughout life. It is now clear that bone marrow contains both the hematopoietic stem cell that gives rise to blood cells and bone marrow stromal cells that can give rise to bone, cartilage, fat and connective tissue cells.

The hemopoietic stem cell is one of the best-characterized stem cells in the body and the major stem cell that is clinically applied in the treatment of diseases, including blood cancers and congenital immunodeficiency. Since the first successful allogeneic (from a genetically different person) hematopoietic stem cell transplant in 1968, thousands of patients have received transplants to treat diseases. Hematopoietic stem cells are rare in bone marrow (perhaps one in 2,000 cells) and give rise to eight quite different types of blood and immune cell. The study of hematopoietic stem cells was significantly enhanced by the now-classical observation that implanting just a few purified stem cells can completely restore an immune system that has been experimentally destroyed (Fig. 29-3A). The ability to utilize a bioassay in which one grafts selected populations of cells and assays their cellular potential *in vivo* was essential to further understanding in this field. Furthermore, hematopoietic stem cells can be prospectively isolated from the mixed bone marrow by virtue of cell surface antigens including CD34 or AC133. In the vertebrate CNS similar bioassays and prospective antibody-based isolation procedures for neural stem cells are not yet well developed.

The bone marrow is not the only source of hematopoietic stem cells. Such cells are present in low numbers in peripheral blood, and these can be expanded in number with specific factors. Peripheral blood stem cells have the major therapeutic advantage that their harvest is relatively painless and less invasive. Likewise, umbilical cord stem cells can also be obtained in a non-invasive manner from

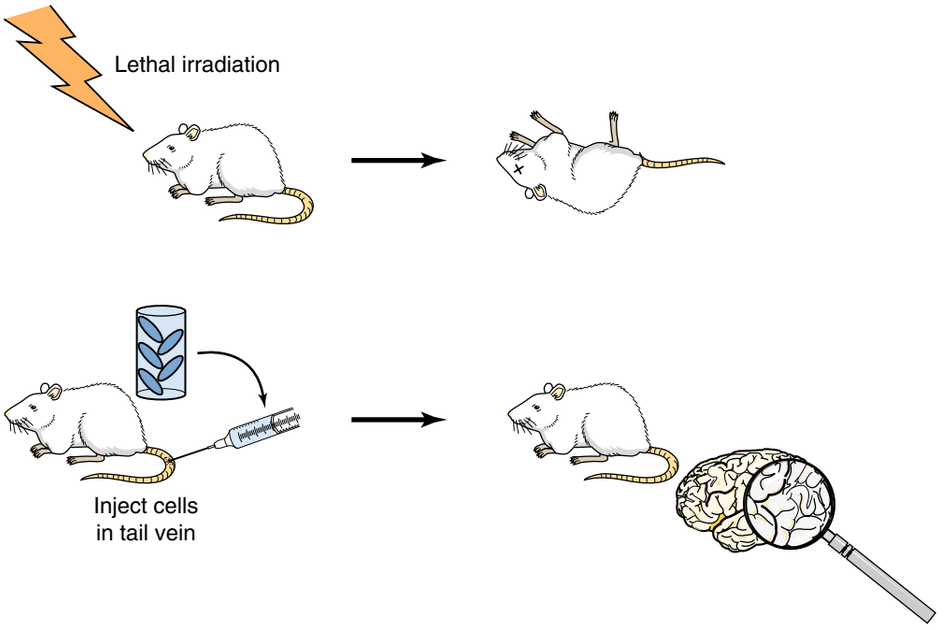

FIGURE 29-3 Intravenous administration of stem cells can reconstitute the blood forming system, and may provide cells to other tissues. In classical studies, Till and McCulloch administered dissociated bone marrow cells in the tail vein of lethally irradiated mice and found that the grafted cells repopulated the hematopoietic system and allowed the animals to survive. More recent studies suggest that blood cells also travel to sites of injury, where they may give rise to non-blood-tissue progeny.

an abundant source of tissue that is typically discarded. These cells have been used in some transplants to brain regions (see below).

The generation of distinct cell populations from hematopoietic stem cells is regulated by multiple factors. Many of the cytokines that regulate progenitor amplification and survival have been identified [1]. One well characterized signal is stem cell factor (SCF), which acts early in the lineage to stimulate proliferation of myeloid, erythroid and lymphoid progenitors, presumably by expanding a multipotent precursor cell. Regulation of each progenitor lineage appears to be mediated by the concentration or combination of specific proliferative factors. For example, a mechanism sensing the oxygen level regulates the level of the red blood cell growth stimulator erythropoietin made largely in the kidney. Erythropoietin binds to high-affinity receptors on the surface of erythroid progenitor cells to maintain their survival. Under the influence of erythropoietin, committed erythroid progenitor cells divide and differentiate. These cells then differentiate into proerythroblasts, in which hemoglobin synthesis can first be detected, and then subsequently mature and lose their nucleus. After mature cells are produced, they must be localized to body sites for function. In the hematopoietic system, long-distance cell migrations throughout the body must be employed, from marrow to lymph or spleen or to peripheral tissues. The targeting of cells to distinct tissue sites is in part mediated by the localized expression of chemotactic cytokines known as chemokines. For example, the final steps in B cell maturation are dependent on marrow-derived differentiation signals and the cells are retained in the appropriate microenvironment as a result of expression of the chemokine CXCL12 and its receptor CXCR4.

An important question is whether stem cells can be directed to produce progenitors in one lineage or another by application of specific factors. In one sense, this experiment is done *in vivo* in anemic individuals or those who have lost a lot of blood. If stem cells were *all* redirected to respond to this stress, one might anticipate a depletion of other blood cell types. This is not observed, but instead stem cells appear to routinely give rise to various progenitor cells, and it is the progenitor cells that respond to the presence or absence of mitogens to expand selected lineages. In this way, the balance of stem and progenitor cells appears maintained.

Bone marrow stem cells may not be restricted to the blood cell lineage. Stem cells that emerge during embryogenesis and in the adult are generally thought to be restricted in their developmental potential and give rise only to cells of the tissue in which they reside. Whether such a restriction is cell intrinsic or environmentally regulated is unclear. Recent studies suggest, however, that cell fate restriction may not be irreversible, as a number of stem cells appear able to produce alternative cell types to those normally produced *in vivo*. For example, adult bone marrow cells retain the ability to give rise to cell derivatives of all three germ layers, including neural cells. After lethal irradiation, bone-marrow-derived cells not only

repopulated the hematopoietic system as expected but also gave rise to cells that expressed neuron specific genes in the CNS. Transgenic mice that expressed green fluorescent protein (GFP) in all cells were used for grafting, and several months after tail vein administration of bone marrow cells, thousands of GFP-labeled cells were found throughout the CNS (Fig. 29-3B). Many transplanted cells in the brain had characteristics of macrophage/microglia. This result is perhaps not surprising given that microglial cells in the CNS are thought to have their origin in the bone marrow although trafficking between the blood and brain in the adult has been controversial. More unexpected, however was the discovery of labeled cells with neural morphologies and that expressed molecular characteristics of neural-tube-derived cells (neuronal or astrocytic markers) integrated into the host brain [2]. Tissue injury may promote the recruitment of bone marrow stem cells to additional cell types. For example, in the *mdx* mouse model of muscular dystrophy, transplanted bone marrow cells gave rise to skeletal myocytes [3]. Because of the potential ability of bone marrow cells to home to site of injury, clinical trials have begun to assess bone marrow transplant for repair of diabetic skin ulceration and myocardial infarctions.

Initially, many assumed that the nervous system might utilize similar stem-cell- and progenitor-cell-based regulatory mechanisms to produce the many types of neuron and glia, but several aspects of the nervous system may require specific mechanisms. Unlike the blood-forming system, the nervous system is largely formed during fetal and neonatal development. In the adult during normal life, neurons do not undergo significant turnover, nor do many neurons or even glial cells appear to be generated once the CNS is formed, and thus there is no great 'need' for large numbers of neural stem cells. Unlike the epithelial system, neurons form intricate connections over long distances with specific synaptic partners in functional networks. These aspects of spatial and cellular restriction suggest that neural stem cells may differ from those in other systems and that specific therapies based on stem cells face unusual challenges in the nervous system. Clearly in many cases injury to the adult nervous system is not functionally repaired by stem cells effectively, and thus neurodegenerative diseases or neural trauma have devastating consequences. If neural stem cells could be isolated, propagated and directed toward particular lineages effectively and then functionally incorporated into existing circuits, their promise as therapeutic agents in neural repair is enormous. Several ongoing studies suggest that these issues may be tractable.

STEM CELLS CONTRIBUTE TO THE DEVELOPING NERVOUS SYSTEM

A central role for neural stem cells in the development of the nervous system is becoming clear. During embryological development, the nervous system originates from ectodermal cells otherwise fated to become skin, and the molecular regulation of neural induction involves the generation of genetic competence as well as cell–cell communication events [4]. Cells that remain in the neural tube give rise to CNS neurons and glia, while cells that migrate from the dorsal portion of the neural tube disperse throughout the body in stereotypic pathways to give rise to the peripheral nervous system (PNS). Both the CNS and the PNS appear to utilize stem cells and neural progenitors in subsequent development. As with tissue-specific stem cells discussed above, it is still not clear how restricted some of these neural stem cells are, or if they are capable of contributing to neurons and glia in more than one region of the nervous system.

Central nervous system stem cells maintain an undifferentiated state and the capacity to self-renew in response to epidermal growth factor and fibroblast growth factor. An important breakthrough was made in the last decade when it was recognized that the embryonic CNS contains multipotent stem cells capable of extensive cell renewal and the generation of neurons, astrocytes and oligodendrocytes [5–7]. A critical assay used in these studies was to culture dissociated CNS cells in 20 ng/ml fibroblast growth factor (FGF)2 and epidermal growth factor (EGF)2 on a nonadherent substrate. In this medium, aggregated, floating 'neurospheres' of cells form (Fig. 29-4). When such neurospheres are plated on to an adhesive

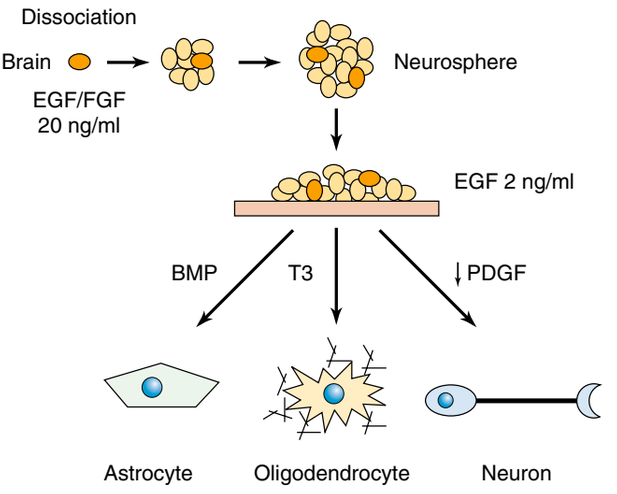

FIGURE 29-4 Neural stem cells can be isolated from the brain and propagated as neurospheres. Dissociated brain cells maintained in epidermal growth factor (*EGF*) and/or fibroblast growth factor (*FGF*) contain a small population of stem cells that continue to propagate in growth factor as floating 'neurospheres'. Neurospheres grown on an adhesive substrate give rise to the major cells of the brain, neurons, astrocytes and oligodendrocytes, *in vitro*, indicating that they contain multipotent cells. These neurospheres can be re-dissociated and give rise to more neurospheres, suggesting that they contain stem cells. *BMP*, bone morphogenetic proteins; *PDGF*, platelet-derived growth factor; *T3*, triiodothyronine.

substrate and growth factors are withdrawn they differentiate into clumps of cells containing neurons and glial cells, suggesting that neurospheres contain multipotent cells. If neurospheres are dissociated into single cells and cultured in FGF and EGF many individual cells again give rise to neurospheres *in vitro*, suggesting that some cells can self-renew. Remarkably, neurospheres could be generated not only from the embryonic CNS but also from adult brain and spinal cord. In general, neurosphere-generating cells were more easily isolated from the ventricular lining of the brain or the central canal of the spinal cord, suggesting that these regions were the preferred location of such stem cells. More recent studies have succeeded in isolating small numbers of neurosphere-forming cells from adult brain parenchyma, which may indicate a wider distribution of stem cells in the adult CNS. It is important to keep in mind, however, that the actual relationship between neurosphere generating cells *in vitro* and true stem cells *in vivo* is not well understood.

Cell lineage studies reveal close associations between distinct neural cell types. One characteristic of the vertebrate CNS is the exquisite cytoarchitectural organization of the tissue, which is retained through the life of the animal. Such a reproducible pattern of cellular development suggest that the fate of multipotential stem cells is modulated by local environmental patterning influences. Consistent with such regional specification, cell lineage studies using replication incompetent retroviruses to label clones of cells derived from one precursor *in vivo* revealed several types of precursor cells that were spatially segregated. For example, following injection into the embryonic spinal cord, clones of cells containing motor neurons and oligodendrocytes were frequently observed, suggesting that these cells share a local common precursor. Subsequent studies demonstrated that both cells originate in the same region of the ventral neural tube and share inductive cues. In more rostral regions of the CNS, precursors give rise to radially arrayed clones of neurons and glial in vertically oriented columns that span multiple cortical layers. Not all clones contain both neurons and glia. Many clones, particularly later in development, are comprised of only glial cells. Such clones contain only astrocytes or only oligodendrocytes or both. In mixed clones astrocytes were largely located in gray matter while oligodendrocytes were largely located in white matter. Several specific progenitors, including a neuron-restricted precursor, glial-restricted precursor and oligodendrocytes–astrocyte (O–2A) precursor have been described. Together these observations lead to the general concept that the multipotent and self-renewing stem cell (detected several years later) gives rise to restricted progenitors with more limited cellular potential and their fate depends on environmental cues.

The development of motor neurons and oligodendrocytes is dependent on sonic hedgehog. One of the most intensely studied cell types in the CNS is the spinal cord motor neuron. These cells arise in a distinct domain in the ventral ventricular zone of the spinal cord during a specific time in development. The induction of motor neuron precursors from 'stem cells' in the ventricular domain appears regulated by the local expression of the patterning molecule sonic hedgehog (Shh) secreted by the notochord and floorplate [8, 9]. Likewise, oligodendrocyte precursors are generated from the same domain later in development, probably from the same cells, and their induction is also dependent on Shh. Other more dorsal domains of the ventral ventricular zone generate precursors to distinct populations of interneurons and this induction is regulated by differing concentrations of Shh. Dorsal ventricular regions of the spinal cord do not produce motor neuron or oligodendrocyte precursors but rather circumferential and other distinct interneuron populations. Dorsal spinal cord has the potential to generate ventral cell types however, if stimulated by Shh. These studies suggest that multipotent stem cells are localized throughout the dorsoventral axis of the developing spinal cord, and that the fate they assume is regulated by local signals [10]. Given the diversity of cell types in the CNS, many other cues must exist to regulate cell fate. It is likely that in most cases a single cue is not sufficient to induce a distinct cell type. Rather, a series of temporal cues instruct cells in increasingly restricted pathways.

Bone morphogenetic proteins stimulate astrogenesis. Dorsal spinal cord generates distinct populations of neurons and glia and specification of their precursor fate also seems to depend on localized cues. During embryonic development members of the transforming growth factor (TGF)β superfamily, including bone morphogenetic proteins (BMPs), are expressed in dorsal regions where they contribute to the induction of dorsal neural cell populations and suppression of ventral cell fates. In rostral regions of the CNS the role of BMPs in cell fate is more complex and depends on the maturity of the responding cells. Early in development BMP2 and BMP4 stimulate neuronal differentiation in cortical cultures while later in development BMP stimulation enhances the appearance of astrocytes in cortical cultures [11, 12]. The induction of astrocytes from cultured mouse neuroepithelial cells by BMPs appears to reflect an inhibition of neuronal development, since exposure of forebrain neural progenitors to BMP2 reduces the number of neurons and increases the number of glia. Additional factors such as platelet-derived growth factor and thyroid hormone are critical in the generation of the full spectrum of neural cells. One clear cellular target for BMP actions *in vitro* is the bipotential O-2A progenitor cell. These cells usually generate oligodendrocytes but can be induced to generate a subset of astrocytes called type 2 astrocytes by a variety of signals. BMP treatment of enriched cultures of bipotential glial precursors results in an increase in astrocyte differentiation and concomitant decrease oligodendrocyte differentiation. Further, altering the spatial and temporal expression of BMPs during CNS development has significant effects

on the subsequent development of astrocytes and oligodendrocytes. In the cerebral cortex of animals that overexpress BMP4 driven by the neuron-specific enolase promoter, increased numbers of astrocytes and reduced numbers of oligodendrocytes are seen [13]. Since gliogenesis persists well into the postnatal period, the expression of regulatory signals such as BMPs is also likely to be persistent. Together these data suggest that BMPs act as a major regulator of neural cell fate determination in the vertebrate CNS, both during early patterning of CNS stem cells and later during glial precursor differentiation. Recent studies suggest that under pathological conditions cells in the adult vertebrate CNS retain the ability to respond to these early fate cues.

Neural crest stem cells give rise to neuronal or glial derivatives in the peripheral nervous system. A wide range of cells in the peripheral nervous system, including autonomic neurons, sensory neurons, neuroendocrine cells and glial cells, are derived from neural crest cell precursors that emerge from the dorsal neural tube during the period of neural tube closure and subsequently migrate throughout the body. Transplantation studies *in vivo* and cell cloning experiments *in vitro* provide strong evidence that the neural crest contains multipotent progenitor cells. The prospective isolation of mammalian neural crest cells by virtue of their p75 expression and absence of markers of differentiation has allowed the analysis of PNS stem cells *in vitro* [14, 15]. Single cell cloning studies indicate that some cells are multipotent and give rise to neurons and glia. Further, multipotent neural crest cells also give rise to multipotent progeny, suggesting the presence of a true stem cell in the neural crest.

Several growth factors have been identified that act to increase particular derivatives from PNS stem cells, but their mode of action as proliferative agents, survival factors or inductive cues is not completely understood. For example, BMPs act on neural crest stem cells to induce adrenergic neurons [16], and glial growth factor (GGF), a member of the neuregulin family, inhibits neurogenesis and enhances gliogenesis [14]. The observation that isolated stem cells can be induced to produce cultures containing numerous cells of a single type, but that such cultures still contain cells of other types, may reflect the fact that PNS stem cells stochastically produce a variety of progenitors, and specific lineages are then amplified by growth factors. This issue has proved difficult to resolve, although it is clear that neural crest populations give rise to mature derivatives largely in response to 'instructive' cues from the microenvironment.

NEUROGENESIS OCCURS IN THE ADULT BRAIN

For many years, it was thought that the adult nervous system was unable to generate new neurons; after all, neural trauma or disease is devastating and essentially irreversible. Immediate exceptions were made to the notion that neurogenesis largely ceased in the adult, and focused initially on the songbird brain. Male songbirds add large numbers of new neurons each year to vocal centers in their brains [17, 18], and their generation is related to seasonal hormone surges and growth factor production. These neurons clearly integrate into the neural circuitry of the brain, providing a strong indication that, under the appropriate conditions, neurons can decipher migratory cues and synaptic partners even within the complex network of adult functional synapses.

The ability to generate new neurons is not restricted to the adult avian CNS. Two areas of the mammalian brain, the dentate gyrus of the hippocampus and the anterior region of the subventricular zone (SVZa), which generates cells in the rostral migratory stream to the olfactory bulb, include dividing cells that gave rise to neurons even in adults (Fig. 29-5). Early thymidine birthdating studies revealed that many neurons were generated after birth in rodents and, using similar birthdating approaches, neurogenesis has been detected in the adult olfactory precursors and hippocampus. More recent studies tracing the fate of the newly generated cells suggests that at least some of the dividing precursors are multipotent and may be stem cells [19–22]. These observations suggest that many regions of the mature brain have the capacity to give rise to new neurons.

If stem cells are retained into adulthood in the CNS it becomes critical to identify, localize and characterize those cells. Neurosphere assays suggest that the majority of stem cells in the adult CNS are localized close to the ventricles, although the precise nature of the cells remains obscure. Several populations have been suggested to include adult neural stem cells, including GFAP-expressing astrocytes, Notch1-expressing ciliated ependymal cells lining the ventricles, and GFAP radial glial cells. The presence of these stem cells has largely been inferred retrospectively and in order to effectively characterize and manipulate these cells it is important to purify them prospectively. Several assays have been suggested to enrich or isolate

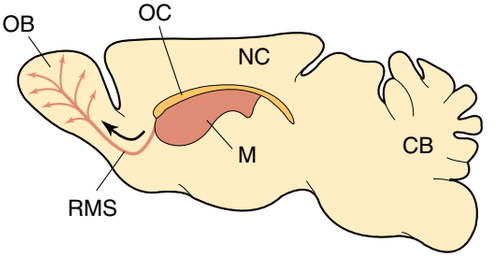

FIGURE 29-5 In the adult rodent brain, dividing cells in the subventricular zone adjacent to the lateral ventricle migrate in the rostral migratory stream (*RMS*) and differentiate into olfactory neurons in the olfactory bulb (*OB*). This is one site of neuronal turnover in the adult that appears to result from persistent generation of neurons from adult CNS stem cells. *CB*, cerebellum; *NC*, neocortex.

stem cells, although none are widely accepted. For example, stem cells may be enriched by removing other cells with features of differentiated neural cells from a mixed population. The problem with this approach is that stem cells are found in vanishingly small numbers so the yield is minimal. Until effective approaches for prospective isolation of reasonable numbers of adult stem cells are identified, it will be difficult to test many ideas about the regulation of adult CNS stem cells.

The findings that the adult CNS contain stem cells and that in some regions neurogenesis occurs in the normal brain raises the question as to why, in neurodegenerative diseases or after CNS trauma, neural repair is ineffective. At least three different phenomena may underlie the inability of the adult CNS to undergo extensive repair: (1) Although stem cells are present in the tissue there are too few to promote effective repair; (2) Although stem cells are present, they are unable to 'home' to the site of pathology; (3) Although stem cells are present in the tissue the molecular environment does not promote appropriate precursors or facilitate precursor expansion. These impediments to neural repair might be overcome if sufficient neural stem cells are delivered to areas of injury in conjunction with modulation of the growth factor environment. Recent studies on specific neural insults suggest that this type of therapy may have some application (see below).

STEM CELLS OFFER THE POTENTIAL FOR REPAIR IN THE ADULT NERVOUS SYSTEM

Mature nerve cells cannot divide to replace those that are lost. Thus, many neural disorders or injuries are characterized by the cells and functions that are lost. For example, in Parkinson's disease, neurons that make the neurotransmitter dopamine in the substantia nigra die. In amyotrophic lateral sclerosis, motor neurons of the spinal cord that activate muscles die. In multiple sclerosis, the oligodendrocytes that protect nerve fibers are lost and, following traumatic injury or stroke, multiple types of neural cell are lost. The ability to treat neurological ailments by transplanting stem cells to replace sick or missing cells in the brain has enormous promise. Much of the interest in stem cells comes from the possibility that these cells offer a source of 'new' neural cells to create functioning nerve tissue, offering new therapeutic possibilities. New findings in animals suggest that transplanted cells survive and may become incorporated in working neural circuits [23]. If stem cell therapeutic approaches are to be effective a number of critical issues have to be addressed. For example: (1) What is a good source of stem cells for neural repair? Is there a single type of stem cell, perhaps in bone marrow, that can generate the cells of any tissue? Are such cells more effective and more easily obtainable than stem cells from the adult CNS? (2) What cues are needed for the stem cells to differentiate efficiently into the desired cell type? Can *in vitro* expanded cells be effectively incorporated into the CNS? (3) What factors stimulate stem cells to home to sites of injury?

Brain cells can be derived from embryonic stem cells. One promising candidate for neural repair is the embryonic stem cell. Recently, techniques have been developed for the *in vitro* culture of ES cells, providing unprecedented opportunities for studying and understanding the regulation of human tissue differentiation. Very early human ES cells can be isolated and spread out on a feeder layer of mouse cells to produce an immortalized pluripotent human stem cell culture. These ES cells can then be stimulated to divide symmetrically to produce large numbers of undifferentiated stem cells [24, 25]. Alternatively, ES cells can be coaxed into forming aggregated clumps of cells called embryoid bodies that can then be stimulated to differentiate into a variety of cell types. One distinct advantage in the use of ES cells is that they are available *in vitro* for genetic manipulation and appear initially homogeneous, thus allowing selected transcription factors or growth factors to be genetically applied to stimulate differentiation. An early success in directed differentiation was obtained with human ES cells that were stimulated to become pancreatic islet cells that produce insulin [26].

Embryonic stem cells can also be manipulated to generate both CNS precursor cells and the terminal neuronal and glial fates of the CNS. For example, ES cells can be stimulated to give rise to dopaminergic neurons *in vitro* and have been transplanted into animal models of neurodegeneration and appear to offer functional benefit. In this case, a transcription factor essential for dopaminergic differentiation in development was transfected into ES cells *in vitro* and cell lines were established. Further neuronal differentiation was promoted with the soluble growth factors FGF8 and sonic hedgehog, with the result that some 80% of the cells contained the rate-limiting enzyme for catecholamine synthesis, tyrosine hydroxylase and dopamine itself were released *in vitro* [27]. When these cells were transplanted into the striatum of mice in which dopaminergic cells had been chemically ablated with 6-OHDA, many stimulated ES cells grafted into the site and extended processes. One and two months after grafting, animals who received these cells continued to show significant synaptic function and behavioral improvement. In another example, mouse embryonic stem cells were stimulated to differentiate into motor neurons and, when introduced into the spinal cord of embryonic chicks, motor axons formed contacts with skeletal muscle [28]. Thus, an understanding of inductive signals involved in normal pathways of neurogenesis has been very useful in directing ES cells to form specific classes of CNS neuron.

ES cells aggregated into embryoid bodies and propagated in growth factors, including platelet-derived growth factor, differentiate rapidly to include CNS glial cells.

About 40% of this population express markers of oligodendrocytes, and a similar proportion have astrocytic markers. To test the potential of these cells *in vitro*, ES cells propagated in this fashion were transplanted into the spinal cord or cerebral ventricles of myelin-deficient rats. Two weeks after transplantation, ES derived cells were present in the dorsal columns of the spinal cord both at the implant and several millimeters in both directions from that site. The mouse origin of the ES cells transplanted into rat was confirmed by analysis of mouse satellite DNA in the grafts. Similarly, intraventricular transplanted cells formed myelin in multiple brain regions [29]. These and other results support the further study of stimulated ES cells for potential therapies in the nervous system.

Even in these studies, the differentiation of stem cells is not complete and, after stimulation, the cultures contain cells at different stages and directions of differentiation. These observations may suggest that stem cells always give rise to particular progenitors and the primary role of exogenously added growth factors is to expand certain progenitor pools. One strong concern in these and other stem cell experiments is to avoid transplanting undifferentiated ES cells that cause teratoma-type cancers. Current studies are directed toward the efficient production of single cell types for use in therapies. The isolation of ES cells from early human embryos or propagation of fetal stem cells from aborted fetal tissues, however, raises many ethical, legal, religious and policy questions and the potential uses of stem cells for generating human tissues is a subject of ongoing public debate.

Brain cells may also be derived from non-neural stem cells. The isolation of human embryonic or nervous tissue for transplant therapy will always be fraught with significant ethical concerns, and thus scientists have explored other cellular sources of stem cells for neural therapies. Surprising recent data suggest that, contrary to traditional expectations, it may be possible to 'transdifferentiate' cells from one classical primary germ lineage to another. Developmental biologists have long known that three embryonic germ layers give rise to selected body cell lineages (endoderm to lining of the gut, mesoderm to blood and muscle, ectoderm to skin and nervous tissues, for example). The notion that segregation of cell fate is irreversible is being challenged by a series of recent discoveries suggesting that neural cells might be obtained from mesodermal lineages.

While it is perhaps not surprising that ES cells can generate neurons, as human embryonic stem cells develop into every tissue of the body, it is surprising that adult stem cells in particular tissues can give rise to cells of another lineage. For example, reports indicate that hemopoietic stem cells can give rise to myocytes [3], bone marrow stromal cells can give rise to astrocytes [30] and umbilical cord cells can be induced to form neurons and glia that can integrate in the brain after transplantation [31]. Further, there are reports that cells derived from the adult forebrain can reconstitute the hematopoietic system of lethally irradiated mice [32], and stem cells isolated from young or adult rodent skin proliferate and differentiate in culture to produce neurons, glia, smooth muscle cells and adipocytes [33]. This type of work suggests that cells from completely different primary germ layers, such as bone marrow and blood, might produce nerve cells. The ability to generate neurons from a non-nervous-system cell tells us that cell potential may be broader than we imagined, and may provide a more convenient source for therapeutic cell approaches. Despite controversies concerning the plasticity of bone-marrow-derived stem cells, early clinical trials are being conducted in patients suffering from myocardial infarct, arthritic and neurological diseases using autologous bone marrow stem cells (see review in [34]). While these studies are in very early stages, one does wonder if there are multipotent stem cells in every tissue or, even more tantalizing, if there is a single type of stem cell, for example in bone marrow, that might generate the cells of any tissue.

One of the complications in this field is that relatively few differentiated cells are present in the graft, despite large numbers of transplanted cells. It is not clear why so few cells are present and whether this reflects the lack of survival factors in the adult host environment or the presence of few plastic cells in the graft. Unfortunately, the small number of differentiated neurons may also indicate that few cells have differentiated, and most cells are derived from cell fusion or other unusual cellular events. Enthusiasm for the utilization of non-neural stem cells for repair of the nervous system must also be tempered, as two recent studies have failed to repeat some of the original transdifferentiation results [35, 36]. In these studies, genetically labeled enriched hematopoietic stem cells were transplanted into lethally irradiated hosts, and non-hematopoietic derivatives were searched for. Extremely rare cells were occasionally seen in other tissues, even after damage, and, more critically, no evidence was seen for hematopoietic cells becoming neurons. The variability in studies of this type is an indication of our lack of fundamental understanding of the biology of stem cells in general.

An important remaining challenge in experimentally assaying the range of cellular derivatives made by stem cells has been to develop a bioassay in which precursors can repopulate the nervous and other systems effectively. One approach has been to inject adult neural stem cell neurospheres into the amniotic cavity of young chick embryos. In some animals, these cells integrate and give rise to cells of multiple germ layers and can be detected by virtue of introduced markers. Adult neural stem cells can also be used to form mouse chimeras with early embryos or when injected into blastocysts [37] and contribute to CNS and other organs, suggesting a very broad range of potential cell fates. These bioassay approaches are important for our understanding of stem cell biology, but are unlikely to be employed therapeutically.

STEM CELL TRANSPLANTS FOR NEURAL REPAIR

Stem cell transplantation to replenish neurons lost in Parkinson's disease. Parkinson's disease is a particularly intriguing clinical target for a cell transplant strategy, in part because it is based upon replacing a clearly defined and discrete population of neurons. In Parkinson's disease, a gradual loss of dopamineric neurons of the substantia nigra cells in the ventral midbrain leads to reduction of dopaminergic input to the striatum, and resulting in motor abnormalities. Management of individuals with Parkinson's disease has focused on symptomatic treatment, largely with drug therapy based on levodopa. Recently, however, there has been renewed interest in restorative or regenerative treatment based on transplantation of cells into the brain. The underlying premise of this approach is that injected cells survive and function as normal dopaminergic neurons and in doing so restore motor function.

Attempts have been made to replace dopaminergic neurons in diseased brain by grafting different types of dopamine secreting cell, including fetal midbrain precursors [38]. As discussed above, ES cells can be stimulated to give rise to dopaminergic neurons *in vitro* and, when transplanted into animal models of neurodegeneration, lead to long-lasting functional benefit [27, 38, 39]. Clinical studies suggest that grafted dopaminergic neurons remain for long periods despite a slow loss of the patient's own neurons. Fetal grafts have also been used as a source of dopaminergic transplants. One concern with this approach is that the results obtained are highly variable, for reasons that are poorly understood. Furthermore, involuntary movements occur in about 10% of patients. The results of these types of cell replacement therapy are encouraging but the heterogeneity of transplanted cells and risks of immunological rejection continue to make this approach challenging.

A number of studies have utilized injection of multiple types of stem cell into the damaged CNS in an attempt to enhance repair. For example, injection of mesenchymal stem cells into the adult rat brain after contusion injury or stroke models has been reported to enhance functional recovery. Likewise, transplantation of mesenchymal stem cells into the cavity created by spinal cord injury in adult rats appears to promote regeneration. In such cases, however, it seems likely that the transplanted cells are not differentiating into neural derivatives but rather acting to supply growth or survival factors that facilitate the endogenous repair process. Thus, it is important to recognize that enhanced functional recovery effected by stem cells may reflect the secretion of growth or survival factors rather than their integration into the injured CNS.

Stem cell transplantation to replenish glial cells lost in multiple sclerosis. The potential augmentation of neurons and glial cells in the pathological adult brain faces very different spatial challenges. In multiple sclerosis, CNS inflammation and widespread oligodendrocyte and axonal losses are hallmarks of the advanced disease. One therapeutic approach has focused on replacing the myelinating oligodendrocyte of the CNS. While neurons may be difficult to produce in large numbers, replacement of the more ubiquitous glia may alternatively be challenging because it is difficult to deliver cells simultaneously to many sites in the adult nervous system.

One model that has been extensively used to determine the repair capacity of glial precursors is the *shiverer* mutant mouse. This animal lacks myelin basic protein and as a consequence is unable to generate compact myelin. These animals develop an extensive tremor postnatally and die early. Classical studies demonstrated that transplantation of normal tissue into the developing shiverer CNS resulted in patchy myelin formation as a result of the integration of the transplanted cells. This type of analysis has subsequently been repeated using a variety of cell sources and delivery approaches. For example, intraventricular injection of a neural stem cell line resulted in widespread myelination and a reduction in the behavioral deficit [40]. The widespread dispersal of the injected cells suggests that either these cells are capable of long-distance migration through the developing CNS or they integrate into different sites as a result of transependymal migration. Similar studies have utilized rodent neurospheres or gliosphere-derived cells with similar results, and more recently the capacity of transplanted human stem cells to generate myelin in the *shiverer* background has been demonstrated.

While such studies are illuminating in terms of the myelinogenic capacity of the transplanted cells, the lack of endogenous compact myelin in the *shiverer* host does not make them a particularly useful model for demyelinating diseases such as multiple sclerosis. Furthermore, while extensive dispersal of glial cells may be feasible in the developing CNS, cellular migration through the adult myelinated CNS appears to be highly restricted and direct injection of stem cells into multiple sites of the adult human CNS is not practical. Remarkably, some studies have raised the possibility that delivery of regenerative stem cells via the blood stream may facilitate repair of demyelinated lesions.

Some aspects of multiple sclerosis are reflected in the animal model experimental autoimmune encephalomyelitis, which is induced by immunization of susceptible animals with appropriate encephalogenic proteins or peptides. In these animals, if cultured adult stem cell neurospheres are injected into the bloodstream, injected cells can find their way to damaged portions of the nervous system and improve function in mice. How the injected cells augmented the recovery process is unclear. One possibility is that cells recruited to the lesions differentiated into oligodendrocytes and generated new myelin sheaths, but this seems unlikely in the face of ongoing cellular destruction.

Repair in the CNS also requires transplanted cells to traverse the blood–brain barrier. To circumvent the blood–brain barrier, in other approaches cells were delivered intracerebroventricularly, and neurophysiological recovery was also noted [41]. As encouraging as these initial studies are, the animal experiment is very different from treating multiple sclerosis, which is a chronic and inflammatory disorder that involves both glial and axonal changes. Furthermore, the scale of repair required in the human CNS is substantially larger than that in murine or rodent models. We still face questions with multifocal diseases as to the best way to introduce cells throughout the nervous system and, in the case of a chronic inflammatory disease, how to keep transplanted cells from succumbing to the same underlying disease.

Hematopoietic stem cell transplants as treatment for glial disease. Hematopoietic stem cell transplants have been used successfully to treat genetic disorders that affect the nervous system, such leukodystrophies. Leukodystrophies are a group of genetic disorders characterized by the imperfect development or maintenance of the myelin sheath and include diseases like adrenoleukodystrophy, Alexander's disease, Canavan's disease, Krabbe's disease, metachromatic leukodystrophy, Pelizaeus–Merzbacher disease, Refsum's disease and phenylketonuria. Globoid-cell leukodystrophy is caused by a deficiency in galactocerebroside, a glycolipid essential for normal myelin. Depending on the particular leukodystrophy, patients either die prematurely, suffer from severe cognitive dysfunction or suffer from seizures. Children with globoid cell leukodystrophy treated with hematopoietic stem cell transplantation develop normal leukocyte galactocerebroside levels, and CNS deterioration can be reversed or prevented [42]. It remains unclear exactly how hematopoietic stem cell transplants result in this neural improvement.

EXPANDING ENDOGENOUS NEURAL STEM CELLS FOR REPAIR

The realization that many regions of the adult CNS contain neural stem cells as well as glial precursors capable of generating oligodendrocytes suggests that approaches designed to expand these cells and stimulate their appropriate differentiation may be useful therapeutically. The ability to locally expand populations of endogenous neural stem cells and have the progeny integrate successfully into the mature CNS would circumvent many of the problems associated with cellular transplantation.

In most regions of the CNS there is little or no turnover of neurons during the life of the animal and following trauma to the adult CNS recruitment of new neurons is extremely limited. This may reflect the low proliferation rate of neural stem cells or the inability of stem cell progeny to survive or target the appropriate location. It may be that recruitment is severely impaired by the neuroinflammatory response that accompanies a wide range of neural pathologies such as Alzheimer's disease, trauma and multiple sclerosis. Consistent with this notion, when a distinct population of cortical neurons is eliminated by retrograde incorporation of a cellular toxin, little activation of the inflammatory pathway occurs and some endogenous cellular repair has been observed [43]. Incorporation of BrdU demonstrated neural precursor proliferation and the newly generated cells migrated to the appropriate laminar location, assumed the correct identity and projected appropriately to the opposite brain hemisphere. In similar studies, when mature dopaminergic neurons are destroyed by the toxin MPTP, the rate of replacement of the lost neurons increases [44]. These observations suggest that under the appropriate conditions endogenous stem cells of the adult CNS might have the capacity to replace lost neurons, although the results have to be interpreted with caution since similar parallel studies have found that only glial cells were generated in the adult [45]. How the adult brain detects the loss of selected neurons and whether this loss serves to 'activate' dormant stem cells or recruit their progeny to particular fates is unknown.

The capacity of the adult CNS to generate new glial cells is well established. Following penetrating lesions or contusion injuries to the brain or spinal cord, a rapid glial response occurs in which astrocytes surrounding the lesion undergo hypertrophy and proliferate. Such a response generates a 'glial scar' that is thought to contribute to the lack of axonal regeneration. The astrocytes of the scar, however, do not appear to functionally integrate into the surrounding neuropil. Similarly, CNS injuries promote the proliferation of a population of cells that have been termed 'adult oligodendrocyte precursors', identified by expression of the NG2 epitope. In adult human white matter these presumptive glial progenitors are very common and may comprise perhaps 3% of all cells. It seems likely that the progeny of these cells contribute to the remyelination that is seen as shadow plaques in some multiple sclerosis patients. Adult oligodendrocyte precursors can also be passaged as neurospheres with the mitogenic and differentiative characteristics of stem or multipotent cells. These cells generate functional neurons and glia *in vitro*, suggesting that a broader range of cell fates are possible under some conditions. Animals implanted with expanded white-matter-derived progenitor cells contained β-tubulin-labeled neurons in the rostral migratory stream to the olfactory bulb as well as GFAP labeled astrocytes and CNP oligodendrocytes in white matter [46], suggesting that white matter $NG2^+$ cells are capable of stem-cell-like properties.

Infusion of growth factors following an injury has been suggested to greatly enhance the replacement of lost cells. For example, infusion of EGF, the major mitogen for neural precursors, was reported to enhance the

recruitment of neural stem cells or their progeny to lesioned areas. In spinal cord injury, direct injection of Shh into the lesion site resulted in dramatic increases in cell proliferation and the proliferating cells had the capacity to give rise to neurons, astrocytes and oligodendrocytes. Further, Shh injection appeared to enhance functional recovery, although it was unclear whether the improved function resulted from enhanced neural cell generation or a reduction in secondary cell death.

Cell fusion may underlie some observations of grafted cells. Better methods are needed to document the birth, proliferation and migration of new neurons. Early encouraging results that transplanted cells differentiated into primary neurons has been tempered by proof that, rather than a single grafted cell differentiating into a neuron, cell fusion events may explain some apparent transdifferentiation. For example, when female patients with various blood diseases who had received human male adult bone marrow transplants were examined postmortem for persistent transplanted cells, Y chromosome markers were present in a few Purkinje cells in the cerebellum [47]. The frequency of such Y-labeled neurons was small but appeared to reflect an immutable marker that could only have been obtained from the transplanted bone marrow. This led to questions about whether blood cells transdifferentiate from blood lineage to neuron lineage cells or if another mechanism transfers the label to adult neurons. In adult mice that received GFP-labeled bone-marrow-derived cells, again labeled Purkinje cells were observed but GFP was present only in heterokaryon products of cell fusion [47]. These heterokaryons increased in a linear fashion over several years. Cell fusion has also been demonstrated to underlie bone marrow contributions to differentiated liver cells [48, 49]. These cell fusion events are essentially equivalent to nuclear reprogramming. The fact that grafted bone marrow cells could participate in the formation or maintenance of neurons is remarkable, but these studies do suggest that some initial euphoria in response to the apparent plasticity of stem cells might need re-examination. While cell fusion may cast doubt on some cell transformation interpretations, this mechanism does suggest that a novel form of therapy might be possible.

COMMON STEM CELL THERAPY CHALLENGES

While promising, stem or progenitor cell research for neural therapeutics still needs to overcome many obstacles before it transfers effectively to the clinic. There are significant gaps in our understanding of how stem cells contribute to the normal development of the nervous system and the nature of the regulatory factors that stimulate appropriate differentiation. Developmental biologists understand that a closely regulated interplay of genetic regulation and cell–cell communication via growth factors will be required. Efficient stem cell therapies are likely to be based upon the ability to prospectively isolate and greatly expand the stem cells, and subsequently efficiently direct their differentiation, and these issues presently pose significant technical hurdles.

The source of cells used for transplantation forms a continuing discussion point. Early reports suggest that ES cells are most efficient for production of large numbers of neurons, but their use involves significant ethical and legal debates. If adult stem cells, or even stem cells from an easily harvested location such as bone marrow, were capable of significant expansion and could be directed to differentiate into a wide range of neural cells, these would be very attractive. Further, the possibility of expanding the patient's own endogenous stem cells would alleviate concerns about immune rejection and the use of immunosuppression drugs. At this point, it is unclear if neurons can be efficiently derived from any source other than ES cells.

No matter how many cells might be generated in the laboratory, this approach is useless if the adult brain does not accept and incorporate the graft correctly. The functional integration of immature cells into the host neural circuitry is essential for neuronal replacement. Animal studies suggest that transplanted cells can incorporate and function in circuits, but the extent of the damaged brain's ability to allow regenerative responses is not entirely clear. Further, little is known about the regulation of injury factors that might direct stem cells to localize in injured regions, or how to deliver cells effectively to large regions of the damaged nervous system. Indeed, very little is known about the possibility that transplanted cells might succumb to the same disease process that affected original cells. By contrast, a remaining major concern is to prevent transplantation of cells that continue to proliferate and create tumors. The long term side effects of transplanting new neural cells is largely unknown.

CONCLUSIONS

In the last decade, the roles of stem and progenitor cells in the differentiation of the embryonic nervous system have become illuminated, leading to fundamental advances in our knowledge of the regulation of cell fates in the brain. Much is still needed for us to understand the interplay between genetic and cell communication events that leads to normal generation of the complex nervous system. These issues are important to resolve if we are to learn how disease or trauma affect the growing brain.

We have also caught a glimpse of how various stem cells might repair damage or disease in the adult nervous system. Embryonic stem cells form an important source of new neurons, but accompanying this success are many ethical issues about their use. Some reports have suggested other non neural tissues might serve as a reservoir of stem cells that might transdifferentiate into neurons and glial

cells, but questions about the interpretation of these experiments leaves this approach uncertain.

Finally, for the field to move forward in an effective way it is critical that new bioassays that efficiently isolate and monitor stem and progenitor cells in the intact nervous system and directly assess their restorative potential are developed. Such advances will allow us to effectively compare what cell fates are possible *in vitro* with their differentiation in a normal or pathologic cellular environment.

Inhibition of neurite growth is mediated through surface receptors and intracellular signaling molecules 523
Axon growth is inhibited by the glial scar 523
Neurotrophic factors promote both cell survival and axon growth after adult central nervous system injury *in-vivo* 524

CENTRAL NERVOUS SYSTEM INJURY AND COMPENSATORY PLASTICITY 524
Neonatal brain damage results in compensatory plasticity 524
Compensatory plasticity and functional recovery can be enhanced in the injured adult central nervous system through blockade of Nogo-A 525

SUMMARY AND CONCLUSIONS 526

The adult mammalian brain and spinal cord have limited capacity for spontaneous functional and structural recovery after injury. However, over the past 20 years a virtual explosion of scientific evidence has shown us that damaged adult neurons are indeed capable of regrowth given the proper conditions, and a number of strategies in which adult CNS neurons can be influenced to regrow following injury have been found. These strategies include suppression of action of growth-inhibitory molecules, which are primarily found in myelin, reduction of scar barriers, enhancement of the neuronal response to axotomy through supplementation with growth factors and enhancement of the growth potential of the injured neuron. These investigations, which will be discussed in this chapter, lay the foundation for understanding CNS repair mechanisms and give hope to a situation previously thought to be hopeless.

There are two important structural processes in which the brain and spinal cord regain function after damage, i.e. regeneration and compensatory plasticity (Fig. 30-1). In regeneration, the cut axon begins to regrow from the

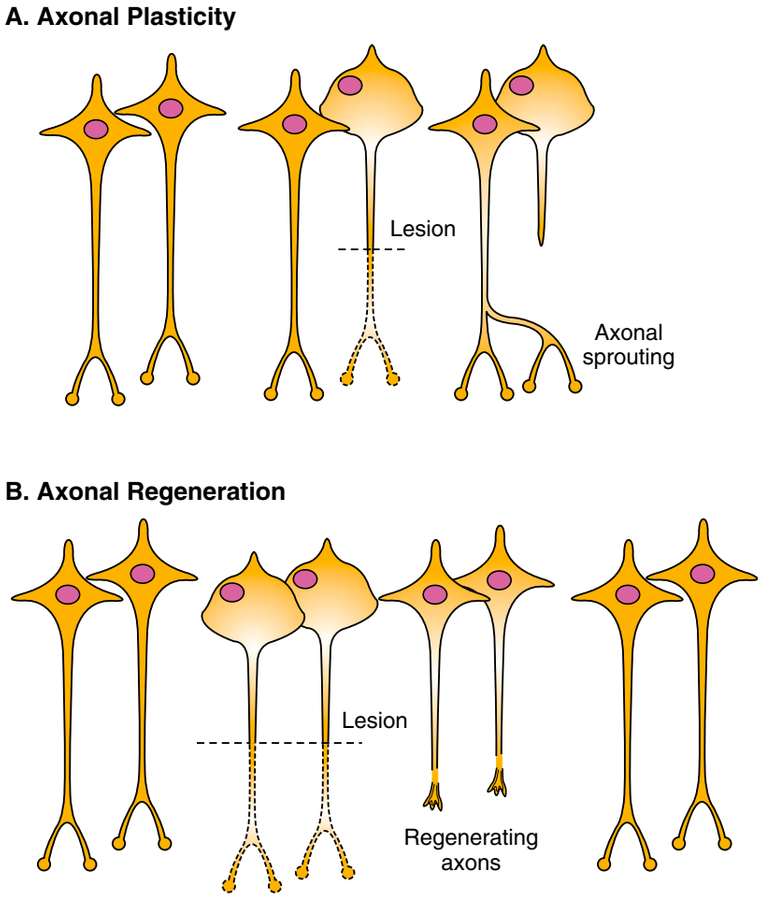

FIGURE 30-1 Simplified drawing depicting the difference between axonal plasticity (**A**), where following axonal injury the cut axon does not regrow, but other undamaged neurons grow new axons to reinnervate denervated targets. In axonal regeneration (**B**), cut axons regrow from the damaged sites and reconnect with denervated targets.

damaged end and elongates either through or around damaged tissue to eventually reconnect with deafferented targets. On the other hand, compensatory plasticity is conceptually quite different, i.e. it is the *undamaged* spared neurons that grow new axonal connections to deafferented targets, and this source of new axonal growth can be quite distant from the original injury site. Interestingly, these two types of recovery mechanisms most probably share a similar molecular basis for promoting axonal regrowth.

REGENERATION IN THE PERIPHERAL NERVOUS SYSTEM

Peripheral nerve injuries are caused by a variety of factors including acute trauma, chronic repetitive insults, and inheritable or acquired metabolic disorders (Ch. 36). As opposed to the CNS, which has traditionally been thought to be fixed, axonal injury in the PNS often results in some degree of spontaneous regeneration, although it is not always completely successful in terms of targeting or full functional recovery.

Wallerian degeneration is the secondary disruption of the myelin sheath and axon distal to the injury. This process was first described in 1850 in frog peripheral nerves by the British physiologist Augustus Waller and was subsequently termed Wallerian degeneration. When either central or peripheral axons are damaged, Wallerian degeneration occurs, but with important differences between these two systems. These differences may underlie at least in part their different regenerative potentials (Table 30-1).

The molecular and cellular events during Wallerian degeneration in the peripheral nervous system transform the damaged nerve into an environment that supports regeneration. First, the cut axon degenerates distal to the injury site and, within 18–48 hours, cytoskeletal disintegration of axonal neurofilaments and microtubules occurs, which is due to proteases such as calpains

TABLE 30-1 Major differences in Wallerian degeneration

Peripheral nervous system	Central nervous system
Schwann cell survival and differentiation	Apoptotic death of oligodendrocytes
Rapid phagocytosis of injured axons and myelin sheaths by invading macrophages	Slow removal of injured axons, myelin sheaths and persistence of some myelin inhibitory factors
Formation of new myelin sheaths	No new myelin reforming

that are stimulated by an increase in intra-axonal concentration of calcium ion [1] (Fig. 30-2). The Schwann cell processes surrounding the axon retract their myelin but do not die, and are supported by autocrine trophic factors. Axotomy induces the production of inflammatory cytokines such as tumor necrosis factor (TNF)α and interleukin (IL)-1α in Schwann cells almost immediately. These cytokines play a critical role in macrophage recruitment to the injury site through endothelial cell activation and chemokine production [2]. After 1–2 weeks, fairly rapidly as compared to the CNS, degenerating axonal and myelin debris is removed primarily by macrophages migrating in from the bloodstream and partly by endogenous endoneurial macrophages and Schwann cells themselves. Invading macrophages also serve a key role by secreting a variety of cytokines, such as IL-1 and platelet-derived growth factor (PDGF), that stimulate Schwann cells to divide, dedifferentiate and proliferate distal to the injury. These stimulated Schwann cells are induced to secrete growth factors such as nerve growth factor (NGF), insulin-like growth factor (IGF)-1 and ciliary neurotrophic factor (CNTF) which increase the chance of neurons to survive the trauma of axotomy and stimulate axons to regenerate.

Both Schwann cells and basal lamina are required for axonal regeneration to proceed. Each axon–Schwann cell unit in a peripheral nerve is surrounded by a basal lamina sheath of collagen, laminin and fibronectin. Following injury, this entire basal lamina/Schwann cell cylinder is known as the band of Büngner, and this unit forms pathways to guide regenerating nerves back to their appropriate target structures. In a localized crush injury, the basal lamina sheaths surrounding the nerves are usually left intact, and therefore axonal regrowth and functional recovery are much better than in a transection injury, where the lamina sheath is cut and guidance mechanisms are therefore lost.

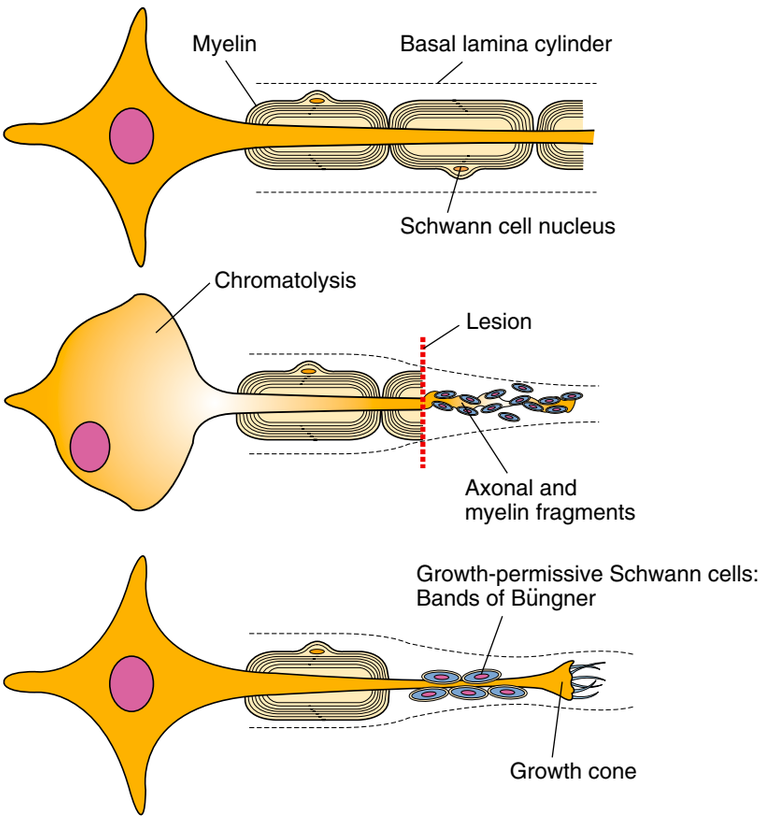

FIGURE 30-2 Wallerian degeneration in the PNS. After an axon is injured, resulting chromatolysis, i.e. stress reaction and increased protein synthesis, occurs in the neuronal cell body, with axonal and myelin degeneration distal to the injury. Growth-permissive Schwann cells secrete growth factors that stimulate axons to regenerate.

Cell surface adhesion molecules, which promote regeneration, are expressed on plasmalemma of both Schwann cells and regenerating peripheral axons. Adhesion molecules such as L1, neural cell adhesion molecule (N-CAM) and *N*-cadherin promote axonal regeneration by homophilic interactions between axons and Schwann cell surfaces (see Ch. 7). The expression of p75 (low affinity NGF receptor, Ch. 27) is also increased at the Schwann cell surface after injury. Extracellular matrix molecules, such as tenascin and proteoglycans, increase the regenerative potential of damaged peripheral nerves by binding to integrins on the axonal surface.

Structural and biochemical changes occur after axotomy. At the site of axonal damage, and within approximately one hour, the cut end of the axon seals off and formation of a motile growth cone-like structure is formed. Within 1–2 days, depending upon how far from the cell body the cut is, major changes in gene expression and protein production occur within the cell body and new proteins are transported to the growing axon tip. These include structural proteins such as tubulin alpha 1, pro-regenerative proteins such as Reg-2 [3] and the growth associated protein GAP-43. This phosphoprotein (also known as B-50, F1, pp46, 48K 4.5) is present on the inside of the growth cone membrane where it interacts with various kinases and plays an important role in communication between the growth cone and its micro-environment [4, 5]. Following axotomy, massive upregulation of GAP-43 occurs in both sensory and motor neurons, and levels remain high until axons reconnect with their targets at which time expression returns to baseline levels.

REGENERATION IN THE CENTRAL NERVOUS SYSTEM

For regeneration in the mammalian CNS to occur, the injured neuron must first survive, and its damaged axon must regrow sometimes long distances through or around the injury site, eventually connecting with appropriate targets. As in the PNS, the axon is driven forward by the growth cone, a dynamic motile structure at the distal tip of regenerating axons containing the molecular machinery for growth and guidance to navigate through the intact and injured CNS. Once contact is made, the axon needs to be remyelinated and functional synapses formed on target cells.

After a CNS axon is injured, Wallerian degeneration distal to the cut end does occur, as in the PNS, but with important differences (Table 30-1). The degenerating myelin and axonal debris persist much longer, with less recruitment of macrophages from the peripheral blood to eliminate the debris; thus myelin inhibitory factors are present much longer than in the injured PNS. Microglia are the first glial cells to react, within a few hours after injury. Astrocytes and meningeal cells are activated and collaborate in forming the glial scar, with inhibitory molecules such as chondroitin sulfate proteoglycans remaining for several weeks to months. Oligodendrocytes persist or die slowly.

As opposed to the PNS, where growth-associated molecules such as GAP-43 are uniformly upregulated by the lesioned neurons after axotomy, CNS neurons vary greatly in their responses to injury. The pattern of expression of GAP-43 in the CNS during development is ubiquitous but, after synaptogenesis is completed and critical periods for activity dependent plasticity are over, GAP-43 is downregulated in most adult CNS neurons. However, some neurons continue to express high levels of GAP-43, including the dopaminergic neurons of the substantia nigra, and neurons associated with adult plasticity, such as hippocampal cells and cells within the olfactory bulb, where axons continue to grow into adulthood. After injury, dopaminergic neurons do not increase their expression of GAP-43, although most central neurons do have some transitory increased response, with greater upregulation of proteins the closer the injury is to the neuronal cell body.

Despite extensive study, the role of Wallerian degeneration in nerve degeneration and regeneration is not completely understood. However, the discovery of a mutant mouse strain has the potential to add some insight into this important reparative process. The Wld^s (Wallerian degenerate, slow) mouse is a spontaneously occurring mutant strain with an interesting phenotype of slow Wallerian degeneration and prolonged axonal survival after both CNS and PNS nerve injury [6]. The Wld^s mutation is made by the splicing of fragments of two genes within an 85 kb triplication on chromosome 4. This splice results in a new open reading frame and codes for a 42 kDa chimeric protein unique to the Wld^s mouse, with an as of yet unknown function. However, introduction of the Wld^s gene into cultured rat DRG neurons made these previously susceptible neurons resistant to axonal degeneration in a model of toxic neuropathy. Further studies are needed to fully elucidate the potential therapeutic role of the Wld^s gene in axonal survival and repair [7].

That the regenerative ability of adult mammalian neurons can be altered by their environment was first suggested by Ramon y Cajal and later demonstrated in the now classic experiment by David and Aguayo [8] (Fig. 30-3). When sciatic nerve segments taken from rats were used as 'bridges' between the medulla oblongata and spinal cord, damaged CNS axons at both of these levels grew into the peripheral nerve grafts for long distances, i.e. for several centimeters in length. Importantly, the suggestion that the peripheral nerve glial environment was permissive to central axonal regrowth led the way for experiments investigating the differences between central oligodendrocytes and peripheral Schwann cells and their products, i.e. myelin.

Central nervous system myelin contains molecules that inhibit neurite growth. One of the major obstacles to new neurite outgrowth in the adult CNS is the presence

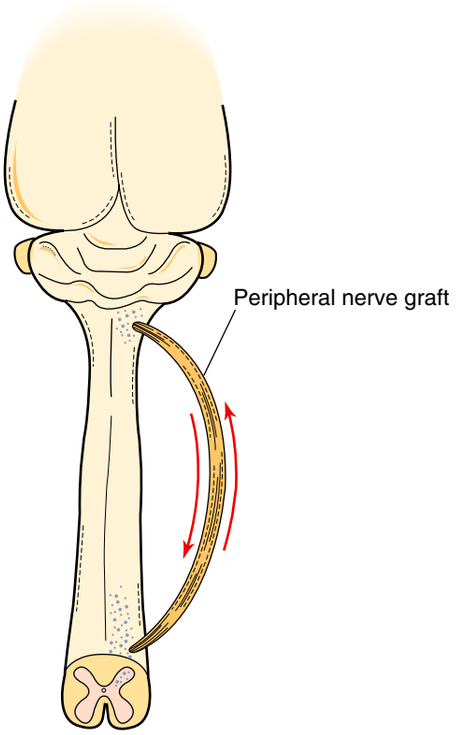

FIGURE 30-3 Diagram of the dorsal surface of the rat CNS, showing a peripheral nerve 'bridge' linking the medulla oblongata and the thoracic spinal cord. As indicated by the arrows, damaged CNS axons from both sites of the nerve implantation grew into the graft and continued for long distances, demonstrating the growth potential of CNS neurons when given the microenvironment of the PNS. (Modified with permission from reference [8].)

of inhibitory molecules in myelin. Studies have elucidated three inhibitors associated with myelin, namely Nogo-A, myelin-associated glycoprotein (MAG) and oligodendrocyte myelin glycoprotein (OMgp) [9].

Nogo-A is a potent inhibitor of neurite growth and blocks axonal regeneration in the central nervous system. Early *in vitro* experiments showed that neurite outgrowth was impeded across a culture dish coated with CNS myelin whereas neurites would actively grow on a dish coated with PNS myelin. Biochemical fractionation of rat brain myelin led to the identification of two membrane proteins of about 250 kDa and 35 kDa with strong inhibitory properties when added to growing neurites. Further purification of the corresponding bovine 220 kDa protein enabled sequencing of six peptides, which ultimately led to the cloning of the cDNA of a gene that was aptly named *Nogo* [10]. So far, three distinct isoforms of Nogo have been identified, Nogo-A, B and C, with Nogo-A being the isoform most studied (Fig. 30-4).

Nogo-A is a membrane protein expressed in the adult mammalian CNS primarily by oligodendrocytes [11]. Neuronal expression is also seen in the dorsal root ganglia, sympathetic ganglia, motor neurons, hippocampal pyramidal cells and cerebellar Purkinje cells of the developing nervous system. Nogo-B is found in many tissues and cell types including adult neurons and oligodendrocytes, and Nogo-C is most highly expressed outside of the CNS, in skeletal muscle. While the functions of Nogo-B and Nogo-C are not entirely known, Nogo-B is found highly expressed in cultured endothelial and smooth muscle cells, as well as in intact blood vessels, and it may be a regulator of vascular homeostasis and remodeling [12].

Peptide fragment analysis of Nogo-A has shown that inhibition of neurite growth, collapse of growth cones and inhibition of fibroblast spreading are associated with two or three distinct regions of the molecule [13]. A principal inhibitory region is found in the middle of the Nogo-A- specific sequence, termed 'Amino-Nogo'. A 66-residue loop between the two hydrophobic regions (Nogo-66) is also able to inhibit neurite growth and to induce growth cone collapse [14] (Fig. 30-5).

The Nogo gene is a member of the reticulon superfamily. Nogo-A comprises approximately 1200 amino acids with two long hydrophobic stretches (transmembrane segments or loops) close to the C-terminus. Only about the last 180 amino acids show homologies to a previously known family of three genes, the reticulons (RTN). The RTN proteins are named after the main subcellular localization of RTN-1, which is in the endoplasmic reticulum. Nogo, i.e. RTN-4, not only colocalizes with the endoplasmic reticulum but is also found on oligodendrocyte

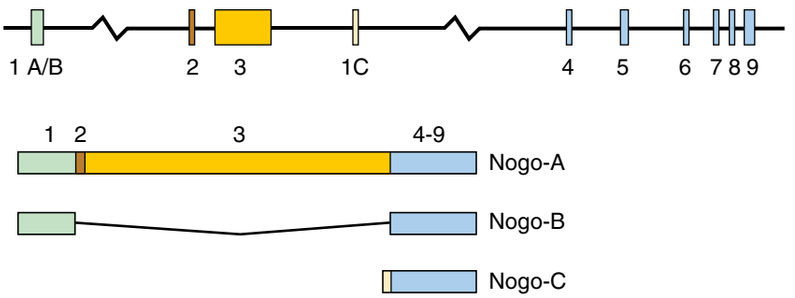

FIGURE 30-4 Isoforms of Nogo. Nogo-A, -B and -C have a common carboxy terminus of about 180 amino acids (the common domain – *blue*– contains Nogo-66). Nogo -A and -B share an amino terminus of about 172 amino acids (*green*).

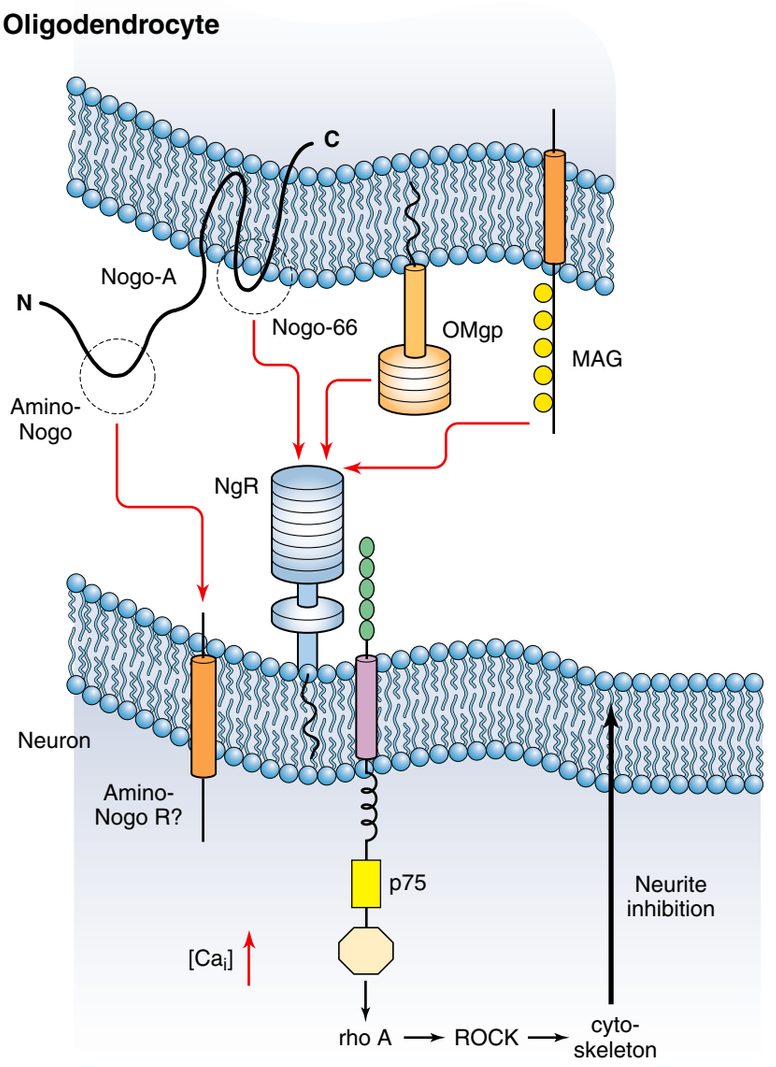

FIGURE 30-5 Nogo-A, MAG and OMgp are the principal inhibitors of neurite growth in CNS myelin. A portion of Nogo-A, i.e. Nogo-66, interacts with the same receptor, NgR, as do MAG and OMgp. NgR in the neuronal membrane complexes with p75 and other possible co-receptors to activate Rho A and its downstream target, ROCK, and may result in neurite inhibition. Another major inhibitory area of Nogo-A, known as Amino-Nogo, interacts with a receptor that is not yet known. [Ca_i], intracellular calcium. (Modified with permission from reference [9].)

plasma membranes. The RTN family is evolutionarily very old and occurs in all eukaryotes including plants and fungi. The RTN family is distributed widely throughout the CNS and other tissues in animals [15].

Most of the known RTN proteins have a relatively short amino (N)-terminal sequence. The very long N-terminal sequence of Nogo-A with its potent inhibitory regions appears late in vertebrate evolution, which suggests that Nogo-A is the result of a fusion between an ancient RTN homology domain at the C-terminus and two to three open reading frame sequences at the N-terminus, allowing the evolved protein to adopt a new function, i.e. that of a neurite-growth inhibitor. The lack of Nogo-A in fish and salamanders would explain the high regeneration potential of the spinal cord after lesions in the latter animals. Whereas Nogo/RTN-4 has a known neurite-growth inhibitory function, more generalized cellular functions relating to the endoplasmic reticulum are suggested for the other proteins in the RTN family as well as for Nogo-A, -B and -C, for example roles in intracellular trafficking or apoptosis.

Nogo-A neutralizing antibodies lead to axonal growth and functional recovery *in vivo*. After cell culture experiments, the next step was to show the ability to block myelin inhibitors and achieve axonal regrowth after spinal cord injury. The monoclonal antibody IN-1 was initially raised against myelin fractions enriched for

Nogo-A. Treatment with IN-1 promoted axonal regeneration and behavioral recovery in rats after thoracic spinal cord injury. These exciting results have since been confirmed using local intrathecal pump infusions of recombinant IN-1 Fab fragments or novel anti-Nogo-A antibodies [9].

Lines of knockout mice null for the Nogo genes have been developed. Different lines of knockout mice for Nogo-A, Nogo-A/-B and Nogo-A/-B/-C have been studied (see [9] for review). It should be noted that, as is often done, hybrids of two different mouse strains that differed greatly in various relevant respects, such as neuroinflammatory response, cell death at lesion sites, scarring response and overall behavior, were used. After spinal cord lesion, the Nogo-A-specific knockout mice showed a moderate but clearly detectable increase in regenerative sprouting and elongation. The same phenotype was quantitatively enhanced in one of the Nogo-A/-B knockout lines. Because Nogo-B was greatly upregulated in the Nogo-A knockout, the Nogo-66 site seemed to compensate partially for the absent Nogo-A-specific active site. At odds with these observations were the results from a different laboratory, in which neither the Nogo-A/-B knockout lines nor the survivors from a single Nogo-A/-B/-C knockout mouse that escaped lethality showed major enhancement of sprouting or regeneration of the lesioned corticospinal tract [9]. The analysis of backcrossed strains on a pure genetic background and conditional knockout mice will hopefully help to resolve these issues in the future.

Myelin-associated glycoprotein and oligodendrocyte myelin glycoprotein are myelin components that have growth-inhibitory activity. MAG is a member of the immunoglobulin (Ig) superfamily and a sialic acid-binding transmembrane glycoprotein. In the CNS, MAG is found in the periaxonal myelin membrane and in the PNS, in the inner and outermost membranes of the myelin sheath [16]. MAG has long been known to have potent neurite inhibitory activity *in vitro*. There is evidence that immunization with myelin or recombinant Nogo-66/MAG promotes axonal regeneration after corticospinal tract lesions in adult mice [17]. However, MAG knockout mice did not show long-distance regeneration in the lesioned spinal cord.

A third myelin inhibitory protein, OMgp, is a GPI-linked protein expressed by oligodendrocytes [18]. OMgp is a relatively minor component of myelin, believed to be localized to the paranodal loops, next to the node of Ranvier. OMgp contains a leucine-rich repeat (LRR) domain and a C-terminal domain with serine/threonine repeats. Like MAG, OMgp is also found in the PNS. Like Nogo, OMgp is also expressed in adult neurons.

To date, the possible roles played by these inhibitors that are found within neurons is not known. In one recent study a high degree of Nogo-A expression was found in rodent regenerating axons in the central and especially the peripheral nervous system, suggesting that neuronal, as distinct from oligodendroglial-derived Nogo also may be involved in axonal growth and guidance [19].

Inhibition of neurite growth is mediated through surface receptors and intracellular signaling molecules. Interestingly, one receptor that binds to Nogo-A, MAG and OMgp has been characterized; it is an 85 kDa GPI-linked, leucine-rich repeat glycoprotein named Nogo receptor (NgR) [14]. This receptor is expressed on the surface of various neurons and was named NgR since it binds to the 66-amino-acid region in the C-terminal domain that is common to Nogo-A, -B and -C, i.e. Nogo-66. Surprisingly, NgR was found to be complexed with the low-affinity p75 nerve growth factor (NGF) receptor (discussed in Ch. 27), which acts as a signal transducing subunit [16] (Fig. 30-5). Recently a third component, LINGO-1, a transmembrane protein that links to NgR and p75, has been identified as an important functional component of this signaling complex [20]. Amino-Nogo, the additional inhibitory domain for Nogo-A, does not require this NgR complex for activity, and the receptor for Amino-Nogo has not yet been found. In studies using NgR-blocking peptides, when infused locally over rodent spinal cord lesions or applied systemically, corticospinal tract regeneration and functional recovery was seen even when given one week after lesions [21]. Interestingly, another *in vivo* study examining the regeneration in $p75^{NGR}$ knockout mice after spinal cord lesion showed no enhancement of regeneration, suggesting that the $p75^{NGR}$ component of the NgR is not the sole mediator of inhibitory function [22].

Two intracellular signaling components of neurite-growth inhibition have been identified so far, namely, calcium ion and the Rho-A/Rho kinase (ROCK) pathway (Fig. 30-5). The inhibitory effects on neurons as mediated by RhoA, a small GTPase, are thought to be via intracellular regulation of cytoskeletal assembly (see Ch. 19). Importantly, inhibition of these intracellular pathways by appropriate blockers can prevent myelin- or Nogo-A-induced collapse of growth cones and inhibition of neurite growth *in vitro*; and these blockers can also induce corticospinal tract sprouting after spinal cord lesions *in vivo* [23]. Finally, several studies have shown that elevated levels of cAMP can cancel the repulsive and inhibitory effects of several inhibitors, including MAG and Nogo [16]. cAMP may act locally on growth cones, as well as on neuronal cell bodies to mediate growth-enhancing effects.

Axon growth is inhibited by the glial scar. Another barrier to CNS regeneration is the glial scar, which consists mainly of reactive astrocytes and proteoglycans. As early as Ramon y Cajal [24], glial scar tissue was implicated as an impediment to adult axonal regeneration after CNS injury. More recent studies since the early 1990s have

demonstrated that failure of axonal regeneration may be due to the nonpermissiveness to neurite growth of extracellular matrix molecules (ECM), including the chondroitin sulfate proteoglycans (CSPGs) and keratin sulfate proteoglycans in the scar [25]. *In vitro*, the inhibitory nature of CSPGs has been attributed both to the core protein and to associated chondroitin sulfate side chains [26]. *In vivo* studies have shown that, after CNS injuries, various CSGPs that are normally expressed on immature glial cells are re-expressed in the glial scar. These include NG2, neurocan, brevican, versican, aggrecan and phosphacan. Degradation of associated chondroitin sulfates after spinal cord injury partially enhanced axonal growth and functional recovery, indicating that reduction in selective scar components can increase regenerative growth in the adult CNS [27]. Furthermore, CSGPs appear to have a role in regulating visual cortical synaptic plasticity. After CSPG degradation in adult rats, monocular deprivation caused an ocular dominance shift toward the nondeprived eye, indicating that the mature ECM is inhibitory for experience-dependent plasticity [28].

Astrocytes play a key role in scar formation in experiments with double knockout mice deficient in vimentin and GFAP and subjected to lateral hemisection of the thoracic spinal cord, axonal sprouting of the corticospinal tract and raphe-spinal pathways was observed and correlated with hindlimb functional recovery on a grid walk test [29]. However, the role of reactive astrocytes in CNS injury is not completely understood. Another study involving adult transgenic mice with selective and conditionally targeted gene deletions has shown that reactive astrocytes actually protected tissue and preserved function after spinal cord injury [30]. This protection was attributed to the action of reactive astrocytes in blood brain barrier repair and restriction of the inflammatory response. Presently, one is left with the conclusion that inflammation, including the role of astrocytes in CNS injury, is a complex and inadequately understood area warranting further study. In particular, a main problem is to overcome the inhibitory environment of the glial scar, without compromising the positive effects of glial cells.

Neurotrophic factors promote both cell survival and axon growth after adult central nervous system injury *in vivo*. Neurotrophic factors comprise several complex families of molecules that support axonal regrowth and neuronal survival in the adult CNS (see detailed discussion in Ch. 27). These molecules include the nerve growth factor (NGF) superfamily (NGF, brain-derived neurotrophic factor (BDNF), neurotrophin (NT)-3, neurotrophin (NT)-4/5), the neurokine or ciliary neurotrophic factor (CNTF) family, the glial-derived neurotrophic factor (GDNF) family and factors such as the bone morphogenetic proteins (BMPs) the IGFs and FGFs, with multiple roles including neurotrophic functions. The trk family of receptor tryrosine kinases is the high-affinity, signal-transducing receptor for the NGF family, with NGF the primary ligand for TrkA, BDNF and NT-4/5 for TrkB, and NT-3 for TrkC. In experiments using neurotrophins to study regenerative properties of adult rubrospinal neurons, Tetzlaff and colleagues found that the application of BDNF or NT-4/5 (but not NGF or NT-3) prevented the atrophy of axotomized rubrospinal neurons, stimulated the expression of GAP-43 and Tα1-tubulin in these neurons, and promoted the regeneration of axotomized neurons into grafts of peripheral nerves implanted into spinal cord lesions [31]. Interestingly, the treatment was most effective when neurotrophic factors were applied in the vicinity of the cell bodies themselves and not at the spinal cord injury site, except for NT-3, which stimulated corticospinal tract regenerative sprouting if applied to the injury site [32]. Surprisingly, it was found that even when animals were treated up to 1 year after axotomy, local infusion of BDNF was still capable of rescuing these axotomized neurons and of stimulating them to regenerate into peripheral nerve implants [33]. These exciting results indicate that the regenerative capabilities of adult CNS neurons are not necessarily lost even after long-standing chronic injury.

Other ways to use neurotrophins in CNS repair paradigms are to combine them with growth-promoting cells or bridging materials or to transplant into lesion sites cells that are genetically engineered to produce specific neurotrophins. In one example, engineered Schwann cells that expressed BDNF were used to stimulate growth of supraspinal axons across the transected adult rat spinal cord. A polymer channel was placed in between the two stumps, and engineered Schwann cells expressing BDNF were seeded into the channel. Although BDNF did provide increased selection for TrkB-expressing axons, neurites did not leave the substrate of the guidance channel, once again demonstrating the importance of a permissive environment in order to achieve long-distance functional regeneration [34].

Despite the extensive use of neurotrophins to induce adult axonal regrowth and neuronal plasticity, results have been mixed, and many challenges remain. Neurotrophins have roles in the CNS that go beyond cell survival and neurite outgrowth and include such diverse and basic activities as modulation of membrane excitability, regulation of cell differentiation and intracellular molecular trafficking. A better understanding of the role of neurotrophins in cellular regulation and control would augment their use as important therapeutic agents in the repair of CNS injury.

CENTRAL NERVOUS SYSTEM INJURY AND COMPENSATORY PLASTICITY

Neonatal brain damage results in compensatory plasticity. Although, without intervention, axonal growth in the injured adult CNS is limited, the immature CNS responds to injury with a remarkable rerouting of neuronal pathways from undamaged areas to re-innervate

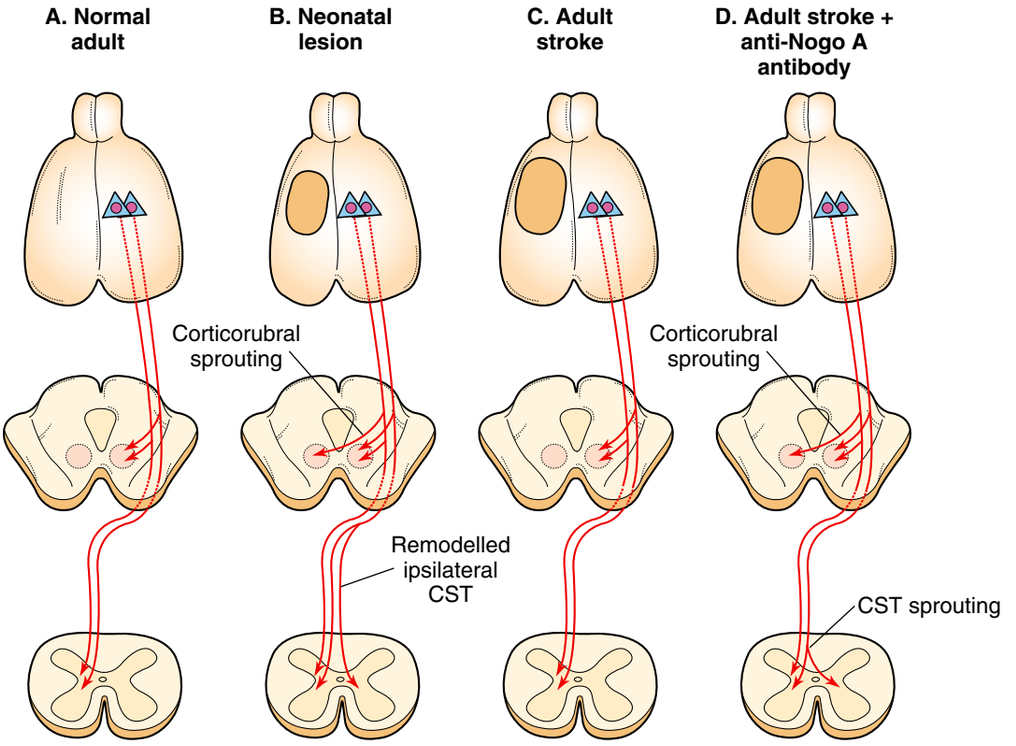

FIGURE 30-6 Diagram depicting cortico-efferent projections from the rodent motor cortex to subcortical areas including the red nucleus and the spinal cord. In the normal adult (**A**), cortical neurons project to the ipsilateral red nucleus and the contralateral spinal cord gray column. After a neonatal cortical lesion (**B**), cortico-efferent fibers spontaneously sprout to the contralateral, denervated red nucleus and the ipsilateral, denervated spinal cord (gray). After an adult stroke lesion (**C**), there is very little spontaneous sprouting seen. However, after adult stroke and treatment with anti-Nogo-A antibody (**D**), plasticity to the denervated red nucleus and spinal cord is again seen, correlating with functional recovery. CST, corticospinal tract

denervated areas. This is called *structural compensatory plasticity*. This lesion-induced plasticity following perinatal brain damage occurs in all systems studied, including the visual, auditory, sensorimotor and limbic systems. For example, following lesion to the motor cortex of 2-day old rat pups, the motor cortex from the opposite, unlesioned hemisphere reroutes corticoefferent connections to bilaterally innervate subcortical areas including the striatum, thalamus, red nucleus, basilar pontine nuclei and spinal cord (see [35] for review, and Fig. 30-6). This new pathway formation is thought to underlie the better functional outcome often seen after neonatal brain injury as compared to the same injuries sustained in adulthood [36]. Therefore, ways to enhance structural plasticity after adult CNS lesions would greatly improve functional recovery and thereby quality of life.

Compensatory plasticity and functional recovery can be enhanced in the injured adult central nervous system through blockade of Nogo-A. Interestingly, some of the same molecules that restrict regeneration in the adult CNS, e.g. Nogo-A, are also responsible for shaping adult lesion-induced neuronal plasticity. In a series of experiments, adult rats were subjected to unilateral ischemic brain damage through middle cerebral artery occlusion and given antibodies to block Nogo-A. A dramatic recovery in skilled forelimb use was seen that correlated with new corticoefferent plasticity from the unlesioned sensorimotor cortex to subcortical motor areas such as the red nucleus and the spinal cord [37, 38] (Fig. 30-6). Furthermore, electrophysiological mapping studies of the opposite, unlesioned hemisphere showed a functional reorganization of the motor map, with new areas of the motor cortex now innervating the previously impaired forelimb [39]. The specificity of these new pathways indicates that developmental mechanisms of neuronal target recognition and synapse specification probably persist throughout life, thus assuring that under conditions of enhanced axonal plasticity and regeneration, functional networks can be formed [40, 41].

These findings of enhanced axonal plasticity and functional recovery after stroke and anti-Nogo-A therapy have now been extended to the aged rat. 24-month-old rats were trained on a reaching task and given anti-Nogo-A antibody treatment via intraventricular pump 1 week after experimental stroke. These old animals showed dramatic returns in skilled forelimb function with this therapy, indicating that even the aged CNS retains the proper molecular cues to allow for neuronal plasticity and functional recovery given the proper conditions.

Another important aspect of this study was that the time window for starting the treatment was extended to 1 week after stroke, demonstrating that anti-Nogo therapy is effective even beyond the time of acute brain damage. These findings open the possibility of treatment options for those suffering from chronic brain or spinal cord injuries.

Even in the case of spinal cord injury where application of anti-Nogo antibodies results in regeneration of the cut axons, an additional important element for functional recovery is enhanced fiber growth from the unlesioned fibers, i.e. compensatory plasticity, as discussed above. After high corticospinal tract injury in the rat at the level of the medullary pyramid and treatment with anti-Nogo antibodies, rubrospinal pathways were shown to sprout into deafferented areas of the spinal cord, resulting in high levels of functional recovery, i.e. a 'functional switch' in the remodeled pathway [42].

Furthermore, various studies suggest that neutralizing Nogo antibodies can induce a transient growth response in the intact adult CNS [40]. Interestingly, while Purkinje cells of the cerebellum do not upregulate GAP-43 at all after axotomy, increased expression of GAP-43 as well as regeneration is seen after application of anti-Nogo antibodies to the intact cerebellum [43].

SUMMARY AND CONCLUSIONS

Research over the past 20 years has shown that the adult mammalian CNS is not a static structure and, in fact, under certain conditions retains a high capacity for at least short-distance axonal growth. Such growth results in structural remodeling of new neural pathways from intact neurons or, under appropriate experimental or therapeutic conditions, regeneration from the cut ends of injured axons. These processes are correlated with a high degree of functional recovery in animal models of CNS injury. A better understanding of the complex molecular and cellular mechanisms underlying regeneration and plasticity is currently unfolding, and future studies are aimed at turning these basic science concepts into therapeutic tools to improve functional outcome and quality of life in patients with brain, spinal cord or peripheral nerve injury.

INTRODUCTION 532
Processes related to signaling require the largest proportion of brain energy utilization but considerable energy is also used to maintain basic cellular functions 532
Metabolism in brain is compartmentalized 532

SUBSTRATES FOR CEREBRAL ENERGY METABOLISM 533
Energy-yielding substrates enter the brain from the blood through the blood–brain barrier 533
Endothelial cells of the blood–brain barrier and brain cells have specific transporters for the uptake of glucose and monocarboxylic acids 533
The uptake of energy substrates by brain cells is influenced by the type and distribution of transporters unique to each cell type 533
The transporters of the blood–brain barrier can be altered under pathological conditions 534

AGE AND DEVELOPMENT INFLUENCE CEREBRAL ENERGY METABOLISM 535
The rate and pathways of metabolism change during development 535
Cerebral metabolic rate increases during early development 535
Cerebral metabolic rate declines from developmental levels and plateaus after maturation 535

REGULATION OF THE CEREBRAL METABOLIC RATE 536
Both excitatory and inhibitory neuronal signals utilize energy derived from metabolism 536
Continuous cerebral circulation is required to sustain brain function 536
The oxygen concentration in cerebral venous blood is substantially lower than in the cerebral arterial blood because of the high oxygen extraction 536
Glucose is the main obligatory substrate for energy metabolism 536

METABOLISM IN THE BRAIN IS HIGHLY COMPARTMENTALIZED 537
Glucose has numerous metabolic fates in brain 537

GLYCOGEN IS ACTIVELY SYNTHESIZED AND DEGRADED IN BRAIN, PROVIDING A DYNAMIC SOURCE OF CARBOHYDRATE 538
The steady-state concentration of glycogen is regulated precisely by the coordination of separate synthetic and degradative enzymatic processes 538
Hormones and neuronal activity affect brain glycogen metabolism 538

GLYCOLYSIS: CONVERSION OF GLUCOSE TO PYRUVATE OR LACTATE 538
Brain hexokinase is inhibited by its product glucose-6-phosphate and to a lesser extent by adenosine diphosphate 539
Brain glycolysis is regulated mainly by phosphofructokinase 540
The glycolytic pathway in brain involves a number of enzymatic reactions that are similar in neurons and glia and similar to those in other tissues 540

THE PENTOSE PHOSPHATE SHUNT IS ACTIVE IN BRAIN 540

GLYCEROL PHOSPHATE DEHYDROGENASE IS AN NADH OXIDIZING ENZYME RELATED TO GLYCOLYSIS 541

THE MALATE–ASPARTATE SHUTTLE HAS A KEY ROLE IN BRAIN METABOLISM 541
The malate–aspartate shuttle is the most important pathway for transferring reducing equivalents from the cytosol to the mitochondria in brain 541
The malate–aspartate shuttle has a role in linking metabolic pathways in brain 542

THERE IS DYNAMIC METABOLISM OF LACTATE IN BRAIN 542
Lactate is formed under both aerobic and anaerobic conditions in brain 542
Compartmentation of the pyruvate–lactate pool is unexpectedly complex 542
The astrocyte–neuron lactate shuttle hypothesis is controversial 542

THE COMPLETE OXIDATION OF GLUCOSE REQUIRES TRICARBOXYLIC ACID (TCA) CYCLE ACTIVITY 543
The pyruvate dehydrogenase complex plays a key role in regulating oxidation of glucose 543

Basic Neurochemistry: Molecular, Cellular and Medical Aspects
0-12-088397-X

Acetyl coenzyme A formed from glucose is the precursor for acetylcholine 543
Pyruvate carboxylation in astrocytes is the major anaplerotic pathway in brain 544

ENERGY OUTPUT AND OXYGEN CONSUMPTION ARE ASSOCIATED WITH TCA CYCLE ACTIVITY 544
The actual flux through the TCA cycle depends on glycolysis and acetyl coenzyme A production 544
Succinate dehydrogenase is the enzyme that catalyzes the oxidation of succinate to fumarate and is also part of the respiratory chain 544
Malate dehydrogenase is one of several enzymes in the TCA cycle present in both the cytoplasm and mitochondria 544
Citrate is a multifunctional compound predominantly synthesized and released by astrocytes 544

MANY TCA CYCLE ENZYMES AND COMPONENTS OF OXIDATIVE PHOSPHORYLATION ARE DIFFERENTIALLY DISTRIBUTED IN NEURONAL AND GLIAL MITOCHONDRIA 545
Mitochondria are distributed with varying densities throughout the central nervous system with the more vascular parts containing most of the mitochondria 545
Mitochondrial heterogeneity leads to multiple simultaneous TCA cycles in astrocytes and neurons 546
Partial TCA cycles can provide energy in brain 546
Adenosine triphosphate production in brain is highly regulated 546
Phosphocreatine has a role in maintaining adenosine triphosphate levels in brain 546
Substrates other than glucose provide energy for brain cells (e.g. glutamate, glutamine, lactate, fatty acids, ketone bodies) 546

GLUTAMATE/GLUTAMINE METABOLISM IS LINKED TO ENERGY METABOLISM 547
Glutamate enters the mitochondria via the aspartate–glutamate carrier or the glutamate carrier 547
Glutamate and glutamine metabolism is compartmentalized in brain 548
A specialized glutamate–glutamine cycle operates in GABAergic neurons and surrounding astrocytes 549
Several shuttles act to transfer nitrogen in brain 549

HOW COMPARTMENTALIZED BRAIN METABOLISM IS STUDIED 549
Since the brain utilizes energy almost exclusively from oxidative metabolism of glucose, brain metabolism has been studied by focusing on net oxygen and glucose uptake 549
Carbon-13 nuclear magnetic resonance spectroscopy is a powerful method for studying brain metabolism 550
Cultured neurons and astrocytes are useful for studying subcellular compartmentation and identifying pathways of metabolism 551
Preparations such as brain slices, axons, synaptosomes and isolated mitochondria are tools for studying specific aspects of metabolism 551
In vivo nuclear magnetic resonance spectroscopy provides information about the regulation of metabolism in the intact brain 551

RELATION OF ENERGY METABOLISM TO PATHOLOGICAL CONDITIONS IN THE BRAIN 552

INTRODUCTION

The human brain is an 'expensive' organ in terms of energy usage since it accounts for only ≈2% of the body weight, yet the energy required to maintain brain function amounts to ≈20% of an individual's resting metabolic rate [1 and references therein]. In tissues such as heart and skeletal muscle, energy use increases greatly during mechanical work. Metabolic activity in brain varies much less than in tissues that do mechanical work. This is explained by the fact that the resting state typically requires considerable energy for maintaining membrane potentials. As a comparison, the ATP consumption per gram per minute used for signaling in the brain is equal to the energy used by a human leg muscle running a marathon or the osmotic work in the kidney [1 and references therein, 2].

Processes related to signaling require the largest proportion of brain energy utilization but considerable energy is also used to maintain basic cellular functions. Approximately 75% of the energy consumed by brain is related to signaling, while the remaining 25% of energy utilization serves to maintain essential nonsignaling cellular activity including protein synthesis and degradation, nucleotide turnover, phospholipid turnover, axoplasmic transport and mitochondrial proton leak [1] (Table 31-1). The overall energy use by human brain is estimated to be 21 μmol ATP/g/min. Metabolic rates are considerably higher in gray matter (rate in rat neocortex is ≈33–55 μmol ATP/g/min) than in white matter as measured in either rat or human brain (Table 31-2).

Metabolism in brain is compartmentalized. The brain contains two major classes of cells: neurons, which include a large number of phenotypes reflecting the many different properties of structure and function found among neurons, and glia, which include astrocytes, oligodendroglia and microglia (see Ch. 1). The proportion of energy used by glial cells is unclear with estimates ranging from about 17.5% (recalculated from [1]) to as high as 40% of oxidative metabolism [9]. *In vivo* studies suggest that glia utilize from ≈14% of brain metabolism [10] to as much as 30% of total tricarboxylic acid (TCA) cycle activity [11]. Some processes with high energy cost, such as

phospholipid turnover and maintenance of phospholipid polarization in membranes, are likely to be higher in glia than in neurons. Most of the biochemical pathways of energy metabolism in the brain are similar to those in other tissues. However, there is compartmentation of metabolism due to the highly specialized cellular and subcellular localization of transporters, enzymes and metabolic pathways that makes brain cells specialized to perform specific functions and also uniquely interdependent. Metabolic compartmentation is defined as the presence in a tissue of more than one distinct pool of a given metabolite. These separate pools of a metabolite are not in rapid equilibrium with each other but maintain their own integrity and turnover rates [12]. Compartmentation makes metabolism in the brain complex and the continuous interactions of neurons and glial cells essential for brain function [13].

SUBSTRATES FOR CEREBRAL ENERGY METABOLISM

Energy-yielding substrates enter the brain from the blood through the blood–brain barrier. The brain requires a continuous supply of oxygen and energy-yielding substrate(s). Glucose is essential for developing brain and is the most important energy-yielding substrate used by adult brain. The rates of glucose transport and utilization are lower in developing brain and increase with maturity [14–16]. Monocarboxylic acids, including lactate and the ketone bodies acetoacetate and β-hydroxybutyrate, are also important energy-yielding substrates. These compounds are also incorporated into lipids, amino acids and proteins in developing brain [17, 18]. Lactate appears to have a special role as a readily available source of energy during the immediate postnatal period [19]. The ketone bodies are essential substrates for brain metabolism throughout the suckling period, which is consistent with the high concentration of fat in the milk of humans and other mammals [16]. In conjunction with the importance of monocarboxylic acids for developing brain, the rates of transport of these substrates from the circulating blood through the blood–brain barrier and into brain are high in animals and humans during the suckling period, when the activity of enzymes for oxidative use of glucose are low, and decline with maturity as glucose metabolism increases [16].

Endothelial cells of the blood–brain barrier and brain cells have specific transporters for the uptake of glucose and monocarboxylic acids. Substrates used by the brain are taken up from the circulation via transporters in the endothelial cells that form the blood–brain barrier (see also discussion of facilitated transport in Ch. 5). The main energy nutrient transporters in the blood–brain barrier are the highly glycosylated 55 kDa form of the glucose transporter GLUT1 and the monocarboxylic acid transporter MCT1 (Fig. 31-1). Other isoforms of these transporters are discussed below. High amounts of MCT1 and GLUT1 and low levels of MCT2 are present in the blood–brain barrier of developing brain [16, 20]. The intense labeling of MCT1 protein in brain microvasculature during the suckling period declines significantly after 14 days of age in rat brain, coincidentally with a dramatic increase in GLUT1 content and with the switch to glucose as the predominant fuel entering brain [16]. The change in substrate use during development is related to the availability of circulating substrates as well as to the developmental changes in the transport properties of the blood–brain barrier (see detailed review by Vannucci and Simpson [16]).

The uptake of energy substrates by brain cells is influenced by the type and distribution of transporters unique to each cell type. The selective distribution of the individual isoforms of transporter molecules contributes to the regulation of overall substrate use in individual types of brain cells and in brain (Fig. 31-1). Although astrocyte end feet cover ≈96% of the blood–brain barrier, experimental results suggest that approximately equal proportions of glucose are taken up by neurons and glia in brain [21]. The 45 kDa form of glucose transporter GLUT1 is found on astrocytes and the choroid plexus [15]. The high-capacity glucose transporter GLUT3 is found only on neurons [14, 15], and GLUT5 is localized primarily on microglia [22]. The levels of both GLUT1 and GLUT3 increase dramatically with cerebral maturation and synaptogenesis. GLUT3 is relatively low in nonvascular portions of rat brain at 7 days of age, then increases almost linearly about 10-fold by 28 days of age [15, 16]. The increase in GLUT1 occurs at

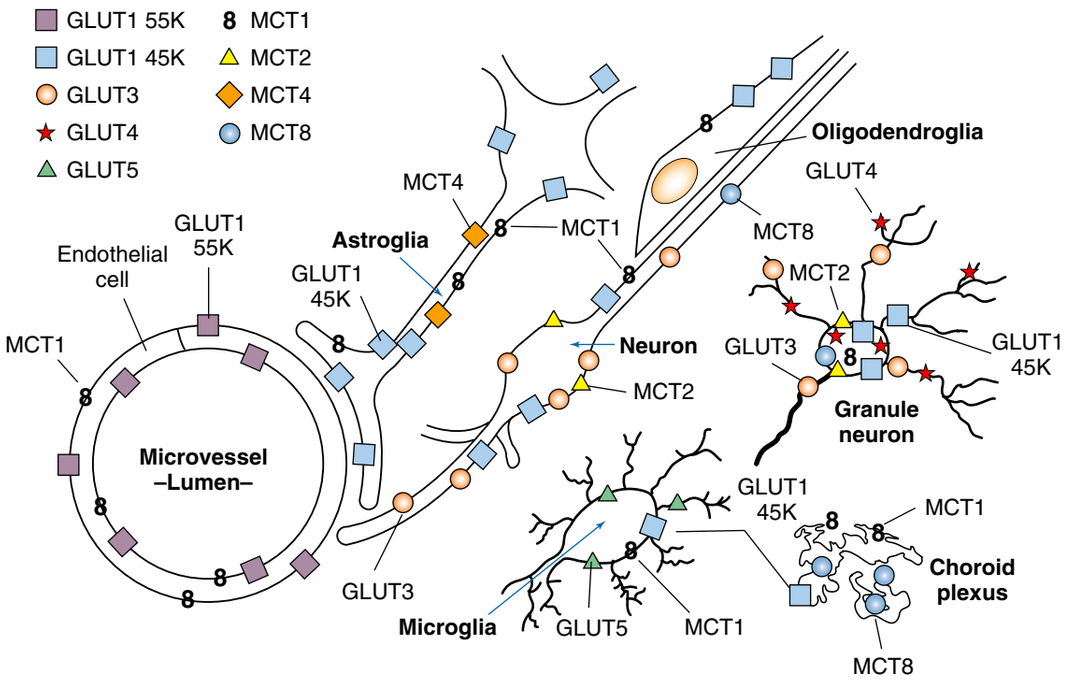

FIGURE 31-1 Glucose and monocarboxylic acid transporters in brain. Specific glucose and monocarboxylic acid transporters in brain are localized on different types of brain cells. (Courtesy of Ian Simpson and Susan Vannucci.)

a slightly later age; levels remain low in nonvascular portions of rat brain until 14 days of age, then increase severalfold until 28–35 days of age [16]. Although the distribution and properties of different transporters give insight into the potential capabilities of brain cells to take up specific substrates, there is still uncertainty about the proportions of glucose actually taken up and metabolized by astrocytes and neurons. Label from infused glucose rapidly appears in glutamate in brain [23] and later in glutamine (see below). These findings illustrate the importance of the high capacity transporter GLUT3 in providing glucose to neurons.

Reports on the distribution of MCT transporters in brain cells are somewhat conflicting, in part as a result of differences between data from *in vivo* studies and data obtained from studies with cultured brain cells, differences in mRNA expression and the contents of transporter proteins, and differences among species [16, 24, 25]. There is evidence that both MCT1 and MCT2 are found in all types of brain cells in developing brain, which is consistent with the importance of monocarboxylic acids as substrates at early ages [16, 20, 26]. MCT1 is localized on the blood–brain barrier and on astrocytes of mature brain, but is not found on all astrocytes *in vivo* [16, 26]. Kinetic studies suggest the possibility of a lower-affinity astrocytic MCT transporter [27], which would be consistent with the identification of MCT4 on some glial cells [28, 29]. The higher-affinity monocarboxylate transporter MCT2 is localized primarily on neurons in mature brain [24, 29–32]. Kinetic properties for lactate transport by neuronal preparations isolated from brain are not totally consistent with the properties of MCT2, suggesting the possible presence of another neuronal MCT transporter [32, 33]. While eight different members of the proton-coupled MCT transporter family have been identified, only the MCT1–4 transporters have been characterized in detail thus far. Although the staining for MCT in brain slices appears more diffuse with maturation, the level of MCT1 in the nonvascular tissue remains fairly constant, and the level of MCT2 transporter protein in neurons increases with development [16].

The transporters of the blood–brain barrier can be altered under pathological conditions. The uptake of glucose and amount of GLUT1 on the blood–brain barrier can both be increased by hypoglycemia [34–36]. There are controversial reports about the effects of chronic hyperglycemia and diabetes mellitus, with some studies showing decreased glucose uptake and others reporting no difference (for review see [37]). A rat model of diabetes mellitus showed no alterations in glucose transport or blood–brain barrier GLUT1 protein content compared to controls, yet there was significantly increased GLUT1 gene expression in the blood–brain barrier of the diabetic rats [34]. MCT1 on the blood–brain barrier may be upregulated by a ketogenic diet and in other conditions with high levels of circulating monocarboxylic acids, such as in diabetes mellitus and cancer [38].

AGE AND DEVELOPMENT INFLUENCE CEREBRAL ENERGY METABOLISM

The rate and pathways of metabolism change during development. The energy metabolism of the brain and the blood flow that sustains the metabolic rate vary considerably from birth to old age. Data on the cerebral metabolic rate in human infants during the early postnatal period have been published [39], and are consistent with results of *in vitro* measurements in animal brain preparations and inferences drawn from cerebral blood flow measurements in intact animals [2]. Such studies suggest that cerebral oxygen consumption is low at birth, rises rapidly during the period of cerebral growth and development and reaches a maximal level at about the time maturation is completed. Significant utilization of ketone bodies by the brain is normal in the neonatal period [16–18, 40]. The newborn infant tends to be hypoglycemic but becomes ketotic when it begins to nurse because of the high fat content of the mother's milk. During the suckling period the brain is highly dependent on the use of ketone bodies for energy since the activities of the enzymes for utilization of these substrates are high, whereas activities of pyruvate dehydrogenase and of some oxidative enzymes are lower [41].

The first two enzymes in the pathway of ketone utilization are D-β-hydroxybutyrate dehydrogenase and acetoacetyl-succinyl-CoA transferase. These exhibit a postnatal pattern of development that is well adapted to the nutritional demands of the brain [41]. At birth, the activities of these enzymes in the brain are low; activities rise rapidly with the ketosis that develops at the onset of suckling. The activities reach their peaks just before weaning and then gradually decline after weaning to normal adult rates of approximately one-third to one-fourth the maximal rates attained at the earlier stages [18, 41]. Ketone bodies are used for energy and are incorporated into the lipids and proteins formed in the rapidly developing brain [17, 41]. When weaned onto the normal, relatively high-carbohydrate diet, the ketosis disappears and cerebral ketone utilization decreases considerably. Studies have been carried out mainly in the newborn rat, but there is evidence that the situation is similar in the human infant [42]. The reports of ketoacidosis and developmental delay in infants with impaired ability to utilize ketone bodies underscore the importance of these substrates during the suckling period [43].

Cerebral metabolic rate increases during early development. Glucose is an essential substrate for developing brain [16, 40]. When ketone bodies and lactate are utilized primarily for energy, the requirement for glucose may reflect metabolism via the pentose phosphate shunt for formation of ribose-5-phosphate as well as production of the NADPH required for lipid biosynthesis. In general, the whole brain local glucose utilization is very significantly correlated with postconceptional age [39, 44]. In the brain of suckling rat, even during intense use of ketone bodies, the postnatal increases in local glucose use appear to be critically linked to the acquisition of new functions and neurological competence [40]. This may also be true for neonatal human brain since local increases in the glucose metabolic rate reflect the functional maturation of these regions [44]. The overall rise in oxidative glucose use is associated with the developmental switch in transporters on the blood–brain barrier. These changes are also consistent with the progressive increases in the levels of a number of enzymes of oxidative metabolism in the brain, and with the increase in the activity of enzymes associated with the malate–aspartate shuttle [2, 16]. The increased use of glucose for energy as the brain matures is accompanied by increased oxidation of glycolytically derived pyruvate via the TCA cycle.

The rate of blood flow in different structures of the brain reaches peak levels at different developmental stages, depending on the maturation rate of the particular structure. In structures that consist predominantly of white matter, the peaks coincide roughly with maximal rates of myelination. From these peaks, blood flow and, probably, cerebral metabolic rate decline to the levels characteristic of adulthood [2, 39, 44].

Cerebral metabolic rate declines from developmental levels and plateaus after maturation. Reliable quantitative data on the changes in cerebral circulation and metabolism in humans from the middle of the first decade of life to old age have been reported [2, 39, 44]. By 6 years of age, cerebral blood flow and oxygen consumption already have attained high rates, and they decline thereafter to the rates of normal young adulthood [45]. Oxygen is utilized in the brain almost entirely for the oxidation of carbohydrates [46]. The equation for the complete oxidation of glucose is:

$$C_6H_{12}O_6 + 6\,O_2 \rightarrow 6\,CO_2 + 6\,H_2O$$

A respiratory quotient (CO_2 production/O_2 consumption) of 0.97 for brain indicates that it depends almost exclusively on carbohydrate oxidation. The consumption of O_2 provides the energy required for intense activity. Cerebral oxygen consumption of 5.2 ml/100 g brain tissue/min in a 5–6-year-old child corresponds to total oxygen consumption by the brain of ≈60 ml/min, or more than 50% of the total body basal oxygen consumption, a proportion markedly greater than that occurring in adulthood. The reasons for the extraordinarily high cerebral metabolic rates in children are unknown, but presumably they reflect the extra energy requirements for the biosynthetic processes associated with growth and development. By early adulthood the rate of cerebral oxygen consumption has decreased to 3.5 ml/100 g brain tissue/min, a rate that is subject to minimal decline in normal elderly brain [2]. Calculated in other terms, the total cerebral metabolic rate in adults is approximately 20 W, or 0.25 kcal/min,

equal to 20% of the whole body metabolism under most conditions (Table 31-2). Even during sleep there is only a relatively small decrease in cerebral metabolic rate; indeed, it may even be increased in rapid eye movement (REM) sleep [2].

REGULATION OF THE CEREBRAL METABOLIC RATE

Both excitatory and inhibitory neuronal signals utilize energy derived from metabolism. As mentioned above, the greatest proportion of energy utilization by brain serves signaling-related processes (Table 31-1). Brain function represents balances between excitatory and inhibitory neuronal signaling integrated with respect to time and location within the brain. Both excitatory and inhibitory signaling depends on transmembrane electrical potentials, which in turn are maintained or restored by energy-dependent ion transport (see Chs 5 and 6). The continual signaling is reflected in the persistent electrochemical activity of the brain. Thus, brain energy metabolism and the flow of energy-yielding substrates via the cerebral blood flow are linked to or regulated by brain function and, in fact, are used as measures of regional brain function (see Ch. 58). The process or processes by which this regulation is achieved is a subject of current research. The regional regulation of cerebral blood flow may be via chemical signals that affect the cerebral vasculature.

Continuous cerebral circulation is required to sustain brain function. Not only does the brain utilize O_2 at a very rapid rate, but the brain is absolutely dependent on uninterrupted oxidative metabolism for maintenance of its functional and structural integrity. Even at its maximal rate, anaerobic glycolysis can provide only a small portion of the required energy. Since the amount of O_2 stored in brain is extremely small compared with its rate of utilization, the brain requires a continuous supply of O_2 from the circulation, and brief disruptions in this supply have an immediate effect on brain function and consciousness.

The oxygen concentration in cerebral venous blood is substantially lower than in the cerebral arterial blood because of the high oxygen extraction. Whereas the glucose extraction is 10%, that for oxygen is 50–70% [47]. Thus, glucose delivery to the neural tissue can be elevated by solely increasing the extraction ratio without change in the blood flow, but for oxygen there is less extraction reserve and blood flow increase is needed [47]. During brain activation, venous oxygen content falls due to a mismatch between increases in cerebral blood flow and oxygen metabolism [48], resulting in decreased tissue deoxyhemoglobin content [49]. Because oxygen reaches the brain cells purely by diffusion and because there are no intracellular oxygen stores in the brain (in contrast to the myoglobin that stores oxygen in muscle), the net consumption of oxygen, defined as the cerebral metabolic rate of oxygen ($CMRO_2$), is reflected in the oxygen concentration gradient across the blood–brain barrier. The precise mechanism by which increased electrical activity, and thus increased metabolism, triggers these massive increases in cerebral blood flow is not totally understood.

In contrast to oxygen, which can freely diffuse across cell membranes, glucose is transported across the blood–brain barrier by facilitated diffusion (see above and Ch. 5). Net uptake of glucose by brain, defined as the cerebral metabolic rate of glucose (CMR_{glc}), is largely independent of the plasma glucose concentration [50]. The brain, like the liver but in contrast to muscle, has a significant tissue glucose concentration (≈1–2 mmol/l) that is about three-fold lower than in blood, and the brain has a high physical distribution space for glucose [51, 52]. Glucose transport is not likely to play a major role in regulating cerebral glucose utilization under physiologic conditions, since at normoglycemia the average intracellular concentration of glucose is well above 0.05 mM, the K_m of hexokinase (see below).

Glucose is the main obligatory substrate for energy metabolism. Brain glucose metabolism exhibits large regional variations at rest (consider, for example, the difference between gray and white matter) and is profoundly affected by local brain activation [8], suggesting a strong link between energy metabolism and brain function (Table 31-2). (See Brain Imaging in Ch. 58 for detailed discussion.) It is of interest that brain glucose concentration appears to be very constant across brain regions, despite strong metabolic differences between white and gray matter and among different brain nuclei. Cerebral blood volume and blood flow, however, differ with respect to the brain region, consistent with differences in regional resting metabolic activity [53]. However, brain glucose concentrations can change acutely, consistent with the facilitative nature of glucose transport, and are higher when metabolism is reduced (e.g. under barbiturate anesthesia). Brain glucose can become rate-limiting to metabolism, e.g. during profound activation, seizures and hypoglycemia. When the intracellular concentration of glucose approaches the K_m of hexokinase, significant facilitated transport of glucose into brain still occurs *in vivo* but cerebral blood flow (CBF) is acutely increased [54], possibly regulated by adenosine and K^+-ATP channels [55]. Glycogen, which is present at only low levels in brain, is the only fuel store endogenous to the brain that can provide significant amounts of energy (in the form of glucosyl equivalents) in periods during which the supply of glucose does not meet the metabolic demand (see below).

In addition, the brain can make limited use of other substrates for metabolism, e.g. during fasting (see above). Under normal circumstances, the venous lactate concentration is slightly higher than the arterial concentration,

suggesting a small net lactate output from the brain. Increased plasma lactate concentrations have recently been reported to lead to a reduced brain glucose metabolic rate, suggesting that the adult human brain can use lactate as a fuel (see below). Despite the ability of the brain to use other fuels, glucose remains the main obligatory substrate for energy metabolism.

METABOLISM IN THE BRAIN IS HIGHLY COMPARTMENTALIZED

Over the past few decades it has become quite clear that the metabolism of neurons and glial cells is interrelated and that these cells function in an integrated fashion. In this context it must be noted that several important enzymes, e.g. pyruvate carboxylase and glutamine synthetase, are found only in astrocytes [56, 57] (Table 31-3). Moreover, transporters for glucose, monocarboxylic acids, glutamate and glutamine are differentially distributed on brain neural and glial cells (see above and Chs 5 and 15). The compartmentation of transporters and enzymes leads to metabolic specialization of brain cells that leads in turn to the requirement for intercellular trafficking of metabolites.

One result of the selective localization of brain enzymes is that astrocytes must provide certain substrates (e.g. glutamine) to neurons for replenishment of the neuronal TCA cycle and for neurotransmitter synthesis [58]. Thus, astrocytes and neurons are essential partners in brain function. See also discussion in Chapter 15.

Glucose has numerous metabolic fates in brain. It is crucial to remember that brain glucose does not function solely as an energy substrate but fulfills many roles, including that of a substrate for inositol biosynthesis and glycogen formation (Fig. 31-2). Moreover, its carbon skeleton may be incorporated into acetylcholine, lactate, glutamate, glutamine, aspartate, GABA and alanine. In developing brain, metabolism via the pentose phosphate shunt (PPS) is particularly important to provide ribose-5-phosphate for nucleotide synthesis and the NADPH required for lipid biosynthesis. The carbon skeleton of glucose is also incorporated into lipids [59].

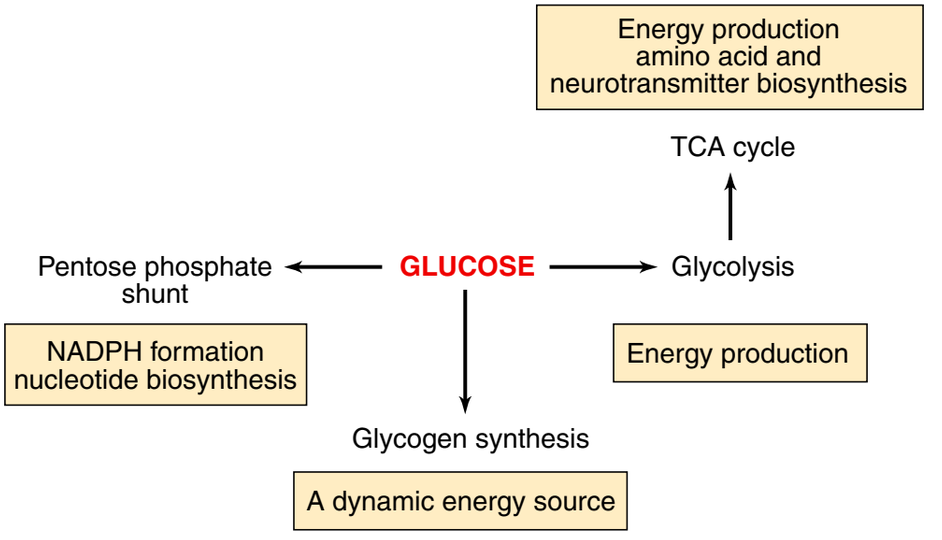

FIGURE 31-2 Glucose has multiple metabolic fates. Glucose is the main substrate for energy production via glycolysis and TCA cycle metabolism. Furthermore, glucose metabolism is closely connected to amino acid and neurotransmitter biosynthesis via TCA cycle intermediates. Glucose is the main precursor for glycogen synthesis. Metabolism of glucose via the pentose phosphate shunt provides ribose-5-phosphate for synthesis of nucleotides and NADPH for lipid biosynthesis and maintenance of reduced glutathione.

GLYCOGEN IS ACTIVELY SYNTHESIZED AND DEGRADED IN BRAIN, PROVIDING A DYNAMIC SOURCE OF CARBOHYDRATE

Compared to liver and muscle, glycogen is normally present in a relatively low concentration in brain, 2–6 μmol glucosyl units per gram wet weight for brain [60], compared to 100–500 μmol/g for liver [61]. However, concentrations as high as 8–12 μmol/g have been reported for rat brain [62]. Yet the brain glycogen concentration normally exceeds that of free brain glucose and glycogen is the only significant energy reserve in brain. The role of glycogen as a significant, endogenous store of fuel has been discounted in brain because of its low concentration compared to the total brain glucose utilization rate (Table 31-2). Indeed, if glycogen were the only source of fuel, it would be utilized in a few minutes. However, glycogen content is not rapidly depleted during hypoglycemia, as it needs to supply only a fraction of total glucose requirement, since glucose continues to be transported across the blood–brain barrier even in hypoglycemia [63].

Glycogen is a unique energy reserve that requires no energy (ATP) for mobilization (with the exception of the ATP required to convert phosphorylase b to phosphorylase a). The evidence that rapid, continual breakdown and synthesis of glycogen occurs at a rate of about 2% of the normal cerebral metabolic rate of glucose in brain [63] and is subject to elaborate control mechanisms suggests that local carbohydrate reserves in the form of glycogen are important for normal brain function. An accepted role of glycogen is that of a carbohydrate reserve utilized when glucose falls below need, yet its precise role remains to be determined.

The steady-state concentration of glycogen is regulated precisely by the coordination of separate synthetic and degradative enzymatic processes. The enzymatic regulation exists at several metabolic steps [2]. The amount of glucose-6-phosphate (Glc-6-P), the initial substrate for glycogen synthesis, usually varies inversely with the rate of brain glycolysis. Thus, a decline in Glc-6-P during energy need slows glycogen formation. The enzymes involved in brain glycogen synthesis and metabolism have different kinetic and regulatory properties from those involved in other tissues.

Glycogen and its enzymes are compartmentalized. Glycogen granules are only present in astrocytes of adult animals but are found in both astrocytes and neurons of immature animals. Of the enzymes involved in glycogen metabolism, glycogen phosphorylase is found in astrocytes only. Under steady-state conditions, it is probable that less than 10% of phosphorylase in brain is in the unphosphorylated b form (requiring AMP). This form is probably not very active at the low AMP concentrations present when intracellular glucose is sufficient to maintain ATP synthesis. Brain phosphorylase b kinase is activated indirectly by cAMP and by the molar concentrations of Ca^{2+} released during neuronal excitation, providing a molecular mechanism through which glycogen metabolism can be related to brain activity.

Synthesis of glycogen from UDP-glucose is catalyzed by glycogen synthase, which is rate-controlling. As in other tissues, glycogen synthase occurs in both a phosphorylated form, synthase-b, which depends on Glc-6-P as a positive modulator, and a dephosphorylated, independent synthase-a form, which is much more active.

As discussed above, glycogen can provide fuel to support metabolism of neurons. However, this is achieved in the form of glucose equivalents, not glucose *per se*, because most glycogen is broken down to Glc-6-P and the brain lacks substantial glucose-6-phosphatase activity. The glycogen-derived substrate transported from astrocytes to neurons is most likely lactate, consistent with recent proposals that glial lactate may be a fuel for neurons (see below, Fig. 31-4). This concept is supported by the observation that astroglial glycogen can support neuronal function [61, 63–65].

Hormones and neuronal activity affect brain glycogen metabolism. Glycogen is affected by hormones endogenous to the brain including vasoactive intestinal peptide and noradrenaline, as well as circulating hormones, such as insulin [61, 63, 64]. The mechanism whereby insulin exerts an effect on glycogen metabolism in brain has not been determined [63]. Glycogen metabolism in brain, unlike in other tissues, is controlled locally, due to differential local metabolic rates.

Brain glycogen concentrations are increased in conditions of decreased electrical activity (such as deep pentobarbital anesthesia) and its metabolism is likely to be affected by focal activity [61]. In addition, glycogen concentrations and enzyme expression are modulated by sleep deprivation. Moreover, glycogen is required to maintain intense firing in the isolated axon even in the presence of adequate extracellular glucose [61]. Altogether, experimental evidence suggests that even under normal conditions, glycogen has an important role in brain function.

GLYCOLYSIS: CONVERSION OF GLUCOSE TO PYRUVATE OR LACTATE

The terms aerobic and anaerobic glycolysis have historically been related to the extent of conversion of glucose to pyruvate or lactate under conditions of 'adequate' oxygen and no oxygen, respectively. Thus, anaerobic glycolysis leads to a complete conversion of glucose to lactate, which allows the maintenance of an optimal cytoplasmic NAD^+/NADH ratio (Fig. 31-3). Glycolytic flux is the rate at which glucose is converted to pyruvate in the cytosol [2]. The first step of glucose metabolism and thus of glycolysis involves phosphorylation of glucose by hexokinase. This essentially irreversible reaction is one key point in the

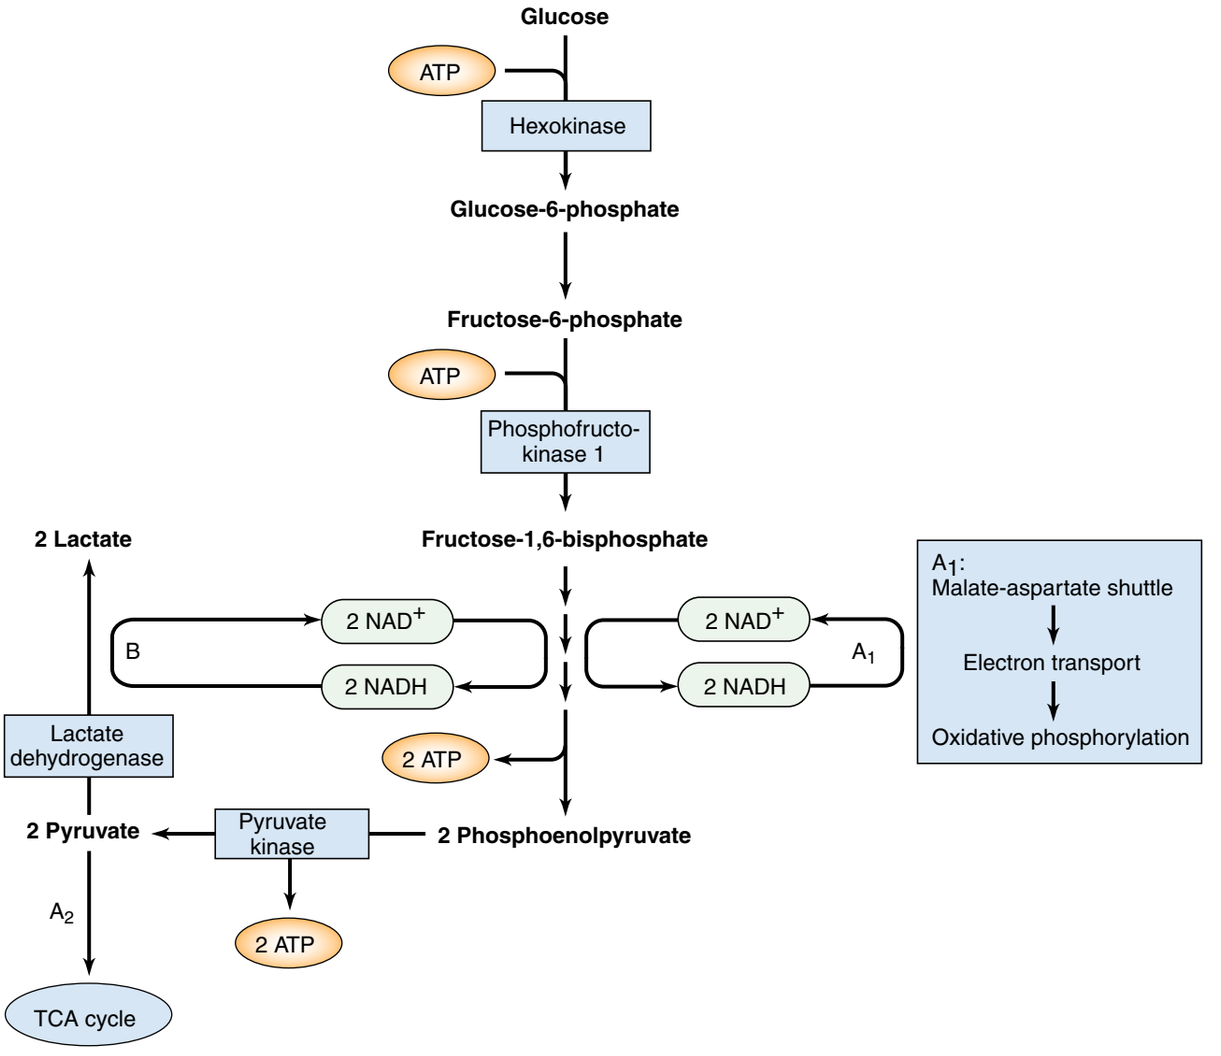

FIGURE 31-3 Glycolysis. A schematic representation of aerobic (A_1 and A_2) and anaerobic (B) glycolysis. Glucose is phosphorylated to glucose-6-phosphate and subsequently to fructose-1,6-bisphosphate via fructose-6-phosphate and phosphofructokinase 1, the main regulating enzyme in brain glycolysis. In one of the following steps, NADH is produced in the conversion of glyceraldehyde-3-phosphate to 1,3-bisphosphoglycerate. The NADH produced is either oxidized in the lactate dehydrogenase reaction reducing pyruvate to lactate (B), or the reducing equivalent from NADH is transferred to the mitochondria via the malate aspartate shuttle to be oxidized in the electron transport chain for oxidative phosphorylation (A_1). Pyruvate from aerobic glycolysis is subsequently metabolized via the tricarboxylic acid (*TCA*) cycle (A_2).

regulation of carbohydrate metabolic rate in brain. The second major regulatory enzyme is phosphofructokinase, discussed later. Figure 31-3 outlines the flow of glycolytic substrates in brain.

Brain hexokinase is inhibited by its product glucose-6-phosphate and to a lesser extent by adenosine diphosphate. The isoenzyme of hexokinase found in brain may be soluble in the cytosol or be attached firmly to mitochondria [2 and references therein]. An equilibrium exists between the soluble and the bound enzyme. The binding changes the kinetic properties of hexokinase and its inhibition by Glc-6-P resulting in a more active enzyme. The extent of binding is inversely related to the ATP:ADP ratio, i.e. conditions in which energy utilization exceeds supply will shift the solubilization equilibrium towards the bound form and produce a greater potential capacity for initiating glycolysis to meet the energy demand. This mechanism allows ATP to function both as the substrate of the enzyme and as a regulator to decrease ATP production through its influence on enzyme binding. It also confers preference on glucose in the competition for the ATP or more precisely its magnesium complex, MgATP ($MgATP^{2-}$) generated by mitochondrial oxidative phosphorylation. Thus, a process that will sustain ATP production continues at the expense of other energy requiring processes.

In addition to acting on enzyme kinetics, Glc-6-P solubilizes hexokinase, thus reducing the efficiency of the enzyme when the reaction product accumulates. The total

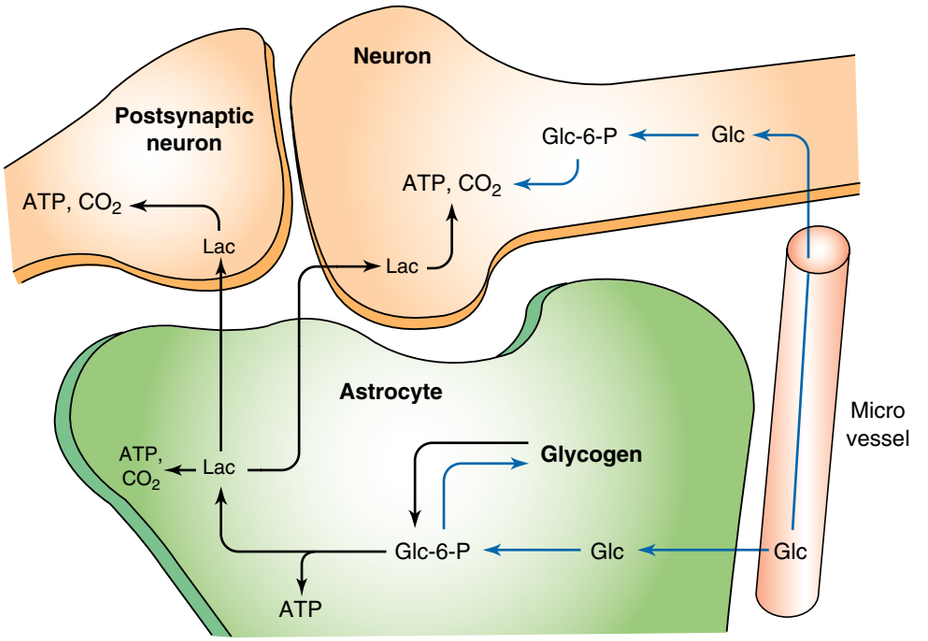

FIGURE 31-4 Scheme of compartmentalized glial glycogen metabolism. When glucose phosphorylation is limited by the low brain glucose concentration, astrocytic glycogenolysis can provide the necessary glucosyl units to maintain ATP synthesis in the glial compartment (*black lines*). Glycogen can provide fuel to neurons, presumably in the form of lactate, during hypoglycemia and thus reduce the energy deficit in the neuronal compartment. When the glucose supply is sufficient, glucose is stored in glial glycogen (*blue lines*). *Glc,* glucose; *Glc-6-P,* glucose-6-phosphate; *Lac,* lactate.

sum of these mechanisms is a fine-tuning of the activity of the initial enzyme in glycolysis in response to changes in the cellular environment. Glc-6-P represents a branch point in glucose metabolism because it is a common substrate for enzymes involved in glycolysis, pentose phosphate shunt (PPS) and glycogen-forming pathways (Fig. 31-2). There is also slight but detectable Glc-6-Pase activity in brain, the significance of which is not clear.

Brain glycolysis is regulated mainly by phosphofructokinase. Fructose-6-phosphate is the substrate of phosphofructokinase-1, a key regulatory enzyme controlling glycolysis [6]. The other substrate is MgATP. Like other regulatory reactions, it is essentially irreversible. It is modulated by a large number of metabolites and cofactors, whose concentrations under different metabolic conditions have a great effect on glycolytic flux. Prominent among these are the availability of ~P and citrate. Brain phosphofructokinase 1 is inhibited by ATP, Mg^{2+} and citrate and stimulated by NH_4^+, K^+, PO_4^{3-}, 5'-AMP, 3',5'-cAMP, ADP and fructose-2,6-bisphosphate. In the steady state, the concentrations of ATP and citrate in brain are apparently sufficient to keep phosphofructokinase-1 relatively inhibited as long as the concentration of positive modulators, or disinhibitors, is low. When the steady state is disturbed, activation of this enzyme produces an increase in glycolytic flux, which takes place almost as fast as events changing the internal milieu.

The glycolytic pathway in brain involves a number of enzymatic reactions that are similar in neurons and glia and similar to those in other tissues. One difference is that neurons contain a specific isoform of enolase called neuronal enolase (NSE). Immunocytochemical detection of the enolases makes them useful in determining neuron:glia ratios in tissue samples. Brain phosphoenolpyruvate kinase controls an essentially irreversible reaction that requires not only Mg^{2+}, as do several other glycolytic enzymes, but also K^+ or Na^+. It should be noted that two reactions are responsible for ATP production in glycolysis, namely phosphoglycerate kinase and pyruvate kinase. The latter step also may be regulatory, since the enzyme can be phosphorylated and dephosphorylated, and is inactive in its phosphorylated form. Overall, the glycolytic pathway consumes two and produces four molecules of ATP, thus providing a net of two ATP molecules per glucose molecule.

THE PENTOSE PHOSPHATE SHUNT IS ACTIVE IN BRAIN

Under basal conditions 5% of brain glucose is metabolized via the pentose phosphate shunt (PPS), also termed the hexose monophosphate pathway [66], a pathway active in both neurons and astrocytes. The PPS has

relatively high activity in developing brain, reaching a peak during myelination. Its main contribution is probably to produce the NADPH needed for reductive reactions in lipid synthesis (see Ch. 3). NADPH is also necessary for the maintenance of reduced glutathione, which is required for the inactivation of reactive oxygen species (see Ch. 32). Thus, the activity of the PPS responds to oxidative stress. The shunt also provides pentose for nucleotide synthesis; however, only a small fraction of the activity of this pathway would be required. Pentose phosphate flux apparently is regulated by the concentrations of Glc-6-P, $NADP^+$, glyceraldehyde-3-phosphate and fructose-6-phosphate. Since transketolase, an enzyme in this shunt, requires thiamine pyrophosphate as a cofactor, poor myelin maintenance in thiamine deficiency may reflect failure of this pathway to provide sufficient NADPH for lipid synthesis [2, 67] (see Peripheral Neuropathy in Ch. 36).

GLYCEROL PHOSPHATE DEHYDROGENASE IS AN NADH OXIDIZING ENZYME RELATED TO GLYCOLYSIS

Glycerol phosphate dehydrogenase (GPDH) is indirectly associated with glycolysis and reduces dihydroxyacetone phosphate to glycerol-3-phosphate, oxidizing NADH in the process. Under hypoxic conditions, glycerol-3-phosphate and lactate increase initially at comparable rates, although the amount of lactate produced greatly exceeds that of glycerol-3-phosphate. The relative concentrations of the oxidized and reduced substrates of the GPDH and lactate dehydrogenase (LDH) catalyzed reactions indicate much higher local concentrations of NADH in brain than are found by gross measurements. In fact, the relative proportions of oxidized and reduced substrates of the reactions that are linked to the pyridine nucleotides may be a better indicator of local redox states (NAD^+/NADH) in brain than the direct measurement of pyridine nucleotides themselves [2, 68].

THE MALATE–ASPARTATE SHUTTLE HAS A KEY ROLE IN BRAIN METABOLISM

The malate–aspartate shuttle is the most important pathway for transferring reducing equivalents from the cytosol to the mitochondria in brain. This shuttle involves both the cytosolic and mitochondrial forms of aspartate aminotransferase and malate dehydrogenase, the mitochondrial aspartate–glutamate carrier and the dicarboxylic acid carrier in brain (Fig. 31-5) [69]. The electrogenic exchange of aspartate for glutamate and a

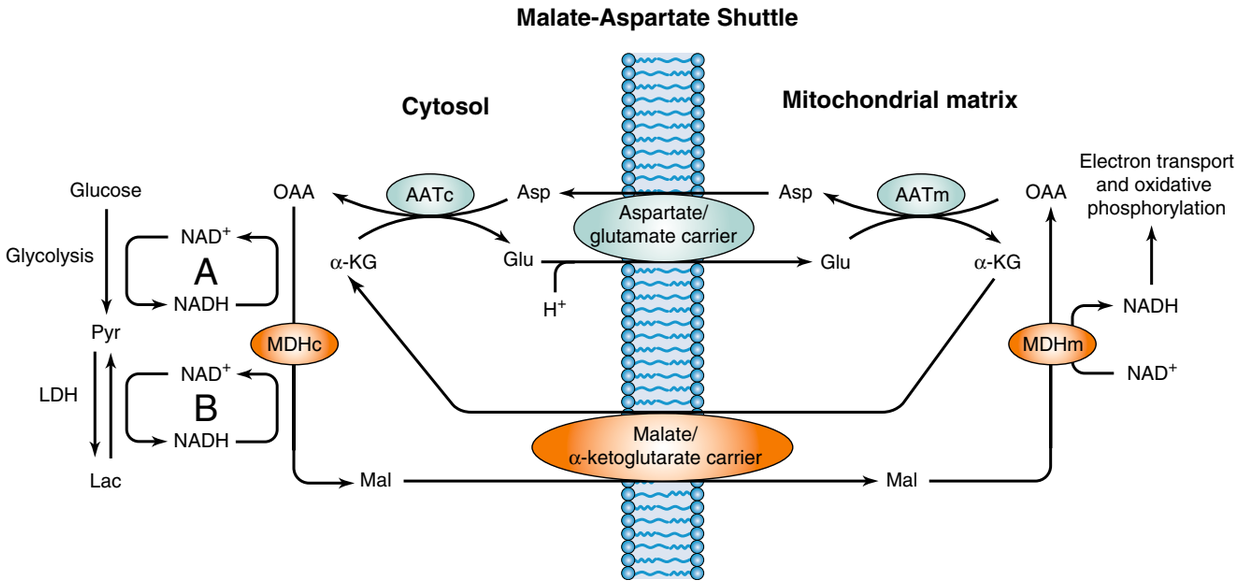

FIGURE 31-5 The malate–aspartate shuttle. NADH is produced in glycolysis (*A*) and in the conversion of lactate (*Lac*) to pyruvate (*Pyr*) via lactate dehydrogenase (*LDH, B*). The reducing equivalents from NADH are transferred via the malate aspartate shuttle to be oxidized via electron transport and oxidative phosphorylation. Oxaloacetate (*OAA*) is converted to malate (*Mal*) by cytosolic malate dehydrogenase (*MDHc*) and NADH is oxidized to NAD^+. Malate is transported into the mitochondrial matrix by a carrier and converted into OAA, and NAD^+ is reduced to NADH via mitochondrial malate dehydrogenase (MDH_m). Within the mitochondria oxaloacetate is converted into aspartate, and α-ketoglutarate (*α-kg*) is formed from glutamate (*Glu*) via mitochondrial aspartate aminotransferase (AAT_m). Aspartate leaves the mitochondrial matrix in exchange for a molecule of glutamate and a proton. In the cytosol aspartate is converted back to oxaloacetate via cytosolic aspartate aminotransferase (AAT_c).

proton via the aspartate–glutamate carrier is irreversible; the exchange favors efflux of aspartate from and entry of glutamate into mitochondria. Exchange via this carrier, which appears to be the overall rate-limiting step of the shuttle [71], is stimulated by Ca^{2+} binding to a domain on the outer side of the inner mitochondrial membrane. Two Ca^{2+}-sensitive aspartate–glutamate carriers have been identified; citrin (AGC2) is found primarily in liver and kidney, and aralar1 (AGC1) is found in skeletal muscle and brain [71]. Aralar1 is highly enriched on neuronal mitochondria and is often found in areas with high levels of cytochrome oxidase [72]. A considerably lower level of aralar1 and malate–aspartate shuttle activity is present in astrocytes [72].

The activity of the malate–aspartate shuttle increases during development in parallel with synaptogenesis, which is consistent with the high activity and importance of this shuttle in neurons and synaptic terminals. Evidence of highly regulated malate–aspartate shuttle in adult human brain has been documented [73 and references therein].

The malate–aspartate shuttle has a role in linking metabolic pathways in brain. It is essential for coordinating the activity of the glycolytic pathway and the TCA cycle by maintaining a low redox state ($NADH/NAD^+$) essential for continuation of glycolysis [74]. Activity of the shuttle is much higher in neurons than astrocytes, which is consistent with the involvement of the shuttle in the synthesis of neurotransmitter glutamate [75] and the enrichment of aralar1 on neuronal mitochondria [72]. The activity of the malate–aspartate shuttle is impaired in pathological conditions including hypoxic/ischemic brain damage [76]. Impaired shuttle activity limits the ability of neurons to oxidize lactate for energy [32].

THERE IS DYNAMIC METABOLISM OF LACTATE IN BRAIN

Lactate is formed under both aerobic and anaerobic conditions in brain. Under anaerobic conditions or upregulation of glycolysis, considerable lactate is produced, presumably in astrocytes, via glycolysis to provide ATP [77, 78]. Conversion of lactate to pyruvate by lactate dehydrogenase (LDH) is necessary for further metabolism of lactate through the tricarboxylic acid (TCA) cycle. Lactate dehydrogenase exists in different isoforms named LDH1–5, consisting of tetramers formed from two distinct subunits. The A (m-type) and B (h-type) subunits of LDH are the products of separate genes and are differentially regulated [79]. These isoforms have slightly different kinetic properties regarding rates of catalysis and affinities for pyruvate. Although the A subunit, hence LDH4 and LDH5 (corresponding to A4 and A3B) are the predominant isoforms in astrocytes [80], and the B subunit, hence LDH1 and LDH2 (corresponding to B4 and B3A) are enriched in synaptic terminals, the enrichment of these isoforms *per se* does not control the direction of metabolism. However, upregulation of LDH may contribute to the cerebral lactate accumulation seen in thiamine deficiency [81]. The expression of LDH isozymes is developmentally regulated. Lactate dehydrogenase functions in the cytoplasm to oxidize NADH, which accumulates as a result of the activity of glyceraldehyde-3-phosphate dehydrogenase in glycolysis. This permits glycolytic ATP production to continue under anaerobic conditions. Lactate dehydrogenase also functions under aerobic conditions because NADH cannot penetrate mitochondrial membranes. Therefore, oxidation of NADH in the cytoplasm depends on this reaction and on the activity of the malate–aspartate shuttle (see above), and to a much lesser extent the glyceraldehyde-3-phosphate shuttle that transfers reducing equivalents to mitochondria. Under normal circumstances there is dynamic turnover of a significant portion of brain lactate in the presence of sufficient O_2 [82 and references therein]. However, the functional significance of this dynamic lactate metabolism is unclear.

Compartmentation of the pyruvate–lactate pool is unexpectedly complex. Studies of cultured brain cells and of *in vivo* brain glucose metabolism have provided evidence for unexpected complexity of the pyruvate–lactate relationship. Using carbon-13 labeling and nuclear magnetic resonance (NMR) spectroscopy, it has been shown that alanine produced from pyruvate exhibits different labeling depending upon whether the pyruvate is derived from glucose or from exogenously supplied lactate [83]. There is much convincing evidence that distinct pools of a given metabolite can exist within the cytosol of a cell [84–86]. This means that the cytosol must not be considered as a free solution but rather as a superbly organized gel containing many proteins and surfaces on which directed transfer of metabolites and cofactors effectively restricts diffusion. Thus, the high protein content and affinity of enzymes for their substrates and co-factors can restrict the diffusion of small molecules through the cytosol [87].

The astrocyte–neuron lactate shuttle hypothesis is controversial. In recent years the possibility that lactate, formed within the brain and released by astrocytes, is an important neuronal substrate both for energy and incorporation into neurotransmitters has been the subject of many studies and considerable controversy. There is evidence that suggests transient release of lactate in human brain on stimulation [48, 8, 88]. Little is known about the highly active metabolism that takes place in the many elaborate, lamellar distal processes of astrocytes dispersed through the neuropil and interacting with an estimated >100,000 synapses [82, and references therein]. However, it is well established that astrocytes do respond to neuronal activity [89]. For example, in the isolated mouse optic nerve preparation, upon stimulation, astrocytic glycogen

is mobilized and transferred as lactate to sustain nerve function [61].

In vitro data demonstrate formation of lactate from metabolism of glucose and from the degradation of glycogen to lactate that is released from cultured astrocytes [77, 90]. The carbon skeleton from lactate is readily incorporated into the neurotransmitters glutamate and GABA in primary cultures of neurons [91, 92]. The high rate of transport and oxidation of lactate in isolated synaptosomes from mature brain, even in the presence of added glucose, is consistent with a role for lactate metabolism in neurons [32]. Lactate is an advantageous substrate for neurons since energy is obtained as NADH without the expense of ATP. The highly localized distribution of MCT2 in neurons (see above and Fig. 31-1) [16, 28, 29] and the findings that in nonvascular tissue the level of MCT1 remains fairly constant with development, whereas the level of MCT2 in neurons increases with maturation, are consistent with a role for these transporters and lactate metabolism in mature brain [16].

There is considerable evidence to support the overall concept of release of lactate, derived from glucose metabolism in astrocytes, and subsequent use by neurons in brain. However, the extent and specific circumstances in which neurons *in vivo* utilize lactate formed within astrocytes for energy and incorporation into neurotransmitters is not known. The likelihood that some trafficking of lactate between astrocytes and neurons has a role in brain metabolism is high, but there is no evidence [1] to support any stoichiometric conversion of brain glucose to lactate or any stochiometric coupling of neuronal/glial lactate transfer to the neuronal/glial glutamate/glutamine cycle as published [93].

Although astrocytes release lactate, they can oxidize lactate for energy and can produce it from TCA cycle intermediates [86, 94]. Astrocytes control the microenvironment of brain and respond to neurotransmitters as well as to changes in the concentrations of substrates in the extracellular milieu [95]. Certain substrates, such as lactate, glutamine [96] and ketone bodies [97], can be produced as well as consumed by astrocytes, depending on the composition of substrates in the extracellular milieu. It is important to recognize the complexity of lactate balance since changes in the lactate level can be the net result of many processes, including: plasma lactate level, altered transport into and release from brain cells, changes in the glycolytic rate, alterations in the rates of the malate–aspartate shuttle activity, activity of the pyruvate dehydrogenase complex, TCA cycle activity, the cytoplasmic pH and redox state, the rate of glycogenolysis in astrocytes and the rate of lactate efflux from brain [82]. Subcellular compartmentation in astrocytes is well documented [12, 13, 58, 65, 83, 84] and it is likely that the astrocyte processes interacting closely with nerve terminals represent a highly metabolically active compartment that may supply energy metabolites *in vivo* [82]. However, the information about *in vivo* metabolism in such discrete areas and short time frames is not yet available [82]. Additionally, astrocytic processes surround capillaries of the blood–brain barrier or interact with other astrocytes forming a syncytium capable of transmitting signals and buffering metabolism [82, 98].

THE COMPLETE OXIDATION OF GLUCOSE REQUIRES TRICARBOXYLIC ACID CYCLE ACTIVITY

The pyruvate dehydrogenase complex plays a key role in regulating oxidation of glucose. In order for glucose to be oxidized to CO_2, pyruvate formed in glycolysis needs to enter the TCA cycle. This is accomplished via the pyruvate dehydrogenase (PDH) complex localized in the mitochondria, which controls the rate of pyruvate entry into the TCA cycle as acetyl coenzyme A (acetyl-CoA)(see also mitochondrial metabolism in Ch. 42). Pyruvate dehydrogenase is a mitochondrial multienzyme complex consisting of pyruvate decarboxylase and two other enzymes, lipoate acetyltransferase and lipoamide dehydrogenase, as well as the coenzymes thiamine pyrophosphate, lipoic acid, CoA, FAD and NAD^+. PDH is inactivated by being phosphorylated at the decarboxylase moiety by a tightly bound Mg^{2+}/ATP^{4-}-dependent protein kinase. PDH is activated by being dephosphorylated by a loosely bound Mg^{2+}- and Ca^{2+}-dependent phosphatase. About half the brain enzyme is usually active. Pyruvate protects the complex against inactivation by inhibiting the kinase. ADP is a competitive inhibitor of Mg^{2+} for the inactivating kinase. Under conditions of greater metabolic demand, increases in pyruvate and ADP and decreases in acetyl-CoA and ATP make the complex more active. Pyruvate dehydrogenase is inhibited by NADH, thereby decreasing formation of acetyl-CoA during hypoxia and allowing more pyruvate to be reduced by lactate dehydrogenase, thus forming the NAD^+ necessary to sustain glycolysis. Pyruvate dehydrogenase defects do occur in several mitochondrial enzyme-deficiency states [99] (see Ch. 42).

Acetyl coenzyme A formed from glucose is the precursor for acetylcholine. Although acetylcholine synthesis normally is controlled by the rate of choline uptake and choline acetyltransferase activity (see Ch. 11), the supply of acetyl coenzyme A (acetyl-CoA) can be limiting under adverse conditions. Choline uptake is, however, independent of the acetyl-CoA concentration. The mitochondrial membrane is not permeable to the acetyl-CoA produced within it, but there is efflux of its condensation product, citrate. Acetyl-CoA can subsequently be formed from citrate in the cytosol by ATP citrate lyase. The acetyl moiety of acetylcholine is formed in a compartment, presumably representing the synaptic terminal, having a rapid glucose turnover. The cytosol of cholinergic nerve endings is rich in citrate lyase, and it is likely that citrate shuttles the acetyl-CoA from the mitochondrial

compartment to the cytosol. During hypoxia or hypoglycemia, acetylcholine synthesis can be inhibited by failure of the acetyl-CoA supply.

Pyruvate carboxylation in astrocytes is the major anaplerotic pathway in brain. Anabolic pathways lead to an ongoing drain on brain TCA cycle intermediates, which would be depleted if there were no mechanism to replenish these compounds. Pyruvate carboxylase, which has been shown to be primarily, if not exclusively, an astrocytic enzyme [56], fulfills this 'anaplerotic' or refilling function in brain by adding a CO_2 to pyruvate forming oxaloacetate which is then combined with acetyl-CoA to form citrate. Although malic enzyme or the combined action of phosphoenolpyruvate carboxykinase (PEPCK) and pyruvate kinase can fix CO_2, they do not perform this function to a significant extent in brain [100, 101]. To export net amounts of citrate, α-ketoglutarate or oxaloacetate from the TCA cycle, the supply of dicarboxylic acids must be replenished. The CO_2 fixation rate sets the upper limit at which biosynthetic reactions can occur. The pyruvate carboxylase reaction in astrocytes is essential for neurons because they are continuously releasing amino acid neurotransmitters and thus require metabolites from astrocytes for the replenishment of the neuronal TCA cycle and neurotransmitter biosynthesis [13].

ENERGY OUTPUT AND OXYGEN CONSUMPTION ARE ASSOCIATED WITH TCA CYCLE ACTIVITY

The actual flux through the TCA cycle depends on glycolysis and acetyl coenzyme A production. However, activity of the TCA cycle is subject to control at several enzymatic steps of the cycle [2, 67] and by the local ADP concentration, which is a prime activator of the mitochondrial respiration to which the TCA cycle is linked (Fig. 31-6). As in other tissues, there are two isocitrate dehydrogenases in brain. One is active primarily in the cytoplasm and requires nicotinamide adenine dinucleotide phosphate ($NADP^+$) as cofactor; the second is the mitochondrial isocitrate dehydrogenase that requires NAD^+ and participates in the TCA cycle. The NAD^+-linked enzyme catalyzes an essentially irreversible reaction and has allosteric properties, i.e. it is inhibited by ATP and NADH and may be stimulated by ADP. The function of cytoplasmic $NADP^+$ isocitrate dehydrogenase is uncertain but it has been postulated that it supplies the NADPH necessary for many reductive synthetic reactions. The relatively high activity of this enzyme in immature brain and white matter is consistent with such a role. α-Ketoglutarate dehydrogenase, which oxidatively decarboxylates α-ketoglutarate, requires the same cofactors as pyruvate dehydrogenase.

Succinate dehydrogenase is the enzyme that catalyzes the oxidation of succinate to fumarate and is also part of the respiratory chain. It is bound tightly to the inner mitochondrial membrane and is an integral part of the respiratory chain, as it constitutes complex II (Fig. 31-6). Isocitrate and succinate concentrations in brain are affected little by changes in the flux of the TCA cycle as long as an adequate glucose supply is available. The highly unfavorable free energy change of the malate dehydrogenase reaction is overcome by the rapid removal of oxaloacetate. The latter is maintained at a very low concentration under steady-state conditions by the condensation reaction with acetyl-CoA catalyzed by citrate synthase [67].

Malate dehydrogenase is one of several enzymes in the TCA cycle present in both the cytoplasm and mitochondria. Both the mitochondrial and cytoplasmic enzymes are components of the malate–aspartate shuttle. This represents a branch point in metabolism since mitochondrial malate dehydrogenase (MDH_m) can lead to metabolism via the TCA cycle or via the malate–aspartate shuttle. The direction of metabolism depends on the redox state and on the association of MDH_m into *metabolons* with either citrate synthase plus α-ketoglutarate dehydrogenase, or with aspartate aminotransferase plus glutamate dehydrogenase [102 and references therein]. The association of MDH_m into transient multienzyme complexes called metabo-lons, and thus directing the pathway of metabolism, is influenced by the concentration of key metabolites in the mitochondria (e.g. oxaloacetate, α-ketoglutarate and citrate) [102].

Citrate is a multifunctional compound predominantly synthesized and released by astrocytes. The steady-state concentration of citrate in brain is relatively high compared to other TCA cycle and glycolytic intermediates, reaching 0.4 mmol/l in the cerebrospinal fluid [103]. This is compatible with the ability of astrocytes to synthesize and release a considerable amount of citrate *in vitro* at a rate reflecting the activity of pyruvate carboxylase; however, the extent to which this occurs *in vivo* is not known. Citrate synthesis is compartmentalized in astrocytes; pyruvate carboxylation has a specific role in the formation of a releasable pool of citrate, but has less of a role in synthesis of the smaller intracellular pool [104, 105]. Bicarbonate stimulates the release of citrate, which is threefold greater from cerebellar astrocytes than from cortical astrocytes [104]. This difference reflects the functional specialization of astrocytes in different brain regions, possibly in response to the neuronal specialization. It has been shown that citrate can attenuate the inhibitory action of Zn^{2+} on NMDA-receptor-mediated glutamate release (see NMDA receptors in Ch. 15). The ability of astrocytes to release large amounts of citrate may be related to the ability of these cells to significantly upregulate glycolysis under certain conditions [105]. This may be so since the release of citrate would decrease its intracellular concentration, thereby relieving the inhibitory action of citrate on PFK1 in the glycolytic pathway (Fig. 31-3).

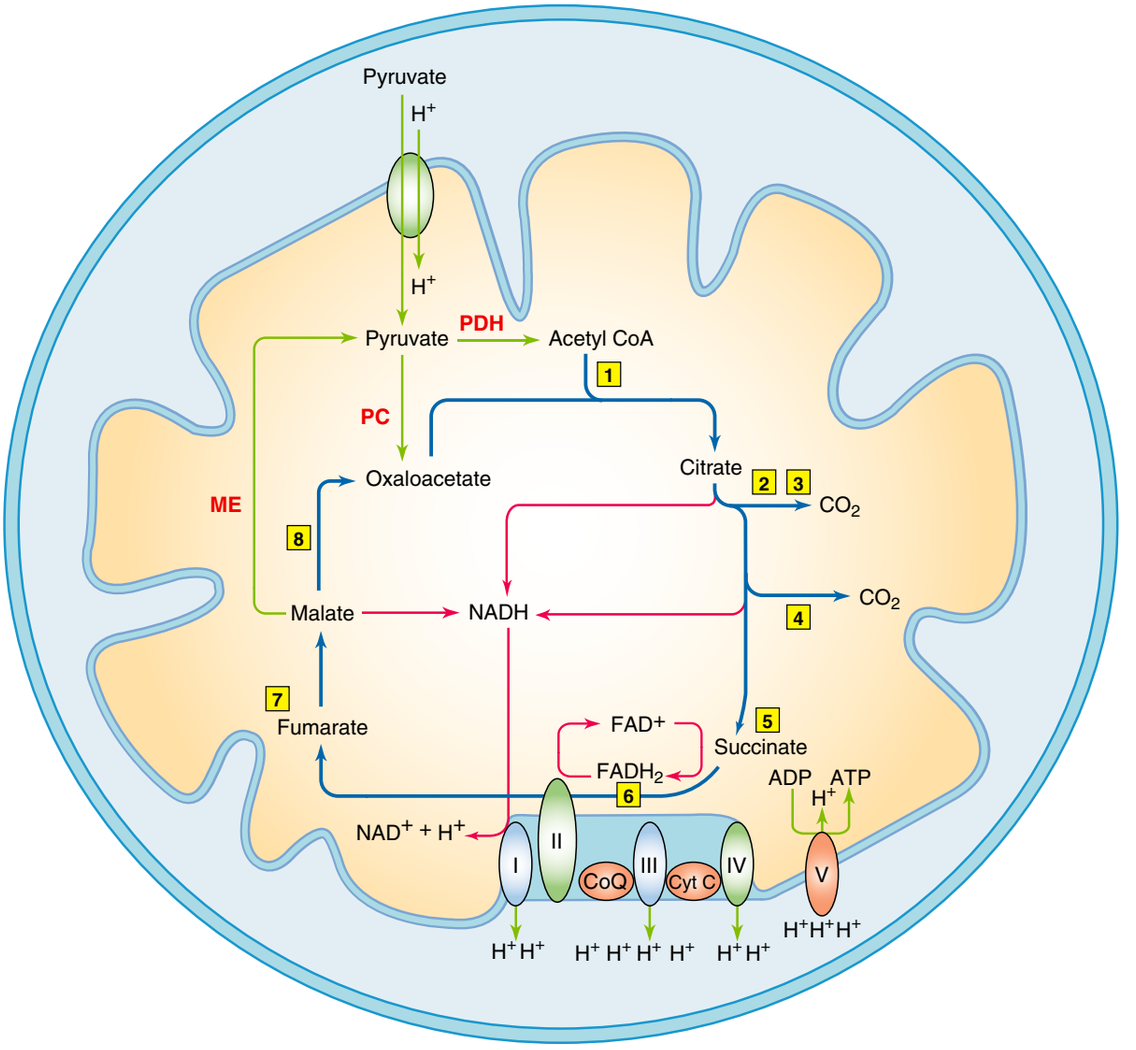

FIGURE 31-6 Tricarboxylic acid cycle and oxidative phosphorylation. Pyruvate is carried into the mitochondrial matrix for oxidative decarboxylation to acetyl-CoA via the pyruvate dehydrogenase complex (*PDH*) or for carboxylation to oxaloacetate via pyruvate carboxylation (*PC*). Acetyl-CoA is condensed via citrate synthase (*1*) to citrate, which is converted to α-ketoglutarate via aconitase (*2*) and isocitrate dehydrogenase (*3*). α-ketoglutarate is subsequently decarboxylated via the α-ketoglutarate dehydrogenase complex (*4*) to succinyl-CoA. Succinate is formed from succinyl-CoA via succinyl CoA synthase (*5*). Complex II of the respiratory chain/succinate dehydrogenase (*6*) oxidizes succinate to fumarate, which is converted into malate via fumarase (*7*). Malate is oxidized to oxaloacetate via malate dehydrogenase (*8*) or it can be converted to pyruvate via malic enzyme (ME). NADH is re-oxidized in complex I, and FADH in complex II of the electron transport chain. The electrons are carried by the complexes, coenzyme Q (*CoQ*) and cytochrome C (*Cyt c*) to O_2, which is reduced to H_2O in complex IV. The electron transport generates a proton gradient over the inner membrane driving the ATP synthesis in complex V.

MANY TCA CYCLE ENZYMES AND COMPONENTS OF OXIDATIVE PHOSPHORYLATION ARE DIFFERENTIALLY DISTRIBUTED IN NEURONAL AND GLIAL MITOCHONDRIA

Mitochondria are distributed with varying densities throughout the central nervous system with the more vascular parts containing most of the mitochondria. Mitochondria have their greatest concentration in neurons and are present throughout the perikaryon, cytoplasm, dendrites, axons and nerve endings (see Ch. 1 and [106, 107]). Regions of particular abundance are nerve endings, the axon hillock and nodes of Ranvier. Mitochondrial heterogeneity has been demonstrated in the brain by separation of mitochondria of synaptic and nonsynaptic (neuronal cell bodies and glial) origin, which showed differences in distribution of enzymes catalyzing the TCA cycle reactions [107]. Another example of mitochondrial heterogeneity is the dramatically different distribution of respiratory chain components in neurons and astrocytes [108]. This may be due in part to the fact that most of the TCA cycle enzymes are encoded by the nuclear DNA in

the host cell and imported into the mitochondrial matrix, in contrast to enzymes of the respiratory chain complexes, which are encoded by the mitochondrial DNA (see Ch. 42 for genetic abnormalities of mitochondria in brain and muscle).

Mitochondrial heterogeneity leads to multiple simultaneous TCA cycles in astrocytes and neurons. While it is clear that mitochondrial heterogeneity exists in the brain as a whole it is less clear if mitochondria in individual cells may exhibit such heterogeneity. However, circumstantial evidence from detailed metabolic studies of cultured brain cells points toward such a possibility [105]. The presence of multiple simultaneous TCA cycles in astrocytes, neurons and freshly isolated synaptic terminals provides additional evidence for mitochondrial heterogeneity [74, 84, 104, 109]. Furthermore, discrete subfractions of synaptic mitochondria have considerable heterogeneity of mitochondrial enzymes that are thought to reflect subcellular compartmentalization and functional metabolic specialization [74]. Moreover, studies of the distribution of α-ketoglutarate dehydrogenase in mitochondria of individual astrocytes provide evidence of distinct subpopulations of mitochondria within individual cells [110]. The question of subcellular compartmentation is of fundamental importance with regard to the full understanding of the extent and intricacies of metabolic compartmentation in brain. The existence of distinct microdomains within astrocytes [111] and neurons [28] are other examples of functionally important subcellular compartmentalization.

Partial TCA cycles can provide energy in brain. Under certain metabolic conditions with low levels of acetyl-CoA, such as in hypoglycemia, only a part of the TCA cycle may operate, particularly in neurons and synaptic terminals [112, 113]. This truncated cycle, which enables utilization of glutamine/glutamate as energy substrates, consists of the steps from α-ketoglutarate to oxaloacetate and leads to aspartate production and sometimes accumulation [112]. The majority of the reducing equivalents produced in the complete TCA cycle are derived from these reactions [67]. The energy production from this truncated TCA cycle corresponds to 75% of that produced from the entire cycle (see below).

Adenosine triphosphate production in brain is highly regulated. Oxidative steps of carbohydrate metabolism normally contribute 36 of the 38 high-energy phosphate bonds (~P) (assuming a P:O ratio of 3:1) generated during aerobic metabolism of a single glucose molecule. However, it is not likely that there is a net production of 38 ATP equivalents per mole of glucose (Table 31-1) since a fraction of the glucose taken up is converted to lactate, and there is a proton leak as well as specific non-ATP synthase uses of protons (e.g. malate–aspartate shuttle, phosphate transport and ATP transport) across the mitochondrial membrane. The steady-state concentration of ATP is high and represents the net sum of very rapid synthesis and utilization. On average, half of the terminal phosphate groups turn over in about 3 seconds; the turnover is probably much faster in certain regions [2]. The level of ~P is kept constant by regulation of ADP phosphorylation in relation to ATP hydrolysis. The active adenylyl kinase reaction, which forms equivalent amounts of ATP and AMP from ADP, prevents any great accumulation of ADP. Only a small amount of AMP is present under steady-state conditions; thus, a relatively small decrease in ATP may lead to a relatively large increase in AMP, which is a positive modulator of AMP kinase, which in turn regulates many reactions that lead to increased ATP synthesis. Such an amplification factor provides a sensitive control for maintenance of ATP levels [68], which are surprisingly constant *in vivo*.

Phosphocreatine has a role in maintaining adenosine triphosphate levels in brain. The concentration of phosphocreatine (PCr) in brain is even higher than that of ATP, and creatine phosphokinase (CPK) is extremely active. The PCr level is exquisitely sensitive to changes in oxygenation, providing ~P for ADP phosphorylation and, thus, maintaining ATP levels. The CPK system also may function in regulating mitochondrial activity. In neurons with a very heterogeneous mitochondrial distribution, the creatine/phosphocreatine shuttle may play a critical role in energy transport [114]. The precise role of CPK in brain (whether as an energy buffer or as transport of ATP equivalents) is uncertain. However, it should be noted that knocking out the CPK enzymes in mouse brain had an effect on spatial learning but not on motor function [115].

Substrates other than glucose provide energy for brain cells (e.g. glutamate, glutamine, lactate, fatty acids, ketone bodies). It is important to note that all of the machinery for using monocarboxylic acids for energy is present in adult brain [116, 117] (see also Ch. 58). Normally, there are no significant cerebral arteriovenous differences for the ketone bodies D-β-hydroxybutyrate and acetoacetate, which are formed in the course of the catabolism of fatty acids by liver. In prolonged starvation, the carbohydrate stores of the body are exhausted and the rate of gluconeogenesis is insufficient to provide glucose fast enough to meet the requirements of the brain; blood ketone concentrations rise as a result of the rapid fat catabolism. The brain then apparently turns to the ketone bodies as the source of its energy supply. Cerebral utilization of ketone bodies appears to follow passively their concentrations in arterial blood [116]. In normal adults, ketone concentrations are very low in blood and cerebral utilization of ketones is negligible. In ketotic states resulting from starvation; fat-feeding or ketogenic diets; diabetes; or any other condition that accelerates the mobilization and catabolism of fat, cerebral utilization of ketones is increased more or less in direct proportion to the degree of ketosis [116].

The enzymes responsible for their metabolism, D-β-hydroxybutyrate dehydrogenase, acetoacetate-succinyl-CoA transferase and acetoacetyl-CoA-thiolase, are present in

brain tissue in sufficient amounts to convert them into acetyl-CoA and to feed them into the TCA cycle at a sufficient rate to satisfy the metabolic demands of the brain [116]. Considerable uptake of ketone bodies by the brain during prolonged fasting for several weeks has been reported [117]. If one assumed that the substances were oxidized completely, their rates of utilization would have accounted for more than 50% of the total cerebral oxygen consumption, more than that accounted for by the glucose uptake. D-β-hydroxybutyrate uptake was several times greater than that of acetoacetate, a reflection of its higher concentration in the blood. It should be noted that D-β-hydroxybutyrate is incapable of maintaining or restoring normal cerebral function in the absence of glucose in the blood [2]. This suggests that, although it can partially replace glucose, it cannot fully satisfy the cerebral energy needs in the absence of some glucose consumption. One explanation may be that the first product of D-β-hydroxybutyrate oxidation, acetoacetate, is metabolized further by its displacement of the succinyl moiety of succinyl-CoA to form acetoacetyl-CoA. A certain rate of glucose utilization may be essential to drive the TCA cycle, to provide enough succinyl-CoA to permit the further oxidation of acetoacetate and, hence, to pull along the oxidation of D-β-hydroxybutyrate.

Several studies document the use of lactate [77, 118] and ketone bodies [119] by mature brain in the presence of glucose. Octanoate and other short chain fatty acids can be used by brain astrocytes *in vitro* for energy [120]. It is important that such backup systems are present to protect the brain when glucose is low [9, 32, 94]. Glucose derived carbohydrates and amino acids together form a large pool of carbon in brain, i.e. ≈15 µmol carbohydrate/g plus another 25 µmol/g in the aggregate amino acid pool that are in a dynamic state of use and replenishment [82]. There is evidence that amino acids can be oxidized *in vivo* by the brain for energy [121]. Since glutamate is formed within brain from glucose and monocarboxylic acids it is not likely to be a significant source of energy. However, under specific circumstances such as hypoglycemia the oxidation of glutamate is an important mechanism for providing energy via a partial TCA cycle from α-ketoglutarate to oxaloacetate (see above). Malic enzyme is required for the complete oxidation of glutamate. Leucine enters the brain at a high rate and can be converted to 3-hydroxybutyrate and subsequently oxidized for energy by brain cells. The use of amino acids for energy requires the disposal of the NH_3 removed.

GLUTAMATE/GLUTAMINE METABOLISM IS LINKED TO ENERGY METABOLISM

Glutamate enters the mitochondria via the aspartate–glutamate carrier or the glutamate carrier. These carriers are illustrated in Figure 31-7. Glutamate participates in a number of metabolic reactions catalyzed by the enzymes glutamate dehydrogenase, a number of aminotransferases, glutamine synthetase, phosphate-activated glutaminase and glutamate decarboxylase (Fig. 31-8). Additionally, glutamate participates in metabolic pathways such as biosynthesis of ornithine and peptides such as glutathione and proteins. While all of these reactions occur in the brain as a whole, no single type of cell is able to perform all of these reactions [122]. This has to do with the fact that many enzymes exhibit selective cellular distribution in the brain (Table 31-3). Hence, glutamate decarboxylase is mainly expressed in GABAergic neurons and glutamine synthetase is present in glial cells. Phosphate activated glutaminase has a much higher activity in neurons than in astrocytes [123], but astrocytes are capable of oxidizing glutamine for energy [13, 94].

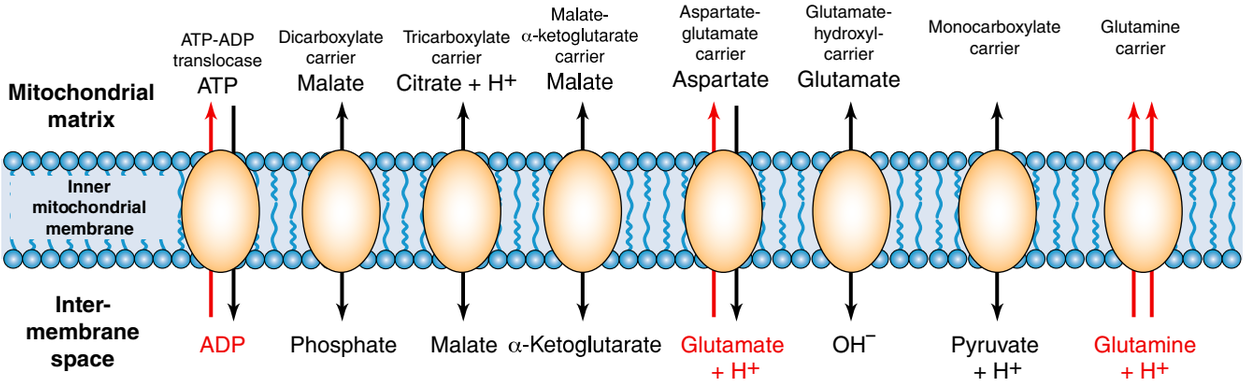

FIGURE 31-7 Mitochondrial carriers. Ions and small molecules enter the intermembrane space, since the outer mitochondrial membrane is not a significant permeability barrier. However, the inner mitochondrial membrane is impermeable to ions except those for which there are specific carriers. Most of the carriers are reversible, as indicated by *two-headed arrows*. Compounds transported in one direction are indicated in red. The ATP/ADP translocase and the aspartate–glutamate carrier are both electrophoretic; their transport is driven in the direction of the mitochondrial membrane potential, as indicated by red arrows. Glutamine is carried into the matrix by an electroneutral carrier. The unimpaired functioning of mitochondrial carriers is essential for normal metabolism. (Adapted with permission from reference [70].)

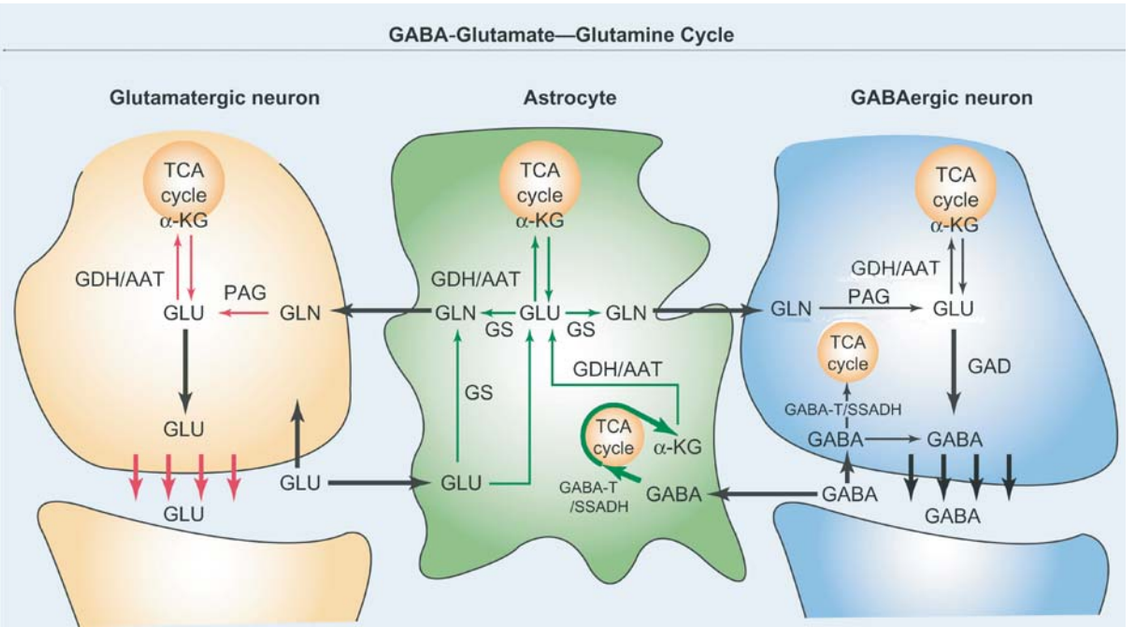

FIGURE 31-8 GABA–glutamate–glutamine cycle. Simplified schematic representation of key metabolic processes and release and uptake of neurotransmitters in glutamatergic and GABAergic synapses interacting with a surrounding astrocyte. The glutamate–glutamine cycle including the glutamine synthetase (*GS*) reaction is indicated in the glutamatergic neuron – astrocyte interaction. Analogously, the GABA–glutamate–glutamine cycle, including the GABA transaminase (*GABA*-T), succinate semialdehyde dehydrogenase (*SSADH*) and glutamate decarboxylase (*GAD*) reactions, is indicated in the GABAergic neuron–astrocyte interaction. The close association of the neurotransmitters, GABA and glutamate, to TCA cycle metabolism is indicated in all three cells. Glutamate is converted to α-ketoglutarate via either glutamate dehydrogenase (*GDH*) or aspartate aminotransferase (*AAT*). *GLN*, glutamine; *GLU*, glutamate; *α-KG*, α-ketoglutarate; *PAG*, phosphate activated glutaminase; *TCA*, tricarboxylic acid.

It should be noted that the reactions catalyzed by glutamate dehydrogenase and several aminotransferases convert glutamate into α-ketoglutarate and thus associate glutamate with the TCA cycle. The aspartate aminotransferase activity in brain is high in comparison with flux through the TCA cycle. Thus amino acids made by transamination of TCA cycle intermediates (e.g. aspartate and glutamate) in the mitochondrial matrix are in equilibrium with the TCA cycle intermediates. However, transport across the inner mitochondrial membrane may influence this process (see above). In spite of the fact that the thermodynamic equilibrium of the glutamate dehydrogenase reaction favors glutamate production, reductive amination of α-ketoglutarate normally does not take place in the brain [122]. This is likely to be related to the high K_m of the enzyme for ammonia and to the fact that brain NAD^+/NADH ratio is high.

Glutamate and glutamine metabolism is compartmentalized in brain. Since the enzymes of glutamate and glutamine metabolism are differentially distributed in astrocytes and neurons, glutamate metabolism in brain is compartmentalized (see above). A small glutamate pool that is precursor for glutamine and a large glutamate pool with a slow turnover characterized the two glutamate compartments originally described in the brain [124]. These pools reflect the glial and neuronal glutamate pools respectively. This is compatible with the cycle of GABA, glutamate and glutamine metabolism shown in Figure 31-8. Synaptically released glutamate is predominantly taken up into astrocytes and converted into glutamine, which subsequently is transferred back to the glutamatergic neuron. This is in keeping with the preferential localization of high-affinity glutamate transporters and glutamine synthetase in astrocytes and the enrichment of phosphate activated glutaminase in neurons [125, 126].

It is important to emphasize, that the glutamate/glutamine cycle does not operate in a stoichiometric fashion, because glutamate in astrocytes is oxidatively metabolized in addition to being converted into glutamine [13, 86, 112, 122]. Furthermore, glutamine can also be oxidized in neurons after conversion to glutamate and subsequently enter the TCA cycle as α-ketoglutarate. In this context it should be noted that the carbon skeleton of glutamate has to exit the TCA cycle in the step of malate or oxaloacetate and subsequently reenter as acetyl-CoA from pyruvate to be completely oxidized. This is part of the 'pyruvate recycling' pathway that has been reported in rat brain [127]. Pyruvate recycling in cultured cells takes place in astrocytes but only to a very small extent [128]. It is conceivable that this process becomes more pronounced during hypoglycemia. However, the opposite is the case with *in vitro* studies; recycling was abolished in astrocytes and did not appear in neurons in culture [129]. To the extent that the carbon skeletons of glutamate and glutamine are quantitatively oxidized to CO_2 obviously there is a need for replenishment of the glutamate pool, which occurs via the anaplerotic enzyme pyruvate carboxylase in astrocytes

(see above). This consideration may also apply to GABA (see below). Because the cycle is not stoichiometric, glutamatergic and GABAergic neurons are incapable of replenishing their neurotransmitter pools unless precursors are received from surrounding astrocytes.

A specialized glutamate–glutamine cycle operates in GABAergic neurons and surrounding astrocytes. The cycle also operates between GABAergic neurons and astrocytes and is of quantitative importance for the maintenance of the neurotransmitter GABA pool [130] (see GABA neurotransmission in Ch. 16). It should be noted that it is a prerequisite for the GABA-glutamate–glutamine cycle to operate that GABA can be converted to glutamate in the astrocytic compartment. This is possible since the carbon skeleton of GABA has access to the TCA cycle by the concerted action of GABA transaminase and succinate semialdehyde dehydrogenase. After conversion to oxaloacetate and condensation with acetyl-CoA, α-ketoglutarate and thus glutamate can be formed. In GABAergic neurons the simultaneous presence of GABA transaminase, succinate semialdehyde dehydrogenase and glutamate decarboxylase provides a means by which the α-ketoglutarate dehydrogenase and succinyl CoA synthetase reactions can be circumvented. This is referred to as the *GABA shunt* of the TCA cycle, the activity of which constitutes approximately 10% of the normal flux in the TCA cycle (see also Fig. 16.1).

Several shuttles act to transfer nitrogen in brain. While the glutamate–glutamine cycle accounts for the transfer of the carbon skeleton of glutamate (between neurons and astrocytes) it does not account for the fate of the ammonia released in the glutaminase reaction and utilized in the glutamine synthetase reaction. In the metabolic communication between muscle and liver, the nitrogen transfer is well known to occur as an alanine–glucose exchange. An analogous mechanism involving alanine and lactate has been proposed for brain, according to which alanine is responsible for the transfer of the ammonia nitrogen between the neuronal (glutamatergic) and the astrocytic compartments. There is evidence that leucine and α-ketoisocaproic acid may also have a role in the transfer of amino groups between neurons and glia [122, 131].

HOW COMPARTMENTALIZED BRAIN METABOLISM IS STUDIED

Since the brain utilizes energy almost exclusively from oxidative metabolism of glucose, brain metabolism has been studied by focusing on net oxygen and glucose uptake. Oxygen consumption was classically measured as the arteriovenous difference of O_2 content. When a substance is exchanged between brain and blood, the difference between its steady state of delivery to brain in the arterial blood and removal in the venous blood must be equal to the net rate of its utilization or production by brain. This relation can be expressed as follows:

$$CMR = CBF(\mathrm{A}-\mathrm{V})$$

See reference [2] for a discussion of these classical methods. Additionally, oxygen consumption can be measured directly by using positron emission tomography (PET) or polarography, or indirectly, by measuring the changing oxygenation of deoxyhemoglobin. The latter method has been exploited by the blood-oxygen-level-dependent (BOLD) functional magnetic resonance imaging (fMRI) or infrared spectroscopy methods (see detailed discussions in Ch. 58). Inherent in all methods designed to measure cerebral oxygen metabolism directly is the intrinsic problem that oxygen can rapidly diffuse across the blood–brain barrier. PET measurements of cerebral metabolic rate $(CMR)O_2$ contain a number of correction factors and are complicated to perform; yet some intriguing results under certain conditions have been reported such as the lack of increase in cerebral oxygen consumption during focal stimulation [8]. Assessment of cerebral oxygen metabolism by the BOLD mechanism, on the other hand [49], is heavily model-dependent, as the apparent increase in venous deoxyhemoglobin during focal stimulation is a transient process critically dependent on the blood flow and volume changes [132]. Nonetheless, imaging brain function using BOLD fMRI has led to renewed interest and insight into cognitive neuroscience, mainly due to its simplicity and ease of use. Other indirect methods to measure cerebral oxygen metabolism have been developed since the late 1980s by measuring the turnover of carbon-13 label from glucose into glutamate C4, which through label exchange with the TCA cycle intermediate α-ketoglutarate, can reflect the rate of the TCA cycle [10]. This approach offers the elegance of trapping the label in an intracellular metabolite and thus does not suffer from the drawback of the direct oxygen methods, such as diffusion of the metabolic product and interference with non-metabolism-related label flow.

In addition to $CMRO_2$, the cerebral metabolic rate of glucose (CMR_{glc}) can be studied using radiotracers. However, the study of metabolism using radiotracers in general is cumbersome due to the need to separate the products of metabolism and thus is not applicable *in vivo*. To alleviate this problem, Sokoloff pioneered an elegant method that consists of applying the radiotracer in a non-metabolizable form, e.g. 2-deoxyglucose, and measuring the amount of radioactivity in the phosphorylation product [133]. This approach has led to the widely used autoradiography approach for experimental animal studies and to the ^{18}F-2-deoxyglucose (FDG) method (FDG-PET) for human use, which is now routinely used for various purposes including cancer detection and developmental studies [44]. See Chapter 58 for detailed discussion.

A drawback to all methods discussed above, however, is that they fail to directly address the metabolic compartmentation inherent in the brain. For example, direct or indirect measurement of oxygen metabolism using labeled

O_2 will measure overall oxygen consumption irrespective of the cellular localization. The same holds true for the deoxyglucose method, although some evidence suggests that astrocytes may be the preferential site of increased glucose uptake during stimulation [134]. Lastly, the measurement of glutamate turnover directly (see above) does not take into account the fact that glutamate, and its metabolism, is known to be compartmentalized in the CNS. For example, as pointed out earlier, studies in the 1960s using carbon-14 labeling reported that glutamate and glutamine have a different product-precursor relationship depending on whether carbon-14-labeled glucose or carbon-14-labeled acetate was administered [135]. From these experiments the existence of at least two TCA cycles associated with a large glutamate and a small glutamine pool was deduced. Indeed, it was demonstrated that acetate selectively enters astrocytes *in vivo* [136]. Since the use of radiotracers fails to separate the tracer not only in different molecules but also in different positions within the molecule, studying compartmentation with radiotracers, although very sensitive, is tedious and complicated.

Carbon-13 nuclear magnetic resonance spectroscopy is a powerful method for studying brain metabolism. On the other hand, ^{13}C-NMR spectroscopy not only allows the simultaneous and separate detection of signals from different compounds, but also within different atoms in a given molecule. For example, carbon-13 from glucose labeled at the C1 (or C6) position is incorporated via the PDH reaction into the C2 of acetyl-CoA, and subsequently into the C4 of α-ketoglutarate (Fig. 31-9), which labels the

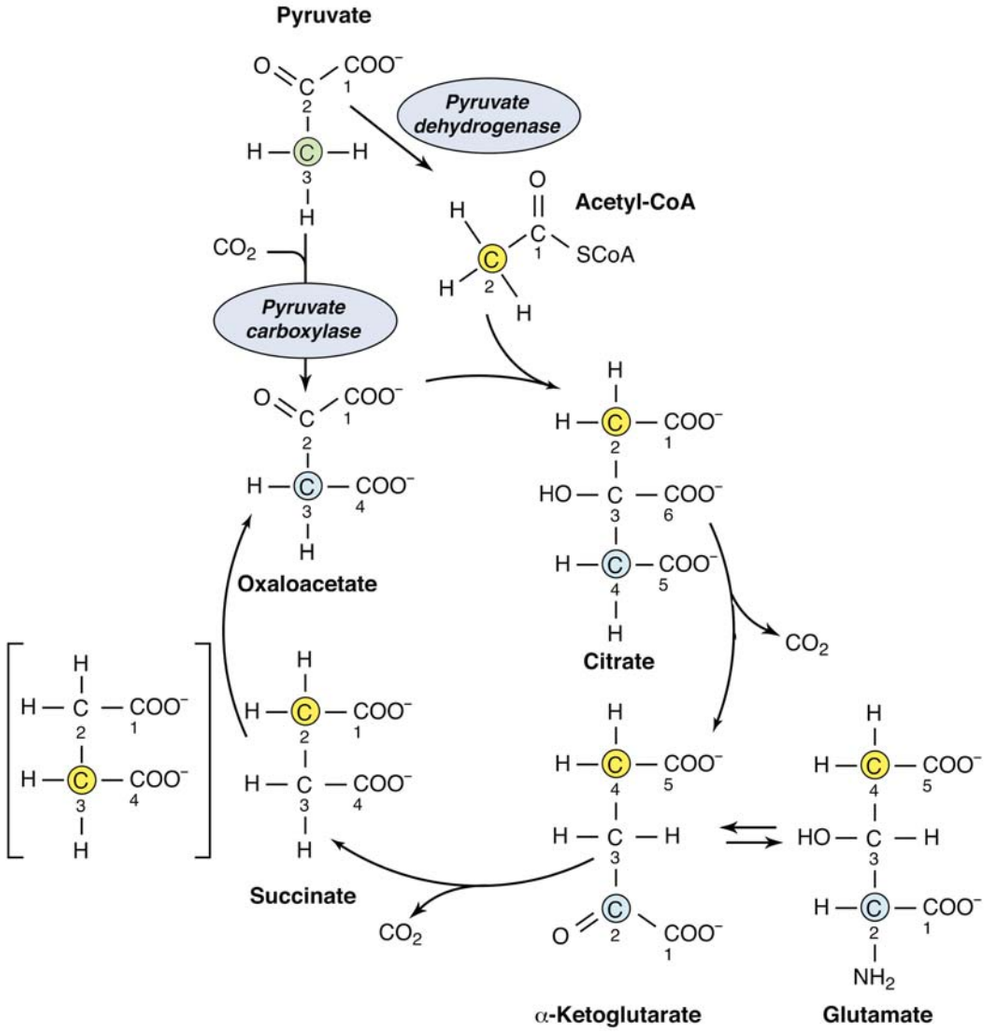

FIGURE 31-9 Labeling pattern for metabolism of [1-^{13}C] or [6-^{13}C] glucose by NMR spectroscopy. Glucose labeled in the C1 or C6 position will give rise to pyruvate labeled in the C3 position (*green*). Metabolism via the pyruvate dehydrogenase pathway (*yellow*) gives rise to acetyl COA labelled in the C2 position, and subsequently to glutamate and glutamine labeled in the C4 position. Metabolism in the TCA: the label is scrambled at the level of succinate, leading to equal labeling of the C2 and C3 of aspartate. Acetate or β-hydroxybutyrate labeled at the C2 position leads to a similar labeling pattern as metabolism of C1- or C6-labeled glucose via pyruvate dehydrogenase. Metabolism via pyruvate carboxylase (*blue*), which occurs only in astrocytes, gives rise to glutamate and glutamine labeled in the C2 position. See text for further details.

C4 of glutamate, which can be measured by NMR spectroscopy. In the TCA cycle, the label is scrambled at the level of succinate, leading to equal labeling of the C2 and C3 of aspartate (Fig 31-9), and in subsequent turns glutamate and glutamine. On the other hand, action of pyruvate carboxylase on C3 labeled pyruvate leads to labeling of the C3 position of oxaloacetate, which labels the C2 of glutamate and glutamine. In addition to determining the amount of label in a given position in a molecule such as glutamate, the amount of different molecules with multiple labels (isotope isomers or isotopomers) such as singly or doubly labeled glutamate C4 can be determined due to the magnetic interaction between adjacent carbon-13 nuclei [127]. A labeling pattern similar to that obtained with glucose as a precursor is obtained when using acetate labeled at the C2 or β-hydroxybutyrate labeled at the C2 (or C4) positions. Because of selective uptake by astrocytes, acetate provides specific information about metabolism in these cells, and about the trafficking of compounds from astrocytes to neurons. β-hydroxybutyrate is taken up by both astrocytes and neurons, and can provide information about TCA cycle activity even when metabolism via pyruvate dehydrogenase is impaired [127].

Cultured neurons and astrocytes are useful for studying subcellular compartmentation and identifying pathways of metabolism. An important approach to study the brain is based on brain cell cultures [128, 129], cell lines [137] and tissue slices [138]. Detailed biochemical information is obtained without interference from metabolism of peripheral organs such as liver or obstructions such as the blood–brain barrier. Cells taken directly from the organism and subsequently grown for at least 24 hours *in vitro* are considered to be primary cultures. Different procedures have been used, often in combination, to enable the establishment of monotypic cultures from mixed cell suspensions. Brain cells are obtained after an initial mechanical and/or enzymatic dissociation of the nervous tissue of newborn mice, rats or other animals [139]. Primary cultures of cortical and cerebellar granule neurons are important models since 90% of the synapses in the brain utilize either glutamate or GABA as the neurotransmitter. Because of the relative abundance of neurotransmitter glutamate, cerebellar granule cells are the preferred model system for excitatory neurotransmission. GABAergic cerebral cortex neurons are the model for inhibitory neurotransmission. Primary cultures of astrocytes are an important model since these cells are responsible for the removal and metabolism of neurotransmitter glutamate and for control of the pH and ion concentrations of the extracellular milieu in brain [13, 95]. Since astrocytes from different brain regions have different properties, astrocytes as counterparts for studies using specific neurons are taken from the same brain region as the neurons [140]. Co-cultures of astrocytes and neurons are a valuable tool for studying neuronal-glial interactions [104]. Cultured cell lines are sometimes used in the study of particular aspects of metabolism, e.g. compartmentalized pyruvate metabolism in C-6 glioma cells using carbon-13-labeled glucose and lactate [137].

Preparations such as brain slices, axons, synaptosomes and isolated mitochondria are tools for studying specific aspects of metabolism. Brain slices are a step closer to the *in vivo* situation without the confounding presence of the blood–brain barrier. Valuable information has been obtained about metabolic pathways and pathological situations from brain slices [138]. Furthermore, subcellular preparations have also been used to analyze particular aspects of metabolism. Studies with synaptosomes can reveal information about the highly specialized metabolism in nerve terminals and neuron-neuron interaction [94, 109, 112]. Isolated optic nerve preparation is a valuable model for studying axonal metabolism [61]. In addition, studies with isolated mitochondria can help to dissect the regulation of mitochondrial enzymes and TCA cycle metabolism [74, 107]; whereas the activity and regulation of cytosolic enzymes can be studied in the soluble fraction from brain [102]. Uptake studies, *in situ* hybridization and Western blots have been invaluable tools for studying the transport of substrates by brain cells [16].

***In vivo* nuclear magnetic resonance spectroscopy provides information about the regulation of metabolism in the intact brain.** Given the compartmentalization of compounds such as glutamate, glutamine and glycogen and related enzymes (see above), important insights into the regulation of brain energy metabolism can be obtained by *in vivo* NMR spectroscopy studies (Fig. 31-10 and Ch. 58). Particularly exciting in this regard is the ability of ^{13}C-NMR to measure glutamine labeling completely noninvasively [50]. Since glutamate measured in tissue *in vivo* mainly reflects the neuronal glutamate pool, the flow of label from glutamate to glutamine thus may reflect glutamate neurotransmission. ^{13}C-NMR spectroscopy thus has opened the avenue of quantifying glutamate neurotransmission *in vivo*, which provides a translational bridge between the information obtained from cellular studies (see above) and studies in patients. In addition to observing the flux from glucose labeled at the C1 (or C6) position into the C4 of glutamate and glutamine, label can be observed directly in other positions of the molecule, such as the C2 position (Fig. 31-10), which is important in assessing pyruvate carboxylase activity which appears to be significant *in vivo* [141, 144]. In addition, by analyzing the flow of label into the other positions in glutamate and glutamine, insight into the regulation of subcellular fluxes can be gained [141]. Lastly, *in vivo* ^{13}C-NMR spectroscopy is the only method capable of assessing *in vivo* brain glycogen metabolism in the human brain [142] (Fig. 31-10).

In vivo H- and ^{31}P-NMR spectroscopy can be used to assess the concentration of clinically relevant compounds

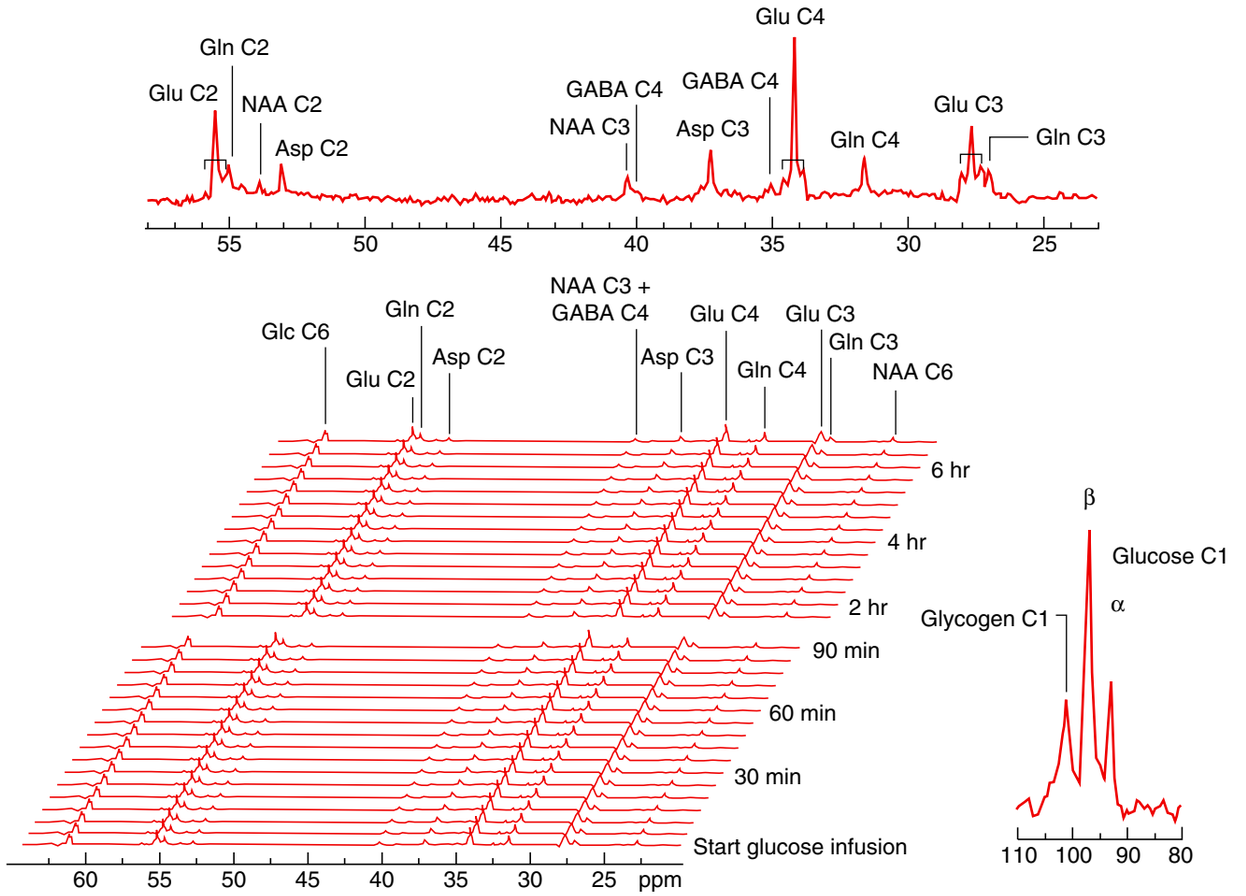

FIGURE 31-10 Cerebral amino acids and carbohydrates incorporate ^{13}C label from infused glucose. The **top panel** shows a ^{13}C NMR spectrum obtained from a gray-matter-rich volume in the human head. (From reference [141].) The **right panel** shows label incorporation into brain glycogen and glucose in humans. (From reference [142].) The **stack plot** illustrates the rate of label incorporation into many compounds and carbons in the rat brain. (From reference [143].) In all studies, glucose labeled at the 1 or 6 position was administered intravenously.

and high-energy phosphates [145]. Determinations of the *N*-acetyl aspartate (NAA), creatine, choline and lactate, and ratios of these compounds are frequently used as indices of the integrity of metabolism and tissue in developing brain [146, 147]. Measurement of high-energy phosphates provides information about the energy status of the brain [145]. These methods, as well as ^{13}C-NMR spectroscopy are used for research and clinically as NMR becomes more widely available.

RELATION OF ENERGY METABOLISM TO PATHOLOGICAL CONDITIONS IN THE BRAIN

Using newer instrumentation, such as PET and NMR, it has been shown that energy metabolism is perturbed in defined brain areas in patients with neurological or psychiatric diseases [145, 146]. Detailed information about pathological conditions that adversely affect brain metabolism can be found in many other chapters of this book. For detailed discussions, see respective chapters: oxidative stress, Chapter 32, hepatic encephalopathy, Chapter 34, psychiatric diseases, Chapters 54 and 55, and imaging techniques, Chapter 58.

ACKNOWLEDGMENT

We would like to acknowledge Donald D. Clarke and Louis Sokoloff for their excellent chapter in the previous volume of this book. We have included parts of that chapter when appropriate. We thank Ian Simpson for his helpful comments and for providing Figure 31-1.

CHAPTER

32

Hypoxic–Ischemic Brain Injury and Oxidative Stress

Laura L. Dugan

Jeong Sook Kim-Han

HYPOXIA–ISCHEMIA AND BRAIN INFARCTION 559
Energy failure, an early consequence of hypoxia–ischemia, causes disruption of ionic homeostasis and accumulation of extracellular neurotransmitters 559
Focal and global ischemia produce different distributions of injury 560
The 'Selective vulnerability' of specific neurons or glial cells is not explained by vascular distribution 562

MICROVASCULAR INJURY IN HYPOXIA–ISCHEMIA 562
Hypoxia–ischemia disrupts the blood–brain barrier and damages endothelial cells 562
Metalloproteinases may be involved in cerebrovascular injury 562
Edema may lead to secondary ischemia, which can produce further brain damage 563
Aquaporins can contribute to brain edema 563

EXCITOTOXIC INJURY IN HYPOXIA–ISCHEMIA 563
Both NMDA and AMPA/kainate receptors contribute to excitotoxic neuronal degeneration of neurons and glia 563
Excitotoxicity leads to increased Ca^{2+} and Zn^{2+}, which can activate cytotoxic intracellular pathways 564
Excitatory amino acid-receptor antagonists can provide neuroprotection in experimental models of hypoxia–ischemia 565

ISCHEMIC APOPTOSIS 565
Hypoxia–ischemia may initiate apoptosis in parallel with excitotoxicity 565
Triggers of ischemic apoptosis may include decreased supply or sensitivity to neurotrophins, oxidative stress, exposure to inflammatory cytokines or damage to mitochondria 566

FREE RADICALS IN HYPOXIA–ISCHEMIA 566
Oxygen free radicals are required intermediates in many biological reactions but may damage macromolecules during oxidative stress 566
Reactive oxygen species generated during ischemia–reperfusion contribute to the injury 567
Mitochondria, nitric oxide synthase and arachidonic acid metabolism are sources of reactive oxygen species during ischemia–reperfusion injury 568
Nitric oxide and peroxynitrite contribute to oxidative damage 569
Production of eicosanoids from polyunsaturated fatty acids such as arachidonic acid may generate reactive oxygen species 570
Brain antioxidant defenses modify ischemia–reperfusion injury 570
Reactive oxygen species may modify both the excitotoxic and the apoptotic components of ischemic brain damage 570

NEUROPROTECTIVE STRATEGIES FOR HYPOXIC–ISCHEMIC INJURY 571
Endogenous protective programs may include ischemic preconditioning and the heat shock response 571
Thrombolytics and drugs targeting several injury pathways have shown efficacy in models of hypoxia–ischemia 571

HYPOXIA–ISCHEMIA AND BRAIN INFARCTION

Hypoxic–ischemic brain injury continues to be the third leading cause of death in the United States, affecting over half a million new victims each year. Of these, nearly one third will die and another third will be left with severe and permanent disability. Unlike ischemic injury to many other tissues, the severity of disability is not predicted well by the amount of brain tissue lost. For example, damage to a small area in the medial temporal lobe may lead to severe disability, such as loss of speech, while damage to a greater volume elsewhere has little effect on function. The degree of disability does not simply reflect the severity or distribution of impaired blood supply. Populations of cells lying side by side in the brain can display dramatically different vulnerabilities to equivalent degrees of ischemia. Although a great deal has been learned about how nervous system anatomy, physiology and biochemistry interact to modify hypoxic–ischemic brain injury, much remains to be learned about what features contribute to the special vulnerability of the brain to stroke and of specific cell populations to hypoxic–ischemic injury during stroke.

Energy failure, an early consequence of hypoxia–ischemia, causes disruption of ionic homeostasis and accumulation of extracellular neurotransmitters. As discussed in Chapter 31, normal energy metabolism in

Basic Neurochemistry: Molecular, Cellular and Medical Aspects
0-12-088397-X

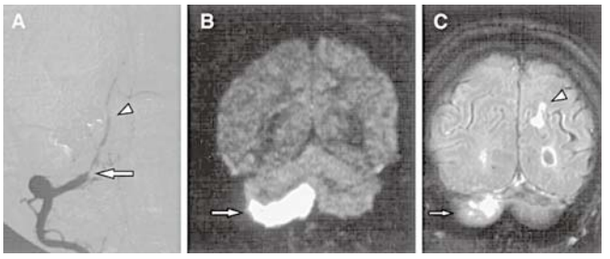

FIGURE 32-1 Focal ischemia produces a core of infarction caused by occlusion of the vessel supplying the affected brain tissue. A 53-year-old man presented with imbalance, various cranial neuropathies and hiccups. (**A**) Angiography revealed high-grade stenosis and clot in his right vertebral artery (*arrow*) and nonfilling (*arrowhead*) of his posterior inferior cerebellar artery (*PICA*). (**B**) Diffusion-weighted magnetic resonance (*MR*) study demonstrates infarction and edema in the right inferior cerebellum (*arrow*), in the distribution of the occluded PICA. (**C**) Fluid-attenuated inversion recovery (*FLAIR*) MR image: in addition to the cerebellar infarct (*arrow*), a small infarct in the left occipital lobe (*arrowhead*) was found, likely resulting from an embolus into the left posterior cerebral artery from plaques in the vertebral artery. (Courtesy of Dr DeWitte Cross, Mallinckrodt Institute of Radiology, Washington University School of Medicine.)

the brain has several unusual features, including a high metabolic rate, limited intrinsic energy stores and critical dependence on aerobic metabolism of glucose. Reflecting this special metabolic status, as well as the existence of several unique injury mechanisms discussed below, the brain exhibits higher vulnerability to ischemic injury than most other tissues. Ischemic brain injury occurs in several clinical settings. The most common is *stroke*, focal disruption of blood supply to a part of the brain (Fig. 32-1). Other settings include transient impairment of blood flow to the entire brain, *global ischemia*, as occurs during cardiac arrest. When brain hypoxia or ischemia occurs, tissue energy demands cannot be met, so ATP levels fall. Loss of ATP results in decreased function of active ion pumps, such as the Na,K-ATPase, the most important transporter for maintaining high intracellular concentrations of K^+ (≈155 mmol/l) and low intracellular concentrations of Na^+ (≈12 mmol/l) (see Ch. 5). Loss of ion pump function allows rundown of transmembrane ion gradients (Fig. 32-2), leading to membrane depolarization, the opening of voltage-sensitive ion channels and a cascade of subsequent events, which, if sustained, lead ultimately to cell death. Depending on the circumstances, this death may be restricted to selectively vulnerable neuronal populations or may involve all cells in a region of brain, termed *tissue infarction*.

Within seconds of an ischemic insult, normal brain electrical activity ceases, as a result of the activation of membrane K^+ channels and widespread neuronal hyperpolarization [1]. The hyperpolarization may be due to opening of K^+ channels responding to acute changes in local concentrations of ATP, H^+ or Ca^{2+}, or it may reflect altered nonheme metalloprotein association with and regulation of specific K^+ channels [2]. This response, presumably protective, however fails to preserve high-energy phosphate levels in tissue as concentrations of phosphocreatine (PCr) and ATP fall within minutes after ischemia onset [3]. The fall in Po_2 during ischemia leads to enhanced lactic acid production as cells undergo a Pasteur shift from a dependence on aerobic metabolism to a dependence on glycolysis. The resulting lactic acidosis decreases the pH of the ischemic tissue from the normal 7.3 to intra-ischemic values ranging from 6.8 to 6.2, depending, in part, on the pre-ischemic quantities of glucose available for conversion to lactic acid. In addition, efflux of K^+ from depolarizing neurons results in prolonged elevations in extracellular $[K^+]$ (Fig. 32-2) and massive cellular depolarization, a state known as *spreading depression*, which can propagate in brain tissue. Rapid inactivation of O_2-sensitive K^+ channels by decreased Po_2 may represent one mechanism whereby neurons put a brake on this ongoing K^+ efflux [2]. Other cellular ion gradients are also lost; thus intracellular Na^+ and Ca^{2+} rise (Fig. 32-3) and intracellular Mg^{2+} falls. Extracellular concentrations of many neurotransmitters are increased during hypoxia–ischemia. Depolarization-induced entry of Ca^{2+} via voltage-sensitive Ca^{2+} channels stimulates release of vesicular neurotransmitter pools, including the excitatory amino acid neurotransmitter glutamate. At the same time, Na^+-dependent uptake of certain neurotransmitters, including glutamate, is impaired (Ch. 5). High capacity uptake of glutamate by the glutamate transporter couples the uptake of one glutamate and two Na^+ with the export of one K^+ and one HCO_3^- (or OH^-) (see Fig. 15–7). When the cellular ion gradients are discharged, the driving force for glutamate uptake is lost. In addition, glutamate uptake by the widely expressed astrocyte high-affinity glutamate transporter GLT-1, or excitatory amino acid transporter-2 (EAAT2), and the neuronal transporter, or EAAT3, can be downregulated by free-radical-mediated oxidation of a redox site on the transporter [4]. Furthermore, since the transporter is electrogenic, i.e. normally transferring a positive charge inward, membrane depolarization can lead to reversal of the transporter, producing glutamate efflux [5]. Thus, both impaired glutamate uptake and enhanced glutamate release contribute to sustained elevations of extracellular glutamate in the ischemic brain. Microdialysis of ischemic rat brain has detected an increase from the resting extracellular glutamate concentrations of 1–2 μmol/l up to concentrations in the high micromolar or even low millimolar range.

Focal and global ischemia produce different distributions of injury. Ischemic injury to the brain can result from several different processes. Focal ischemia, which accounts for a majority of strokes, occurs when an artery supplying a region of the brain is occluded, either by an embolus, which is generally material broken off from a plaque in a large artery or a thrombus in the heart, or by a thrombus or platelet plug that forms directly in the affected artery (Fig. 32-1). While focal ischemic insults generally reflect the distribution of vascular supply to a region, the area of infarction is typically less than the entire distribution of the occluded artery because of the presence of collateral circulation at the borders of the

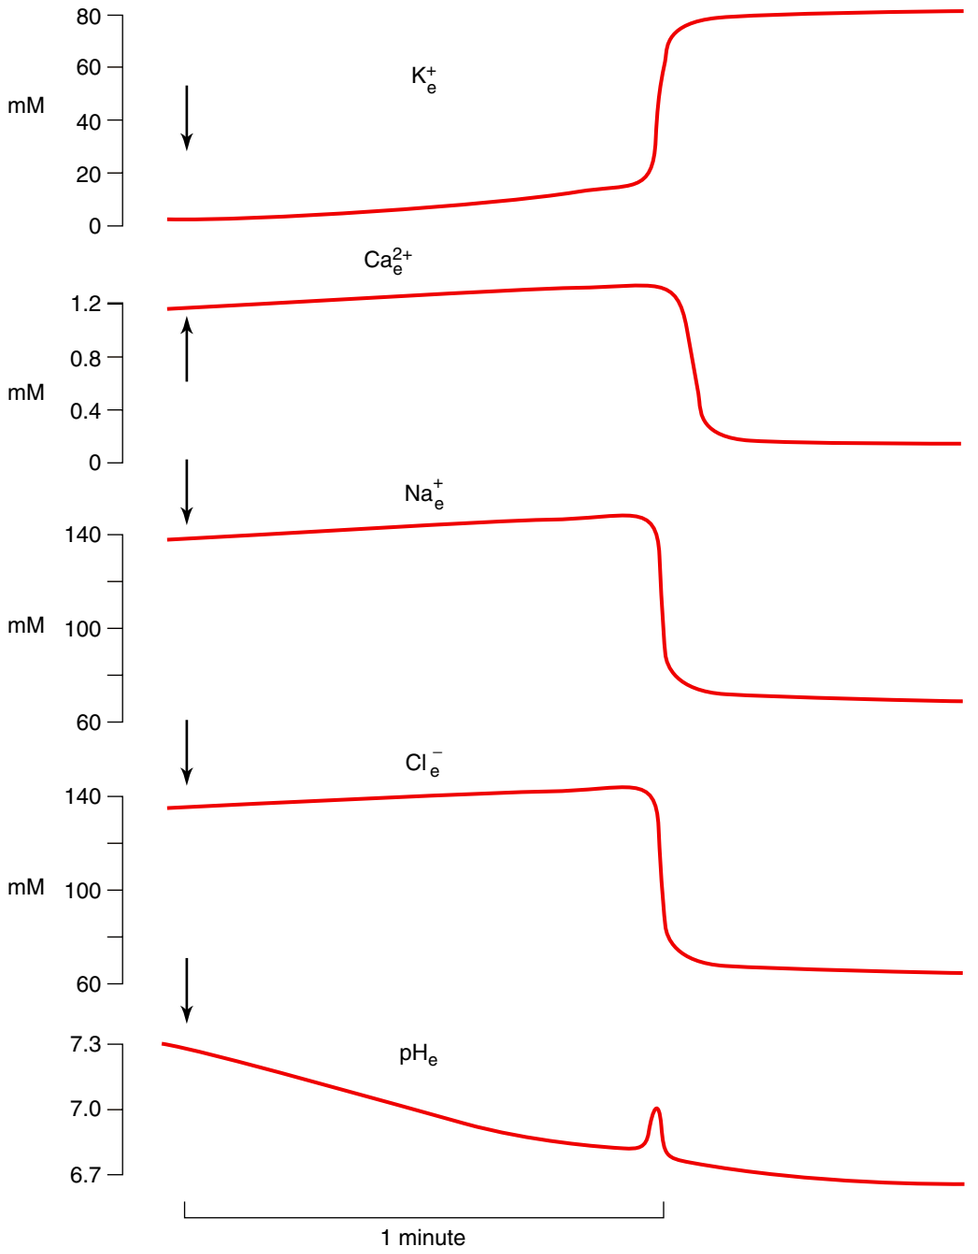

FIGURE 32-2 Changes in extracellular ion concentrations following ischemia. Extracellular pH starts to decrease immediately after the onset of ischemia. This change is accompanied by slight increases in the extracellular concentrations of K^+, Cl^- and Na^+. After about 1 min of ischemia, a dramatic shift of ions occurs, with K^+ leaving cells and Ca^{2+}, Cl^- and Na^+ leaving the extracellular space (from [1] with permission).

region supplied by the occluded vessel. The ultimate area of infarction will depend on the duration and degree of vascular occlusion and the availability of collateral blood supply [6]. The region of the brain supplied uniquely by the occluded artery develops the most severe injury, termed the *ischemic core*, while the rim of tissue surrounding the core, termed the *penumbra*, which has the benefit of some maintained blood flow supplied by collateral circulation, sustains less severe injury. Focal ischemia may also accompany other acute brain insults, such as intracerebral hemorrhage or trauma.

Reversible global ischemia, such as occurs during cardiac arrest and resuscitation, reflects a transient loss of blood flow to the entire brain and generally results in the death of certain selectively vulnerable neuronal populations. Hypoxia accompanies ischemic insults but may also occur without loss of blood flow, for example during near-drowning or carbon monoxide poisoning. Hypoglycemia produces brain injury that has several features in common with ischemic injury. Neurons are more susceptible than glial cells to ischemia, hypoxia or hypoglycemia; and the phylogenetically newer regions of the brain, including the cortex

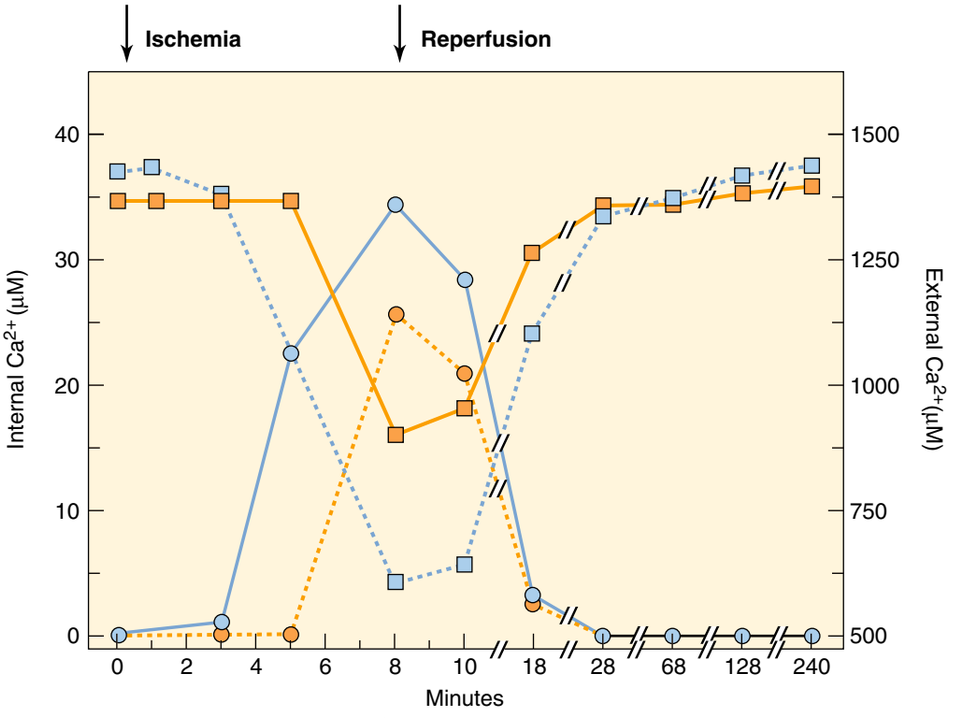

FIGURE 32-3 Changes in intracellular and extracellular Ca^{2+} during ischemia–reperfusion and the effects of the *N*-methyl-D-aspartate receptor antagonist MK-801. Intracellular Ca^{2+}, *circles*; extracellular Ca^{2+}, *squares*; with MK-801, *orange*; without MK-801, *blue*. (From Silver and Erecinska, in [3].)

and cerebellum, are affected to a greater extent than the brainstem [6].

The 'Selective vulnerability' of specific neurons or glial cells is not explained by vascular distribution. As first recognized by Vogt and Vogt (see [6]), the juxtaposition of relatively vulnerable and relatively resistant neuronal populations within a single vascular distribution suggests that intrinsic tissue factors contribute heavily to ischemic neuronal vulnerability. For example, pyramidal neurons in the CA1 subfield of the hippocampus die after 5–10 min of global ischemia, while neurons in the nearby CA3 region are preserved. Populations of neurons that are selectively vulnerable to ischemia include cortical pyramidal neurons, cerebellar Purkinje cells, hippocampal CA1 pyramidal neurons and subpopulations in the amygdala, striatum, thalamus and brainstem nuclei (Fig. 32-4). Some of the mechanisms that may contribute to selective vulnerability of certain cell populations to ischemic injury are discussed further below.

MICROVASCULAR INJURY IN HYPOXIA–ISCHEMIA

Hypoxia–ischemia disrupts the blood–brain barrier and damages endothelial cells. Damage to the blood–brain barrier (BBB), which occurs gradually following ischemia–reperfusion, reflects the vulnerability of the cellular components of the BBB to damage, both directly by the ischemic insult itself and indirectly as a consequence of brain parenchymal responses. Damage to microvascular endothelial cells can lead to vasospasm and promote adhesion of platelets and leukocytes, leading to vessel plugging. Maneuvers that limit the postischemic recruitment of inflammatory cells to the ischemic zone and the subsequent inflammatory response can protect the integrity of the BBB and improve postischemic cerebral blood flow [3]. Transgenic mice that do not express intercellular adhesion molecule (ICAM)-1, a protein that is important in promoting adhesion of leukocytes to endothelial cells (see Ch. 7), are less vulnerable to ischemic injury than littermate controls and have improved cerebral blood flow.

Metalloproteinases may be involved in cerebrovascular injury. Matrix metalloproteinases (MMPs) also contribute to disruption of the blood–brain-barrier during ischemia. MMPs are Zn^{2+} endopeptidases that are secreted as the precursor zymogen, and are then cleaved to the active form of the protein. MMP-2 and MMP-9 are type IV collagenases that have been shown to degrade the perivascular extracellular matrix following ischemia, causing disruption of the BBB. Inhibition of MMPs limits BBB opening and decreases edema formation following ischemia [7]. More recently, MMPs have been suggested to have a role in promoting hemorrhagic transformation after stroke, especially in the context of tissue plasminogen activator administration as thrombolytic therapy to stroke patients [8].

FIGURE 32-4 Rat hippocampus showing neuronal populations that are selectively vulnerable to ischemic damage. (**A**) control; (**B**) ischemia. A brief period of global ischemia causes nearly complete loss of neurons in the CA1 region (*arrows*) of the hippocampus, while neurons in the nearby CA3 region are almost completely spared. (Courtesy of Dr Chung Y. Hsu, Washington University School of Medicine.)

Besides increased ischemia, another consequence of damage to the endothelial cells or astrocytes that comprise the BBB may be the entry of components of the vascular compartment, such as cytokines and inflammatory cells, to the brain parenchyma. Agents that protect endothelial cells, such as antioxidants, can help preserve BBB integrity following ischemia–reperfusion [9]. The response of nonvascular or parenchymal cells to the ischemic insult also affects BBB function. For example, *N*-methyl-D-aspartate (NMDA) receptor antagonists, which reduce neuronal death and tissue infarction after focal ischemia (see below), decrease BBB disruption, possibly by blocking neuronal production of reactive oxygen species (ROS) triggered by NMDA receptor activation, thus reducing their deleterious effects on endothelial or astrocyte cell function.

Edema may lead to secondary ischemia, which can produce further brain damage. As a result of the breakdown of the BBB after ischemia, the tissue content of water in the affected area of the brain may increase, leading to swelling or edema of the ischemic region. Some of the increased tissue water is intracellular, reflecting impaired cellular ion homeostasis due to energy failure, as well as the action of glutamate, which triggers excess cation influx in neurons and glia (Ch. 15). Some of the increased tissue water is extracellular, because of breakdown of the BBB followed by leakage of solute and water from the intravascular space.

Aquaporins can contribute to brain edema. Recently, aquaporins have been implicated in edema formation after ischemia. Aquaporins are small, homotetrameric membrane channels that mediate rapid water flux through cell membranes. The main aquaporin in brain, AQP4, is assembled into multimeric square arrays (orthogonal arrays) in astrocyte foot process membranes adjacent to capillary basement membranes. Like AQP1, AQP4 is constitutively active and is therefore believed to be involved in normal regulation of brain water flux. However, AQP4 knockout mice develop less postischemic edema and smaller infarcts than littermate controls, suggesting that AQP4 may contribute to early edema formation during ischemia–reperfusion injury [10]. Finally, because tissue edema in the rigid intracranial cavity can restrict blood flow, secondary ischemia can ensue. If edema is substantial enough, uncal or central brainstem herniation may result, leading to respiratory arrest and death.

EXCITOTOXIC INJURY IN HYPOXIA–ISCHEMIA

Both NMDA and AMPA/kainate receptors contribute to excitotoxic neuronal degeneration of neurons and glia. Excitotoxicity (toxic glutamate receptor activation) is a key mediator of central neuronal loss consequent to hypoxic–ischemic insults [11]. While brain gray matter contains glutamate concentrations in the average range of 10 mmol/l, much of which is stored in synaptic vesicles for release as a neurotransmitter, the extracellular concentration of glutamate is normally maintained in the range of ≈1 μmol/l by Na^+-flux-coupled transport (see Ch. 5). During hypoxia–ischemia, as cellular energy reserves and Na^+ gradients fall, increased release and impaired uptake of glutamate mediate a toxic buildup of extracellular glutamate, leading to overstimulation of glutamate receptors and consequent neuronal cell death. Excitotoxicity can be exacerbated by decreased cellular energy stores.

In vitro studies on excitotoxicity suggest that while both NMDA and α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA)/kainate (KA) receptors can mediate excitotoxicity (see Ch. 15), these classes of glutamate receptors do not do so equally. Experiments with cortical or hippocampal cell cultures suggest that much of the neuronal death associated with brief, intense glutamate exposure is mediated by NMDA receptor activation, probably because this can induce lethal amounts of Ca^{2+} influx more rapidly than can AMPA/KA receptor stimulation.

However, overactivation of AMPA or KA receptors can also lead to intracellular Ca^{2+} overload and neurodegeneration. This may be especially true under conditions where NMDA-receptor activity is reduced by extracellular acidity or a buildup of extracellular Zn^{2+} [12]. It is also true with respect to specific neuronal subpopulations that express AMPA-sensitive Ca^{2+} channels (see Ch. 15). G-protein-linked metabotropic glutamate receptors (mGluRs) appear not to mediate excitotoxicity directly but, rather, to modify the degree of excitotoxic injury.

Excitotoxicity leads to increased Ca^{2+} and Zn^{2+}, which can activate cytotoxic intracellular pathways. The prolonged availability of extracellular glutamate during hypoxia–ischemia is transduced by neuronal membrane receptors into potentially lethal intracellular ionic derangements, in particular, intracellular Na^+ and Ca^{2+} overload. Excitotoxic neuronal cell death, which tends to occur by necrosis, correlates well with measures of total Ca^{2+} influx, and removal of extracellular Ca^{2+} attenuates glutamate-induced neuronal death. Sustained elevations in intracellular Ca^{2+} can initiate 'toxic cascades', which are capable of ultimately killing the cell (Fig. 32-5). These cascades include activation of catabolic enzymes, such as proteases, phospholipases and endonucleases [13]. Elevated concentrations of intracellular Ca^{2+} can further lead to initiation of protein-kinase and lipid-kinase cascades (Ch. 22), impairment of metabolism and generation of ROS. While many of these events occur early and can result in rapid cell death, others, such as energy compromise and ROS formation, may initiate more delayed death processes, discussed in more detail in the next section. In addition, most of these Ca^{2+}-dependent events may be common to both NMDA- and AMPA/KA-receptor-mediated excitotoxicity.

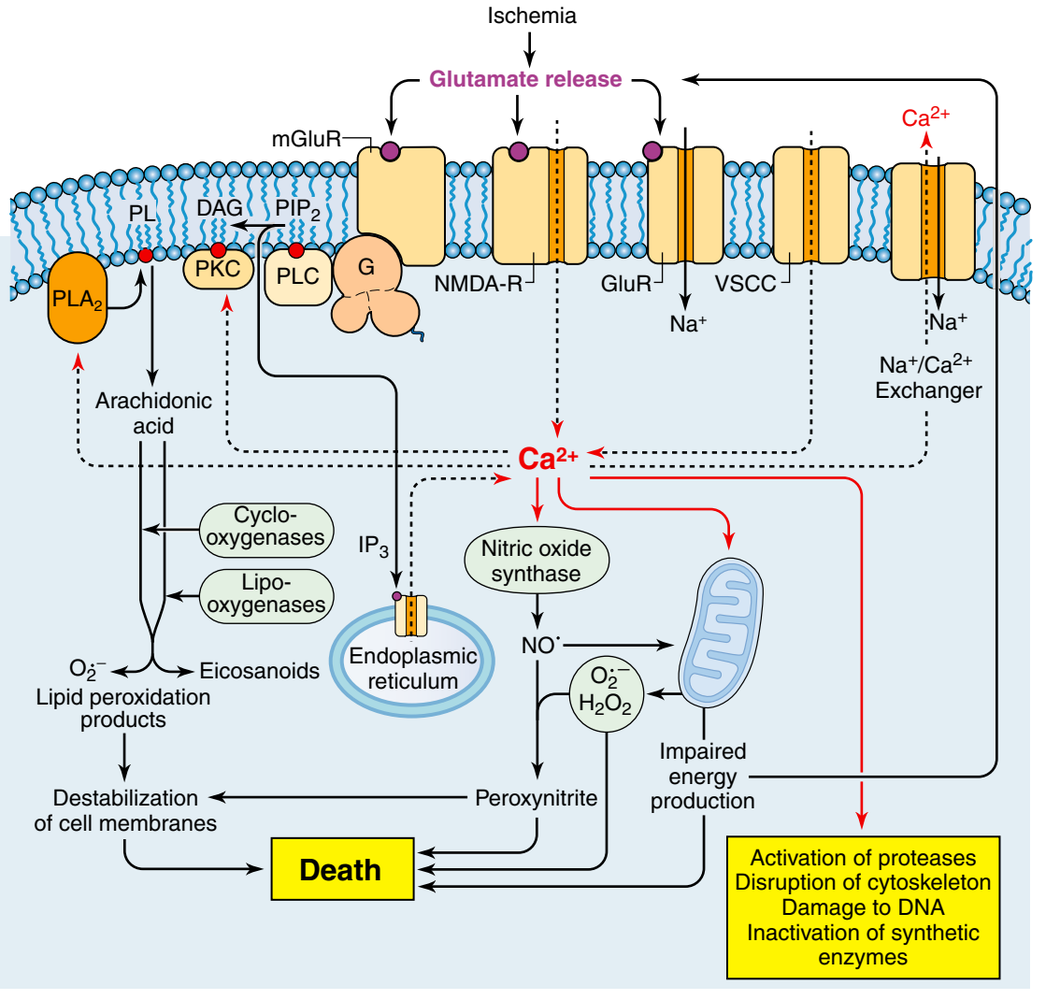

FIGURE 32-5 Mechanisms contributing to neuronal injury during ischemia–reperfusion. Simplified diagram showing several pathways believed to contribute to excitotoxic neuronal injury in ischemia. *DAG*, diacylglycerol; *G*, G protein; *GluR*, AMPA/Kainate type of glutamate receptors; H_2O_2, hydrogen peroxide; IP_3, inositol 1,4,5-trisphosphate; *mGluR*, metabotropic glutamate receptor; *NMDA-R*, *N*-methyl-D-aspartate receptor; $NO^{\cdot}$, nitric oxide; $O^{\cdot-}_2$, superoxide radical; PIP_2, phosphatidylinositol 4,5-bisphosphate; *PKC*, protein kinase C; *PL*, phospholipids; PLA_2, phospholipase A_2; *PLC*, phospholipase C; *VSCC*, voltage-sensitive Ca^{2+} channel.

Ca^{2+}-dependent activation of the cysteine protease calpain occurs early in ischemia and may lead to disruption of the cytoskeleton [3]. Endonuclease activation can be triggered by influx of large amounts of Ca^{2+}, which may lead to DNA breakdown during hypoxia–ischemia [14]. Increased intracellular Ca^{2+} also activates a variety of protein kinases. In particular, Ca^{2+}/calmodulin kinase (CaMK) and the classical Ca^{2+}-dependent isoforms of protein kinase C (PKC) can modify the function of many ion channels, including NMDA- and AMPA/KA- receptor-gated channels and voltage-gated Ca^{2+} channels [15]. An especially important deleterious consequence of Ca^{2+} overload following excitotoxic glutamate receptor activation is formation of ROS. Free radical production is linked to elevated $[Ca^{2+}]i$ in several ways: (1) Ca^{2+}-dependent activation of phospholipase A2, with liberation of arachidonic acid and further metabolism, leading to 'by-product' free radical production and lipid peroxidation (see Chs 3 and 33); (2) stimulation of NMDA receptors, leading to activation of nitric oxide synthase (NOS) and the release of nitric oxide (NO), which can then interact with ROS from other sources to generate highly reactive peroxynitrite [16]; and (3) dysfunction of the mitochondrial electron transport chain, enhancing mitochondrial production of free radicals [17]. Activation of NMDA receptors triggers Ca^{2+}-dependent production of ROS from the mitochondrial electron-transport chain, although the exact mechanism behind this process is still not well understood. In cell cultures, ROS production is stimulated by concentrations of NMDA that are not neurotoxic and, in awake rats, NMDA receptors are responsible for a low baseline production of ROS, suggesting that even 'physiological' NMDA receptor activity may trigger production of ROS. However, cell culture studies suggest that substantially greater amounts of mitochondrial ROS are generated when NMDA receptors are overstimulated sufficiently to produce excitotoxicity. Since AMPA/KA receptor activation, possibly in conjunction with the group 1 metabotropic glutamate receptors (see Ch. 15), may also elicit enhanced mitochondrial ROS production, it is likely that excitotoxicity may be an important trigger for mitochondrial free radical production in ischemia–reperfusion injury. Supporting the idea that free radicals are important downstream mediators of excitotoxicity, treatment with free radical scavengers can attenuate NMDA- or AMPA-receptor-mediated neuronal death.

Excitatory amino acid-receptor antagonists can provide neuroprotection in experimental models of hypoxia–ischemia. Supporting the glutamate hypothesis of hypoxic–ischemic brain damage, substantial evidence indicates that antagonists of ion channel-linked glutamate receptors can reduce infarct volume in animal models of focal brain ischemia. This is true both for NMDA antagonists and for AMPA/KA antagonists [11]. The magnitude of infarct reduction is model-dependent but is typically on the order of 25–30%, and the reduction can exceed 50%.

An additional injury mechanism, ischemic apoptosis (discussed below), may evolve in parallel with excitotoxic necrosis, but apoptosis has little chance to be manifested under circumstances in which fulminant excitotoxicity predominates. Evidence favoring the concurrence of apoptosis and necrosis can be found in the observation that the application of an NMDA antagonist drug together with a drug designed to inhibit apoptosis leads to greater neuroprotection than does either drug treatment alone. Each agent alone, administered at optimal doses systemically just after the ischemic insult, reduces infarction by about half, but combination therapy can reduce infarct volume by as much as 80%.

Growing evidence suggests that, in addition to Ca^{2+}, the ubiquitous metal ion Zn^{2+} may contribute to neuronal injury during cerebral ischemia-hypoxia. Zn^{2+} is necessary for the proper function of many metalloenzymes and transcription factors. In the nervous system, Zn^{2+} appears to serve an additional function as a mediator of central neural signaling [12]. Low concentrations of Zn^{2+} can modify the function of Na^{+}, K^{+} and Ca^{2+} channels as well as certain subtypes of $GABA_A$ receptor, and Zn^{2+} strongly attenuates activation of the NMDA subclass of glutamate receptors. Free Zn^{2+} is present in synaptic vesicles within excitatory boutons throughout the brain, and the neuropil of the hippocampus and neocortex is especially rich in releasable pools of Zn^{2+}. Neuronal firing causes a Ca^{2+}-dependent release of Zn^{2+}; with intense neuronal activity, it has been estimated that Zn^{2+} concentrations of several hundred micromoles per liter could be achieved in synaptic clefts. A pathogenic role for Zn^{2+} in ischemic brain damage has been suggested, based on the following observations: presynaptic Zn^{2+} translocates into selectively vulnerable hippocampal hilar neurons, which degenerate after transient forebrain ischemia, and into limbic or cortical neurons, which degenerate after seizures induced by KA or perforant path stimulation; and chelation of extracellular Zn^{2+} by Ca^{2+}-EDTA reduces selective neuronal death in multiple regions of rat brain in an experimental model of transient global ischemia [18].

ISCHEMIC APOPTOSIS

Hypoxia–ischemia may initiate apoptosis in parallel with excitotoxicity. In 1972, Wyllie and colleagues (see [19]) described two distinct patterns of cell death. One form, apoptosis, progressed through a set of morphological changes characterized by condensation and margination of large nuclear chromatin aggregates and extrusion of membrane-bound cytoplasmic and nuclear material, termed apoptotic bodies, with progressive loss of cell volume. Since these features were prominent in cells dying by programmed cell death during normal development, the concept emerged that apoptosis reflects the execution of a death 'program', in many cases requiring new protein synthesis. The mechanisms underlying apoptosis are

outlined in more detail in Chapter 35. As discussed above, growing evidence has implicated not only excitotoxicity but also apoptosis as important processes leading to brain cell death after hypoxic–ischemic insults. Inhibitors of macromolecular synthesis and of caspase activity can limit apoptotic death of neurons exposed to hypoxia–ischemia. In addition, transgenic mice overexpressing the antiapoptotic gene *bcl*-2 have smaller infarcts than their littermates after hypoxia–ischemia. Intrinsic mechanisms of neural cell apoptosis are discussed in more detail in Chapters 27 and 35.

Triggers of ischemic apoptosis may include decreased supply or sensitivity to neurotrophins, oxidative stress, exposure to inflammatory cytokines or damage to mitochondria. One factor that may promote apoptosis after ischemic insults is deprivation of growth factor support. Deprivation may result from damage to neuronal or glial targets responsible for providing growth factor support. However, tissue concentrations of several growth factors increase in the brain following hypoxic–ischemic insults, suggesting that either there may be decreased sensitivity of neurons to neurotrophins after ischemia, or increased concentrations of neurotrophins are required to counter pro-apoptotic stimuli, such as free-radical exposure. Addition of exogenous growth factors, such as nerve growth factor (NGF) or basic fibroblast growth factor (bFGF) (see Ch. 27) [20], can reduce hypoxic–ischemic damage. However, while neurotrophins may attenuate ischemic apoptosis, they may, in contrast, have deleterious effects by enhancing the excitotoxic necrosis induced by ischemia.

In addition, oxidative stress may trigger apoptosis following hypoxia–ischemia. Exposure of neurons to a free radical stress, either by application of H_2O_2, exposure to ultraviolet irradiation or depletion of antioxidant defenses, such as glutathione or superoxide dismutase (SOD; see below), may trigger apoptosis. Free radicals not only may serve as inducers of apoptotic cell death, they may also be a signal in the apoptotic cascade: neurons deprived of growth factors demonstrate an early increase in oxygen free radical formation and can be rescued from growth factor deprivation-induced apoptosis by application of antioxidants [21]. Thus, free radicals may serve as triggers, signals or effectors of neuronal apoptosis.

Persistent impairment of cellular energy metabolism after an ischemic insult may also play a role in triggering apoptotic neuronal degeneration. Studies in cell culture and animal models of stroke suggest that inhibition of mitochondrial function by mitochondrial toxins such as 3-nitropropionic acid or rotenone not only worsens excitotoxic injury but also can trigger apoptotic neuronal death. Prolonged deficits in mitochondrial function and energy metabolism have been observed after ischemia–reperfusion and may represent a trigger for apoptotic neurodegeneration after ischemia.

Increased expression and enhanced concentrations of inflammatory cytokines, such as interleukin (IL)-1β, tumor necrosis factor (TNF)α and transforming growth factor (TGF)β, are observed in brain following ischemia and may derive from inflammatory cells, such as macrophages or microglia, as well as neurons and glia. Because cytokines are capable of triggering apoptosis in many cell types, including neurons, increased concentrations of these molecules might be expected to trigger apoptotic cell death in vulnerable cells. Thus, ischemic apoptosis may be induced by free radicals, cytokines, metabolic insults and changes in growth factor sensitivity, which may result from excitotoxic damage to intracellular systems such as the cytoskeleton, axonal transport, and mitochondria.

FREE RADICALS IN HYPOXIA–ISCHEMIA

The brain has a number of characteristics that make it especially susceptible to free- radical-mediated injury. Brain lipids are highly enriched in polyunsaturated fatty acids and many regions of the brain, for example, the substantia nigra and the striatum, have high concentrations of iron. Both these factors increase the susceptibility of brain cell membranes to lipid peroxidation. Because the brain is critically dependent on aerobic metabolism, mitochondrial respiratory activity is higher than in many other tissues, increasing the risk of free radical 'leak' from mitochondria; conversely, free radical damage to mitochondria in brain may be tolerated relatively poorly because of this dependence on aerobic metabolism.

Oxygen free radicals are required intermediates in many biological reactions but may damage macromolecules during oxidative stress. Free radicals are molecules that possess an outer electron orbital with a solitary unpaired electron; these include the hydrogen atom ($H^{\cdot}$); the diatomic oxygen molecule O_2, which possesses two unpaired electrons with the same spin in two separate orbitals; $NO^{\cdot}$; superoxide ($O_2^{\cdot -}$); hydroxyl radical ($^{\cdot}OH$); and transition metals, such as copper and iron. While O_2 qualifies as a radical by having two unpaired electrons, its reactivity with nonradical compounds is limited because the unpaired electrons in O_2 have the same spin state. The two electrons in a covalent bond have opposite spins so, in order for O_2 to react with a nonradical, one of the electrons must undergo 'spin inversion' so that both are antispin to the electrons on O_2, an extremely slow process. O_2 does react readily with radicals, accepting one electron at a time to form the very reactive superoxide radical $O_2^{\cdot -}$, which has one unpaired electron [22].

Although some radical species may persist for prolonged periods, most are generally unstable and will attempt to donate their unpaired electron to a nearby molecule or to remove or 'abstract' a second electron, usually in the form of a hydrogen atom, from a neighboring molecule to pair with their free electron. Free-radical reactions are intrinsic to a majority of the metabolic and

synthetic reactions carried out by eukaryotic cells and, as such, are required for life. ATP production by the mitochondrial electron chain, for example, uses a controlled set of oxygen radical reactions to couple the reduction of free-radical electrons with the movement of protons across the mitochondrial membrane. Cytochrome oxidase, complex IV of the mitochondrial electron transport chain (see Ch. 31), catalyzes transfer of these free electrons to molecular oxygen as the final acceptor with water as the end product.

The addition of O_2 to macromolecules, such as in the metabolism of arachidonic acid to eicosanoids or oxidation of small molecules by P450 enzymes, requires 'activation' of molecular oxygen to permit transfer of atomic oxygen ($O^{\cdot}$) from O_2 to the biological compound. Most enzymes that catalyze biological radical reactions bind a metal ion (Fe, Cu, Co or the group VI element Se), which destabilizes the O_2 molecule. These reactions also involve cofactors such as flavin adenine dinucleotide or flavin mononucleotide to help stabilize the resulting oxygen atoms until the reaction is complete.

Although such reactions are generally very efficient, there is often some small amount of leak of ROS, including radicals such as $O_2^{\cdot-}$, its acid HO_2, hydroxyl radical ($^{\cdot}OH$) and $NO^{\cdot}$, as well as nonradicals such as hydrogen peroxide (H_2O_2), singlet oxygen ($^1O\Delta g$) and hypochlorous acid (HOCl).

While H_2O_2 is not a free radical, it can be rapidly decomposed via the *Fenton reaction*:

$$Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + {}^{\cdot}OH + OH^-$$

In addition, superoxide, hydrogen peroxide and hydroxyl radicals can be interconverted via the so-called *Haber–Weiss reaction*:

$$Fe^{3+} + O_2^{\cdot-} \rightleftharpoons Fe^{2+} + O_2$$
$$Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + {}^{\cdot}OH + OH^-$$
$$O_2^{\cdot-} + H_2O_2 \rightarrow {}^{\cdot}OH + OH^- + O_2$$

Cuprous and cupric ions may substitute for ferrous and ferric ions in the Haber–Weiss reaction [22]. Peroxynitrite can be formed from the reaction of $NO^{\cdot}$ with $O_2^{\cdot-}$:

$$NO^{\cdot} + O_2^{\cdot-} \rightarrow ONOO^- \rightarrow NO_2^{\cdot-} + {}^{\cdot}OH$$

Oxidative stress generally describes a condition in which cellular antioxidant defenses are inadequate to completely detoxify the free radicals being generated, because of excessive production of ROS, loss of antioxidant defenses or, typically, both [23]. This condition may occur locally, as antioxidant defenses may become overwhelmed at certain subcellular locations while remaining intact overall, and selectively with regard to radical species, as antioxidant defenses are radical-specific – for example SOD for superoxide and catalase or glutathione peroxidase for H_2O_2.

A major consequence of oxidative stress is damage to cellular macromolecules. Addition of a free radical electron to a fatty acid causes fragmentation of the lipid or alteration of its chemical structure (Fig. 32-6). For example, the unconjugated *cis* double bonds in unsaturated fatty acids may be shifted to produce a conjugated *trans* double bond system (see Ch. 3). Peroxyl or hydroxyl groups may be added to the unsaturated fatty acid, or the fatty acid carbon chain may be cleaved during reaction with the free electron to generate a fatty aldehyde, both processes termed *lipid peroxidation*. Fatty aldehydes such as 4-hydroxynonenal can then react with free thiol groups such as cysteines on proteins to produce thioesters, which may affect protein function and stability [22]. Free-radical damage to proteins may cause cross-linking, carbonyl formation and protein denaturation. DNA bases may be modified by oxidation, resulting in single- and double-strand breaks or mispairing of purine and pyrimidine during DNA replication.

Reactive oxygen species generated during ischemia–reperfusion contribute to the injury. Evidence for free radical production and oxidative stress during ischemia–reperfusion comes from a variety of studies. While free radicals may be generated to a small extent during ischemia, far greater production of reactive oxygen intermediates occurs after reintroduction of oxygen during reperfusion. Early studies with animal models of ischemia–reperfusion injury showed decreased brain concentrations of antioxidants such as ascorbic acid, vitamin E and glutathione, as well as production of aldehydic lipid peroxidation products, detected as thiobarbituric acid-reactive substances. Additional evidence for ROS generation has been obtained with intra-ischemic microdialysis with solutions containing salicylic acid or spin-trapping agents, which react with ROS to form relatively stable products that can be detected in the microdialysis solution, or with oxidation-sensitive fluorescent probes, such as dihydroethidine, which detects superoxide radical. Oxidative damage to macromolecules has provided another index of ROS-mediated injury in ischemia–reperfusion. Lipid- and protein-oxidation products, as well as DNA-oxidation products, have been detected in brain tissue after ischemia–reperfusion.

Treatment with antioxidants such as vitamin E, 21-aminosteroids, and spin-trapping agents such as phenyl tert-butyl *N*-nitrone (PBN), can reduce ischemic brain infarction. In addition, transgenic mice that overexpress the cytosolic antioxidant enzyme CuZn-SOD (SOD1; see below) [24] or the extracellular SOD3 [25] are resistant to ischemic brain injury compared to wild-type controls. Conversely, reduction of cellular antioxidant defenses can potentiate ischemic injury. Transgenic mice that are *SOD1*$^{-/-}$ exhibit enhanced susceptibility to ischemic brain injury, even though they have a grossly normal CNS phenotype under unstressed conditions, for example in the absence of ischemia or nerve transection. This suggests that other antioxidant defenses are adequate to handle physiological concentrations of cytosolic superoxide anion.

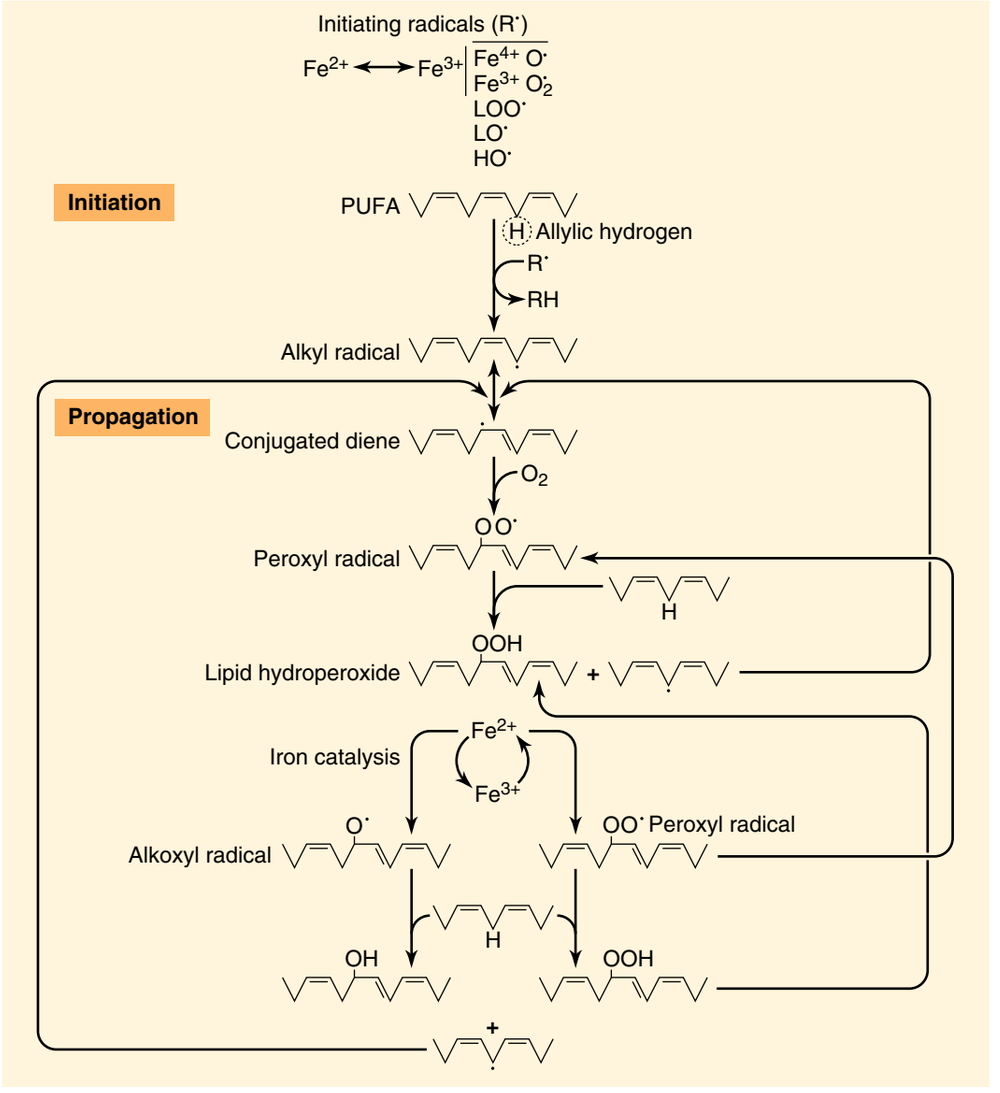

FIGURE 32-6 Lipid peroxidation leads to fragmentation or oxidation of polyunsaturated fatty acids (PUFA). *HO·*, hydroxyl radical; *LO·*, lipid alkoxylradical; *LOO·*, lipid peroxyl radical; $O^{\cdot-}_2$, superoxide radical; *O·*, atomic oxygen radical. (From Hall in [3].)

In contrast, mice lacking the mitochondrial antioxidant enzyme Mn^{2+}-SOD (SOD2) die soon after birth, and mice that are heterozygous for the *sod2* gene, which exhibit half the SOD2 activity of wild-type mice, have larger areas of infarction after focal ischemia. A large body of literature now links oxidative stress, produced by both increased production of ROS and impaired defenses against ROS, to ischemic injury (reviewed in [24]).

Mitochondria, nitric oxide synthase and arachidonic acid metabolism are sources of reactive oxygen species during ischemia–reperfusion injury. ROS generation during ischemia–reperfusion may come from several sources, including NOS activity, mitochondrial electron transport, multiple steps in the metabolism of arachidonic acid and, in some species, xanthine oxidase, which is produced by hydrolysis of xanthine dehydrogenase. In addition, the decreased intracellular pH accompanying ischemia may alter the binding of transition metals such as iron, increasing their participation in the Haber–Weiss reaction [22]. P450 enzymes and NAD(P)H oxidase are two additional potential sources of oxygen radicals whose contribution to enhanced radical production during CNS ischemia has not been systematically explored. Mitochondria were among the earliest sites of cellular ROS production to be identified. Studies on isolated mitochondria have suggested that as much as 3–4% of O_2 utilized by resting mitochondria may be leaked as superoxide and H_2O_2. Mitochondrial production of ROS can be enhanced by increased electron-transport activity, as well

as by disturbances in electron transfer down the transport chain. The lipid electron-transport molecule ubiquinone (Q9, Q10) is the major site of free radical leak from mitochondria via the ubiquinone cycle. Ubiquinone undergoes a two-electron reduction, first to a semiquinone and then to a diol, at mitochondrial complex I (NADH dehydrogenase, NADH:ubiquinone oxidoreductase) or complex II (succinate dehydrogenase) and subsequently delivers the two electrons to the iron–sulfur center of complex III (cytochrome bc1 in mammalian mitochondria). Inhibition of either complex I or complex III will impair the efficiency of electron transfer and may allow a free semiquinone to be produced. The semiquinone can then interact with O_2 to generate $O_2^{\cdot-}$ (Fig. 32-7). Elevated intracellular Ca^{2+}, exposure to fatty acids or other molecules that alter the physical properties of the mitochondrial membrane and inhibition of mitochondrial respiratory components may enhance this leak of ROS from mitochondria. Mitochondria appear to be an important and perhaps dominant source of free radicals in brain tissue subjected to ischemia–reperfusion. Microdialysis studies using salicylate to detect ROS release from ischemic brain cortex show that mitochondrial inhibitors such as rotenone eliminate ROS production during ischemia–reperfusion. Elevated concentrations of intracellular Ca^{2+} and Na^+, a consequence of energy failure and excitotoxic glutamate receptor stimulation, can be expected to inhibit complex I as well as overproduction of superoxide anion. The resultant oxidative stress may lead to further inhibition of mitochondrial respiratory components, promoting further free radical production in a vicious, feed-forward cycle. Although xanthine oxidase has been implicated in animal models of ischemia, its role in human stroke is less clear.

Nitric oxide and peroxynitrite contribute to oxidative damage. As discussed above, NOS has been identified as a source of ROS with special relevance to pathological conditions. NOS is homologous to P450 cytochrome *c* reductase; cofactors in the reaction are flavin mononucleotide, flavin adenine dinucleotide, tetrahydrobiopterin and NAD(P)H (Fig. 32-7). NOS normally converts arginine and molecular oxygen to citrulline and $NO^{\cdot}$, a free radical gas; this process is itself leaky and associated with free radical generation [16]. $NO^{\cdot}$, originally identified as endothelial-derived relaxing factor (EDRF), is a potent vasodilator. $NO^{\cdot}$ also binds to guanylyl cyclase to increase GTP production and can nitrosylate the small G protein Ras on a specific cysteine to cause constitutive activation. Three family members have been identified: Ca^{2+}/calmodulin-activated brain NOS (nNOS), endothelial NOS (eNOS) and inducible NOS (iNOS). High concentrations of nNOS are found in a subpopulation of neurons previously identified as NAD(P)H-diaphorase cells. $NO^{\cdot}$, which has limited radical reactivity, can combine readily with $O_2^{\cdot-}$ and possibly H_2O_2 to produce a highly oxidizing, nonradical compound, peroxynitrite [16]. When protonated, peroxynitrite has reactivity similar to that of $^{\cdot}OH$. Cell culture studies suggest that, while $NO^{\cdot}$ itself is relatively nontoxic, peroxynitrite is quite neurotoxic. Peroxynitrite reacts

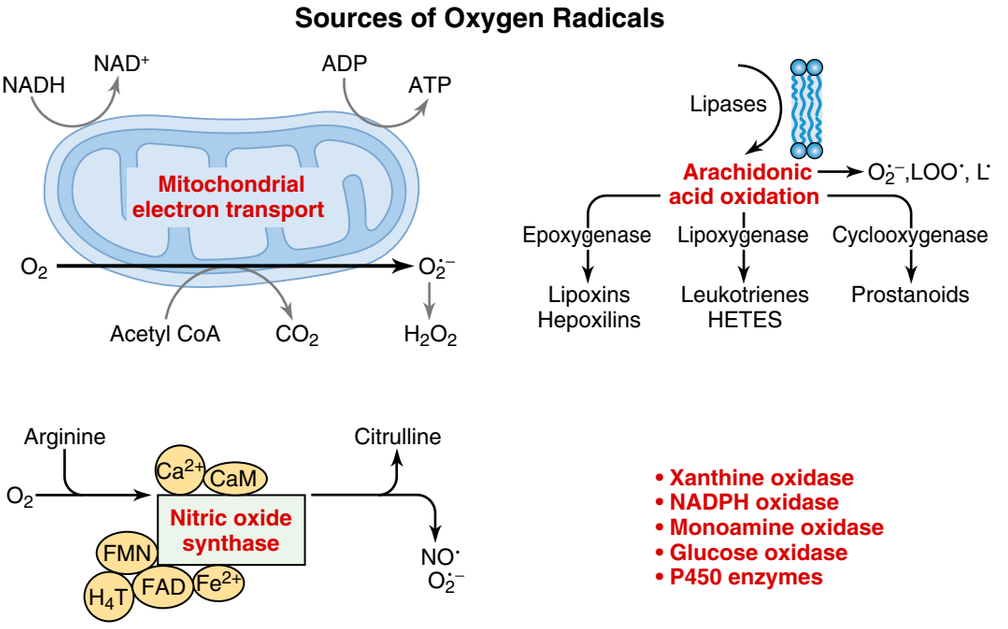

FIGURE 32-7 Sources of free radical formation which may contribute to injury during ischemia–reperfusion. Nitric oxide synthase, the mitochondrial electron-transport chain and metabolism of arachidonic acid are among the likely contributors. *CaM*, calcium/calmodulin; *FAD*, flavin adenine dinucleotide; *FMN*, flavin mononucleotide; H_4T, tetrahydrobiopterin; *HETES*, hydroxyeicosatetraenoic acids; *L·*, lipid alkoxyl radical; *LOO·*, lipid peroxyl radical; *NO·*, nitric oxide; $O^{\cdot-}_2$, superoxide radical.

with protein tyrosine residues to produce nitrotyrosine. Potential targets of tyrosine nitrosylation include many important cellular proteins, including Cu,Zn-SOD, aconitase, Mn-SOD and cytochrome oxidase (mitochondrial complex IV), all of which are inactivated by nitrosylation. Peroxynitrite may cause lipid peroxidation but may also generate nitrosolipids, which decrease lipid peroxidation by acting as peroxidation 'chain-breakers'. In addition, peroxynitrite targets DNA, leading to chain breaks and DNA base oxidation. Involvement of nNOS as a mediator of ischemic injury is suggested by the ability of nNOS inhibitors to reduce ischemic injury and by the neuroprotective effect of nNOS gene deletion in knockout mice. Peroxynitrite-mediated DNA damage can activate poly (ADP-ribose) polymerase (PARP or PARS), an enzyme involved in DNA repair. It has been suggested that activation of PARP-1 contributes to ischemic injury by causing release of apoptosis-inducing factor (AIF) from mitochondria, with subsequent entry of AIF into the nucleus to promote components of the nuclear changes associated with apoptosis [26]. Pharmacological studies *in vitro* and experiments with PARP knockout mice have suggested that inhibition of PARP provides substantial neuroprotection against ischemic neuronal injury. Another potentially neuroprotective agent may be hydrogen sulfide which, although a toxic gas, is present physiologically in brain in 10–150 μM concentrations and has been shown to inhibit peroxynitrite-mediated tyrosine nitration and inactivation of α_1 antiproteinase and peroxynitrite-induced cytotoxicity, protein nitration and oxidation in human neuroblastoma SH-SY5Y cells [26a]. H_2S also has been shown to protect neurons against glutamate-induced stress in primary cultures of embryonic rat cortical neurons via increasing levels of glutathione, which is an important anti-oxidant (see below) [26b].

Production of eicosanoids from polyunsaturated fatty acids such as arachidonic acid may generate reactive oxygen species. Arachidonic acid metabolism may also be a source of ROS production [27]. As discussed in Chapters 3 and 33, arachidonic acid undergoes an extensive array of reactions to biologically active lipids, the eicosanoids. These reactions may be accompanied by free-radical production. In particular, cyclooxygenase isoforms and 5-lipoxygenase contain heme iron and may generate a low concentration of superoxide anion constitutively. 12-lipoxygenases, which possess nonheme iron, may not release superoxide anion but may induce lipid peroxidation after translocation to membranes.

Brain antioxidant defenses modify ischemia–reperfusion injury. The high metabolic rate of brain cells implies a high baseline ROS production, and brain cells possess high concentrations of both enzymatic and small-molecule antioxidant defenses. SOD1 may represent as much as 1% of total protein in brain; it converts $O_2^{\cdot-}$ to H_2O_2, which is then further metabolized to water and oxygen by catalase and glutathione peroxidase. The SOD1 gene is located on chromosome 21 and codes for a 16–18 kDa subunit that binds one Cu^{2+} and one Zn^{2+}; the active enzyme is a homodimer. SOD2 is a homotetramer and the gene is on chromosome 6. An extracellular, glycosylated form, SOD3, has been shown in rodents to overlap in activity with SOD1. Several other enzymes unrelated to CuZn-SOD, for example, the *atx1-HAH* gene product, are also capable of acting as SODs. It remains to be determined to what extent SOD3 and these alternative dismutases complement SOD1 and SOD2 as antioxidant systems in humans.

Catalase and glutathione peroxidase provide two important cellular systems for eliminating H_2O_2. Catalase, a 56 kDa cytosolic hemoprotein homotetramer that can act without a cofactor, although it may bind NAD(P)H, functions as a peroxidase to convert H_2O_2 to water. It can be irreversibly inactivated by oxidation and demonstrates decreased activity after ischemia–reperfusion. Catalase is more abundant in astrocytes than in neurons and in white matter than in gray matter, but it can be induced in neurons by neurotrophins. There is substantially less catalase activity in brain than in other tissues, such as liver.

The human genes have been identified for four members of the glutathione peroxidase (GPx) family of selenoproteins. Classical GPx (GPx1) is a complex of four 23 kDa subunits. Plasma GPx (GPx3), GPx2 and a fourth enzyme, phospholipid hydroperoxide glutathione peroxidase (PHGPx), are monomers with extensive homology to classical GPx1. All four enzymes contain one selenium atom per subunit in the form of a selenocysteine and all use glutathione (GSH) as a cofactor to convert H_2O_2 to water. PHGPx is unique in its ability to detoxify not only H_2O_2 but fatty acid and cholesterol lipid hydroperoxides directly. In addition, it has a cytosolic isoform and an isoform with a mitochondrial targeting sequence. Both GPx1 and PHGPx proteins are present in the brain. The components of the glutathione peroxidase system, GPx, GSH, glutathione reductase and NAD(P)H, are present in the mitochondria as well as the cytoplasm. Several other proteins, including glutathione *S*-transferase, may contribute minor peroxidase activity.

Small-molecule antioxidants include glutathione, ascorbic acid (vitamin C), vitamin E and a number of dietary flavonoids. Because humans, in contrast to most other animals, are unable to synthesize vitamin C, this important antioxidant must be supplied entirely from dietary intake. Other proteins, such as thioredoxin and metallothionein, may also contribute to some extent to the cellular antioxidant pool.

Reactive oxygen species may modify both the excitotoxic and the apoptotic components of ischemic brain damage. In addition to direct effects of oxidative injury during ischemia–reperfusion, ROS may modify ischemic excitotoxicity by downregulating current through NMDA receptors. However, exposure to oxidative stress can be

expected to enhance NMDA-receptor-mediated neurotoxicity by depleting intracellular antioxidant defenses. Free radicals also contribute to apoptosis at several points in the apoptotic cascade, serving as initiators, early signals and possibly late effectors of apoptotic neuronal death. It may be this interaction of injury mechanisms, including excitotoxicity, ischemic apoptosis, oxidative injury, inflammation and impaired metabolism, that, in part, makes the brain so vulnerable to ischemic damage.

NEUROPROTECTIVE STRATEGIES FOR HYPOXIC–ISCHEMIC INJURY

Endogenous protective programs may include ischemic preconditioning and the heat shock response. Ischemic preconditioning (or ischemic tolerance) is 'the acute and/or chronic reaction to a potentially noxious stimulus, such as hypoxia, ischemia or inflammation … which protects the brain against subsequent ischemia' [28]. In a general sense, preconditioning is produced by exposure of tissue to a stimulus that can cause damage at close to (but below) the threshold for injury, and it is now clear that one stressor can induce tolerance against a different type of subsequent injury ('cross-tolerance'), indicating that changes associated with ischemic tolerance, *per se*, are not necessarily specific for ischemia. Preconditioning produces an extensive array of presumably protective responses that range from changes in excitotoxic cascades, to inhibition of inflammation and apoptosis, to enhancement of late repair mechanisms (reviewed in [28]).

One specific process that may contribute to protection in preconditioning is the *heat shock* response. This process was first described in response to mild thermal stress, which causes denaturation of proteins and induces expression of heat-shock proteins (HSPs). HSPs are now known to be induced by any stress that results in protein denaturation. Denatured proteins bind to HSP90, causing association with, and suppression of, HSFs (heat-shock factor proteins). Dissociation of HSFs from HSP90 allows them to be phosphorylated to the active form. Activated HSFs form trimers that then bind to the promoters of various HSPs to increase transcription. HSPs (which include a number of protein chaperones) bind to denatured proteins to restore their native conformation and activity. Overexpression of a number of HSPs, including HSP70 and HSP27, has been shown to protect cells from both necrotic and apoptotic death. In addition, HSP70 protects brain against ischemic injury or prolonged seizures *in vivo* [29]. Strategies that seek to induce the heat shock response have been targeted as potential therapies in ischemia in many organs, including brain.

Thrombolytics and drugs targeting several injury pathways have shown efficacy in models of hypoxia–ischemia. A number of neuroprotective strategies have been identified in animal models of ischemia, and many of these have been tested in human stroke patients. One therapeutic modality that has shown efficacy in humans is thrombolysis using either intravenous or intra-arterial infusion of tissue plasminogen activator. In addition to thrombolysis, many other drug therapies have shown protection in animal models of ischemic injury, including agonists of GABA receptors, antagonists of ionic glutamate (i.e. NMDA and AMPA), glycine, dopamine, opioid, endothelin and angiotensin receptors, ion channel blockers, phosphodiesterase inhibitors, minocycline (an antibiotic that has anti-inflammatory properties), estrogen, erythropoietin and a spectrum of antioxidants. Although most of these therapies have not consistently shown significant neuroprotection in clinical trials, a few appear to produce improvement after acute ischemic injury. Ebselen, an anti-inflammatory selenocompound that mimics glutathione peroxidase, inhibits DNA damage and lipid peroxidation after focal ischemic injury in animal studies, and has been found to reduce functional deficits after stroke in humans. Another compound, NXY-059, a nitrone spin trap with antioxidant properties, is currently undergoing clinical testing in stroke. Future studies on stroke therapy will focus on (1) engaging endogenous neuroprotective programs, such as ischemic preconditioning or the heat shock response, (2) combining thrombolytics with neuroprotective agents, such as antioxidants, and (3) maximizing the ability of the ischemic brain to recover tissue integrity and function.

BOX 32-1

Hydrogen Sulfide: Potential Neuroprotectant and Neuromodulator

George J. Siegel

A novel potentially neuroprotective reducing agent is hydrogen sulfide which, although a toxic gas and potent inhibitor of purified cytochrome oxidase c (Ki 0.3 μM [1]), is present physiologically in brain of humans and various species in 50 to 150 μM concentrations. It has been shown to inhibit peroxynitrite-mediated tyrosine nitration and inactivation of α_1 antiproteinase and peroxynitrite-induced cytotoxicity, protein nitration and oxidation in human neuroblastoma SH-SY5Y cells [2]. H_2S also has been shown to protect neurons against glutamate-induced stress in primary cultures of embryonic rat cortical neurons via increasing levels of glutathione, which is an important anti-oxidant (see Ch. 32) [3]. Of further interest is that H_2S induces non-glutamate calcium ion entry and calcium waves in primary rat embryonic astrocyte cultures and in hippocampal slices [4] in addition to enhancing NMDA receptor responses to glutamate and LTP in hippocampus (see Ch. 10 [5]). H_2S activates smooth muscle ATP-dependent K^+ channels (see Ch. 6) resulting in membrane hyperpolarization and muscle relaxation [6]. It has been reported that brain concentrations of H_2S are reduced in Alzheimer's disease [7].Thus, H_2S has complex biochemical effects in brain function not all understood and the conditions determining the balance between potentially toxic versus physiologically beneficial effects in intact brain are not known. Comparable metabolic together with physiologic data from intact brain under H_2S exposure are not yet available. A report that H_2S can induce a reversible state resembling hibernation with decreased core body temperature and decreased metabolic rate in mice may be of considerable significance with respect to protection of brain function under conditions of metabolic compromise if confirmed by further investigation and analysis of intact brain parameters [8].

Eicosanoids, Docosanoids, Platelet-Activating Factor and Inflammation

Nicolas G. Bazan

STORAGE OF LIPID MESSENGERS IN NEURAL MEMBRANE PHOSPHOLIPIDS 576

Excitable membranes maintain and rapidly modulate substantial transmembrane ion gradients in response to stimuli 576

Specific lipid messengers are cleaved from reservoir phospholipids by phospholipases upon activation by various stimuli 576

Phospholipids in synaptic membranes are an important target in seizures, head injury, neurodegenerative diseases and cerebral ischemia 576

Some molecular species of phospholipids in excitable membranes are reservoirs of bioactive lipids that act as messengers 576

Mammalian phospholipids generally contain polyunsaturated fatty acyl chains almost exclusively esterified to the second carbon of glycerol 577

PHOSPHOLIPASE A_2 577

Phospholipase A_2 catalyzes cleavage of the fatty acyl chain from the second carbon of the glycerol backbone of phospholipids 577

Calcium-ion-dependent phospholipase A_2 with a preference for polyunsaturated fatty acyl chains is involved in bioactive lipid formation 578

Synaptic stimulation, ischemia or seizure activates phospholipase A_2 and releases arachidonic and docosahexaenoic acids 578

Secretory phospholipases A_2 are of relatively low molecular weight and have a high number of disulfide bridges, making them relatively more resistant to denaturation 579

There are high-affinity receptors that bind secretory phospholipase A_2 579

EICOSANOIDS 579

Arachidonic acid is converted to biologically active derivatives by cyclooxygenases and lipoxygenases 579

Prostaglandins are very rapidly released from neurons and glial cells 579

Arachidonic acid is also the substrate for lipoxygenase and, as in the case of cyclooxygenase, molecular oxygen is required 579

PLATELET-ACTIVATING FACTOR 579

Platelet-activating factor is a very potent and short-lived lipid messenger 579

Ischemia and seizures increase platelet-activating factor content in the brain 580

CYCLOOXYGENASES 581

Cyclooxygenase-1 is a constitutive enzyme that converts arachidonic acid to prostaglandin H_2 581

Platelet-activating factor is a transcriptional activator of cyclooxygenase-2 582

Cyclooxygenase-2 participates in aberrant synaptic plasticity during epileptogenesis 582

DIACYLGLYCEROL KINASES 584

The slow glutamate responses are mediated through metabotropic receptors coupled to G proteins 584

LIPID SIGNALING PATHWAYS AND NEUROINFLAMMATION 584

A platelet-activating-factor-stimulated signal-transduction pathway is a major component of the kainic-acid-induced cyclooxygenase-2 expression in hippocampus 584

In cerebrovascular diseases, the phospholipase-A_2-related signaling triggered by ischemia–reperfusion may be part of a delicate balance between neuroprotection and neuronal cell death 584

Free arachidonic acid, along with diacylglycerols and free docosahexaenoic acid, is a product of membrane lipid breakdown at the onset of cerebral ischemia, seizures and other forms of brain trauma 585

Free fatty acid release during cerebral ischemia is a complex process that includes the activation of signaling cascades 585

The rate of free fatty acid production in the mammalian brain correlates to the extent of resistance to ischemia 586

Activation of the arachidonic acid cascade during ischemia–reperfusion is a multistage process 586

Cyclooxygenase and lipoxygenase products accumulate during reperfusion following cerebral ischemia 586

The cerebrovasculature is also an abundant source of eicosanoids 586

DOCOSAHEXAENOIC ACID 586

Brain and retina are the tissues containing the highest contents of docosahexaenoic acid 586

Rhodopsin in photoreceptors is immersed in a lipid environment highly enriched in phospholipids containing docosahexaenoic acid, which is essential for rhodopsin function 587

LIPID PEROXIDATION AND OXIDATIVE STRESS 587

Docosahexaenoic-acid-containing phospholipids are a target for lipid peroxidation 587

NEUROPROTECTIN D1: A DOCOSAHEXAENOIC-ACID-DERIVED MEDIATOR 587

Docosanoids, enzyme-derived docosahexaenoic acid metabolites, were identified initially in the retina 587

Basic Neurochemistry: Molecular, Cellular and Medical Aspects

THE FUTURE OF LIPID SIGNALING IN THE NERVOUS SYSTEM 587
The significance of lipid signaling in the nervous system will be greatly expanded by newer experimental approaches 587
An evolving area is the understanding of the fundamental inner workings of the dendrites, which contain complex intracellular membranes rich in polyunsaturated phospholipids 588
Although arachidonic acid is widely implicated in signaling in brain, there are several gaps in our understanding of the release of this fatty acid from membrane reservoirs 588
The knowledge evolving from lipidomic neurobiology will be potentiated by multidisciplinary approaches, such as multiphoton confocal analysis 588

STORAGE OF LIPID MESSENGERS IN NEURAL MEMBRANE PHOSPHOLIPIDS

Excitable membranes maintain and rapidly modulate substantial transmembrane ion gradients in response to stimuli. This function requires the presence of ion pumps, neurotransmitter receptors and other associated membrane proteins. Excitable membranes have a phospholipid composition that differs from other membranes, a property assumed to be related to their highly specialized functions. The understanding of excitable membrane organization has conceptually evolved from the lipid bilayer with embedded proteins to a highly dynamic, heterogeneous patchwork of microdomains that contain ion channels, receptors, transporters and other proteins. Cellular membranes in the nervous system were divided in the past into relatively more fluid membranes (e.g. those of cells of gray matter) and relatively more rigid membranes (e.g. oligodendrocyte plasma membrane that spirals around the axon to form the myelin), according to the higher or lower content of polyunsaturated fatty acids (PUFA) in phospholipids (see also Chs 1–4). Currently in neurons, glia and endothelial cells of the cerebrovasculature, several phospholipid pools are recognized as reservoirs of lipid messengers. In addition, *lipid rafts* have been described, isolated and their chemical composition studied in specific cellular compartments of the nervous system, including dendrites, where they are associated with specific postsynaptic proteins. Lipid rafts are microdomains enriched in cholesterol and sphingolipids. Interestingly, there are subtypes of lipid raft, which vary by their resistance to detergent extraction, density and their raft marker proteins, Thy-1 and caveolin. Several proteins have been found segregated in these microdomains, including glycophosphatidyl (GPI) anchors, signaling proteins, proteins interacting with the actin cytoskeleton and proteins involved in cell trafficking and in endocytosis. PSD-95, GRIP and glutamate AMPA receptors have been found in lipid rafts isolated from rat brain. Moreover, the normal density of synapses and dendritic spines seems to depend on lipid rafts, since changes in cholesterol availability modify rafts and in turn the properties of synapses and spines. The same study also demonstrated that AMPA receptor internalization is affected by compositional changes in the rafts (see also Ch. 15).

Specific lipid messengers are cleaved from reservoir phospholipids by phospholipases upon activation by various stimuli. These stimuli include neurotransmitters, neurotrophic factors, cytokines, membrane depolarization, ion channel activation and others. Lipid messengers regulate and interact with multiple other signaling cascades, contributing to the development, differentiation, function, protection and repair of the cells of the nervous system.

Under physiologic conditions, the balance of membrane lipid metabolism, particularly that of arachidonoyl and docosahexaenoyl chains, favors a very small and tightly controlled cellular pool of free arachidonic acid (AA, 20:4n-3) and docosahexaenoic acid (DHA, 22:6n-3), but levels increase very rapidly upon cell activation, cerebral ischemia, seizures and other types of brain trauma [1, 2]. Other free fatty acids (FFAs) in addition to AA, released during cell activation and the initial stages of focal and global cerebral ischemia, are stearic acid (18:0), palmitic acid (16:0) and oleic acid (18:1).

Phospholipids in synaptic membranes are an important target in seizures, head injury, neurodegenerative diseases and cerebral ischemia. Synaptic membranes are excitable membranes enriched in phospholipids esterified with the polyunsaturated fatty acids AA and DHA which form a significant proportion of the FFAs rapidly released during ischemia, seizure activity and other brain trauma.

Some molecular species of phospholipids in excitable membranes are reservoirs of bioactive lipids that act as messengers. Signals, such as those resulting from neurotransmitter receptor occupancy, trigger the release of phospholipid moieties via the activation of phospholipases. Some of the breakdown products are bioactive, such as inositol 1,4,5-trisphosphate (IP3), diacylglycerol (DAG; see Ch. 20) and AA. Another product, lysoplatelet-activating factor (lyso-PAF), upon further metabolism, gives rise to the bioactive lipid PAF (1-*O*-alkyl-2-acetyl-sn-3-glycerol-3-phosphocholine). Eicosanoids are derived from enzyme-mediated oxygenation of AA. AA and its metabolites function as intra- and intercellular messengers. In contrast, the significance of DHA remains an enigma. DHA-containing phospholipids may provide a specific milieu in which the membrane proteins of excitable membranes function. For example, the high concentrations of DHA phospholipids of outer segments of retinal rod photoreceptors provide a highly specialized membrane environment for rhodopsin (see also Ch. 49). In fact, a specific requirement for DHA phospholipids in rhodopsin function has been documented [3]. Recently, the isolation and structural characterization of neuroprotectin

D1 (10,17*S*-docosatriene) from DHA using tandem liquid chromatography-photodiode array-electrospray ionization-tandem mass spectrometry (LC-PDA-ESI-MS-MS)-based lipidomic analysis have been documented in ischemic brain [4] and retinal pigment epithelium [5]. This new lipid is called neuroprotectin D1 (1) because of its *neuroprotective* properties in brain ischemia–reperfusion [4] and in oxidative stress-challenged retinal pigment epithelial cells [5]; (2) because of its potent ability to *in*activate proapoptotic signaling (see apoptosis, Ch. 35) [5]; and (3) because it is the first identified neuroprotective mediator derived from DHA.

Mammalian phospholipids generally contain polyunsaturated fatty acyl chains almost exclusively esterified to the second carbon of glycerol. Phospholipase (PL)A_2 activation cleaves the acyl chains at C2 of the glycerol backbone, thus releasing free polyunsaturated fatty acids AA and DHA. There are a number of potential fates for the phospholipase products. They may be reincorporated into membrane lipids or further metabolized to biologically active derivatives. The remaining lysophospholipid can be either re-esterified and reincorporated into a membrane phospholipid or further metabolized. The discovery of neuroprotectin D1 [5] from DHA suggests that docosanoids may arise as well.

This chapter surveys the neurochemistry of lipid messengers, as well as the mechanisms by which bioactive lipids accumulate upon stimulation in response to injury, cerebral ischemia, seizures, neurotrauma or neurodegenerative diseases, and their significance in pathophysiology. Emphasis is placed on three groups of bioactive lipids: AA and its metabolites, known collectively as eicosanoids; PAF, a highly potent ether phospholipid; and the newly identified DHA-derived mediator, neuroprotectin D1.

AA metabolites and PAF have initially been studied in terms of their roles in the inflammatory response, such as increased vascular permeability and the activation of and infiltration by inflammatory cells. It is now becoming apparent, however, that these bioactive lipids have significant neurobiological actions in ion channel functions, receptors, neurotransmitter release, synaptic plasticity and neuronal gene expression.

Moreover, bioactive lipids may be considered dual messengers: they modulate cell functions as messengers and they become part of the response of the nervous tissue to injury, broadly referred to as the inflammatory response. This response occurs in ischemia–reperfusion damage associated with stroke, various forms of neurotrauma, infectious diseases and neurodegenerative diseases such as Alzheimer's disease. Inflammation in the nervous system differs from that in other tissues. If the blood-brain barrier is broken, blood-borne inflammatory cells (e.g. polymorphonuclear leukocytes, monocytes, macrophages) invade the intercellular space and glial cells are activated, particularly microglia, which play a prominent role in the inflammatory response. These responses may lead to neuronal cell injury and death [6]. In addition, ischemia, seizures and other forms of injury upregulate lipid signaling in neurons, mainly through *N*-methyl-D-aspartate (NMDA)-type glutamate receptors (see also details in Ch. 15) (Fig. 33-1). As a consequence, PLA_2 is activated, AA is released, eicosanoids and PAF are synthesized and cyclooxygenase (COX)-2 is induced in neurons. Other neuronal correlates of the inflammatory response include signaling by cytokines, nitric oxide and various growth factors. Activation of arriving inflammatory cells also plays a role in initial defenses against injury, removal of cellular debris, and the longer-term repair/wound healing of the nervous system. Several lipid messengers are released from these cells and may participate in beneficial actions. Much remains to be learned in this area of integration of our knowledge of the inflammatory response and neuroimmune/repair signaling.

Identification of lipids with biological activity has progressed remarkably over the last few years. While the inositol phosphates have been known for some time to play fundamental roles in cell biology, others, such as lysophosphatidic acids, previously considered only as intermediates in phospholipid metabolism, have recently been found to possess important functions, and lysophosphatidic acid and sphingosine receptors have recently been cloned [16–18]. Although the specific roles of many of these bioactive lipids and lipid derivatives in neuroscience remain sparsely explored, this review should give the reader a broad appreciation of the diversity of bioactive lipids, particularly eicosanoids, docosanoids and PAF, which are produced in brain during injury (e.g. trauma or ischemia), during seizures and under inflammatory conditions.

PHOSPHOLIPASE A_2

Phospholipase A_2 catalyzes the cleavage of the fatty acyl chain from the second carbon of the glycerol backbone of phospholipids. There are a wide variety of PLA_2 types [19] that include, in addition to intracellular PLA_2, a low-molecular-weight secretory PLA_2 ($sPLA_2$) that synergizes glutamate-induced neuronal damage [13]. Whereas pathways leading to PLA_2 activation are part of normal neuronal function, ischemia–reperfusion enhances these events, overproducing PLA_2-derived lipid messengers, such as enzymatically produced AA- and DHA-oxygenation derivatives, and nonenzymatically generated lipid-peroxidation products and other reactive oxygen species (ROS), all of which may be involved in neuronal damage. Among the consequences of PLA_2 activation by ischemia are alterations in mitochondrial function by the rapid increase in the brain FFA pool size, for example the uncoupling of oxidative phosphorylation from electron transport in the mitochondrial respiratory chain and the generation of ROS. Intracellular PLA_2 types are located either in the cytosol or in noncovalent association with membranes and consist of Ca^{2+}-dependent types ($iPLA_2$).

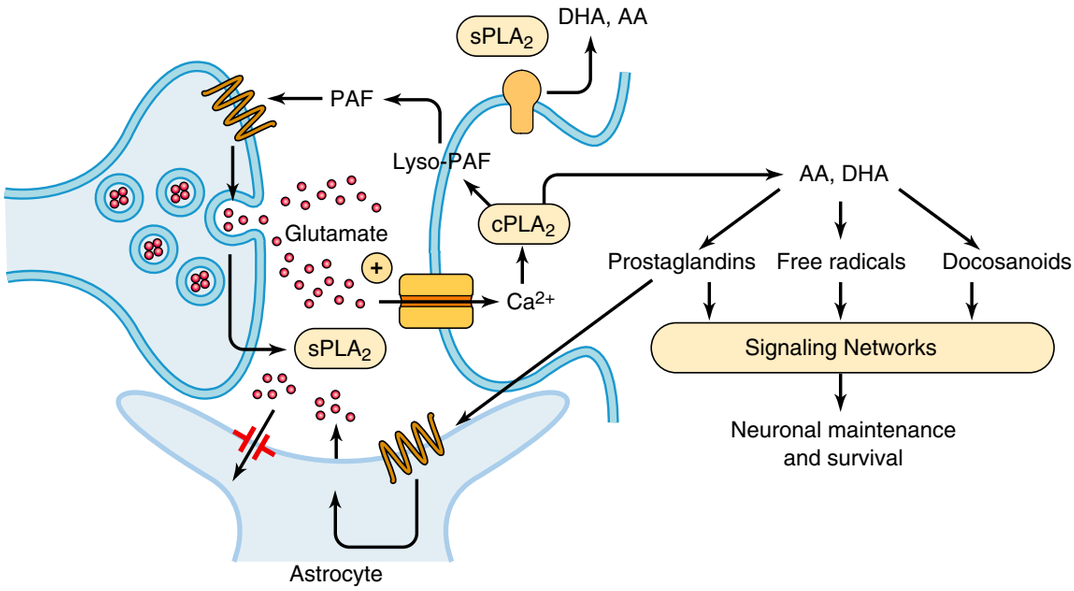

FIGURE 33-1 A depolarizing stimulus at the presynaptic terminal triggers glutamate release. Glutamate binds to the NMDA receptor and as a consequence an influx of calcium ions occurs in the postsynaptic neuron. Calcium-mediated activation of the cytoplasmic PLA_2 (*cPLA*$_2$) results in the release of arachidonic acid (*AA*), docosahexaenoic acid (*DHA*) and lyso-PAF, the PAF precursor. Although PAF has a very short biological half-life, on repeated stimulus sufficient PAF accumulates to diffuse back across the synaptic cleft. Experimental evidence for this was provided by injecting PAF into the postsynaptic neuron and monitoring neurotransmitter release [7]. PAF binds to its presynaptic receptor and enhances glutamate exocytosis by an as yet undefined mechanism. During synaptic plasticity events, PAF may also activate gene expression that in turn is probably involved in long-term alterations of synaptic function (not shown here). Cell-surface PAF-receptor antagonists confer neuroprotection during ischemia–reperfusion and inhibit PAF-induced glutamate release from hippocampal neurons and CA1 LTP formation, presumably through the same mechanism. The inhibitory effects of this antagonist on glutamate release could account in part for its neuroprotection in ischemia–reperfusion. Secretory PLA_2 (*sPLA*$_2$) may be released from the presynaptic terminal [8]: $sPLA_2$ binding sites are present in neurons [9–12], and $sPLA_2$ promotes active AA remodeling in neurons in culture [13] and may also promote DHA release. DHA may also be released by $cPLA_2$. Free DHA may subsequently follow enzyme-mediated oxygenation pathways and lead to the synthesis of docosanoids, messengers made in the retina [14] and brain [4]. Free radicals would accumulate during oxidative stress. Downstream lipid signaling modulates neuronal function and survival. Synapses are intimately surrounded by astrocytes, which express glutamate transporters that remove the excitatory neurotransmitter from the vicinity of the synaptic cleft. Astrocytes also respond to prostaglandins by releasing glutamate through a Ca^{2+}-dependent mechanism [15].

Calcium-ion-dependent phospholipase A_2 with a preference for polyunsaturated fatty acyl chains is involved in bioactive lipid formation. Calcium-ion-dependent phospholipase A_2 ($cPLA_2$) is regulated by transcription, post-translational modulation of enzyme activity and membrane translocation. Membrane translocation of $cPLA_2$ to endoplasmic reticulum and nuclear membranes is mediated via a specific Ca^{2+}-dependent domain similar to those seen in protein kinase C, phospholipase C and GTPase-activating protein [20, 21]. This site is consistent with that of other enzymes of AA metabolism, such as prostaglandin G/H synthases (PGS), also termed cyclooxygenases (COX-1 or -2) [22], as well as 5-lipoxygenase and its activator protein [23].

The catalytic activity of $cPLA_2$ is stimulated by phosphorylation catalyzed by the mitogen-activated protein kinase (MAPK) at Ser505. This modification stimulates enzyme activity only, indicating that translocation and phosphorylation are independent mechanisms of $cPLA_2$ regulation [21].

Synaptic stimulation, ischemia or seizure activates phospholipase A_2 and releases arachidonic and docosahexaenoic acids. Ischemia or seizure triggers accumulation of free AA, DHA and other FFA in the brain(see also Chs 32, 37). This reflects PLA_2 activation in excitable membranes [24]. While little is known about the mechanisms that control its activity, the importance of $cPLA_2$ in ischemic brain injury is strongly supported by the recent finding that $cPLA_2$-knockout mice have substantially reduced infarcts and neurologic deficits in a model of stroke [25].

Shifts in intracellular pH may be another mechanism by which intracellular PLA_2 activity can be regulated. Glutamate-induced AA release in mouse cortical neuronal cultures is mediated in part by a membrane-associated PLA_2 activity, which is upregulated in alkaline pH and is therefore sensitive to the shifts in pH induced by excitatory neurotransmission.

There are also mechanisms in the brain for the downregulation of intracellular PLA_2 activity by lipocortins, a

family of Ca^{2+}- and phospholipid-binding proteins that act as endogenous inhibitors of PLA_2. The steroid-inducible lipocortin-1 is present in neuronal and glial cells, especially in the hippocampus, where it may act as an endogenous neuroprotective agent [26]. Exogenous lipocortin-1 administered intracerebroventricularly to rats significantly reduces the infarct size and edema induced by cerebral ischemia and attenuates excitotoxic damage mediated by NMDA receptors. Glucocorticoid hormones inhibit lipocortin synthesis.

Secretory phospholipases A_2 are of relatively low molecular weight and have a high number of disulfide bridges, making them relatively more resistant to denaturation. The mammalian $sPLA_2$ types can be subdivided on the basis of amino acid sequence into several groups that include pancreatic or group I $sPLA_2$, the members of which function in pancreatic secretions, smooth muscle contraction, cell proliferation and fertilization; and synovial or group II PLA_2, the members of which function in inflammatory responses. Both have been found also to be expressed in the nervous system.

There are high-affinity receptors that bind secretory phospholipases A_2. The muscle (M-type) and neuronal (N-type) receptors are structurally and pharmacologically distinct. The M-type consists of a single ≈180 kDa subunit and binds both OS1 and OS2 $sPLA_2$ (purified from the venom of the Australian taipan snake *Oxyuranus scutellatus scutellatus*). The N-type is composed of three major polypeptides of 34, 48 and 82 kDa and binds OS2 and bee venom $sPLA_2$ but not OS1 [24, 27]. Expression of the M- and N-type receptors is not limited to their nominal sites. In fact, both types are widely distributed in different cells and tissues. The M-type receptor has been cloned from rabbit and human tissues and, independently, from mouse and bovine tissues; it mediates group I $sPLA_2$ cellular actions. The receptor consists of a single 180–200 kDa glycoprotein subunit that bears significant sequence homology to the macrophage mannose receptor and to other members of the C-type lectin superfamily. The recombinant receptor binds both mammalian group I and group II $sPLA_2$ with high affinity. Studies using enzymatically inactive mutants of group I $sPLA_2$ to stimulate prostaglandin E_2 (PGE_2) synthesis in rat mesangial cells suggest that at least some of the effects mediated through the receptor are independent of $sPLA_2$ enzymatic activity. Potential ligands for the N-type receptor may be the group II $sPLA_2$ induced in rat brain during ischemia.

EICOSANOIDS

Arachidonic acid is converted to biologically active derivatives by cyclooxygenases and lipoxygenases. These metabolites, referred to collectively as eicosanoids (Figs 33-2, 33-3), are potent messengers that modulate cell function and are also involved in pathophysiology. Several nervous system functions engage eicosanoids. In addition, these messengers participate in inflammatory responses and other pathologic processes in the nervous system. COXs are inhibited by nonsteroidal anti-inflammatory drugs (NSAIDs), such as aspirin or ibuprofen. Mainly as a consequence of studies on NSAIDs, the significance of prostaglandins as critical modulators of immune responses, pain, fever, inflammation, mitogenesis and apoptosis has been established.

Prostaglandins are very rapidly released from neurons and glial cells. Synaptic activation and certain forms of injury, such as ischemia–reperfusion or seizures, trigger prostaglandin synthesis and rapid efflux into the intercellular space [28]. These lipid mediators, in turn, elicit their signaling through autocrine and paracrine routes. Several prostaglandin receptors have been cloned. Figure 33-4 depicts the PGE_2 receptor (EP receptor), which in turn generates cAMP by activating adenylyl cyclase. The PGE_2 receptor belongs to the seven-transmembrane-domain receptor family and is coupled via G proteins to cAMP signaling (see Ch. 19). This depends on the activity of protein kinase A (PKA), a heteromeric enzyme that, upon binding cAMP to its regulatory subunit, releases the catalytic subunit. The catalytic subunit, in turn, activates gene transcription by phosphorylation of a DNA-binding protein, namely, the cAMP response element binding (CREB) protein (discussed in detail in Ch. 26). Several genes contain consensus sequences for CREB. Expression of these genes in turn is modulated by this lipid signaling pathway, as well as by other signaling pathways. CREB has been implicated in plasticity changes of synaptic circuits, memory formation, and in behavior.

Arachidonic acid is also the substrate for lipoxygenase and, as in the case of cyclooxygenase, molecular oxygen is required. The exact mechanisms controlling the channeling of AA through COXs or lipoxygenases are not clearly understood. However, there is growing evidence that subcellular compartmentalization is a major factor in the channeling of AA through either pathway.

PLATELET-ACTIVATING FACTOR

Phospholipid molecules of membranes from neurons and glial cells store a wide variety of lipid messengers. Receptor-mediated events and changes in $[Ca^{2+}]i$, such as occur during excitatory neurotransmission and activity-dependent synaptic plasticity, activate phospholipases that catalyze the release of bioactive moieties from phospholipids, which then participate in intra- and/or intercellular signaling pathways.

Platelet-activating factor is a very potent and short-lived lipid messenger. It is known to have a wide range

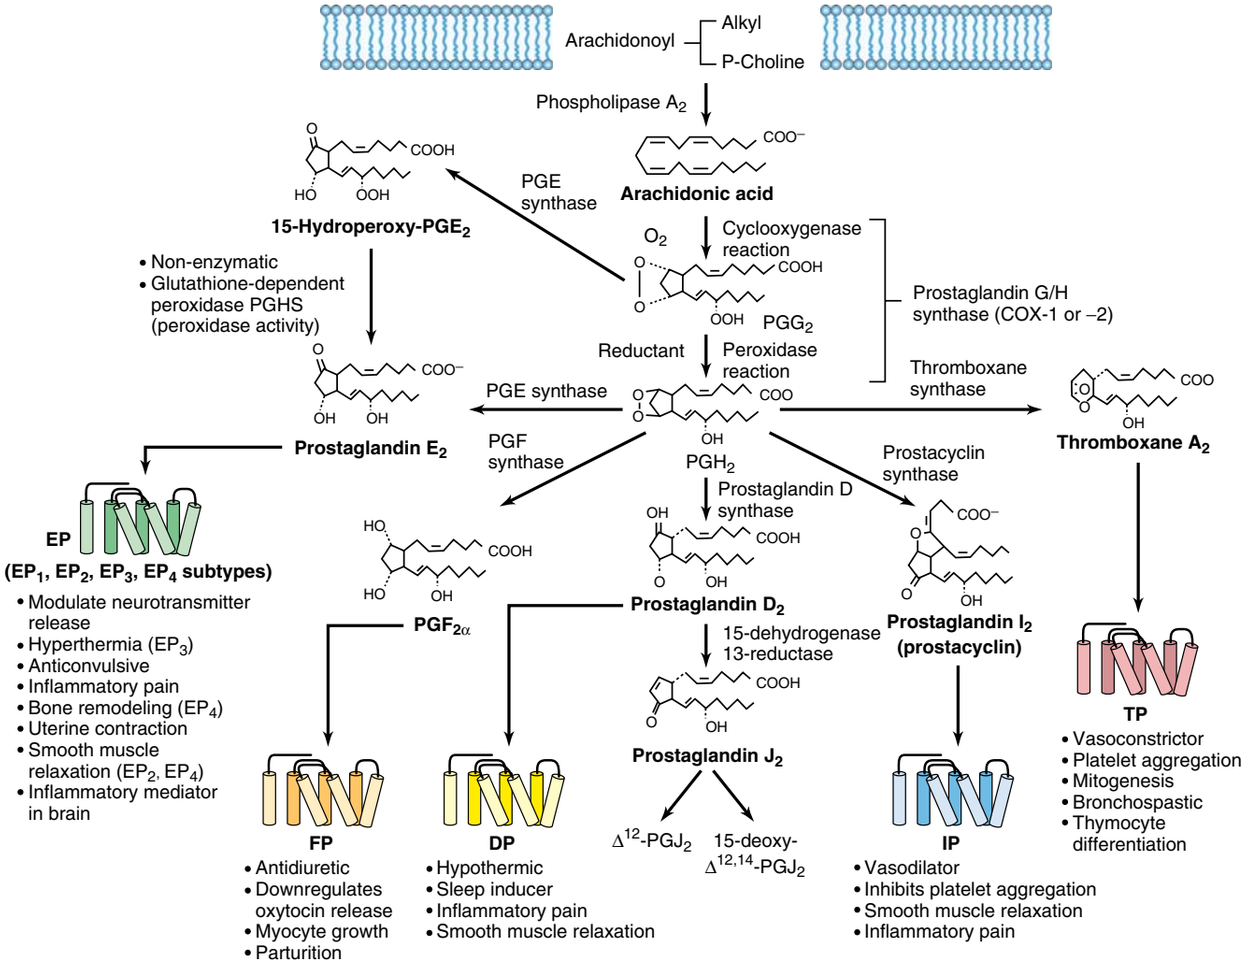

FIGURE 33-2 The arachidonic acid cascade. Free AA released by phospholipase A_2 (or PLC-diacylglycolipase-monoacylglycerollipase) undergoes cyclooxygenation and peroxidation mediated by prostaglandin G/H synthase. Specific tissue and product-specific isomerases mainly utilize PGH_2 to generate prostaglandins, prostacyclin and thromboxane. Receptors as well as some of the bioactivities of specific eicosanoids are illustrated.

of actions: as a mediator of inflammatory and immune responses, as a second messenger, and as a potent inducer of gene expression in neural systems (Fig. 33-5). Thus, in addition to its acute roles, PAF can potentially mediate longer-term effects on cellular physiology and brain functions.

PAF enhances glutamate release in synaptically paired rat hippocampal neurons in culture [27]. The PAF analog methylcarbamoyl (mc-PAF), but not the biologically inactive lyso-PAF, increases excitatory synaptic responses. Action of the inhibitory neurotransmitter GABA is unaffected by mc-PAF under these conditions. The presynaptic PAF-receptor antagonist BN 52021 blocks the mc-PAF-enhanced glutamate release. In addition, mc-PAF increases presynaptic glutamate release since it does not augment the effects of exogenously added glutamate, and it evokes spontaneous synaptic responses characteristic of enhanced neurotransmitter release. Therefore, as a modulator of glutamate release, PAF participates in long-term potentiation (LTP) [7, 30], synaptic plasticity and memory formation (see LTP and memory in Ch. 53) [31, 32].

Ischemia and seizures increase platelet-activating factor content in the brain. Furthermore, the brain is endowed with a variety of degradative enzymes that rapidly convert PAF to biologically inactive lyso-PAF [33, 34]. Presynaptic membranes display PAF binding that can be displaced by BN 52021, a terpenoid extracted from the leaf of the *Ginkgo biloba* tree. It is likely that this PAF-binding site is identical to a seven-transmembrane PAF receptor. BN 52021 inhibits both PAF-induced glutamate release [27] and long-term potentiation [7]. Moreover, this antagonist is neuroprotective in ischemia–reperfusion damage in the gerbil brain [35]. These findings together indicate that PAF, when overproduced at the synapse during ischemia, promotes enhanced glutamate release, which in turn contributes to excitotoxicity through the activation of postsynaptic receptors.

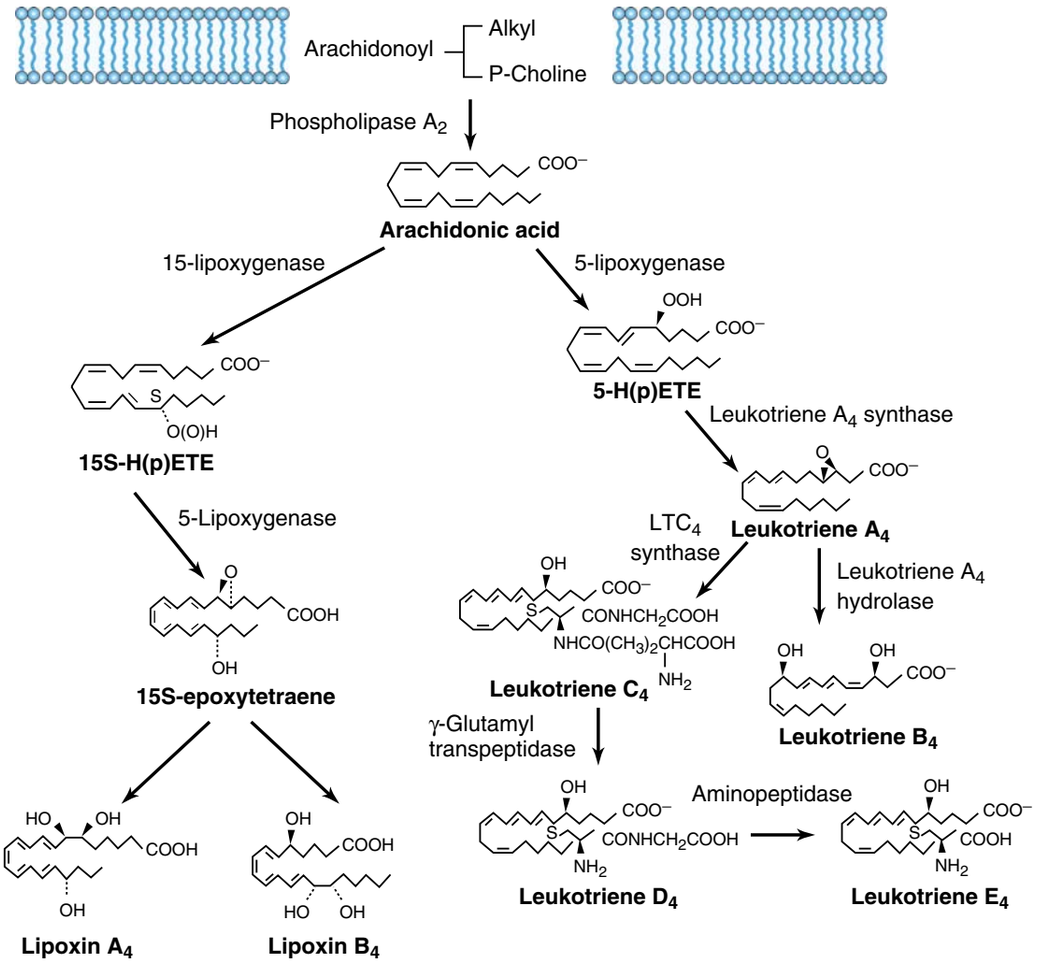

FIGURE 33-3 Arachidonic acid lipoxygenation. Lipoxygenase enzymes oxygenate arachidonic acid in different positions, thus they are named the 5-, 8-, 11-, 12- and 15-lipoxygenases and catalyze reactions that produce bioactive arachidonic acid derivatives. This figure illustrates as an example the synthesis of leukotriene B_4 and of sulfidopeptide leukotrienes (C_4, D_4 and E_4), the 5-lipoxygenase pathway. It also depicts the synthesis of lipoxins by 15-lipoxygenase.

CYCLOOXYGENASES

Cyclooxygenase-1 is a constitutive enzyme that converts arachidonic acid to prostaglandin H_2. COX-2 is inducible by cytokines, glutamate, growth factors, PAF and other mediators and is inhibited by glucocorticoids. COX-2 is encoded by an early-response gene, and its mRNA has a short half life (Table 33-1). In the human neocortex, the half-life is about 3 hours, as compared to 12 hours for COX-1 mRNA. In most tissues, stimulation, injury, inflammatory stimuli and other forms of cellular stress trigger expression of the COX-2 gene. However, brain, macula densa of kidney, testes and the female reproductive system also display constitutive levels of COX-2. In brain, the relatively high constitutive COX-2 expression appears to be almost exclusively neuronal. Dendrites and the perinuclear region are enriched in COX-2. Moreover, COX-2 expression seems to be regulated by synaptic activity [36]. Recently, COX-3 was characterized as generated from COX-1 intron-1 retention [37]. COX-3 is expressed in brain [37], brain microvasculature [38] and has been proposed to be a target of the analgesic/antipyretic acetaminophen [37, 39].

COXs thus catalyze the same first committed step of the AA cascade (Fig. 33-2). COX-2, however, is expressed in response to mitogenic and inflammatory stimuli and encoded by an early-response gene. To date we do not understand how COX-3 expression is regulated. In contrast, COX-1 expression is not subject to short-term regulation. Neurons in the hippocampus, as well as in a few other brain regions, are unlike other cells in that they display basal COX-2 expression [36]. This expression is modulated by synaptic activity, such as long-term potentiation, and involves the NMDA glutamate receptors [36, 40].

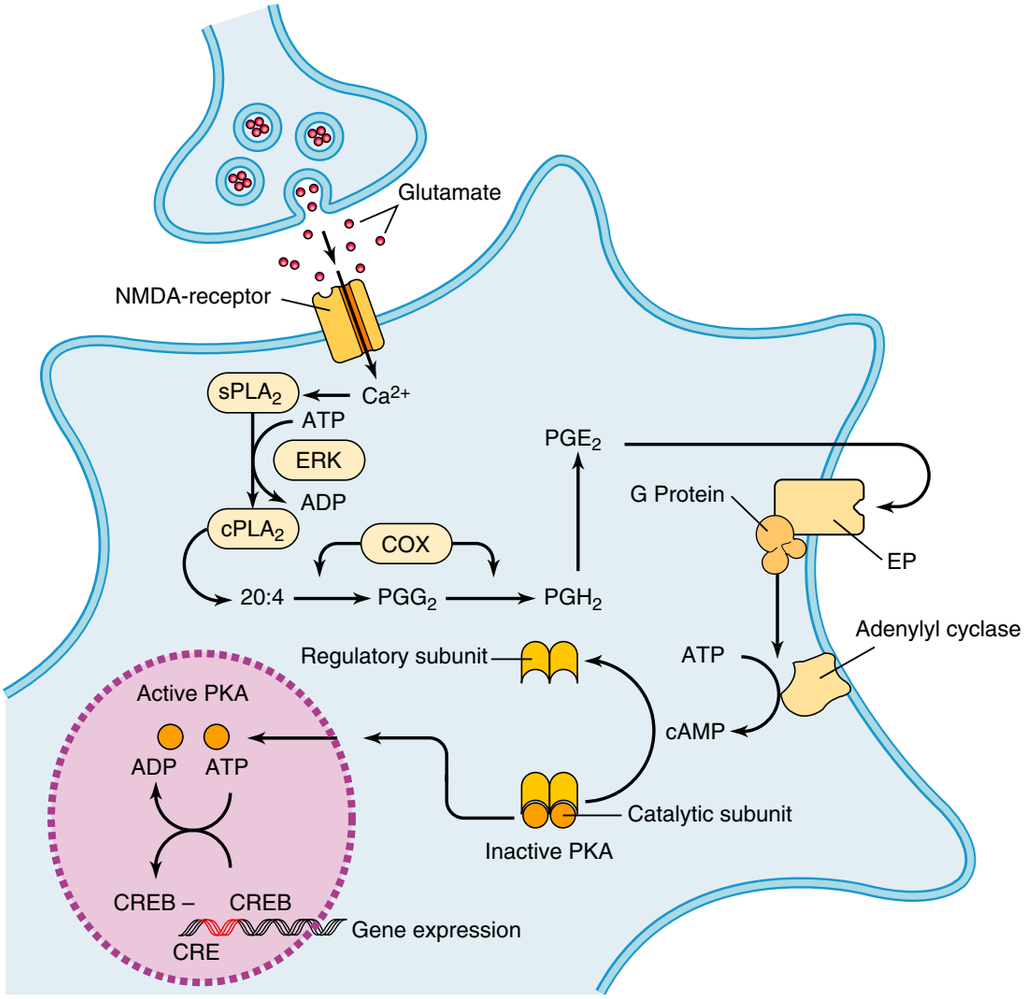

FIGURE 33-4 Prostaglandin signaling pathway triggered by the excitatory amino acid neurotransmitter glutamate. *COX*, cyclooxygenase; *cPLA$_2$*, calcium-dependent phospholipases A$_2$; *CRE*, cAMP response element; *CREB*, cAMP-response element binding protein; *EP receptor*, prostaglandin E2 receptor; *ERK*, extracellular signal-regulated kinase; *NMDA*, *N*-methyl-D-aspartate; *PGG$_2$* and *PGH$_2$* are short-lived intermediates in the synthesis of prostaglandin E$_2$ (*PGE$_2$*); *PKA*, protein kinase A; *sPLA$_2$*, secretory phospholipase A$_2$.

Platelet-activating factor is a transcriptional activator of cyclooxygenase-2. PAF induces mouse COX-2-promoter-driven luciferase activity transfected in neuroblastoma cells, such as NG108–15 or SH-SY5Y, and in NIH 3T3 cells (Fig. 33-5). The intracellular PAF antagonist BN 50730 inhibits PAF activation of this construct [41].

The abundance in brain of several early-response gene transcripts shows rapid and transient increases during cerebral ischemia and after seizures. Several early-response genes encode transcription factors, which in turn modulate the expression of other genes, whereas others encode inducible enzymes (Fig. 33-5). The glutamate analog kainic acid promotes extensive neuronal damage, particularly in the hippocampus, and induces early-response genes such as the transcription factor *zif-268*. *COX-2* is also induced under these conditions, but there are striking differences in the magnitude and duration of the induction of *COX-2* as compared with *zif-268*. *COX-2* mRNA, 2 hours after kainic acid injection, showed a 35-fold increase in hippocampus, as compared to only a 5.5-fold increase for *zif-268* [42]. Also, a peak in *COX-2* mRNA abundance was evident at 3 hours, a 71-fold increase, as compared with 1 hour for *zif-268*, a 10-fold increase. The *zif-268* mRNA time course of changes in the hippocampus corresponds to the expected profile of early-response genes, that is, a rapid decrease in abundance after the peak. *COX-2*, however, displayed sustained upregulation for several hours after kainic acid injection, a 5.2-fold increase remaining at 12 hours [42].

Cyclooxygenase-2 participates in aberrant synaptic plasticity during epileptogenesis. Neuronal COX-2 expression is also upregulated in experimental epileptogenesis, when aberrant synaptic plasticity is thought to

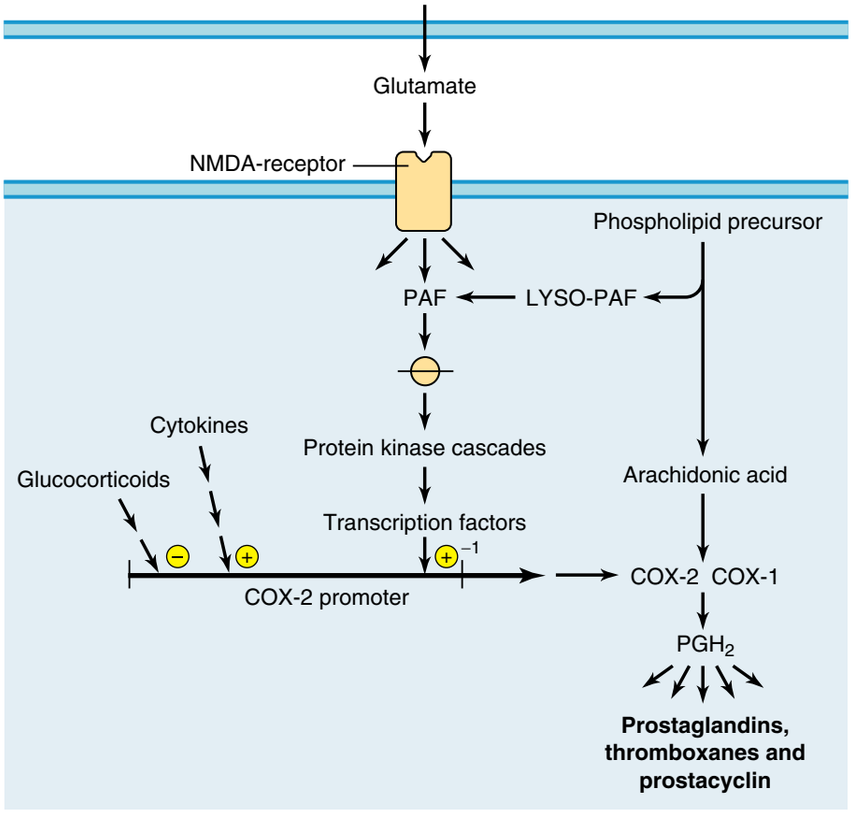

FIGURE 33-5 Seizure- or ischemia-triggered signaling events linking synapse activation and cyclooxygenase-2 (*COX-2*) gene expression in neurons. *N*-methyl-D-aspartate (NMDA) receptor activation by glutamate leads to phospholipase A_2 (*PLA_2*) activation and the generation of platelet-activating factor (*PAF*) and of arachidonic acid. PAF is synthesized through other metabolic routes as well [29], and elicits its actions through a PAF receptor. PAF activates COX-2 gene expression through protein kinase cascades and transcription factors. The COX-2 promoter is also a target for cytokines (activation) and glucocorticoids (inhibition). COX-2 protein then catalyzes the conversion of arachidonic acid into prostaglandin H2 (PGH2), the precursor of eicosanoids. Constitutive activity of COX-1 also catalyzes this metabolic step.

TABLE 33-1 Characteristics of cyclooxygenases or prostaglandin synthetases (IUPAC:IUB EC 1.14.99.1)

	Cyclooxygenase-1	Cyclooxygenase-2
	Constitutive	Inducible in neurons, macula densa of kidney; testes and female reproductive system also contain constitutive COX-2
Chromosome localization		1q25 10 exons, 7.5 kb
mRNA	≈5.2 kb ≈2.8 kb	≈4.3–4.6 kb ≈2.8 kb
Half-life	≥12 h	≤3 h (human neocortex) ≈1–2 h (IMR-90 cells) ≈1–3 h (IM9, HUVEC)
Function	Primarily cellular homeostasis	Inflammation and mitogenesis, neuronal Constitutive COX-2 is involved in synaptic plasticity Plays a role in neurodegenerative disease, epilepsy and stroke

be activated. The experimental kindling model resembles aspects of mesial temporal lobe epilepsy [43]. Kindling epileptogenesis is triggered by repeated subconvulsive stimulation, which gradually results in intensified seizures (Ch. 37). Both COX-2 and $cPLA_2$ expression are activated, indicating that the free AA released is converted into prostaglandins during epileptogenesis [44]. Nimesulide, a COX-2 blocker, decreases kindling epileptogenesis. The inability of nimesulide to completely inhibit kindling development suggests either a limited bioavailability of the drug to neuronal COX-2 to attain full blockade and/or a redundancy of the signaling involved. For example, COX-1, which is not inhibited by nimesulide, may catalyze the synthesis of prostaglandins, minimizing the action of nimesulide.

The exact mechanism by which COX-2 inhibition attenuates kindling epileptogenesis is not understood. Notwithstanding, COX-2 inhibition may diminish prostaglandin and/or PAF synthesis, lipid messengers that are both involved in synaptic facilitation [45]. Moreover, kindling epileptogenesis promotes selective neuronal COX-2

expression, initially in the hippocampus and subsequently in the neocortex. The stimulating electrode in this particular experiment was placed in the ventral hippocampus. Taken together, these studies suggest that the spreading of kindling-induced COX-2 expression from hippocampal neurons to neocortical neurons is a major event in the permanent facilitation of aberrant functional connectivity, and that COX-2 is a mediator [44].

Several tissue-specific, eicosanoid-selective isomerases catalyze the conversion of PGH2 into PGE_2, $PGF_{2\alpha}$, PGD_2, PGI_2, and thromboxanes (Fig. 33-2). An alternative pathway is the direct conversion of PGG_2 into PGE_2 through 15-hydroperoxy-PGE_2. This route is not well understood, although it may have modulatory implications [46]. The synthesis of PGE_2 is catalyzed by three different enzymes. Two of them are membrane-bound (mainly to the endoplasmic reticulum) and one is soluble. Interestingly, these enzymes are differentially coupled to the COXs, thus channeling released AA through constitutive COX-1 or through inducible COX-2, which has important regulatory consequences on the availability of PGE_2. mPGES-1 is a glutathione (GSH)-requiring perinuclear-enriched protein that belongs to the MAPEG (membrane-associated proteins involved in eicosanoid and glutathione metabolism) family. This enzyme is functionally coupled to COX-2 and is induced by proinflammatory stimuli, cytokines, growth factors or lipopolysaccharide, and its induction is downregulated by anti-inflammatory glucocorticoids. The second membrane-bound PGE synthase is mPGES-2, which, unlike the former, is constitutively expressed and may be coupled to COX-1 or COX-2. This enzyme has glutaredoxin–thioredoxin-like domains and is activated by thiol reagents. The cytosolic enzyme (cPGES) is coupled to COX-1 and allows rapid PGE_2 synthesis upon free AA release. It is a 23 kDa glutathione-requiring enzyme regulated by phosphorylation through casein kinase II and requiring the molecular chaperone HSP90 [47].

DIACYLGLYCEROL KINASES

The slow glutamate responses are mediated through metabotropic receptors coupled to G proteins. For review of metabotropic receptors (mGluRs) and G proteins, see Chapters 15 and 19 and reference [48]. One of the mGluR family, mGluR1, is linked to the inositol lipid-PLC pathway. Activation of neuronal inositol lipid signaling through mGluR1 and PKC_γ is involved in synaptic plasticity such as in learning, memory, LTP and long-term depression [49] and has been implicated in neurological and psychiatric diseases such as epilepsy, Alzheimer's disease and depression [24, 48, 50, 51]. Activation of mGluR1 triggers a short-lived signal with potent and sustained consequences in other signaling pathways. DAG-activated PKC contributes to feedback inhibition of the PLC pathway and, at the same time, may lead to PLD and PLA_2 activation. The termination of the DAG signal is mainly accomplished by DAG kinase $(DGK)_\varepsilon$, which selectively phosphorylates AA-DAG to generate AA-PA [52, 53]. Eight other mammalian DGKs have been identified, but only DGK_ε uses AA-DAG [54]. The central role played by DAG_ε in the inositol lipid-PLC pathway was revealed using mice with targeted disruption of the DGKε gene [55]. *DGKε*$^{-/-}$ mice display higher resistance to seizures and attenuation of LTP in the hippocampus. Interestingly, not only the inositol lipid-PLC pathway was greatly affected by the mutation, but also the $cPLA_2$-AA and PLD-DAG pathways, reflecting the impact of the former in modulating multiple pathways that participate in synaptic activity and neuronal plasticity.

The DAG signal itself can also be terminated by DAG lipases with the sequential release of 2-AA glycerol (2-AG) and then free AA and glycerol. As the primary second messengers are removed to terminate their functions, other bioactive lipids are generated; 2-AG is an endogenous ligand for the CA1 cannabinoid receptor with neuromodulatory functions [56], while PA and its PLA_2 product lyso-PA are potent intra- and intercellular messengers. Lyso-PA is released from the cells and interacts with cell surface G-protein-coupled receptors. Lyso-PA inhibits neurite growth and neuroblastome differentiation, stimulates neurotransmitter release in PC12 cells and has been implicated in Alzheimer's disease.

LIPID SIGNALING PATHWAYS AND NEUROINFLAMMATION

A platelet-activating-factor-stimulated signal-transduction pathway is a major component of the kainic-acid-induced cyclooxygenase-2 expression in hippocampus. Both PAF [57] and COX-2 are potent mediators of the injury/inflammatory response (Fig. 33-5). PAF and COX-2 are also interrelated in neuronal plasticity. The PAF transcriptional activation of COX-2 may provide clues about novel neuronal cell-death pathways. In fact, the delayed induction of COX-2 by kainic acid precedes selective neuronal apoptosis by this agonist in the hippocampus [42, 58].

In cerebrovascular diseases, the phospholipase-A_2-related signaling triggered by ischemia–reperfusion may be part of a delicate balance between neuroprotection and neuronal cell death. Events that would tilt the balance toward neuroprotection are possible therapeutic targets. It is interesting to note that PAF, being short-lived and rapidly degraded by PAF acetylhydrolase [59], is a long-term signal with consequences for neurons [60] through sustained expression of COX-2 (Fig. 33-6). Overexpression of hippocampal COX-2 during cerebral ischemia [61] and seizures may in turn lead to the formation of neurotoxic metabolites, such as ROS. The regulatory subunit of

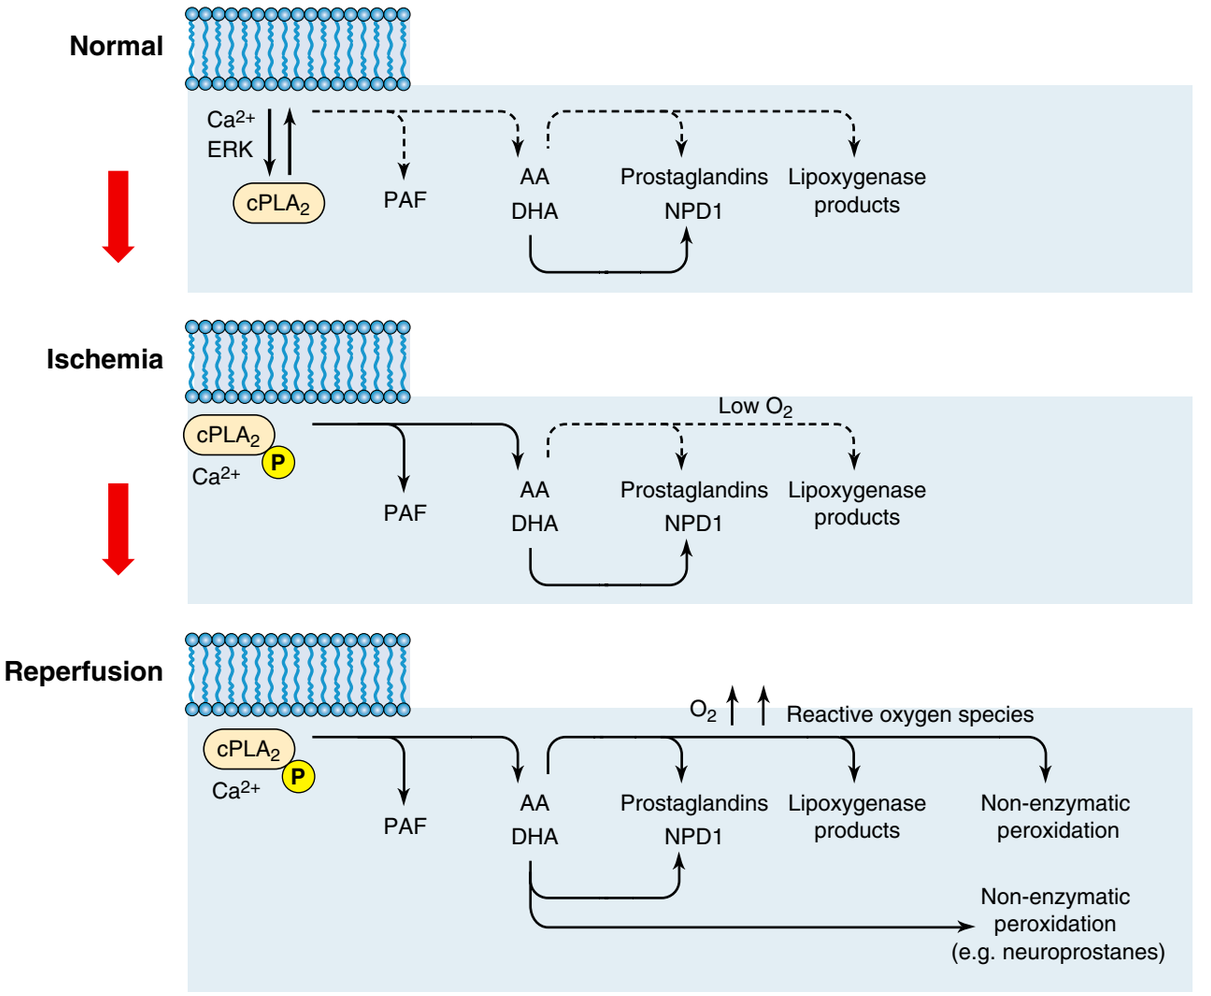

FIGURE 33-6 Phospholipases A_2 (*cPLA*$_2$) in the generation of eicosanoids, docosanoids, and lipid peroxidation products during brain, retina, or spinal cord ischemia and reperfusion. During the ischemic phase, phospholipase overactivation and the downregulation of oxidative and energy metabolism, and of fatty acid reacylation, promote the accumulation of free arachidonic acid (*AA*), free docosahexaenoic acid (*DHA*) and lysophospholipids such as lyso-PAF. The reperfusion phase facilitates eicosanoid and docosanoid synthesis. Reactive oxygen species are generated at rates that can overload the antioxidant and free radical scavenger systems of the brain, thus promoting peroxidation of polyunsaturated fatty acids. *ERK*, extracellular signal-regulated kinase; *NPD1*, neuroprotectin D1.

PAF-acetylhydrolase (intracellular) is the *lis-1* gene, mutated in Miller–Diecker syndrome, a neuronal disease characterized by the absence of gyri and sulci in the cerebral cortex (lissencephaly). A defect in neuronal migration during brain development may underlie the smooth cerebrum of people afflicted with the syndrome, and PAF and PAF-acetylhydrolase may be involved in neuronal migration [62]. Current investigations aim at determining whether other messengers, such as nitric oxide, cooperate to enhance neuronal damage and to what extent astrocytes and microglial cells are involved. Further understanding of these potentially neurotoxic events involving lipid messengers and COX-2 will contribute to the identification of new therapeutic strategies for the management of cerebrovascular diseases, neurodegenerative diseases and other pathologic conditions involving neuroinflammation.

Free arachidonic acid, along with diacylglycerols and free docosahexaenoic acid, is a product of membrane lipid breakdown at the onset of cerebral ischemia, seizures and other forms of brain trauma. Because polyunsaturated fatty acids are the predominant FFA pool components that accumulate under these conditions, this further supports the notion that fatty acids released from the C2 position of membrane phospholipids are major contributors to the FFA pool, implicating PLA_2 activation as the critical step in FFA release [1, 2] (Fig. 33-6).

Free fatty acid release during cerebral ischemia is a complex process that includes the activation of signaling cascades. In addition to $cPLA_2$, these cascades probably involve the simultaneous and/or sequential activation of other phospholipid degradation pathways and the

successive recruitment of different phospholipid pools. This is alluded to by the fact that, in focal and global cerebral ischemia, FFA accumulation is preceded by a lag of a few seconds after the start of ischemia (Fig. 33-6). Moreover, the initial release of FFA is, at least partially, derived from the activity of phospholipase C on inositol lipids (mainly phosphatidylinositol 4,5-bisphosphate), with FFAs being subsequently released from DAG by DAG lipase and monoacylglycerol lipase. FFAs and DAGs enriched in stearic and AAs accumulate during cerebral ischemia and seizures, concomitant with a rapid decrease in the inositol lipid pool. A sequential activation of PLC and PLA_2 is suggested as a mechanism for the time-dependent metabolism of different phospholipid pools during brain ischemia. The inositol lipid pool is initially a contributor to release of FFAs that are further metabolized via the PLC–DAG lipase pathway. However, as the ischemia progresses or after seizures, the calcium-dependent PLA_2 pathway prevails, with the FFA now derived from other phospholipids. A mechanism could be envisaged to explain these observations in which PI-PLC activation leads to the release of DAG and inositol trisphosphate (IP3). DAG activates protein kinase C, which in turn may modulate PI-PLC. At the same time, IP3 mobilizes intracellular calcium and thus stimulates $cPLA_2$ translocation to the membrane.

The rate of free fatty acid production in the mammalian brain correlates to the extent of resistance to ischemia. FFA production rate is much lower in the brains of neonatal mammals and poikilothermic animals, organisms that display a greater resistance to cerebral ischemic insults than mature mammals [63]. In addition, within the mammalian brain, FFA release is higher in the gray matter compared with white matter, and there is a greater accumulation of AA in areas of the brain, such as the hippocampus, selectively vulnerable to cerebral ischemic damage.

Activation of the arachidonic acid cascade during ischemia–reperfusion is a multistage process. During the ischemic phase, activation of phospholipases, inhibition of energy-dependent reacylation of membrane lipids and the lowering of oxygen tension in the brain promote the accumulation of free AA. When, or if, blood flow is restored, the rise in oxygen tension, coupled with a large pool of free AA, stimulates oxygenation-dependent reactions, some of them enzyme-mediated (e.g. for the synthesis of eicosanoids; Figs 33-2, 33-3) and others non-enzyme-mediated, which promote the formation of lipid hydroperoxides. Platelet-activating factor (PAF) synthesis is also enhanced under these conditions. Accordingly, eicosanoids accumulate during reperfusion.

Cyclooxygenase and lipoxygenase products accumulate during reperfusion following cerebral ischemia. The levels of lipoxygenase products (Fig. 33-3) increase more slowly than COX products but remain raised for longer periods of time. The cellular sites of synthesis of ischemia–reperfusion-induced eicosanoids within the brain have not yet been fully assessed. Glia and microglia comprise major inflammatory cells of the brain, as are leukocytes that infiltrate the brain during reperfusion or traumatic injury [4]. In the unstimulated brain, both 5-lipoxygenase and COX-1 and -2 have been localized to neurons. The rapid (2–3 min) activation of 5-lipoxygenase through membrane translocation is in response to reperfusion following transient (5 min) forebrain ischemia. In this study postischemic LTC4 accumulation was found to be threefold greater in the hippocampus than in the cerebral cortex and thus correlated with the high vulnerability of this region to ischemia. COX-1 activity is governed by the availability of substrate (AA and oxygen), and thus activation of the COX pathway during ischemia–reperfusion is triggered by AA release in the presence of sufficient oxygen. Induction of COX-2 transcription is rapid in ischemia and in seizures [47]. Given the involvement of glutamatergic neurotransmission in the induction of neuronal COX-2, it may be predicted that the release of glutamate triggered by cerebral ischemia would provide a trigger for COX-2 induction. There are several early-response genes that encode transcription factors that are rapidly induced under these conditions, such as hypoxia-inducible factor (HIF)-1α and NF-κB. The COX-2 promoter contains consensus sequences for these transcription factors. Nonetheless, brain displays 'constitutive' inducible COX-2 under physiological conditions. This is explained by the involvement of COX-2 in synaptic plasticity and long-term potentiation [64].

The cerebrovasculature is also an abundant source of eicosanoids. Platelets, leukocytes and vascular endothelium are all capable of synthesizing eicosanoids (see above). Brain microvessels isolated from ischemic rat brain demonstrate enhanced synthesis of eicosanoids, and leukocytes and platelets may account for much of the LTD4 produced during ischemia–reperfusion in the gerbil.

DOCOSAHEXAENOIC ACID

Brain and retina are the tissues containing the highest contents of docosahexaenoic acid. DHA is used continuously for the biogenesis and maintenance of neuronal and photoreceptor membranes (see also Ch. 49). This system is supported by the liver, which supplies DHA incorporated into plasma lipoproteins [65]. The uptake of DHA by the retina involves the retinal pigment epithelium (RPE) and its subsequent delivery to photoreceptors. During the daily photoreceptor renewal, an active recycling of phagosome-derived DHA by RPE via the interphotoreceptor matrix retains DHA within photoreceptors. A signal generated in brain or retina to control DHA

delivery from the liver has been postulated [65]; this would allow activation of DHA export during development, when DHA is required for active synapse and photoreceptor outer segment formation. This activation may also occur when injury or neurodegenerations result in loss of DHA from excitable membranes and replenishment of DHA is needed [65].

Rhodopsin in photoreceptors is immersed in a lipid environment highly enriched in phospholipids containing docosahexaenoic acid, which is essential for rhodopsin function. Moreover, retinal DHA, like brain DHA, is very resistant to n-3 fatty acid dietary deprivation [65]. Because of this constant systemic flow of DHA via a 'long loop', it is highly relevant that retinitis pigmentosa is associated with alterations in lipoprotein metabolism. The most frequently reported phenotype is low plasma and red blood cell levels of DHA [66–69]. In Usher's syndrome, an autosomal recessive retinitis pigmentosa that is associated with hearing loss, lower plasma levels of 22:6- and 20:4-phospholipids are also found [70]. Interestingly, changes show a direct correlation to the severity of disease and are more accentuated in patients with Usher's type I than in those with the less severe type II form.

Low plasma levels of 22:6n-3 in retinitis pigmentosa patients have also been interpreted as a mechanism to protect the retina from oxidative damage resulting from photochemical function of rhodopsin [71]. Stress signals originating from retinas undergoing degeneration (e.g. retinitis pigmentosa) may shut off the communication between the retina and the liver [65], reducing the systemic liver supply of 22:6n-3. In dogs with progressive rod–cone degeneration (prcd; [72]) as well as in other retinal degeneration models [71], low levels of DHA in photoreceptor phospholipids occur. Moreover, the synthesis of DHA from 20:5n-3 in RPE cultures from prcd is not affected by the retinal degeneration [73], and dietary supplementation with DHA failed to prevent the loss of photoreceptor DHA and the prcd phenotype [72]. Moreover, cultured hepatocytes from prcd dogs display higher accumulation of 22:6-phospholipids in the liver and impaired hepatocyte secretion of DHA-containing very low-density lipoproteins [74], supporting the hypothesis that in retinal degenerations a systemic DHA metabolic defect occurs that leads to reduced liver DHA supply to the retina. Whether DHA dietary supplementation protects the retina of retinitis pigmentosa patients is not known.

LIPID PEROXIDATION AND OXIDATIVE STRESS

Docosahexaenoic-acid-containing phospholipids are targets for lipid peroxidation. As a result of free-radical-catalyzed peroxidation, F4-isoprostanes are formed [75, 76]. F2-isoprostanes are also derived from free-radical-catalyzed peroxidation, although from AA instead [77]. F4-isoprostanes are found esterified in phospholipids and it has been reported that their content is increased in the brains of patients with Alzheimer's disease [78].

NEUROPROTECTIN D1: A DOCOSAHEXAENOIC-ACID-DERIVED MEDIATOR

Docosanoids, enzyme-derived docosahexaenoic acid metabolites, were identified initially in the retina. These have been proposed to elicit neuroprotective actions [14, 79]. Very recently it was ascertained by tandem LC-PDA-ESI-MS-MS-based lipidomic analysis [4] that the synthesis of DHA-oxygenation messengers occurs during brain ischemia–reperfusion (Fig. 33-6). Two DHA-oxygenation pathways operate: one that gives rise to 10,17*S*-docosatriene and one that results in the synthesis of resolvin-type messengers (17*R*-DHA). Resolvins were elegantly identified outside the nervous system as a response to aspirin treatment [80]. The brain resolvins are also made upon treatment with aspirin [4]. Both DHA-oxygenation pathways generate messengers that are counter-proinflammatory signals [80–82]. The docosanoid neuroprotectin D1 (10,17*S*-docosatriene) is a potent inhibitor of brain ischemia–reperfusion-induced polymorphonuclear infiltration, as well as of NF-κB and COX-2 expression [4]. Moreover, marked attenuation of the stroke volume was observed when neuroprotectin D1 was infused into the third ventricle during ischemia–reperfusion [4]. Discovery of these DHA-oxygenation messengers sheds new light on how the brain modulates its response to inflammatory injury and raises the exciting potential for designing new drugs to treat neurologic disorders that have a neuroinflammatory component, such as stroke, traumatic brain injury or spinal cord injury. In particular, the very high biological activity of neuroprotectin D1 marks it a potent modulator of neuronal survival.

THE FUTURE OF LIPID SIGNALING IN THE NERVOUS SYSTEM

The significance of lipid signaling in the nervous system will be greatly expanded by newer experimental approaches. Following the genomics era, we are now in 'proteomics times', when not only is the proteome being defined but metabolomics are emerging. Among the powerful new tools available are lipidomic analyses. Lipidomics is beginning to allow us to precisely define lipid organization, metabolism, synthesis of stereospecific mediators (e.g. neuroprotectin D1) and signal transduction in a given cell or part of a cell (e.g. dendrites). This is mainly due to the power, ease and versatility of what has evolved from the development of electrospray ionization mass spectrometry (ESI/MS) [83]. The detailed composition of

lipid classes and molecular species can now be approached more accurately. Moreover, the detailed identification of changes in the lipidome during the development, function, aging and dysfunctions of the nervous system will be tackled. These studies will be integrated with nutritional approaches and clinical neurosciences.

An evolving area is the understanding of the fundamental inner workings of the dendrites, which contain complex intracellular membranes rich in polyunsaturated phospholipids. Dendrites undergo profound changes during neuronal function, including the membrane vesicular transport of neurotransmitter receptors, ion channels and other proteins destined to the dendritic spine, where critical postsynaptic elements of neurotransmission are located. Definition of the dendritic lipidome will also define the participation of lipid signaling in dendritic development and in the establishment of synaptic contacts as well as overall dendritic plasticity.

Although arachidonic acid is widely implicated in signaling in brain, there are several gaps in our understanding of the release of this fatty acid from membrane reservoirs. Reports that AA is released primarily by G-protein-mediated PLA_2 activation remain to be confirmed [84, 85]. In addition, modulation of PLA_2 by Ca^{2+} and protein kinase needs to be better defined. It is clear that NMDA receptor activation promotes the release of AA [86], and that a variety of eicosanoids are then generated (Fig 33-2, 33-3). The modulatory events that channel AA towards specific eicosanoids are not understood. The endocannabinoid family of lipid messengers will remain an active focus of interest because of the growing evidence of their actions in synaptic function, learning, memory, and other forms of behavior [56, 87].

The essential fatty acid of the linolenic acid family, DHA, is most highly concentrated in brain and retina. The significance of this polyunsaturated fatty acid, in addition to being a target for nonenzymatic peroxidation under various pathologic conditions, will be a focus of continued research. Clearly, DHA-containing molecular species of phospholipids confer a unique environment for ion channels, receptors, transporters and protein–protein interactions critical in signaling. How these events are regulated, including the synthesis and remodeling of these highly unsaturated phospholipids, is not clearly understood. The enzyme-mediated synthesis of docosanoids raises the possibility of exploring the specific generation of novel DHA-oxygenation messengers that are neuroprotective [4]. How these docosanoid messengers are synthesized, through which receptors they elicit their actions, how they are affected by pharmacologic agents and how the docosanoids themselves may become a template for drug design are questions for the near future. The use of tandem LC-PDA-ESI-MS-MS-based lipidomic analysis in combination with other experimental approaches will greatly contribute to our understanding of the significance of DHA in health and in pathologic conditions.

The knowledge evolving from lipidomic neurobiology will also be potentiated by multidisciplinary approaches such as multiphoton confocal analysis. Structural neurobiology will also come into play, because the lipidome will provide new insights into the precise stereochemical structure of lipids of excitable membranes, as well as of intracellular membranes. There is also growing evidence of the exquisite signaling interplay among neurons, astrocytes, oligodendrocytes and microglia. Prostaglandins are among the lipid messengers explored to date as modulators of astrocyte release of glutamate [15]. Microglia also actively make prostaglandins in response to injury [88–90], although prostaglandin E2 may be engaged in neuroprotection [91]. Moreover, the renewed interest in defining the significance of non-neuronal cells in the nervous system [92–94] will be greatly enhanced by lipidomic approaches. Overall, the near future will witness breakthroughs using lipidomic neurobiology to more precisely define synaptic lipid signaling that will contribute to a renewed vista of the function of the nervous system as well as of the neurobiology of diseases.

Metabolic encephalopathies result from alterations of brain chemistry at both neocortical and brainstem ARAS centers. Respiration may be diminished and pupils appear small but reactive. As encephalopathy progresses, asterixis, also termed 'flapping tremor', is encountered, particularly in hepatic disease, uremia and sedative intoxication. Asterixis results from the loss of postural tone in voluntary muscles of the limbs, trunk, head or tongue. More advanced stages of metabolic encephalopathy may be characterized by seizures (for example in hypoglycemia and acute liver failure) and, ultimately, Cheyne–Stokes pattern of respiration resulting from loss of brainstem respiratory control. In addition, many metabolic encephalopathies, including those caused by vitamin deficiencies and ingestion of toxic substances, are characterized by focal metabolic changes in basal ganglia and cerebellar structures, resulting in disorders of movement control and coordination.

BRAIN ENERGY METABOLISM

The brain has an absolute dependence on the blood for its immediate supply of oxygen and energy substrates. Interruption of oxygen or substrate supply by compromise of pulmonary or cardiovascular function or metabolic factors results in encephalopathy and, if prolonged, neuronal cell death. The brain uses approximately 20% of the total oxygen supply of the body. While glucose remains the primary energy substrate for the brain, alternative substrates may be used under certain circumstances (see Ch. 31).

Given the high dependency of cerebral energy production and neurotransmitter synthesis on glucose and oxygen, limitations in supply of these substrates results in metabolic encephalopathy.

METABOLIC ENCEPHALOPATHY DUE TO LACK OF ENERGY SUBSTRATE

Hypoglycemia results in depression of CNS function, with rostral brain regions being affected before more caudally situated regions. For example, in severe hypoglycemia associated with isoelectric EEG tracings, cerebral cortical activity is absent but medullary function persists, as indicated by the maintenance of effective respiratory and cardiovascular activity.

Early clinical signs in hypoglycemia include sweating, also termed diaphoresis, tachycardia and anxiety. If unheeded, these symptoms give way to a more serious CNS disorder progressing through confusion, lethargy and delirium followed by seizures and coma. Prolonged hypoglycemia may lead to neuronal cell death and irreversible brain damage.

During the progression of hypoglycemia, as blood glucose falls below 2.5 mmol/l, confusion and delirium occur and the cerebral metabolic rate for glucose (CMR_{glc}) falls more rapidly than does the cerebral metabolic rate for oxygen ($CMRO_2$), a finding that signifies the utilization of substrates other than glucose by the brain. Such substrates include tricarboxylic acid (TCA) cycle intermediates as well as amino acids, particularly glutamine and glutamate. However, these substrates are quickly used up and support cerebral energy requirements for only a few minutes in the absence of glucose. As blood glucose concentrations fall below 2 mmol/l, the electroencephalogram (EEG) initially shows increased amplitude and decreased frequency as blood glucose concentrations approach 1 mmol/l. Below 1 mmol/l blood glucose concentrations, brain ATP levels become depleted [1] (Fig. 34-1), the EEG becomes isoelectric and coma develops.

The initial neurological symptoms of hypoxia and hypoglycemia result from reduced synthesis of neurotransmitters rather than a global cerebral energy deficit. Glucose oxidation by the brain not only provides energy in the form of the anhydride bonds of ATP but also provides precursors for the synthesis of some key excitatory and inhibitory neurotransmitters, including acetylcholine (ACh), γ-amino-butyric acid (GABA) and glutamate.

The metabolic encephalopathies comprise a series of neurological disorders not caused by primary structural abnormalities; rather, they result from systemic illness, such as diabetes, liver disease and renal failure. Metabolic encephalopathies usually develop acutely or subacutely and are reversible if the systemic disorder is treated. If left untreated, however, metabolic encephalopathies may result in secondary structural damage to the brain.

There are two major types of metabolic encephalopathy: those due to lack of glucose, oxygen or metabolic cofactors (vitamins, for example) and those due to peripheral organ dysfunction. This chapter will review the neurochemistry of the major metabolic encephalopathies, which are listed in Table 34-1.

Clinical signs and symptoms of metabolic encephalopathies consist of a generalized depression of cerebral function, including consciousness. The effects on consciousness may be a consequence of decreased integrative capacity of the neocortex. Arousal of the neocortex and other forebrain structures involved in cognition is mediated by specific brainstem nuclei and their projecting fiber tracts, which together constitute the ascending reticular activating system (ARAS). Activating pathways ascend from the ARAS via thalamic synaptic relays to the neocortex.

Most evidence suggests that the neurological symptoms characteristic of hypoglycemic encephalopathy prior to isoelectric EEG stages result from 'neurotransmission failure' involving one or more of these neurotransmitter systems. Pyruvate derived from glucose is the major precursor of the acetyl group of ACh. Inhibition of pyruvate oxidation results in reduced ACh synthesis both *in vitro* and *in vivo*. Incorporation of [^{14}C] choline into ACh in brain *in vivo* is decreased in rats with insulin-induced hypoglycemia. That hypoglycemic encephalopathy results in decreased synthesis of the neurotransmitter pool of ACh is supported by the observation that administration of the cholinesterase inhibitor physostigmine to hypoglycemic animals delays the onset of seizures and coma [2].

Similar findings of an adverse effect of hypoglycemia on the synthesis of the amino acid neurotransmitters GABA and glutamate have also been reported. Utilization of amino acids such as glutamate and glutamine as alternative energy substrates in moderate to severe hypoglycemia results in accumulation of aspartate and ammonia in the brain [3]. Hypoglycemia also produces a transient but substantial increase in extracellular concentrations of glutamate, GABA and dopamine, as measured using *in vivo* cerebral microdialysis. Alterations of neurotransmission mediated by ACh, glutamate, GABA and/or dopamine could contribute to the neurological signs and symptoms that characterize moderate hypoglycemia.

As hypoglycemia progresses below 1 mmol/l the EEG becomes isoelectric and neuronal cell death ensues. As is the case in other metabolic encephalopathies, cell death is not global in distribution; rather, certain brain structures, in particular hippocampal and cortical structures, are selectively vulnerable to hypoglycemic insult. Pathophysiological mechanisms responsible for neuronal cell death in hypoglycemia include glutamate excitotoxicity. Neuronal cell death mechanisms related to glutamate excitotoxicity are discussed in Chapter 32.

An uninterrupted supply of oxygen is vital for cerebral function. Normal human brain consumes 3.3 ml of oxygen per 100 g of brain per minute ($CMRO_2$), a value that remains relatively stable during periods of wakefulness.

Experimental studies demonstrate that cerebral energy metabolism remains normal when mild to moderate hypoxia (P_aO_2 = 25–40 mmHg) results in severe cognitive dysfunction in human volunteers [1]. In mild hypoxia, cerebral blood flow (CBF) increases in order to maintain oxygen delivery to the brain. However, CBF can increase only about twofold; beyond this $CMRO_2$ starts to fall and symptoms of hypoxia occur. In normal individuals exposed acutely to high altitudes (Table 34-2), difficulties with complex learning tasks and short-term memory appear at altitudes of 10,000 feet as P_aO_2 falls below 45 mmHg, and above 20,000 feet, where P_aO_2 = 30 mmHg, cognitive disturbances and problems with motor coordination start to appear. Acute hypoxia of less than P_aO_2 = 20 mmHg generally results in coma. In graded hypoxia in experimental animals, brain ATP levels remain normal at P_aO_2 = 20–25 mmHg despite EEG slowing and attenuated sensory evoked responses.

TABLE 34-2 Hypoxic thresholds for CNS dysfunction

Simulated altitude (feet)	F_iO_2 (%)	P_aO_2 (mmHg)	Neurological status
Sea level	21	90	Normal
500	17	80	Impaired dark vision
8,000–10,000	15–14	55–45	Impaired short-term memory, difficulty learning complex tasks
15,000–20,000	11–9	40–30	Loss of judgment, euphoria, obtundation
>20,000	<9	<25	Coma

Values derived from young volunteers subjected to acute (minutes) decompression hypoxia.
F_iO_2, fractional percentage of ambient oxygen.

Glycolysis is stimulated to maintain brain adenosine triphosphate levels in moderate hypoxia. Studies in experimental animals reveal that, at P_aO_2 = 50 mmHg, an oxygen tension well in excess of that necessary to cause impaired ATP synthesis, an increase in the lactate:pyruvate ratio and a decrease in brain tissue pH are observed. Increased lactate production is accompanied by a rise in CMR_{glc} [1], indicating accelerated glycolysis. The cytosolic redox potential measured by the NADH:NAD^+ ratio is shifted toward a more reduced state at P_aO_2 of 20 mmHg. This steep fall in phosphocreatine coincides with a decrease in ATP and reflects failure of mitochondrial respiration and oxidative phosphorylation.

Hypoxia results in alterations of neurotransmitter synthesis and release. As in hypoglycemia (above) neurotransmitter synthesis in brain is exquisitely sensitive to hypoxia. When rats are made to breathe 10% oxygen, ACh synthesis is decreased by 68% [4]. Hypoxia of a similar magnitude also results in altered synthesis and release of other neurotransmitters, including those derived from glucose. Arterial oxygen tension of less than 50 mmHg results in reductions in synthesis of glutamate and GABA in brain. Synthesis of the biogenic amines may also be susceptible to hypoxia since tyrosine hydroxylase and tryptophan hydroxylase, the rate-limiting enzymes in monoamine neurotransmitter synthesis, require molecular oxygen, for which the K_m (O_2) is 12 µmol/l, equivalent to 7 mmHg.

HYPONATREMIC ENCEPHALOPATHY

If uncontrolled, hyponatremia may cause increased intracranial pressure, brain herniation and death. The major cause of hyponatremic encephalopathy is an osmotic imbalance between extracellular fluid and neural cells leading to a net movement of water into the brain

and, consequently, brain edema. If uncontrolled, this process may lead to increased intracranial pressure and brain herniation. Symptoms of hyponatremia include lethargy and decreased responsiveness progressing to seizures and, if uncontrolled, death. Hyponatremia is commonly encountered in a wide range of disorders including liver cirrhosis, diabetes and acquired immune deficiency syndrome (AIDS).

Regulation of the fluid–electrolyte environment of the brain is influenced by a neuroendocrine system that affects the capillary endothelium, the choroid plexus and astroglial cells. These barrier system tissues express receptors for endogenous neuropeptides whose action affects water and ion movement. Brain responds to hyponatremia by extrusion of cations (Na^+, K^+, some amino acids) in order to lower its osmolarity towards that of plasma; water then enters brain, reducing the progression towards edema. Steroid hormones modulate these peptidergic systems and evidence suggests that the interplay between steroid hormones and endogenous vasoactive peptides is important in the pathogenesis of hyponatremic encephalopathy [5]. Circulating steroid hormones are lipophilic and readily cross the blood–brain barrier.

Ovarian hormones influence fluid intake by interaction with the brain renin–angiotensin system and it has been shown that gonadal steroids affect brain fluid–electrolyte balance by interactions with vasopressin. Both hyperosmolarity and increased intracranial pressure stimulate vasopressin release and intraperitoneal administration of vasopressin antagonists decrease brain volume.

Treatment of hyponatremia involves the use of hypertonic saline. However, care is required since correction at rates in excess of 1 mEq/l/h may result in central pontine myelinolysis (CPM) [5]. Symptoms of CPM include progressive weakness leading to quadriparesis, pseudobulbar palsy and altered mental status. CPM is often fatal and is characterized neuropathologically by demyelinating lesions in the central pons.

HYPERCAPNIC ENCEPHALOPATHY

Respiratory acidosis leads to decreased brain pH. Patients with chronic pulmonary disorders may exhibit lethargy, confusion, memory loss and stupor. The combined insults of hypoxia and hypercapnia, which result in CO_2 retention, contribute to the encephalopathy but neurological symptoms correlate best with the degree of CO_2 retention. Acute moderate hypercapnia associated with 5–10% CO_2 in the expired air, leads to arousal and excitability whereas higher CO_2 concentrations, >35% in the expired air, are anesthetic.

Although CO_2 is a normal metabolite, it is toxic at elevated levels. CO_2 exists in equilibrium with carbonic acid (H_2CO_3) and with bicarbonate (HCO_3^-), a major H^+ buffer. Renal conservation of HCO_3^- is generally sufficient to buffer hypercapnia; however, an added insult, such as an infection, fatigue or ingestion of a sedative, may further compromise pulmonary function, resulting in further CO_2 retention and disruption of the normal buffering mechanisms. The respiratory acidosis associated with CO_2 retention in blood leads to a proportional increase in brain tissue $[H^+]$.

The combination of hypoxia and hypercapnia in pulmonary insufficiency results in cerebral vasodilation and increased CBF and may lead to increased intracranial pressure. Arteriovenous differences for oxygen across the brain generally decrease as a function of increased CBF, leaving $CMRO_2$ unchanged [6].

Acute hypercapnic acidosis leads to an increase in concentrations of glycolytic intermediates above the phosphofructokinase step; a decrease below this step is probably due to inhibition of phosphofructokinase by $[H^+]$. Brain ATP concentrations are unchanged in hypercapnia and it is generally believed that decreased brain glucose utilization is the result of decreased neuronal activity and, hence, reduced fuel (glucose) requirements. As in hypoglycemia and hypoxia, neurotransmitter-related mechanisms that could contribute to hypercapnic encephalopathy include decreased neurotransmitter glutamate and GABA pools and decreased synthesis of acetylcholine.

METABOLIC ENCEPHALOPATHY DUE TO PERIPHERAL ORGAN FAILURE

Hepatic encephalopathy.

Hepatic encephalopathy is a neuropsychiatric disorder resulting from liver failure. Neurologically, hepatic encephalopathy evolves slowly. Early symptoms include altered sleep patterns and personality changes, followed by shortened attention span and asterixis progressing through stupor to coma as liver function deteriorates. Hepatic encephalopathy in acute liver failure progresses rapidly through altered mental status to stupor and coma within hours or days. Seizures are occasionally encountered and mortality rates are high. Death most frequently results from brainstem herniation caused by increased intracranial pressure as a consequence of astrocytic swelling and brain edema.

Hepatic encephalopathy in chronic liver failure, on the other hand, is characterized neuropathologically by astrocytic changes known as Alzheimer type II astrocytosis. The Alzheimer type II astrocyte has a characteristic swollen shape with a large, pale nucleus, prominent nucleolus and margination of chromatin (Fig. 34-2). In addition, astrocytes in chronic liver failure manifest reduced expression of key astrocytic proteins, such as glial fibrillary acidic protein (GFAP), glutamine synthetase and monoamine oxidase type B, and increased expression of astrocytic 'peripheral-type' benzodiazepine receptors (PTBRs) [7]. These changes suggest that normal astrocytic functions, such as ammonia removal and the uptake and metabolism of monoamine and amino acid neurotransmitters, are impaired; and it has been proposed that hepatic

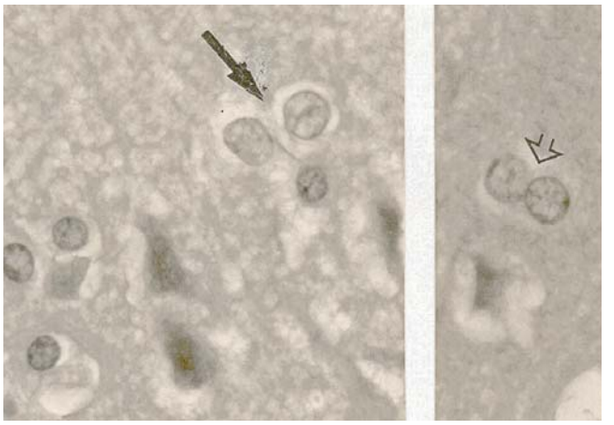

FIGURE 34-2 Typical pattern of Alzheimer type II astrocytosis in frontal cortex of a 51-year-old cirrhotic patient who died in hepatic coma. Note astrocytes with large pale nucleus and margination of chromatin (*large arrow*). Dodoublets of Alzheimer type II cells frequently appear (*open arrowhead*).

encephalopathy in chronic liver failure results from a disorder of 'neuron-astrocyte trafficking' of key substrates.

Liver failure leads to the accumulation of toxic substances in brain. Two such substances have been identified, namely ammonia and manganese. Magnetic resonance imaging (MRI) reveals increased signal intensity in pallidum on T1-weighted MRI in the majority of patients with chronic liver disease, suggesting the presence of a paramagnetic substance in this region of the brain. Evidence to date suggests that this substance is manganese. Blood manganese concentrations are increased in cirrhotic patients, and a positive correlation is observed between blood and brain manganese content and the magnitude of pallidal MRI signal hyperintensity in these cases [8]. Manganese deposition in the basal ganglia could explain the extrapyramidal symptoms frequently encountered in hepatic encephalopathy patients, such as tremor and rigidity (see Ch. 46).

Both ammonia and manganese may be responsible for the astrocytic morphological changes observed in hepatic encephalopathy. Exposure of cultured astrocytes to ammonia results in decreased expression of GFAP and decreased capacity of cells to take up glutamate, phenomena that are consistently observed in the brains of humans or experimental animals with hepatic encephalopathy. Similar reduced glutamate uptake is observed following exposure of cultured astrocytes to manganese and exposure to manganese causes Alzheimer type II astrocytosis.

Ammonia concentrations in arterial blood of patients with liver failure rise to 0.5–1 mmol/l, in contrast to the normal range of 0.01–0.02 mmol/l. Using positron emission tomography (PET; see Ch. 58), increases of the cerebral metabolic rate for ammonia (CMRA), i.e. the rate at which ammonia is taken up and metabolized by the brain, have been reported in chronic liver failure [9]. Increased CMRA in chronic liver failure is accompanied by increases in the permeability/surface area product (PS), a measure of blood–brain barrier permeability to ammonia (Fig. 34-3).

Ammonia has deleterious effects on brain function by direct and indirect mechanisms. Concentrations of ammonia in the 1–2 mmol/l range, equivalent to those reported in the brain in liver failure, impair postsynaptic inhibition in cerebral cortex and brainstem by a direct effect on Cl^- extrusion from the postsynaptic neuron. Millimolar concentrations of ammonia also inhibit excitatory neurotransmission. Synaptic transmission from Schaffer collaterals to CA1 hippocampal neurons is reversibly depressed by 1 mmol/l ammonia, and the firing of CA1 neurons by iontophoretic application of glutamate is inhibited by 2 mmol/l ammonia [10].

Addition of millimolar concentrations of ammonia to brain preparations results in inhibition of α-ketoglutarate dehydrogenase (αKGDH). αKGDH is a rate limiting enzyme of the TCA cycle and, consistent with decreased oxidation of pyruvate (and α-ketoglutarate), both acute and chronic liver failure result in increased brain lactate concentrations. Ammonia-precipitated coma in portacaval-shunted rats results in decreased brain ATP, but these changes are not apparent until late (preterminal) stages associated with deep coma.

Hepatic encephalopathy is a disorder of multiple neurotransmitter systems. In common with hypoglycemic and hypoxic encephalopathies, early stages of hepatic encephalopathy do not result from a cerebral energy deficit; rather they are associated with alterations of multiple neurotransmitter systems in the brain. In most cases, these changes appear to be directly or indirectly the consequence of ammonia or manganese toxicity. Neuron-astrocyte trafficking of substrates is impaired results in glutamatergic synaptic dysregulation, a phenomenon that could contribute to the pathogenesis of hepatic encephalopathy. Glutamate uptake into cultured astrocytes is reduced by exposure to submillimolar concentrations of ammonia. Furthermore, consistent with diminished clearance of glutamate from the synaptic cleft in hepatic encephalopathy, microdialysis studies in animals with experimental acute liver failure reveal increased extracellular concentrations of glutamate as a function of the degree of neurological impairment, and reduction of expression of the astrocytic glutamate transporter (EAAT-2) has been reported in brain in experimental acute liver failure.

Many of the neuropsychiatric symptoms in early hepatic encephalopathy, such as altered sleep patterns, are signs that have classically been attributed to modifications of serotoninergic neurotransmission. Serotonin turnover, as indicated by the ratio of the concentrations of the metabolite 5-hydroxyindoleacetic acid to serotonin, is increased in brain in both human and experimental hepatic encephalopathy.

	Normal (5)	Hepatic encephalopathy Patients (5)
Arterial ammonia μmol/l	30 ± 7	62 ± 20*
Cerebral metabolic rate for ammonia (CMRA) (μmol/l100 g/min)	0.35 ± 0.15	0.91 ± 0.36*
Blood–brain barrier permeability (PS) to ammonia (ml/g/min)	0.13 ± 0.03	0.22 ± 0.07*

*$p < 0.01$, compared to normal values

FIGURE 34-3 Positron emission tomography using $^{13}NH_3$ showing increased brain ammonia uptake in a patient with liver cirrhosis and mild hepatic encephalopathy. *CMRA*, cerebral metabolic ratio for ammonia; *HE*, hepatic encephalopathy; *PS*, permeability/surface area product. (With permission from reference [9].)

The PTBR is expressed in increased amounts in hepatic encephalopathy. In the CNS, PTBRs are localized mainly on the mitochondrial membranes of astrocytes. Increases of expression and maximal binding site densities of PTBRs have consistently been described in brain and peripheral tissues in experimental and human hepatic encephalopathy brain. Increased PTBR expression also occurs in cultured astrocytes exposed to ammonia or manganese. Precisely how the increased expression of PTBRs in brain is related to the neuropsychiatric symptoms in hepatic encephalopathy is unclear, but it has been demonstrated that activation of the PTBR leads to the production of neurosteroids, such as 3-α-hydroxy-5α-pregnan-20-one (allopregnanolone), a compound that has a high affinity for the $GABA_A$ receptor and for which it is a positive allosteric modulator. These findings suggest that PTBR activation could contribute to 'increased GABAergic tone' in hepatic encephalopathy via the production of neurosteroids [7].

Finally, there is an emerging body of evidence to suggest that the endogenous opioid system of the brain may be involved in the mediation of some of the effects of chronic liver failure on cerebral function. Increased plasma concentrations of the endogenous opioid peptide met-enkephalin have been described in patients with primary biliary cirrhosis, and β-endorphin concentrations are increased in the brains of rats following portacaval shunting together with alterations of μ and δ opioid-binding sites [11].

Bilirubin encephalopathy.

Bilirubin, a product of hemoglobin metabolism, causes brain dysfunction and apoptotic cell death. In many premature neonatal infants, high levels of unconjugated bilirubin (UCB) occur in the blood, causing jaundice. In severe cases this can lead to bilirubin encephalopathy characterized by hypotonia and lethargy, which may progress to neuronal damage and death if not treated promptly. Surviving infants have an increased prevalence of cerebral palsy and mental retardation [12].

Both astrocytes and neurons are susceptible to UCB exposure. Isolated neurons treated with UCB show increased evidence of apoptosis with release of cytochrome

c and activation of caspase-3. In addition, UCB exposure decreases mitochondrial transmembrane potential and increases mitochondrial-associated BAX protein levels while concomitantly disrupting membrane lipid and protein structure. Apoptosis has also been reported in the cerebellum of jaundiced Gunn rat pups. The Gunn rat has an autosomal recessive deficiency of glucuronyl transferase resulting in hyperbilirubinemia.

Exposure of rat cortical astrocytes to UCB results in a significant reduction of high-affinity glutamate uptake which is time, concentration and pH-dependent leading to increased extracellular glutamate. Consequently, NMDA-receptor-mediated excitotoxicity may be implicated in the pathogenesis of neuronal cell death due to UCB exposure. In favor of this possibility, the NMDA receptor antagonist MK801 attenuates the severity of cerebellar neuronal loss in the Gunn rat [13].

Uremic and dialysis encephalopathies. Patients with renal failure continue to manifest neuropsychiatric symptoms despite significant advances in therapeutics and management. Patients with renal failure who are not yet on dialysis develop an array of symptoms, including clouding of consciousness, disturbed sleep patterns, tremor and asterixis that may progress to coma and death.

Uremia is characterized by retention in the blood of urea, phosphates, proteins, amines and a number of poorly defined low-molecular-weight compounds. Despite acidemia, the pH of brain, muscle and CSF are normal in humans with renal failure. Whereas brain water, K^+ and Mg^{2+} content are normal, Al^{3+} and Ca^{2+} concentrations are significantly increased [14].

Uremia leads to alterations of the blood–brain barrier. Uremia results in increased permeability of the blood–brain barrier to sucrose and insulin; K^+ transport is enhanced whereas Na^+ transport is impaired. There is an increase in brain osmolarity in acute renal failure due to the increase in urea concentrations. However, in contrast to acute renal failure, the increase in osmolarity in chronic renal failure results from the presence of idiogenic osmoles in addition to urea. CBF is increased in uremic patients but $CMRO_2$ and CMR_{glc} are decreased. In the brains of rats with acute renal failure, ATP, phosphocreatine and glucose are increased whereas AMP, ADP and lactate are decreased, most probably as a result of decreased energy demands.

Parathyroid hormone (PTH) produces CNS effects in normal subjects and neuropsychiatric symptoms are frequently encountered in patients with primary hyperparathyroidism, where EEG changes resemble those described in acute renal failure. Circulating PTH is not removed by hemodialysis. In uremic patients both EEG changes and neuropsychiatric symptoms are improved by either parathyroidectomy or medical suppression of PTH. The mechanism whereby PTH causes disturbances of CNS function is not well understood, but it has been suggested that increased PTH might facilitate the entry of Ca^{2+} into the cell resulting in cell death.

Aluminum neurotoxicity may play a role in dialysis encephalopathy. This condition, also termed 'dialysis dementia', is a progressive, frequently fatal neurological disorder that occurs in patients on chronic hemodialysis. Symptoms progress through personality changes, psychosis, seizures and dementia. Dialysis dementia may result from aluminum accumulation in brain: the aluminum content of cerebral gray matter from patients with dialysis dementia is 11 times higher than normal and three times higher than that observed in patients on chronic hemodialysis but without dialysis dementia. Aluminum is normally excreted by the kidney.

Epidemiological studies have shown a strong association between the aluminum content of the water used to prepare dialysates and the incidence of dialysis dementia. Reducing water aluminum content below 20 μg/l appears to prevent the onset of the disease in patients who have just started dialysis.

THIAMINE DEFICIENCY (WERNICKE'S) ENCEPHALOPATHY

Thiamine deficiency results in early decreases in activity of the mitochondrial enzyme α-ketoglutarate dehydrogenase in brain. Wernicke's encephalopathy, also known as the Wernicke–Korsakoff syndrome is a neuropsychiatric disorder characterized by ophthalmoplegia, ataxia and memory loss. Wernicke's encephalopathy is encountered in chronic alcoholism, in patients with HIV-AIDS and in other disorders associated with grossly impaired nutritional status. The condition results from thiamine deficiency.

In the 1930s, Peters and co-workers showed that thiamine deficiency in pigeons resulted in the accumulation of lactate in the brainstem [15]. Furthermore, they showed that the addition of small quantities of crystalline thiamine to the isolated brainstem tissue from thiamine-deficient birds *in vitro* resulted in normalization of lactate levels. These findings led to the formulation of the concept of 'the biochemical lesion' in thiamine deficiency. Subsequent studies showed that the enzyme defect responsible for the 'biochemical lesion' was α-KGDH rather than pyruvate dehydrogenase (PHDC), as had previously been presumed. α-KGDH and PHDC are major thiamine diphosphate (TDP)-dependent enzymes involved in brain glucose oxidation (Fig. 34-4).

In brain, as in most mammalian cells, thiamine occurs predominantly in the form of TDP, the remainder being made up of thiamine monophosphate (10%), thiamine triphosphate (5–10%) and trace amounts of free thiamine. Thiamine is transported into brain and phosphorylated by the action of thiamine pyrophosphokinase, and inhibition of this enzyme by thiamine antagonists such as pyrithiamine results in decrease synthesis of TDP. Treatment of experimental animals with pyrithiamine results in a generalized reduction of TDP concentrations and an early selective loss in activity of α-KGDH in regions

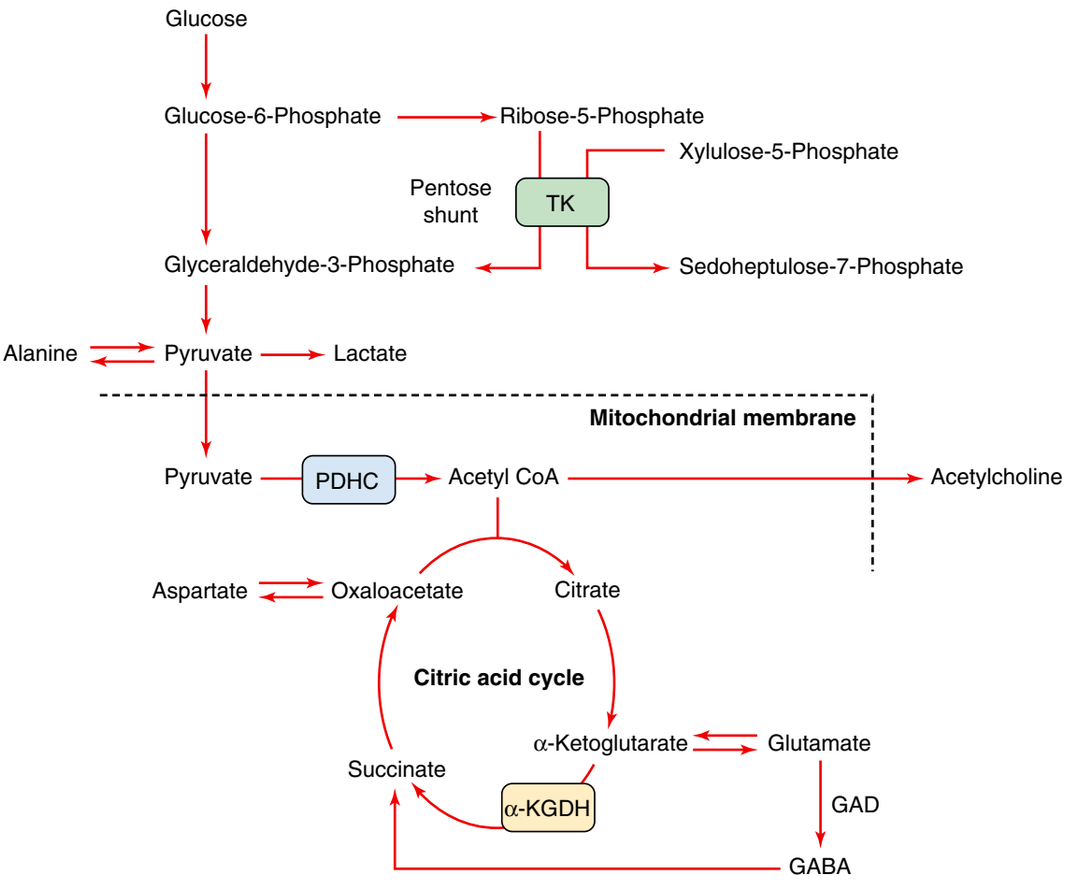

FIGURE 34-4 Thiamine-diphosphate-dependent enzymes associated with the tricarboxylic acid cycle and glucose oxidation. Thiamine deficiency results in an early loss of activity of α-KGDH in brain and reduced synthesis of acetylcholine, glutamate and GABA. *α-KGDH,* α-ketoglutarate dehydrogenase; *PDHC,* pyruvate dehydrogenase complex; *TK,* transketolase in the pentose shunt.

of the brain such as thalamus, which are destined to manifest selective neuronal cell loss. Decreased activities of α-KGDH following treatment with pyrithiamine are associated with decreased synthesis of glucose-derived excitatory and inhibitory amino acids including glutamate, aspartate and GABA with a concomitant increase in lactate and alanine consistent with decreased flux of carbon through the TCA cycle. Both the α-KGDH decreases and the changes in synthesis of amino acids are initially reversible following thiamine rehabilitation in pyrithiamine-treated animals [16], suggesting that these changes are an integral part of 'the biochemical lesion' originally proposed by Peters.

Oxidative decarboxylation of α-ketoglutarate (and pyruvate) are decreased in isolated mitochondria from the brains of thiamine deficient rats, consistent with reduction in activity of α-KGDH. Moreover, studies in mitochondrial preparations from thiamine-deficient animals revealed that state 3 respiration is significantly decreased using α-ketoglutarate as substrate but was unchanged using succinate (succinate is oxidized independently of TDP-dependent enzymes, Fig. 34-4). Cultured cerebellar granule cells exposed to pyrithiamine manifest significant reductions in TDP and activities of α-KGDH and increased lactate production indicative of decreased TCA cycle flux and a significant lowering of cellular pH [17]. More prolonged exposure to thiamine deficiency leads to depolarization, lactate accumulation, decreased ATP production and cell necrosis.

Oxidative stress contributes to selective neuronal cell death in thiamine-deficiency. Increasing evidence suggests a role for oxidative stress in the pathophysiology of selective neuronal cell death due to thiamine deficiency. Increased production of reactive oxygen species has been reported in the brains of pyrithiamine-treated rats [18] and increased peroxidase activity indicative of oxidative stress is related to the neuropathology in Wernicke's encephalopathy in humans. Other findings consistent with oxidative stress as a contributing factor to thiamine-deficiency-related neuropathology include reports of increase in heme oxygenase, early induction of endothelial NOS (eNOS) and microglial activation.

Neuropathologic studies in animals with experimental thiamine deficiency consistently show early damage to glial cells rather than neurons. Studies in human patients with Wernicke's encephalopathy likewise show changes in astroglia, together with microglial proliferation, which is

apparent even in regions of the brain showing little if any neuronal cell death. A systematic study of astroglial integrity in thiamine deficiency using cell-specific markers (ED-1 for microglial activation; GFAP for astrocytic proliferation) revealed early microglial activation in brains of thiamine-deficient animals [19]. Increased ED-1 immunolabeling was confined to vulnerable brain structures such as thalamus, inferior colliculus and vestibular nuclei and was found to precede neuronal cell loss, breakdown of the blood–brain barrier and reactive astrocytosis in the brains of these animals. These findings suggest that metabolically compromised neurons (due to thiamine deficiency) could initiate, by cell-to-cell signaling pathways, microglial activation as an initial cellular event.

A recent study showed significant increases of expression of eNOS in the brains of rats treated with pyrithiamine [20]. Increased eNOS expression was apparent prior to the onset of neurological symptoms and was restricted to vulnerable medial thalamus and inferior colliculus. Expression of inducible (iNOS) and neuronal (nNOS) isoforms were minimally altered in brain in thiamine deficiency and it has also been shown that targeted disruption of the eNOS (but not the iNOS or nNOS) gene results in reduced extent of neuropathological damage in thalamus of thiamine deficient animals [21] (Fig. 34-5).

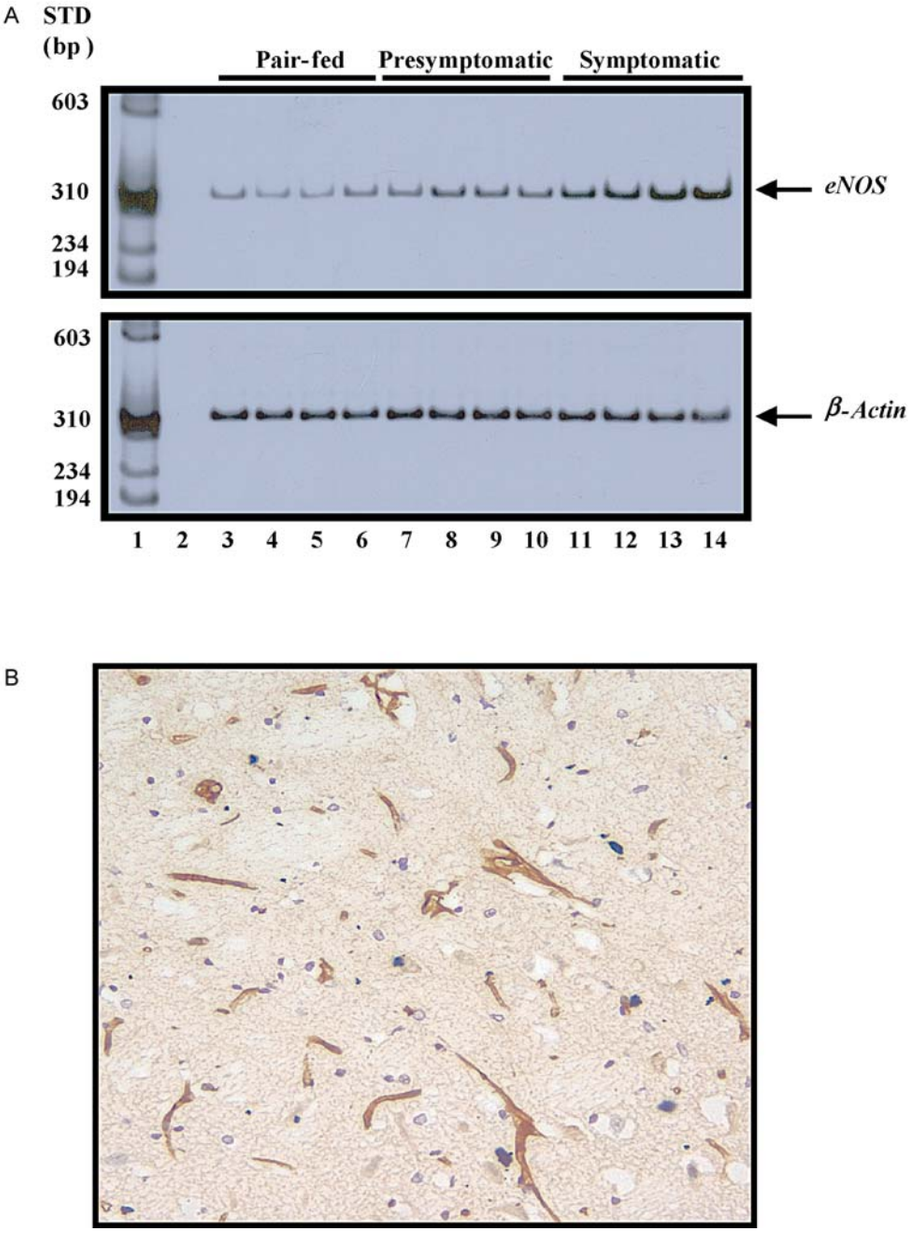

FIGURE 34-5 Induction of endothelial nitric oxide synthase (*eNOS*) in medial thalamus of thiamine-deficient rats. (A) Increased eNOS mRNA. (B) Increased eNOS immunolabeling of vascular endothelial cells (magnification ×200).

The suggestion that eNOS-derived NO is implicated in neuronal cell death mechanisms in thiamine deficiency contrasts with current views in cerebral ischemia in which increased eNOS-derived NO is thought to play a neuroprotective role by virtue of its vasodilatory potential.

PYRIDOXINE (VITAMIN B_6) DEFICIENCY

Pyridoxine, in its phosphorylated form, pyridoxal phosphate, is an important coenzyme in several enzymic reactions, some of which are involved in neurotransmitter synthesis (e.g. decarboxylation of glutamate to GABA–see Ch. 16). Developing brain is particularly sensitive to pyridoxine deficiency, resulting in impaired synaptogenesis and hypomyelination. Adult animals fed pyridoxine-deficient diets develop learning disabilities, irritability, gait ataxia and seizures; the latter develop in parallel with the fall in activity of glutamic acid decarboxylase and GABA synthesis.

COBALAMIN (VITAMIN B_{12}) DEFICIENCY

Cobalamins have two biochemical functions. Adenosylcobalamin is the cofactor for the mutase enzyme that converts methylmalonyl CoA to succinyl CoA. Methylcobalamin, on the other hand, is a cofactor for the enzyme that converts homocysteine to methionine. Cobalamin deficiency occurs relatively commonly in the clinic and involves both hematological and neurological changes. Neurologically, cobalamin deficiency results in paresthesias, loss of sensation and spastic weakness. Neuropathologically, a spongy demyelination of the long fiber tracts of spinal cord, particularly the posterior columns, is noted. Whether the CNS symptoms and neuropathology are the consequence of deficiency of the mutase or the methyltransferase enzymes is unresolved.

Apoptosis and Necrosis

Mark P. Mattson

Nicolas G. Bazan

DISTINGUISHING FEATURES OF APOPTOSIS AND NECROSIS 603
During embryonic and postnatal development, and throughout adult life, many cells in the nervous system die 603
Many of the morphological and biochemical changes that occur in cells that die by necrosis are very different from those that occur in apoptosis 604

APOPTOSIS 604
Adaptive apoptosis occurs in the developing and adult nervous system 604
Apoptosis occurs in acute neurological insults 605
Apoptosis occurs in neurodegenerative disorders 607
There are many triggers of apoptosis 608
Once apoptosis is triggered, a stereotyped sequence of premitochondrial events occurs that executes the death process 609
Several different changes in mitochondria occur during apoptosis 610
The postmitochondrial events of apoptosis include activation of the caspases 610
A widely used criterion for identifying a cell as 'apoptotic' is nuclear chromatin condensation and fragmentation 611
Cells in the nervous system possess many different mechanisms to prevent apoptosis 611
The morphological and biochemical characteristics of apoptosis are not always manifest in cells undergoing programmed cell death 612
Apoptotic cascades can be triggered, and pre- and postmitochondrial events can occur, without the cell dying 613

NECROSIS 613
Necrosis is a dramatic and very rapid form of cell death in which essentially every compartment of the cell disintegrates 613
There are few cell death triggers that are only capable of inducing either apoptosis or necrosis 614

TARGETING APOPTOSIS AND NECROSIS IN NEUROLOGICAL DISORDERS 613

DISTINGUISHING FEATURES OF APOPTOSIS AND NECROSIS

During embryonic and postnatal development, and throughout adult life, many cells in the nervous system die. Such cell deaths are called 'programmed' because they are normal, being either adaptive or neutral with regards to their impact on the function of the nervous system. One particular form of programmed cell death (PCD) that has been extensively studied is called apoptosis. The details of the molecular cascades and morphological features of apoptosis vary somewhat depending on cell type, death stimulus and other factors [1]. However, there are several morphological and biochemical changes that are generally considered to be defining features of apoptosis (Table 35-1). Morphological changes include cell shrinkage, blebbing of the plasma membrane and nuclear chromatin condensation and fragmentation with preservation of the structure of mitochondria and the endoplasmic reticulum. Biochemical events that define apoptosis include: upregulation and/or mitochondrial translocation of proapoptotic proteins such as Bax and Par-4; formation of mitochondrial permeability transition pores and the release of cytochrome c and/or apoptosis-inducing factor (AIF) from the mitochondria; activation of effector caspases, which control the cell death process by cleaving a range of cytoplasmic, membrane-associated and nuclear protein substrates; exposure of phosphatidylserine on the plasma membrane surface, which serves as a signal for recognition and engulfment of the dying cell by macrophages and microglia. If the preceding events occur *and* if the death of the cells can be prevented by caspase inhibitors and inhibitors of protein synthesis, then the mode of cell death can be considered to be apoptosis.

Basic Neurochemistry: Molecular, Cellular and Medical Aspects
0-12-088397-X

TABLE 35-1 Examples of caspase substrates

Cytoskeletal and associated proteins	Actin, spectrin, tau, vimentin, β-catenin, gelsolin, kinectin
Nuclear and DNA-associated proteins	Ataxia telangiectasia mutated (ATM), poly(ADP ribose) polymerase (PARP), DNA-dependent protein kinase, DNA replication factor C, DNA topoisomerase I, DNA fragmentation factor (DFF)45, inhibitor of caspase-activated DNAse (ICAD), lamins A, B1, and C
Signal transduction proteins	TRAF-1, Raf1, Ras, GAP, GDP dissociation inhibitor of Rho family GTPases, phospholipase A_2, Stat1
Kinases and phosphatases	Protein kinase Cd, Akt kinase, calcium/calmodulin-dependent protein kinase IV, mitogen-activated protein kinase kinase (MEKK-1), focal adhesion kinase (FAK), protein phosphatase (PP)2A, calcineurin
Transcription factors	NF-κB subunits p65 and p50, AP-2α, forkhead transcription factor FOXO3a, Max
Ion channels	IP3R1 and IP3R2, glutamate (AMPA) receptor subunits GluR1 and GluR4
Neurological-disorder-related proteins	Amyloid precursor protein (APP), presenilin-1, presenilin-2, parkin, tau, huntingtin, ataxin-3

Many of the morphological and biochemical changes that occur in cells that die by necrosis are very different from those that occur in apoptosis. During necrosis cells swell, mitochondria and endoplasmic reticulum lose their structure and become dysfunctional and the nuclear membrane becomes disrupted (Fig. 35-1). Necrotic death is independent of premitochondrial apoptotic proteins such as Bax, cytochrome c release and caspase activation. Necrosis is further distinguished from apoptosis by the fact that necrosis usually occurs as the result of a traumatic physical injury or stroke and cells die *en masse*, whereas apoptosis typically occurs in individual cells within a population of surviving neighbors.

The information presented in this chapter concerns the mammalian nervous system. However, it should be recognized that similar mechanisms may occur in other organisms and, indeed, many important aspects of the process of apoptosis were initially discovered in studies of the nematode *Caenorhabditis elegans* [2].

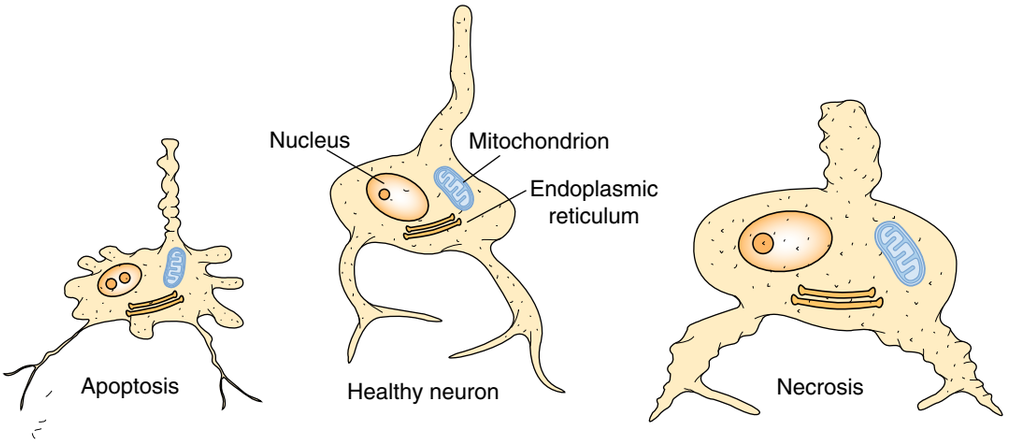
APOPTOSIS

The conditions and signaling pathways that trigger or prevent apoptosis, and the molecular control of the apoptotic process, are topics of intense interest in the field of neuroscience. Knowledge of the cellular and molecular mechanisms of apoptosis is necessary for a full understanding of how the brain and other regions of the nervous system develop. Evidence is increasing that apoptosis and related forms of cell death occur in a range of neurodegenerative disorders such as Alzheimer's, Parkinson's and Huntington's diseases and stroke; there is therefore intense interest in developing approaches directed toward apoptosis as a therapeutic means in these diseases (see respective chapters for details related to therapy).

Adaptive apoptosis occurs in the developing and adult nervous system. During embryonic and early postnatal development, many cells undergo apoptosis in most regions of mammalian nervous systems. Such developmental apoptosis is believed to be adaptive in that it eliminates cells that are not integrated into neuronal circuits and are therefore unnecessary for the proper function of the nervous system. While initially established in populations of neurons that innervate peripheral targets (dorsal root ganglia, sympathetic ganglia and motor neurons), developmental apoptosis has also been documented in several populations of neurons in the brain. There appear to be two major 'waves' of apoptosis, one occurring early and involving neuronal progenitor cells and another occurring later and involving neurons that are in the process of forming synaptic connections with target cells [3]. While neuronal apoptosis is well established, the extent to which glial cells (oligodendrocytes and astrocytes) undergo apoptosis during development is unclear (see Development in Ch. 25).

Developmental processes continue in at least some locations in the adult nervous system. For example, relatively large numbers of neural stem cells are located in the subventricular zone of the cerebral cortex and in the subgranular layer of the dentate gyrus of the hippocampus (see Stem Cells in Ch. 29). The subventricular zone stem cells give rise to interneurons in the olfactory bulb, while hippocampal stem cells can differentiate into dentate granule neurons. Although some newly generated neurons that arise from stem cells in the adult brain become integrated into neuronal circuits, many of these cells undergo apoptosis [4]. Neurogenesis increases in response to brain injury, which is probably an adaptive mechanism designed to replace damaged neurons (see Regeneration in Ch. 30).

The signals that determine whether neural stem cells and their progeny survive or undergo apoptosis include growth factors (Ch. 27), cytokines (Chs 30, 32 and 33) and cell adhesion molecules (Ch. 7). The discovery of nerve growth factor (NGF) heralded investigations into the roles of neurotrophic factor signaling in determining whether neurons live or die during development. It was shown by Levi-Montalcini and Hamburger in the 1950s that sensory and sympathetic neurons depend on a substance later identified as nerve growth factor (NGF) for their survival



Apoptosis	Necrosis
Cell shrinkage	Cell swelling
Maintenance of organellar integrity	Organellar swelling and damage
Maintenance of ATP levels	Depletion of ATP
Maintenance of ion homeostasis	Loss of ion homeostasis
Membrane surface blebbing	Membrane rupture
Nuclear chromatin condensation/fragmentation	Nuclear lysis
Requires synthesis of death effector proteins	Cessation of protein synthesis
Prevented by blocking steps in the death cascade	Irreversible
Does not adversely affect neighbor cells	Promotes death of neighbor cells

FIGURE 35-1 Distinguishing features of apoptosis and necrosis.

and maintenance. Neurons that do not receive sufficient trophic support undergo apoptosis. Other factors that can determine whether stem cells and/or neurons live or die include basic fibroblast growth factor (bFGF), brain-derived neurotrophic factor (BDNF) and epidermal growth factor [4, 5]. Examples of other signaling molecules that may regulate developmental apoptosis include nitric oxide, Par-4 and ceramide, PTEN (phosphatase and TENsin homolog) and the transcription factor E2F1.

Apoptosis occurs in acute neurological insults. Traumatic and ischemic injury to the nervous system are common events that result in considerable morbidity and mortality. Accordingly, there is intense interest in understanding the cellular and molecular mechanisms responsible for the death of neurons in such acute neurodegenerative conditions. Many neurons may undergo apoptosis in response to a traumatic injury to the brain, spinal cord or peripheral nerves, as indicated by activation of various proapoptotic proteins including p53 and caspases [6]. In particular, neurons adjacent to the necrotic region of severe trauma are prone to apoptosis. Drugs that attenuate apoptosis have been shown to be beneficial in animal models of traumatic brain and spinal cord injury, suggesting a potential for such an approach in human patients.

Ischemic stroke occurs when a blood vessel in the brain becomes occluded, usually as the result of atherosclerosis and clot formation (Ch. 32). Neurons in the brain supplied by the affected vessel may undergo apoptosis [7]. Indeed, biochemical, morphological and functional evidence of apoptosis has been documented in animal models of stroke. Triggers of ischemic apoptosis include oxygen free radicals, glutamate receptor activation, calcium influx and release from intracellular stores, and lipid mediators. DNA damage and activation of poly(ADP ribose) polymerase (PARP) and p53 are also implicated in stroke-induced neuronal apoptosis. Mediators of ischemic neuronal apoptosis may include Bax, Par-4, cytochrome c, apoptosis-inducing factor and caspases. Activation of glutamate receptors may play a particularly important role [8].

Phospholipids of cellular membranes in the nervous system are endowed with the highest content of ω-3 docosahexaenoic acid (DHA). So far, the interpretation

of the significance of this high degree of unsaturation in excitable membranes has been the resulting relatively high-membrane-fluidity environment, where specific proteins (e.g. receptors, transporters, ion channels) perform their functions. Oxidative stress targets these highly unsaturated phospholipids, resulting in phospholipids containing peroxidated acyl chains that in turn impair membrane function. Thus, DHA-containing phospholipids are a target for free radical-catalyzed peroxidation (Fig. 35-2) and, as a result, F4-isoprostanes are formed [9, 10]. F2-isoprostanes are also derived from free-radical-catalyzed peroxidation, although from arachidonic acid instead [11]. F4-isoprostanes (neuroprostanes) are found esterified in phospholipids, and it has been reported that their content is increased in the brains of patients with Alzheimer's disease [12]. Excessive accumulation of free-radical-mediated lipid peroxidation products promotes cellular damage and death.

As an example, rhodopsin in photoreceptors is immersed in a lipid environment highly enriched in phospholipids containing DHA, and DHA is essential for rhodopsin function [13–15]. Moreover, retinal DHA, like brain DHA, is very resistant to n-3 fatty acid dietary deprivation. On the other hand, DHA was recently shown to be the precursor of a retinal and brain neuroprotective signaling, the docosanoids. These are enzyme-derived, stereospecific compounds, identified initially in the retina and proposed to elicit neuroprotection, which were detected by lipidomic analysis. The docosanoid 10,17*S*-docosatriene is a potent inhibitor of brain ischemia–reperfusion-induced polymorphonuclear leukocyte infiltration, as well as of NF-κB and cyclooxygenase (COX)-2 expression [16]. Moreover, marked attenuation of the stroke volume was observed when 10,17*S*-docosatriene was infused into the third ventricle during ischemia–reperfusion [16]. The elucidation of this DHA-oxygenation messenger sheds new light on how the brain modulates its response to oxidative stress and inflammatory injury, and raises the exciting potential for designing new drugs to treat neurologic disorders that have a neuroinflammatory component, such as stroke, traumatic brain injury, spinal cord injury, or Alzheimer's disease. In particular, the very high biological activity of the docosanoid 10,17*S*-docosatriene marks it as a potential effector of neuroprotection.

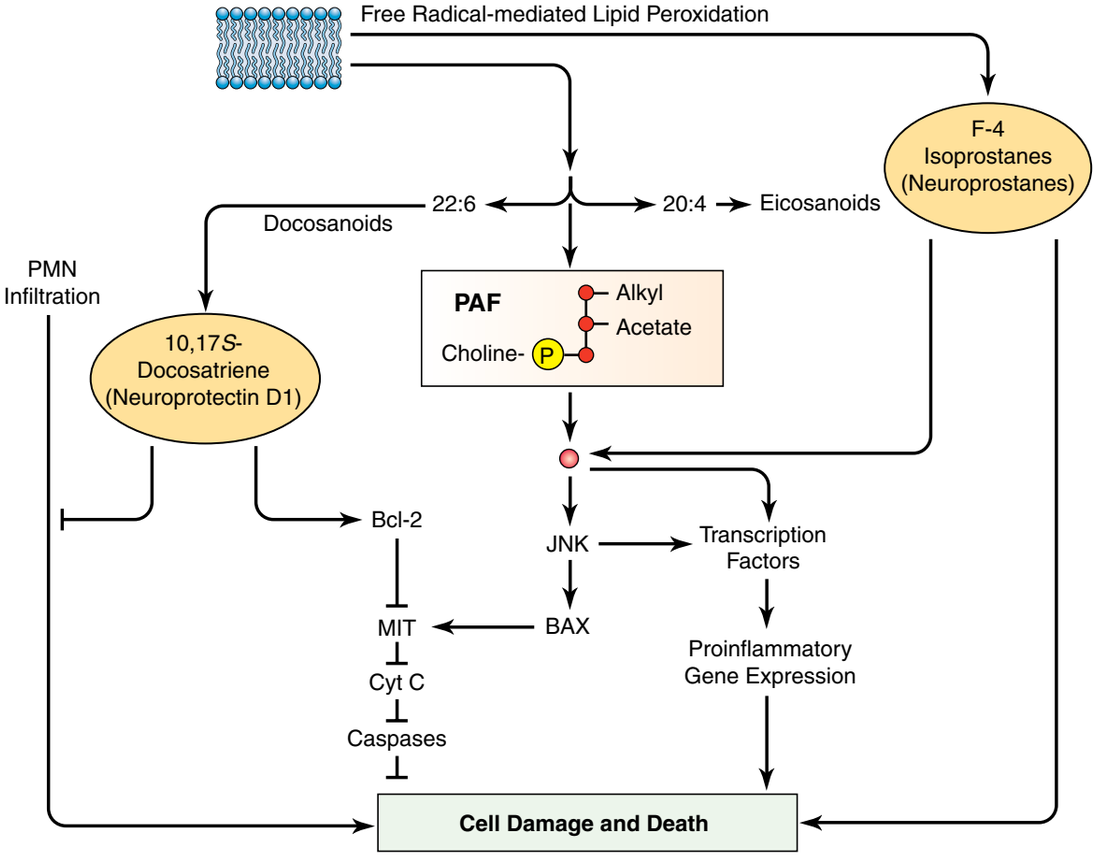


FIGURE 35-2 Phospholipids of cellular membranes can be peroxidized by free-radical-catalyzed reactions. Excessive accumulation of lipid peroxides contributes to cell damage and death. In the nervous system, these phospholipids contain the largest quantities of docosahexaenoic acid (22:6), which was recently demonstrated to be the precursor of the neuroprotective docosanoid 10,17*S*-docosatriene (neuroprotectin D1, NPD1). NPD1 counteracts proinflammatory cellular signaling and decreases polymorphonuclear leukocyte (PMN) infiltration in ischemic brain [16], and inactivates proapoptotic signaling and upregulates antiapoptotic signaling in oxidatively stressed retinal pigment epithelial cells [17].

The newly isolated dihydroxy-containing DHA derivative is called 'neuroprotectin D1' (NPD1) (1) because of its neuroprotective properties in brain ischemia–reperfusion [16] and in oxidative-stress-challenged retinal pigment epithelial cells [17]; (2) because of its potent ability to inactivate proapoptotic signaling (Bad and Bid) and to upregulate Bcl-2 and Bcl-xl; and (3) because it is the first identified neuroprotective mediator of DHA.

Apoptosis occurs in neurodegenerative disorders. Alzheimer's disease, Parkinson's disease, Huntington's disease and amyotrophic lateral sclerosis (ALS) are four prominent fatal neurodegenerative disorders that involve the death of specific populations of neurons (see details in respective chapters). Studies of patients and animal and culture models have provided considerable insight in the cellular and molecular mechanisms responsible for synaptic dysfunction and neuronal degeneration in each disorder [18]. In Alzheimer's disease, abnormalities in proteolytic processing of the amyloid precursor protein, due to gene mutations (in the amyloid precursor protein or in the presenilins) or age-related factors, result in accumulation of neurotoxic forms of amyloid beta peptide (Fig. 35-3). In Parkinson's disease, age-related increases in oxidative stress and possibly environmental neurotoxins cause selective degeneration of dopaminergic neurons in the substantia nigra. In Huntington's disease, inheritance of a mutant huntingtin gene that encodes a huntingtin protein with increased numbers of polyglutamine repeats causes degeneration of striatal neurons. ALS, which is characterized by selective degeneration of motor neurons, can result from mutations in Cu/Zn-superoxide dismutase or from other unknown genetic and environmental causes. While the causes of these neurodegenerative disorders may differ, they each involve increased oxidative stress, metabolic compromise and disruption of cellular calcium ion homeostasis as important contributors to the cell death process [18].

There is considerable evidence that many of the neurons that die in Alzheimer's disease, Parkinson's disease,

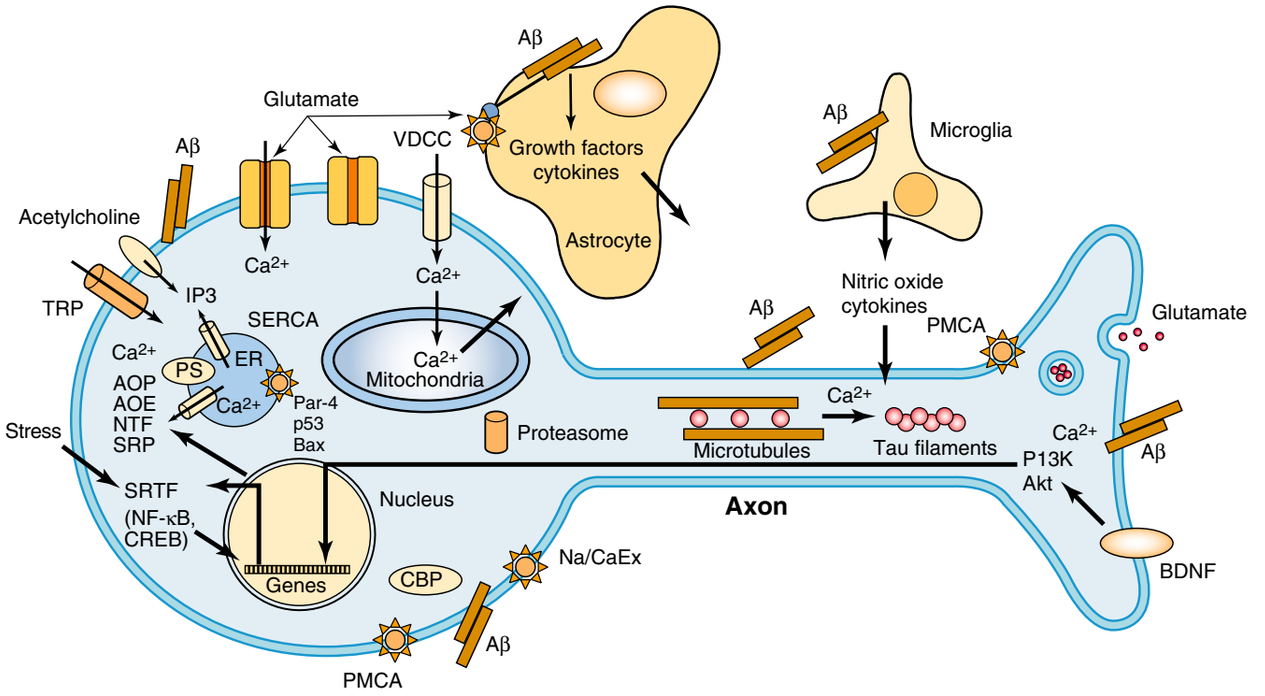

FIGURE 35-3 Examples of inter- and intracellular signaling mechanisms and biochemical cascades that can determine whether a neuron lives or dies in physiological and pathological settings. Neurons respond to a wide array of extracellular signals that can either prevent or promote cell death; examples include neuroprotective growth factors and neurotoxic amyloid β-peptide (*Aβ*). The calcium ion (Ca^{2+}) often plays important roles in determining whether neurons live or die. Excessive influx of Ca^{2+} through glutamate receptor channels, voltage-dependent Ca^{2+} channels and capacitative Ca^{2+} entry channels (*TRP*) in the plasma membrane, and/or excessive release of Ca^{2+} from endoplasmic reticulum (*ER*) and mitochondrial stores, can trigger apoptosis. On the other hand, effective removal of Ca^{2+} from the cytoplasm via the activities of plasma membrane (*PMCA*) and ER (*SERCA*) Ca^{2+}-ATPases, the plasma membrane Na^+/Ca^{2+} exchanger (*Na/CaEx*) or sequestration by Ca^{2+}-binding proteins (*CBP*) can prevent apoptosis. Cell death may also be triggered by oxidative stress, insufficient trophic factor support and abnormalities in the cytoskeleton, such as occur, for example, in Alzheimer's disease where microtubules depolymerize and the microtubule-associated protein tau forms abnormal aggregates. By activating transcription factors that induce the expression of cytoprotective genes, some signaling pathways can prevent cell death. For example, stress-responsive transcription factors such as NF-κB and CREB induce the expression of antiapoptotic proteins (*AOP;* Bcl-2 and IAPs, for example), antioxidant enzymes (*AOE*), neurotrophic factors (*NTF*) and stress resistance proteins (*SRP;* HSP-70 and GRP-78, for example). Microglia may facilitate neuronal death by producing neurotoxic substances such as nitric oxide and proinflammatory cytokines.

Huntington's disease and ALS undergo apoptosis or a related form of PCD. The spatial and temporal patterns of neuronal death in these neurodegenerative disorders are consistent with apoptosis in that neurons in vulnerable brain regions do not die in unison; instead, individual neurons die on a progressive basis. Examinations of the brains of Alzheimer's disease, Parkinson's disease and Huntington's disease patients and of the spinal cords of ALS patients have revealed evidence for activation of caspases and upregulation of apoptotic proteins such as Bax, p53 and Par-4. Perhaps the strongest evidence that apoptosis is a major mode of cell death comes from studies in which mutant genes that cause disease (amyloid precursor protein and presenilin mutations in Alzheimer's disease, alpha-synuclein mutations in Parkinson's disease, huntingtin mutations in Huntington's disease and Cu/Zn-SOD mutations in ALS) have been shown to increase the vulnerability of neurons to apoptosis [19, 20]. Dietary modifications such as dietary restriction and folate supplementation, and/or drugs that block apoptotic pathways have proved to be effective in reducing neuronal degeneration and improving functional outcome in animal models of Alzheimer's disease, Parkinson's disease, Huntington's disease and ALS. When taken together with epidemiological studies that have identified risk factors for Alzheimer's disease and Parkinson's disease, findings from animal studies support a role for apoptosis in these disorders. For example, dietary restriction can protect hippocampal and dopaminergic neurons in models of Alzheimer's disease and Parkinson's disease by a mechanism involving upregulation of BDNF and stress resistance proteins, and epidemiological data suggest that individuals with low calorie intakes have a reduced risk of Alzheimer's disease and Parkinson's disease [21].

There are many triggers of apoptosis. Hundreds of factors that can trigger apoptosis of neural cells have been described, and there are surely many others that remain to be discovered. Examples of five prominent types of apoptotic trigger are described below.

Insufficient trophic support. When developing neurons are deprived of neurotrophic support, either by withdrawal of the neurotrophic factor in cell culture or by removal of the target cells for the neurons *in vivo*, they undergo apoptosis. For example, when sympathetic neurons in culture are deprived of NGF they upregulate Bax, release cytochrome c from their mitochondria, activate caspases and exhibit cell body shrinkage and nuclear chromatin condensation and fragmentation [22]. Depletion of neurotrophic factors may also contribute to the deaths of neurons that occur during aging and in various neurodegenerative conditions and, indeed, there is evidence that this is the case in Alzheimer's disease, Parkinson's disease and Huntington's disease.

Death receptor activation. Several different ligands can induce apoptosis of neural cells including certain cytokines (Fas ligand and interleukin-1β), the neurotransmitter glutamate and thrombin. Like tumor necrosis factor (TNF) receptors, Fas is coupled to downstream death effector proteins that ultimately induce caspase activation (Ch. 22). Fas and TNF receptors recruit proteins called FADD and TRADD respectively; FADD and TRADD then activate caspase-8, which, in turn, activates caspase-3 (Fig. 35-4). Calcium ion influx mediates neuronal apoptosis induced by glutamate receptor activation; calcium induces mitochondrial membrane permeability transition pore opening, release of cytochrome c and caspase activation. Interestingly, in the absence of neurotrophic factors some neurotrophic factor receptors can activate apoptotic cascades, the low-affinity NGF receptor being one example of such a death receptor mechanism [23].

DNA damage. Considerable evidence suggests that DNA damage may be a pivotal trigger of apoptosis in both physiological and pathological settings. Neurons undergoing developmental apoptosis exhibit DNA damage and upregulation of DNA-damage-responsive proteins. The causes of DNA damage during development have not been clearly established but may include increased oxyradical production, reduced trophic support and impaired DNA repair mechanisms. DNA damage can induce the upregulation of proapoptotic proteins including ATM kinase, p53 and PARP. Damage to telomeric DNA (located at the ends of chromosomes) may be a particularly potent trigger of apoptosis in neural progenitor cells and newly generated neurons. DNA damage has been documented in vulnerable neuronal populations in patients suffering from traumatic brain injury, stroke, Alzheimer's disease, Parkinson's disease, Huntington's disease and ALS. An increase in the amounts of oxidatively modified DNA bases in these disorders suggests a major role for oxidative stress. In addition, abnormalities in one carbon metabolism that may be induced by homocysteine, for example, may contribute to accumulation of damaged DNA during aging and in neurodegenerative disorders.

Oxidative and metabolic stress. Studies of cell culture and animal models have clearly shown that oxidative stress and impaired energy metabolism can trigger neuronal apoptosis. For example, exposure of cultured neurons to hydrogen peroxide, Fe^{2+} or amyloid β-peptide induces membrane-associated oxidative stress and activates a mitochondrial-dependent apoptotic cascade. Oxidative stress may trigger apoptosis by activating membrane-associated apoptotic signaling cascades; for example, ceramide generated from membrane sphingomyelin in response to oxidative stress can be a potent inducer of apoptosis [24]. Oxidative damage to various membrane transporters, mitochondrial proteins and membranes and nuclear DNA can also trigger apoptosis. The ability of metabolic compromise to induce apoptosis is evident from the fact that various mitochondrial toxins (e.g. rotenone, MPP^+, cyanide and 3-nitropropionic acid) can

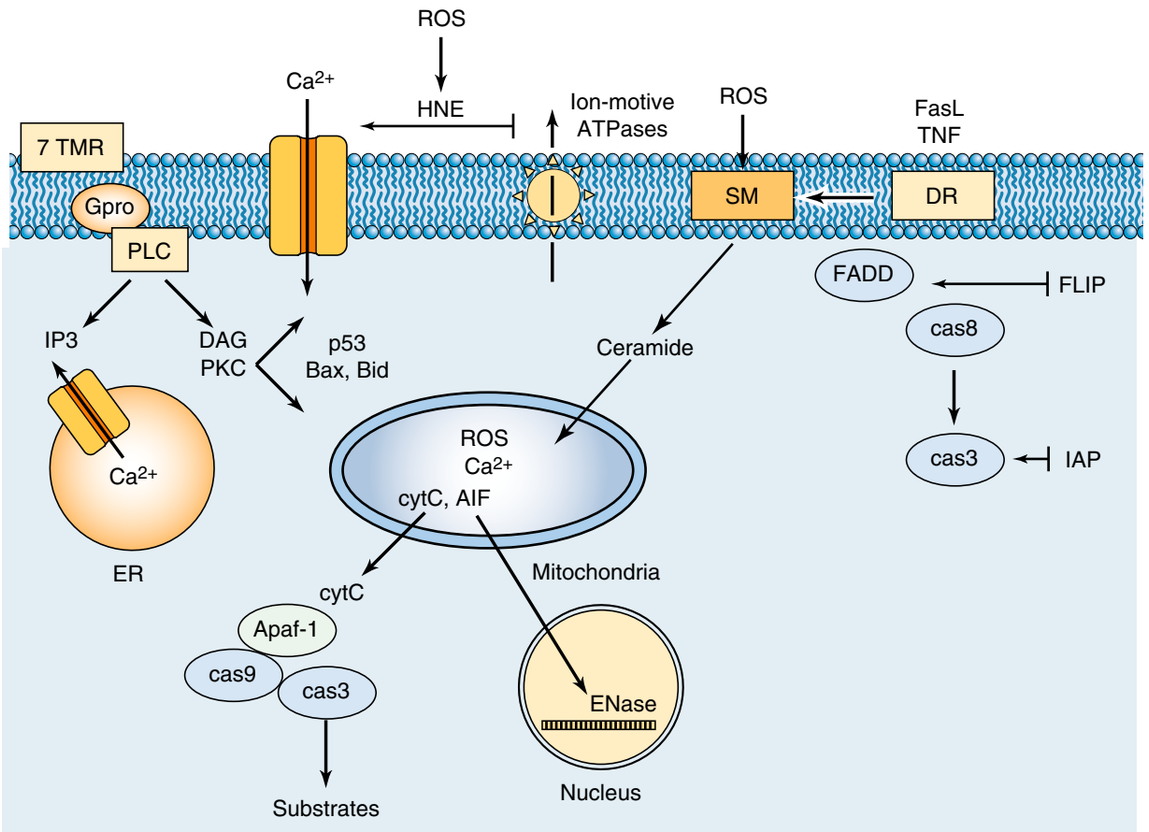

FIGURE 35-4 Examples of plasma-membrane-initiated cell death cascades. Many cells, including neurons, express so-called death receptors (*DR*). In the example shown, a receptor for Fas ligand (*FasL*) or tumor necrosis factor (*TNF*) binds a protein called FADD (Fas-associated death domain), which then recruits and activates caspase 8 (*cas8*). Caspase 8 then activates caspase 3, which plays a major role in executing the cell death process. The latter death receptor pathway can be blocked by the activities of FLIP (FLICE inhibitory protein) and IAPs (inhibitor of apoptosis proteins). Cell death can also be triggered by reactive oxygen species (*ROS*) that induce membrane-associated oxidative stress. Membrane lipid peroxidation generates the aldehyde 4-hydroxynonenal (*HNE*) which can induce apoptosis by covalently modifying various membrane proteins including ion-motive ATPases and calcium channel proteins. Membrane oxidative stress also activates sphingomyelinases, which cleave sphingomyelin (*SM*), resulting in the production of ceramide, which can trigger apoptosis by inducing mitochondrial membrane permeability transition. Receptors with seven transmembrane domains (*7TMR*) coupled to GTP-binding proteins (*Gpro*) and activation of phospholipase C (*PLC*) can trigger cell death by inducing calcium release from IP3-sensitive ER stores. Once initiated, such cell death cascades often involve proapoptotic proteins acting at mitochondrial membranes (p53, Bax and Bid, for example), proteins released from mitochondria (cytochrome C and AIF), caspases and endonucleases (*ENase*).

trigger apoptosis. While impaired energy metabolism clearly plays a role in many neurodegenerative disorders, its role in physiological cell death remains to be established.

Once apoptosis is triggered, a stereotyped sequence of premitochondrial events occurs that executes the cell death process. In many cases proteins and/or lipid mediators that induce changes in mitochondrial membrane permeability and calcium regulation are produced or activated. For example, the pro-apoptotic Bcl-2 family members Bax, Bad and Bid may associate with the mitochondrial membrane and modify its permeability. Membrane-derived lipid mediators such as ceramide and 4-hydroxynonenal can also induce mitochondrial membrane alterations that are critical for the execution of apoptosis.

Numerous mechanisms have been described that are involved in early, premitochondrial steps in apoptosis (Figs 35-3, 35-4). For example, the polymerization state of actin filaments and microtubules can determine whether or not apoptosis is triggered by glutamate because these cytoskeletal proteins modulate the activity of ionotropic glutamate receptors and voltage-dependent calcium ion channels [8]. Similarly, the presence and amounts of calcium-binding proteins and antioxidants such as glutathione and vitamin E can shift the threshold for activation of the cell death cascade by different apoptotic triggers. Events occurring in the endoplasmic reticulum (ER) have been shown to induce, prevent or modify apoptotic cascades at a premitochondrial step; calcium ion release and uptake by the ER appears to be particularly important in this regard (see Chs 5 and 22).

Apoptosis requires macromolecular synthesis. In this regard, several transcription factors and target genes have been identified as playing pivotal roles in apoptosis. For example, stress-activated protein kinases (SAPK) and c-Jun N-terminal kinase (JNK) mediate apoptotic responses to various triggers and affect cell death by activating the transcription factors AP-1 and GADD153. Another prominent example is the transcription factor p53, which is activated in response to DNA damage and which induces the transcription of proapoptotic genes including those encoding Bax and p21. Another protein whose upregulation is required for at least some cases of apoptosis is Par-4, which can be induced at the translational level.

Several different changes in mitochondria occur during apoptosis. These include a change in membrane potential (usually depolarization), increased production of reactive oxygen species, potassium channel activation, calcium ion uptake, increased membrane permeability and release of cytochrome c and apoptosis inducing factor (AIF) [25]. Increased permeability of the mitochondrial membranes is a pivotal event in apoptosis and appears to result from the formation of pores in the membrane; the proteins that form such permeability transition pores (PTP) may include a voltage-dependent anion channel (VDAC), the adenine nucleotide translocator, cyclophilin D, the peripheral benzodiazepine receptor, hexokinase and creatine kinase (Fig. 35-5). Pro-apoptotic Bcl-2 family members, such as Bax and Bid, promote PTP formation. Permeabilization of the mitochondrial membranes provides a route for the release of cytochrome c into the cytoplasm where it binds to a protein called Apaf-1. The synchronous release of cytochrome c from all mitochondria in a cell is thought to be orchestrated by calcium ion release from IP3-sensitive ER stores [26]. Smac/DIABLO and Omi/HtrA2 are two other mitochondrial intermembrane proteins that are released from mitochondria during apoptosis; they then bind to and neutralize cytosolic inhibitors of apoptosis proteins (IAPs). Because IAPs normally bind and inhibit caspases 9 and 3, the binding of IAPs by Smac/DIABLO and Omi/HtrA2 enhance the activation of these caspases. Two DNA-degrading enzymes (AIF and endonuclease G) are also released from mitochondria and then translocate to the nucleus where they cleave DNA into nucleosomal fragments. AIF is a flavoprotein with an oxidoreductase domain and may, in addition to its pro-apoptotic function, modulate mitochondrial redox state.

The postmitochondrial events of apoptosis include activation of the caspases. Cytochrome c binds to the protein Apaf-1 in the cytosol, resulting in the recruitment and activation of caspase-9, which in turn activates caspase-3 (Figs 35-4, 35-5). Fourteen different mammalian caspases have been identified and each may play a key role

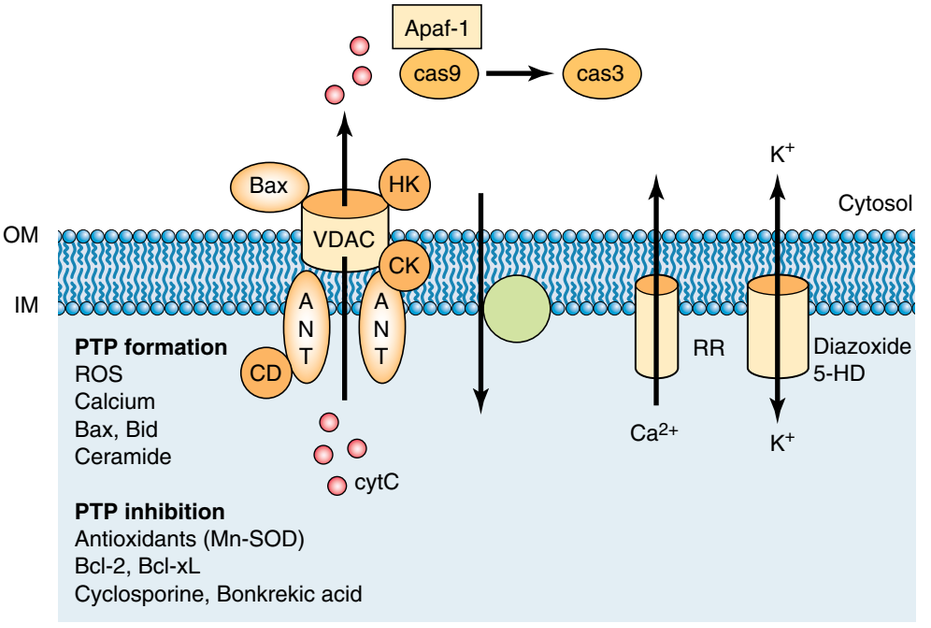

FIGURE 35-5 The presumptive mitochondrial permeability transition pore complex and its regulation by Ca^{2+} and K^+ fluxes. The membrane permeability transition pore is believed to consist of VDAC (voltage-dependent anion channel) and ANT (adenine nucleotide translocator) and associated proteins that modulate its opening including hexokinase (*HK*), creatine kinase (CK), cyclophilin D (*CD*) and Bax. Formation and opening of the channel results in the release of cytochrome C (*cytC*), which then binds to Apaf-1, resulting in the sequential activation of caspases 9 and 3. Mitochondrial membrane permeability pore formation is subject to regulation by fluxes of Ca^{2+} and K^+. Agents that suppress Ca^{2+} flux (*RR*, ruthenium red) and K^+ flux (*5-HD*, 5-hydroxydecanoate) can prevent pore formation. Interestingly, activation of mitochondrial K^+ channels with diazoxide can also prevent apoptosis by inducing a preconditioning response.

in apoptosis depending upon the cell type and the nature of the specific cell death stimulus [27]. For example, caspases 8 and 10 can be activated by death receptor engagement, independently of mitochondria, and caspase-12 is activated in response to ER stress. Numerous caspase substrates have been identified (Table 35-1), and in several cases the consequences of cleavage of the substrate in the context of the cell death process is known. Cleavage of a protein by a caspase may disable the protein or, in some cases, may activate the protein. Indeed, effector caspases themselves (caspases 3, 6 and 7) can be activated by cleavage of their procaspase forms by initiator caspases (caspases 8, 9 and 10). Cellular processes modified by caspase-mediated proteolysis include inactivation of antiapoptotic proteins, impairment of homeostatic and repair processes (DNA repair enzymes, for example), disruption of the cell cytoskeleton, nuclear and plasma membrane morphological changes, and marking of cells for phagocytosis.

A widely used criterion for identifying a cell as 'apoptotic' is nuclear chromatin condensation and fragmentation. The nature of the molecular alterations that occur in the nucleus and the proteins responsible for inducing these changes are in the process of being identified [28]. Some caspases (caspase-6, for example) enter the nucleus and cleave nuclear matrix proteins including lamins and NuMA. Other caspases that cleave nuclear proteins involved in regulating DNA replication and repair processes include topoisomerases, PARP, DNA-dependent protein kinase and Rad51. Caspases may also activate endonucleases such as ICAD and DNAses I and II, resulting in DNA fragmentation. Caspase-3 can cleave acinus resulting in chromatin condensation. Granzyme B, cathepsin B and histone-associated protease also cleave nuclear substrates during apoptosis. Other apoptotic proteins, such as DEDD and Daxx, that act in the nucleus may influence the apoptotic process by altering gene transcription.

Dramatic morphological changes in the plasma membrane occur during apoptosis; as the cell shrinks, membrane blebs form. Individual apoptotic cells are removed from tissues via phagocytosis by macrophages/microglia. The phagocytic cells recognize the apoptotic cell because during the process of apoptosis, phosphatidylserine, which is normally present in the inner leaflet of the plasma membrane bilayer, translocates to the cell surface (see Chs 2 and 20). The phosphatidylserine binds to a specific phosphatidylserine receptor (PSR) on the surface of the phagocytic cells [29]. In this way, apoptotic cells are removed when their membrane is still intact, thereby preventing release of potentially damaging intracellular contents. Indeed, mice lacking the PSR accumulate dead cells, particularly in the brain and lungs, which process results in damage to adjacent living cells and ultimately these animals cannot survive.

Cells in the nervous system possess many different mechanisms to prevent apoptosis. These include intercellular signals and the pathways activated by those signals, intrinsic antiapoptotic proteins, antioxidants, protein chaperones and systems that regulate ion homeostasis [30] (Fig. 35-6).

Neurotrophic factors, cytokines and cell adhesion molecules. A remarkable number of growth factors and cytokines have been identified that can prevent neuronal apoptosis [30]. A short list includes NGF, bFGF, BDNF, neurotrophin-4/5, glial-cell-line-derived neurotrophic factor (GDNF), ciliary neurotrophic factor (CNTF), insulin-like growth factor (IGF)-1, transforming growth factor (TGF)β, tumor necrosis factor (TNF)α, interleukin-6 and secreted forms of amyloid precursor protein. In addition to such soluble ligands, extracellular matrix (laminin, fibronectin, etc.) or cell-surface-bound ligands (NCAM, cadherins) bind to receptors such that are involved in cell–substratum adhesion. The latter receptors are coupled to intracellular signaling pathways similar to those employed by growth factors. For example, engagement of integrins by laminin activates the PI3-kinase–Akt pathway, a signaling pathway also activated by BDNF and IGF-1. In general, signaling by growth factors and cell adhesion molecules results in activation of transcription factors, which activate genes that encode antiapoptotic proteins such as Bcl-2, IAPs, antioxidant enzymes and calcium-regulating proteins. However, these signaling pathways can also antagonize apoptosis by modifying the phosphorylation state of apoptosis-related proteins such as Bcl-2 family members.

Antiapoptotic proteins. There are many different intracellular proteins that can prevent apoptosis by inhibiting specific steps in the cell death process. These include Bcl-2 family members such as Bcl-2 and Bcl-xL which can stabilize (mitochondrial, ER and plasma) membranes (Bcl-2 may also have intrinsic antioxidant activity). Other proteins, IAPs such as XIAP (X-linked) and NIAP (neuronal), which can directly inhibit caspases [31]. Additional examples of antiapoptotic proteins include protease inhibitors such as calpastatin, and protein chaperones such as GRP-78 and heat shock protein (HSP)-70.

Hormesis-based mechanisms. When cells are exposed to sublethal levels of stress (heat, oxidative stress, metabolic stress, or other stresses) they often become resistant to being killed by more severe stress. This process, which is a form of hormesis or 'preconditioning', typically involves the activation of stress signaling pathways that activate transcription factors that induce the expression of genes encoding cytoprotective proteins. Examples of antiapoptotic proteins upregulated in response to a preconditioning stress are neurotrophic factors such as BDNF and bFGF, protein chaperones such as HSP-70 and glucose-regulated protein-78, Bcl-2 and antioxidant enzymes such as Mn-superoxide dismutase (Mn-SOD). Interestingly, hormesis appears to be a major mechanism whereby mild

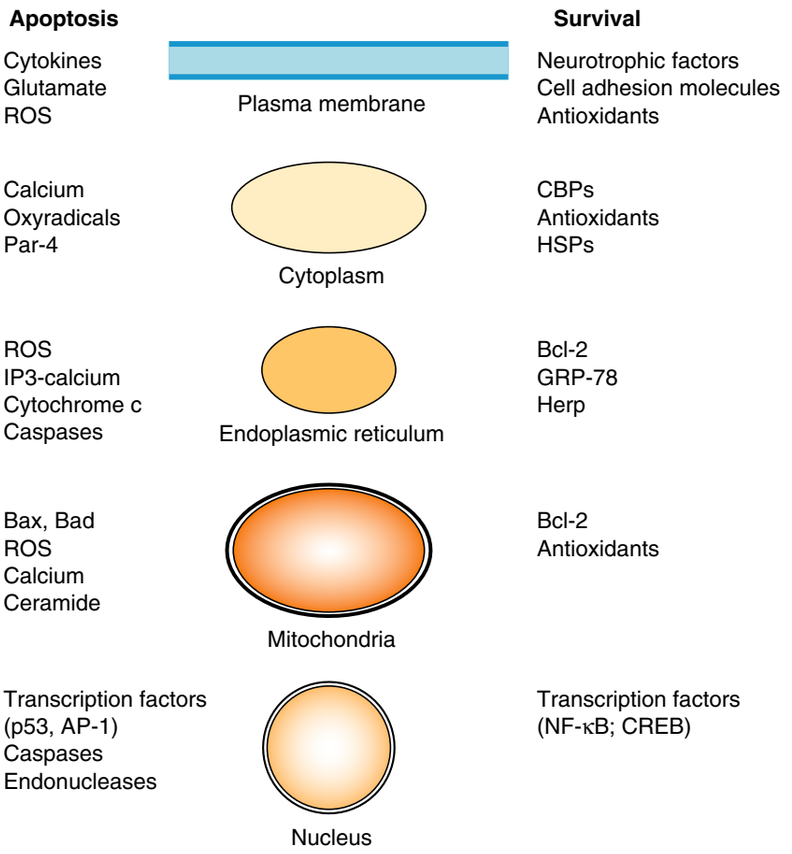

FIGURE 35-6 Examples of apoptotic and antiapoptotic mechanisms that act on or within different subcellular compartments. CBP, Ca^{2+} binding protein; CREB, cyclic AMP response element binding protein; HSP, heat shock protein; IP3, inositol 1,4,5-trisphosphate; ROS, reactive oxygen species.

stresses such as dietary calorie restriction, physical exercise and environmental enrichment (mental gymnastics) protect neurons against apoptosis [21].

Antioxidants and calcium-stabilizing proteins. Oxidative stress and perturbed cellular calcium homeostasis have been shown to play pivotal roles in the apoptosis of neural cells in physiological and pathological settings. Accordingly, cells possess multiple mechanisms to reduce levels of oxidative stress and to maintain and restore calcium homeostasis. Oxidative stress is suppressed by antioxidant enzymes (Cu/Zn-SOD, Mn-SOD, catalase, glutathione peroxidase) and molecules with intrinsic radical-scavenging ability such as glutathione, bilirubin, vitamins E and C, uric acid and creatine. Proteins that stabilize calcium homeostasis include calcium-binding proteins (calbindin, calreticulin and parvalbumin, for example), calcium pumps in the plasma and ER membranes, and sodium/calcium exchangers. Interestingly, antiapoptotic proteins such as Bcl-2 may act, in part, by suppressing oxidative stress and enhancing calcium homeostasis.

The morphological and biochemical characteristics of apoptosis are not always manifest in cells undergoing programmed cell death. Studies have clearly shown that there are several, and perhaps many, variant forms of PCD and that there can be a continuum of cell death cascades that is related to the specific cell death trigger involved and its intensity and duration. In some cases cells exhibit characteristics of both apoptosis and necrosis [1]. A form of PCD involving autophagy occurs in many instances, including developmental apoptosis of neurons in sympathetic and isthmo-optic nuclei. Autophagy is a lysosome-mediated mechanism by which cells degrade and recycle damaged proteins and organelles (see Lysosomes in Ch. 41). Autophagy is characterized by the formation of cytoplasmic vacuoles with double membranes that enclose fragments of mitochondria and ER and contain high concentrations of lysosomal hydrolases. Autophagic cell death is often a variant of apoptosis in which caspase activation plays a pivotal role. Proteins that may play a role in autophagic PCD include Beclin1, PI3 kinase, TOR (target of rapamycin), p70S6 kinase, AMPA receptors and Bcl-2. There is evidence that at least some neurons undergo autophagic cell death in Parkinson's, Huntington's and Alzheimer's diseases.

Neuronal PCD with features of necrosis was reported in studies of naturally occurring motor neuron death in which the cells exhibited dilation of ER, Golgi and nuclear membranes but not condensation of chromatin. A similar

form of necrotic PCD may occur in response to Fas activation; such cell deaths involve swelling of ER and mitochondria but cytochrome c is not released. Perturbed ER calcium homeostasis, sustained increases in cytoplasmic calcium ion concentrations and activation of calpains can trigger necrotic PCD in some types of cells.

Apoptotic cascades can be triggered, and pre- and postmitochondrial events can occur, without the cell dying. For example, studies have shown that apoptotic cascades involving Par-4, p53, mitochondrial membrane permeabilization and caspase activation can be induced locally in synaptosomes and in growth cones and neurites of cultured neurons [32]. Such cascades can be triggered locally by activation of glutamate receptors and can occur in a reversible manner. Interestingly, the cleavage of certain synaptic substrate proteins by caspases (AMPA receptor subunits and cytoskeletal proteins, for example) may play roles in synaptic plasticity (learning and memory) and perhaps in remodeling of synaptic structure and the regulation of growth cone motility (Fig. 35–7).

NECROSIS

Necrosis is a dramatic and very rapid form of cell death in which essentially every compartment of the cell disintegrates. Necrosis is characterized by marked dysregulation of ion homeostasis resulting in cell swelling, dilation of mitochondria and the ER and the formation of vacuoles in the cytoplasm [33]. Proteases play important roles in the degradation of cells during necrosis. In contrast to apoptosis, where caspases are the key death proteases, calpains and lysosomal proteases (cathepsins B and D, in particular) are major players in necrosis. Caspases may be activated in response to mitochondrial damage and

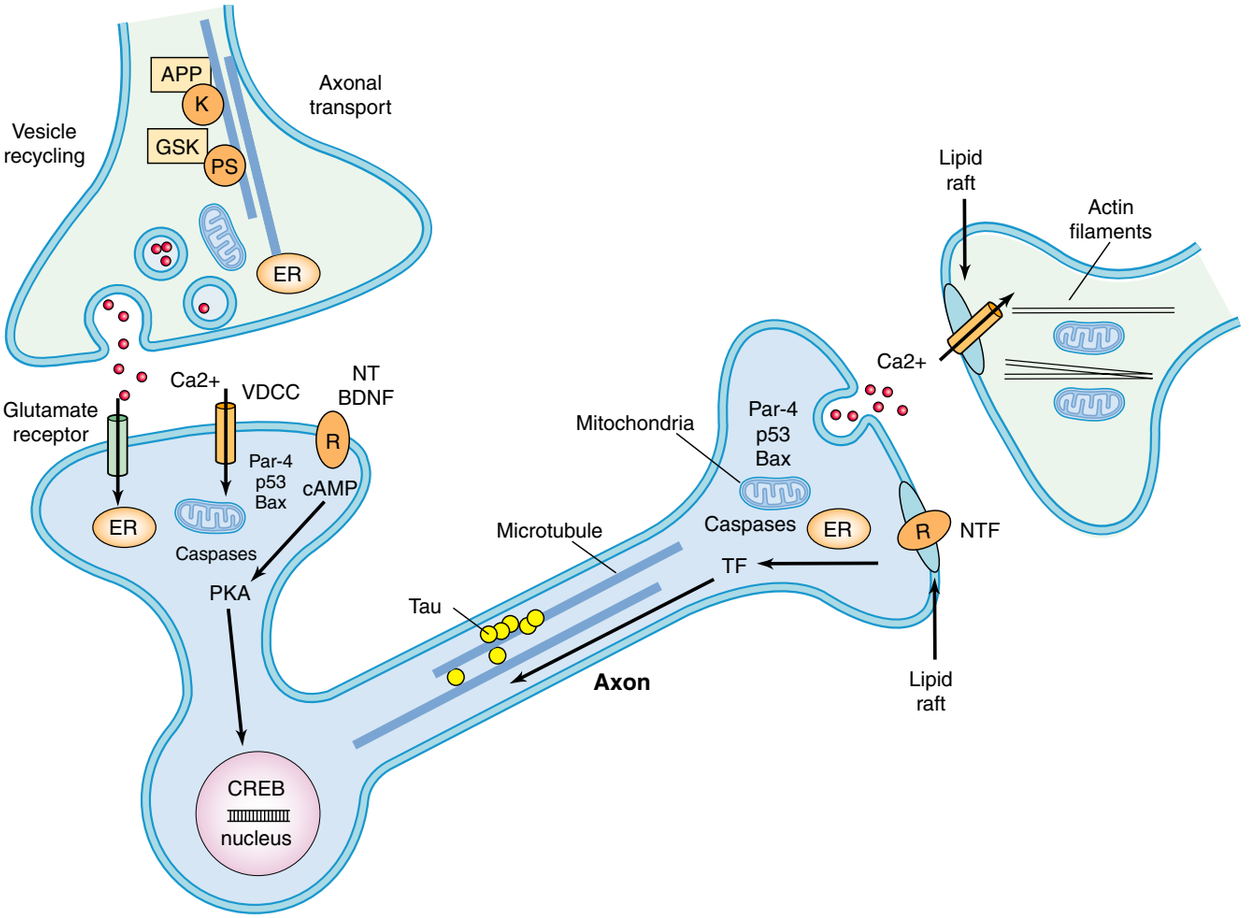

FIGURE 35-7 Apoptotic and anti-apoptotic synaptic signaling mechanisms. Synapses are sites where various signal transduction pathways are activated including those of neurotransmitters (*NT*; glutamate receptors linked to calcium influx and receptors coupled to cAMP production are shown), and neurotrophic factors (*NTF*). Synapses contain all the major organelles (except the nucleus) and proteins involved in apoptosis including *Bcl-2* family members, p53, Par-4, mitochondria and ER, and caspases. Alterations in axonal transport may also trigger apoptosis. *APP*, amyloid precursor protein; *CREB*, cyclic AMP response element binding protein; *ER*, endoplasmic reticulum; *GSK*, glycogen synthase kinase; *K*, kinesin; *PKA*, protein kinase A; *PS*, presenilin; *R*, receptor; *TF*, transcription factor; *VDCC*, voltage-dependent calcium channel.

cytochrome c release during necrosis but appear not to be essential for cell death. During the cell death process the chromatin clumps and the nuclear membrane is disrupted. Finally, the cell lyses, releasing its contents into the extracellular compartment, where the contents may damage neighboring cells and induce an inflammatory response. Transcription of genes and protein synthesis stop and ATP is rapidly depleted in cells undergoing necrosis.

There are few cell death triggers that are only capable of inducing either apoptosis or necrosis. Instead, whether a cell undergoes apoptosis or necrosis is usually determined by the intensity and/or duration of the death-inducing stimulus. In general, severe and/or sustained insults trigger necrosis whereas less severe transient stresses induce apoptosis. For example, moderate overactivation of glutamate receptors may trigger apoptosis while more intense and sustained activation of glutamate receptors induces excitotoxic necrosis (Chs 15 and 32). The environment of the cell at the time it is subjected to the death stimulus can also determine the mode of death. Thus, a certain level of glutamate receptor activation may induce apoptosis in a cell receiving normal amounts of oxygen and glucose but may cause necrosis when that same cell is subjected to ischemia.

Trauma. Acute trauma as in head injury (e.g. automobile accidents, sports injuries) can induce necrosis of the tissue at and surrounding the site of the trauma. Physical damage to cellular membranes may induce necrosis in the traumatized tissue, while disruption of ion homeostasis and energy depletion may trigger necrosis in cells adjacent to the directly damaged cells. Traumatized cells release the contents of their organelles into the extracellular space, resulting in exposure of adjacent cells to various lysosomal proteases and to acidosis. Marked changes in pH can also trigger necrosis; interestingly, intracellular acidification may contribute to necrotic cell death induced by extensive DNA damage.

Energy failure/ischemia. Cellular energy failure is one defining feature of necrosis, and severe reduction in glucose and/or oxygen availability is sufficient to trigger necrosis. Mitochondrial toxins can trigger apoptosis at low levels but at higher levels they induce necrosis as the result of severe depletion of ATP.

Excitotoxicity. Overactivation of glutamate receptors, particularly when neurons are subjected to metabolic and oxidative stress, can trigger excitotoxic necrosis. Sodium ion influx through AMPA/kainate receptors and voltage-dependent sodium channels induces cell swelling, and calcium ion influx through NMDA receptors and voltage-dependent calcium channels activates various proteases (calpains, for example) that degrade various structural and metabolic proteins.

Calcium ion release from the ER and the accumulation of misfolded proteins in the ER can trigger necrosis, and agents that inhibit such calcium release can protect cells against necrosis.

TARGETING APOPTOSIS AND NECROSIS IN NEUROLOGICAL DISORDERS

Studies of cell culture and animal models of neurodegenerative conditions that involve apoptosis have established the preventative and therapeutic potential of antiapoptotic approaches [18, 30, 34]. The most effective means of preventing apoptosis is to abolish the triggering event. Examples include: dietary and drug treatments that suppress atherosclerosis and blood clot formation to prevent a stroke from occurring; eliminating exposure to neurotoxins that may cause Parkinson's disease; blocking the production of amyloid β-peptide to prevent Alzheimer's disease; and wearing a safety helmet when riding a motorcycle to prevent traumatic brain injury. Once the initiating events in the neurodegenerative process have been triggered, specific early events in the apoptotic cascade can be targeted. Examples include: antagonists of glutamate receptor or calcium channels to prevent excitotoxic apoptosis; drugs that block production of, or receptors for, apoptotic cytokines; antioxidants such as vitamin E and glutathione; and agents that block DNA damage response pathways such as PARP and p53 inhibitors. Drugs that modulate the cytoskeleton, such as cytochalasins and taxol, have also proved to be effective in experimental models of neuronal apoptosis. Targets further downstream of the triggering events have also been successfully blocked to prevent apoptosis. Among such agents are cyclosporin, which blocks mitochondrial membrane permeability transition pores, dantrolene, which blocks ER calcium channels, and caspase inhibitors.

An alternative (or complementary) strategy for preventing apoptosis is to activate antiapoptotic pathways. This might be accomplished by administering a growth factor (bFGF, BDNF, GDNF, or others) that activates a signaling pathway which induces the expression of Bcl-2, antioxidant enzymes or IAPs, for example. Mild preconditioning stimuli which upregulate stress resistance proteins and neurotrophic factor signaling can prevent neuronal apoptosis in models of Alzheimer's disease, Parkinson's disease, Huntington's disease and stroke. Examples of such hormetic stimuli include dietary calorie restriction, environmental enrichment and physical exercise [21].

In regards to necrosis, it is clear that the old adage 'an ounce of prevention is worth a pound of cure' applies. Agents that stabilize ion homeostasis have proved to be effective in preventing necrosis in cell culture studies. For example, drugs that activate plasma membrane potassium ion channels or chloride ion channels can prevent membrane depolarization and so inhibit sodium and calcium ion influx. Agents that prevent large sustained increases in intracellular free calcium levels can also prevent neuronal

necrosis; examples include the calcium chelator BAPTA and dantrolene, which blocks calcium release from the ER. Calpain inhibitors can prevent necrosis, as can inhibitors of lysosomal proteases. Treatments that promote maintenance of cellular ATP levels, such as pyruvate and uridine, and creatine can also prevent necrosis of neurons under some conditions.

HEREDITARY AND ACQUIRED DISEASES INVOLVING THE ENTERIC NERVOUS SYSTEM 626

INTRODUCTION: CLINICAL FEATURES OF NEUROPATHIES

This chapter provides a short review of peripheral nerve diseases. Diseases that involve motor neurons, the presynaptic compartment of neuromuscular junctions, or the enteric nervous system are also discussed.

Peripheral neuropathies may be widely disseminated or focal. Patients with disseminated polyneuropathy, whether demyelinative or axonal, usually demonstrate distal sensory and/or motor impairment. Multifocal neuropathy, also referred to as mononeuropathy multiplex, is often a consequence of lesions affecting the vasa nervorum, the blood vessels that supply peripheral nerves. The most common diseases to compromise the vasa nervorum and cause infarction of nerve fascicles are diabetes mellitus and periarteritis nodosa. Other frequent causes of mononeuropathy multiplex include infection (e.g. Lyme disease and leprosy) and multiple compression injury (e.g. bilateral carpal tunnel syndrome). When mononeuropathy multiplex progresses to affect myriad peripheral nervous system (PNS) sites, distal motor and sensory deficits in all limbs clinically indistinguishable from those in polyneuropathy may result.

Diseases selectively targeting spinal cord and brainstem motor neurons (e.g. amyotrophic lateral sclerosis and the familial spinal muscular atrophies) or the presynaptic component of neuromuscular junctions (e.g. Lambert–Eaton syndrome, botulism and *Ixodes* tick paralysis) cause weakness without sensory impairment. Disorders involving the enteric nervous system (e.g. Chagas' disease and Hirschsprung's disease) impair bowel motility.

Electromyography and nerve conduction studies are helpful in evaluating PNS disease [1]. Needle electromyography in patients in whom motor neurons or their axons are damaged will often demonstrate fibrillations (spontaneous action potentials of single denervated muscle fibers) and fasciculations (spontaneous firings of motor units, which include all muscle fibers innervated by a motor neuron) in muscle at rest, and recruitment of lesser numbers than normal of motor units with volitional muscle contraction. These motor units become progressively larger than normal with chronic muscle denervation, because of collateral reinnervation of denervated muscle fibers by surviving axons.

Determining the rate of propagation of action potentials elicited by transcutaneous nerve electrical stimulation helps to discriminate between primarily demyelinative and primarily axonal neuropathies. The electrophysiological hallmark of demyelination is a diminution in nerve conduction velocity of 25% or more. However, the severity of slowing of nerve conduction in demyelinative or dysmyelinative neuropathies often fails to correlate with the extent of clinical neurological deficits. For example, patients in the early stages of subacute idiopathic demyelinative polyneuropathy (Guillain–Barré syndrome) can become paralyzed, yet have normal nerve conduction velocities. This discrepancy between clinical and electrophysiological severity may be attributable to a

Basic Neurochemistry: Molecular, Cellular and Medical Aspects
0-12-088397-X

combination of demyelination confined at this early stage to nerve segments not sampled by the electrophysiological study (i.e. nerve roots), and to failure of the conduction studies to detect subpopulations of axons in which conduction has been blocked because multiple contiguous segments of myelin have been stripped from them. Conversely, during recovery from segmental demyelination, the thin new myelin sheaths that are first formed are sufficient to permit restoration of conduction of action potentials and recovery of normal neurological function but not to restore normal conduction velocities, which require reconstitution of full thickness myelin.

In axonal neuropathies, the velocity of action potential propagation in surviving axons is well maintained but the number of axons capable of conducting action potentials is diminished. Transcutaneous nerve stimulation and recording, the method routinely used for studying nerve conduction in the clinic, does not permit evaluation of the function of autonomic or unmyelinated sensory axons. These smaller, slow-conducting axons can be analyzed, in research studies, by intraneural recording with needle electrodes.

Measuring muscle-evoked responses to repetitive motor nerve electrical stimulation permits detection of presynaptic neuromuscular junction dysfunction. In botulism and the Lambert–Eaton syndrome, repetitive stimulation elicits a smaller than normal skeletal muscle response at the beginning of the stimulus train, due to impaired initial release of acetylcholine-containing vesicles from presynaptic terminals of motor neurons followed by a normal or accentuated incremental muscle response during repeated stimulation. This incremental response to repetitive stimulation in presynaptic neuromuscular disorders can be distinguished from the decremental response that characterizes autoimmune myasthenia gravis, which affects the postsynaptic component of neuromuscular junctions.

Diagnostic indications for nerve biopsy have become less frequent with improvements in EMG and nerve conduction techniques and the advent of specific molecular and biochemical tests for many inherited and acquired neuropathies. However, nerve biopsy does remain useful for diagnosis of vasculitis and amyloidosis, and plays an important role in research.

FEATURES COMMON TO THE PERIPHERAL AND CENTRAL NERVOUS SYSTEM IMPORTANT IN THE PATHOGENESIS AND PATHOPHYSIOLOGY OF NEUROPATHIES

Somatic motor and sensory neurons that give rise to PNS axons maintain large fractions of their total protoplasmic bulk within the CNS. Many of the extracellular matrix components and axonal guidance molecules involved in CNS development are employed for the same purpose in the PNS. PNS microglia-like cells, like microglia in the CNS, are bone-marrow-derived and have a similar repertoire of responses to activation [2]. Both oligodendroglia and Schwann cells speed axonal action potential propagation by assembling and maintaining myelin. Capillary endothelial cells linked by tight junctions restrict entry of polar molecules into the PNS, as into the CNS [3].

As might be predicted from these similarities between PNS and CNS, many disease entities can affect both these tissues. It should be noted, however, that the clinical expression of such diseases is variable and is sometimes restricted to the PNS. For example, patients with thiamine deficiency may display symmetrical distal sensorimotor polyneuropathy without accompanying CNS degeneration. Untreated infection with human immunodeficiency virus (HIV) may cause early polyneuropathy, with dementia appearing months or years later. Similarly, patients with sulfatidase deficiency or adrenoleukodystrophy may present initially with polyneuropathy, while their CNS dysfunction remains clinically undetectable.

FEATURES OF PERIPHERAL NERVES THAT INFLUENCE THEIR VULNERABILITY TO DISEASE AND CAPACITY FOR REGENERATION

Table 36-1 lists some of the mechanisms important in governing the susceptibility of the PNS to disease and injury. Peripheral nerves, although toughened by their high content of collagen, are prone to injury to myelin by compression (e.g. carpal tunnel syndrome and tardy ulnar palsy) and to axons by excessive stretch (e.g. brachial plexopathy in newborn infants following a difficult delivery). Subcutaneous nerves, because of their exposed position, are also vulnerable to cold or heat injury.

Neuropathies can result from mutations that alter the structure or level of expression of PNS myelin proteins (e.g. overexpression of PMP22 in Charcot–Marie–Tooth syndrome (CMT) type 1A), the metabolism of myelin lipids (e.g. metachromatic leukodystrophy), or the capacity of PNS neurons to support their axons in patients with CMT caused by mutations of *KIF1B* [4] or *NF-L* [5, 6]. Both acquired and inherited amyloid neuropathies can result from the deposition of poorly soluble proteins, for example cryoglobulins or mutant transthyretins, in and around endoneurial blood vessels [7–9].

Schwann cells are responsible for PNS trophic functions that, in CNS, are carried out by both oligodendroglia and astroglia. Schwann cell diseases usually present as disorders of myelination. Axonal degeneration and diminution in axonal diameter may also occur in primary disorders of Schwann cells, as a consequence of loss of Schwann cell trophic support for axons. (See also Chs 4 and 38.)

TABLE 36-1 Mechanisms of pathogenesis of PNS-specific disease

Mechanism	PNS-specific disease
Mutation affecting gene expressed exclusively in PNS (e.g. *PMP22*)	Charcot–Marie–Tooth type 1A
Toxin penetrates PNS, not CNS	Botulism, cisplatin neuropathy
Immune attack on antigen accessible in PNS, not CNS (e.g. gangliosides GQ1b and GT1a)	Miller–Fisher syndrome
Mechanical injury to exposed segment PNS	Nerve compression and stretch injuries
Superficial nerves maintained at lower than normal core body temperature	Cryoglobulinemic neuropathy; lepromatous neuropathy

Early in the course of Wallerian degeneration in the PNS, mononuclear cells from the bloodstream enter the injured nerve and assist resident Schwann cells, microglia-like cells and fibroblasts to clear fragmented myelin [10, 11]. Activated macrophages and fibroblasts in the injured nerve secrete a variety of cytokines that enhance Schwann cell proliferation and axonal regrowth [12, 13]. Axonal regeneration is more robust in PNS than in CNS. This is attributable, at least in part, to the stimulatory effect of Schwann cells on neurite growth, versus the inhibition of neurite outgrowth by oligodendroglia in CNS. Schwann cells in the injured nerve aggregate to form longitudinally oriented tubes ('bands of Bungner') through which regenerating axons penetrate through the injured nerve segment to reach their end-organs [14]. Perineurium, flattened, basal lamina-lined cells derived from fibroblasts [15], may also help to guide regenerating axons.

PATHOGENESIS OF NEUROPATHIES

Infections can damage nerves directly, or via exotoxins.

The lepromatous form of leprosy is characterized by loss of cutaneous sensibility. Hansen's bacillus (*Mycobacterium leprae*), which proliferates only in environments cooler than the core temperature maintained by most mammals, is capable of infecting Schwann cells in subcutaneous nerves because the basal lamina of these cells contains α-dystroglycan, to which this mycobacterium binds, and because subcutaneous nerves are often cooler than deeper tissues. Lepromatous neuropathy is a common cause of sensory mononeuropathy multiplex in the developing World [16, 17].

Neuropathy in human immunodeficiency virus infection has many causes. Multiple mechanisms cause neuropathy in patients with HIV. An immune-mediated, Guillain–Barré-like syndrome (see below) may occur at the time of HIV seroconversion. Later in the course of infection, patients may present with mononeuropathy multiplex, sometimes as a consequence of vasculitis associated with coinfection with hepatitis C. Distal sensory–autonomic axonal polyneuropathy may develop in patients with more advanced HIV, either as a consequence of high titers of HIV itself or of the neurotoxicity of antiretroviral drugs [18, 19].

Diphtheria causes a demyelinative neuropathy. *Corynebacterium diphtheriae* colonizes the pharynx or open wounds, and secretes a protein exotoxin. The B subunit of this exotoxin binds to plasma membranes and facilitates entry into cytosol of the A subunit, which catalyzes ADP-ribosylation, and inactivation of an elongation factor required for protein synthesis. Cardiac muscle and Schwann cells are particularly susceptible to this toxin, and hence patients with diphtheria develop cardiomyopathy and demyelinative polyneuropathy [20]. While diphtheria is now uncommon because of childhood immunization against *C. diphtheriae*, the disruption in preventative medicine programs caused by disintegration of the Soviet Union was followed by a substantial incidence of diphtheritic polyneuropathy in Russia.

Botulinum exotoxin impedes release of neurotransmitter vesicles from cholinergic terminals at neuromuscular junctions. Botulinum exotoxin is ingested with food or, in infants, synthesized *in situ* by anaerobic bacteria that colonize the gut. A characteristic feature of botulinum paralysis is that the maximal force of muscle contraction increases when motor nerve electrical stimulation is repeated at low frequency, a phenomenon attributable to the recruitment of additional cholinergic vesicles with repetitive depolarization of neuromuscular presynaptic terminals. Local administration of *Clostridium botulinum* exotoxin is now in vogue for its cosmetic effects and is used for relief of spasticity in dystonia and cerebral palsy [21].

Antibody- and cell-mediated mechanisms of neuropathy.

Both antibody-mediated (Table 36-2) and cell-mediated mechanisms contribute to the pathogenesis of this diverse group of neuropathies.

Acute inflammatory demyelinating polyneuropathy is a common cause of reversible paralysis. Acute inflammatory demyelinating polyneuropathy (AIDP), the classic form of the Guillain–Barré syndrome, often begins a week or two after recovery from cytomegalovirus, Epstein–Barr virus or *Mycoplasma* infection. Patients present with rapidly advancing symmetrical weakness, loss of deep tendon reflexes, often with distal numbness, and limb or back pain. Cerebrospinal fluid (CSF) protein concentration is elevated, but in most cases there is little or no increase in number of inflammatory cells in the CSF. This 'albuminocytologic dissociation' contrasts with the elevation of both

TABLE 36-2 Antibody-mediated PNS disorders

Neuropathic syndrome	Antigenic specificity
Paraneoplastic sensory neuropathy	HuB, HuC, HuD
Lambert–Eaton myasthenic syndrome	Presynaptic voltage-gated calcium channel
Neuromyotonia (Isaacs' syndrome)	Voltage-gated potassium channel
Idiopathic autonomic neuropathy	Ganglionic acetylcholine receptor
Chagas' disease	M2 muscarinic acetylcholine receptors
Anti-MAG IgM paraproteinemic sensory neuropathy	Myelin-associated glycoprotein (MAG), sulfated glucuronyl paragloboside, sulfated glucuronyl lactosaminyl paragloboside
Vasculitic mononeuritis multiplex	Myeloperoxidase (MPO), proteinase 3 (PR3)
Multifocal motor neuropathy	GM1, GD1b, asialo-GM1 gangliosides
Miller–Fisher syndrome, Bickerstaff's brainstem encephalitis	GQ1b, GT1a gangliosides
Acute motor axonal neuropathy	GM1, GM1b, GD1a, GalNac-GD1a gangliosides
Immunoglobulin light-chain amyloid neuropathy	Unknown
Cryoglobulinemic neuropathy	Unknown

protein and cell count in the CSF of patients with paralysis caused by assault on primary motor neurons by neurotropic viruses (e.g. poliovirus and West Nile virus). Histological examination of peripheral nerves in AIDP demonstrates segmental demyelination and infiltration by lymphocytes. Most patients recover full neurological function within months, particularly if treated early by plasmapheresis or immunoglobulin infusion [22].

Acute motor axonal neuropathy also causes reversible paralysis. Acute motor axonal neuropathy (AMAN) resembles AIDP in clinical features and favorable long-term prognosis but differs in that axons, rather than myelin sheaths, are primarily injured. AMAN occurs sporadically in the USA but has sometimes reached epidemic proportions in China. Immunogenetic studies in China have demonstrated that there are also marked distinctions in the frequency of HLA class II antigens between those patients with AIDP and those with AMAN [23]. In many patients with AMAN, axonal injury appears to be a consequence of complement-fixing antiganglioside antibodies generated in response to an antecedent *Campylobacter jejuni* infection [24]. Plasmapheresis or immunoglobulin infusion is recommended for AMAN, and prognosis is similar to that for AIDP [22].

Miller–Fisher syndrome is mediated by pathogenic antibodies. Patients with the Miller–Fisher syndrome present subacutely with paralysis of extraocular muscles (ophthalmoplegia), ataxia and loss of deep tendon reflexes, sometimes after an antecedent *C. jejuni* infection. Most of these patients express serum antibodies against GQ1b ganglioside [24]. These antibodies bind complement and form membrane attack complexes on motor axons. Infusion of immunoglobulins accelerates recovery of normal neurological function in these patients, as in AIDP and AMAN, probably by inhibiting binding of the pathological antibodies to neural targets [25].

Autoimmune autonomic neuropathy is also associated with autoimmune antibodies. The most common presentation of autoimmune autonomic neuropathy is the acute onset of orthostatic hypotension, impaired bowel motility, and loss of sweating, often following a nonspecific viral infection. Both sympathetic and parasympathetic dysfunction are present in most patients. More than 50% of the patients with this syndrome demonstrate high titers of nicotinic acetylcholine receptor autoantibodies [26].

Experimental autoimmune neuritis and experimental autoimmune autonomic neuropathy are robust models for human autoimmune neuropathies. The most widely accepted hypothesis about the pathogenesis of AIDP, AMAN, the Miller–Fisher syndrome and autoimmune autonomic neuropathy is that they are initiated by sensitization to epitopes shared by an infecting microorganism and a component of the PNS ('molecular mimicry') [24]. Both cellular and antibody-mediated effector mechanisms then contribute to nerve damage [27, 28]. Which form of autoimmune neuropathy affects a given patient depends both upon the characteristics of the infecting microorganism and the immunogenetic determinants expressed by the patient [23].

Experimental autoimmune neuritis (EAN) mirrors AIDP in clinical, electrophysiological, CSF and pathological features. It is induced in susceptible strains of rats by sensitization to whole PNS myelin or to P2 or P0 peptide epitopes, and in rabbits by immunization with the myelin glycolipid galactocerebroside (galC) [29–32]. A similar syndrome has been recognized in humans immunized with a rabies vaccine prepared in brain tissues [33]. Like AIDP, EAN is typically a monophasic illness, although recurrent attacks can be elicited in Lewis rats if they are subjected to low-level immunosuppression. P2-EAN and P0-EAN are mediated primarily by sensitized T lymphocytes, whereas galC-EAN appears to be largely antibody-mediated. The PNS selectivity of P2- and P0-EAN is due to the restricted distribution of P2 and P0 to PNS myelin. GalC, on the other hand, is a constituent of CNS myelin, as well as PNS myelin, and the PNS selectivity of galC-EAN may be a consequence of more ready ingress of pathogenic complement-fixing galC antibodies to the PNS than to the CNS.

Experimental autoimmune autonomic neuropathy can be induced in rabbits by immunization with a neuronal

acetylcholine receptor α3 subunit fusion protein. These rabbits develop severe panautonomic failure closely resembling that seen in patients with autoimmune autonomic neuropathy [34].

Immune-mediated neuropathies, often vasculitis, are associated with systemic inflammatory disorders. Systemic inflammatory disorders (e.g. periarteritis nodosa, rheumatoid arthritis and Sjögren's syndrome) are often associated with mononeuropathy multiplex. In general, neuropathy in these diseases is caused by damage to vasa nervorum by inflammatory cells that infiltrate the blood vessel walls [9, 35], sometimes in conjunction with cryoglobulins. Many patients with vasculitic mononeuropathy multiplex express antibodies against myeloperoxidase and proteinase 3, demonstration of which is helpful in diagnosis [36].

Immune mechanisms contribute to paraneoplastic neuropathies.

Paraneoplastic neuropathies often occur in patients with carcinoma. Subacute sensory or sensorimotor axonal polyneuropathy, often with associated limbic encephalitis and cerebellar degeneration, is a common complication of small-cell lung cancer and other carcinomas, occasionally presenting even prior to diagnosis of the underlying neoplasm. Some patients with paraneoplastic neuropathy express anti-Hu antibodies, which recognize epitopes associated with the HuD neuronal RNA binding protein [37, 38].

Lambert–Eaton syndrome is an antibody-mediated neuromuscular junction disorder. This disorder, which is most frequently encountered in patients with small-cell lung carcinoma, is characterized clinically by weakness and hyporeflexia. The impaired release of acetylcholine vesicles from presynaptic terminals at neuromuscular junctions that causes the weakness is a consequence of autoantibodies against small cell carcinoma epitopes that cross-react with and downregulate the expression of motor nerve terminal Ca^{2+} channels [39]. (See in Ch. 43.)

Neuromyotonia (Isaacs' syndrome) is an immune-mediated hyperexcitability syndrome often associated with tumors. Neuromyotonia is a neuromuscular hyperexcitability syndrome characterized clinically by frequent muscle twitching, muscle enlargement, and excessive sweating. Electromyography shows repetitive high frequency discharges of motor units. Some patients with this disorder have associated thymoma, small cell lung carcinoma, or myasthenia gravis. More than a third of the patients with neuromyotonia have antibodies against voltage-gated potassium channels, with lesser numbers expressing antibodies against ganglionic or muscle acetylcholine receptors [40, 41].

Several forms of neuropathy occur in patients with plasma cell dyscrasias. In light chain amyloid neuropathy, insoluble aggregates of immunoglobulin light chains accumulate in the nerves of patients with multiple myeloma or other plasma cell dyscrasias. Clinical features of this acquired form of amyloid polyneuropathy include sensory, autonomic and motor deficits. Serum and/or urine protein electrophoresis in such patients demonstrates the presence of a monoclonal light chain protein, and amyloid is demonstrable in nerve biopsy specimens [7].

The syndrome of IgM_k paraproteinemia and sensory ataxia is usually encountered in elderly men. Nerve biopsy in these patients shows focal abnormalities in compaction of PNS myelin lamellae, and their IgM paraprotein recognizes epitopes of myelin-associated glycoprotein (MAG) and sulfate-3-glucuronyl paragloboside [24, 42].

POEMS is an eponym applied to patients with a variety of plasma cell dyscrasias who present with *p*olyneuropathy, *o*rganomegaly, *e*ndocrinopathy, an *M* protein and *s*kin changes; this disorder is also referred to as Crow–Fukase syndrome. Additional manifestations of this disorder are pulmonary hypertension, renal failure, a predisposition to thrombosis and congestive heart failure; some of these features are likely to be attributable to vascular endothelial growth factor (VEGF) and matrix metalloproteinases, which are often elevated in the plasma of these patients [43].

Toxins and hormone deficiency states are frequent causes of neuropathy.

Toxins and medications that affect the axonal cytoskeleton cause neuropathy. Axonal polyneuropathy is a common complication of the administration to cancer patients of the microtubule depolymerizing drug vincristine and a rare complication of therapy with another microtubule-interacting agent, colchicine [44, 45]. Exposure to *N*-hexane or its metabolite 2,5-hexanedione, to carbon disulfide or to β,β′-iminodiproprionitrile results in cross-linking of neurofilaments and produces a giant axonal neuropathy [46]. Secondary demyelination of enlarged axonal segments causes a multifocal nerve conduction block more suggestive of demyelinative than of axonal polyneuropathy. Many other frequently used drugs, such as the statin HMG-CoA reductase inhibitors, also cause distal axonal degeneration in occasional patients [47].

Megadosage vitamin B6 (pyridoxine) and cisplatin cause sensory neuronopathy. Pyridoxine toxicity, usually the result of inappropriate self-overmedication, kills dorsal root ganglion neurons. Affected individuals become severely ataxic because of loss of proprioceptive afferent input to the cerebellum. A similar syndrome is elicited by cisplatin chemotherapy. Neurotrophin-3 treatment is effective in protecting dorsal root ganglion neurons in experimental animals against these toxins [48, 49].

Neuropathy can result from deficiency of vitamins or hormones. Alcoholics often obtain a large proportion of their caloric needs from ethanol, and hence become thiamine-deficient. Alcoholic neuropathy results from a combination of thiamine deficiency, which impairs

carbohydrate metabolism, and a direct toxic effect of ethanol on the PNS [50]. More than a third of patients newly diagnosed with hypothyroidism demonstrate clinical and electrophysiological evidences of sensorimotor axonal polyneuropathy, which resolves with thyroid hormone replacement therapy [51]. Diabetic neuropathy, a late consequence of insulin deficiency, is discussed below.

Many genetically determined neuropathies are now recognized.

Diabetes mellitus is the most common cause of peripheral neuropathy in the United States. Approximately half of all diabetics demonstrate evidences of neuropathy. The usual clinical pattern is that of a slowly progressive, mixed sensorimotor and autonomic polyneuropathy. More acute, asymmetrical motor neuropathies are also seen, usually affecting the lumbosacral plexus, particularly in older persons with type 2 (non-insulin-dependent) diabetes mellitus. Patients with diabetes mellitus are also prone to develop isolated palsies of cranial nerve III or VII, and there is a high incidence of asymptomatic focal demyelination in the distal median nerve.

Among the pathogenetic mechanisms that have been proposed for diabetic neuropathy are excess glycation of neural proteins, alteration in nerve polyol metabolism induced by hyperglycemia, deficiency of a trophic factor necessary for PNS survival (e.g. sonic hedgehog) and nerve ischemia [52, 53]. The presence of small-vessel disease in human diabetic nerves suggests that diminished endoneurial blood flow plays a role in human diabetic neuropathy, particularly with respect to the scattered infarctions of the proximal regions of peripheral nerves attributable to vasa nervorum inflammatory vasculopathy [54].

Familial demyelinative/dysmyelinative neuropathies may be caused by impaired peroxisomal lipid metabolism. Refsum's disease is an autosomal recessive peroxisomal disorder characterized by accumulation of phytanic acid and other 3-alkyl-branched fatty acids [55]. Patients develop hypertrophic demyelinative polyneuropathy, retinitis pigmentosa, ichthyosis and deafness. The disorder can be successfully treated by institution of a diet poor in phytanic acid, in conjunction with plasmapheresis to remove circulating phytanic acid.

Adrenoleukodystrophy is an X-linked dysmyelinative disorder caused by mutations in the *ABCD1* gene, which encodes the peroxisomal integral membrane ALD protein, a member of the ATP binding cassette transporter family. These mutations result in impaired clearance of plasma very-long-chain fatty acids. Affected males may present with symmetrical distal axonal polyneuropathy, adrenocortical insufficiency or CNS demyelination, while occasional heterozygous women demonstrate deficits suggestive of multiple sclerosis [56]. Manipulation of dietary fatty acid intake has some minimal therapeutic effect, while bone marrow transplantation has diminished deficits in a few patients. (See in Ch. 41.)

Familial demyelinative/dysmyelinative and axonal neuropathies may also be caused by impaired lysosomal lipid metabolism. Metachromatic leukodystrophy (sulfatide lipidosis) results from mutations of the arylsulfatase A gene, which encodes a lysosomal enzyme required for sulfatide turnover. Myelin is affected in both CNS and PNS, though dysfunction is restricted to the PNS in some patients, and the onset of symptoms can occur at any time between infancy and adulthood. Bone marrow transplantation can slow disease progression and improve nerve conduction velocities [57]. (See in Ch. 41.)

Fabry's disease results from mutations of lysosomal α-galactosidase-A, which causes accumulation of α-D-galactosyl-conjugated glycosphingolipids. Neuropathy in this disorder affects small but not large axons and presents with pain and hypohidrosis. Another major feature of this disease is vasculopathy affecting the kidneys and CNS. Periodic infusion of patients with Fabry's disease with recombinant human α-galactosidase-A diminishes neuropathic pain and improves sweating function [58].

Acute intermittent porphyria is a dominantly inherited partial deficiency of porphobilinogen deaminase, and causes axonal polyneuropathy. Acute intermittent porphyria is caused by partial deficiency of porphobilinogen deaminase, an enzyme required for heme biosynthesis. Patients may present with acute abdominal pain, rapidly progressive sensorimotor axonal polyneuropathy or psychosis, and have elevated concentrations of the heme precursor δ-amino-levulinic acid in their urine. Symptoms may be precipitated by treatment with barbiturates or other drugs and are suppressed by treatment with hematin [59].

Several familial forms of amyloid neuropathy are now recognized. The dominantly inherited amyloid neuropathies are caused by mutations of the transthyretin, gelsolin or apolipoprotein A1 genes that diminish the solubility of these proteins, resulting in the formation of protein aggregates in vasa nervorum and perineurium in peripheral nerves. The familial amyloid neuropathies present with autonomic dysfunction, often together with progressive distal sensory or sensorimotor neuropathy [7]. Liver transplantation may prevent progression of amyloid neuropathy caused by transthyretin mutations.

There are multiple forms of hereditary motor and sensory neuropathy. Charcot–Marie–Tooth syndrome is a diverse group of demyelinative and axonal polyneuropathies caused by mutations of myelin-associated proteins (PMP22, MPZ and Cx32) [60] or other genes expressed by Schwann cells or PNS neurons (e.g. *GDAP1* and *NF-L*). Collectively, the CMTs rival neurofibromatosis type 1 as the most common genetic disorder affecting the PNS. Demyelinative forms of CMT are characterized by reduced velocity of nerve action potentials, prominent segmental demyelination and Schwann cell proliferation, sometimes

with onion-bulb formation. There is typically also a paucity of large axons in patients with these primarily demyelinative polyneuropathies, probably resulting from deficient provision by Schwann cells of trophic influences necessary for maintenance of a normal axonal cytoskeleton. Axonal forms of CMT manifest distal Wallerian degeneration.

CMT1A, the most common form of CMT [61], results from a 1.5 Mb duplication in chromosome 17p11.2–12. Among the genes encoded in this duplicated segment is PMP22, a component of PNS myelin, and patients with CMT1A therefore have three copies of this gene. Mice transgenic for PMP22 also develop demyelinative polyneuropathy. It is of considerable interest that treatment of these transgenic mice with ascorbic acid results in PNS remyelination and enhanced life expectancy, probably because ascorbic acid represses PMP22 expression [62].

A deletion of the same 1.5 Mb segment of chromosome 17 that is duplicated in CMT1A is the cause of hereditary neuropathy with predisposition to pressure palsies (HNPP). Patients with HNPP, who have only one copy of the *PMP22* gene, develop repeated focal demyelinative mononeuropathy or mononeuropathy multiplex, and many also eventually manifest demyelinative polyneuropathy as well. Histological examination of their nerves demonstrates segmental demyelination and scattered sausage-shaped myelin sheath swellings, hence the alternative name for HNPP, tomaculous neuropathy [63]. A point mutation of the *PMP22* gene is responsible for recessively inherited demyelinative polyneuropathy in the *trembler* mouse [64]. Both recessive and dominant forms of hereditary motor and sensory neuropathy result from mutations in the gene encoding PNS myelin P0 glycoprotein, and these may be primarily demyelinative or primarily axonal. An X-linked form of CMT (CMT1X) is typically a mixed demyelinative and axonal polyneuropathy caused by mutations of a gene encoding the gap-junction protein connexin32 [65]. Gap junctions containing connexin32 are expressed in Schmidt–Lantermann incisures and in paranodal myelin of myelinating Schwann cells. Recessively inherited forms of CMT, caused by *GDAP1*, *ER2*, *MTMR2*, *NDRG1*, *PRX* or *A/C* gene mutations and manifested as either demyelinating or axonal polyneuropathies, are relatively frequent in regions where consanguineous marriages are common [66]. (See also Ch. 38.)

Familial motor neuron disease can result from mutations of a variety of genes. Inherited diseases targeting motor neurons include familial amyotrophic lateral sclerosis (FALS) associated with superoxide dismutase (SOD)1 mutations, X-linked familial bulbospinal muscle atrophy, infantile and adult forms of glycogen-storage disease type IV caused by mutations of the gene encoding the glycogen branching enzyme, and familial infantile, juvenile and adult forms of spinal muscular atrophy caused by mutations of the survival motor neuron (*SMN*) gene, which plays an essential role in pre-mRNA processing [67, 68].

X-lined bulbospinal muscular atrophy, also termed Kennedy's syndrome, is caused by an unstable expanded CAG repeat in the first exon of the androgen receptor gene. Affected men demonstrate progressive proximal limb and bulbar weakness together with gynecomastia. As in Friedreich's ataxia and other neurological disorders associated with unstable triplet expansions, there is a tendency toward earlier onset and greater severity of symptoms with each succeeding generation in a family, which correlates with increasing repeat number [69]. Mutations of SOD1 that result in a toxic gain of function are the most common cause of FALS [70]. (See also Ch. 44.)

Friedreich's ataxia is caused by an intronic triplet repeat expansion. Friedreich's ataxia is an autosomal recessive disorder characterized by progressive ataxia, nystagmus, distal sensory polyneuropathy and corticospinal tract degeneration. It is caused by an unstable expanded GAA repeat in intron 1 of the frataxin gene on chromosome 9q13. This diminishes expression of frataxin, a mitochondrial iron-storage protein that participates in free radical metabolism [71].

Neurofibromatosis is a frequent cause for peripheral nerve tumors.

Neurofibromatosis type 1 is a common cause of PNS tumors. Neurofibromatosis type 1 (NF1, von Recklinghausen's disease) is the most frequent dominantly inherited disorder of the PNS, with an incidence of about 1 in 2,000 persons. Among its diagnostic features are benign Schwann cell tumors arising from small cutaneous nerves, termed subcutaneous neurofibromas, or within larger nerves, plexiform neurofibromas; cutaneous accumulations of melanocytes, termed *café-au-lait spots*; focal accumulations of pigmentary cells in the iris, termed Lisch nodules; and a variety of orthopaedic deformities, including absence of a segment of the sphenoid bone, causing pulsating exophthalmos; kyphosis; and tibial non-union. While all these features can be attributed to abnormalities of neural-crest- or placode-derived tissues, patients with NF1 may also manifest various CNS abnormalities, including mental retardation and gliomas, particularly of the optic nerves or optic chiasm. Patients with NF1 are prone to develop Schwann cell malignancies, termed neurofibrosarcomas, as well as other forms of cancer. NF1 is caused by mutations in the neurofibromin gene, situated on chromosome 17, which encodes a large tumor-suppressor protein with a GTPase-activating domain and many other domains of unknown function. It has been demonstrated that NF1-deficient Schwann cells contain elevated levels of Ras-GTP [72], and that the second copy of the neurofibromin gene is inactivated or lost in benign neurofibromas [73]. Studies in mouse models of NF1 have demonstrated that other cellular components of neurofibromas (e.g. mast cells) contribute to tumor growth in NF1 [74].

Neurofibromatosis type 2 affects the acoustic nerves and CNS glia. Neurofibromatosis type 2, a much rarer disorder than NF1, is characterized by bilateral acoustic schwannomas and CNS glial tumors, and is caused by mutations of a tumor suppressor gene on chromosome 22q that encodes the protein merlin. Merlin, closely homologous to the ERM proteins, ezrin, radixin and moesin, inhibits Rac signaling, thus favoring Schwann cell tumorigenesis [75].

HEREDITARY AND ACQUIRED DISEASES INVOLVING THE ENTERIC NERVOUS SYSTEM

The enteric nervous system (ENS) is derived from the neural crest. Neurons in enteric ganglia resemble various classes of CNS neurons in neurotransmitter specificity and growth factor requirements [76]. Enteric neuroglia resemble astroglia in expressing GFAP and glutamine synthetase [77]. Many diseases that affect the PNS also involve the ENS. Among these are infections such as Chagas' disease [78] and metabolic disorders such as diabetes mellitus and amyloidosis. Some disorders selectively involve the ENS. Among these is Hirschsprung's disease, which presents typically in infancy with massive segmental dilatation of the colon. The dilatation is the result of segmental absence of colonic enteric ganglia, among the causes of which are mutations of the RET receptor tyrosine kinase and of the endothelin B receptor [79].

The Epilepsies: Phenotype and Mechanisms

John W. Gibbs

James O. McNamara

EPILEPSY IS A COMMON NEUROLOGICAL DISORDER 629
The term 'seizure' denotes a fleeting change of behavior caused by the disordered, synchronous and rhythmic firing of populations of neurons 629
Disrupting the delicate balance of inhibitory and excitatory synaptic transmission can trigger the disordered, synchronous firing of neurons that underlies a seizure 630
Cellular mechanisms underlying hyperexcitability have been analyzed by electrophysiological studies of hippocampal slices isolated from animals with epilepsy 632
Normally the dentate granule cells of hippocampus limit excessive activation of their targets, the CA3 pyramidal cells 632
Analyses of afferents of dentate granule cells from epileptic animals reveal abnormal inhibitory and excitatory synaptic input 633
Axonal and dendritic sprouting lead to abnormal recurrent excitatory synaptic circuits among the dentate granule cells in epileptic brain 633
Epileptogenesis is the process by which a normal brain becomes epileptic 633
Identifying molecular mechanisms of epileptogenesis will provide new targets for developing small molecules to prevent epilepsy 633

MECHANISMS OF ANTISEIZURE DRUGS 634
Many antiseizure drugs act on voltage-gated sodium channels to limit high-frequency but not low-frequency firing of neurons 634
Other antiseizure drugs enhance GABA-mediated synaptic inhibition 634
Other antiseizure drugs regulate a subset of voltage-gated calcium currents 634

GENETICS OF EPILEPSY 635
Many forms of epilepsy have genetic determinants 635
Some spontaneous and some engineered mutations of mice result in epilepsy 635

EPILEPSY IS A COMMON NEUROLOGICAL DISORDER

The epilepsies constitute a common, serious neurological disorder in humans, affecting approximately 60 million people worldwide. Well in excess of 40 distinct epileptic syndromes have been identified to date. Current treatment is only symptomatic except in uncommon instances when surgical treatment is possible. While available antiseizure medications target ion channels such as the γ-amino-butyric acid $(GABA)_A$ receptor and voltage activated sodium (Na^+) channels, current research seeks to elucidate the cellular and molecular mechanisms by which a normal brain becomes epileptic. Hopefully, this research will lead to the identification of new targets for which small molecules can be identified and used for prevention or cure of epilepsy.

The term 'seizure' denotes a fleeting change of behavior caused by the disordered, synchronous and rhythmic firing of populations of neurons. The term 'epilepsy' denotes a disorder of brain function expressed as the periodic and unpredictable occurrence of seizures. Pharmacological agents in current clinical use inhibit epileptic seizures and thus are referred to as *antiseizure* drugs. It is currently unknown, however, whether any of these agents has any prophylactic value in preventing the development of epilepsy (*epileptogenesis*). Other commonly used terms include electroencephalographic (EEG) descriptors such as *ictal* (seizure-like) and *interictal*

Basic Neurochemistry: Molecular, Cellular and Medical Aspects

TABLE 37-1 Classification of partial epileptic seizures

Partial Seizure	Features	Antiseizure Drugs
Simple partial	Phenotype determined by cortical region activated (e.g. if motor cortex representing left thumb is activated, then left thumb jerking results). Consciousness is preserved	Carbamazepine, phenytoin, valproate, gabapentin, lamotrigine, levetiracetam, tiagabine, topiramate, zonisamide
Complex partial	Impaired consciousness lasting seconds to minutes, often associated with automatisms such as lip smacking	Carbamazepine, phenytoin, valproate, gabapentin, lamotrigine, levetiracetam, tiagabine, topiramate, zonisamide
Partial with secondary generalization	Simple or partial complex seizure evolves into a tonic–clonic seizure with loss of consciousness. There are sustained muscular contractions (tonic) followed by periods of relaxation (clonic) lasting 1–2 min	Carbamazepine, phenytoin, phenobarbital, valproate, gabapentin, lamotrigine, levetiracetam, tiagabine, topiramate, zonisamide

(between seizures), as used by clinicians to describe individual EEG patterns.

Seizures are thought to arise from the cerebral cortex, and not from other CNS structures such as the thalamus, brainstem or cerebellum. Epileptic seizures have been classified as *partial* seizures, which are those beginning focally in a cortical site, and *generalized* seizures, those that involve discharges from both hemispheres widely from the outset [1]. The behavioral manifestations of a seizure are determined by the functions normally served by the cortical site at which the seizure arises. For example, a seizure involving motor cortex is associated with the clonic jerking of the body part controlled by this region of cortex. A *simple* partial seizure is associated with preservation of consciousness whereas a *complex* partial seizure is associated with impairment of consciousness. The majority of complex partial seizures originate from the temporal lobe (Table 37-1). Examples of *generalized* seizures include absence, myoclonic, and tonic–clonic seizures (Table 37-2). The type of epileptic seizure, diagnosed both by clinical and EEG methodology, is one determinant of the drug selected for therapy as different antiseizure medications often demonstrate varying abilities to control different seizure phenotypes.

Apart from this epileptic seizure classification, an additional classification specifies *epileptic syndromes,* which refer to a cluster of symptoms frequently occurring together and include seizure type, etiology, age of onset and other factors [2]. The epileptic syndromes have been categorized into partial *versus* generalized epilepsies. The partial epilepsies account for roughly 60% of all epilepsies. The etiology commonly consists of a lesion in some part of the cortex, such as a tumor, developmental malformation, damage due to trauma or stroke, etc. Such lesions often are evident on brain imaging studies such as magnetic resonance imaging. Alternatively, the etiology may be genetic (Table 37-3). The generalized epilepsies are characterized by one or more generalized seizure types (listed in Table 37-2). These account for approximately 40% of all epilepsies and are thought to have a genetic etiology. The most common generalized epilepsy is juvenile myoclonic epilepsy (JME), accounting for approximately 10% of all epileptic syndromes. The age of onset is in the early teens and the condition is characterized typically by myoclonic, tonic–clonic and often absence seizures. Like most generalized epilepsies, JME is usually due to the inheritance of multiple susceptibility genes; often, there is a familial clustering of cases but the pattern of inheritance is not mendelian.

Disrupting the delicate balance of inhibitory and excitatory synaptic transmission can trigger the disordered, synchronous firing of neurons that underlies a seizure. More than a century ago, John Hughlings Jackson, an extraordinarily insightful clinician, proposed that seizures

TABLE 37-2 Classification of generalized epileptic seizures

Generalized Seizure	Features	Antiseizure Drugs
Absence	Abrupt loss of consciousness associated with staring and cessation of activities normally lasting less than 30 seconds	Ethosuximide, valproate, lamotrigine
Myoclonic	Brief muscular contraction, either focal or generalized in nature	Valproate
Tonic–clonic	Sustained muscular contractions (tonic) followed by periods of relaxation (clonic) lasting 1–2 min	Carbamazepine, phenobarbital, phenytoin, primidone, valproate, topiramate

TABLE 37-3 Idiopathic human epilepsies: genes and syndromes

Syndrome	Gene
Autosomal dominant nocturnal frontal lobe epilepsy, 1	Nicotinic receptor subunit: α_4
Autosomal dominant nocturnal frontal lobe epilepsy, 3	Nicotinic receptor subunit: β_2
Benign neonatal epilepsy, type 1	K^+ channel subunit: KCNQ2
Benign neonatal epilepsy, type 2	K^+ channel subunit: KCNQ3
Generalized epilepsy with febrile seizures plus ($GEFS^+$), severe myoclonic epilepsy of infancy (SMEI)	Na^+ channel subunit: $Na_V1.1$
Febrile and afebrile seizures, benign familial neonatal-infantile seizures	Na^+ channel subunit: $Na_V1.2$
$GEFS^+$	Na^+ channel subunit: β_1
$GEFS^+$, childhood absence epilepsy	$GABA_A$ receptor: γ_2
Juvenile myoclonic epilepsy	$GABA_A$ receptor: α_1
Partial epilepsy with auditory features	Leucine-rich, glioma-inactivated 1

were caused by 'occasional, sudden, excessive, rapid and local discharges of gray matter', and a generalized convulsion resulted when normal brain tissue was invaded by the seizure activity initiated in the abnormal focus. In fact, this prediction provided a valuable framework for current thinking about mechanisms of partial epilepsy. The advent of the EEG in the 1930s permitted the recording of electrical activity from the scalp of human beings and demonstrated that the epilepsies are disorders of neuronal excitability.

The pivotal role of synapses in mediating communication among neurons in the mammalian brain suggested that defective synaptic function might lead to an epileptic seizure, with a delicate synaptic balance necessary to maintain the normal state of neurons. In other words, a reduction of inhibitory synaptic activity or enhancement of excitatory synaptic activity might be expected to trigger a seizure. Indeed, pharmacological studies of seizures have supported this hypothesis. The neurotransmitters mediating the bulk of synaptic transmission in the mammalian brain are amino acids, GABA and glutamate being the principal inhibitory and excitatory neurotransmitters, respectively (see Chs 15 and 16). Pharmacological studies in normal animals disclosed that injection of antagonists of the $GABA_A$ receptor or of agonists of different glutamate-receptor subtypes (NMDA, AMPA or kainic acid) triggered seizures in otherwise normal animals *in vivo*. In contrast, pharmacological agents that enhance GABA-mediated synaptic inhibition, such as benzodiazepines, reduce seizure activity. Likewise, glutamate receptor antagonists inhibit seizures in diverse models, including seizures evoked by electroshock or chemical convulsants.

These findings were confirmed and extended by *in vitro* electrophysiological studies of slices from normal animals that revealed that subtle (e.g. 20%) reductions of inhibitory synaptic function could lead to epileptiform activity. Importantly, activation of excitatory synapses is often pivotal in the expression of a seizure in distinct models *in vitro*. In addition to these important pharmacological observations, electrophysiological analyses of individual neurons during a partial seizure revealed that neurons undergo a massive depolarization and fire action potentials at high frequencies (Fig. 37-1) [3]. This pattern of

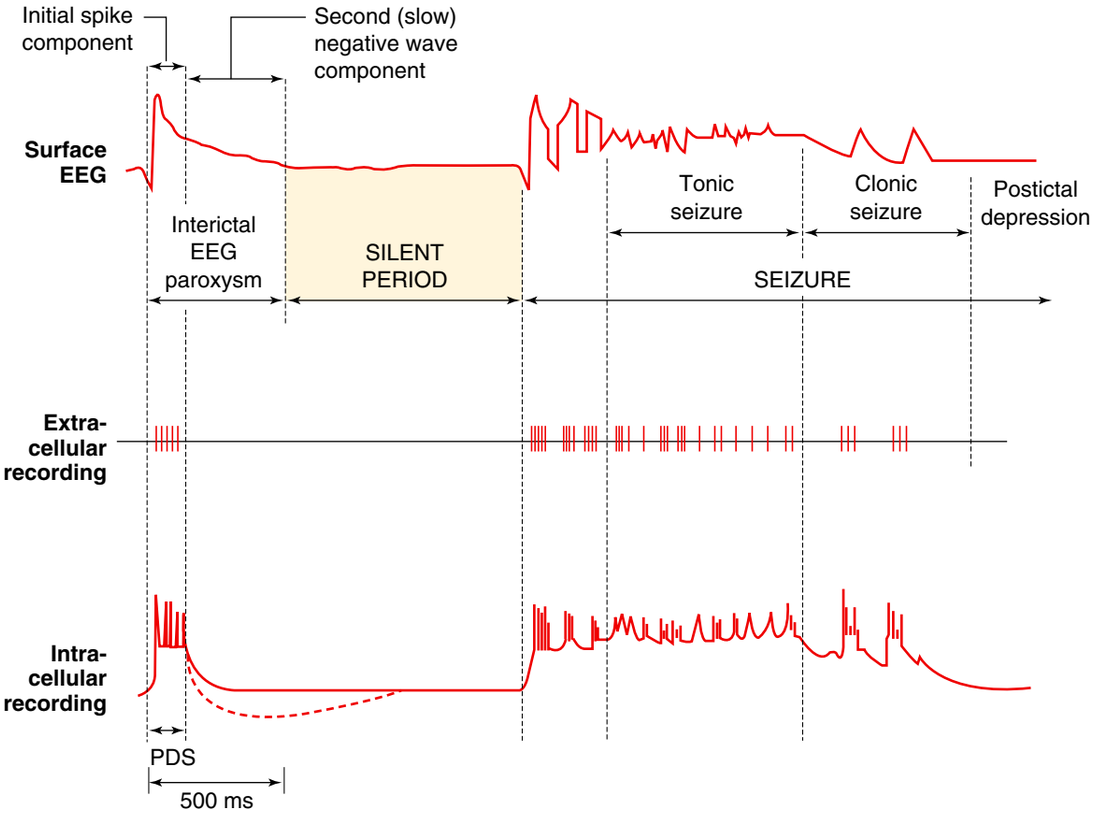

FIGURE 37-1 Relationship among cortical EEG, extracellular and intracellular recordings in a seizure focus exposed to a convulsant agent in cortex. Note the high-frequency firing of the neuron in both intracellular and extracellular recordings during the paroxysmal depolarization shift (*PDS*) [3]. Cellular electrophysiological studies of epilepsy over roughly two decades beginning in the mid-1960s were focused on elucidating the mechanisms underlying the DS, the intracellular correlate of the 'interictal spike'. The interictal spike is a sharp waveform recorded in the EEG of patients with epilepsy; it is asymptomatic in that it is accompanied by no detectable change in a patient's behavior. However, the location of the interictal spike helps to localize the brain region from which seizures originate in a given patient. The DS consists of a large depolarization of the neuronal membrane associated with a burst of action potentials. In most cortical neurons, a large excitatory synaptic current that can be enhanced by activation of voltage-regulated intrinsic membrane currents generates the DS.

neuronal firing is characteristic of a seizure and is uncommon during physiological neuronal activity, a finding that provides a plausible explanation for the ability of some antiseizure drugs to inhibit seizures with minimal effect on normal functions of mammalian brain. While synapses are important, the initiation and expression of a seizure can involve a diversity of additional mechanisms including nonsynaptic mechanisms such as the volume of the extracellular space and intrinsic properties of a neuron such as voltage-regulated ion channels, including those gating K^+, Na^+ and Ca^{2+} ions [4]. Identification of these diverse synaptic and nonsynaptic factors controlling seizures *in vitro* provides potentially valuable pharmacological targets for regulating seizure susceptibility *in vivo* in humans.

Cellular mechanisms underlying hyperexcitability have been analyzed by electrophysiological studies of hippocampal slices isolated from animals with epilepsy. The pharmacological evidence implicating GABA and glutamatergic synapses in the expression of seizures both *in vivo* and *in vitro* led to hypotheses as to the mechanism of the enduring hyperexcitability of the epileptic brain. That is, scientists hypothesized that one mechanism accounting for the hyperexcitability of the epileptic brain might be an impaired function of inhibitory synapses and/or enhanced function of excitatory synapses. The availability of animal models of epilepsy provided a powerful tool to test these hypotheses, particularly when *ex vivo* study of hippocampal slices isolated from epileptic animals permitted analysis of synaptic function. Also, the anatomical focus on the properties of an identified population of neurons thought to be important for epilepsy was critical, with the dentate granule cells of hippocampus providing one such anatomic locale. Consideration of the animal models and the rationale for study of the dentate granule cells will be followed by review of the analyses of the synaptic properties of these neurons in epilepsy models.

A diversity of animal models of epilepsy have been identified [5]. Two of the most commonly studied models are 'kindling' and 'status epilepticus' models. Kindling is a model of temporal lobe epilepsy (TLE) that is induced by the periodic administration of brief, low-intensity electrical stimulation of the amygdala or other limbic structures. Described by Graham Goddard and his colleagues [6], initial stimulations evoke a brief electrical seizure recorded on EEG without behavioral change, but repeated (e.g. 10–20) stimulations result in progressive intensification of seizures, culminating in tonic–clonic seizures. Once established, the enhanced sensitivity to electrical stimulation persists for the life of the animal. Despite the lifelong propensity to express intense seizures in response to low intensity stimulation, spontaneous seizures or a truly epileptic condition do not occur until approximately 100 stimulation-evoked seizures have occurred. The ease of control of kindling induction (i.e. stimulations administered at the investigator's convenience), its graded onset and the ease of quantifying epileptogenesis (number of stimulations required to evoke tonic–clonic seizures) simplify study of early stages of epileptogenesis with this model.

A variety of models exist in which epilepsy arises weeks after an episode of status epilepticus, a state of continuous seizures lasting hours. Whether triggered by chemoconvulsants (e.g. pilocarpine or kainic acid) or continuous electrical stimulation, the fleeting episode of status epilepticus is followed in the coming weeks by the onset of spontaneous seizures [7, 8], an intriguing parallel to the scenario of complicated febrile seizures in young children followed by the emergence of spontaneous seizures years later. In contrast to the limited or absent neuronal loss characteristic of the kindling model, overt destruction of hippocampal neurons occurs in both the pilocarpine and kainate models, mimicking characteristics of hippocampal sclerosis observed in many humans with medically refractory TLE. Indeed, the discovery that complicated febrile seizures are followed by and thus almost certainly one cause of hippocampal sclerosis in young children establishes yet another commonality between these models and the human condition [9].

Normally the dentate granule cells of hippocampus limit excessive activation of their targets, the CA3 pyramidal cells. Insight into the structural and functional properties of diverse populations of principal neurons of the hippocampus and its connections have provided a context for considering how the function of these neurons underlie normal behaviors such as learning and memory as well as the hyperexcitability of TLE. The extensive recurrent excitatory synaptic connections among CA3 pyramidal neurons together with the propensity of individual CA3 pyramidal neurons to fire action potentials in a bursting pattern explained the propensity of these neurons to exhibit seizures [10]. Given this propensity, it became clear that the principal afferents of the CA3 pyramidal cells, the dentate granule cells, must function as a gatekeeper to limit the activation of the CA3 pyramidal cells and their subsequent explosion into seizure activity [11]. The uniqueness of the innervation of their targets by the granule cells underscores their function as gatekeeper. That is, excitatory principal neurons (e.g. CA3 pyramidal cell innervation of its targets in CA1) of mammalian forebrain typically innervate other excitatory neurons directly in great quantitative preference to inhibitory interneurons [12]. In stark contrast, the dentate granule cells innervate approximately 10 inhibitory interneurons for every one CA3 pyramidal neuron; these inhibitory interneurons mediate feedforward inhibition of the CA3 pyramidal neurons, thus underlying the net inhibitory and tight control of CA3 pyramidal cell firing by the dentate granule cells [13]. Using deoxyglucose autoradiography studies, the dentate granule cells did indeed appear to function as a barrier for invasion of hippocampus by seizure activity *in vivo* [14]. These findings led to the hypothesis that

compromise of the normal barrier function of the granule cells permits activation of the CA3 pyramidal cells and recruitment of the hippocampal circuit into seizure activity, thereby contributing to the hyperexcitability of TLE.

Analyses of afferents of dentate granule cells from epileptic animals reveal abnormal inhibitory and excitatory synaptic input. Enhanced function of excitatory synapses selectively using NMDA receptors has been identified in afferents of the dentate granule cells in hippocampal slices isolated from kindled animals [15]. In the pilocarpine model, net reductions of inhibitory synaptic transmission mediated by $GABA_A$ receptors have been demonstrated in dentate granule cells; this may be due in part to altered responses to GABA by $GABA_A$ receptors, which in turn may be due to altered subunit composition of the $GABA_A$ receptor [16]. Not surprisingly, the reality is substantially more complex than described here. Paradoxically, enhanced function of $GABA_A$ synaptic input has been identified in the dentate granule cells in slices isolated from kindled animals, most probably underlying a compensatory response aimed at preventing emergence of spontaneous seizures in these animals [17].

Axonal and dendritic sprouting lead to abnormal recurrent excitatory synaptic circuits among the dentate granule cells in epileptic brain. Repeated seizures have been demonstrated to result in a structural reorganization of hippocampal circuitry, a reorganization that increases substantially in the presence of cell death as occurs often in temporal lobe epilepsy. The best described structural reorganization is that in which axons of the excitatory granule cells sprout and reinnervate themselves and/or their neighbors through recurrent collaterals forming a feed-forward excitatory loop termed 'mossy fiber sprouting' [18]. More recently, sprouting of basilar dendrites of the granule cells has also been identified and these provide additional targets for the sprouted axons [19]. The recurrent axonal collaterals are readily identified experimentally in various seizure models and the human condition using the Timm's stain. The fact that networks of recurrent excitatory synapses represent an efficient substrate for initiation and propagation of seizure activity underscores the appeal of the idea that this reorganized granule cell synaptic network may contribute to the hyperexcitability of TLE. Functional evidence for the presence of recurrent excitatory synapses has emerged from synaptic physiological studies of slices in the pilocarpine model. Nonetheless, the extent to which this reorganized network of dentate granule cells contributes to the hyperexcitability of the epileptic brain is uncertain at present.

While alterations in dentate granule synaptic physiology and anatomy provide a snapshot to begin to understand how a normal brain changes to an 'epileptic' brain, the dentate granule cells represent only one small piece of the complex puzzle of how a normal brain becomes epileptic. A myriad of changes have been reported to occur in neurons elsewhere in the hippocampus and other regions of the brain. Not all of these changes involve excitatory or inhibitory synapses. For example, the defective inactivation of voltage-gated sodium channels has been identified in CA1 pyramidal neurons in slices isolated from the kindling model [20]. Therefore, when one begins to assess the hyperexcitability of the epileptic brain, it is imperative to view these alterations on a global platform and not just localized to a single population of neurons, in order to appreciate the vast complexities that are involved.

Epileptogenesis is the process by which a normal brain becomes epileptic. The very complexity of understanding mechanisms underlying the hyperexcitability of the epileptic brain has contributed to enhanced emphasis in attempts to prevent development of epilepsy, i.e. epileptogenesis.

Interestingly, many forms of partial epilepsy are characterized by a seizure-free interval lasting months to years between the occurrence of the causative insult and the emergence of epilepsy; termed the 'latent period', this provides a valuable window of opportunity during which pharmacologic intervention might be implemented in high-risk individuals so that development of epilepsy could be prevented.

Identifying molecular mechanisms of epileptogenesis will provide new targets for developing small molecules to prevent epilepsy. Understanding the cellular mechanisms of epileptogenesis in molecular terms will hopefully lead to identification of molecular targets for which small molecules might be identified for the prevention of epilepsy. Studies of the kindling model established the critical role of pathological activity in the pathogenesis of partial epilepsy. This led to the question as to what molecular consequences of pathologic activity might mediate the transformation of a normal brain to an epileptic brain. In turn, this led to focus on neurotrophins such as nerve growth factor and brain derived neurotrophic factor (BDNF) that have been implicated in transducing fleeting experiences into lasting changes in phenotypes (see Growth Factors, Ch. 27). In fact, seizures produce striking increases in the expression of BDNF. Indeed enhanced activation of the tyrosine kinase receptor of BDNF, TrkB, occurs in multiple models of epileptogenesis [21]. BDNF somehow contributes to epileptogenesis in the kindling model because epileptogenesis is partially inhibited in mice in which one or both alleles of the BDNF gene have been eliminated. By contrast, epileptogenesis in the kindling model is prevented altogether in mice in which both alleles of the TrkB gene are eliminated [21], providing the first genetic or pharmacological perturbation that is required for epileptogenesis in this model. These findings focus the search for mechanisms of epileptogenesis on structural and functional consequences of TrkB activation. They also implicate TrkB and its downstream signaling pathways as highly attractive targets for

development of small molecule inhibitors for the prevention of epilepsy.

MECHANISMS OF ANTISEIZURE DRUGS

Insights into the mechanisms of action of medications effective against partial seizures [22] emerged from electrophysiological studies of reduced preparations, such as CNS neurons maintained in primary culture. The experimental control and accessibility available in these models combined with use of clinically relevant concentrations led to clarification of the mechanisms of various antiseizure medications. Although difficult to prove that a given antiseizure drug effect observed *in vitro* is the mechanism by which a drug acts *in vivo* to inhibit a seizure, there is a strong likelihood that the putative mechanisms identified in the laboratory underlie actions *in vivo* in humans. To date, most antiseizure drugs target voltage-gated sodium channels or synapses using $GABA_A$ receptors.

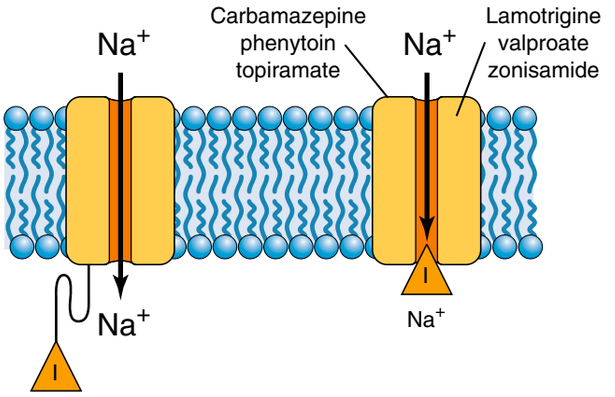

FIGURE 37-2 Antiseizure Na^+ channel inactivation. Some antiseizure drugs work mechanistically by prolonging the inactivation of the Na^+ channel, thereby reducing the ability of neurons to fire at high frequencies. Antiseizure drugs known to promote inactivation of this channel include carbamazepine, phenytoin, topiramate, lamotrigine, valproate and zonisamide. Note that the inactivated channel appears to remain open but is blocked by the inactivation gate (I) at the pore.

Many antiseizure drugs act on voltage-gated sodium channels to limit high-frequency but not low-frequency firing of neurons. As described earlier, electrophysiological analyses of individual neurons during a partial seizure demonstrate that neurons undergo depolarization and fire action potentials at high frequencies (Fig. 37-1). This pattern of neuronal firing is the hallmark of a seizure and is rare during physiological activity. Therefore, the selective inhibition of this high-frequency firing pattern would be expected to reduce seizures, hopefully with minimal unwanted effects. Carbamazepine, lamotrigine, phenytoin and valproic acid modulate high-frequency firing at concentrations known to be effective in the limitation of seizures in humans [22]. The mechanism by which the drugs limit high-frequency firing involves slowing the recovery of voltage-gated Na^+ channels from inactivation, also termed use-dependent blockade (Fig. 37-2).

Stated differently, depolarization-triggered opening of the Na^+ channels in the axonal membrane of a neuron is required for an action potential; after opening, the channels spontaneously close, a process termed *inactivation* (see Ch. 6). This inactivation is thought to mediate the refractory period, the brief period following an action potential during which it is not possible to evoke another action potential. Upon recovery from inactivation, the Na^+ channels are poised to participate in generation of another action potential. Because firing at a slow rate permits sufficient time for Na^+ channels to recover from inactivation, inactivation has little or no effect on low-frequency firing. However, reducing the rate of recovery of Na^+ channels from inactivation would limit the ability of a neuron to fire at high frequencies, an effect that most probably underlies the effects of carbamazepine, lamotrigine, phenytoin, topiramate, valproic acid and zonisamide against partial seizures.

Other antiseizure drugs enhance GABA-mediated synaptic inhibition. Insights into mechanisms of seizures suggest that enhancing GABA-mediated synaptic inhibition, particularly $GABA_A$ inhibition, would reduce neuronal excitability and therefore raise the seizure threshold. Several drugs are thought to inhibit seizures by regulating GABA-mediated synaptic inhibition through an action at distinct sites of the synapse [22]. The principal postsynaptic receptor of synaptically released GABA is the $GABA_A$ receptor. Activation of the $GABA_A$ receptor effects inhibition of the postsynaptic cell by increasing the flow of Cl^- ions into the cell, which tends to hyperpolarize the neuron (see Ch. 16). Clinically relevant concentrations of both benzodiazepines and barbiturates can enhance $GABA_A$-receptor-mediated inhibition through distinct actions on the $GABA_A$ receptor (Fig. 37-3) [22]. This mechanism probably underlies the effectiveness of these compounds against partial and tonic–clonic seizures in humans. At higher concentrations, such as might be used for status epilepticus, these drugs also can inhibit high-frequency firing of action potentials. γ-vinyl GABA (vigabatrin) is thought to exert its antiseizure action by irreversibly inhibiting an enzyme that degrades GABA, GABA transaminase; this probably leads to increased amounts of GABA available for synaptic release [22]. A third mechanism of enhancing GABA-mediated synaptic inhibition is thought to underlie the antiseizure mechanism of tiagabine; tiagabine inhibits the GABA transporter, GAT-1, and reduces neuronal and glial uptake of GABA [22] (Fig. 37-3).

Other antiseizure drugs regulate a subset of voltage-gated calcium currents. In contrast to partial seizures, which arise from localized regions of the cerebral cortex, the 'absence' or 'petit mal' form of generalized-onset seizures arise from the reciprocal firing of the thalamus and

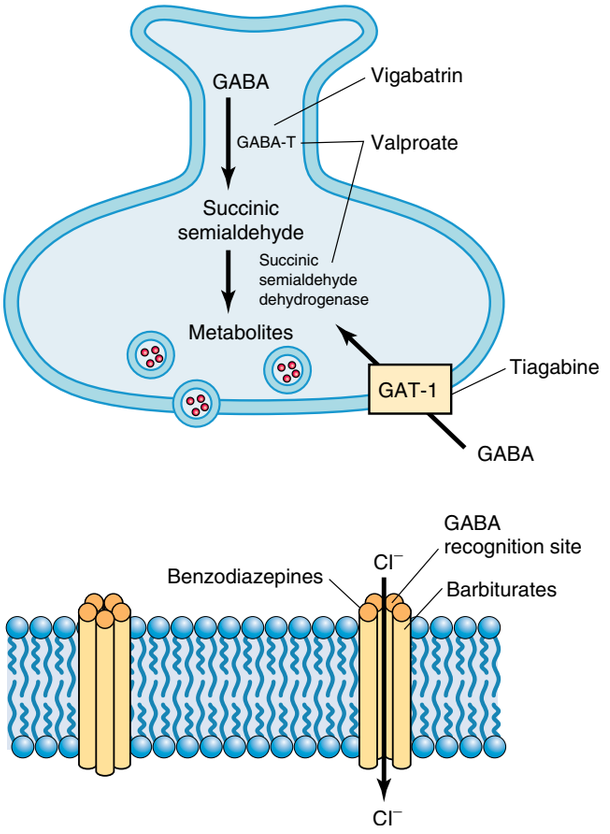

FIGURE 37-3 Increased GABAergic transmission mediated by antiseizure drugs. Some antiseizure drugs mediate the increased opening of $GABA_A$ receptors in turn increasing membrane hyperpolarization like benzodiazepines and barbiturates. Others inhibit GABA reuptake (tiagabine) or the degradation of synaptically released GABA (vigabatrin).

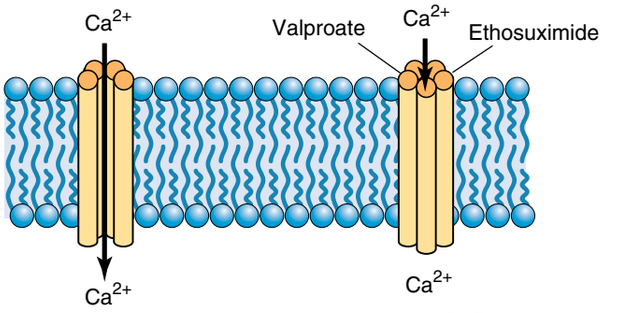

FIGURE 37-4 Antiseizure mediated reduction of I_T. Certain antiseizure drugs reduce the flow of calcium through T-type Ca^{2+} channels (ethosuximide, valproate), thereby reducing the pacemaker current that underlies spike-wave discharges of generalized absence epilepsy.

cerebral cortex [23]. Although a detailed consideration of the mechanisms is beyond the scope of this chapter, many of the structural and functional properties of thalamus and cortex that underlie the generalized spike-and-wave discharges of petit mal or absence seizures have been clarified in the past decade [23]. The EEG hallmark of an absence seizure is generalized spike-and-wave discharges at a frequency of 3 Hz. These bilaterally synchronous spike-and-wave discharges, recorded locally from electrodes in both the thalamus and the neocortex, represent oscillations between thalamus and cortex. Correlative EEG and intracellular recordings reveal that the EEG spikes are associated with the firing of action potentials and the following slow wave with prolonged inhibition. These reverberatory, low-frequency rhythms are made possible by a combination of factors, including reciprocal excitatory synaptic connections between the cortex and thalamus as well as intrinsic properties of neurons in the thalamus, most importantly the low-threshold calcium current or I_T [23]. The expression of I_T in thalamic neurons is critical to the generation of the 3 Hz spike and waves. In contrast to its small size in most cortical and hippocampal pyramidal neurons, the thalamic I_T is of large amplitude with bursts of action potentials superimposed on this current. Thus the I_T serves an amplifying role in thalamic oscillations, with each oscillation being the three-per-second spike and wave of the absence seizure. Importantly, the principal mechanism by which some antiabsence seizure drugs (ethosuximide, valproic acid) are thought to act is by inhibition of the I_T [24] (Fig. 37-4).

GENETICS OF EPILEPSY

Many forms of epilepsy have genetic determinants. Progress in molecular biology and molecular genetics has fueled discovery of genes causing epilepsy in humans and mice in the past 10–15 years [25]. Overall perhaps 50–60% of all human epilepsies have genetic determinants. A small fraction (less than 5%) of the epilepsies are inherited in a mendelian pattern in which the cause can be traced to a single mutant gene. The gene(s) causing a mendelian form are typically found to be responsible for a single or a few pedigrees but do not cause common forms of human epilepsy such as most cases of JME or childhood absence epilepsy (CAE). Disorders such as JME and CAE appear to be caused by simultaneous inheritance of two or more susceptibility genes interacting with environmental factors [26], a scenario similar to late-onset Alzheimer's disease in which apolipoprotein E isoforms powerfully influence risk but alone are not sufficient to produce Alzheimer's disease (see Ch. 47]. By analogy with the rare pedigrees of Alzheimer's disease that are inherited in a mendelian pattern (such as the mutation in amyloid precursor protein in a Swedish pedigree), a single JME pedigree was identified in which a mutation of the α_1 subunit of a $GABA_A$ receptor was causal [27]. In contrast to Alzheimer's disease, the gene(s) conferring susceptibility to the common forms of epilepsy like JME are unknown.

Tables 37-3 and 37-4 list the genes responsible for idiopathic and symptomatic epilepsies in humans, respectively. Table 37-5 lists genes identified as causing epilepsy

TABLE 37-4 Symptomatic human epilepsies: genes and syndromes

Syndrome	Inheritance Pattern	Gene
Miller–Dieker Syndrome	*De novo*	Platelet-activating factor acetylhydrolase
Unverricht–Lungborg disease	Autosomal recessive	Cystatin B
Myoclonic epilepsy with ragged red fibers (MERRF)	Mitochondrial	$tRNA^{lys}$
Batten disease	Autosomal recessive	*CLN3*
Angelman syndrome	Mostly *de novo*	*UBE3A*
Lafora' disease	Autosomal recessive	*EPM2A*, *EPM2B*
Subcortical band heterotopia	X-linked	Doublecortin
Periventricular nodular heteropia	X-linked	Filamin
Lissencephalic cortical neuronal migration defect	X-linked	Reelin
Rett's syndrome	X-linked	*MECP2*
Cerebral cavernous malformations	Autosomal dominant	*KRIT1*
Infantile neuronal ceroid lipofuscinosis (CLN1)	Autosomal recessive	Palmitooylprotein thioesterase
Late infantile neuronal ceroid lipofuscinosis (CLN2)	Autosomal recessive	Pepstatin-insensitive lysosomal peptidase
Juvenile Gaucher's disease	Autosomal recessive	Glucocerebrosidase
Sialidosis I	Autosomal recessive	α-neurominidase
Sialidosis II	Autosomal recessive	Stabilizing protein of the α-neurominidase-β-galactosidase complex
Mitochondrial myopathy, encephalopathy, lactic acidosis, and stroke like episodes (MELAS)	Mitochondrial	tRNA (leu)
Dentatorubalpallidoluysian atrophy (DRPLA)	Autosomal dominant	CAG trinucleotide repeat
Acanthocytosis	Autosomal recessive	Chorein

in mice. Several themes emerge from this immense information. As noted above in descriptions of epilepsy syndromes, the idiopathic epilepsies affect individuals who are otherwise normal and no structural cause has been identified. Perhaps the most remarkable feature of the genetic causes of the idiopathic epilepsies is that all but one of these genes encodes an ion channel gated by voltage or a neurotransmitter. This is of particular interest because several other episodic disorders involving other organs also are caused by mutations of genes encoding ion channels. For example, episodic disorders of the heart (cardiac arrhythmias), skeletal muscle (periodic paralyses), cerebellum (episodic ataxia), vasculature (familial hemiplegic migraine) and other organs all have been linked to mutant genes encoding a component of an ion channel [28]. In none of these episodic disorders is it understood what triggers an event or what terminates the event. The sole gene that does not encode an ion channel is partial epilepsy with auditory features in which the gene encoding 'leucine-rich glioma-inactivated' is responsible; loss of both of these alleles is associated with enhanced progression of glial tumors but the function of the protein encoded by this gene is obscure [29]. Whether this gene is somehow related to localization or degradation of an ion channel remains to be determined.

Except for JME, each of these syndromes is rare and, together, these forms probably account for considerably less than 1% of all human epilepsies. The *GABRA1* mutation identified in JME involved a single pedigree and was not evident in multiple sporadic cases of JME. In no instance is it clear how the genotype leads to the phenotype of epilepsy. Identification of the genes permits the engineering of mutant mice that hopefully will exhibit epilepsy. To date, however, no mouse exhibiting a 'knocked-in' human mutation or even a transgenic mouse overexpressing a human mutation has been demonstrated to exhibit a well documented form of epilepsy similar to the human form. Arguably the closest mimic at present is the *K_v1.1*-null mutant mouse, which exhibits complex partial and secondarily generalized tonic–clonic seizures, forms of seizures similar to some humans carrying mutations that are probably haploinsufficient [30]. Such mice will provide tools vital to determining how the genotype leads to the phenotype.

Apart from determining steps, if any, between expression of a mutant ion channel and emergence of epileptic seizures, in some instances the mutant channels suggest some intriguing molecular targets for development of antiseizure drugs acting by novel mechanisms. For example, the mutations of the K^+ channel (KCNQ2 and KCNQ3) underlie a slowly inactivating K^+ current and mediate spike frequency adaptation. These channels provide a novel molecular target for development of antiseizure drugs.

Table 37-4 lists a number of symptomatic epilepsies of humans for which mutant genes have been identified. As suggested by the terminology, these epilepsies are symptomatic of some overt underlying disease, some of which begin at various times in the first decade of life or later and are progressive whereas others exhibit catastrophic neurological abnormalities at birth and do not progress further. These diseases include epileptic seizures as a prominent feature but are also associated with additional prominent abnormalities of CNS function and often structure. In contrast to the striking homogeneity with respect to genes encoding ion channels in the idiopathic epilepsies, the genes causing the symptomatic epilepsies are striking in their diversity. The syndromes include

TABLE 37-5 Mouse epilepsy genes

Gene	Protein	Human Gene (and Location)
Induced mutations		
npy	Neuropeptide Y	*NPY* (7pter-q22)
syn-1	Synapsin 1	*SYN1* (Xp 11.2)
syn-2	Synapsin 2	*SYN2* (3p)
slc-1a (*glt-1*)	Glutamate transporter	*SLC1A2* (11p13-p12)
akp-2	Tissue-nonspecific alkaline phosphatase	*ALPL* (1p36.1-p34)
gad-2	Glutamic acid decarboxylase	*GAD2* (10p21.3)
gabrβ3	$GABA_A$ receptor subunit	*GABRB3* (15q11.2-q12)
gabrδ	$GABA_A$ receptor subunit	*GABRD* (1p)
gria-2	Glutamate receptor subunit 2	*GRIA2* (4q32-q33)
htr-2c	Hydroxytryptamine receptor 2c	*HTR2C* (Xq24)
kcna-1	Voltage-gated K^+ channel	*KCNA1* (12p13)
scn-2a	Sodium channel type 2a	*SCN2A1* (2q23-q24.3)
kcnj-6 (*girk-2*)	Inward-rectifying K^+ channel	*KCNJ6* (21q22.2)
camka	Calcium calmodulin kinase α subunit	*CAMKA* (5q31.3-q32)
itrp-1	Inositol 1,4,5 triphosphate receptor	*ITPR1* (3p26–25)
gap-43	Growth-associated protein	*GAP43* (3q21-qter)
cdk-5r	Neuronal specific activator of cyclin kinase	*CDK5R* (17p)
otx-1	Orthodenticle homolog	*OTX1* (p13.3)
jrk	Jerky	*JH8* (8q24.3)
pcmt-1	Protein L-isoaspartate (D-aspartate) *O*-methyltransferase	*PCMT1* (6q22.3–6q24)
hex-a	α subunit of β-hexosaminase	*HEX-A* (15q23-q24)
hex-b	β subunit of β-hexosaminase	*HEX-B* (5q13)
stfb (*cstb*)	Cystatin-B	*STFB* (21q22.3) (*CSTB*)
psap	Sphingolipid activator protein	*PSAP* (10q22.1)
Il-6	Cytokine, interleukin 6	*IL6* (7p21)
app	Amyloid precursor protein	*APP* (21q21.2)
hdh	Huntingtin's amino-terminal polyglutamine sequence	*HD* (4p16.3)
Polyglutamine repeat	146 unit CAG repeat inserted in *hprt* gene	–
Spontaneous mutations		
ccha-1a	Calcium channel α 1a subunit (tottering)	*CACNA1A* (19p13.1)
ccha-2a	Calcium channel α 1a subunit (tottering leaner)	*CACNA1A* (19p13.1)
cch-b4	Calcium channel β4 subunit (tottering leaner)	*CACNB4* (2q22-q23)
cacng-2	Calcium channel γ subunit (tottering leaner)	*CACNG2* (22q)
slc-9a1	Na^+/H^+ antiporter (slow wave epilepsy)	*SLC9A1* (1p36.1-p35)
kcnj-6 (*girk-2*)	Inwardly rectifying K^+ channel (Weaver)	*KCNJ6* (21q22.2)
itpr-1	Inositol 1,4,5 triphosphate receptor 1 (opisthotonus)	*ITPR1* (3p26–25)
cacna-2d2	Calcium channel α2δ2 subunit (ducky)	*CACNA2D2*

genetically determined abnormalities of neuronal migration, segmentation and patterning as seen in periventricular nodular heteropia, as well as dysregulation of transcription factors as observed in diseases such as Rett's syndrome.

Some spontaneous and some engineered mutations of mice result in epilepsy. In parallel to identifying the genes causing human epilepsies, a diversity of genes causing epilepsy in mice have been identified (Table 37-5). In most instances, the genes were overexpressed or eliminated by homologous recombination and the epileptic phenotype was an unexpected consequence. Genes encoding proteins subserving a component of the synaptic function constitute the single most common subset of mutations in this category (Table 37-5). This is no surprise given the role of synapses in the CNS and the delicate balance that exists between excitation and inhibition. For example, the fact that deletion of a gene encoding a subunit found in the $GABA_A$ receptor or a K^+ channel leads to epilepsy is not surprising. However, the occurrence of an epileptic phenotype in mice carrying null mutations of synapsin 1 was unexpected until this mutation was shown to preferentially compromise the efficacy of inhibitory synaptic transmission [31].

Finally, linkage analysis followed by sequencing led to identification of genes in spontaneously arising mutations that had been found to cause epilepsy in mice. In most of these, the nature of the epilepsy was a generalized spike and wave, mimicking the generalized-onset epilepsies such as absence. In contrast to absence epilepsy in humans, many of these mutant mouse strains exhibit cerebellar ataxia and often degeneration. Like the idiopathic epilepsies of humans, many of these genes encode ion channels. Interestingly, none of the mutant genes in these mouse strains have been identified to cause a form of absence epilepsy in humans.

Diseases Involving Myelin

Richard H. Quarles

†Pierre Morell

Henry F. McFarland

GENERAL CLASSIFICATION 639
Myelin deficiency can result from failure of synthesis during development or from myelin breakdown after its formation 639
Many of the biochemical changes associated with central nervous system demyelination are similar regardless of etiology 640

ACQUIRED ALLERGIC AND/OR INFECTIOUS DISEASES OF MYELIN 640
Nervous system damage in acquired demyelinating diseases is directed rather selectively against myelin or myelin-forming cells, but axons also are often affected 640
Experimental allergic encephalomyelitis is an animal model of autoimmune demyelination 640
A number of animal diseases caused by viruses involve primary demyelination and often are associated with inflammation 641
Multiple sclerosis is the most common demyelinating disease of the central nervous system in humans 641
Some human peripheral neuropathies involving demyelination are immune-mediated 645
Other acquired disorders affecting myelin in humans may be secondary to viral infections, neoplasias or immunosuppressive therapy 646

GENETICALLY DETERMINED DISORDERS OF MYELIN 647
The human leukodystrophies are inherited disorders of central nervous system white matter 647
Deficiencies of peripheral nerve myelin in common inherited human neuropathies are caused by mutations of genes for sheath proteins 648

TOXIC AND NUTRITIONAL DISORDERS OF MYELIN 649
A variety of biological and chemical toxins can impair myelin formation or cause its breakdown 649
General undernourishment or dietary deficiencies of specific substances can lead to a preferential reduction in myelin formation 649

DISORDERS PRIMARILY AFFECTING NEURONS WITH SECONDARY INVOLVEMENT OF MYELIN 649

REPAIR IN DEMYELINATING DISEASES 650
The capacity for remyelination is generally greater in the peripheral than in the central nervous system 650
Remyelination in the CNS can be promoted by various treatments 650
Measures to enhance axonal survival and regeneration also are critical in demyelinating conditions 650

†Pierre Morell tragically passed away early in the preparation of this chapter. A remembrance of his life and work appears on p. xxiii

The integrity of myelin sheaths is dependent upon the normal functioning of myelin-forming oligodendrocytes in the CNS and Schwann cells in the PNS as well as on the viability of the axons that they ensheathe. Neuronal death inevitably leads to subsequent degeneration of both axons and the myelin surrounding them. The title of this chapter was chosen to emphasize that myelin cannot be considered an isolated entity in the context of disease processes. Deficiencies of myelin can result from a multitude of causes, including autoimmunity, viral infections, genetic defects, toxic agents, malnutrition and mechanical trauma, that affect myelin, myelin-forming cells or myelinated neurons. More comprehensive clinical descriptions of most of the diseases described in this chapter are available in specialized books about myelin [1, 2].

GENERAL CLASSIFICATION

Myelin deficiency can result from failure of synthesis during development or from myelin breakdown after its formation. An impediment of normal myelin formation is referred to as *hypomyelination* or, in some cases, *dysmyelination*. According to the definition of Poser, dysmyelination is a genetically determined disorder of myelinogenesis in which 'myelin initially formed was abnormally constituted, thus inherently unstable, vulnerable, and liable to degeneration' [1]. Diseases involving loss of normal myelin after it is formed, i.e. demyelination, can be subdivided into primary and secondary categories

Basic Neurochemistry: Molecular, Cellular and Medical Aspects
0-12-088397-X

on the basis of morphological observations. *Primary demyelination* involves the early destruction of myelin with relative sparing of axons; subsequently, other structures may be affected. However, in recent years it has become increasingly apparent that some diseases that had been classified as primary demyelination may involve more injury to axons than originally thought. This axonal damage could be caused by inflammation in autoimmune and viral disorders or loss of the influence of myelin proteins on axonal structure. It is now known from transgenic knockout mice that the absence of some proteins localized in myelin sheaths, including proteolipid protein (PLP), 2′3′-cyclic nucleotide 3′-phosphodiesterase (CNPase) and myelin-associated glycoprotein (MAG) results in pathological axonal changes *in vivo* (see Ch. 4). *Secondary demyelination* includes those disorders in which myelin is involved only after damage to neurons and axons. The classification for myelin disorders used in this chapter is based on etiology as well as on comparative neuropathology. Disorders causing hypomyelination and demyelination are both included in four categories: (1) acquired allergic and infectious diseases; (2) genetic disorders; (3) toxic and nutritional disorders; and (4) disorders primarily affecting neurons with secondary involvement of myelin.

Many of the biochemical changes associated with central nervous system demyelination are similar regardless of etiology. The most pronounced changes occur in white matter where there is a marked increase in water content, a decrease of myelin proteins and lipids and, in many demyelinating diseases, the appearance of cholesterol esters and/or glial fibrillary acidic protein (GFAP) [1]. Particularly noteworthy with regard to lipids are dramatic decreases in galactocerebroside, ethanolamine plasmalogens and cholesterol, all of which are enriched in myelin membranes (see Ch. 4). The major structural proteins of CNS myelin, myelin basic protein (MBP) and proteolipid protein (PLP), are also invariably decreased. These changes can be explained by the breakdown and gradual loss of myelin (which is relatively rich in solids) and its replacement by extracellular fluid, astrocytes and inflammatory cells (which are more hydrated, relatively lipid-poor and free of myelin-specific constituents). The frequent appearance of cholesterol esters in demyelinating diseases is related to the fact that cholesterol is not readily degraded and is esterified by phagocytes that often remain at the site of the lesion for some time. Since cholesterol esters are essentially absent from normal mature brain, their presence in myelin disorders is indicative of inflammation and recent demyelination. Such compounds are also responsible for the neutral fat staining, or *sudanophilia*, demonstrated histochemically in many demyelinating diseases. In the CNS, GFAP is specific to astrocytes, and an increase of this protein during demyelination is due to reactive astrocytes associated with the pathology (see Ch. 1). The magnitudes of the changes mentioned above vary considerably from disease to disease and from specimen to specimen in the same disease, depending on the severity, location, duration and activity of the pathological processes.

ACQUIRED ALLERGIC AND/OR INFECTIOUS DISEASES OF MYELIN

Nervous system damage in acquired demyelinating diseases is directed rather selectively against myelin or myelin-forming cells, but axons also are often affected. In most of these disorders (except where noted otherwise), the lesions are disseminated and characterized by perivenular demyelination and inflammation, macrophage activity, sudanophilic deposits consisting of myelin degradation products and relative sparing of axons. The extent to which these criteria are fulfilled depends on the particular type and phase of disease. Also, as mentioned above, axonal pathology may be more frequent than previously thought. Furthermore, it is not always clear whether the immunological activity is autoimmune in nature or whether it is related primarily to an antecedent viral infection, nor is the amount of damage directly caused by the virus always clear. The acquired diseases discussed here are reviewed in more detail elsewhere [1, 2].

Experimental allergic encephalomyelitis is an animal model of autoimmune demyelination. The animal model thought to most clearly resemble multiple sclerosis (MS) is experimental allergic encephalomyelitis (EAE). EAE is an acute or chronic demyelinating disease of the CNS; the disease is induced by immunization of susceptible animals with either myelin or various myelin components that are encephalitogenic. The EAE model was initially identified through efforts to understand the cause of encephalomyelitis developing after inoculation of patients with the Pasteur rabies vaccine, which was prepared from virus-infected nervous tissue. It was noted that even control experimental animals inoculated with uninfected neural tissue developed an encephalomyelitis, and EAE has been carefully studied since then as a model of human diseases such as MS. A detailed examination of the EAE model and the extensive immunological data that have been obtained are beyond the scope of this chapter, and readers are referred to recent reviews for more detail [3, 4].

In brief, EAE can be induced by immunization with several encephalitogenic proteins from myelin, most notably MBP, PLP and myelin-oligodendrocyte glycoprotein (MOG). MBP was the first protein shown to cause EAE, and this classical form of the disease is mediated primarily by $CD4^+$, MHC class II restricted T cells, because it can be transferred from an immunized animal to a naive animal using these cells. These data document the importance of $CD4^+$ lymphocytes for EAE induction, but additional pathogenic roles for other T cell populations are possible, especially in later stages of the disease. Also, there is

considerable variation in susceptibility of various animals, and this variation is largely due to the genetic background, especially that of MHC genes. It is now understood that elements of the three components of antigen recognition, the T cell receptor (TCR), antigen and the MHC molecule that presents antigen, together known as the trimolecular complex, are central to disease induction. The encephalitogenic immunodominant part of MBP that causes the disease varies between different strains of mice and other species. The exquisite specificity seen for the trimolecular complex of encephalitogenic T cells has resulted in the development of numerous therapies that target the trimolecular complex and can modify disease. These include generating an immune response to the TCR or administration of a peptide that can bind to MHC but without activating T cells.

The most characteristic component of the EAE lesion is perivascular inflammation, and the extent of demyelination varies between species and the identity of the immunogen used to induce the disease. Evidence from studying EAE in the rat or mouse indicates that activated T cells, regardless of specificity, can cross the blood–brain barrier and enter the nervous system. If the T cell encounters its antigen, the cell will be further activated and begin production of proinflammatory cytokines such as gamma-interferon (INFγ) and tumor necrosis factor (TNF)α, which in turn activate the endothelial cells with upregulation of cell adhesion molecules (see Ch. 7) promoting an inflammatory response. The outcome of this process, at least in some animals, is myelin damage. The actual effector mechanisms for myelin damage include a direct toxic effect of TNFα or nitric oxide on oligodendrocytes or damage mediated by macrophages and microglial cells. The later possibility can be enhanced by the presence of antibodies, which bind to myelin and provide a ligand for activated monocytes. Indeed, demyelination associated with EAE in several animals including the rat, mouse and marmoset, a nonhuman primate, is increased by the presence of antibodies to surface components of myelin, such as galactocerebroside or MOG. In fact, immunization of rodents with MOG alone has been shown to induce a relapsing–remitting demyelinating disease with both cellular and humoral immunity to this glycoprotein [3].

A number of animal diseases caused by viruses involve primary demyelination and often are associated with inflammation. These diseases are studied as animal models, which may provide clues about how a viral infection could lead to immune-mediated demyelination in humans [1, 5, 6]. Canine distemper virus causes a demyelinating disease, and the lesions in dog brain show a strong inflammatory response with some similarities to acute disseminated encephalomyelitis in man [1]. Visna is a slowly progressive demyelinating disease of sheep caused by a retrovirus [1].

Two neurotropic viruses of mice are of particular interest with regard to the way in which immune-mediated demyelination of the CNS can be induced by a viral infection [5, 6]. JHM virus, which infects oligodendrocytes and produces acute and chronic inflammatory demyelination in rodents, is a neurotropic strain of mouse hepatitis virus in the coronavirus family. Theiler's virus is a picornavirus that infects many neural cell types and induces a chronic CNS encephalomyelitis. Investigation of animal models such as these has revealed several mechanisms by which viral infections can cause demyelination including: (1) a direct infection of oligodendrocytes resulting in cell death; (2) a virus-specific inflammatory response in which cytokines or other immune mediators damage oligodendrocytes/myelin indirectly as a 'bystander' effect; and (3) activation of an immune response directed at components of oligodendrocytes/myelin by molecular mimicry or epitope spreading. Molecular mimicry occurs when a viral antigen has structural homology to a myelin/oligodendrocyte component, resulting in cross-reactivity, and epitope spreading results from host immune cell processing of myelin/oligodendrocyte antigens released following tissue injury.

Multiple sclerosis is the most common demyelinating disease of the central nervous system in humans. Multiple sclerosis is a chronic demyelinating disease affecting the CNS [1, 2, 7, 8]. The disease primarily affects young adults and is characterized by a highly variable course. Most often the disease begins in the third or fourth decade with neurological dysfunction, such as decreased vision, dysarthria, weakness in limbs, diplopia, nystagmus, sensory deficits and paresthesias. The initial course is characterized by acute episodes of one or more of these symptoms followed by subsequent recovery, and this course is known as relapsing–remitting MS. Over time, the improvement after attacks may be incomplete and the relapsing–remitting course may evolve into one of increasing progression of disability, termed secondary progressive MS. A small number of patients develop a form of disease that begins as a slowly progressive process, without acute episodes of worsening followed by improvement, which has been termed primary progressive MS. A few patients will have a very aggressive course, which can even lead to death over a short period.

The diagnosis of MS is dependent on clinical evidence of central nervous system involvement separated in both time and space. Thus, evidence that two areas of the CNS are involved and a history that this involvement occurred at two different times and without any other identifiable cause, is necessary to establish a diagnosis of clinically definite MS. While there is no diagnostic test that is specific for MS, the appearance of MBP, oligoclonal protein bands or elevated IgG/protein ratios in the CSF, as well as abnormalities in electrophysiological tests of visual, auditory and somatosensory evoked potentials and magnetic resonance imaging (MRI), can help to identify subclinical lesions and assist in establishing the diagnosis. Of all of these tests, the use of MRI has probably resulted in the greatest change in our understanding of MS. T2-weighted MRI images are extremely effective in identifying MS lesions.

The areas of increased signal seen on T2-weighted MRI reflect increased water and therefore are neither specific for MS nor able to distinguish new from old lesions. This is because both inflammation and tissue loss associated with demyelination or gliosis after ischemic events will result in increased signal. Therefore, the interpretation must include the clinical context. A second technique, T1-weighted imaging after the administration of gadolinium-DTPA, which does not normally cross the blood–brain barrier, can identify new lesions in which the blood–brain barrier has been compromised. Serial studies of patients with early relapsing–remitting MS have shown that the first event in the development of a new MS lesion as seen on a T2-weighted MRI is disruption of the blood–brain barrier seen on a gadolinium-enhanced MRI. Thus, postcontrast MRI provides a very sensitive technique for following at least one aspect of disease activity. Using this approach, several groups of investigators have shown that MS is an active and progressive disease even in the early relapsing–remitting phase and during periods of clinical stability in many patients. Newer imaging techniques now hold promise for providing greater specificity for the various stages of lesion development (see Ch. 58).

MS lesions or plaques can be identified grossly at autopsy (Fig. 38-1) and are sharply demarcated from the surrounding tissue. Plaques occur throughout the white matter, but areas of predilection such as the periventricular white matter are well known. Microscopic examination characteristically shows loss of myelin with preservation of axons (primary demyelination). However, although the most prominent pathology in MS is demyelination, there are recent indications also for axonal and cortical pathology. Now techniques of confocal microscopy and immunocytochemistry have clearly demonstrated that transected axons are common in MS lesions [9].

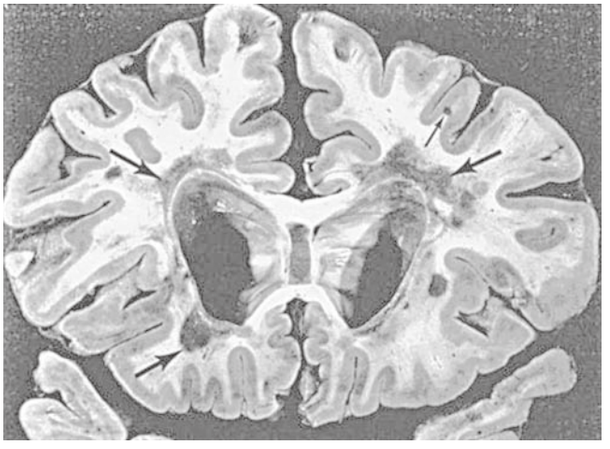

FIGURE 38-1 Coronal slice of brain from a patient who died with MS. Demyelinated plaques are clearly visible in white matter (*large arrows*). Small plaques are also observed at the boundaries between gray and white matter (*small arrows*). (Reproduced with permission from Raine, C. S. The neuropathology of myelin diseases. In P. Morell (ed.) *Myelin*. New York: Plenum Press, 1984, ch. 8.)

It has become generally accepted that axonal loss is an important aspect of MS pathology and may account for much of the irreversible neurological impairment in this disease. Plaques commonly develop around venules, and 'early lesions' contain many lymphocytes, plasma cells and macrophages. The greatest cellularity is found at the margins of acute lesions, which are believed to be the locations at which some of the earliest changes associated with myelin loss are occurring.

For many years there has been discussion about whether the primary pathological effect in this disease is directed at myelin sheaths themselves or at the myelin-forming oligodendrocytes. Investigators utilizing sophisticated neuropathological and immunocytochemical methods for examining lesions have now reported that there are actually several subtypes of MS patients [10], and myelin sheaths are the primary target in some whereas oligodendrocytes are targeted in others. Most common were cases that resembled EAE in which myelin was the primary target. The pathology was characterized by macrophage/T-cell-mediated or antibody/complement-mediated demyelination. However, other MS patients had lesions characterized by oligodendrocyte dystrophy, which is reminiscent of viral or toxin-induced demyelination rather than autoimmunity. These patients were less frequent, and lesions of this type were generally observed in patients with a shorter disease course than those with EAE-like lesions. These findings indicate that the demyelinated plaque may be a common endpoint resulting from a variety of different immunological and pathological mechanisms. The pathogenic heterogeneity in different patients may have fundamental implications for the diagnosis and therapy of this disease. Generally, chronic lesions are sharply defined containing bare nonmyelinated axons and many fibrous astrocytes.

The biochemistry of demyelination in MS was reviewed in detail [11]. Affected areas of MS white matter exhibit the expected decrease of myelin constituents and a buildup of cholesterol esters. For example, polyacrylamide gel electrophoresis of homogenates of macroscopically normal appearing white matter, outer periplaque, inner periplaque and plaque shows the expected decline of MBP and PLP in going from the normal appearing white matter to the center of the plaque in both chronic and acute lesions (Fig. 38-2). There is a virtual absence of these myelin proteins in the center of the chronic plaque and an accumulation of glial fibrillary acidic protein (GFAP) indicative of astrogliosis (Fig. 38-2B). A plaque from a more acute lesion is not completely demyelinated, as indicated by the presence of some MBP and PLP, and there is no accumulation of GFAP (Fig. 38-2C). The more acute plaque contains albumin as a result of breakdown of the blood–brain barrier. Immunocytochemical and quantitative biochemical analyses of myelin proteins have revealed that MAG is often decreased more than other myelin proteins at the periphery of plaques (reviewed in [12]), and this may be indicative of early pathological events in the

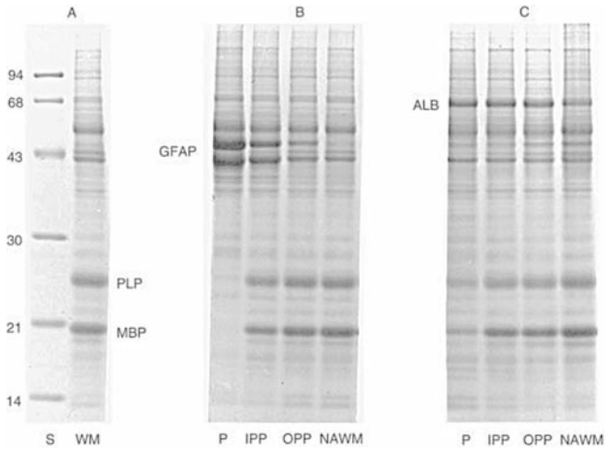

FIGURE 38-2 Polyacrylamide gel electrophoresis of proteins in control and MS tissue. Total proteins of the tissue samples were solubilized with a detergent (sodium dodecyl sulfate) and electrophoresed on a polyacrylamide gel system that separates proteins according to their size. After electrophoresis, the proteins were stained with Coomassie brilliant blue dye. **(A)** Molecular weight standards (*S*) labeled according to their molecular mass (kDa) and the proteins of control white matter (WM). **(B)** Samples from the region of a chronic MS plaque. **(C)** Samples from the region of an acute MS plaque. *ALB*, serum albumin; *GFAP*, glial fibrillary acidic protein; *IPP*, inner periplaque; *MBP*, myelin basic protein; *NAWM*, macroscopically normal appearing white matter near the plaque; *OPP*, outer periplaque; *P*, plaque center; *PLP*, proteolipid protein. (With permission from reference [39].)

distal periaxonal regions of oligodendroglial processes where MAG is selectively localized (see Ch. 4). Evidence suggests that this selective loss of MAG is characteristic of the subset of MS patients who exhibit oligodendroglial dystrophy, and the MAG loss may reflect a dying-back oligodendrogliopathy [10]. A number of biochemical studies have indicated that myelin constituents are significantly reduced even in some areas of macroscopically normal-appearing white matter of MS brain in comparison to control white matter [11], and this is most probably explained by the presence of microlesions throughout the affected brain. Although the yield of myelin from MS tissue is reduced, most studies indicate that there is no compositional difference between isolated MS and control myelin, suggesting that the etiology of MS is unlikely to be related to an underlying defect in myelin composition. On the other hand, comparisons of post-translational modifications of MBP from MS brain with those from controls have demonstrated an increase of the least cationic, deaminated citrulline-rich isoform, increased methylation at arginine 107 and decreased phosphorylation [13]. These changes could alter the stability of myelin, but it is not clear whether the modifications reflect inborn abnormalities of myelin or result from the disease process.

The cause of MS is not known, but most evidence points to an immunologically mediated disease with important genetic and environmental risk factors [1, 2, 7, 8]. The evidence for an autoimmune process is largely circumstantial and based in part on evidence derived from animal models of autoimmune demyelinating disease such as EAE. In addition to providing insights into the natural history of the disease and a tool that can be used to monitor new treatments, MRI is also providing insights into the nature of the MS lesion. As indicated previously, blood–brain barrier disruption seems to be the initial event in lesions, and pathological studies suggest that enhancement is often characterized by acute inflammation. From findings derived from studies of EAE, it is likely that migration of activated T cells represents the initial step in lesion development.

What is not clear is the specificity of the T cells. There are numerous studies of T cell reactivity to myelin antigens such as MBP, PLP and MOG, all of which are encephalitogenic in animals. However, the evidence taken as a whole has failed to demonstrate a substantially increased response to these antigens in most patients with MS compared to healthy controls. Nevertheless, at this time, MOG appears to be a leading candidate among myelin proteins to be an important target in the autoimmune aspects in many patients because of: (1) its accessibility to immune attack due to its surface localization on oligodendrocytes; (2) its capacity to produce a relapsing–remitting form of EAE resembling MS when used as an immunogen; and (3) the detection of immunoreactivity to MOG in a relatively high proportion of MS patients [3, 14]. It may be that several myelin antigens play a role in MS, and that the relative importance of different antigens varies among individuals depending on their immunogenetic background and environmental factors encountered during their life. Further, studies of TCR usage have generally failed to provide evidence for a restricted or limited TCR usage in myelin-antigen-specific T cells. What has emerged from studies of the T cell response to antigens such as MBP is that some portions of the molecule are immunodominant (e.g. MBP (83–99)), and these portions are regions that can be encephalitogenic in some animal models. Also, the HLA types that most readily present MBP to MBP-specific T cells, namely, the DR2 haplotype, are those that are over-represented in Caucasian patients with MS. Thus, it can be postulated that the T cell response to myelin antigens could represent one component of lesion development but one that, alone, is not sufficient for disease. Other factors could influence the integrity of the blood–brain barrier and regulation of cytokines.

Once a T cell enters the CNS and encounters antigen, it is postulated that a proinflammatory cytokine cascade is initiated that produces further compromise of the blood–brain barrier and amplifies the inflammatory response, which eventually results in demyelination. The cause of myelin damage is not known. Possibilities include direct toxic effects of some cytokines such as TNFα and NO on oligodendrocytes, or macrophage-mediated damage either through production of proteases or through ligand-mediated interaction with the myelin membrane. Electron microscopy of active MS lesions indicates that one

mechanism for myelin destruction is the direct removal, by macrophages, of myelin lamellae from the surface of intact sheaths. This involves the attachment of superficial lamellae to coated pits at the macrophage surface, implying the presence of receptors that bind to a ligand on the myelin. The Fc receptors on the macrophages may bind to immunoglobulins attached to the myelin and, as mentioned previously, studies of EAE have shown that antibodies to galactocerebroside, MOG or other surface molecules of myelin can augment demyelination.

There is much evidence indicating that proteases and other catabolic enzymes are involved in the myelin loss in MS [11]. MBP is highly susceptible to proteases even when present in myelin membranes. A neutral protease released by stimulated macrophages catalyzes the conversion of plasminogen to plasmin, which rapidly degrades MBP. Acid proteinase and other degradative enzymes, presumably lysosomal and of macrophage origin, are elevated in affected MS tissue and are likely to be involved in breakdown of myelin proteins and lipids. In addition, protease activities intrinsic to myelin sheaths (such as Ca^{2+}-activated neutral protease) may facilitate myelin destruction. Immunologically reactive, proteolytic fragments of MBP appear in the cerebrospinal fluid (CSF) and urine of MS patients during exacerbations of the disease, presumably reflecting myelin breakdown. However, the presence of this material is not specific for MS since it occurs in other conditions with myelin damage such as stroke and encephalitis. Matrix metalloproteases (MMPs) have attracted interest in recent years with regard to MS, because they participate in degradation of extracellular matrix, thereby allowing immune cells to move from the blood into the white matter.

In addition to immunological elements, it is likely that both genetic and environmental factors contribute to disease susceptibility [1, 2, 7, 8]. Two types of study have provided data that favor a genetic component in MS. First, the prevalence of MS varies substantially among ethnic groups, with Caucasian populations showing a higher frequency than some other groups. For example, MS occurs at low frequency both in Japan and in Japanese Americans living in high-prevalence regions of the United States. Secondly, there is increased risk among first-degree relatives of individuals with the disease, especially in monozygotic twins where the rate of concordance for the disease is 20–30% and even higher with careful examination by techniques such as MRI. Several possible genetic loci have been examined in MS and, as mentioned above, a fairly consistent association, although weak, with HLA makeup has been found in most studies. Investigators have attempted to examine the entire genome in patients with MS. While some areas of possible significance have been found, it is certain that the effect of any single genetic locus is relatively small. It is almost certain that multiple genes are involved, each with a small influence on susceptibility.

Several types of evidence point to an environmental influence in MS. These include unequal geographic distribution of the disease, effect of migration between low- and high- risk areas on susceptibility, and evidence for epidemics or clusters. Each of these sets of observations is open to variable interpretation and in many cases the genetic influence is difficult to separate from that of the environment. However, the bulk of evidence suggests that environment contributes to risk. The nature of an environmental influence is not known, but an infectious agent has long been suspected [1, 2]. There are a number of naturally occurring and experimental disorders in animals caused by viruses that have long incubation periods and involve primary demyelination with relative sparing of axons (see above). A possible viral etiology for MS has stimulated an extensive amount of research over the years, leading to many reports of viruses associated with MS. One way in which a viral infection could set off an autoimmune attack on myelin would be by molecular mimicry, in which a foreign peptide has sufficient sequence similarity to a neural antigen to set off an autoimmune attack. There is currently a substantial amount of interest in a possible involvement of human herpes virus 6 [15]. However, at this time a definite causative infectious agent has not been established. Nevertheless, a viral infection occurring before puberty and possibly modifying immune function, rather than resulting in a persistent infection, seems likely. Thus, although it is widely thought that MS is an autoimmune disease and associated with an infectious agent, the putative antigen(s) and virus(es) remain elusive. Furthermore, as stated above there is growing evidence that all cases of MS may not be associated with the same virus or antigen but rather the disease process may be set in motion by a variety of infectious agents leading to a spectrum of immune cascades varying from patient to patient depending on their genetic background, but leading to a similar final pathology as represented by demyelinated plaques.

Therapies that are thought to modify immunopathogenic aspects of the disease have been approved for use in treating patients with relapsing–remitting MS, including interferon beta and copolymer-1 (Cop-1, glatiramer acetate) [8, 16]. The mechanism of action of the beta interferons is not entirely clear, but appears to involve modulation of the expression of adhesion molecules and matrix metalloproteases, resulting in a decrease of blood–brain barrier breakdown, as well as suppressing T cell activation and inhibiting proinflammatory cytokine production. Cop-1 is a synthetic random polymer, composed of the amino acids L-alanine, L-glutamic acid, L-lysine and L-tyrosine, which is believed to selectively bind to HLA class II molecules and to block antigen presentation. It also induces a shift in cytokine production and the generation of Th2 cells, which cross-react with myelin components and mediate bystander suppression. Although these therapies are moderately effective, they only reduce disease exacerbations by about 30% or delay disease progression. Therefore, research aimed at interfering with the autoimmune process at different levels is under way

in many laboratories [7, 8, 16], and MRI is providing a powerful tool for monitoring the initial testing of experimental therapies. One example is mitoxantrone, approved for treatment of secondary progressive and progressive-relapsing MS, a synthetic antineoplastic anthrocenedione that inhibits proliferation of B and T cells and macrophages, impairs antigen presentation and secretion of INFγ, TNFα and interleukin (IL)-2 *in vitro* [17]. Another pharmacologic approach is to inhibit migration of T cells across the blood–brain barrier by antibody blocking of α4-integrin. An example is natalizumab, a humanized monoclonal antibody presently under clinical trials [18]. Other examples of therapeutic approaches under investigation are inhibitors of metallic proteinases, which also alter cell migration across blood–brain barrier; vaccination with pathogenic T cells specific for candidate autoantigens in myelin; and treatment with altered peptide ligands that block T cell activation or induce bystander suppression. Increasing use of powerful technologies such as gene microarray analysis of MS tissues and proteonomics should help identify more disease markers and effectors that can be targeted and ultimately lead to therapies tailored to different stages of disease or subsets of MS patients. Alternative approaches to therapy involve repair both by stimulating remyelination and promoting the survival and regeneration of axons. The latter is likely to be a major emphasis in the future, now that it is known that much of the irreversible neurological damage in MS is caused by axonal loss. However, a serious problem to the use of methodologies to stimulate repair in MS is that the lesions of MS develop at different times and locations in optic nerve, cerebrum, cerebellum, brainstem and spinal cord, each of which may have its own unique requirements. The various approaches to repair tissue damage in myelin diseases is discussed in greater detail at the end of this chapter, because they also apply to other myelin disorders with differing etiologies.

Some human peripheral neuropathies involving demyelination are immune-mediated. Guillain–Barré syndrome (GBS) is an acute inflammatory demyelinating polyneuropathy that is monophasic, self limiting and frequently occurs following an antecedent bacterial or viral infection [1, 2, 19] (see also Ch. 36). It is generally characterized by primary demyelination, although variants with severe axonal involvement also exist. Chronic inflammatory demyelinating polyneuropathy (CIDP) is similar but is progressive or relapsing–remitting with a duration of many months or years [1, 2, 20]. With regard to potential target antigens for autoimmune diseases of the PNS, it should be kept in mind that, although PNS and CNS myelin are morphologically similar, they differ significantly in chemical composition, especially in protein constituents (see Ch. 4). Cumulative evidence suggests that nerve injury in GBS and CIDP is mediated by immunological mechanisms but, as in MS, the roles of the patients' cell mediated and humoral responses in causing the demyelination have not been fully defined. An important role of humoral immunity in these diseases is strongly suggested by findings that sera from GBS patients cause demyelination in appropriate test systems and that plasmapheresis and intravenous administration of immunoglobulin are effective therapies in many of these patients. Neuropathies also occur in association with monoclonal gammopathy (also called paraproteinemia) in which there is expansion of a clone of plasma cells leading to large amounts of a monoclonal antibody in the patient's serum. It is thought that the neuropathies in these patients are likely to be caused by binding of the monoclonal antibodies to neural antigens [21].

Although experimental allergic neuritis (EAN) is often considered to be a good animal model for GBS, and the P2 myelin protein is implicated as an important antigen in this model (see Ch. 36), neither cellular nor humoral immunity to P2 or other myelin proteins has been detected consistently in GBS. Similarly, although antibodies to galactocerebroside have been shown to cause peripheral demyelination in experimental animals, evidence for significant levels of antibodies to this glycolipid in GBS is lacking. However, a substantial body of research now indicates that antibodies to more complex glycolipids, such as gangliosides (see Ch. 3), are involved in the pathogenesis in many of the human immune-mediated neuropathies described above [21]. The first indications of this came from patients with demyelinating sensorimotor neuropathy in association with IgM gammopathy. The monoclonal antibodies in these patients were shown to react with a carbohydrate epitope in MAG that is shared with complex glycolipids and other glycoproteins, including P0 and peripheral myelin protein-22 (PMP-22) of compact PNS myelin. The principal antigenic glycolipid, which is present in much larger amounts in the mature PNS than the CNS, is sulfate-3-glucuronyl paragloboside (SGPG). The specificity of these human antibodies is very similar to that of the HNK-1 antibody, which reacts with a number of adhesion proteins in the nervous system (see Ch. 4). Several animal models involving administration of the human anti-MAG/SGPG antibodies or immunization with SGPG strongly suggest that this disease is caused by the antibodies, but the relative importance of the potential glycolipid and glycoprotein target antigens in contributing to the pathology remains to be established. About half of patients with neuropathy in association with IgM gammopathy have antibodies of this specificity. It is also noteworthy that monoclonal IgM antibodies in patients with neuropathy who are MAG/SGPG-negative frequently react with gangliosides, suggesting that complex glycolipids may be important target antigens in immune-mediated neuropathies.

Once the monoclonal antibodies reacting with complex glycolipids were shown to occur frequently in patients with neuropathy in association with gammopathy, antibodies were demonstrated in some patients with GBS and other forms of inflammatory demyelinating neuropathy [21].

For example, antibodies to GM1 ganglioside are strongly associated with a subset of GBS that is particularly severe, has a high degree of axonal degeneration and presents with predominantly motor symptoms. Antibodies to GM1 ganglioside are also found frequently in a distinct chronic progressive neuropathy defined by multifocal motor conduction blocks. This condition, known as multifocal motor neuropathy (MMN), is characterized by weakness, muscle atrophy and motor nerve demyelination, while sensory function is normal or only slightly affected. Generally, there appears to be a strong correlation between antibodies to GM1 ganglioside and motor nerve disorders, including GBS, MMN and the neuropathies in association with monoclonal gammopathy described below. Another correlation of clinical presentation with antibody specificity involves patients with ataxic neuropathies and antibodies to disialosyl epitopes in gangliosides such as GD1b, GT1b and GQ1b. This correlation is found both in patients with monoclonal gammopathy and those with the Miller–Fisher variant of GBS.

Research has resulted in major advances in animal modeling of anti-glycolipid antibody-associated neuropathies *in vitro* and *in vivo*, which make a strong case that the antibodies cause much of the neurological impairment in these patients [21]. Furthermore, molecular mimicry between immunogens expressed by antecedent infectious agents and neural gangliosides appears to account for the presence of the glycolipid antibodies in some cases. Thus, carbohydrate configurations very similar or identical to those of gangliosides occur in the lipopolysaccharide (LPS) of strains of *Campylobacter jejuni* that are associated with these subsets of GBS (Fig. 38-3). Although it is now well established that anti-glycolipid antibodies are important pathogenic agents in many patients, not all patients with acquired acute or chronic peripheral neuropathies express these antibodies. Therefore, much remains to be learned about the pathogenic roles of antibody and T cell responses to other neural antigens, the importance of cytotoxic immune mediators and other factors in the acquired immune-mediated neuropathies.

Other acquired disorders affecting myelin in humans may be secondary to viral infections, neoplasias or immunosuppressive therapy. Acute disseminated encephalomyelitis, also called postinfectious or postimmunization encephalitis, represents a group of disorders usually of mixed viral–immunological etiology. The condition is most commonly related to a spontaneous viral infection, of which major examples are measles, smallpox or chickenpox [1, 2].

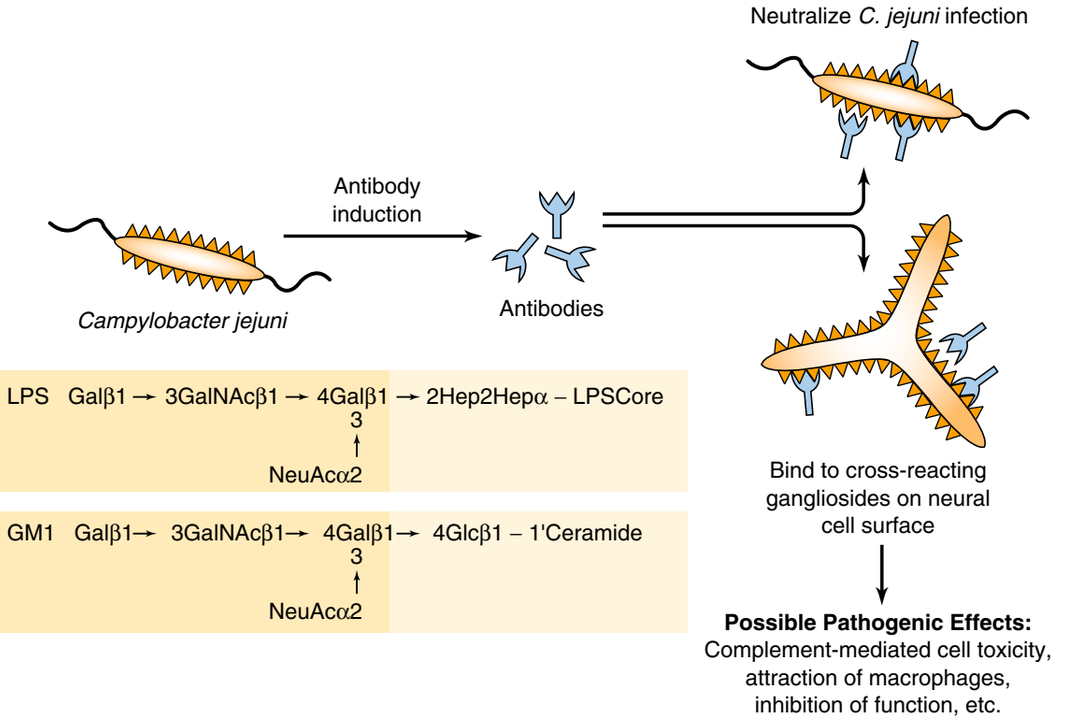

FIGURE 38-3 Molecular mimicry in subsets of patients with Guillain–Barré syndrome. Carbohydrate configurations (*dark orange triangles*) in the lipopolysaccharide (*LPS*) on some strains of *Campylobacter jejuni* are the same as in GM1 ganglioside on neural membranes. The chemical structures of LPS and GM1 are shown in the inset with the shared terminal tetrasaccharide in *dark orange*. Antibodies produced in response to LPS during a *C. jejuni* infection are intended to fight the infection but may cross-react with GM1 on neural cells, causing pathogenic effects in Guillain–Barré syndrome by mechanisms such as those listed in the lower right of the figure. Similarly, the LPS in other strains of *C. jejuni* have carbohydrate structures similar to those in GQ1b ganglioside, and these strains are associated with the Miller–Fisher variant of Guillain–Barré syndrome with prominent cranial nerve involvement, ataxia and areflexia. Antibodies to GQ1b are found in essentially all patients with this variant.

The demyelination occurring in these conditions is likely to be mediated at least in part by immune mechanisms since T cells sensitized to MBP are detected in many of these patients.

The nervous system is affected in a high proportion of patients with acquired immunodeficiency syndrome (AIDS) [2, 22]. Abnormalities related to myelin include a generalized myelin pallor observed histologically, vacuolar myelopathy and focal demyelination. Although it was originally thought that the widespread myelin pallor could be indicative of substantial demyelination, it now appears that the reduced staining is related to accumulation of fluid resulting from breakdown of the blood–brain barrier and not to extensive myelin loss. It is generally accepted that HIV infection in the nervous system *in vivo* is largely restricted to macrophages and microglia, and that the myelin and oligodendrocyte damage associated with HIV may be mediated by cytokines released by infected macrophages (see section on toxins, below).

Progressive multifocal leukoencephalopathy (PML) is historically a rare demyelinating disease that is usually associated with disorders of the reticuloendothelial system, neoplasias and immunosuppressive therapy [1, 2]. However, it has become more important in clinical medicine because it is frequently seen as an opportunistic secondary infection in immunocompromised persons with AIDS. PML is characterized by focal lesions that are noninflammatory and caused by infection of oligodendrocytes with the JC papovavirus.

GENETICALLY DETERMINED DISORDERS OF MYELIN

The human leukodystrophies are inherited disorders of central nervous system white matter. These disorders are characterized by a diffuse deficiency of myelin caused by a variety of genetic lesions and often manifest before 10 years of age (Table 38-1). Some are caused by mutations in the *PLP* gene and resemble the *PLP* animal mutants described in Chapter 4 [1, 23]. As with the animal models, depending on the nature of the mutation, they vary from a severe form in connatal Pelizaeus–Merzbacher disease (PMD) through an intermediate phenotype in classical PMD to a mild phenotype in spastic paraplegia. It is noteworthy that some mutations of the *PLP* gene also cause a peripheral neuropathy [24], very probably related to the expression of low levels of PLP in peripheral nerve (see Ch. 4).

Other leukodystrophies are associated with the lysosomal and peroxisomal disorders in which specific lipids or other substances accumulate due to a deficiency in a catabolic enzyme – for example Krabbe's disease, metachromatic leukodystrophy (MLD) and adrenoleukodystrophy (ALD) [1, 2]. (These are discussed in detail in Ch. 40.) Similarly, disorders of amino acid metabolism can lead to hypomyelination – for example phenylketonuria and Canavan's disease (spongy degeneration) [1, 2, 25] (Ch. 40). The composition of myelin in the genetically

TABLE 38-1 Genetically determined disorders affecting myelin in humans

Disorder	Inheritance	Genetic lesion	Comments	References
Adrenoleukodystrophy	X-linked	Peroxisomal membrane protein in the ABC transporter family	Decreased peroxidation of saturated, very-long-chain fatty acids, causing their accumulation in brain, adrenals and other tissues; variable phenotypes with regard to hypomyelination; see text	1, 26, Ch. 40
Canavan's disease (spongy degeneration)	AR	Aspartoacylase	Widespread white matter edema with diminished myelin; *N*-acetylaspartic aciduria; see text	1, 25, Ch. 40
Charcot–Marie–Tooth disease and other inherited neuropathies	AD, AR or X-linked	PMP-22, P0, connexin-32 and other genes	Variable degrees of myelin deficiency specific for the PNS; see text	1, 28–30
Krabbe's leukodystrophy	AR	Galactocerebroside-β-galactosidase	Globoid cells contain galactocerebroside; see text	1, 2, Ch. 40
Metachromatic leukodystrophy	AR	Aryl sulfatase A	Accumulation of sulfatide in brain; see text	1, 2, Ch. 40
Pelizaeus–Merzbacher disease (classical and connatal forms) and spastic paraplegia	X-linked	PLP	Variable hypomyelination due to different mutations in the major structural protein of CNS myelin; similar to rodent mutants such as the *jimpy* mouse	1, 23
Phenylketonuria	AR	Phenylalanine hydroxylase	White matter is up to 40% deficient in myelin; hypomyelination may be caused by inhibition of amino acid transport and/or protein synthesis by the high level of phenylalanine that accumulates	1, Ch. 40
Refsum's disease	AR	Oxidation of branched chain fatty acids; phytan-olyl CoA 2-hydroxylase in some cases	Increase of branched-chain phytanic acid, especially in PNS myelin	1, 38, Ch. 40
Vanishing white matter disease	AR	Eukaryotic initiation factor 2B (eIF2B)	Also referred to as childhood ataxia with central hypomyelination (CACH); see text	27

AD, autosomal dominant; AR, autosomal recessive

determined disorders can be normal, have a specific alteration reflecting the genetic lesion or show a nonspecific pathological composition that is found in many myelin disorders. The composition of the small amount of myelin isolated from Krabbe's disease is normal, and the hypomyelination is believed to be caused by the accumulation of galactosylsphingosine (psychosine) which has a cytotoxic effect on myelin-forming cells. By contrast, myelin isolated from postmortem metachromatic leukodystrophy (MLD) brain is highly enriched in sulfatide, but it is not known for certain if the myelin membrane contains more sulfatide or if the excess is due to sulfatide-enriched micelles that are co-isolated during the myelin purification. In some genetic disorders such as ALD and Canavan's disease, as well as in a wide variety of disorders involving secondary demyelination, the myelin preparations have similar abnormal chemical compositions. In each case, the isolated pathological myelin has a generally normal ultrastructural appearance but has much more cholesterol, less cerebroside and less phosphatidal ethanolamine than does normal myelin. Certain experimental disorders induced in animals by toxic agents show the same type of abnormal myelin. Myelin with this abnormal composition is referred to as the 'nonspecific pathological type' and probably represents a partially degraded form.

X-linked ALD has long been known to be a peroxisomal disease that involves a defect in the β-oxidation of very-long-chain fatty acids (VLCFAs), leading to their accumulation in complex lipids of myelin (Ch. 40) [1, 26] and it was thought that the genetic defect would turn out be in an enzyme such as VLCFA-CoA synthetase. However, the positional cloning approach showed that the defective gene is a 70 kDa peroxisomal membrane protein (ALD/ABCD1) in the ATP binding cassette transporter protein family (Ch. 5). An interesting aspect of ALD is that the phenotype can vary from a major neurological problem in the childhood form with a severe deficiency of myelin in the brain, through a milder form known as adrenomyeloneuropathy that occurs in young men and affects primarily spinal cord and peripheral nerve, to less common phenotypes without neurological involvement.

The function of the ALD protein is not fully understood, and knockout mice lacking it do not exhibit the severe CNS neurological deficits commonly associated with the human disease despite a similar accumulation of VLCFAs [26]. Furthermore, the clinical variability in human patients cannot be accounted for by the severity of the biochemical abnormality or the nature of the gene defect. These observations, plus other data from mice with defects in VLCFA metabolism, raise the issue of whether the accumulation of VLCFAs in myelin is crucial to the pathological mechanisms or is an epiphenomenon. Unlike most other lipid-storage diseases, active ALD brain lesions are characterized by perivascular accumulation of lymphocytes. For this reason, it has been hypothesized that the severity of CNS pathology may relate to an autoimmune reaction that varies from patient to patient and is minimal or missing in the ALD-deficient mice. Because of the inflammation, it is not surprising that substantial amounts of cholesterol ester accumulate in the ALD brain. Similar to other disorders in which myelin debris is phagocytosed, most of the cholesterol esters are in an abnormal floating fraction of lower density than the density of isolated myelin.

MRI has led to the frequent identification of inherited leukodystrophies of unknown cause, many of which exhibit a syndrome now called childhood ataxia with central nervous system hypomyelination (CACH) or vanishing white matter disease (VWMD) [27]. The syndrome is usually characterized by the onset of ataxia in early childhood followed by progressive neurological deterioration. Also, histological examination frequently reveals novel foamy-appearing oligodendrocytes with numerous round inclusions in these patients. Most patients with this syndrome have mutations in the mRNA translation initiation factor eIF2B.

Deficiencies of peripheral nerve myelin in common inherited human neuropathies are caused by mutations of genes for sheath proteins. Remarkable progress in elucidating an expanding number of gene loci and pathogenic mechanisms for inherited neuropathies has been achieved, based on our increasing knowledge of the biology of Schwann cells, axons and their interactions [28–30]. From a historical perspective, the most common inherited neuropathies were divided into two forms of Charcot–Marie–Tooth (CMT) disease largely on the basis of electrophysiology – type 1 (CMT1), which primarily affects myelin, and type 2 (CMT2), which primarily affects axons. In addition, there are milder (hereditary neuropathy with liability to pressure palsies), more severe (Dejerine–Sottas syndrome), and congenital (congenital hypomyelinating neuropathy) inherited neuropathies. Mutations affecting the same gene can cause neuropathies falling into more than one of these clinical categories depending on the exact nature of the mutation, with gain-of-function phenotypes usually being more severe than those associated with loss of function. Common forms of CMT1 are caused by dominant mutations of genes for compact myelin proteins, PMP-22 in CMT1A and P0 protein in CMT1B. CMT1A is usually due to duplication of the PMP-22 gene with onset in the second or third decade of life and characterized by segmental demyelination, remyelination and onion bulb formation. Hereditary neuropathy with liability to pressure palsies is a milder neuropathy brought on by pressure or trauma to an affected nerve and is caused by a heterozygous deletion of the PMP-22 gene. These human disorders, caused by over and under expression of PMP-22, respectively, illustrate the importance of dosage of some myelin proteins for myelin stability (see Ch. 4). Some more severe forms of CMT1A and Dejerine–Sottas syndrome have missense mutations in transmembrane regions of PMP-22 similar to the murine *trembler* mutations (see Ch. 4). CMT1B and some forms of Dejerine–Sottas

syndrome are caused by a variety of mutations in the major P0 glycoprotein of compact myelin, presumably impairing its capacity to stabilize the intraperiod and/or major dense lines or interfering with a function in signal transduction (see Ch. 4).

There are other forms of inherited neuropathy affecting myelin that are caused by mutations of genes that alter Schwann cell proteins not localized in compact myelin [28–30]. Some examples include: (1) an X-linked form (CMT1X) caused by mutations of the gap junction protein connexin 32 (CX32), which is localized in paranodal loops and incisures where it probably forms gap junctions between adjacent layers of myelin sheaths; (2) a recessive form (CMT4F) caused by mutations of periaxin, which is part of a protein complex linking the extracellular basal lamina to the actin cytoskeleton of Schwann cells; and (3) a dominant form of CMT1 caused by mutations of a zinc finger transcription factor (EGR2, also called Krox 20). It is clear that genetic defects in a variety of Schwann cell functions can cause myelin deficiencies, but discussion of the likely pathogenic mechanisms is beyond the scope of this chapter. Furthermore, as is the case for disorders of CNS myelin, it is becoming increasingly apparent that axonal pathology and degeneration are often responsible for much of the neurological impairment in these inherited disorders caused by mutations expressed in Schwann cell genes, possibly due to defects in Schwann cell–axon interactions.

TOXIC AND NUTRITIONAL DISORDERS OF MYELIN

A variety of biological and chemical toxins can impair myelin formation or cause its breakdown. Biological toxins affecting myelin-forming cells can be produced by exogenous infectious agents in diseases such as diphtheria or endogenously by lymphocytes and macrophages. For example, diphtheritic neuropathy [1] is a possible complication of *Corynebacterium diphtheriae* infection and is characterized by vacuolation and fragmentation of myelin sheaths in the PNS. Also, cytokines, such as tumor necrosis factor and lymphotoxins, released by lymphocytes and macrophages can be toxic to oligodendrocytes *in vitro*, but the nature of their involvement in the pathogenic mechanisms of autoimmune diseases *in vivo* may be quite complex [31]. Activated immune cells also release oxygen radicals and nitric oxide, which are harmful to oligodendrocytes. These toxins could lead to loss of myelin- forming cells and myelin independently of whether the immune reaction is directed against myelin or an exogenous infectious agent. Damage to myelin by an immune reaction directed to an unrelated antigen is referred to as a 'bystander effect'.

Lead is a common environmental pollutant that is well known to cause hypomyelination and demyelination. Other chemical toxins affecting myelin-forming cells or myelin and that have been investigated experimentally include cuprizone, lysolecithin, triethyltin, hexachlorophene and tellurium. The effects of these and other chemical toxins on the biochemistry of myelin is beyond the scope of this chapter but have been covered in more detail in earlier editions of this book or in other sources [1].

General undernourishment or dietary deficiencies of specific substances can lead to a preferential reduction in myelin formation. Much of the CNS myelin in mammals is formed during a relatively restricted time period of rapid development. During this period, a large portion of the brain's metabolic activity and synthetic capacity are involved in myelinogenesis. Therefore, any metabolic insult during this 'vulnerable period' may lead to a preferential reduction in myelin formation [1]. The most vulnerable period appears to be the time of oligodendroglia proliferation, since animals deprived of food in this period have an irreversible deficit of myelin-forming cells and hypomyelination (see also Ch. 25). However, animals deprived at a later age can often demonstrate significant catch-up with regard to the amount of myelin when nutritional rehabilitation is instigated after a period of underfeeding. Failure to myelinate properly and demyelination are also associated with deficiencies of dietary protein, essential fatty acids, copper and several vitamins, including thiamine, B_{12} and B_6 [1].

DISORDERS PRIMARILY AFFECTING NEURONS WITH SECONDARY INVOLVEMENT OF MYELIN

Many insults to the nervous system initially cause damage to neurons but eventually result in regions of demyelination as a consequence of neuronal degeneration. The archetypical model for secondary demyelination is Wallerian degeneration (see Ch. 30). When a nerve (in the PNS) or a myelinated tract (in the CNS) is cut or crushed, the proximal segment often survives and regenerates [1]. In the distal segment, Wallerian degeneration occurs with disappearance of both axons and myelin and phagocytosis of the debris. From such experiments, it is clear that the integrity of the myelin sheath depends on continued contact with a viable axon. Any disease that causes injury to neurons may result in axonal degeneration and lead to the onset of myelin breakdown secondary to the neuronal damage. During Wallerian degeneration in the PNS, there is a rapid loss of myelin-specific lipids and proteins within a week or two with a concomitant increase in lysosomal enzymes. Between the second and fourth week after nerve section most of the myelin debris has been removed by Schwann cells and macrophages, and remyelination of regenerating axons begins. Degeneration of CNS myelin is a much slower process than in the PNS and takes place primarily within macrophages/microglia (not within the myelin-synthesizing cells, as in the PNS).

Secondary demyelination occurs in a variety of acquired and genetic CNS disorders that initially affect neurons, including mechanical trauma, infarcts, tumors, motor neuron disease, viral diseases such as subacute sclerosing panencephalitis, and sphingolipidoses such as Tay–Sachs disease, generalized gangliosidosis and Niemann–Pick disease (see Ch. 40). The isolated myelin from these diseases is usually of the 'nonspecific pathological type' that was discussed earlier in the context of some inherited primary demyelinating disorders. No cholesterol esters are found in the myelin, although they are abundant in the white matter, indicative of phagocytosis by macrophages.

REPAIR IN DEMYELINATING DISEASES

The capacity for remyelination is generally greater in the peripheral than in the central nervous system. Much of this chapter has considered biochemical mechanisms of myelin loss, but the capacity of nervous tissue to repair the damage by remyelination is also an important factor in the eventual clinical outcome of disorders affecting myelin. Following transection of peripheral nerve, as described in the previous section, myelination of the regenerating axons occurs soon after the final clean-up of myelin debris by Schwann cells [1]. The Schwann cells that form the new myelin are probably not the same ones that phagocytose the debris but appear to arise by cell division. The smaller capacity for remyelination in the CNS in comparison to the PNS may be caused in part by the nature of the myelin-forming cells, i.e. in the requirement for oligodendrocytes to myelinate many axons in contrast to the single segments of myelin formed by Schwann cells. Under some circumstances, such as in EAE and MS, it has been demonstrated that Schwann cells will migrate into the spinal cord and remyelinate demyelinated CNS axons.

Remyelination in the CNS can be promoted by various treatments. Substantial remyelination can occur in the CNS depending on the nature of the pathogenic insult, and it is likely that therapeutic procedures that enhance remyelination are feasible [2, 32, 33] (discussed in detail in Ch. 30). For example, rapid remyelination by oligodendrocytes does occur following acute demyelination caused by toxins such as cuprizone or lysolecithin, although the myelin sheaths are thinner than normal. The failure of significant remyelination in other circumstances may relate to the continuing effect of pathogenic processes. However, even in MS, careful observations of acute lesions have demonstrated the presence of healthy oligodendrocytes and regeneration of myelin in the presence of myelin breakdown. Although the remyelination attempt eventually fails and oligodendrocytes are lost from lesions that progress to advanced demyelinated plaques, such observations raise the possibility that management of patients with demyelinating diseases of the CNS may eventually involve treatments that take advantage of the capacity of oligodendrocytes for remyelination.

Research on experimental animals as well as human diseases indicates that remyelination can occur by proliferation and differentiation of host progenitor cells, which are quiescent in normal adult tissue (Ch. 29). Several approaches are being used to attempt to enhance the natural capacity of oligodendrocytes or their progenitors to remyelinate. Because a large number of growth factors (Ch. 27), such as epidermal growth factor, basic fibroblast growth factor, platelet derived growth factor, ciliary neurotrophic factor and insulin-like growth factor, are known to affect the survival, proliferation, migration and differentiation of oligodendrocyte progenitors, it is feasible that remyelination might be promoted in patients by treatment with one or more of these factors. An interesting finding in MS is that transforming factor-β produced by inflammatory cells induces expression in hypertrophic astrocytes of *jagged*, which activates the Notch signaling pathway in oligodendroglial precursors [34]. This appears to inhibit their capacity for remyelination and may provide a specific site for therapeutic intervention. Another observation that has relevance for enhancing remyelination is that various immunoglobulin preparations containing antibodies reacting with surface antigens of oligodendrocytes have the capacity to promote remyelination in experimental animals by activating a calcium ion signaling system [35]. An approach actively being pursued at this time in many laboratories involves the capacity of transplants of myelin-forming glial cells to repair demyelinated lesions [2, 35]. Much of this research involves the transplantation of Schwann cells, oligodendrocytes, oligodendrocyte progenitors, glial cell lines or stem cells into hypomyelinated mutants or focally demyelinated lesions and has clearly demonstrated that transplanted cells have the capacity to remyelinate. A promising report shows that xenografting isolated fetal or adult human oligodendroglial progenitors into dysmyelinated *shiverer* mouse brain results in widespread and robust myelination [36]. A serious problem in MS is that, if there is a window of time after an insult during which a particular stimulus is effective for regeneration, in MS there are multiple windows of time for multiple locations. Finally, it is worth noting that a combination of these different therapies may provide the best results, and the optimal treatment may vary from one myelin disorder to another. Further research is needed to evaluate the success of these approaches in the presence of astrocytic gliosis and inflammation (Ch. 30).

Measures to enhance axonal survival and regeneration also are critical in demyelinating conditions. With the increasing awareness that substantial axonal degeneration occurs in many diseases that had previously been thought to affect primarily myelin and that this may account for much of the permanent neurological deficit, increasing attention is being given to therapies that promote axonal

survival and regeneration. Various growth factors are likely to be beneficial in this regard. However, a complicating factor is that white matter is well known to contain a number of inhibitors of axonal regeneration, including Nogo, MAG and OMgp [37] (see Ch. 30). Nevertheless, it is promising that each of these inhibitory proteins appears to act through the same Nogo receptor signaling system, so that it may be feasible to block the effects of all three simultaneously. In conclusion, therapy for myelin disorders in the future may involve a combination of approaches aimed at preventing myelin loss, while at the same time promoting the survival, regeneration and remyelination of axons.

CONCLUDING REMARKS 663

GENETIC ASPECTS OF COMMON NEURODEGENERATIVE DISEASES

Introduction to the genetics of neurodegenerative disease. For most of the neurodegenerative conditions outlined in this chapter, familial aggregation had already been recognized as a salient feature decades before any of the underlying molecular genetic and biochemical properties came to light. As a matter of fact, it was often only the identification of specific, disease-segregating mutations in previously unknown genes that directed the attention of molecular biologists to particular proteins and pathways (via 'positional cloning', see caption to Fig. 39-1) that are now considered to be crucial in the development of the various diseases. These include the discovery of mutations in the β-amyloid precursor protein causing Alzheimer's disease (AD), mutations in α-synuclein causing Parkinson's disease, or more recently mutations in the microtubule-associated protein tau causing frontotemporal dementia with parkinsonism. Another feature observed in most common neurodegenerative diseases – as well as in other common conditions like diabetes or certain forms of cancer – is the prominent dichotomy of familial (rare) *versus* seemingly nonfamilial (common) forms. The latter are also frequently described as 'sporadic' or 'idiopathic' forms, although this terminology has proven overly simplistic and would best be abandoned. This is based on the growing body of evidence suggesting that a large proportion of nominally 'sporadic' cases are significantly influenced by genetic factors, e.g. reflected by a significant increase in disease risk in first-degree relatives of index cases. In most cases of neurodegenerative disease, the rule of thumb is that the earlier the age-at-onset, the greater the impact of genetic factors on causation/susceptibility.

Basic Neurochemistry: Molecular, Cellular and Medical Aspects

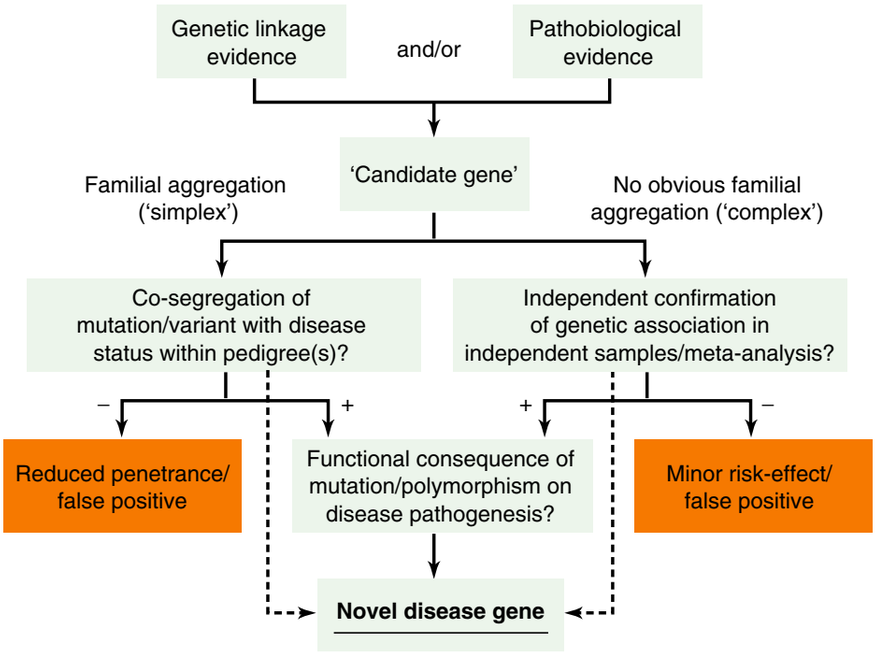

FIGURE 39-1 Simplified flow-chart of the strategies used to identify novel disease genes. This schema outlines one popular strategy to identify mutations and polymorphisms causing or predisposing to disease. Candidate genes are chosen on the basis of genetic linkage data and/or known or hypothesized pathobiological relevance to disease mechanisms. This procedure is typically referred to as 'candidate gene approach' (and contributed to the identification of *APOE* as a risk factor for AD). An alternative and inherently similar strategy is based on the detection of formerly unknown genes/proteins purely driven by genetic linkage data and is referred to as 'positional cloning' (examples include the identification of *PSEN1* mutations in AD). Broken lines indicate 'shortcuts' allowing for the elucidation of a novel disease gene based on the genetic evidence alone, e.g. *APOE*-ε4, of which the precise functional consequences still remain unknown. Note, that there are examples of genes/mutations with reduced penetrance or minor risk effects (*red boxes*) which are considered to be *bona fide* disease genes (e.g. certain mutations in *PSEN1* in Alzheimer's disease); however, it is usually much more difficult to conclusively prove their genetic and biochemical roles, which is why they are depicted separately.

Methods to find neurodegenerative disease genes. Despite the previous successes and recent advances in molecular and analytical techniques, the identification of genuine risk factors for the diseases outlined in this chapter – genetic and nongenetic – is aggravated by several circumstances. First, while diagnostic criteria have been proposed for all syndromes, these are usually based on clinical and/or neuropathological observations, which are never 100% specific and may even be assessed differently from one research center to the next. Thus, a sample described to consist of probable (i.e. clinically diagnosed) late-onset Alzheimer's disease cases, may actually be a conglomerate of patients with Alzheimer's, Lewy body dementia and frontotemporal dementia. A second, and related issue is that most neurodegenerative diseases manifest in old age, i.e. beyond 60 or 70 years. This makes the assessment of reliable familial histories – a prerequisite for genetic analyses – very difficult because a number of relatives may not have lived through the typical onset age, or may suffer from other conditions, which can mask or mimic the phenotype of interest. Third, common diseases typically display a large degree of genetic and phenotypic heterogeneity. This means that the same phenotype can be caused or modified by a number of different genetic loci and alleles but also that mutations or polymorphisms in the same gene may lead to clinically distinct syndromes. Further, certain combinations of genetic and nongenetic risk factors may significantly increase the odds of developing a disease in one ethnic group or geographical area, while another set of factors may be acting together elsewhere. The complexities observed in a variety of late-onset, multifactorial diseases are schematically displayed in Figure 39-2, using familial versus nonfamilial Alzheimer's disease as an example.

Collectively, these and other issues have led to the accumulation of a large number of proposed susceptibility genes and environmental risk factors in all the diseases covered in this chapter. However, these have received inconsistent support at best from subsequent and independent studies. Novel, more sophisticated analytical methods are needed to more efficiently filter genuine signals from background noise (i.e. false-positive findings) and to elucidate the complex interaction patterns between variables. Meta-analysis, i.e. the estimation of summary effect sizes and significances across a variety of independent studies, is one such technique, which is becoming

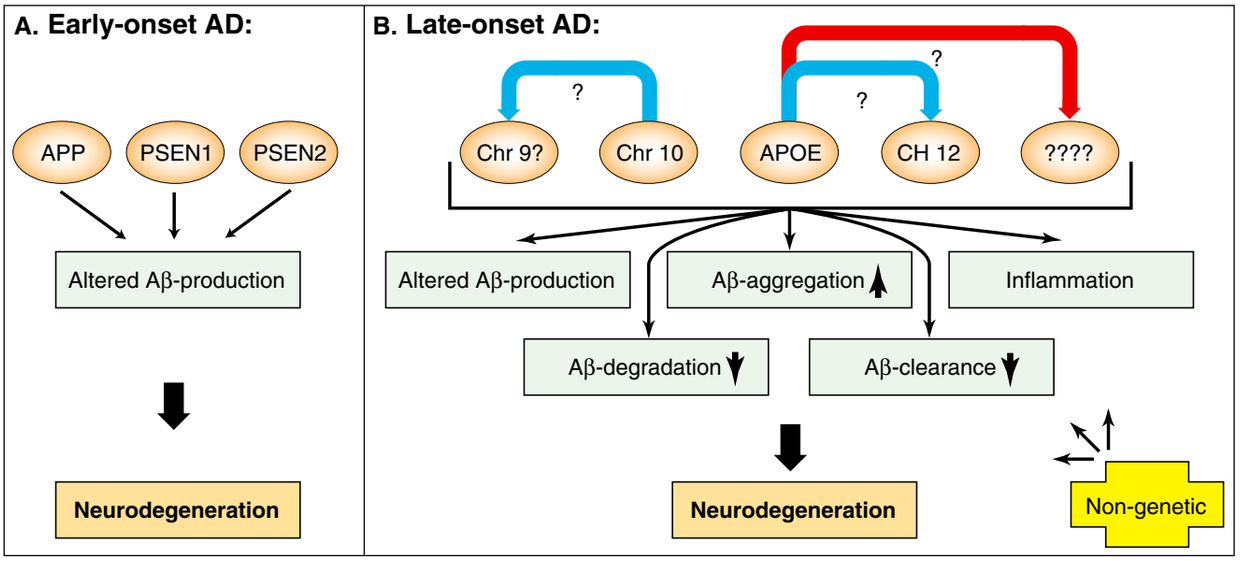

FIGURE 39-2 Scheme of contribution and interaction pattern of known and putative Alzheimer's disease (AD) genes. (**A**) Mutations in the familial, early-onset AD genes *APP*, *PSEN1*, *PSEN2* lead to an increase in Aβ-production and neurodegeneration without any other known essential factors. (**B**) Simplified scheme of the interaction pattern of known and proposed nonMendelian, late-onset AD genes. Probably, these risk-factor genes each affect one or more of the known or postulated pathogenetic mechanisms leading to neurodegeneration in AD. Their effects are further influenced by gene–gene interactions and the contribution of nongenetic risk factors. Note that none of the interaction patterns outlined here for didactic purposes has actually been established. (With permission from reference [97].)

increasingly more popular in the field of neurodegenerative diseases. Figure 39-1 outlines a simplified scheme of experimental strategies typically involved in the identification of novel disease genes.

Notwithstanding these difficulties, genetic analyses have laid the foundation to advance our understanding of a wide variety of disease mechanisms leading to neurodegeneration and associated symptoms. Likewise, a detailed understanding of the genetic basis of neurodegeneration will be essential for the development of effective strategies aimed at the early-prediction and early-prevention/treatment of these devastating diseases. In the following sections, we outline both the peculiarities and the similarities of genetics findings across a number of common neurodegenerative conditions. Note that more details on the molecular genetic consequences as well as neuropathogenetic mechanisms influenced by the various disease genes discussed here can be found in subsequent chapters of this book.

ALZHEIMER'S DISEASE

Alzheimer's disease is the most common form of age-related dementia and one of the most serious health problems in the industrialized world. AD is an insidious and progressive neurodegenerative disorder that accounts for the vast majority of dementia and is characterized by global cognitive decline and the accumulation of β-amyloid deposits and neurofibrillary tangles in the brain. Family history is the second greatest risk factor for the disease after age. The growing understanding of AD genetics over the last two decades has been central to the explosion in knowledge of the biology of the disease from the neuropathological to molecular levels. Genetically, AD is complex, heterogeneous and appears to follow an age-related dichotomy in which rare and highly penetrant early-onset (<60) familial AD (EOFAD) mutations are transmitted in an autosomal dominant fashion, while increased risk for late-onset AD without clear Mendelian inheritance (LOAD) is mainly conferred by common polymorphisms with relatively low penetrance but high prevalence [1]. Adding to the complexity and heterogeneity of AD genetics – as well as to the genetics of other neurodegenerative disorders – are currently ill-defined and difficult to model gene-gene and gene-environment interactions.

Early-onset familial Alzheimer's disease. Early-onset familial AD (EOFAD) represents only a small fraction of all AD cases (<5%) and typically presents with onset ages prior to the completion of the sixth decade, showing Mendelian, autosomal dominant disease transmission within affected families. To date, more than 160 mutations in three genes have been reported to cause EOFAD (Table 39-1). These include the β-amyloid precursor protein (*APP*) on chromosome 21 [2], presenilin 1 (*PSEN1*) on chromosome 14 [3] and presenilin 2 (*PSEN2*) on chromosome 1 [4, 5]. The most frequently mutated gene, *PSEN1*, generally leads to AD with onset ages in the 40s, and accounts for the majority of AD cases with onset prior to age 50 [6].

TABLE 39-1 Established genes causing Alzheimer's disease

Gene	Protein	Location	Inheritance	Relevance to Alzheimer's disease pathogenesis
APP	β-amyloid precursor protein	21q21	Dominant	Aβ production (Aβ↑; $A\beta_{42}$:$A\beta_{40}$ ratio↑)/aggregation
APOE	Apolipoprotein E	19q13	Risk factor	Unknown (Aβ clearance? Lipid metabolism?)
PSEN1	Presenilin 1	14q24	Dominant	Aβ production ($A\beta_{42}$:$A\beta_{40}$-ratio↑)
PSEN2	Presenilin 2	1q31	Dominant	Aβ production ($A\beta_{42}$:$A\beta_{40}$-ratio ↑)

While these AD-causing mutations occur in three different genes located on three different chromosomes, they all share a common biochemical pathway, i.e. the altered production of Aβ most frequently leading to a relative overabundance of the $A\beta_{42}$ species, eventually resulting in neuronal cell death and dementia. Aβ is produced by the sequential cleavage of *APP* by two enzymatic events, β- and γ-secretase cleavage. In contrast, the more common α-secretase cleavage (e.g. by ADAM10 or ADAM17) results in the production of a nonamyloidogenic soluble APPα fragment. Interestingly, all currently known AD-causing mutations in the APP gene are located in the vicinity of the secretase cleavage sites, encoded by exons 16 and 17. Moreover, the presenilins, together with three other proteins (Pen-2, Aph-1a and nicastrin) are essential components of the enzymatic complex responsible for γ-secretase cleavage of *APP* [7]. These discoveries have provided the essential connection between the occurrence of disease-causing mutations in *APP*, *PSEN1* and *PSEN2* and the increase in Aβ (particularly $A\beta_{42}$) production in the brains of AD patients.

***APOE* is the best established late-onset Alzheimer's disease gene.** Late-onset AD (LOAD) is classically defined as AD with onset ≥65 years and represents the vast majority of all AD cases. While segregation and twin-studies conclusively suggest a major role of genetic factors in this form of AD [8], to date, only one such gene has been firmly established for LOAD, the ε4 variant of the apolipoprotein E gene (*APOE*; Table 39-1) [9, 10]. In contrast to all other association-based findings in AD, the risk effect of *APOE*-ε4 has been consistently replicated in a large number of studies across many ethnic groups with odds ratios ranging from 1 to 6 for heterozygous and from 2 to 33 for homozygous carriers of the ε4 allele (for meta-analysis, see [11]). The three major alleles of the *APOE* locus, ε2, ε3 and ε4, correspond to combinations of two amino acid changes at residues 112 and 158 (ε2: Cys/Cys; ε3: Cys/Arg; ε4: Arg/Arg). In addition to the increased risk for AD exerted by the ε4-allele, several studies have also reported a weak, albeit significant, protective effect for the minor allele, ε2. Unlike the mutations in the known EOFAD genes, the *APOE*-ε4 allele is not sufficient to cause AD but instead operates as a genetic risk-modifier by decreasing the age of onset in a dose-dependent manner.

Despite its long-known and well-established genetic association with AD, the biochemical consequences of *APOE*-ε4 on AD pathogenesis are not yet fully understood. Current hypotheses are based on the observation that Aβ accumulation is clearly enhanced in the brains of carriers as well as in transgenic mice expressing the human ε4 allele and mutant APP (reviewed in [12]). Furthermore, the apoE protein normally plays a role in cholesterol transport and lipid metabolism; *APOE*-ε4 predisposes to heart disease as a result of its association with increased plasma cholesterol levels. High plasma cholesterol, in turn, has been correlated with increased β-amyloid deposition in the brain. Interestingly, cholesterol has also been shown both to increase Aβ production and to stabilize the peptide in the brains of transgenic AD mice. Thus, it is possible that *APOE*-ε4 confers risk for AD via a mechanism that is shared in common with its effect on cardiovascular disease by increasing a carrier's risk for hypercholesterolemia, as this would be expected to elevate accumulation of Aβ.

Other late-onset Alzheimer's disease loci. Several lines of evidence suggest that numerous additional LOAD and EOFAD loci still remain to be identified, since the four known AD genes together account for less than 30% of the genetic variance of AD [13]. There is also direct evidence for such genes based on simulation as well as empirical data. For instance, a recent simulation study predicted the existence of four to seven additional AD genes when searching for age of onset modifiers simulating a variety of different disease and inheritance models [13]. This number corresponds well with empirical data obtained in several full genome screens for novel AD genes performed to date, which indicate overlap on 11 chromosomes. Five different chromosomes reveal 'significant' results in at least one study in addition to the *APOE* region on chromosome 19 (i.e. chromosomes 6q, 9p, 10q, 12p, 21q) [14]. These disease-specific characteristics, together with the advent of relatively inexpensive and powerful high-throughput genotyping technologies and the completion of the human genome sequence have led to a steep increase in the number of laboratories investigating the genetics of AD worldwide.

Currently, more than three dozen genes that have been tested on positional (chromosomal location) and/or functional (biological) grounds have been reported to be associated with AD [15, 16]. Despite these vast efforts, however, no single gene has yet emerged with the degree of replication and consistency that has been observed by literally hundreds of laboratories that have addressed the association of *APOE*-ε4 and AD. While no firm conclusions can be drawn at this time, it is noteworthy that several of the more extensively studied (and replicated) putative novel AD candidates are – similar to the proposed role for *APOE* – directly involved in the clearance and/or degradation of extracellular Aβ (e.g. *LRP1* (lipoprotein

receptor related protein-1), *A2M* (α2-macroglobulin), *IDE* (insulin degrading enzyme)), lending further support to the hypothesis put forward by several authors that LOAD may be caused by deficits in the removal of Aβ, in contrast to the EOFAD mutations, which lead to increased *production* of the peptide (Fig. 39-2). Other physiological pathways that have been genetically associated with AD include inflammation (e.g. *IL1A* and *IL1B* (interleukin-1α and 1β), *IL6* (interleukin-6)), cholesterol metabolism (e.g. *SOAT1* (acyl-coenzyme A:cholesterol acyltransferase, or ACAT), *CYP46* (cholesterol 24-hydroxylase) and *CH25H* (cholesterol 25-hydroxylase), as well as the production of Aβ, itself (e.g. *PSEN1* and *NCSTN* (nicastrin, see above)). An up-to-date overview on the status of these and other potential AD candidate genes, including meta-analyses across published genetic association studies, can be found in the Alzheimer's Research Forum genetic database at www.alzgene.org.

PARKINSON'S DISEASE

Parkinson's disease (PD) is the second most common neurodegenerative disease of adult onset and, like almost all the other diseases outlined in this chapter, exhibits an increased prevalence with age but with an average age of onset between 50 and 60 years. Histopathologically, it is characterized by a severe loss of dopaminergic neurons in the substantia nigra and cytoplasmic inclusions consisting of insoluble protein aggregates (Lewy bodies) leading to a progressive movement disorder including the classic triad of tremor, bradykinesia and rigidity. Although the heritability – and thus the contribution of genetic factors to the overall prevalence of PD – is probably smaller than that of AD, genetics has played a major role in elucidating the potential causes of nigrostriatal neuronal loss across a wide spectrum of clinically and histopathologically heterogeneous cases of PD. As in AD, there appears to be an age-dependent dichotomy, the majority of cases with an early or even juvenile onset showing typical Mendelian inheritance. However, unlike AD, these cases show a predominantly autosomal recessive mode of inheritance and there is an ongoing debate as to whether genetic factors play any substantial role in contributing to disease risk in cases with onset beyond ≈50 years [17–19]. Notwithstanding these complexities, there are a plethora of genetic studies for both forms of the disease, and mutations in at least five genes have now been shown to cause familial early-onset PD (Table 39-2), with several other linkage regions pending characterization and/or replication. However, no single genetic susceptibility factor for late-onset PD has yet received anything like the same degree of support as *APOE*-ε4 in late-onset AD (see above).

Early-onset familial Parkinson's disease. Early-onset familial PD represents only a minority of all PD cases. While currently nearly a dozen chromosomal regions have been reported to potentially harbor disease-causing PD loci, only mutations in five of these have been shown to actually segregate with the disease beyond the initial study (Table 39-2). Similar to AD, the first locus to be characterized – *PARK1*, on chromosome 4q21 – involves the protein that is the major constituent of one of the classic neuropathological hallmarks of PD, α-synuclein (*SNCA*) [20]. Aggregated α-synuclein is at the core of Lewy bodies, round eosinophilic intracellular inclusion bodies that are found in affected brain regions. To date, three missense mutations in *SNCA* (Ala53Thr, Ala30Pro and E46K) have been described in a handful of families worldwide (reviewed in [21]). While the exact mechanisms underlying α-synuclein toxicity currently remain only incompletely understood, recent evidence suggests that *SNCA* mutations may change normal protein function quantitatively rather than qualitatively [22]. This is based on the observation that triplication of the α-synuclein gene causes PD in a large early-onset autosomal dominant pedigree [23]. Again, this bears a striking similarity to AD, where triplication of the *APP*-containing chromosome 21 causes an AD-like neurodegeneration in middle-aged patients with trisomy 21 (Down's syndrome). Subsequently, other autosomal-dominant PD pedigrees have been identified showing either triplication [24] or duplication of *SNCA* [22, 25], suggesting that genetic variants in this gene may play a more prominent role in PD pathogenesis than was previously assumed. Furthermore, in the few families studied to date, there appears a correlation between gene dose and clinical phenotype: while *SNCA* duplications apparently lead to a more 'typical' PD syndrome with onset ages around 50 years, triplication of the gene leads to a less typical clinical picture with earlier onset (in the 30s) and signs of Lewy body dementia (LBD, see below) in one of the pedigrees [23]. In addition to these findings in familial PD, there is some – albeit less clearly established – support for a potential role of *SNCA* polymorphisms on risk of late-onset PD [26]. Recently, mutations in a second gene with dominant inheritance have been identified by several different laboratories (*LRRK2* [26a, 26b]). While the functional consequences of *LRRK2* mutations are still unknown, it was suggested that at least some mutations could interfere with the protein's kinase activity [26c].

TABLE 39-2 Established genes causing Parkinson's disease

Gene	Protein	Location	Inheritance	Relevance to Parkinson's disease pathogenesis
SNCA	α-synuclein	4q21	Dominant	Neurotoxicity by aggregation of α-synuclein (?)
PARK2	Parkin	6q25	Recessive	Impaired protein degradation via proteasome
PARK7	DJ1	1p36	Recessive	Impaired oxidative stress response (?)
PINK1	PTEN-induced putative kinase 1	1p36	Recessive	Mitochondrial dysfunction (?)
LRRK2	Leucine-rich repeat kinase; dardarin	12q12	Dominant	Unknown

Parkin accounts for the majority of early-onset Parkinsonism. While *SNCA* and *LRRK2* mutations are the leading cause of autosomal dominant familial forms of PD, the majority of affected pedigrees actually exhibit a recessive mode of inheritance. To date, mutations in three genes have been reported to cause this latter form of familial parkinsonism (Table 39-2). The most frequently involved gene is *parkin* [27], formerly designated as *PARK2*, on chromosome 6q25 [28], which probably causes nearly half of all early-onset cases. Parkin is an ubiquitin ligase that is involved in the ubiquitination of proteins targeted for degradation by the proteasomal system. Because the spectrum of parkin variants ranges from amino-acid-changing single-point mutations to complex genomic rearrangements and exon deletions, it is likely that *parkin* mutations confer their pathogenetic effects via a loss of function. More specifically, it has been speculated that a loss of parkin activity may trigger cell death by rendering neurons more vulnerable to cytotoxic insults, e.g. the accumulation of glycosylated α-synuclein [29]. However, as none of the various parkin substrates identified to date show a specific enrichment in dopaminergic neurons, further research is required to elucidate the exact role of parkin dysfuntion in PD neuropathogenesis. It is noteworthy, that – unlike α-synuclein-related PD – Lewy bodies are typically not found in brains of cases bearing *parkin* mutations, potentially suggesting the existence of additional, α-synuclein-independent disease mechanisms.

***DJ1* and *PINK1* are recessively acting Parkinson's disease genes.** Two recessively acting early-onset PD genes, *DJ1* and *PINK1*, have been discovered more recently. Thus, only a little evidence has been accrued on their potential functional involvement in PD neuropathogenesis. In 2003, genetic analyses of two early-onset PD pedigrees from the Netherlands and Italy revealed two independent, homozygous mutations in the *DJ1* gene [30] on chromosome 1p36 (previously designated as *PARK7*) [31]. Both result in a loss of function of DJ1, a ubiquitously expressed protein that is suggested to be involved in oxidative stress response. While several subsequent studies in independent early-onset PD samples have confirmed the presence of additional DJ1 mutations, the frequency of disease-causing variants in this gene is estimated to be low, i.e. in the order of ≈1% [32]. Less than 13 Mb away on the same chromosome, two PD-causing mutations were discovered in *PINK1*, encoding PTEN-induced putative kinase I [33], previously designated as *PARK6* [34]. This enzyme is ubiquitously expressed with particularly high levels in brain, and the first two identified mutations (G309D and W437ter) were predicted to lead to a loss of function that – similar to the effects of *parkin* mutations – may render neurons more vulnerable to cellular stress. Interestingly, the predominant subcellular localization of the PINK1 protein is mitochondrial, which is also the primary target of 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), a potent neurotoxin that produces a syndrome almost indistinguishable from sporadic PD [35]. In only 4 months after its original discovery, there have been reports of at least a dozen additional disease-causing *PINK1* mutations [36, 37], rendering this locus the second most common cause of early-onset familial PD. With regard to pathology, it remains unclear whether or not mutations in *DJ1* and *PINK1* lead to the formation of Lewy bodies in the brains of affected patients.

Other proposed early-onset Parkinson's disease loci. In addition to the confirmed early-onset familial PD genes, at least six other candidate PD loci, including mutations in two genes, have been described. The putative disease-causing latter are located in the ubiquitin carboxy-terminal hydrolase L1 (*UCHL1*) [38] on chromosome 4p14 (also designated *PARK5*), and in a nuclear receptor of subfamily 4 (*NR4A2* or *NURR1*) [39] located on 2q22. However, in contrast to the previously outlined PD genes, neither of these genes maps to a known PD linkage region, and no studies beyond the initial reports were able to confirm the existence of either the reported or additional mutations in screens of independent samples. In fact, missense mutations in *NR4A2* were also found in patients with schizophrenia and bipolar affective disorder, arguing against a specific role of variants in this gene in neurodegeneration [40]. Furthermore, polymorphisms in both genes have been – albeit inconsistently – associated with PD in some case-control studies. In this context, it is noteworthy that a recent meta-analysis on all currently available association studies for the S18Y polymorphism in *UCHL1* showed a modest, but significant protective effect of the Y-allele [41], suggesting that this gene may actually be a susceptibility factor rather than a causal PD gene.

Late-onset Parkinson's disease. Late-onset PD is caused by a variety of different factors, to which genes may only contribute to a relatively minor extent in comparison with early-onset forms of the disease [17] (see above). As outlined above, the heritability of this form of parkinsonism is probably low, which attenuates the ability to find consistent gene signals. Despite these concerns, a number of whole-genome screens across several independent later-onset PD family samples have been performed. As might be expected, the results have varied considerably, with only few overlapping genomic intervals. One of the more extensively studied chromosomal regions is located on 17q21, near the gene encoding the microtubule-associated protein tau (*MAPT*) [42]. Previously, it had been shown that rare missense mutations in *MAPT* lead to a syndrome of frontotemporal dementia with parkinsonism (FTDP-17, see below). However, to date, no mutations have been identified to cause parkinsonism without frontotemporal degeneration. Meanwhile, haplotype analyses of the tau gene have revealed some evidence of genetic association of the H1-haplotype with both PD [43] and earlier with a related syndrome, progressive supranuclear palsy [44]. Interestingly, these findings were recently corroborated in a meta-analysis [45]. This study estimated an increase of ≈30–60% in PD risk in carriers of the H1 haplotype as

compared to noncarriers, and suggested that up to 25% of the population-attributable risk for PD may be caused by this variant. However, there is typically no evidence of tau-related pathology in classic PD brains, so it remains to be determined whether this genetic link can be corroborated by biochemical analyses. Several other putative late-onset PD regions have been reported, although the overall evidence supporting the presence of genuine PD loci in these regions is still weak.

Since the discovery of the genetic association between *APOE*-ε4 and AD, variants in this gene have also been tested for a role in PD and related syndromes, despite the lack of genetic linkage evidence to chromosome 19q13. To date, nearly three dozen studies have investigated the potential role of *APOE* in PD, but no obvious or consistent pattern of association has emerged. While some authors report a significant risk effect of ε4 on PD risk in general, others only see association with PD and concurrent dementia, or age of onset, but not risk. Some have even observed correlations opposite to those found in AD, i.e. an increase in risk related to the ε2 allele, which has been reported to be protective in AD (see above). It is noteworthy that a recent meta-analysis on the putative *APOE* effects in PD concludes that it is only this latter finding that remains significant when all published studies are considered jointly [46]. The authors report a modest but significant 20% increase in risk in carriers of the ε2 allele *versus* noncarriers, while no significant effects where detected for the ε3 or ε4 alleles. Although this result clearly warrants more research regarding the possible connection between *APOE* and PD, it appears unlikely that this gene plays nearly as pronounced a role in PD as in AD.

However, there is some preliminary evidence that other genetic risk factors may be shared across the two diseases. For example, recent linkage studies for AD and PD overlap – to some degree – in at least three instances: on chromosomes 9q [47, 48], 10q [49, 50] and 12p [51, 52]. These observations could indicate the presence of common risk or age-at-onset modifiers across different neurodegenerative diseases and potentially shed more light on the pathogenesis of neurodegeneration in general.

LEWY BODY DEMENTIA

According to some studies, Lewy body dementia (LBD) is the second most common type of degenerative dementia in the elderly, possibly accounting for up to 15% of all dementia cases in autopsy samples [53]. Clinically, LBD is characterized by progressive cognitive impairment with fluctuating course, recurrent visual hallucinations and parkinsonism. Although formal clinical criteria have been proposed [53], there is a pronounced overlap with AD as well as with PD with dementia (PDD), on both clinical and neuropathological grounds. The predominant histological feature of LBD is the presence of cortical and subcortical Lewy bodies, but many patients with LBD also have AD pathology, i.e. cortical amyloid plaques and neurofibrillary tangles. Conversely, Lewy bodies are also frequently observed in cases of classic AD, including patients with mutations in *APP*, *PSEN1* and *PSEN2* [54]. While a familial aggregation of LBD has been described [55], the identification of specific LBD genetic factors is aggravated by the still uncertain phenotypic classification of LBD, in particular its distinction from AD and PDD.

The genetics of Lewy body dementia remains largely uncertain. In contrast to studies of AD and PD, to date, no systematic full-genome screen has been performed in LBD-only samples. However, there exists some evidence arguing for the presence of potentially genuine genetic risk factors. For instance, in follow-up analyses to the original AD full-genome screen, which led to the identification of linkage to chromosome 12 [51], evidence for substantial heterogeneity in the investigated sample was detected [56]. Specifically, the initial AD linkage assigned to chromosome 12q13 near 50 Mb was found to be largely caused by a subset of families (eight of 54 families) that actually fulfilled the neuropathological criteria for LBD. In these families, the linkage evidence was shifted to an interval on 12p11, with a maximum signal at the position of 27 Mb distal of the telomere of the short arm. Interestingly, this same region was also implicated in a large Japanese pedigree with autosomal dominant PD (*PARK8*) [52], although none of the four patients that came to autopsy in this latter family, displayed any clinical signs of LBD or evidence for the presence of cortical or subcortical Lewy bodies. The underlying genetic defect in these families has now been shown to lie within *LRRK2* [52a], and it remains to be seen whether or not mutations in this gene also cause cases of LBD. The only susceptibility gene from this chromosomal region studied in LBD is the five-base-pair insertion/deletion polymorphism in *A2M* [57] that was found associated with the disease in one study of a population isolate in the Netherlands [58] but not in another [59]. Finally, and not surprisingly, a potential association of LBD with *APOE*-ε4 has been observed, but only inconsistently. However, a recent meta-analysis on all case-control studies from 2000–2004 investigating the possibility of an *APOE*-ε4 risk-effect suggested that this allele does lead to a significantly increased risk for LBD, while the ε2-allele, which may lead to an increase in risk for PD (see above), does not [60]. Furthermore, the very recent observation that the occurrence of cortical Lewy bodies and dementia in PD may be dependent on the gene dose of α-synuclein [22, 23] strongly suggests a potential role of this gene in LBD pathogenesis as well.

FRONTOTEMPORAL DEMENTIA

Frontotemporal dementia (FTD) is a heterogenous group of syndromes defined clinically by a gradual and progressive change in behavior and personal conduct and/or a gradual and progressive language dysfunction [61]. The initial symptoms typically occur without affecting other

cognitive domains, such as memory, and rarely present with an onset age beyond 75 years. In some cases, behavioral and language deficits are accompanied by parkinsonism or progressive motor neuron disease. The major neuropathological finding consists of frontal and/or temporal lobe atrophy caused by neuronal degeneration. Frequently, affected neurons display intracellular, tau-positive inclusions that characteristically are distinct from the neurofibrillary tangles observed in AD [62].

There is an ongoing debate regarding which of the various clinical syndromes to include under the 'superordinate concept' of FTD. Recent guidelines on FTD [61] have suggested embracing entities such as Pick's disease, FTD with parkinsonism linked to chromosome 17 (FTDP-17), corticobasal degeneration, progressive supranuclear palsy, neurofibrillary tangle dementia, frontotemporal lobar degeneration and FTD with motor neuron disease. Other authors use a very similar classification scheme but are in favor of the term 'Pick's complex' [63].

While there is clear evidence for a familial aggregation of most of these syndromes (25–40% of all cases are believed to be familial [64]), their clinical and neuropathological variability suggests the existence of several distinct genetic factors underlying these disorders. On the other hand, recent advances in the genetics of FTDP-17 have shown that different mutations in the same gene (or even exon) can lead to a diverse spectrum of FTD-type syndromes, providing genetic support for merging the apparently diverse clinical entities into one overarching category.

Frontotemporal dementia with parkinsonism linked to chromosome 17. FTDP-17 was the first FTD-syndrome found to harbor mutations in the tau gene (*MAPT*; Table 39-3) [65], following linkage evidence pointing to the chromosomal region on 17q21 near tau [66, 67]. Currently, there are over 30 known *MAPT* mutations in more than 100 families worldwide, the majority of which are located in exon 10 and the intron immediately downstream [6]. The phenotype observed with *MAPT* mutations ranges from classic Pick's disease, to corticobasal degeneration, frontotemporal lobar degeneration, and progressive supranuclear palsy [64]. Although to date no case of pathologically proven AD has been reported to harbor mutations in *MAPT*, there have been sporadic observations of early progressive memory loss reminiscent of AD, e.g. segregating with the R406W mutation in exon 13 [68, 69]. However, the same mutation was found also in families segregating more typical FTD [65]. Molecular genetic studies could show that the biochemical consequences of the various mutations on the protein level are quite diverse, including reducing or increasing the binding of tau to microtubules, enhancing tau aggregation and affecting the ratio of the specific tau-isoforms (i.e. towards an increased ratio of four-repeat *versus* three-repeat tau) by affecting alternative splicing (reviewed in [70]). Interestingly, it appears that *MAPT* mutations almost exclusively lead to FTD with immunohistochemical evidence of both three- and four-repeat tau, while classic Pick's disease, which lacks the four-repeat isoform, has not yet been conclusively linked to *MAPT* or any other genetic defect [71]. The correlation between four-repeat tau and genetic variants in *MAPT* is further supported by genetic association studies showing almost unanimous support for a *MAPT* risk haplotype (H1) in samples with progressive supranuclear palsy or corticobasal degeneration, both characterized by the abundance of four-repeat tau, but no evidence of association with Pick's disease. Note, that this is the same haplotype that has also frequently been associated with PD (see above), possibly suggesting common and as yet uncharacterized tau-related pathogenic mechanisms between FTD and late-onset PD and/or the presence of substantial heterogeneity within the commonly defined late-onset PD samples.

While tau mutations have provided an important piece in the puzzle of FTD genetics, they probably account for less than 50% of the genetic variance in familial FTD [64]. However, the successful identification of additional contributing genetic factors largely depends on the development of precise phenotypic classification schemes, which

TABLE 39-3 Established genes causing other common neurodegenerative diseases

Gene	Protein	Location	Inheritance	Relevance to FTD pathogenesis
FTDP-17				
MAPT	Microtubule-associated protein tau	17q21	Dominant	Altered tau-production (4R:3R ratio ↑) and/or altered binding to microtubules
Amyotrophic lateral sclerosis				
SOD1	Superoxide dismutase 1	21q22	Dominant and recessive	Impaired oxidative stress response (?)
ALS2	Alsin	2q33	Recessive	Impaired neuroprotection (?)
Huntington's disease				
HD	Huntingtin	4p16	Dominant	Unknown
Familial prion diseases (fCJD, FFI, GSS)				
PRNP	Prion protein	20p13	Dominant and risk factor	Transformation of PrP^{c} into PrP^{sc}

fCJD, familial Creutzfeldt–Jakob disease; FFI, fatal familial insomnia; FTDP-17, Frontotemporal dementia with parkinsonism linked to chromosome 17; GSS, Gerstmann–Sträussler–Scheinker disease.

is particularly applicable to the FTD cluster of diseases. One relatively circumscribed phenotypic entity within the FTD-related syndromes is the co-occurrence of frontal lobe degeneration with motor neuron disease (i.e. amyotrophic lateral sclerosis, ALS). A recent full genome screen on a sample of familial ALS found significant evidence of linkage to chromosome 9q21, which was restricted to families showing both ALS and FTD [72]. Interestingly, this putative locus almost precisely overlaps with a late-onset AD linkage region [72a], again possibly suggesting a common genetic background for neurodegeneration in more than one disease entity. Finally, only relatively few studies have investigated the influence of *APOE* variation on the risk for FTD, yielding highly variable results. However, these studies were collectively based on only very small case-populations (none greater than 100 cases), leading to substantially reduced power in the face of only moderate effect sizes. On the other hand, a recent meta-analysis on all data published for *APOE* in FTD [73] detected a significant risk-effect associated with the ε2 allele, but no significant results with ε4, a finding similar to meta-analyses done on late-onset PD and opposite to those reported for AD (see above). While this observation may be purely incidental, it is similar to the findings of the H1-tau haplotype that has also been associated in some FTD syndromes and PD (see above).

AMYOTROPHIC LATERAL SCLEROSIS

Amyotrophic lateral sclerosis (also known as motor neuron disease or Lou Gehrig's disease) is characterized by a rapidly progressive degeneration of motor neurons in the brain and spinal cord, which ultimately lead to paralysis and premature death. The prevalence of ALS overall is low (≈5/100,000), but incidence increases with age, showing a peak between 55 and 75 years. Neuropathological features of ALS include intracellular accumulations and perikaryal inclusions of neurofilament, and Lewy-body-like cytoplasmic inclusions. While the precise pathogenic mechanism leading to neuronal death remains elusive, a number of biochemical events have been suggested to be probably involved: protein misfolding and aggregation, defective axonal transport, mitochondrial dysfunction and glutamate-related excitotoxicity [74]. Cognitive impairment and dementia co-occurs with ALS in at least 5% of cases and it was actually in a family displaying FTD with parkinsonism and amyotrophy that evidence of linkage to chromosome 17 was first described (see above).

Familial amyotrophic lateral sclerosis. Familial amyotrophic lateral sclerosis (FALS) is observed in ≈10% of all cases, but substantially more ALS cases are suspected to be influenced to some degree by genetic factors [75]. Mutations in two genes (*SOD1* and *ALS2*; Table 39-3) have been shown to cause FALS, apart from mutations in tau (*MAPT*) leading to FTD with parkinsonism and amyotrophy (see above). Following evidence in 1991 of genetic linkage to chromosome 21q [76], disease-causing mutations were identified in the gene encoding superoxide dismutase 1 (*SOD1*) [77], which catalyzes the conversion of superoxide radicals into hydrogen peroxide. More than 100 mutations in *SOD1* have been described worldwide since 1991 in over 200 pedigrees with FALS. These mutations account for ≈20% of FALS and for up to 10% of the 'sporadic' cases of ALS, i.e. those not showing an obvious Mendelian transmission [78]. Most of the known *SOD1* mutations are inherited in an autosomal dominant fashion, although one mutation (D90A) can act both dominantly and recessively [79]. The latter mode of inheritance was mainly observed in Scandinavian countries, a geographical region generally showing increased ALS incidence. Although the precise mechanisms of SOD1 dysfunction are still unknown, there is a growing consensus that it is most probably based on a toxic gain of function of mutant SOD1. Recently, mutations in a second FALS gene (*ALS2*, encoding alsin) were identified in independent families with a rare, juvenile-onset autosomal recessive form of ALS and primary lateral sclerosis, a syndrome restricted to upper motor neuron degeneration [80, 81]. Additional mutations in *ALS2* have also been described in families suffering from infantile-onset ascending hereditary spastic paralysis, suggesting considerable phenotypic variability of the *ALS2* mutations. The function of the encoded protein is unknown but it was recently suggested that it protects neurons from mutant SOD1 *in vitro* [82].

Several other FALS loci have been described by means of linkage analysis in individual families or larger FALS samples but none of the underlying gene defects has yet been uncovered. A recent full-genome screen in FALS has pinpointed significant linkage to the immediate vicinity of a putative AD locus on chromosome 9q21 in families with ALS and FTD [72], possibly indicating a common pathophysiological basis for neurodegeneration or dementia in these two disorders. Furthermore, various genetic associations with mostly nonfamilial ALS have been claimed but have met with only inconsistent replication to date. Specifically – as one of the few neurodegenerative conditions discussed in this chapter – *APOE*-ε4 has almost unanimously shown no evidence for association with risk or disease progression of ALS. Moreover, the genetic data supporting the postulated association between ALS and the neurofilament heavy-chain gene (*NFH*) on chromosome 22q12, a component of the neuronal inclusions observed histopathologically, remains scarce, despite the fact that it was initially described over a decade ago [83].

NEURODEGENERATIVE TRIPLET REPEAT DISORDERS

Triplet repeat disorders are characterized by 3-base-pair nucleotide repeats that lie in either coding or non-coding regions and give rise to a multitude of different

phenotypes that are inherited in an autosomal dominant, recessive or X-linked fashion. The nucleotide triplets are inherently unstable and the number of repeats tends to increase ('expand') across consecutive generations, especially following paternal transmission. This can lead to a decrease in onset age of the particular disease, a phenomenon described as 'anticipation'. The molecular basis of repeat instability is not well understood but the presence of pathogenetic triplet repeats gives rise to a variety of neurological and developmental disorders, such as Huntington's disease, spinocerebellar ataxias and fragile X-syndrome. Neurodegenerative triplet repeat disorders are all caused by coding poly-CAG expansions, which are translated into an elongated polyglutamine (polyQ) tract. Although most of these proteins do not share any homology aside from polyQ, several salient features are shared by the CAG-repeat disorders. For instance, they generally strike in mid-life and cause increasing neuronal dysfunction and eventual neuronal loss ≈10–20 years after onset of symptoms. Furthermore, all polyQ repeats confer a gain of function when they are pathologically expanded, and disease develops typically when the number of uninterrupted repeats exceeds 35–36 glutamines. Finally, despite the widespread expression of all currently known genes throughout the brain and other tissues, only a certain subset of neurons is vulnerable to dysfunction in each of the various diseases. In the remainder of this section we will discuss the genetics underlying Huntington's disease as an example of a neurodegenerative triplet repeat disorder leading to dementia.

Huntington's disease. Huntington's disease (HD) is caused by degeneration of neurons in the basal ganglia followed by cortical regions, leading clinically to involuntary movements (chorea), psychiatric symptoms and dementia. Its prevalence is similar to that of ALS but much less than that for most of the other dementing illnesses discussed above. Approximately 90% of HD cases are hereditary and are transmitted in an autosomal dominant fashion. The other 10% are considered to be '*de novo*', i.e. these cases originate from asymptomatic parents with normal repeat lengths that have expanded to symptomatic range (see below). The genetic locus underlying HD was originally mapped to chromosome 4q16 via conventional linkage analysis [84]. This was the first time that the genetic cause for an autosomal dominant disorder had been pinpointed solely via the genetic analyses of DNA variants. 10 years later the gene responsible for HD was identified as encoding a 350 kDa protein (huntingtin; gene: *HD*), the *HD* gene containing a poly-CAG repeat in exon 1 (Table 39-3) [85]. As is typical for CAG-repeat disorders, HD is symptomatic in the presence of 36 repeats or more, although lengths of 36–39 have been found to show only incomplete penetrance. The mean repeat length in HD patients is 40–45, although the variability is quite wide, ranging from 35 to 120 repeats [86]. The precise function of huntingtin remains elusive, but cloning experiments have demonstrated that it is highly conserved throughout evolution. Interestingly, CAG repeats in other mammalian and nonmammalian species are less frequent than in humans, suggesting that the polyQ segment is of little, if any, physiological importance [86]. One of the leading hypotheses regarding the mechanism underlying neurodegeneration in HD is that the pathologically expanded polyQ can cause mutant huntingtin to interact abnormally with other proteins. However, to date none of the many identified huntingtin-interacting proteins has shown a regional distribution correlating with neurodegeneration in the brains of HD patients, suggesting a more complex etiology [87].

It is well established that repeat length of the polyQ tract shows a strong inverse correlation with onset age. However, only ≈50% of the interindividual onset age variation can be explained by triplet number, suggesting the presence of other factors (genetic and nongenetic) as modifiers of onset age. A recently completed full genome screen performed to identify such onset age modifiers has revealed several suggestive linkage regions [88]. The most promising of these on chromosome 6q25 is close to the glutamate receptor 6 (*GRIK2*), which has been associated with a younger HD onset age in some studies, potentially supporting the notion of glutamate-induced excitotoxicity [89, 90]. However, this finding awaits further replication and functional characterization. Only few studies have investigated a potential onset-age effect of the *APOE* polymorphisms in HD but, as with ALS, the results thus far have been largely negative.

CREUTZFELDT–JAKOB DISEASE AND OTHER PRION DISEASES

Prion diseases include a rare and heterogenous spectrum of clinical and histopathological phenotypes, which are unique in the group of neurodegenerative diseases as they can be familial (e.g. familial Creutzfeldt–Jakob disease (fCJD), fatal familial insomnia (FFI), Gerstmann–Sträussler–Scheinker disease (GSS)), sporadic (e.g. CJD, sporadic fatal insomnia), or acquired by infection (e.g. kuru, iatrogenic CJD, variant CJD). While most forms are characterized by a rapidly progressing neurodegeneration with spongiosis and amyloid plaques consisting of prion protein (PrP) aggregates, this is not the case for all forms. Further, only a relatively small subset of cases with prion disease show a familial aggregation, but genetics has played a crucial role in elucidating the molecular mechanisms as well as facilitating the clinical classification of the various subtypes of disease [91]. In particular, mutations and polymorphisms in the gene encoding PrP (*PRNP*) on chromosome 20p13 at ≈5 Mb are major determinants of disease onset and phenotypic variation of familial prion diseases but also appear to affect risk for the sporadic forms (Table 39-3).

***PRNP* mutations cause neurodegeneration and influence disease progression.** The mechanisms by which

PRNP influences disease outcome are 2-fold. First, more than two dozen different amino-acid-changing mutations in the coding region of the gene have been identified as causing familial prion diseases, transmitted in an autosomal dominant fashion with nearly 100% penetrance. There is a remarkable heterogeneity in the sense that different mutations throughout the gene can give rise to a variety of different phenotypes associated with all three familial forms of prion disease, fCJD, FFI and GSS (reviewed in [91]). In addition to these point mutations, there are also rare cases of fCJD and GSS caused by variable numbers of octapeptide (i.e. 24 bp) repeats within the coding sequence of the *PRNP* gene. Second, clinical presentation and disease progression are further modified by a common polymorphism at codon 129, leading to a methionine (M) to valine (V) change. Most of the mutated *PRNP* missense alleles are on the same haplotype as the 129M allele, which includes virtually all forms of fCJD. In the rare cases where they co-occur with the 129V allele, they lead to a distinct clinical phenotype and, in the case of D178N–129M *versus* D178N–129V, even to a different disease entity: While the latter haplotype leads to typical fCJD, the former (i.e. M-associated) haplotype represents the only currently known genetic cause of FFI, which presents with a quite distinct clinical picture.

In addition to its effects on familial forms of prion disease, the M129V polymorphism was also found to increase the risk for sporadic forms of CJD (sCJD) [92, 93]. In particular, it was found that the homozygous state for either allele (i.e. M/M or V/V) was disproportionately more frequent in sCJD than the M/V genotype [92]. Furthermore, homozygosity at this polymorphism leads to a faster disease progression than heterozygosity in nearly all genetic as well as sporadic (including iatrogenic) forms of prion disease and, in most instances, the M/M genotype was associated with the most aggressive course of disease [94]. Interestingly, almost all individuals thus far known to be affected by the newly described 'variant' form of CJD (vCJD), which is characterized by a prion protein isotype resembling that found in bovine spongiform encephalopathies (BSE), have also been carriers of the M/M genotype. Furthermore, at least in Caucasian populations, there is evidence suggesting an overrepresentation of the M allele and M/M genotype in samples with AD as well (see above). This contrasts with observations made by other groups suggesting that the V allele predisposes to cognitive decline in the elderly [95], and Down's syndrome patients [96]. Only a few other genetic risk factors for the nonfamilial forms of CJD have been investigated and none of them has shown any noteworthy results to date. This includes *APOE*-ε4, which was found to both increase risk and/or accelerate disease progression in some studies. The majority of samples failed to replicate either of these effects, although more studies and meta-analyses on the available data are needed to more definitely exclude a prominent role of this gene in the etiology and progression of prion diseases.

CONCLUDING REMARKS

While displaying a diverse array of clinical and histopathological characteristics, the neurodegenerative disorders discussed in this chapter share a variety of epidemiologic and genetic aspects. First, with the exception of Huntington's disease, they all feature an etiological dichotomy with less frequent, relatively early-onset familial forms on the one hand, and more frequent multifactorial forms on the other. It is possible (and likely) that a substantial number of the hitherto nonfamilial cases of neurodegeneration will eventually turn out to originate from specific disease-causing mutations and that some, if not the majority, of the remaining seemingly 'sporadic' cases will prove to be governed by a variety of different, but *bona fide* genetic risk factors (such as *APOE*-ε4 in AD). Second, in some cases, the same mutations and polymorphisms have been linked and associated across clinically and neuropathologically diverse disease entities. For instance, based on recent meta-analyses the *APOE* polymorphisms may not only contribute to risk for AD but also for PD and FTD (albeit with different alleles). Along these lines, there have been reports of overlapping linkage regions for AD and PD (chromosome 10q), AD, PD and ALS-FTD (chromosome 9q), and AD, PD and LBD (chromosome 12p), possibly suggesting genetic commonalities. One possible explanation for such overlaps is that the samples were imperfectly ascertained and actually represent heterogenous diseases. Alternatively, these overlaps could point to one or several common genetic and mechanistic denominators for neuronal cell death. Finally, genetics has been one of the essential prerequisites for elucidating the molecular and biochemical pathways leading to neurodegeneration for almost all of the syndromes and disease entities discussed in this chapter. Likewise, a detailed understanding of the genetic basis of neurodegeneration will probably also be essential for the development of effective early-prediction and early-intervention/treatment strategies, with the prospect of largely decreasing the incidence of these devastating disorders in the future.

Disorders of Amino Acid Metabolism

Marc Yudkoff

INTRODUCTION 668

An aminoaciduria usually results from the congenital absence of an enzyme needed for metabolism of an amino acid 668

The major metabolic fate of amino acids is conversion into organic acids; absent an enzyme to oxidize an organic acid, an organic aciduria results 668

Untreated aminoacidurias can cause brain damage in many ways, often through impairing brain energy metabolism 670

An imbalance of amino acids in the blood often alters the rate of transport of these compounds into the brain, thereby affecting levels of neurotransmitters and rates of protein synthesis 670

Treatment of aminoacidurias with a low-protein diet may influence brain chemistry 671

Imbalances of brain amino acids may hinder the synthesis of brain lipids, leading to a diminution in the rate of myelin formation 671

In many aminoacidurias, there may occur deficits in neurotransmitters and receptors, particularly the *N*-methyl-D-aspartate receptor 671

Brain edema, often associated with increased intracranial pressure, may accompany the acute phase of metabolic decompensation in the aminoacidurias 671

DISORDERS OF BRANCHED-CHAIN AMINO ACIDS: MAPLE SYRUP URINE DISEASE 671

Maple syrup urine disease involves a congenital failure to oxidize the three branched-chain amino acids 671

Effective treatment of maple syrup urine disease involves the restriction of dietary branched-chain amino acids 672

DISORDERS OF PHENYLALANINE METABOLISM: PHENYLKETONURIA 672

Phenylketonuria usually is caused by a congenital deficiency of phenylalanine hydroxylase 672

The outlook for patients who are treated at an early age is favorable 673

Rarely, phenylketonuria results from a defect in the metabolism of biopterin, a cofactor for the phenylalanine hydroxylase pathway 673

DISORDERS OF GLYCINE METABOLISM: NONKETOTIC HYPERGLYCINEMIA 673

Nonketotic hyperglycinemia results from the congenital absence of the glycine cleavage system, which mediates the interconversion of glycine and serine 673

Nonketotic hyperglycinemia causes a severe seizure disorder and profound brain damage 673

Treatment for nonketotic hyperglycinemia is less effective than that available for other aminoacidurias 674

DISORDERS OF SULFUR AMINO ACID METABOLISM: HOMOCYSTINURIA 674

The transsulfuration pathway is the major route for the metabolism of the sulfur-containing amino acids 674

Homocystinuria is the result of the congenital absence of cystathionine synthase, a key enzyme of the transsulfuration pathway 676

Homocystinuria can be treated in some cases by the administration of pyridoxine (vitamin B_6), which is a cofactor for the cystathionine synthase reaction 676

Patients with homocystinuria are at risk for cerebrovascular and cardiovascular disease and thromboses 676

Prognosis is more favorable in the pyridoxine-responsive patients 677

Homocystinuria can occur when homocysteine is not remethylated back to form methionine 677

One form of remethylation deficit involves defective metabolism of folic acid, a key cofactor in the conversion of homocysteine to methionine 677

Methionine synthase deficiency (cobalamin-E disease) produces homocystinuria without methylmalonic aciduria 677

Cobalamin-c disease: remethylation of homocysteine to methionine also requires an 'activated' form of vitamin B_{12} 677

Hereditary folate malabsorption presents with megaloblastic anemia, seizures and neurological deterioration 678

THE UREA CYCLE DEFECTS 678

The urea cycle is essential for the detoxification of ammonia 678

Urea cycle defects cause a variety of clinical syndromes, including a metabolic crisis in the newborn infant 679

Urea cycle defects sometimes result from the congenital absence of a transporter for an enzyme or amino acid involved in the urea cycle 680

Successful management of urea cycle defects involves a low-protein diet to minimize ammonia production as well as medications that enable the excretion of ammonia nitrogen in forms other than urea 680

DISORDERS OF GLUTATHIONE METABOLISM 681

The tripeptide glutathione is the major intracellular antioxidant 681

DISORDERS OF γ-AMINOBUTYRIC ACID METABOLISM 681

Congenital defects in the metabolism of γ-aminobutyric acid have been described 681

DISORDERS OF *N*-ACETYL ASPARTATE METABOLISM 682

Canavan's disease is the result of a deficiency of the enzyme that breaks down *N*-acetylaspartate, an important donor of acetyl groups for brain myelin synthesis 682

INTRODUCTION

An aminoaciduria usually results from the congenital absence of an enzyme needed for metabolism of an amino acid. Aminoacidopathies typically involve an inherited deficiency of an enzyme that is important for the metabolism of a particular amino acid (Table 40-1). The concentration of that amino acid and its metabolites consequently rise sharply in blood, urine and body tissues, including the brain. When the enzymatic deficiency is nearly complete, the onset of disease tends to occur in infancy, even in the neonatal period. Partial enzyme deficiencies may not become apparent until later in life [1, 2].

Most untreated aminoacidopathies damage the brain. The pathophysiological factors that explain the encephalopathy remain unknown. Injury probably results from the accumulation of an amino acid or amino acid metabolite that is toxic to the nervous system, especially to the developing brain. Mental retardation and other manifestations of brain damage can result. Fortunately, these disorders often are amenable to therapy with a diet that is purposely low in the potentially offending amino acid. In some instances treatment is possible with a vitamin that serves as a cofactor for the defective biochemical reaction (Table 40-1). Antidotes to the neurotoxicity have been developed for a few syndromes. Outcome often depends upon early institution of treatment. The advent of mass screening of newborns for metabolic diseases has greatly improved the prognosis.

The major metabolic fate of amino acids is conversion into organic acids; absent an enzyme to oxidize an organic acid, an organic aciduria results. Three features characterize the metabolism of essentially all amino acids: (1) incorporation into protein; (2) conversion into messenger compounds such as hormones and neurotransmitters;

TABLE 40-1 Disorders of amino acid metabolism

Disorder	Biochemical derangement	Classical findings	Treatment
Branched-chain aminoaciduria (maple syrup urine disease)	Defective branched-chain amino acid breakdown (Fig. 40-1)	Coma, convulsions, vomiting, respiratory failure in neonate	Diet low in branched-chain amino acids Thiamine for B_1-responsive disorders (rare) Hepatic transplantation
Glutaric acidurias	Type I: Primary defect of glutarate oxidation Type II: Defect of electron transfer flavoprotein	Type I: Severe basal ganglia/cerebellar disease with macrocephaly. Onset 1–2 years Type II: Fulminant neurological syndrome of the neonate. Often with renal/hepatic cysts. Usually fatal	Diet low in lysine and tryptophan Supplementation with coenzyme Q, riboflavin, carnitine
Phenylketonuria (PKU)	Usually defect of phenylalanine hydroxylase. In care cases, defect of biopterin metabolism (Fig. 40-3; reaction 1)	Normal at birth. Mental retardation in untreated children. Avoidable with early institution of diet therapy. Prognosis less favorable in PKU secondary to defect of biopterin metabolism	Diet low in phenylalanine Carbidopa
Nonketotic hyperglycinemia	Defect of the glycine cleavage system (Fig. 40-4)	Intractable seizures in neonate. Usually fatal in first few weeks of life	Diet low in glycine NMDA receptor blockers (variable efficacy) Sodium benzoate to lower blood glycine
Homocystinuria	Usually a failure of cystathionine synthase (Fig. 40-2; reaction 6). Rarely associated with aberrant vitamin B_{12} metabolism (Fig. 40-2)	Thromboembolic diathesis, marfanoid habitus, ectopia lentis. Mental retardation is frequent.	Diet low in methionine Vitamin B_6 in pyridoxine-responsive syndromes Vitamin B_{12} in responsive syndromes Anticlotting agents
Urea cycle defects	Failure to convert ammonia to urea via urea cycle (Fig. 40-5).	Coma, convulsions, vomiting, respiratory failure in neonate. Often mistaken for sepsis of the newborn. Mental retardation, failure to thrive, lethargy, ataxia and coma in the older child. Associated with hyperammonemia and abnormalities of blood aminogram	Low protein diet Acylation therapy (sodium benzoate, sodium phenylacetate) Arginine therapy in selected syndromes Hepatic transplantation
Disorders of glutathione	Defective synthesis of glutathione, the major intracellular antioxidant	Spinocerebellar degeneration, mental retardation, cataracts, hemolysis. Severe acidosis in some cases	*N*-acetylcysteine (variable response)
Disorders of GABA	Vitamin B_6-dependent seizures Often an absence of succinic semialdehyde dehydrogenase	Hypotonia, ataxia, mental retardation in older child. Increased urine 4-OH-butyric acid.	Pyridoxine (B6-dependent disorder) Inhibitors of GABA transaminase
Canavan's disease	Absence of *N*-acetylaspartate acylase	Rapidly progressive demyelinating disease of infancy	Gene therapy (experimental)

For disorders of carbohydrate metabolism and the primary lactic acidoses, see Chapter 34.

and (3) oxidation, which involves the conversion of amino acid nitrogen into ammonia and of amino acid carbon into organic acids that enter the tricarboxylic acid cycle, where they become oxidized.

Generalized defects of protein synthesis have not yet been described, presumably because they would be lethal early in development. Disturbances in the synthesis of messenger compounds such as thyroxine or neurotransmitters may occur but they do not result in an aminoaciduria because relatively little amino acid is so disposed.

Many organic acidurias originate in the breakdown of the three branched-chain amino acids, leucine, isoleucine and valine (Fig. 40-1). Metabolism of the organic acids requires the presence of specific enzymes, congenital deficiencies of which give rise to the organic acidurias (Fig. 40-1). The clinical features of the organic acidurias are described in Table 40-2.

On rare occasions an organic aciduria occurs not because of an enzyme deficiency but from a failure to transport or activate a water-soluble vitamin that serves as a cofactor for the reaction in question. Thus, congenital deficiencies in the metabolism of vitamin B_{12} commonly give rise to methylmalonic aciduria (Fig. 40-1, Table 40-2). Similarly, deficiencies of biotin metabolism can cause a severe organic aciduria (Table 40-2). It is very important to be aware of the defects of vitamin metabolism because the administration of large doses of these cofactors may completely prevent brain damage.

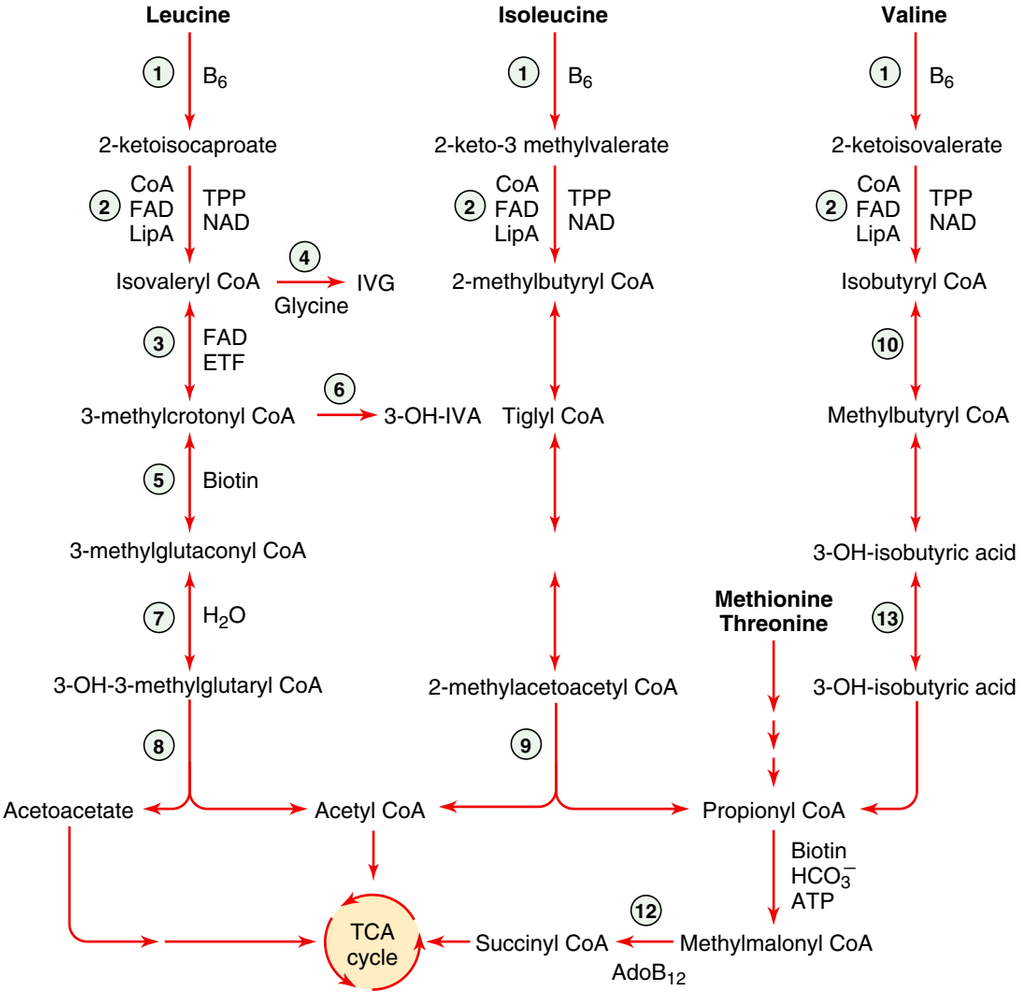

FIGURE 40-1 Major pathways of branched-chain amino acid metabolism. Maple syrup urine disease is caused by a congenital deficiency of reaction (2). Many of the primary organic acidurias, e.g. isovaleric acidemia and methylmalonic acidemia, are referable to inherited defects of enzymes involved in the oxidation of organic acids derived from the branched-chain amino acids. Enzymes: (1) Branched-chain amino acid transaminase; (2) Branched-chain amino acid decarboxylase; (3) Isovaleryl-CoA dehydrogenase; (4) Glycine-N-acylase; (5) 3-methylcrotonyl-CoA carboxylase; (6) 3-methylglutaconyl-CoA hydroxylase; (7) 2-methylglutaconyl-CoA hydratase; (8) 3-OH-3-methylglutaryl-CoA lyase; (9) 2-ketothiolase; (10) Isobutyryl-CoA dehydrogenase; (11) Propionyl-CoA carboxylase; (12) Methylmalonyl-CoA mutase; (13) 3-OH-isobutyryl-CoA deacylase. *$AdoB_{12}$*, adenosylcobalamin; *ETF*, electron transfer flavoprotein; *LipA*, lipoic acid; *T-PP*, thiamine pyrophosphate.

TABLE 40-2 The organic acidurias

Organic aciduria	Enzyme deficiency	Clinical findings	Treatment
Isovaleric acidemia	Isovaleryl-CoA dehydrogenase	Neonate: fulminant syndrome: coma, convulsions. Rancid odor of 'sweaty socks' Older child: developmental delay, mental retardation, recurrent vomiting. Odor of 'sweaty socks' Carnitine Glycine to promote acylation of isovaleryl-CoA	Low protein diet to restrict intake of leucine (precursor to isovaleric acidemia)
3-methylcrotonic aciduria	3-methylcrotonyl-CoA carboxylase (biotin dependent)	Infancy: vomiting, metabolic acidosis, hyperlactatemia, convulsions, coma Older child (2–5 years): recurrent vomiting, metabolic acidosis, hypoglycemia and progressive lethargy	Low protein diet to restrict intake of leucine
3-methylglutaconic aciduria	3-methylglutaconyl-CoA hydratase	Speech delay; developmental delay usually is mild	Low protein diet to restrict intake of leucine
3-hydroxy-3-methyl-glutaric aciduria	3-hydroxy-3-methyl-glutaryl-CoA lyase	Vomiting, lethargy, coma, convulsions, metabolic acidosis. Hypoglycemia without significant ketoaciduria	Low protein diet to restrict intake of leucine Avoidance of fasting to prevent hypoglycemia
2-methylacetoacetyl-CoA thiolase deficiency	2-methylacetoacetyl-CoA thiolase	Recurrent acidosis, ketosis, vomiting, often with hypoglycemia. Prompt clinical response to intravenous glucose. Mental retardation not usual	Avoid prolonged fasting. Glucose infusion during acute episode
3-OH-butyryl-CoA deacylase deficiency	3-OH-butyryl-CoA deacylase	Multiple congenital anomalies, tetralogy of Fallot, facial dysmorphism, brain dysgenesis	None
Propionic acidemia	Propionyl-CoA carboxylase	Fulminant syndrome in neonate: coma, convulsions. Hyperglycinemia and hyperammonemia common Milder, later-onset form: developmental retardation, failure to thrive, recurrent vomiting	Special diet low in isoleucine, valine, methionine, threonine. Carnitine supplementation. Liver transplantation may be beneficial.
Methylmalonic acidemia	Two forms: 1. Methylmalonyl-CoA mutase 2. Deficiency of metabolism of vitamin B_{12}, a cofactor for the reaction	Severe form: acidosis, hyperammonemia, hepatomegaly, hyperglycinemia, hypoglycemia, coma, convulsions, growth failure, psychomotor retardation. Basal ganglia damage ('metabolic stroke') is frequent, especially involving globus pallidus Defects of vitamin B_{12} metabolism may show homocystinemia	Special diet low in isoleucine, valine, methionine, threonine. Carnitine supplementation. Liver transplantation may be beneficial. Glucose and bicarbonate during acute episodes
Type I glutaric aciduria	Glutaryl-CoA dehydrogenase	Macrocephaly common. Initially normal. Develop hypotonia, opisthotonus, seizures, rigidity, dystonia, facial grimacing. Atrophy of caudate and putamen	Special diet low in lysine and tryptophan
Type II glutaric aciduria	Deficiency of electron transport flavoprotein or of ETF:ubiquinone reductase	Hepatomegaly, hypoglycemia without ketonuria, lipid storage myopathy with hypotonia, metabolic acidosis, rancid urine odor ('sweaty socks'), enlarged and cystic kidneys, hepatic cysts, facial dysmorphism	Typically fatal in infancy. Profound developmental delay in rare surviving infant
Biotinidase deficiency	Biotinidase	Eczema, seizures, deafness, lactic acidosis, hypotonia, lethargy, ataxia, neuropathy, immune deficiency, optic atrophy, alopecia	Biotin supplementation
Holocarboxylase synthetase deficiency	Holocarboxylase synthetase	Profound acidosis with ketonuria, lactic acidosis, tachypnea, lethargy, hypotonia, seizures, unusual urinary odors. Usually severe neonatal onset	Biotin supplementation

Untreated aminoacidurias can cause brain damage in many ways, often through impairing brain energy metabolism. Various biochemical changes occur in experimental models of these disorders. An adverse effect on brain energy metabolism has been observed in virtually all *in vitro* and animal models. *In vivo* evidence indicates that similar pathophysiological mechanisms probably occur in humans, particularly during metabolic decompensation. Thus, studies with ^{31}P-magnetic resonance spectroscopy in adults with phenylketonuria showed increases of brain levels of ADP in the basal state (see Ch. 58 for detailed discussion of spectroscopy). Loading with phenylalanine caused slowing of the electroencephalogram (EEG) and a further increase in the concentration of ADP [3]. Similarly, an elevation of brain lactate has been observed during metabolic decompensation in the brains of patients with maple syrup urine disease [4]. A variety of related factors probably are involved, including an uncoupling of oxidative metabolism, inhibition of the tricarboxylic acid cycle, impaired glucose homeostasis, alterations of the intracellular redox potential and excessive stimulation of brain *N*-methyl-D-aspartate (NMDA) receptors, thereby leading to consumption of ATP via activation of Na^+,K^+-ATPase (see pertinent topics of metabolism and neurotoxicity in Chs 5, 31, 32 and 42). These mechanisms are not necessarily mutually exclusive. For example, during hyperammonemia more than one mechanism probably is operative (see also Ch. 34) [5].

An imbalance of amino acids in the blood often alters the rate of transport of these compounds into the brain, thereby affecting levels of neurotransmitters and rates of protein synthesis. In almost all aminoacidopathies the blood concentrations of one or more amino acids

increase markedly. This factor may competitively inhibit the transport of other amino acids across the blood–brain barrier [6]. Amino acids are transferred into the CNS via specialized transporters that mediate the uptake of neutral compounds. Excessive plasma levels of one compound may inhibit the transport of others. This phenomenon has been studied most carefully with respect to phenylketonuria, in which there occurs diminished entry into brain of tyrosine and tryptophan, the respective precursors of dopamine and serotonin (see Chs 12 and 13). *In vivo* studies with magnetic resonance support this hypothesis. When adults with phenylketonuria receive dietary supplements of neutral amino acids, the blood concentrations of tyrosine and tryptophan increase but blood levels of phenylalanine are unchanged. In contrast, the brain concentration of phenylalanine declines toward the level observed in heterozygotes [7]. Some patients reported that neutral amino acid supplementation afforded relief from depression, perhaps reflecting a relative increase in brain levels of dopamine and/or tryptophan (see Catecholamines in Depression, Ch. 55).

Distortion of the plasma aminogram in individuals with an aminoaciduria also may lead to a relative failure of brain protein synthesis. Thus, in mice with a deficiency of phenylalanine hydroxylase, the blood concentration of phenylalanine is more than 20 times greater than the control value, leading to partial saturation of the transport system and a diminution in the brain level of neutral amino acids other than phenylalanine. Rates of protein synthesis were concomitantly reduced [8].

Treatment of aminoacidurias with a low-protein diet may influence brain chemistry. It should be emphasized that the treatment of the patient with an aminoaciduria may affect brain chemistry, perhaps in an adverse manner. Nearly all patients receive a low-protein diet. Indeed, undiagnosed patients sometimes avoid consumption of protein, which they feel intuitively can cause lethargy, headache, nausea and mental confusion. As dietary protein declines, the intake of carbohydrate frequently increases. The concomitant rise of endogenous insulin secretion favors an increase in the ratio of the concentration of blood tryptophan to that of other amino acids, thereby promoting the entry of tryptophan to the brain. The latter amino acid is precursor to brain serotonin, which tends to increase. This physiology is known to be operative in patients with urea cycle defects.

Imbalances of brain amino acids may hinder the synthesis of brain lipids, leading to a diminution in the rate of myelin formation. Decreases of lipids, proteolipids and cerebrosides (Ch. 3) have been noted in several of these syndromes, e.g. maple syrup urine disease, when intramyelinic edema is a prominent finding, particularly during the acute phase of metabolic decompensation [9]. Pathological changes in brain myelin are common, especially in infants who die early in life. The fundamental lesion may involve a failure of myelin protein synthesis as a consequence of the imbalanced brain amino acid content. It also is probable that disturbances of energy metabolism lead to a failure of myelin synthesis during development, when lipid formation is very active (see myelin formation in Ch. 4). Amino acid metabolites may directly inhibit the synthesis of crucial lipids such as arachidonic acid and docosahexaenoic acid (see detailed discussion of these lipids in Ch. 33) [10]. Similarly, excessive levels of phenylalanine appear to inhibit the synthesis of cholesterol [11].

In many aminoacidurias, there may occur deficits in neurotransmitters and receptors, particularly the *N*-methyl-D-aspartate receptor. Brain damage and dysfunction in the aminoacidurias may reflect injury to neurotransmitter receptors and transporters [12]. Thus, the presence of a glycine binding site on the NMDA glutamatergic receptor (see Ch. 15) prompted the hypothesis that the severe seizure disorder that typifies the congenital absence of the glycine cleavage system might be responsive to treatment with NMDA receptor antagonists [13]. Excessive stimulation of the NMDA receptor presumably contributes to the severe seizure disorder (see Ch. 37). Similarly, hyperammonemia appears to impair the high-affinity uptake of glutamate into both astrocytes and neurons. A compensatory decrease of NMDA receptors may then occur as an adaptation to increased external glutamate [14].

Brain edema, often associated with increased intracranial pressure, may accompany the acute phase of metabolic decompensation in the aminoacidurias. Brain swelling and increased intracranial pressure may occur during acute illness. As indicated above, intramyelinic edema may occur in maple syrup urine disease. Swelling of brain astrocytes occurs with acute hyperammonemia because water is drawn into glia secondary to accumulation of glutamine, which is preferentially formed in astrocytes from glutamate and ammonia (see Ch. 15). Increased brain blood flow during hyperammonemia accentuates swelling [15].

DISORDERS OF BRANCHED-CHAIN AMINO ACIDS: MAPLE SYRUP URINE DISEASE

Maple syrup urine disease involves a congenital failure to oxidize the three branched-chain amino acids. The first congenital defect of branched-chain amino acid (BCAA) catabolism to be described was maple syrup urine disease (MSUD), a deficiency of mitochondrial branched-chain ketoacid dehydrogenase (Fig. 40-1; reaction 2). The ketoacids are freely reaminated to the parent amino acids, the latter being readily measured in the blood

and urine. The characteristic odor of the branched-chain ketoacids imparts to the urine a smell that resembles maple syrup or burned sugar.

The decarboxylase is composed of four subunits: E1-a, E1-b, E2 and E3. A specific kinase and phosphatase, respectively, activate and deactivate the enzyme complex. Most MSUD patients have mutations involving the E1-a subunit that decarboxylates the ketoacid, although defects of the E1-b protein have been described [16]. The E1-a mutation usually causes faulty assembly of the heterotetrameric (a_2b_2) E1 protein. Mutations of either the E2 or E3 moieties are extremely rare. The E3 subunit is common to other decarboxylating systems, including pyruvate dehydrogenase and 2-oxo-glutarate dehydrogenase. Hence, mutations in this protein can cause lactic acidosis and deranged tricarboxylic acid cycle activity as well as an accumulation of the BCAAs.

Infants are protected during gestation because the placenta clears most potential toxins. The classical form of the disease therefore does not become clinically manifest until a few days after birth. An initial phase of alternating irritability and lethargy progresses over a period of days to frank coma and respiratory embarrassment. Irreversible brain damage is common in babies who survive, particularly those whose treatment is delayed until after the first week of life.

Survivors may suffer a metabolic relapse at any time. The most common cause of relapse is intercurrent infection, which favors endogenous protein catabolism. As a consequence, the patient's limited capacity to oxidize BCAAs is overwhelmed and these compounds, together with their cognate ketoacids, accumulate to a toxic level. Relapse also can occur in association with surgery, trauma and emotional upset.

Patients with partial enzymatic deficiencies may present later in life with intermittent ketoacidosis, prostration and recurrent ataxia. The plasma concentrations of BCAA are elevated during these episodes but they may be normal or near-normal during the periods when patients are metabolically compensated.

Rare patients respond to the administration of thiamine in large doses (10–30 mg/day). The clinical course is even more mild than that of patients with intermittent disease. Thiamine is a cofactor for the branched-chain ketoacid dehydrogenase, and the presumed mutation involves faulty binding of the apoprotein to this vitamin.

In many localities, newborn screening has become standard for this disorder, which in the general population has an approximate incidence of 1/250,000 live births. Carrier detection is possible, either by measurement of enzymatic activity in cultured fibroblasts or by study of restriction endonuclease fragments of DNA. Antenatal testing is also available.

Effective treatment of maple syrup urine disease involves the restriction of dietary branched-chain amino acids. Long-term treatment entails the dietary restriction of the BCAAs. This is accomplished by administration of a special formula from which these amino acids are removed. The outlook for intellectual development is favorable in youngsters in whom diagnosis is made early and who do not suffer recurrent, severe episodes of metabolic decompensation [17].

Gene therapy for this metabolic defect may become available within the next few years. *In vitro* studies have demonstrated the feasibility of retroviral-mediated gene transfer of both the E1-a and E2 subunits of the branched-chain decarboxylase complex [16, 18].

DISORDERS OF PHENYLALANINE METABOLISM: PHENYLKETONURIA

Phenylketonuria usually is caused by a congenital deficiency of phenylalanine hydroxylase. Phenylketonuria (PKU) is among the more common aminoacidurias (≈1:20,000 live births). The usual cause is a nearly complete deficiency of phenylalanine hydroxylase, which converts phenylalanine into tyrosine (Fig. 40-2; reaction 1).

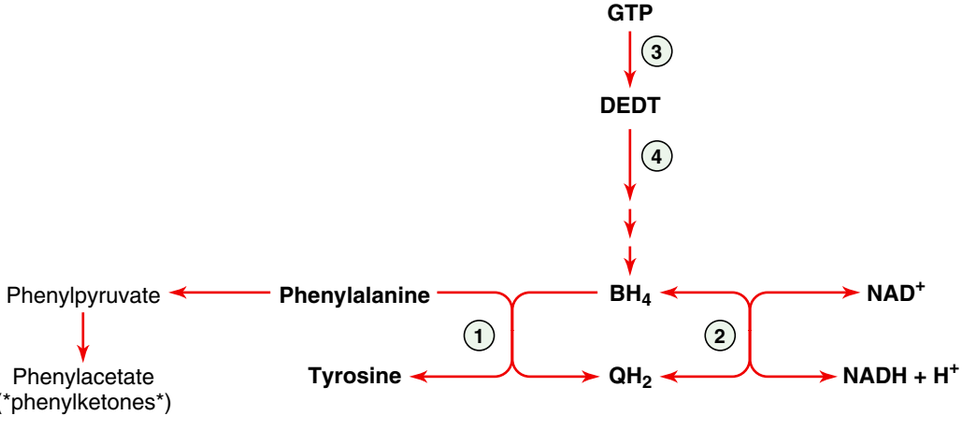

FIGURE 40-2 The phenylalanine hydroxylase (PAH) pathway. Phenylketonuria usually is caused by a congenital deficiency of PAH (reaction 1), but it also can result from defects in the metabolism of biopterin, which is a cofactor for the hydroxylase. Enzymes: (1) Phenylalanine hydroxylase; (2) Dihydropteridine reductase; (3) GTP cyclohydrolase; (4) 6-pyruvoyltetrahydrobiopterin synthase. *BH_4*, tetrahydrobiopterin; *DEDT*, D-*erythro*-dihydroneopterin triphosphate; *QH_2*, dihydrobiopterin.

In addition to 'classical' PKU, many youngsters have hyperphenylalaninemia caused by a partial deficiency of the enzyme. They do not suffer mental retardation but they may have more subtle neurological problems [19, 20].

The hydroxylase is a trimer (mol. wt ≈150,000) made up of identical subunits. It is located predominantly in the liver. The enzyme has been mapped to human chromosome 12q22–24.1, where the gene is made up of 13 exons extending over 90≈kb of genomic DNA.

Frank deletions of the gene are not common. A frequent mutation among northern Europeans (≈40%) is a G to A transition at the 5′ donor splice site in intron 12, resulting in absence of the C terminus. Another relatively common (≈20%) mutation in northern Europeans involves a C to T transition in exon 12, resulting in substitution of a tryptophan for an arginine residue [21]. Over 70 different mutations have been described to date in the American population [22].

Specific mutations have been associated with specific haplotypes, the latter determined by analysis of restriction fragment length polymorphisms. This approach has been utilized for prenatal diagnosis. The study of haplotypes also has revealed that the majority (≈75%) of northern European patients are compound PKU heterozygotes.

The outlook for patients who are treated at an early age is favorable. Affected babies are normal at birth but almost all will be impaired unless they receive dietary restriction by age 3 months. Mass screening has largely eliminated the untreated PKU phenotype of eczema, poor growth, irritability, musty odor (caused by phenylacetic acid) and tendency to self-mutilation. Progressive motor dysfunction has been described in children with long-term hyperphenylalaninemia.

The clinical utility of dietary restriction of phenylalanine (200–500 mg/day of phenylalanine) is clear. Well-controlled patients have normal intelligence, although there may be an increased risk of perceptual–learning disabilities, emotional problems and subtle motor difficulties [23]. Diet therapy must probably be maintained throughout adolescence and perhaps indefinitely. Performance may deteriorate after the diet is discontinued.

The genotypically normal offspring of an untreated mother may have microcephaly and irreversible brain injury as well as cardiac defects. Scrupulous monitoring of dietary phenylalanine intake in these women has improved outcome [24].

Rarely, phenylketonuria results from a defect in the metabolism of biopterin, a cofactor for the phenylalanine hydroxylase pathway. The electron donor for phenylalanine hydroxylase is tetrahydrobiopterin (BH4), which transfers electrons to molecular oxygen to form tyrosine and dihydrobiopterin (QH2; Fig. 40-2; reaction 2). BH_4 is regenerated from QH_2 in an NADH-dependent reaction that is catalyzed by dihydropteridine reductase (DHPR), which is widely distributed. In the brain, this enzyme and BH4 also are involved in hydroxylation of tyrosine and tryptophan (Chs 12 and 13). Human DHPR has been mapped to human chromosome 4p15.1–p16.1. The coding sequence shows little homology to other reductases, e.g. dihydrofolate reductase.

In rare instances, PKU is caused by defects in the metabolism of BH4, which is synthesized from GTP via sepiapterin (Fig. 40-2; reactions 3 and 4) [25]. Even careful phenylalanine restriction fails to avert progressive neurological deterioration because patients are unable to hydroxylate tyrosine or tryptophan, the synthesis of which also requires tetrahydrobiopterin. Thus, neurotransmitters are not produced in sufficient amount.

Patients sustain convulsions and neurological deterioration. The urine contains low levels of the metabolites of serotonin, norepinephrine and dopamine. The reductase also plays a role in the maintenance of tetrahydrofolate levels in brain, and some patients have had low folate levels in the serum and CNS. Treatment has been attempted with tryptophan and carbidopa to improve serotonin homeostasis and with folinic acid to replete diminished stores of reduced folic acid. This therapy is sometimes effective. Diagnosis involves assay of DHPR in skin fibroblasts or amniotic cells. Phenylalanine hydroxylase activity is normal.

Other causes of PKU secondary to defective tetrahydrobiopterin synthesis include GTP cyclohydrolase deficiency and 6-pyruvoyltetrahydrobiopterin synthase deficiency. Patients with either defect have psychomotor retardation, truncal hypotonia with limb hypertonia, seizures and a tendency to hyperthermia. The intravenous administration of BH4 may lower blood phenylalanine levels but this cofactor may not readily cross the blood–brain barrier. Treatment with synthetic pterin analogs or supplementation with tryptophan and carbidopa may prove more efficacious, particularly if treatment is started early in life.

DISORDERS OF GLYCINE METABOLISM: NONKETOTIC HYPERGLYCINEMIA

Nonketotic hyperglycinemia results from the congenital absence of the glycine cleavage system, which mediates the interconversion of glycine and serine. Glycine catabolism proceeds primarily via the glycine cleavage system, a mitochondrial system that interconverts glycine and serine (Fig. 40-3; reaction 1). Pyridoxal phosphate and tetrahydrofolate are cofactors. This reaction also provides precursor to the 'one-carbon pool' of folic acid intermediates that are pivotal to many synthetic reactions [26].

Nonketotic hyperglycinemia causes a severe seizure disorder and profound brain damage. Infants affected by deficiency of the glycine cleavage system become ill with seizures by the first or second day of life.

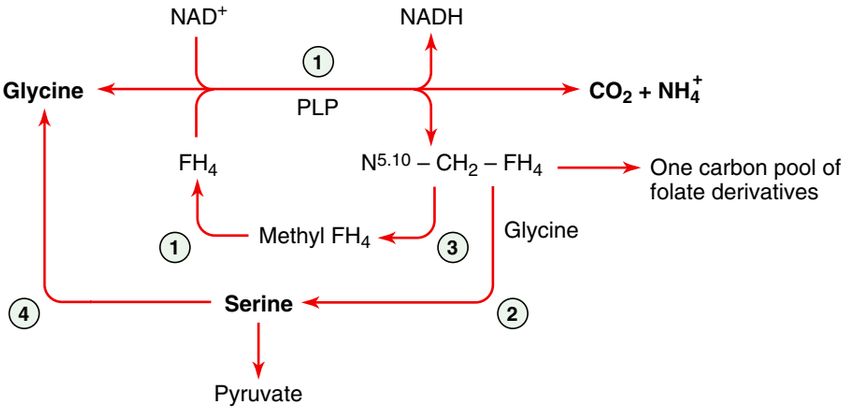

FIGURE 40-3 Glycine cleavage system and some related reactions. Glycine and serine are readily interchangeable. Enzymes: (1) Glycine cleavage system; (2) and (4) Serine hydroxymethyltransferase; (3) $N^{5,10}$-methylenetetrahydrolate reductase. *$N^{5,10}$-CH_2-FH_4*, $N^{5,10}$-methylenetetrahydrolate; *FH_4*, tetrahydrofolic acid.

Intrauterine seizures may occur. The electroencephalogram often displays a hypsarrhythmia or a burst-suppression pattern. Patients display myoclonic jerks, hiccuping and a profound hypotonia. The few patients who survive past the first week usually sustain profound mental retardation and neurological disability. Brain imaging shows atrophy and a loss of myelin. Rarely, patients present later in life with psychomotor retardation and growth failure. Others have had initial normal development followed by a progressive loss of developmental milestones. Some patients have manifested spinocerebellar degeneration and other symptoms of motor dysfunction [27].

In nonketotic hyperglycinemia, glycine is extremely high in the blood, often rising to >1 mmol/l (normal = 150–350 mmol/l). The concentration in the cerebrospinal fluid almost always exceeds 100 µmol/l (normal ≈10 µmol/l). The cerebrospinal fluid (CSF):blood ratio of glycine usually is five to ten times the control value (0.02), especially with the classical form of the disease. A transient form of nonketotic hyperglycinemia, probably reflecting delayed maturation of the glycine cleavage system, has been described in neonates with seizures but an otherwise normal neurological examination. The seizures ceased by 8 weeks of age and did not recur. Glycine concentrations of both the blood and the CSF were high. Urine organic acid analysis was normal. Prognosis is favorable in this situation.

Treatment for nonketotic hyperglycinemia is less effective than that available for other aminoacidurias. There is no specific therapy. Exchange transfusion and dialysis usually do not alter the progressive neurological deterioration. Sodium benzoate has been administered in the hope that glycine would react with it to form hippuric acid, but this approach is not helpful. It may be that a combination of benzoate and carnitine therapy is more effective [28]. Similarly, the restriction of dietary protein and the administration of pyridoxine or choline have not proved useful.

Glycine is a neurotransmitter, having a postsynaptic inhibitory activity in the spinal cord and in some central neurons (Ch. 16). Therapy with strychnine, which blocks the action of glycine at postsynaptic inhibitory receptors, has been unhelpful. Treatment with diazepam has been attempted because this drug displaces strychnine from its binding sites. The combination of benzoate and diazepam may be more effective, since high doses of the former reduce glycine levels in the CNS, thereby potentiating the ability of strychnine to block the glycine effect.

A few infants have been treated with antagonists of the NMDA receptor, an excitatory glutamatergic receptor for which glycine is a co-agonist (see Ch. 15) [29]. Ketamine and dextromethorphan have been used with inconclusive results. Some infants may have had an improvement of their irritability and electroencephalogram. One infant, treated with both benzoate and dextromethorphan, was seizure-free by 12 months of age and had only moderately delayed development. However, this favorable experience has not always been duplicated. Treatment with dextromethorphan at the recommended dosage (maximum 5 mg/kg/day) seems to be well-tolerated.

DISORDERS OF SULFUR AMINO ACID METABOLISM: HOMOCYSTINURIA

The transsulfuration pathway is the major route for the metabolism of the sulfur-containing amino acids. The transsulfuration pathway (Fig. 40-4) entails the transfer of the sulfur atom of methionine to serine to yield cysteine. The first step is activation of methionine, which reacts with ATP to form *S*-adenosylmethionine (Fig. 40-4; reaction 1). This compound is a key methyl donor and plays a prominent role in the synthesis of several

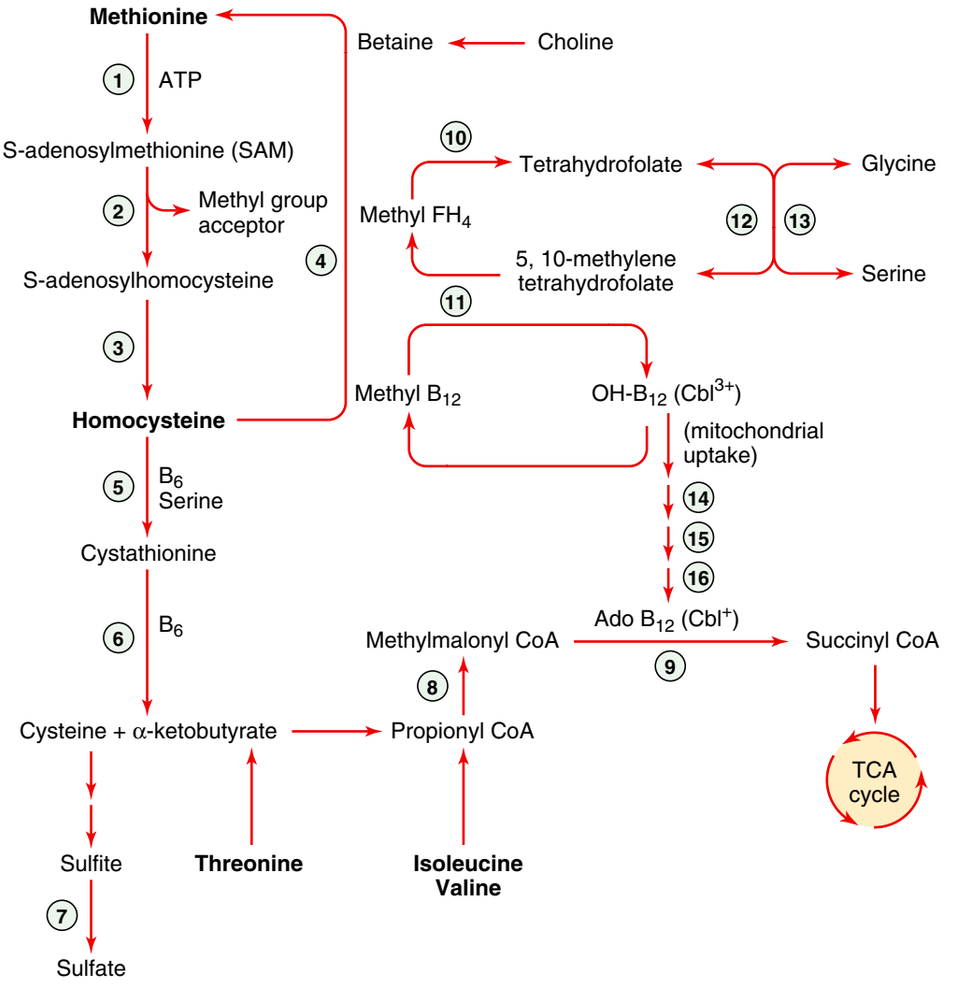

FIGURE 40-4 The transsulfuration pathway and related metabolic routes. Homocystinuria usually is caused by a congenital deficiency of cystathionine-β-synthase (reaction 5). Sometimes homocystinuria is caused by a failure of the remethylation of homocysteine. This may occur because of a failure to generate methylfolate or methylcobalamin. If there is a generalized failure of cobalamin activation or absorption, methylmalonic aciduria as well as homocystinuria may result because cobalamin derivatives are essential to both pathways. Enzymes: (1) Methionine-activating enzyme; (2) Generic depiction of methyl group transfer from *S*-adenosylmethionine; (3) *S*-adenosylhomocysteine hydrolase; (4) Homocysteine: methionine methyltransferase; (5) Cystathionine-β-synthase; (6) Cystathionase; (7) Sulfite oxidase; (8) Propionyl-CoA carboxylase; (9) Methylmalonyl-CoA mutase; (10) Homocysteine:methionine methyltransferase (essentially same as reaction 4, in which methyltetrahydrofolate is the methyl donor); (11) $N^{5,10}$-methylenetetrahydrolate reductase; (12) and (13) Glycine cleavage system; (14) and (15) Hydroxocobalamin reductases; (16) Cobalamin adenosyltransferase. *Ado-B_{12}*, adenosylcobalamin; *Methyl-B_{12}*, methylcobalamin; *OH-B_{12}*, hydroxocobalamin.

neurotransmitters and of creatine (Fig. 40-4; reaction 2). A portion of the carbon of spermidine and spermine is formed by decarboxylation of *S*-adenosylmethionine.

Transfer of a methyl group from *S*-adenosylmethionine yields *S*-adenosylhomocysteine, which potently inhibits several methyltransferases; this may partially explain the pathology of homocystinuria. Tissue levels of *S*-adenosylhomocysteine ordinarily are very low, since this metabolite is rapidly cleaved by a specific hydrolase to homocysteine and adenosine (Fig. 40-4; reaction 3).

About half of the homocysteine so generated is remethylated to methionine, with either betaine or 5-methyltetrahydrofolic acid (methyl-FH_4) serving as methyl donor. The enzyme mediating remethylation, 5-methyltetrahydrofolate-betaine methyltransferase (Fig. 40-4; reaction 4), utilizes methylcobalamin as a cofactor. The kinetics of the reaction favor remethylation. Faulty remethylation can occur secondary to: (1) dietary factors, e.g. vitamin B_{12} deficiency; (2) a congenital absence of the apoenzyme; (3) a congenital inability to convert folate or B_{12} to the methylated, metabolically active form (see below); or (4) the presence of a metabolic inhibitor, e.g. an antifolate agent that is used in an antineoplastic regimen.

The most common cause of homocystinuria is a congenital deficiency of cystathionine-β-synthase, a pyridoxine-dependent enzyme that condenses homocysteine and

serine to form cystathionine (Fig. 40-4; reaction 5). S-adenosylmethionine stimulates the forward reaction [30]. This enzyme has been mapped to human chromosome 21. The equilibrium favors cystathionine synthesis. Thus, homocysteine levels normally are very low, since both the remethylation pathway and the cystathionine synthetase route efficiently dispose of this amino acid.

Cleavage of cystathionine is accomplished by cystathionase, another pyridoxine-dependent enzyme that is coded on human chromosome 16 (Fig. 40-4; reaction 6). The enzyme functions almost entirely to produce cysteine, there being virtually no reversal of the reaction.

Homocystinuria is the result of the congenital absence of cystathionine synthase, a key enzyme of the transsulfuration pathway. A variety of mutations have been described, including the synthesis of an unstable enzyme, of a protein that loosely binds either pyridoxal phosphate, serine or homocysteine, or of an enzyme differing in size from the wild strain [31]. Cystathionine synthase is present in many organs, including the brain, and homocystinuric patients typically manifest deficient enzyme activity in these tissues. Blood homocysteine levels are elevated (50–200 μmol/l; normal <10 μmol/l) and the blood cysteine concentration tends to be low, reflecting the failure of cysteine synthesis. Increased remethylation of homocysteine that is not converted to cystathionine results in elevated blood methionine, often in excess of 200 μmol/l (normal = 20–40 μmol/l).

Homocystinuria can be treated in some cases by the administration of pyridoxine (vitamin B_6), which is a cofactor for the cystathionine synthase reaction. Some patients respond to the administration of pharmacological doses of pyridoxine (25–100 mg daily) with a reduction of plasma homocysteine and methionine. Pyridoxine responsiveness appears to be hereditary, with sibs tending to show a concordant pattern and a milder clinical syndrome. Pyridoxine sensitivity can be documented by enzyme assay in skin fibroblasts. The precise biochemical mechanism of the pyridoxine effect is not well understood but it may not reflect a mutation resulting in diminished affinity of the enzyme for cofactor, because even high concentrations of pyridoxal phosphate do not restore mutant enzyme activity to a control level.

About half of individuals who do not respond to pyridoxine will sustain *ectopia lentis* by age 5–10 years. Indeed, the diagnosis commonly is made by an ophthalmologist. The median IQ score for B_6 responsive and nonresponsive patients is 78 and 56 respectively. Some children present at 1–2 years with psychomotor retardation, convulsions (≈20% of cases) and psychiatric difficulties such as depression and personality disorders (≈50% of cases).

Patients with homocystinuria are at risk for cerebrovascular and cardiovascular disease and thromboses. The most striking feature is a thromboembolic diathesis that can occur in virtually any vessel, with thrombi common in the cerebral, cardiac and renal vasculature. Almost 25% of pyridoxine nonresponders sustain a major vascular insult during childhood. The comparable risk in untreated pyridoxine-responsive subjects is 25% by age 20 years. Vascular insults sometimes occur in association with dehydration secondary to vomiting and diarrhea. The stress of major surgery and anesthesia increase the risk of thrombosis by ≈5%. Homocystinuric patients who also have the relatively common Leiden mutation of clotting factor V are at sharply increased risk for developing a thrombosis [32].

Patients commonly manifest a marfanoid habitus with arachnodactyly, high-arched palate, tall stature and pes cavus. Bony abnormalities are common, with osteoporosis and scoliosis being frequent findings. The orthopedic features are more common and severe in patients who do not respond to pyridoxine treatment. Demyelination and spongy degeneration of the white matter have been reported. Frank infarctions are relatively common in virtually all parts of the brain. The arterial wall shows thickening of the intima and splitting of the smooth musculature of the media. The changes are not dissimilar to those of atherosclerosis.

The probable cause of the pathology is hyperhomocysteinemia rather than hypermethioninemia. The biochemical basis of homocysteine toxicity is the subject of intense scrutiny. Homocysteine increases the adhesiveness of platelets *in vitro*, perhaps by favoring the synthesis of selected thromboxanes. The administration of homocysteine to rats or baboons can cause endothelial injury. Homocysteine may diminish the mean survival time of peripheral blood platelets, possibly by a direct toxic effect on the vascular endothelium, which becomes denuded and thereby provides an atherogenic nidus. A direct effect of homocysteine on the blood clotting cascade also is possible. Thus, activation of factor V in cultured endothelial cells has been noted. This favors the conversion of prothrombin to thrombin. Homocysteine also promotes accumulation of copper in the vascular endothelium. This induces the oxidation of ceruloplasmin and the concomitant release of sufficient H_2O_2 to injure endothelial cells. Supplementation of the medium with catalase protects against such insult, thus confirming the role of oxidant injury.

High levels of homocysteine or one of its metabolites may directly affect brain function. The administration of homocysteine to rats induces grand mal convulsions, a phenomenon that is aggravated by either methionine or pyridoxine. Homocysteine-induced blockade of the γ-aminobutyric acid (GABA) receptor may be involved. In addition, brain can oxidize homocysteine to homocysteic acid, which has a glutamatergic activity.

A high intracerebral level of *S*-adenosylhomocysteine may inhibit methylation reactions involving *S*-adenosylmethionine. The metabolic repercussions would be extensive, including deficient methylation of proteins and of phosphatidylethanolamine as well as an inhibition of catechol-*O*-methyltransferase and histamine-*N*-methyltransferase.

Prognosis is more favorable in the pyridoxine-responsive patients. Patients who respond to large doses of vitamin B_6 (250–500 mg/day for several weeks) have the best prognosis. Efficacy of treatment usually is reflected in a reduction of blood homocystine and methionine to normal or near-normal levels. Since supplementation with pyridoxine can cause a deficiency of folic acid, the latter should be given (2–5 mg daily) at the same time. Any patient receiving pyridoxine should be monitored carefully for any signs of hepatotoxicity and for a peripheral neuropathy (see Ch. 36).

Management of the pyridoxine nonresponsive patient is difficult. Dietary restriction of methionine would seem logical, but this often is unpalatable, especially to an adult patient who has adapted to a diet that has not been purposefully restricted in protein.

A newer therapeutic approach is the administration of betaine (6–12 g daily), which lowers homocysteine levels by favoring remethylation [33]. A theoretical hazard of betaine treatment is increasing the blood methionine, sometimes to an extravagant degree (≈1 mmol/l). Experience to date indicates that betaine administration is safe, with no major side effects except for a 'fishy' odor to the urine. Other therapeutic approaches have included the administration of salicylate to ameliorate the thromboembolic diathesis. Patients also have been treated with dietary supplements of L-cystine, since the block of the transsulfuration pathway in theory could diminish the synthesis of this amino acid.

Homocystinuria can occur when homocysteine is not remethylated back to form methionine. This situation is termed 'remethylation deficiency homocystinuria'. In the form of *S*-adenosylmethionine, methionine is the major methyl donor for biosynthetic reactions in the brain. Most remethylation defects result from aberrant metabolism of methylfolate or methylcobalamin. Patients often present early in life with lethargy, poor feeding, psychomotor retardation and growth failure. Hematological abnormalities are common, including megaloblastosis, macrocytosis, thrombocytopenia and hypersegmentation of the leukocytes. Occasional patients present later, when seizures, dementia, hypotonia, mental retardation, spasticity or a myelopathy become evident.

Biochemical findings are variable. The blood cobalamin and folate levels often are normal. Patients often have homocysteinemia with hypomethioninemia, the latter finding discriminating this group from homocystinuria secondary to cystathionine-β-synthase deficiency. Urinary excretion of methylmalonic acid may be high, reflecting the fact that vitamin B_{12} serves as a cofactor for the methylmalonyl-CoA (coenzyme A) mutase reaction.

One form of remethylation deficit involves defective metabolism of folic acid, a key cofactor in the conversion of homocysteine to methionine. Methylenetetrahydrofolate reductase (Fig. 40-4; reaction 11) reduces $N^{5,10}$-methylenetetrahydrofolate to methyltetrahydrofolate in a reaction that is NADPH-dependent and inhibited by *S*-adenosylmethionine. In brain this enzyme also is important for the reduction of dihydropteridines (see Disorders of Phenylalanine Metabolism, above).

Patients typically present by 6–12 months with severe developmental retardation, convulsions, microcephaly and homocysteinemia (≈50 μmol/l) with hypomethioninemia (<20 μmol/l). A few individuals have had psychiatric disturbances. The blood concentration of vitamin B_{12} is normal, and, unlike individuals with defects of cobalamin metabolism, these patients manifest neither anemia nor methylmalonic aciduria. The blood folic acid level is usually low.

A thromboembolic diathesis is not unusual and strokes have been reported. Other pathological changes have included microgyri, demyelination, gliosis and brain atrophy. Lipid-laden macrophages have been described.

A relatively large number of agents have been utilized to treat this intractable disorder: folinic acid (5-formyltetrahydrofolic acid), folic acid, methyltetrahydrofolic acid, betaine, methionine, pyridoxine, cobalamin and carnitine. Betaine, which provides methyl groups to the betaine:homocysteine methyltransferase reaction, is a safe treatment that lowers blood homocysteine and increases methionine.

Methionine synthase deficiency (cobalamin-E disease) produces homocystinuria without methylmalonic aciduria. This enzyme mediates the transfer of a methyl group from methyltetrahydrofolate to homocysteine to yield methionine (Fig. 40-4; reaction 4). A cobalamin group bound to the enzyme is converted to methylcobalamin prior to formation of methionine.

In cobalamin-E (cblE) disease there is a failure of methyl-B_{12} to bind to methionine synthase. It is not known if this reflects a primary defect of methionine synthase or the absence of a separate enzyme activity. Patients manifest megaloblastic changes with a pancytopenia, homocystinuria and hypomethioninemia. There is no methylmalonic aciduria. Patients usually become clinically manifest during infancy with vomiting, developmental retardation and lethargy. They respond well to injections of hydroxocobalamin.

Cobalamin-c disease: remethylation of homocysteine to methionine also requires an 'activated' form of vitamin B_{12}. In the absence of normal B_{12} activation, homocystinuria results from a failure of normal vitamin B_{12} metabolism. Complementation analysis classifies defects in vitamin B_{12} metabolism into three groups: cblC (most common), cblD and cblF. Most individuals become ill in the first few months or weeks of life with hypotonia, lethargy and growth failure. Optic atrophy and retinal changes can occur. Methylmalonate excretion is excessive, but less than in methylmalonyl-CoA mutase deficiency, and without ketoaciduria or metabolic acidosis.

The fibroblasts do not convert cyanocobalamin or hydroxocobalamin to methylcobalamin or adenosylcobalamin, resulting in diminished activity of both N^5-methyltetrahydrofolate:homocysteine methyltransferase and methylmalonyl-CoA mutase. Supplementation with hydroxocobalamin rectifies the aberrant biochemistry. The precise nature of the underlying defect remains obscure. Diagnosis should be suspected in a child with homocystinuria, methylmalonic aciduria, megaloblastic anemia, hypomethioninemia and normal blood levels of folate and vitamin B_{12}. A definitive diagnosis requires demonstration of these abnormalities in fibroblasts. Prenatal diagnosis is possible.

Treatment involves the administration of large doses (as much as 1 mg) of intramuscular hydroxocobalamin. Administration of folate and betaine (see above) may be helpful, as is a reduction of protein intake.

Hereditary folate malabsorption presents with megaloblastic anemia, seizures and neurological deterioration. Levels of folate in both the blood and the cerebrospinal fluid have been very low. The anemia is correctable with injections of folate, or with the administration of large oral doses, but the concentration in the CSF is still low, suggesting that a distinct carrier system mediates folate uptake into the brain and that this system is the same as that facilitating intestinal transport.

THE UREA CYCLE DEFECTS

The urea cycle is essential for the detoxification of ammonia. The urea cycle (Fig. 40-5) converts ammonia to urea (10–20 g/day in the healthy adult). A urea cycle enzymopathy, whether associated with cirrhosis or an inherited metabolic defect, often causes a hyperammonemic encephalopathy and irreversible brain injury (see also Ch. 34).

The cycle 'begins' in hepatic mitochondria, where NH_3^-, HCO_3^- and ATP form carbamyl phosphate in a reaction catalyzed by carbamyl phosphate synthetase (CPS; Fig. 40-5; reaction 1). *N*-acetylglutamate (NAG), formed from glutamate and acetyl-CoA via *N*-acetylglutamate synthetase (Fig. 40-5; reaction 9), is an obligatory effector of CPS and an important regulator of ureagenesis. Various influences, including dietary protein, arginine and corticosteroids, augment the concentration of NAG.

Carbamyl phosphate condenses with ornithine to yield citrulline in the ornithine transcarbamylase (OTC) reaction. OTC is encoded on band p21.1 of the X chromosome, where the gene contains 8 exons and spans 85 kb of DNA. The activity of this enzyme is directly related to dietary protein. There may be 'tunneling' of ornithine transported from the cytosol to OTC, with the availability of intramitochondrial ornithine serving to regulate the reaction.

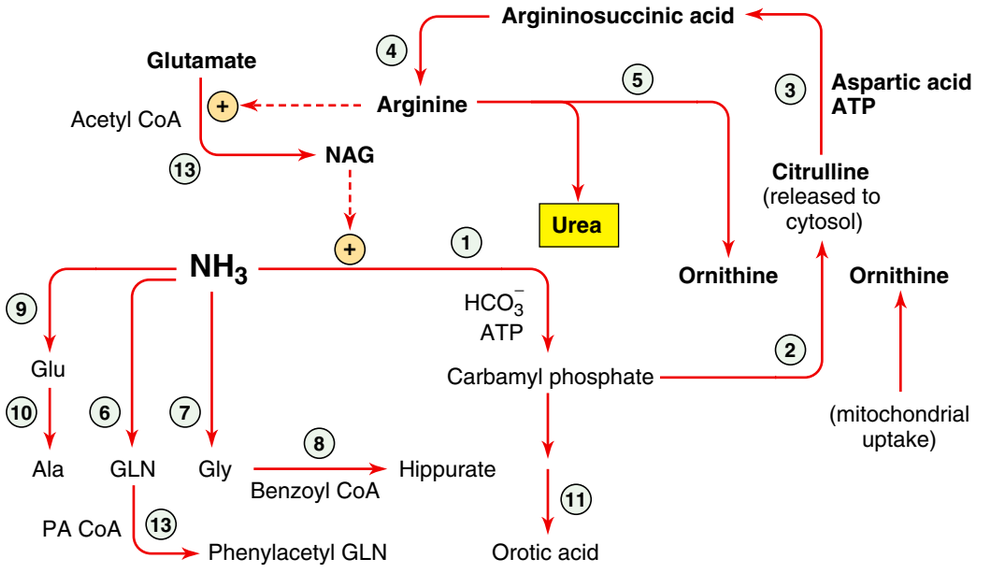

FIGURE 40-5 The urea cycle and related reactions of ammonia metabolism. Congenital hyperammonemia syndromes usually are caused by a deficiency of one of the enzymes of the urea cycle. Ammonia also can be metabolized to glutamate, alanine, glutamine and glycine. The administration of phenylacetate or of benzoate favors the formation of phenylacetylglutamine and hippurate, respectively, thereby providing an effective 'antidote' to ammonia toxicity. Enzymes: (1) Carbamyl phosphate synthetase; (2) Ornithine transcarbamylase; (3) Argininosuccinate synthetase; (4) Argininosuccinate lyase; (5) Arginase; (6) Glutamine synthetase; (7) Glycine cleavage system; (8) Glycine-*N*-acylase; (9) Glutamate dehydrogenase; (10) Alanine aminotransferase; (11) The cytosolic pathway of orotic acid synthesis (becomes prominent when there is a block at the level of reaction 2, thus resulting in increased orotic acid excretion); (12) N-acetylglutamate synthetase; (13) Phenylacetyl-CoA:glutamine transferase. *NAG*, *N*-acetylglutamate; *PA-CoA*, phenylacetyl-CoA. The + symbols denote that arginine and NAG are positive effectors for reactions 12 and 1 respectively.

In the hepatic cytosol, citrulline reacts with aspartate to form argininosuccinate, catalyzed by argininosuccinate synthetase (AS; Fig. 40-5; reaction 3). The mRNA for this enzyme is increased by starvation, corticosteroids or cyclic-AMP. Citrulline itself potently induces the mRNA.

Argininosuccinate lyase (AL) (Fig. 40-5; reaction 4) cleaves argininosuccinate to form fumarate, which is oxidized in the tricarboxylic acid cycle, and arginine, which is hydrolyzed to urea and ornithine via hepatic arginase. Both AL and arginase are induced by starvation, dibutyryl cyclic-AMP and corticosteroids.

Urea cycle defects cause a variety of clinical syndromes, including a metabolic crisis in the newborn infant. Severe urea cycle defects become manifest in infants with a severe syndrome of coma, convulsions and vomiting during the first few days of life. Clinical confusion with septicemia is common, and many infants are treated futilely with antibiotics. Hyperammonemia is usually severe, even in excess of 1 mmol/l (normal in term infants <100 μmol/l).

Diagnosis usually is made from the blood aminogram. The plasma concentrations of glutamine and alanine, the major nitrogen-carrying amino acids, are usually high and that of arginine is low. Patients with citrullinemia (deficiency of AS) or argininosuccinic aciduria (deficiency of AL) will manifest marked increases of the blood citrulline and argininosuccinate respectively.

Urinary orotic acid generally is very elevated in babies with OTC deficiency and normal or even low in the infant with CPS deficiency. Patients with OTC deficiency have orotic aciduria because carbamyl phosphate spills into the cytoplasm, where it enters the pathway of pyrimidine synthesis.

Diagnosis of CPS or OTC deficiency may not be apparent from the blood aminogram. Ornithine levels typically are normal. The presence of hyperammonemia, hyperglutaminemia, hyperalaninemia and orotic aciduria in a critically ill infant affords presumptive evidence for OTC deficiency. The presence of this blood aminogram without orotic aciduria suggests carbamyl phosphate synthetase deficiency.

Diagnosis of a urea cycle defect in the older child can be elusive. Patients may present with psychomotor retardation, growth failure, vomiting, behavioral abnormalities, perceptual difficulties, recurrent cerebellar ataxia and headache. It is therefore essential to monitor the blood ammonia in any patient with unexplained neurological symptoms, but hyperammonemia is inconstant with partial enzymatic defects. Measurement of blood amino acids and urinary orotic acid is indicated.

Hyperammonemia also occurs in some organic aciduria, particularly those that affect neonates. Therefore, the urine organic acids should be quantitated in all patients with significant hyperammonemia.

Except for patients with argininosuccinic aciduria, who may demonstrate varying degrees of hepatic fibrosis, there is little pathological change outside of the central nervous system.

Carbamyl phosphate synthetase deficiency. Carbamyl phosphate synthetase deficiency is rare. Neonates quickly develop lethargy, hypothermia, vomiting and irritability. The hyperammonemia typically is severe, even exceeding 1 mmol/l. Occasional patients with a partial enzyme deficiency have had a relapsing syndrome of lethargy and irritability upon exposure to protein. Brain damage can occur in both neonatal and late-onset groups.

***N*-acetylglutamate synthetase deficiency.** A deficiency of CPS also can arise because of the congenital absence of NAG synthetase, which catalyzes the formation of NAG from glutamate and acetyl-CoA. NAG is an obligatory effector of CPS. The few patients reported have had a malignant course of neonatal onset.

Ornithine transcarbamylase deficiency. This is the most common of the urea cycle defects. Presentation is variable, ranging from a fulminant, fatal disorder of neonates to a schizophrenic-like illness in an otherwise healthy adult. Males characteristically fare more poorly than do females with this X-linked disorder because of random inactivation (lyonization) of the X chromosome. If inactivation affects primarily the X chromosome bearing the mutant OTC gene, then a more favorable outcome can be anticipated. Conversely, the 'unfavorably lyonized' female has a more active disease.

The study of restriction fragment length polymorphisms is important to diagnosis. More than 80% of carriers can be detected, and antenatal diagnosis often is possible. Approximately one-third of the mothers of males and two-thirds of the mothers of females have been found to be noncarriers, reflecting the greater propensity for mutation in the male gamete.

Diagnosis of carriers (85–90%) can be made with measurement of urinary orotic acid following protein loading or administration of allopurinol. Loading studies with [^{15}N]-NH_4Cl as metabolic tracer indicate that symptomatic female carriers for OTC produce less [^{15}N]-urea than a control population. Asymptomatic heterozygotes form urea at a normal rate but overproduce [5-^{15}N]-glutamine. Thus, whole body nitrogen metabolism is abnormal even in this group [34].

Animal models for OTC deficiency include the 'sparse fur' (*spf*) mouse (15% control enzyme activity) and the 'sparse fur–abnormal skin and hair' (*spf-ash*) mouse (5% of control). Both kinds of mutant mouse manifest hyperammonemia, orotic aciduria, growth failure and sparse fur.

OTC deficiency must be suspected in any patient, male or female, with unexplained neurological symptoms. The absence of hyperammonemia should not rule out the diagnosis, especially with a history of protein intolerance, a suggestive family history or an untoward reaction

to infections. The blood amino acids and urinary orotic acid should be quantified in such individuals.

Citrullinemia. Neonates with AS deficiency usually die, and most survivors suffer major brain injury. Patients with a partial deficiency may have a milder course, and a few individuals with citrullinemia have been phenotypically normal. The diagnosis usually is apparent from the hyperammonemia and the extreme hypercitrullinemia. The activity of AS can be determined in both fibroblasts and chorionic villus samples, thus simplifying the problem of antenatal diagnosis.

Argininosuccinic aciduria. Patients manifest high levels of argininosuccinate in urine, blood and cerebrospinal fluid. Neonates have a stormy clinical course. Almost all have died or sustained severe brain injury. A peculiar finding is *trichorrhexis nodosa*, or dry brittle hair with nodular protrusions that are best visible with light microscopy. The precise cause is unknown.

Arginase deficiency. Most patients are thought to have psychomotor retardation during the first year of life, but the dominant presentation is a leukodystrophy with progressive spastic tetraplegia, especially in the lower extremities. Seizures and growth failure may occur, although some patients are of normal size. The motor dysfunction usually comes to clinical attention by age 2–3 years. Hyperammonemia is less severe than in neonatal-onset disorders. Plasma arginine is usually two to five times normal. Urine orotate is high, perhaps because arginine stimulates flux through the CPS reaction by favoring the synthesis of *N*-acetylglutamate.

Urea cycle defects sometimes result from the congenital absence of a transporter for an enzyme or amino acid involved in the urea cycle.

Hyperornithinemia, hyperammonemia, homocitrullinuria. Affected neonates commonly suffer growth failure and varying degrees of mental retardation. Sometimes symptoms are deferred until adulthood. Vomiting, lethargy and hypotonia are noted after protein ingestion. Recurrent hospitalizations for hyperammonemia are the rule. Some patients have manifested a bleeding diathesis and hepatomegaly. Electron microscopy of the liver has shown irregularities of mitochondrial shape.

The underlying biochemical defect is a failure of mitochondrial uptake of ornithine. This results in a failure of citrulline synthesis and a consequent hyperammonemia. Urinary orotic acid is high, presumably because of underutilization of carbamyl phosphate. In contrast, excretion of creatine is low, reflecting the inhibition of glycine transamidinase by excessive levels of ornithine.

Lysinuric protein intolerance. Infants manifest growth failure, hepatosplenomegaly, vomiting, hypotonia, recurrent lethargy, coma, abdominal pain and, in rare instances, psychosis. Rarefaction of the bones is common, and both fractures and vertebral compression have been reported. Most patients are not mentally retarded. Patients have died with interstitial pneumonia, which may respond to corticosteroid therapy.

The cause is defective transport of dibasic amino acids by the proximal tubule and intestine. The transport defect occurs at the basolateral rather than the luminal membrane. Hyperammonemia reflects a deficiency of intramitochondrial ornithine. An effective treatment is oral citrulline supplementation, which corrects the hyperammonemia by allowing replenishment of the mitochondrial pool of ornithine.

Successful management of urea cycle defects involves a low-protein diet to minimize ammonia production as well as medications that enable the excretion of ammonia nitrogen in forms other than urea. Protein restriction is the mainstay of therapy. In patients with severe disease, tolerance for dietary protein may be so limited that it is not possible to support growth.

Treatment with sodium benzoate and sodium phenylacetate represents an important therapeutic advance. Benzoyl-CoA reacts in the liver with glycine to form hippurate and phenylacetyl-CoA reacts with glutamine to yield phenylacetylglutamine, thereby allowing waste nitrogen elimination not as urea but as conjugates of benzoate and phenylacetate [35–37]. The clinical utility of phenylacetate is limited by its objectionable odor. Sodium phenylbutyrate, which is less malodorous and is converted to phenylacetate, has been used with success. Acylation therapy has greatly improved survival and morbidity. Thus, the outlook for female heterozygotes with OTC deficiency is favorable for those who are treated from an early age [37].

Patients who survive the neonatal period can be maintained with a low-protein diet and sodium benzoate. A useful therapeutic adjunct for citrullinemia and argininosuccinic aciduria is dietary arginine supplementation, which enhances the ability to eliminate nitrogen as either citrulline or argininosuccinate. Maintaining normal arginine levels also facilitates protein synthesis.

Liver transplantation has been employed, but the long-term utility is uncertain. Transplantation affords metabolic correction, although relatively minor deviations of amino acid concentration may persist postoperatively. The morbidity of organ transplantation restricts the utility of this approach.

Dialysis, including hemodialysis and peritoneal dialysis, relieves acute toxicity during fulminant hyperammonemia. Exchange transfusions also have been performed, but this technique has not been equally useful in removing ammonia.

The possibility of gene therapy for these disorders is a subject of intense scrutiny [38]. An adenoviral vector containing a cDNA for the OTC gene has been given to mice with a congenital deficiency of OTC. The result was

complete correction of hepatic OTC activity over a 2-month period. Transient correction of serum glutamine and urine orotic acid was reported. This experimental approach holds enormous promise for the management of this enzymopathy and other inborn errors of intermediary metabolism.

DISORDERS OF GLUTATHIONE METABOLISM

The tripeptide glutathione is the major intracellular antioxidant. The tripeptide glutathione (γ-glutamyl-cysteinyl-glycine) is the major intracellular antioxidant. It is synthesized via these reactions (Fig. 40-6):

1. Glutamate + cysteine + ATP → γ-glutamylcysteine + ADP + P_i
2. γ-glutamylcysteine + glycine + ATP → glutathione + ADP + P_i

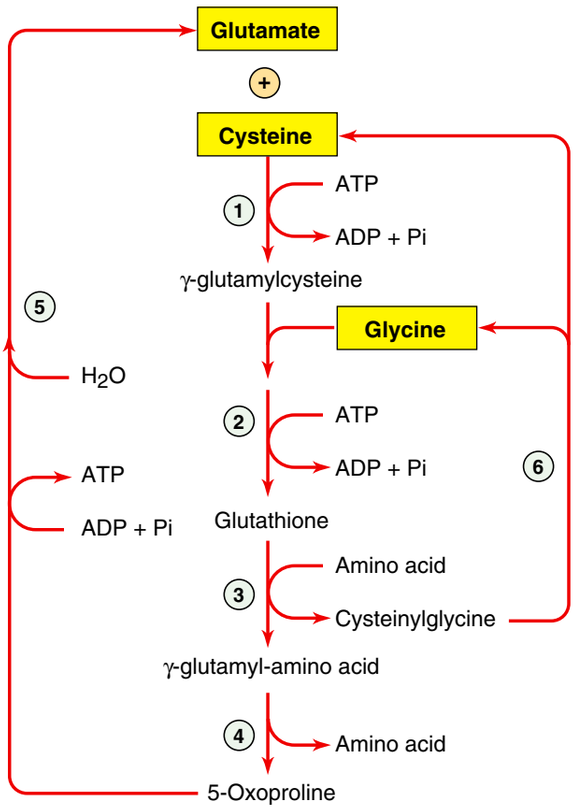

FIGURE 40-6 Metabolism of glutathione. Deficiency in reaction 2 leads to severe metabolic acidosis caused by excessive formation of 5-oxoproline from γ-glutamylcysteine in reaction 4. Deficiencies in reactions 1 and 3 also have neurological effects. Deficiencies in reaction 5 are known, but these patients have no significant neurological symptoms. Enzymes: (1) γ-glutamylcysteine synthetase; (2) Glutathione synthetase; (3) γ-glutamyltranspeptidase; (4) Cyclotransferase; (5) 5-oxoprolinase; (6) Peptidase.

Glutathione is subsequently metabolized in the γ-glutamyl cycle:

3. Glutathione + amino acid → γ-glutamyl-amino acid + cysteinylglycine
4. γ-glutamyl-amino acid → 5-oxoproline + amino acid
5. 5-oxoproline + ATP + $2H_2O$ → glutamate + ADP + P_i
6. Cysteinylglycine → cysteine + glycine.

The cycle is renewed after the cysteine formed in reaction 6 and the glutamate derived from reaction 6 are converted to γ-glutamylcysteine via γ-glutamylcysteine synthetase (reaction 1).

5-oxoprolinuria: glutathione synthetase deficiency. Patients have metabolic acidosis caused by excessive formation of 5-oxoproline (pyroglutamic acid; Fig. 40-6, reaction 2). This occurs because the diminution of intracellular glutathione relieves the feedback inhibition on the γ-glutamylcysteine synthetase pathway (reaction 1), thereby augmenting the concentration of γ-glutamylcysteine and the subsequent conversion of this dipeptide to cysteine and 5-oxoproline in the cyclotransferase pathway (reaction 4).

Clinical findings include mental retardation, severe metabolic acidosis, and evidence of a spastic quadriparesis and cerebellar disease. Some patients develop normally until late childhood, when a progressive loss of intellectual function became appreciated. Patients also may manifest a mild hemolysis. Pathological changes have included atrophy of the cerebellum and lesions in the cortex and thalamus. There is no specific therapy.

γ-glutamylcysteine synthetase deficiency. Patients with this rare disorder (Fig. 40-6, reaction 1) have spinocerebellar degeneration, peripheral neuropathy, myopathy and an aminoaciduria secondary to renal dysfunction. Psychosis and a hemolytic anemia have been noted.

γ-glutamyltranspeptidase deficiency. These patients display glutathionuria and varying degrees of mental retardation (Fig. 40-6, reaction 3). The enzyme is present in the brain, primarily in the capillaries. No specific treatment is available.

5-oxoprolinase deficiency. These patients excrete increased amounts of oxoproline and have a somewhat elevated plasma concentration (Fig. 40-6, reaction 5). They have not had significant neurological symptoms.

DISORDERS OF γ-AMINOBUTYRIC ACID METABOLISM

Congenital defects in the metabolism of γ-aminobutyric acid have been described. GABA is formed via the action of glutamate decarboxylase (see Ch. 16). Metabolism of this neurotransmitter is mediated first by uptake into

neurons and glia and subsequent transamination to succinic semialdehyde via γ-aminobutyric acid transaminase (GABA-T). The semialdehyde is oxidized to succinate via succinic semialdehyde dehydrogenase.

Pyridoxine dependency. Pyridoxine dependency is characterized by severe seizure activity of early onset, perhaps even *in utero*. Patients respond dramatically to parenteral administration of pyridoxine (10–100 mg). Speculation has centered on the possibility that the disease involves faulty binding of pyridoxine, a cofactor in the glutamate decarboxylase reaction, to the enzyme protein.

γ-aminobutyric acid transaminase deficiency. Patients with this rare disorder have severe psychomotor retardation and hyperreflexia. The concentrations of GABA and β-alanine are high in cerebrospinal fluid and blood. GABA-T activity is much diminished in blood lymphocytes and in the liver. A curious finding is increased stature, perhaps reflecting the ability of GABA to evoke release of growth hormone.

Succinic semialdehyde dehydrogenase deficiency. Patients have mental retardation, cerebellar disease, and hypotonia. They excrete large amounts of both succinic semialdehyde and 4-hydroxybutyric acid. There is no known therapy.

DISORDERS OF *N*-ACETYL ASPARTATE METABOLISM

Canavan's disease is the result of a deficiency of the enzyme that breaks down *N*-acetylaspartate, an important donor of acetyl groups for brain myelin synthesis. Infants seem normal at birth, but developmental delay is apparent by 3 months. Increased head circumference (>98th percentile) is common, and hydrocephalus sometimes is suspected. Neurological function deteriorates rapidly over a period of months. Optic atrophy leads to blindness. Infants manifest minimal interest in their environment. Spasticity is frequent and seizures may occur. Imaging of the brain shows demyelination and brain atrophy with enlargement of the ventricles and widening of the sulci. Pathological examination shows swelling of the astrocytes with elongation of the mitochondria. Vacuoles appear in the myelin sheets.

Urinary excretion of *N*-acetylaspartate is elevated and the cerebrospinal fluid concentration may be 50 times control values. The cause is a deficiency of aspartoacylase, which cleaves *N*-acetylaspartate to form aspartate and acetyl-CoA. The enzyme occurs primarily in the white matter, but *N*-acetylaspartate is most abundant in gray matter. The defect is expressed in skin fibroblasts.

N-acetylaspartate is among the most abundant amino acids in the brain, although its precise function remains elusive. Putative roles have included osmoregulation and the storage of acetyl groups that subsequently are utilized for myelin synthesis. The relationship of the enzyme defect to the clinical findings remains problematic. No specific therapy is yet available.

PATHOGENESIS OF LYSOSOMAL AND PEROXISOMAL DISORDERS 692

THERAPY OF LYSOSOMAL AND PEROXISOMAL DISORDERS 693

The past decade has witnessed a dramatic transition in studies of lysosomal and peroxisomal disorders, from a focus on gene products to the gene themselves. For most of these genetic disorders, the normal cDNAs and the genes responsible for the respective disorders have been isolated and characterized and, in many instances, specific disease-causing mutations have been identified. As expected, information at the genetic level demonstrates the highly complex genetic heterogeneity of these diseases, even when they appear homogeneous in clinical manifestations, analytical biochemistry and enzymatic defects. Detailed description of these disorders are found in the standard reference volume [1].

LYSOSOMAL DISEASES

The lysosome is the subcellular organelle responsible for physiological turnover of cellular constituents. Their combined incidence is estimated to be 1:8,000 [2]. Knowledge about the molecular and cellular defects has advanced a great deal in recent years. Platt and Walkley [3] have proposed a new classification based on the nature of the molecular defects (Table 41-1). This system will be used here.

Primary lysosomal hydrolase defects. Two-thirds of the lysosomal storage diseases involve defects in genes that code for acid hydrolases. Table 41-2 lists 29 defects that have been defined so far. They have an autosomal recessive mode of inheritance, except for Hunter's syndrome and Fabry's disease, where the mode is X-linked recessive. The defective genes have been identified and mutations have been defined for nearly all. The nervous system is involved in most. Many of the disorders show a wide range of clinical severity, which may range from death in early childhood to a moderate disability in adulthood.

Farber's disease is a rare disorder caused by deficiency of acid ceramidase and is associated with the accumulation of ceramide in subcutaneous tissues, joints, kidney, lung and neurons. Gangliosides also accumulate.

There are three allelic types of **Gaucher's disease**, all caused by deficiency of glucosylceramidase. The non-neuropathic type 1 is most common. The nervous system is not involved. Age of onset varies widely and it may not manifest until adulthood. Glucosylceramide is present in excess in the greatly enlarged liver and spleen and in the bone marrow, where it leads to anemia, thrombocytopenia and skeletal changes. In type II the nervous system is severely and progressively and this leads to death in early childhood. Type III is intermediate with nervous system abnormalities developing in adolescence. The accumulation of a toxic metabolite, glucosylsphingosine, may play

TABLE 41-1 Lysosomal storage diseases classified on basis of molecular defects

1.	Primary lysosomal hydrolase defect	$n = 29$
2.	Post-translational processing defect	$n = 1$
3.	Trafficking defect of lysosomal enzymes	$n = 3$
4.	Defect in lysosomal enzyme protection	$n = 1$
5.	Defect in soluble non-enzymatic proteins	$n = 4$
6.	Transmembrane (non-enzyme) protein defect	$n = 8$

TABLE 41-2 Primary lysosomal hydrolase defects

No. and name of disorder	Enzyme defect	Substrate
1. Farber's disease (lipogranulomatosis)	Acid ceramidase	Ceramide
2. Gaucher's disease	Glucosylceramidase	Glucosylceramide Galactosylceramide
3. Globoid cell leukodystrophy (Krabbe's disease)	Galactosylceramidase Galactosylsphingosine	Galactosylceramide
4. Metachromatic leukodystrophy	Sulfatide	Arylsulfatase A ('sulfatidase')
5. G_{M1}-gangliosidosis, Morquio B	G_{M1}-ganglioside galactose-rich fragments of glycoproteins	G_{M1} ganglioside Keratan sulfate
6. Tay–Sachs disease	G_{M2}-ganglioside	Hexosaminidase A
7. Sandhoff's disease	G_{M2}-ganglioside asialo-G_{M2}-ganglioside, globoside	Hexosaminidases A and B
8. Niemann–Pick A and B	Sphingomyelin	Acid sphingomyelinase
9. Fabry's disease	α-galactosidase (trihexoceramidase)	Trihexosylceramide (gal-gal-glc-cer digalactosylceramide)
10. Hurler's syndrome MPS1H Scheie's syndrome MPS1S	Alpha-iduronidase	Dermatan sulfate Heparan sulfate
11. Hunter's syndrome MPS 11	Iduronate sulfatase	Dermatan sulfate Heparan sulfate
12. Sanfilippo A MPS IIIA	Heparan-*N* sulfatase	Heparan sulfate
13. Sanfilippo B MPS IIIB	*N*-acetyl-glucosaminidase	Heparan sulfate
14. Sanfilippo C MPS IIIC	Acetyl CoA glucosamine N-acetyl transferase	Heparan sulfate
15. Sanfilippo D MPS IIID	*N*-acetyl-glucosamine 6-sulfatase	Heparan sulfate
16. Morquio A MPS IVA	*N*-acetyl-galactosamine 6-sulfatase	Keratan sulfate
17. Maroteaux–Lamy MPS VI	*N*-acetyl-galactosamine-4-sulfatase	Dermatan sulfate
18. Sly syndrome MPS VII	β-glucuronidase	Heparan sulfate Dermatan sulfate
19. Hyaluronidase deficiency	Hyaluronidase	Hyaluronic acid
20. Fucosidosis	Fucosidase	Fucoside glycolipids
21. α-mannosidosis	α-mannosidase	α-mannosides
22. β-mannosidosis	β-mannosidase	β-mannosides
23. Aspartylglucoaminuria	Aspartyl-glucosaminidase	Aspartyl-glucosamine
24. Schindler's disease	α-galactosidase-B	*N*-acetyl-galactosamide glycolipids
25. Sialidosis; mucolipidosis I	α-neuraminidase	Sialic acid
26. Pompe's disease	α-glucosidase	Glycogen
27. Wolman's disease Cholesterol ester storage disease	Acid lipase	Cholesterol ester
28. Infantile neuronal ceroid lipofuscinosis CNL1	Palmitoyl protein thioesterase	Saposins
29. Late infantile neuronal lipofuscinosis (*CNL2*)	Carboxypeptidase	Subunit C mitochondrial ATP synthase

an important role in the pathogenesis of Gaucher's disease. The gene for glucosylceramidase has been cloned and characterized and many mutations responsible for the disease have been characterized. The most common N370S mutation has never been found in association with a neuropathic phenotype, either alone or in association with another mutation.

Globoid leukodystrophy (Krabbe's disease) is caused by a defect in galactocerebrosidase. 85–90% present with the infantile form before 6 months of age with general irritability, stiffness, arrest of mental and motor development, progressing to a decerebrate state with no voluntary movements. The main histopathological change is extensive demyelination and gliosis with the presence of characteristic globoid cells. The latter can be induced experimentally by injection of galactocerebroside. Biochemically there is accumulation not only of galactocerebroside but also of psychosine (galactosylsphingosine). Psychosine is a substrate for galactocerebrosidase. Even small accumulations of psychosine are toxic. The defective gene maps to 14q31. The 502T/del in which there is a 30 kb deletion is present in 40–50% of patients, is associated with the severe infantile form.

Metachromatic leukodystrophy is due to a defect in arylsulfatase A (ASA). There are three major forms: late infantile, juvenile and adult. The overall incidence is 1:40,000. In the late infantile and early juvenile forms, which comprise about 80% of patients, the initial symptoms involve the motor system, with falls, loss of ability to walk, flaccid paralysis, difficulty in swallowing, loss of speech, vision, seizures, decerebrate state and death 1–7 years after onset of symptoms. In the adolescent and

adult forms, which account for about 20% of cases, the initial symptoms are behavioral disturbances that may resemble a psychosis and dementia. The main biochemical abnormality is the accumulation of sulfatide in brain, peripheral nerve, kidney and gall bladder. In the brain there is also an increase in the concentration of lysosulfatide, the deacylated form of sulfatide, and the cytotoxicity of this compound is believed to contribute to the demyelinative process in MLD. The ASA gene has been mapped to chromosome 22 distal to q13. More than 100 variations have been found in patients with MLD. The most common is a G-to-A transition that eliminates a donor splice site at the start of intron 2. This causes a loss of all enzyme activity and is associated with the severe early onset disease.

G_{M1} gangliosidosis and Morquio's disease type B (Morquio B) are both caused by defects of acid β-galactosidase. These apparently clinically distinct disorders represent extremes of phenotypic variations of the same genetic defect. G_{M1} gangliosidosis is subdivided into infantile, juvenile and adult forms. Patients with the infantile form present at about 6 months with hypotonia and retarded psychomotor development and have facial and skeletal abnormalities that may have been recognized at birth. The neurological deficits are progressive and resemble those in Tay–Sachs disease (see below). Morquio B is a primary skeletal disorder without neurological manifestations except those caused by bone deformity. The main and characteristic biochemical abnormality is the accumulation of ganglioside G_{M1} and of keratan sulfate. More than 20 disease-causing mutations have been identified. Demonstration of diminished β-galactosidase activity with the G_{M1} ganglioside or artificial chromogenic or fluorogenic substrates is the recommended diagnostic procedure.

Tay–Sachs disease is due to hexosaminidase-A deficiency and is associated with the accumulation of G_{M2} ganglioside. It is panethnic but occurs most frequently in the Ashkenazi Jewish population, where, prior to the use of genetic counseling and prenatal screening, 1 in 4,000 births were affected. The infantile form is most frequent. The affected child may startle easily in the newborn period, appear listless, fail to follow objects visually at 3–6 months, and lose previously gained milestones. After age 1 year the child becomes increasingly immobile, with seizures and decerebrate posturing. Death occurs usually by 4–5 years. The cherry-red macular spot, due to the accumulation of gangliosides in retinal neurons except in the fovea, is a striking and characteristic finding. Juvenile variants and adult variants occur more rarely. Pathological studies show severe cortical atrophy and ballooned neurons that contain concentrically arranged electron dense lamellar structures known as membranous cytoplasmic bodies. Tay–Sachs disease is due to deficiency of the α subunit of HexA. At least 100 alterations in its nucleotide sequence are now known. Screening for virtually known mutations of the HexA subunit can be accomplished by mass screening of serum or leukocyte samples for HexA activity at pH 4.5 at 50° or 55°C. HexB is relatively stable at that temperature, whereas HexA is inactivated after 3 minutes at that temperature. Heterozygote screening of at-risk populations combined with prenatal diagnosis has greatly reduced the incidence of Tay–Sachs disease.

Sandhoff's disease is due to a deficiency of the HexB gene. Clinical features are similar to those of Tay–Sachs disease. Late infantile, juvenile and adults variants have also been described.

Niemann–Pick disease types A and B are due to a deficiency of acid sphingomyelinase. This leads to the accumulation of sphingomyelin in many organs and tissues. Type A patients present in the first few months of life with greatly enlarged liver and spleen, hypotonia, muscular weakness and feeding difficulties. The clinical features in type B patients are more variable but differ strikingly from type A patients in that neurological function is generally normal.

Fabry's disease is caused by α-galactosidase A deficiency. It is an X-linked recessive panethnic disorder with an estimated incidence of 1:40,000. It manifests in childhood and adolescence. Recurring episodes of excruciatingly severe burning pain in the fingers and toes, referred to as acroparesthesias, are the most distressing symptom. Other manifestations are angiokeratomas and characteristic opacities in the cornea and lens. Progressive renal failure and ischemic strokes occur in adulthood. The mean age at death in untreated males is 41 years. One variant, which has been recognized only recently, is late-onset cardiac disease without the other manifestations. Approximately 50% of heterozygous women have a milder corneal dystrophy, acroparesthesias in middle age or later. A variety of glycosphingolipids with a terminal α-glycosphingolipids with a terminal α-galactosyl moiety accumulate, particularly in the lysosomes of the endothelial cells in small blood vessels.

Clinically the **mucopolysaccharidoses (MPS)** can be subdivided into four major categories. Hurler's, Hunter's and Scheie's syndromes present with coarse facial features, hepatosplenomegaly, corneal clouding, skeletal abnormalities and psychomotor retardation. Scheie's syndrome is a milder variant and may be associated with survival to adulthood and normal intellect. Hunter's syndrome resembles Hurler's, except that the cornea is not involved. In patients with Sanfilippo's syndrome, the facial coarsening, hepatosplenomegaly and skeletal abnormalities are less severe, but psychomotor retardation and behavioral disturbances are severe. Conversely, patients with Maroteaux–Lamy syndrome have severe somatic manifestations, but normal intellect. Morquio's syndrome is associated with severe skeletal abnormalities, different in pattern from those in Hurler's syndrome. Intellectual function remains intact.

Patients with **fucosidosis** present with hypotonia, progressive mental retardation and motor deficits and also angiokeratomas in the skin, which resemble those in Fabry's disease. **Mannosidosis** patients show dysmorphic features, hepatosplenomegaly and mental retardation.

Patients with **sialidosis** show a striking syndrome characterized by action myoclonus, cerebellar ataxia and a macular cherry red spot similar to that in Tay–Sachs disease but with preserved intellect.

Pompe's disease is of historical significance because it was the first lysosomal storage disorder to be recognized (H. G. Hers, 1963). The most common infantile form presents at or soon after birth and is characterized by massive deposition of glycogen, especially in heart, muscle and liver. Severe hypotonia and weakness are associated with massive cardiomegaly, hepatomegaly and macroglossia. Cardiac or respiratory failures cause death, usually before the first year and invariably before the second year. In the rarer childhood and adult forms there is progressive weakness of muscles and respiratory insufficiency due to diaphragmatic involvement without cardiomegaly.

The neuronal ceroid lipofuscinoses (CLN), also referred to as Batten's disease, are a group of disorders characterized by the accumulation of autofluorescent lipopigments. Clinical hallmarks include blindness, seizures, cognitive and motor decline and early death. Age of onset varies from infancy to adulthood. Eight genetic forms have been identified [4]. Two involve lysosomal acid hydrolases. CLN1 codes for palmitoyl protein thioesterase 1. Clinically it presents most often in infancy and leads to loss of active movement and visual contact by 3 years of age. It is most common in Finland, where its incidence is 1:20,000. CLN2 codes for a lysosomal pepstatin-insensitive acid protease.

Other types of lysosomal disorder. These are listed in Table 41-3.

TABLE 41-3 Other types of lysosomal disease

Disease type	Disorder
Post-translational processing defect	Multiple sulfatase deficiency
Trafficking defects of lysosomal enzymes	Mucolipidosis type II (I-cell disease) Mucolipidosis type IIIA (pseudo-Hurler's) Mucolipidosis type IIIB
Defect in lysosomal enzyme protection	Galactosialidosis
Defects in soluble non-enzymatic lysosomal proteins	Niemann–Pick disease C type 2 G_{M2} activator protein deficiency Sphingolipid activator protein deficiency Neuronal; ceroid lipofuscinosis (CNL5)
Transmembrane (non-enzyme) protein defect	Danon's disease (LAMP-2 deficiency) Niemann–Pick disease C type 1 Cystinosis Infantile free sialic storage disease Salla's disease (free sialic acid storage) Juvenile ceroid lipofuscinosis (CNL3) Neuronal ceroid lipofuscinosis (CNL5) Neuronal ceroid lipofuscinosis (CNL6 and CNL8) Mucolipidosis type IV (mucolipin deficiency)

Source: adapted from reference [3]

Multiple sulfatase deficiency (MSD). The clinical presentation of MSD includes features of MLD and the MPS, with the features that resemble MLD, such as gait disturbances, psychomotor retardation and polyneuropathy predominating. MPS-like features, such as facial coarsening, hepatosplenomegaly and joint stiffness, are present to a milder and variable extent. A reduction in the activity of all sulfatases is the key diagnostic abnormality. Von Figura and associates have demonstrated that catalytic activity of all sulfatases requires a post-translational modification in which a cysteine residue (cysteine 69 in arylsulfatase A) is oxidized to an aldehyde. It is this modification that is defective in MSD [5].

The term mucolipidosis (ML) was coined because of the combined storage of lipids and mucopolysaccharides in the tissues and cells of these patients. Four subtypes have now been characterized. All involve the lysosome; three of them have entirely different genetic defects. **Mucolipidosis 1** (sialidosis, neuraminidase deficiency) presents clinically with myoclonus and seizures and gait disturbances that begin in the second decade. Cognitive function is usually intact. Eye examinations show a macular cherry red spot that resembles that seen in Tay–Sachs disease. **Mucolipidosis II** is also referred to as I cell disease, because of the striking inclusions in cultured skin fibroblasts. Patients present in infancy or early childhood with coarse facial features, large liver and spleen, a large tongue, gingival hyperplasia, an enlarged heart and kyphoscoliosis. The biochemical abnormalities are characteristic and their definition by Hickman and Neufeld [6] added greatly to the understanding of lysosomal biology. The levels of lysosomal enzymes are increased in serum and urine but deficient in cultured skin fibroblasts. The enzymes lack the mannose-6-phosphate signal that targets lysosomal enzymes to the lysosome; therefore they are excreted. The mannose-6 phosphate is added to the lysosomal enzymes by UDP-*N* acetylglucosamine: *N*-acetylglucosaminyl-1 phosphotransferase, and it is the deficiency of this enzyme that represents the basic defect in I cell disease and also in mucolipidosis III. **Mucolipidosis III**, also referred to as pseudo-Hurler's polydystrophy, has the same enzymatic defect basis as I cell disease, but clinical features are milder. Clinical onset is between 2 and 4 years of age; patients may live to adulthood and mental function may be normal. Joint and bone involvement are the principal source of disability. **Mucolipidosis IV** presents clinically during the first 2–3 years with psychomotor retardation, corneal clouding, retinal degeneration and strabismus. Patients may then remain relatively stable for the first two or three decades. The defective gene codes for mucolipin-1, a membrane protein that is involved in endosome processing and transport. It is of interest that patients with MLIV also have constitutive achlorhydria, suggesting a specific defect cellular trafficking in the gastric parietal cell. 80% of patients are of Ashkenazy Jewish origin, and a population screening program has been started in Israel as a prevention strategy.

Niemann–Pick disease type C (NPC) patients with the classical phenotype present with progressive neurological disease in late infancy to adolescence, manifested by clumsy gait, ataxia, school failure, behavior problems and a characteristic supranuclear downward gaze paralysis. There are varying degrees of hepatosplenomegaly. Infantile and adult-onset variants exist. Neuronal inclusions are present throughout the nervous system. Unesterified cholesterol, sphingolipids and glycolipids are stored in excess. Impaired processing of endocytosed free cholesterol is the fundamental defect. NPC can be caused by two different molecular defects: NPC1 and NPC2. 95 families have the NPC1 defect. The NPC1 gene maps to 18q11–12. It has homology to other proteins that are involved in cholesterol homeostasis. It is postulated that NPC1 regulates or mediates the retrograde transport of multiple lysosomal cargo in the late endosomal/lysosomal pathway. NPC1 and NPC2 function cooperatively [7]. The biochemical diagnosis of NPC depends on the demonstration of a specific defect of cholesterol processing in cultured skin fibroblasts. Cholesterol-depleted normal and NPC fibroblasts are cultured with low density lipoproteins for 24 hours, and the amount of free cholesterol is assessed by the degree of filipin-fluorescent staining.

Galactosialidosis is characterized by the simultaneous deficiencies of β-galactosidase and α-neuroaminidase. Clinical and pathological manifestations resemble those in G_{M1} gangliosidosis and like it show a range of severity. The underlying defect involves a protective protein, which stabilizes these two enzymes by a mechanism that is not understood. Curiously, the protective protein is itself a peptidase. The disorder is most common in Japan. The defective gene has been cloned and mutations have been identified.

G_{M2} activator deficiency was identified in 1977 during the analysis of a patient with the Tay–Sachs disease phenotype and massive storage of ganglioside G_{M2} and glycolipid GA2 in the brain in spite of the presence of hexosaminidases A and B. This led to the purification of an activator protein that itself is not catalytically active. It is a lysosomal glycoprotein of 17.6 kDa in the deglysosylated form. It 'lifts' the membrane-bound G_{M2} ganglioside a few angstroms out of the membrane and thus makes it accessible to the degradative enzymes. The gene is located on chromosome 5 and five different mutations have been identified.

PEROXISOMAL DISORDERS

Peroxisomes are single-membrane, typically spherical, organelles ranging in size from 0.1–1 μm in diameter and numbering from a few hundred to a few thousand in mammalian cells [8]. The matrix contains 50 or more enzymes that participate in various metabolic pathways; particularly those involved in the β-oxidation of straight and 2-methyl branched very-long-chain and long-chain fatty acids and in the synthesis of ether lipids. H_2O_2 produced by many of the peroxisomal oxidases is detoxified *in situ* by peroxisomal catalase. The peroxisomal membrane contains a unique set of peroxisomal membrane proteins (PMPs) including four ATP binding cassette (ABC) transporters and several proteins required for importing peroxisomal matrix proteins. Synthesized on free cytosolic ribosomes, peroxisomal matrix proteins are targeted post-translationally to the organelle by specific cytosolic receptors that recognize *cis*-acting sequences (peroxisomal targeting signals, PTSs) in the primary peptide sequence. Most peroxisome matrix proteins are targeted by peroxisome targeting sequence 1 (PTS1), a C-terminal serine–lysine–leucine–COOH (SKL) or conservative variant thereof. A few matrix proteins, particularly those with ether lipid and branched chain fatty acid metabolism, are targeted by PTS2, a degenerate sequence (–R/KX_5Q/HL–). Like matrix proteins, the peroxisomal membrane proteins (PMPs) are synthesized on free cytosolic ribosomes and targeted to the organelle by *cis*-acting targeting sequences, which are long and have only been partially characterized. The number and matrix content of peroxisomes is dynamic and varies with the metabolic state of the organism, and is mediated by activation of peroxisome proliferator receptor α. An increase in peroxisome number is achieved by maturation, enlargement and division of pre-existing peroxisomes but *de novo* synthesis is possible. The human peroxisomal disorders are subdivided into two major categories: the disorders of peroxisome biogenesis, in which the organelle fails to be formed normally, and defects that involve a single peroxisomal protein.

Disorders of peroxisome biogenesis.

Molecular defects. Proteins necessary for peroxisome biogenesis are termed peroxins and the genes encoding these proteins are referred to as PEX genes. More than 30 peroxins have been identified. 13 genetically determined human disorders have been shown to be associated with defects in a peroxin and are referred to as peroxisome biogenesis disorders (PBDs) [8]. They are listed in Table 41-4. Three peroxins (PEX19, PEX16 and PEX3) involve the formation or import of peroxisomal membrane proteins. When they are defective, the organelle is not formed and the phenotype has been severe in all patients reported so far. All the 10 other defects involve peroxisomal matrix proteins, and membranous structures that contain PMP and varying amounts of peroxisomal matrix proteins ('peroxisome ghosts') can be demonstrated by cytoimmunological techniques. Two of the defects involve PTS receptors: PEX5 involves the PTS1 receptor and PEX7 the PTS2 receptor. Defects that involve PEX7 account for 20% of human PBD. PEX5 and PEX7 are present mainly in the cytosol, where interaction with the proteins that contain the targeting sequence takes place. The other eight peroxins that are associated with human disease states are involved in the docking and import processes and in the

TABLE 41-4 Peroxisome biogenesis disorder

Peroxin	Function	Phenotype	Frequency (%)
19	Peroxisome membrane formation and import	ZS	<1
16	Peroxisome membrane import	ZS	<1
3	Peroxisome membrane import	ZS	<1
5	PTS1 receptor	ZS, NALD	2
7	PTS2 receptor	RCDP1, 2	20
14	PEX5 docking, recycling	ZS, NALD	<1

6	Stabilizes *PEX5* Interacts with *PEX1*	ZS, NALD, IRD	8
26	Interacts with *PEX6*	ZS, NALD, IRD	4

See text and reference [9] for discussion.
IRD, infantile Refsum's disease; NALD, neonatal adrenoleukodystrophy; ZS, Zellweger's syndrome.

recycling of the receptor. PEX14 and PEX13 are required for docking, PEX2, PEX10 and PEX12 are thought to be involved with translocation into the matrix. PEX1, PEX6 and PEX26 are involved in the recycling of the receptors. PEX1 defects account for approximately 50% of human PBD.

Genotype–phenotype correlations. Most of the PBD were described and named before their relationship to the peroxisome was recognized. Re-evaluation of these clinical groupings has led to the conclusion that they fall into two major groups, the Zellweger spectrum and rhizomelic chondrodysplasia punctata (RCDP) [9, 10]. The Zellweger spectrum includes the classical Zellweger's syndrome, which was the first to be described, as well as neonatal adrenoleukodystrophy (NALD) and infantile Refsum's disease (IRD). They form a clinical continuum, with Zellweger's syndrome the most severe, IRD the least severe and NALD intermediate. Zellweger's syndrome patients present with characteristic dysmorphic features, hypotonia, severe psychomotor retardation, enlarged liver and spleen, impaired hearing and a characteristic defect in neuronal migration. Most patients also have seizures, cataracts, retinopathy renal cysts and chondrodysplasia punctata. Most patients die during the first 2 years. NALD and IRD patients are more mildly involved. Some survive to adulthood [11]. Patients with classical RCDP also have dysmorphic features different from those in Zellweger's syndrome, severe psychomotor delay, cataracts, impaired hearing, shortened limbs, chondrodysplasia punctata and coronal vertebral clefts. Clinically, the PBDs lead to malformations and dysfunction of many organs and tissues. Table 41-5 shows that the pattern of biochemical abnormalities of the Zellweger spectrum disorders is entirely

TABLE 41-5 Single peroxisomal protein deficiencies

Function	Disorder	Enzyme/protein defect	Phenotype
Fatty acid β-oxidation	X-ALD Acyl-CoA oxidase deficiency D-bifunctional protein deficiency Racemase deficiency	ALDP Acyl-CoA oxidase D-bifunctional Racemase	CNS childhood–adult adrenal insufficiency NALD-like Zellweger-spectrum-like Late onset neuropathy

ALDP, ; DHAP, dihydroxyacetone phosphate; DHAPAT, dihydroxyacetone phosphate acyltransferase; NALD, neonatal adrenoleukodystrophy; RCDP, rhizomelic chondrodysplasia punctata; X-ALD, X-linked adrenoleukodystrophy; ZS, Zellweger's syndrome.

distinct from RCDP. The clinical manifestations of 12 of the PBDs in which the gene defect has now been identified fall into the Zellweger spectrum. Only one, PEX7, is associated with the RCDP phenotype. In patients with *PEX7* defects the biochemical abnormalities involve phytanic acid and ether lipids. The metabolism of these substances involves enzymes that contain the PTS2 signal.

Table 41-4 shows that nine of the 12 Zellweger spectrum disorders show a considerable range of severity of clinical manifestations. Clinical and biochemical studies do not correlate with the type of gene defect. There is, however, considerable correlation between the severity of clinical manifestations and the degree to which a specific mutation compromises import function *in vitro.* For example in PEX1 deficiency, 75% of patients with the G843D allele, in which import is 15% retained, had the relatively mild IRD phenotype, compared to those with the C.2097insT, which abolishes import completely, where only 13% had the IRD phenotype. Such correlations also exist in patients with the PEX 7 defect [10].

Defects of single peroxisomal enzymes. **X-linked adrenoleukodystrophy (X-ALD)** is the most common peroxisomal disorder, with an estimated frequency of 1:17,000. *ABCD1*, the defective gene, maps to X-28 and codes for ALDP, a peroxisomal membrane protein that is a member of the ATP-binding cassette (ABC) transporter superfamily of proteins. More than 500 different mutations have been identified in X-ALD patients [12]. It is associated with the accumulation of saturated very-long-chain fatty acids (VLCFA) in the nervous system, adrenal cortex and Leydig cells in the testis, probably as a result of impaired capacity to oxidize these substances in the peroxisome. The pathogenesis of X-ALD and the function of ALDP is not yet understood. Most patients have primary adrenocortical insufficiency. There are two types of nervous system involvement. In the cerebral forms, which are most common in childhood, there is extensive demyelination associated with an intense inflammatory response. This manifests initially as a behavioral disturbance that resembles a hyperactivity-deficit disorder, but then progresses rapidly to severe neurological disability. In the adult form there is a noninflammatory distal axonopathy that affects the spinal cord most severely. It presents as slowly progressive paraparesis. The two different nervous system phenotypes often co-occur in members of the same family and do not correlate with the nature of the mutation. Search for modifier genes is in progress. Demonstration of abnormally high VLCFA in plasma is the most frequently used diagnostic technique.

Acyl-coenzyme (Co)A oxidase deficiency is a rare disorder that presents with progressive psychomotor and neurological deterioration and demyelination demonstrable by magnetic resonance imaging. Its clinical presentation and progression resembles that seen in NALD [13].

Bifunctional protein deficiency. The enzyme defect involves the D-bifunctional protein. This enzyme contains two catalytic sites, one with enoyl-CoA hydratase activity, the other with 3-hydroxyacyl-CoA activity [13]. Defects may involve both catalytic sites or each separately. The severity of clinical manifestations varies from that of a very severe disorder that resembles Zellweger's syndrome clinically and pathologically, to somewhat milder forms. Table 41-6 shows that biochemical abnormalities involve straight chain, branched chain fatty acids and bile acids. Bifunctional deficiency is often misdiagnosed as Zellweger's syndrome. Approximately 15% of patients initially thought to have a PBD have D-bifunctional enzyme deficiency. Differential diagnosis is achieved by the biochemical studies listed in Table 41-7 and by mutation analysis.

Refsum's disease. This disorder, first described nearly 60 years ago, was recently been shown due to a defect in the enzyme phytanoyl-CoA hydroxylase. Phytanic acid is a 3-methyl fatty acid that because of this methyl group cannot be oxidized directly. It is degraded by a peroxisomal α-oxidation to pristanic acid, a 2-methyl fatty acid which can be degraded by β-oxidation. The principal clinical features of Refsum's disease are progressive polyneuropathy, retinal degeneration, hearing loss, cardiomyopathy and ichthyosis, beginning in late childhood or later.

TABLE 41-7 Therapies of lysosomal and peroxisomal disorders that have shown success in clinical trials

Method	Disorder
Enzyme replacement	Gaucher's disease type I
	Fabry's disease
	Hurler's disease
	Pompe's disease
Hematopoietic cell transplantation	Hurler's syndrome
	Globoid leukodystrophy
	Metachromatic leukodystrophy
	X-linked adrenoleukodystrophy
Substrate reduction	Refsum's disease
	Cystinosis
	Adrenoleukodystrophy

Most, and possibly all of these changes result from the tissue accumulation of phytanic acid. Phytanic is of dietary origin exclusively, and dietary restriction of phytanic and plasmapheresis are of clinical benefit. The defective gene and pathogenic mutations have been identified. The clinical manifestations can also be mimicked by defects of PEX7.

Racemase deficiency. The biological role of 2-methylacyl-CoA racemase has only recently been clarified. This peroxisomal enzyme is essential for certain steps of the oxidation of phytol and bile acid derivatives, which are stereospecific. Biochemically there is accumulation of pristanic acid and C27 bile acid intermediates. Clinical symptoms may include adult-onset peripheral neuropathy, pigmentary degeneration of the retina and liver disease [13].

Alkyl-dihydroxy phosphate synthase and dihydroxyphosphate acyltransferase deficiencies. Both these disorders lead to severe deficiencies of ether phospholipids and lead to syndromes that are similar to RCDP, and point to the key physiological roles of ether phospholipids.

Mevalonate kinase deficiency. Mevalonate kinase and farnesyl-diphosphate synthase are localized in the peroxisome and are involved in the synthesis of isoprenoids. Mevalonate kinase deficiency causes severe developmental delay, dysmorphic features and early death. Mevalonate deficiency has also been observed in the hyperimmunoglobulinemia-and periodic fever syndrome.

Hyperoxaluria type 1 is due to functional efficiency of the liver specific peroxisomal enzyme alanine-glyoxylate aminotransferase. It leads to severe renal failure. The nervous system is not affected.

DIAGNOSIS OF LYSOSOMAL AND PEROXISOMAL DISORDERS

The diagnosis of lysosomal disorders is usually based on enzymatic assays in white blood cells or cultured skin fibroblasts [1]. Molecular studies required for identification of carriers. Initial diagnosis of peroxisomal disorders is based upon a panel of biochemical assays in blood or cultured skin fibroblasts. Table 41-6 shows that this scheme can be used to differentiate PBD disorders from those of single protein defects. Reference [13] provides an algorithm to accomplish this. Definition of the gene defects in the PBD and identification of heterozygote requires mutation analysis.

PATHOGENESIS OF LYSOSOMAL AND PEROXISOMAL DISORDERS

While the molecular defects in many of the lysosomal and peroxisomal disorders have now been defined, their pathogenesis is still poorly understood. Walkley has emphasized that many children with lysosomal storage disease exhibit little or no evidence of disease at birth. The primary gene defects do not, in themselves, necessarily impede an orderly and normal development of many organ systems, including brain. This suggests that the primary defect leads to a series of downstream or cascade events [14]. Some of these events have been defined. Some are specific to particular diseases, others apply generally. Animal models are now available for most of the lysosomal [15] and peroxisomal disorders [8], and their study will enhance greatly our understanding of pathogenesis.

The earlier hypothesis that storage in tertiary lysosomes itself leads to mechanical disruption of cytoplasm appears insufficient, in light of the realization that tertiary lysosomes cannot be viewed as end-organelles but are part of a continuum consisting of the entire endosomal–lysosomal system. The metabolic defects may lead not only to accumulation of the compounds that make up the bulk of the storage material, such as galactocerebroside in globoid leukodystrophy and sulfatide in metachromatic leukodystrophy, but also to lesser accumulation in terms of total quantity of other compounds that play a key role in pathogenesis, such as psychosine in globoid leukodystrophy. Extralysosomal accumulation of G_{M2} ganglioside in the perikaryon, axon hillocks and dendrites appears to be a major cause of nerve system damage in Tay–Sachs and Sandhoff's diseases. The accumulation in axons and dendrites leads to the formation of meganeurites and, intriguingly, to ectopic dendritogenesis. The ectopic dendrites become functional in the overall dendritic arbor and contribute to the seizure disorder. Other pathogenetic cascades lead to apoptosis that involves neurons in infantile ceroid lipofuscinosis and Farber's disease, and oligodendrocytes in globoid leukodystrophy. Macrophage infiltration and release of inflammatory cytokines contribute to oligodendrocyte damage in metachromatic leukodystrophy. In X-ALD the accumulation of saturated VLCFAs increases membrane viscosity, decreases the stability of biological membranes and impairs their function. This may the cause of the distal axonopathy in adrenomyeloneuropathy. Mitochondrial damage also appears to contribute. The inflammatory demyelination in the

childhood cerebral X-ALD may involve autoimmune response to gangliosides or proteolipids containing saturated VLCFAs that involves $CD8^+$ cytotoxic cells and CD1-mediated lipid antigen presentation. Studies in the mouse model of Zellweger's syndrome suggest that the characteristic defect in neuronal migration is secondary to glutamate receptor dysfunction [8].

THERAPY OF LYSOSOMAL AND PEROXISOMAL DISORDERS

New therapeutic approaches are now available. Table 41-7 lists the therapies that have been shown to be beneficial in clinical trials. The development of intravenously administered enzyme replacement therapy is an exciting new development. Successful therapy of type 1 Gaucher's disease with macrophage-targeted glucocerebrosidase [16] is now well documented. Key to its development was the recognition that lysosomal enzymes are targeted by mannose 6 phosphate [6]. It was only after glucocerebrosidase was modified to uncover the signaling mannose residues that efficient endocytosis was achieved. Results of enzyme replacement therapy for Fabry's disease [17], Hurler's syndrome [18] and Pompe's disease [19] are highly encouraging. While these therapies benefit the hematological, skeletal, hepatic, corneal and connective tissue abnormalities, a serious limitation is that intravenously administered enzyme does not cross the blood–brain barrier and thus has little or no effect on neurological manifestations. Methods to circumvent the blood–brain barrier for lysosomal enzyme delivery are under study.

Hematopoietic cell transplantation has been shown to provide some degree of neurological benefit in lysosomal disorders, specifically in Hurler's disease [20], globoid leukodystrophy [21] and metachromatic leukodystrophy [21]. Studies in experimental animals and postmortem studies on individuals who had received sex-mismatched bone marrow transplants suggest that 1–10% of microglia are bone-marrow-derived. The degree of neurological benefit is variable. The benefit usually consists of stabilization rather than the reversal of neurological deficits, so that the best chance for clinically meaningful favorable effect occurs when it is performed when neurological disability is still mild. It is not clear to what extent the benefit results from the bone-marrow-derived cells themselves and how much is the result of secretion of enzyme from donor cells and uptake by host glial cells and neurons. Direct evidence of active enzyme in neurons following bone marrow transplant has been demonstrated in the feline model of α-mannosidosis. Hematopoietic cell transplantation is beneficial in the childhood cerebral form of X-ALD when performed in the early stage of the illness [22]. It is not clear to what extent this relates to immunomodulation or anti-inflammatory effects, versus reduction of brain VLCFA levels or other metabolic effects attributable to donor-derived microglia.

Gene therapy and stem cell therapy are under intensive investigation in animal models. Other promising new approaches are the inhibition of substrate synthesis by pharmacological agents [23] and chemical chaperone therapy designed to increase the stability of mutant enzymes that have retained some degree of catalytic activity. Results in a mouse model of G_{M1} gangliosidosis are encouraging [24]. Last but not least, therapy of Refsum's disease by dietary restriction of phytanic acid intake and cysteamine therapy of cystinosis are well established forms of therapy.

CHAPTER

42

Diseases of Carbohydrate, Fatty Acid and Mitochondrial Metabolism

Salvatore DiMauro

Darryl C. De Vivo

DISEASES OF CARBOHYDRATE AND FATTY ACID METABOLISM IN MUSCLE 696

One class of glycogen or lipid metabolic disorders in muscle is manifest as acute, recurrent, reversible dysfunction 696

A second class of disorders of glycogen and fatty acid metabolism causes progressive weakness 699

The impairment of energy production from carbohydrate or fatty acids, which is the common consequence of these defects, should result in similar, exercise-related signs and symptoms 702

DISEASES OF CARBOHYDRATE AND FATTY ACID METABOLISM IN BRAIN 703

Defective transport of glucose across the blood–brain barrier is caused by deficiency in the glucose transporter protein 703

One class of carbohydrate and fatty acid metabolism disorders is caused by defects in enzymes that function in the brain 703

Another class of carbohydrate and fatty acid metabolism disorders is caused by systemic metabolic defects that affect the brain 704

DISEASES OF MITOCHONDRIAL METABOLISM 706

Mitochondrial dysfunction produces syndromes involving mainly muscle and the central nervous system 706

Mitochondrial DNA is inherited maternally 706

The genetic classification of mitochondrial diseases divides them into three groups 707

The biochemical classification of mitochondrial DNA is based on the five major steps of mitochondrial metabolism 708

Defects of energy metabolism cause profound disturbances in the function of muscle and brain. Such defects may present as a myopathy, encephalopathy or encephalomyopathy. Clinical features are best appreciated by understanding the preferred oxidizable substrates for brain and muscle.

Muscle in the resting state predominantly utilizes fatty acids. The immediate source of energy for muscle contraction is ATP, which is rapidly replenished at the expense of creatine phosphate by the phosphorylation of ADP by creatine kinase. During exercise of moderate intensity, the fuel choice depends on the duration of work. Initially, glycogen is the main fuel source; after 5 or 10 minutes, blood glucose becomes the more important fuel. As work continues, fatty acid utilization increases and, after approximately 4 hours, lipids are the primary source of energy. During high-intensity exercise, at near-maximal power, additional ATP is generated by the anaerobic breakdown of glycogen and by glycolysis. Intense exercise is performed in essentially anaerobic conditions, whereas mild or moderate exercise is accompanied by increased blood flow to exercising muscles, facilitating substrate delivery and favoring aerobic metabolism. This adaptation is known as the 'second-wind' phenomenon [1].

Brain utilizes glucose predominantly, with regional variations of the metabolic rate depending on the mental or motor task being performed. As with muscle, the immediate intracellular energy source is ATP, buttressed by the creatine phosphate stores. Glycogen provides very little energy reserve because brain concentrations of glycogen are extremely low, approximately only one-tenth the amount found in muscle per gram wet weight. Therefore, brain is exquisitely sensitive to fluctuations in the blood glucose concentration. Movement of glucose across the blood–brain barrier is facilitated by a carrier protein, the glucose transporter (GLUT-1) [2]. The facilitated transport of glucose ensures adequate brain glucose concentrations to meet the needs of cerebral metabolism under normal conditions. During starvation, the brain uses little, if any, fatty acids. However, fatty acids of varying chain lengths may be taken up by brain, as the efficiency of transport across the blood–brain barrier is much greater for short- or medium-chain fatty acids than for

Basic Neurochemistry: Molecular, Cellular and Medical Aspects
0-12-088397-X

long-chain fatty acids. Ketone bodies represent the preferred cerebral fuel source during starvation when glucose supply is limited [3] (see Ch. 31). Defective fatty acid oxidation, therefore, may affect muscle directly by blocking oxidation of this substrate and brain indirectly by limiting hepatic ketogenesis. Elevated circulating free fatty acids may also have a direct toxic effect on brain, but the precise mechanisms for this effect are poorly understood (see Chs 35 and 38).

Energy metabolism has been studied extensively in skeletal muscle, and several metabolic disorders have been documented [1, 4]. Comparatively less is known about metabolic defects in cerebral energy metabolism. This may be because muscle tissue is more accessible for biochemical analysis and because certain cerebral enzyme defects are lethal.

DISEASES OF CARBOHYDRATE AND FATTY ACID METABOLISM IN MUSCLE

One class of glycogen or lipid metabolic disorders in muscle is manifest as acute, recurrent, reversible dysfunction. These disorders occur with exercise intolerance and myoglobinuria, with or without cramps. Among the glycogenoses, this is characteristic of deficiencies in phosphorylase, phosphofructokinase (PFK), aldolase, phosphoglycerate kinase (PGK), phosphoglycerate mutase (PGM), β-enolase and lactate dehydrogenase (LDH). Among the disorders of lipid metabolism, this is characteristic of deficiencies in very-long-chain acyl-CoA dehydrogenase (VLCAD), trifunctional protein (TP), carnitine palmitoyltransferase II (CPT II) and short-chain 3-hydroxyacyl-CoA dehydrogenase (SCHAD). Figures 42-1 and 42-2 schematically illustrate the pathways of glycogen and fatty acid metabolism.

Phosphorylase deficiency (McArdle's disease, glycogenosis type V) is an autosomal recessive myopathy caused by a genetic defect of the muscle isoenzyme of glycogen phosphorylase (Fig. 42-1). Intolerance of strenuous exercise is present from childhood, but usually onset is in adolescence, with cramps after exercise [1, 5]. Myoglobinuria occurs in about one-half of patients. If they avoid intense exercise, most patients can live normal lives; however, about one-third of them develop some degree of fixed weakness, usually as a late-onset manifestation of the disease. In a few patients, weakness rather than exercise-related cramps and myoglobinuria characterizes the clinical picture.

In patients with myoglobinuria, renal insufficiency is a possible life-threatening complication. Physical examination between episodes of myoglobinuria may be completely normal or show some degree of weakness and, occasionally, wasting of some muscle groups.

Even between episodes, most patients have increased serum creatine kinase (CK); forearm ischemic exercise causes no rise of venous lactate concentration. This is a useful but nonspecific test in McArdle's disease. The electromyogram (EMG) at rest shows nonspecific myopathic features in about one-half of patients.

Muscle biopsy demonstrates subsarcolemmal blebs that contain periodic-acid–Schiff (PAS)-positive material, a marker for glycogen [1]. The histochemical stain for phosphorylase is negative, except in regenerating fibers. Biochemical documentation of the enzyme defect requires muscle biopsy because the defect is not expressed in more easily accessible tissues, such as leukocytes, erythrocytes and cultured fibroblasts. The gene encoding muscle phosphorylase has been assigned to chromosome 11, and more than 30 distinct mutations have been identified in patients [5]. By far the most common among these in Caucasian patients is a nonsense mutation in codon 49 (*mut-49*). This allows diagnosis of 90% of patients through molecular analysis of genomic DNA isolated from blood, thus making muscle biopsy unnecessary in most cases [5].

Phosphofructokinase deficiency (Tarui's disease, glycogenosis type VII) is an autosomal recessive myopathy caused by a genetic defect of the muscle (M) subunit of the rate-limiting enzyme of glycolysis, PFK (Fig. 42-1). Presenting symptoms are cramps after intense exercise, followed by myoglobinuria in some patients. A few patients may have mild jaundice, reflecting excessive hemolysis, or typical symptoms and signs of gout. In patients with typical presentation, fixed weakness appears to be less common than in phosphorylase deficiency. However, in PFK deficiency, as in phosphorylase deficiency, a few patients have only weakness, without cramps or myoglobinuria. In addition to renal insufficiency due to myoglobinuria, other possible complications include renal colic due to urate stones and gouty arthritis [1].

Physical examination may show slight jaundice. Neurological examination is normal. Serum CK is variably increased in most patients. Forearm ischemic exercise causes no rise of venous lactate concentration. Serum bilirubin is elevated in most patients and the number of reticulocytes is increased. Serum uric acid is also increased in most patients. The EMG is usually normal. Muscle biopsy shows focal, mostly subsarcolemmal, accumulation of glycogen. In some patients, a small portion of the glycogen is abnormal. By histochemical analysis, it is shown to be diastase-resistant; by electron microscopy, it appears finely granular and filamentous in structure. The enzyme defect can be demonstrated by a specific histochemical reaction for PFK. Although a partial defect of PFK activity is manifest in erythrocytes from patients, firm diagnosis usually requires biochemical studies of muscle. The gene encoding PFK-M is on chromosome 1, and about 15 mutations have been identified in patients of different ethnic origins. Recognition of a specific mutation in genomic DNA from blood cells can eliminate the need for a muscle biopsy in suspected PFK-deficient patients [1].

Muscle aldolase deficiency. The first patient with muscle aldolase deficiency was identified in 1996: this young boy suffered from a hemolytic trait but also

complained of exercise intolerance and experienced several episodes of myoglobinuria during febrile illnesses [1].

Phosphoglycerate kinase deficiency is an X-linked recessive disease (type IX, Fig. 42-1). The most common clinical presentation includes hemolytic anemia with or without CNS involvement (see below). Thus far, ten patients have been described with a purely myopathic syndrome, characterized by exercise-induced cramps and myoglobinuria. Between episodes of myoglobinuria, physical and neurological examinations were normal. Forearm ischemic exercise caused contracture and no rise of venous lactate concentration.

Because the enzyme defect is expressed in all tissues except sperm, diagnosis can be made by biochemical

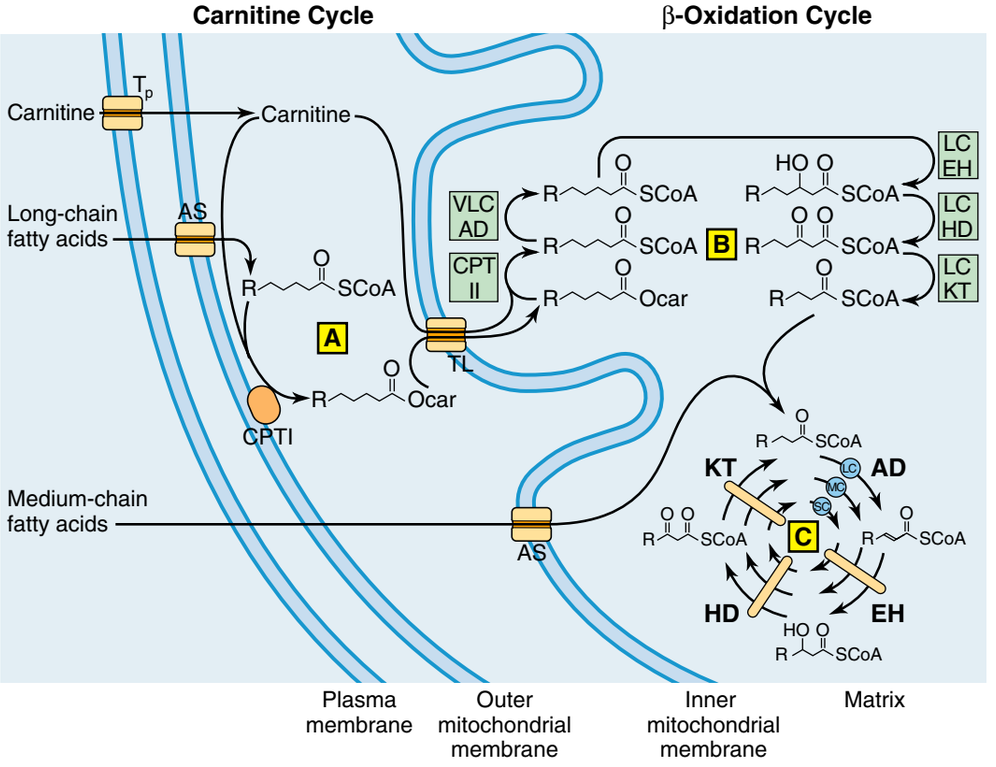

FIGURE 42-2 Schematic representation of fatty acid oxidation. This metabolic pathway is divided into the carnitine cycle (**A**), the inner mitochondrial membrane system (**B**), and the mitochondrial matrix system (**C**). The carnitine cycle includes the plasma membrane transporter (*Tp*), carnitine palmitoyltransferase I (*CPT I*), the carnitine–acylcarnitine translocase system (*Tl*) and carnitine palmitoyltransferase II (*CPT II*). The inner mitochondrial membrane system includes the very-long-chain acyl-CoA dehydrogenase (*VLCAD*) and the trifunctional protein with three catalytically active sites. Long-chain acylcarnitines enter the mitochondrial matrix by the action of CPT II to yield long-chain acyl-CoAs. These thioesters undergo one or more cycles of chain shortening catalyzed by the membrane-bound system. Chain-shortened acyl-CoAs are degraded further by the matrix β-oxidation system. Medium-chain fatty acids enter the mitochondrial matrix directly and are activated to the medium-chain acyl-CoAs before degradation by the matrix β-oxidation system. *AD*, acyl-CoA dehydrogenase; *AS*, acyl-CoA synthetase; *CoA*, coenzyme A; *CPT*, carnitine palmitoyltransferase; *EH*, 2-enoyl-CoA hydratase; *HD*, 3-hydroxyacyl-CoA dehydrogenase; *KT*, 3-ketoacyl-CoA thiolase; *LC*, long chain; *MC*, medium chain; *SC*, short chain; *TL*, carnitine-acylcarnitine translocase; T_p, carnitine transporter; *VLC*, very long chain. studies of muscle, erythrocytes, leukocytes and cultured fibroblasts. Two distinct mutations have been identified in patients with myopathy [1].

Phosphoglycerate mutase deficiency is an autosomal recessive myopathy caused by a genetic defect of the muscle subunit of the enzyme PGM (type X, Fig. 42-1). 12 patients with this enzyme deficiency have been identified thus far.

The clinical picture includes cramps and recurrent myoglobinuria following intense exercise. Aside from episodes of myoglobinuria, none of the patients was weak. Forearm ischemic exercise caused a 1.5–2.0-fold increase in venous lactate concentration, an abnormally low but not absent response. Muscle biopsy showed normal or only moderately increased glycogen concentration. Because other accessible tissues, such as erythrocytes, leukocytes and cultured fibroblasts, express a different isoenzyme, the diagnosis of PGM-M subunit deficiency must be established by biochemical studies of muscle. Four different mutations have been identified in the PGM-M gene, which is located on chromosome 7 [1].

Beta-enolase deficiency (type XIII, Fig. 42-1) has been identified in a 47-year-old man with late-onset but rapidly progressive exercise intolerance and exercise-triggered myalgia. He did not complain of cramps, never experienced pigmenturia, but had chronically elevated serum CK. The patient was a compound heterozygote for two mutations in the *ENO3* gene, which is located on chromosome 17 [1].

Lactate dehydrogenase deficiency is an autosomal recessive myopathy caused by a genetic defect of the muscle subunit, which is encoded by a gene on chromosome 11 (type XI, Fig. 42-1). Thus far, several Japanese families and two Caucasian patients with this disease have been described. The clinical picture is characterized by cramps and myoglobinuria after intense exercise.

Forearm ischemic exercise showed a subnormal rise of lactate concentration, contrasting with an increased rise

of pyruvate. The diagnosis can be established by electrophoretic studies of LDH in serum, erythrocytes and leukocytes, showing lack of subunit-M-containing isoenzymes. Nevertheless, it should be confirmed by biochemical studies of muscle or by molecular analysis of genomic DNA as five different mutations have been documented in patients [1].

Carnitine palmitoyltransferase deficiency is an autosomal recessive myopathy caused by a genetic defect of the mitochondrial enzyme CPT (Fig. 42-2). The disease is prevalent in men (male:female ratio, 5.5:1) and appears to be the most common cause of recurrent myoglobinuria in adults [4].

Clinical manifestations are limited to attacks of myoglobinuria not preceded by contractures and usually precipitated by prolonged exercise of several hours duration, prolonged fasting or a combination of the two conditions. Less common precipitating factors include intercurrent infection, emotional stress and cold exposure, but some episodes of myoglobinuria occur without any apparent cause. Most patients have two or more attacks, probably because the lack of muscle cramps deprives them of a warning signal of impending myoglobinuria.

For unknown reasons, some women seem to have milder symptoms, such as myalgia after prolonged exercise, without pigmenturia. This has been observed in sisters of men with recurrent myoglobinuria. The only serious complication is renal failure following myoglobinuria.

Physical and neurological examinations are completely normal. Prolonged fasting at rest, which should be conducted under close medical observation, causes a sharp rise of serum CK in about one-half of patients. Also, in about one-half of patients, ketone bodies fail to increase normally after prolonged fasting. Forearm ischemic exercise causes a normal increase of venous lactate concentration. Aside from episodes of myoglobinuria, the serum CK concentration and EMG are normal. A muscle biopsy specimen may appear completely normal or show variable, but usually moderate, accumulation of lipid droplets. Most patients with CPT deficiency benefit from a high-carbohydrate, low-fat diet and the therapeutic response may serve as an indirect diagnostic clue. Because the enzyme defect appears to be generalized, tissues other than muscle, such as mixed leukocytes or isolated lymphocytes or platelets, can be used to demonstrate CPT deficiency; but the diagnosis should be confirmed in muscle.

The myopathic form of CPT deficiency is due to a defect of CPT II. The gene for CPT II has been localized to chromosome 1, and several mutations have been identified in patients [4]. As in the case of McArdle's disease (see above), one mutation, a serine-to-leucine substitution at codon 113, is far more common than the others in Caucasians and can be screened for in genomic DNA from blood cells, thus potentially avoiding muscle biopsy.

Very-long-chain acyl-CoA dehydrogenase and trifunctional protein are the two inner membrane-bound enzymes of fatty acid β-oxidation. Genetic defects of either can mimic the clinical presentation of CPT II deficiency by causing recurrent myoglobinuria in otherwise apparently healthy young adults. As in CPT II deficiency, precipitating factors include prolonged exercise, prolonged fasting, cold exposure, intercurrent illnesses or emotional stress [4].

Short-chain 3-hydroxyacyl-CoA dehydrogenase deficiency has been described in three patients. It is associated with additional defects of β-oxidation, which have been associated with limb weakness and attacks of myoglobinuria, and it is potentially fatal.

A second class of disorders of glycogen and fatty acid metabolism causes progressive weakness. These disorders are associated with acid maltase, debrancher enzyme, brancher enzyme and triosephosphate isomerase deficiencies among the glycogenoses. These are also associated with carnitine deficiency, some defects of β-oxidation and other biochemically undefined lipid-storage myopathies among the disorders of lipid metabolism. Figures 42-1 and 42-2 schematically illustrate the pathways of glycogen and fatty acid metabolism.

Acid maltase deficiency (AMD; glycogenosis type II) is an autosomal recessive disease caused by a genetic defect of the lysosomal enzyme acid maltase, an α-1,4- and α-1,6-glucosidase capable of digesting glycogen completely to glucose (Fig. 42-1). Two major clinical syndromes are caused by AMD. The first is Pompe's disease, which is a severe, generalized and invariably fatal disease of infancy; the second is a less severe neuromuscular disorder beginning in childhood or in adult life (see Ch. 41).

Infantile, generalized cardiomegalic AMD, or Pompe's disease, usually becomes manifest in the first weeks or months of life, with failure to thrive, poor suck, generalized hypotonia and weakness, also termed floppy infant syndrome. Macroglossia is common, as is hepatomegaly, which, however, is rarely severe. There is massive cardiomegaly, with congestive heart failure. Weak respiratory muscles make these infants susceptible to pulmonary infection; death usually occurs before the age of 1 year and invariably before the age of 2 years [6].

The childhood- and adult-onset forms of AMD cause signs and symptoms that are limited to the musculature, with progressive weakness of truncal muscles and of proximal, more than distal, limb muscles, usually sparing facial and extraocular muscles. In the childhood form, onset is in infancy or childhood and progression tends to be rapid. In the adult form, onset is usually in the third or fourth decade but occasionally even later and the course is slower [7].

The clinical picture in male children can closely resemble Duchenne-type muscular dystrophy; in adults, it mimics limb-girdle dystrophy or polymyositis. The early and severe involvement of respiratory muscles in most patients with AMD is a distinctive clinical clue. Respiratory failure and pulmonary infection are the most common causes of death.

Serum CK is consistently increased in all forms of AMD. Forearm ischemic exercise causes a normal rise of venous lactate concentration in patients with childhood or adult AMD. The electrocardiogram (ECG) is altered in Pompe's disease, with a short P-R interval, giant QRS complexes and left ventricular or biventricular hypertrophy, but is usually normal in the later-onset forms. The EMG shows myopathic features and fibrillation potentials, bizarre high-frequency discharges and myotonic discharges.

Muscle biopsy shows vacuolar myopathy of very severe degree affecting all fibers in Pompe's disease but of varying degree and distribution in childhood and adult AMD. In adult AMD, biopsy specimens from unaffected muscles may appear normal by light microscopy. The vacuoles contain PAS-positive material, a marker for glycogen. Electron microscopy shows abundant glycogen, both within membranous sacs, presumably lysosomes, and free in the cytoplasm.

The enzyme defect is expressed in all tissues, and the diagnosis can be made by biochemical analysis of urine, lymphocytes (mixed leukocytes do not give reliable results) or cultured skin fibroblasts. Fibroblasts cultured from amniotic fluid can be used for prenatal diagnosis of Pompe's disease. The gene encoding acid maltase is on chromosome 17, and numerous mutations have been identified in patients with both forms of AMD, confirming that infantile and late-onset AMD are allelic disorders. Predictably, more severe mutations are associated with Pompe's disease; however, many patients are compound heterozygotes, and there is no strict genotype/phenotype correlation [6].

Debrancher enzyme deficiency (glycogenosis type III, Cori–Forbes disease) is an autosomal recessive disease (Fig. 42-1). In its more common presentation, debrancher enzyme deficiency causes liver dysfunction in childhood, with hepatomegaly, growth retardation, fasting hypoglycemia and seizures [1]. Myopathy has been described in about 20 patients [1]. In most, onset of weakness was in the third or fourth decade. Wasting of distal leg muscles and intrinsic hand muscles is common, and the association of late-onset weakness and distal wasting often suggests the diagnosis of motor neuron disease or peripheral neuropathy. The course is slowly progressive. In a smaller number of patients, onset of weakness is in childhood, with diffuse weakness and wasting. The association of hepatomegaly and growth retardation facilitates the diagnosis.

There is no glycemic response to glucagon or epinephrine (Fig. 42-1), whereas a galactose load causes a normal glycemic response. Forearm ischemic exercise produces a blunted venous lactate rise or no response. Serum CK activity is variably, often markedly, increased. The ECG shows left ventricular or biventricular hypertrophy in most patients, and the EMG may show myopathic features alone or associated with fibrillations, positive sharp waves and myotonic discharges. This 'mixed' EMG pattern in patients with weakness and distal wasting often reinforces the erroneous diagnosis of motor neuron disease. Motor nerve conduction velocities are moderately decreased in one-fourth of patients, suggesting a polyneuropathy.

Muscle biopsy shows severe vacuolar myopathy with glycogen storage. On electron microscopy, the vacuoles correspond to pools of glycogen free in the cytoplasm.

In most patients, the enzyme defect is generalized, and it has been demonstrated in erythrocytes, leukocytes and cultured fibroblasts. In patients with myopathy, the diagnosis is securely established by measurement of debrancher enzyme activity in muscle biopsy specimens or by studies of iodine adsorption spectra of glycogen isolated from muscle; there is a shift in the spectrum toward lower wavelengths, indicating that the polysaccharide has abnormally short peripheral branches. The gene for the debrancher enzyme has been assigned to chromosome 1, and more than 15 mutations have been identified in patients [1].

Branching enzyme deficiency (glycogenosis type IV; Andersen's disease) is an autosomal recessive disease of infancy or early childhood, typically causing liver dysfunction with hepatosplenomegaly, progressive cirrhosis and chronic hepatic failure (Fig. 42-1). Death usually occurs in childhood. Myopathy has been reported in numerous patients, either alone or in association with hepatopathy or cardiopathy. Some infants had severe hypotonia, wasting, contractures and hyporeflexia, suggesting the diagnosis of spinal muscular atrophy [1].

There are no diagnostic laboratory tests. A muscle biopsy specimen may be normal or show focal accumulations of abnormal glycogen, which is intensely PAS-positive and partially resistant to diastase digestion. With the electron microscope, the abnormal glycogen is found to have a finely granular and filamentous structure. The gene that encodes the branching enzyme has been cloned and assigned to chromosome 3 and several mutations have been identified in patients. [1].

Carnitine deficiency is a clinically useful term describing a diversity of biochemical disorders affecting fatty acid oxidation. Carnitine deficiency may be tissue-specific or generalized.

Tissue-specific carnitine deficiency has previously been termed myopathic carnitine deficiency because patients have generalized limb weakness, starting in childhood. Limb, trunk and facial musculature may be involved. The course is slowly progressive, but weakness may fluctuate in severity. Laboratory investigations show normal or near-normal serum carnitine concentrations and variably increased serum CK values. The EMG shows myopathic features with or without spontaneous activity at rest. Muscle biopsy reveals severe triglyceride storage, best seen with the oil red O stain in frozen sections. This condition is transmitted as an autosomal recessive trait. Originally, it was thought that the primary biochemical defect involved the active transport of carnitine from blood into muscle. However, no such defect has ever been documented [4]. Rather, an increasing number of patients have a tissue-specific defect involving the short-chain isoform of

acyl-CoA dehydrogenase (SCAD). As such, the muscle carnitine deficiency is secondary to a primary enzyme defect.

Generalized carnitine deficiency, in its primary form and inherited as an autosomal recessive trait, is due to a defect of the specific high-affinity, low-concentration, carrier-mediated carnitine-uptake mechanism. The defect has been documented in cultured fibroblasts and muscle cultures, but the same uptake system is probably shared by heart and kidney, thus explaining the cardiomyopathy and the excessive 'leakage' of carnitine into the urine. Oral L-carnitine supplementation results in dramatic improvement in cardiac function [4, 8].

Systemic carnitine deficiency was first described in 1975 and was thought to represent a defect in the *de novo* biosynthesis of carnitine [4]. However, no such defect has been documented. Patients with systemic carnitine deficiency have a generalized decrease in the tissue and plasma concentrations of carnitine and an excessive urinary excretion of carnitine. Many of the patients originally reported to have systemic carnitine deficiency have been reinvestigated and found to have a primary enzyme defect, such as medium-chain acyl-CoA dehydrogenase deficiency (MCAD). This deficiency is the prototype of a defect in β-oxidation that produces secondary carnitine deficiency. β-oxidation defects are also associated with dicarboxylic aciduria. This finding is particularly prominent during a metabolic crisis and may be rather inconspicuous between attacks. The differential diagnosis of systemic carnitine deficiency and dicarboxylic aciduria includes other defects of β-oxidation, such as deficiencies of the long-chain isoform of acyl-CoA dehydrogenase (LCAD), SCAD, electron transfer flavoprotein (ETF) and ETF oxidoreductase [4], the long- and short-chain isoforms of 3-hydroxyacyl CoA dehydrogenase (LCHAD, SCHAD), β-ketothiolase and the newly described TP enzyme that includes the catalytic activities of enoyl hydratase, LCHAD and β-ketothiolase. Cardiac involvement is particularly prominent in conditions that involve the metabolism of long-chain fatty acids. Other genetically determined biochemical defects involving organic acid metabolism and respiratory chain function may produce secondary carnitine deficiency. Carnitine deficiency also may result from acquired diseases, such as chronic renal failure treated by hemodialysis, renal Fanconi's syndrome, chronic hepatic disease with cirrhosis and cachexia, kwashiorkor and total parenteral nutrition in premature infants [4]. The mechanisms of carnitine depletion in these diverse conditions include excessive renal loss and excessive accumulation of acyl-CoA thioesters. These potentially toxic compounds are esterified to acylcarnitines and excreted in the urine, resulting in an excessive loss of carnitine.

The genetically determined defect of membrane carnitine transport is the only known condition that fulfills the criteria for primary carnitine deficiency [4, 9]. This condition, like the other conditions involving the carnitine cycle, is not associated with dicarboxylic aciduria. It is transmitted as an autosomal recessive trait and produces a life-threatening cardiomyopathy in infancy or early childhood, which is effectively treated with carnitine supplementation. The untreated patient also manifests systemic features of hypotonia, failure to thrive and alterations of consciousness, including coma. Carnitine concentrations are extremely low in plasma and body tissues, and the excretion of carnitine in the urine is extremely high. The excessive urinary carnitine losses are caused by a defect in renal tubular uptake of filtered carnitine, resulting from the primary defect of the plasma membrane carnitine transporter. This condition can be documented by carnitine-uptake studies in cultured skin fibroblasts from patients. Uptake studies in parents give intermediate values, consistent with a heterozygous state.

A few patients have been described with a defect involving the carnitine–acylcarnitine translocase system, which facilitates the movement of long-chain acylcarnitine esters across the inner membrane of the mitochondrion (Fig. 42-2). These patients have extremely low carnitine concentrations and minimal dicarboxylic aciduria [4].

Carnitine concentrations are normal to high in patients with a primary defect of CPT I. Patients with CPT II have normal carnitine concentrations. Two clinical syndromes have emerged in relationship to CPT II. The more common syndrome, as discussed previously, involves recurrent myoglobinuria provoked by fasting or intercurrent infection and later may be associated with fixed limb weakness. The less common syndrome involves infants and produces hypoketotic hypoglycemic coma with a Reye-like clinical signature. All cases thought to be recurrent Reye's syndrome should be investigated for defects involving fatty acid oxidation. Low serum carnitine concentrations and increased urinary dicarboxylic acids implicate a biochemical defect of β-oxidation. Low serum carnitine concentrations and normal urinary dicarboxylic acids implicate a defect of the membrane carnitine transporter or the mitochondrial inner membrane carnitine–acylcarnitine translocase system. Normal to high serum carnitine concentrations and no dicarboxylic aciduria suggests a defect of CPT I or CPT II.

Oral administration of L-carnitine is life-saving in patients with the genetically determined defect of the plasma membrane carnitine transporter [4, 8, 9]. It also is recommended as a supplement in all patients who have documented carnitine deficiency, even though clear evidence of benefit is lacking. Medium-chain triglyceride supplementation has proved beneficial in CPT I deficiency and should be beneficial also in the other defects of the carnitine cycle. Medium-chain fatty acids cross the plasma membrane and the mitochondrial membranes directly and are esterified to the thioesters in the mitochondrial matrix (Fig. 42-2). A ketonemic response to medium-chain triglycerides documents the biological integrity of β-oxidation and implicates a biochemical defect of the carnitine cycle or of β-oxidation involving the metabolism of the longer-chain fatty acids.

The impairment of energy production from carbohydrate or fatty acids, which is the common consequence of these defects, should result in similar, exercise-related signs and symptoms. Except for debrancher deficiency, this is the case [1]. Of the nine glycolytic enzyme defects described above, eight affect glycogen breakdown or glycolysis: phosphorylase, debrancher, PFK, aldolase, PGK, PGAM, β-enolase, LDH deficiencies. Patients with phosphorylase, PFK, aldolase, PGK, β-enolase, PGAM or LDH deficiency have exercise intolerance manifested by premature fatigue, cramps and, often, myoglobinuria. As predicted by the crucial role of glycogen as a fuel source, these patients are more prone to experience cramps and myoglobinuria when they engage in isometric exercise, such as lifting weights, or in intense dynamic exercise, such as walking uphill. Energy for these types of exercise derives mainly from anaerobic or aerobic glycolysis. The block of glycogen utilization leads to a shortage of pyruvate and, therefore, of acetyl CoA (Fig. 42-3), the pivotal substrate of the Krebs cycle, and to a decreased mitochondrial energy output. Moderate exercise typically causes premature fatigue and myalgia, but these symptoms usually resolve after brief rest or slowing of pace; thereafter, patients find that they can resume or continue exercise without problems. This second-wind phenomenon seems to be due to early mobilization of fatty acids and to increased blood flow to exercising muscles.

Conversely, patients with fatty-acid oxidation defects experience myalgia and myoglobinuria after prolonged, though not necessarily high-intensity, exercise. Fasting exacerbates these complaints. Thus, myoglobinuria occurs in CPT deficiency under metabolic conditions that favor oxidation of fatty acids in normal muscle [4]. This observation suggests that impaired cellular energetics are the common cause of myoglobinuria in diverse metabolic myopathies. However, biochemical proof of energy depletion is still necessary. No abnormal decrease of ATP concentration has yet been measured in muscle of patients with McArdle's disease during fatigue, which is defined as failure to maintain the required or expected force, or during ischemic exercise-induced contracture. The possibility cannot be excluded, however, that contracture as well as necrosis may involve only a relatively small percentage of fibers. Measurements of ATP and

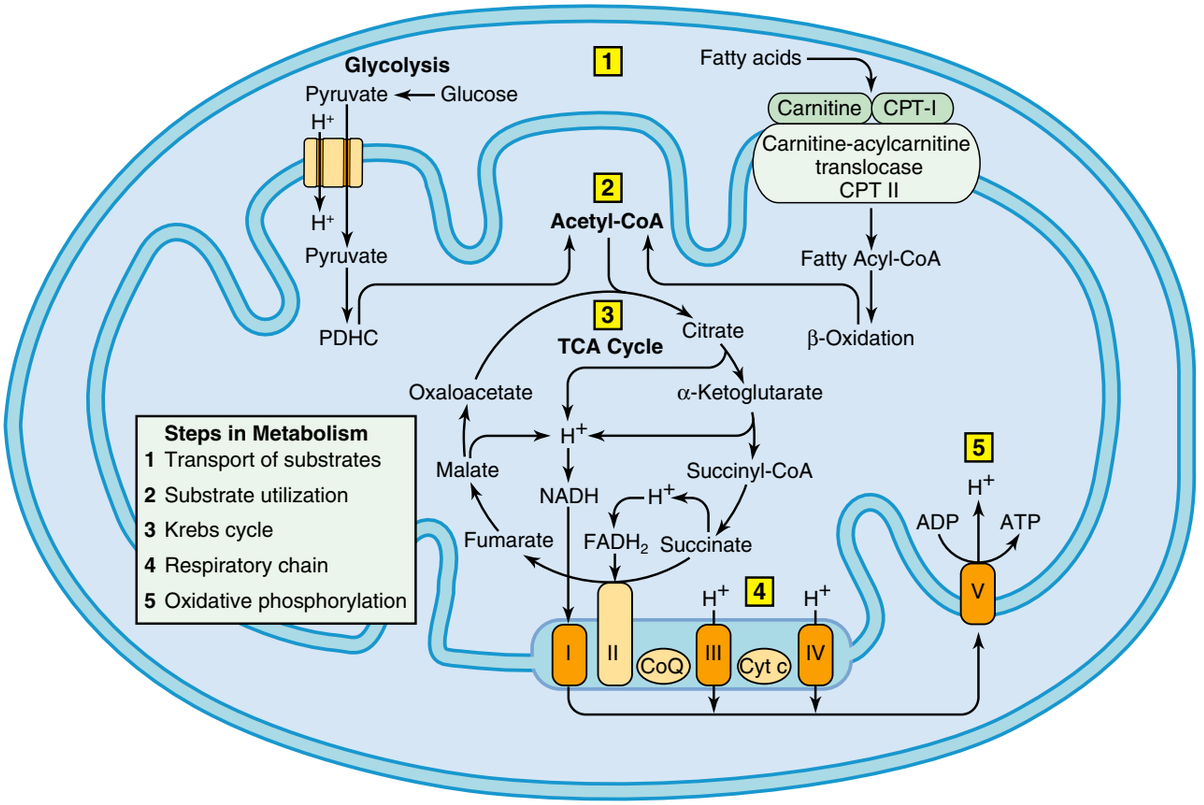

FIGURE 42-3 Schematic representation of mitochondrial metabolism. Respiratory chain complexes or components encoded exclusively by the nuclear genome are *light orange*. Complexes containing some subunits encoded by the nuclear genome and others encoded by mitochondrial DNA are *dark orange*. *CPT*, carnitine palmitoyltransferase; *PDHC*, pyruvate dehydrogenase complex; *CoA*, coenzyme A; *TCA*, tricarboxylic acid; *CoQ*, coenzyme Q; *Cyt c*, cytochrome c. (Modified from reference [12], with permission of McGraw-Hill, New York).

phosphocreatine in whole muscle might fail to detect loss of high-energy phosphate compounds in selected fibers. Additionally, ATP deficiency may affect a specific subcellular compartment.

The cause of weakness is also poorly understood. Chronic impairment of energy provision is unlikely because two of the three glycogenoses causing weakness involve a glycogen-synthesizing enzyme, branching enzyme deficiency, and a lysosomal glycogenolytic enzyme, acid maltase deficiency (see Ch. 41), neither of which is directly involved in energy production [1].

A more likely explanation is that weakness may be due to a net loss of muscle fibers because regeneration cannot keep pace with the rate of degeneration. With fewer functioning fibers, the muscle cannot exert full force. EMG reinforces this interpretation: motor unit potentials are of smaller amplitude and briefer duration than normal due to loss of muscle fibers from a motor unit. Fibrillations are attributed to areas of focal necrosis of muscle fiber, isolating areas of the cell from the neuromuscular junction in a form of 'microdenervation'. Muscle fiber degeneration may be due to excessive storage of glycogen, as in acid maltase and debrancher enzyme deficiencies, or lipid droplets, as in carnitine deficiency. In agreement with this hypothesis is the observation that in at least two of the glycogenoses causing weakness, infantile acid maltase deficiency and debrancher enzyme deficiency, glycogen storage is much more severe than in the glycogenoses causing cramps and myoglobinuria. Similarly, lipid storage is much more severe in carnitine deficiency than in CPT deficiency [4, 8, 9].

An additional cause of weakness may be involvement of the anterior horn cells of the spinal cord, which is very conspicuous in infantile acid maltase deficiency. All three glycogenoses causing weakness are in fact due to generalized enzyme defects, but histological signs of denervation are not evident.

DISEASES OF CARBOHYDRATE AND FATTY ACID METABOLISM IN BRAIN

The concentration of glycogen in brain is small: approximately 0.1 g per 100 g fresh tissue, compared with 1.0 g per 100 g in muscle and 6–10 g per 100 g in liver. The functional significance of glycogen in the brain is not completely understood, but it is generally assumed that it represents available energy to be tapped during glucose depletion; however, the limited glycogen reserve renders the brain vulnerable to injury within minutes of onset of hypoglycemia or hypoxia.

The role of fatty acids as oxidizable fuels for brain metabolism is negligible, but ketone bodies, derived from fatty acid oxidation, can be utilized, particularly in the neonatal period. Diseases of carbohydrate and fatty acid metabolism may affect the brain directly or indirectly [1, 10].

Defective transport of glucose across the blood–brain barrier is caused by deficiency in the glucose transporter protein. Glucose crosses the blood–brain barrier by a mechanism of facilitated diffusion (see Chs 5 and 32). This stereospecific system has a relatively high K_m for glucose, approximately 6 mmol/l. Normally, transport of glucose across the blood–brain barrier is not rate-limiting for cerebral metabolism. Two patients were reported with a defect involving the GLUT-1 carrier protein [2]. The clinical presentation was infantile-onset seizures and developmental delay. One patient had deceleration of head growth with resulting microcephaly. The metabolic signature of this condition is a persistent hypoglycorrhachia with low–normal or low CSF lactate values. The patients responded to a ketogenic diet that was implemented to provide ketone bodies as an alternative fuel source for cerebral metabolism [2, 3]. The GLUT-1 protein also is present in erythrocyte membranes. Decreased binding of cytochalasin B, a ligand that selectively binds to glucose transporters, was documented in both cases, and decreased uptake of 3-*O*-methylglucose by freshly isolated erythrocytes was documented in one case. The molecular and genetic basis for this condition involves mutation in the GLUT-1 gene on chromosome 1 [11]. These patients may be misdiagnosed as examples of cerebral palsy, suspected hypoglycemia or sudden infant death syndrome.

One class of carbohydrate and fatty acid metabolism disorders is caused by defects in enzymes that function in the brain. **Acid maltase deficiency** is characterized by large amounts of glycogen in the perikaryon of glial cells in both gray and white matter, whereas cortical neurons contain much smaller quantities of glycogen. In the spinal cord, the neurons of the anterior horn appear ballooned and contain glycogen, as shown by the abundant PAS-positive material that is digested by diastase. Schwann cells of both anterior and posterior spinal roots and of peripheral nerves also contain excessive glycogen. By electron microscopy, the most striking feature is the presence of glycogen granules within membrane-bound vacuoles. These glycogen-laden vacuoles are particularly abundant in anterior horn cells, in neurons of brainstem motor nuclei and in Schwann cells, whereas they are scarce in cortical neurons. Glycogen is increased in postmortem brain, and acid maltase activity is undetectable. The severe involvement of spinal and brainstem motor neurons and the massive accumulation of glycogen in muscle contribute to the profound hypotonia, weakness and hyporeflexia seen in Pompe's disease [6].

Debrancher enzyme deficiency appears to be generalized. Accordingly, although neither pathology nor debrancher enzyme activity has been reported, increased glycogen concentration has been observed in the brain of a patient. Thus, in debrancher enzyme deficiency, the nervous system seems to be involved biochemically, although clinical signs of brain dysfunction are limited to hypoglycemic seizures in childhood [1].

Branching enzyme deficiency has been described in multiple tissues, reflecting the fact that the enzyme is expressed as a single molecular form. Branching enzyme deficiency causes the accumulation of an abnormal glucose polymer resembling amylopectin and called polyglucosan. A form of polyglucosan body disease (adult polyglucosan body disease, APBD) was described in patients with a characteristic neurological syndrome consisting of progressive upper and lower motoneuron involvement, sensory loss, neurogenic bladder, and, in one-half of the patients, dementia without myoclonus or epilepsy. Onset is in the fifth or sixth decade, and the course varies between 3 and 30 years. Polyglucosan bodies are disseminated throughout the CNS and PNS in processes of neurons and astrocytes but not in perikarya. Other tissues are also affected, including liver, heart and skeletal and smooth muscle. In Ashkenazy Jewish patients with this disorder, branching enzyme activity is decreased in leukocytes, peripheral nerve and, presumably, brain, but is normal in muscle. A 'mild' mutation in the branching enzyme gene was found in seven patients from five Ashkenazy Jewish families with APBD. The mild nature of the mutation may explain the late onset of this variant, but the preferential brain involvement remains unclear [1].

Phosphoglycerate kinase deficiency, as it is most commonly manifest, includes nonspherocytic hemolytic anemia and CNS dysfunction. Neurological problems vary in severity. All patients show some degree of mental retardation, with delayed language acquisition and behavioral abnormalities, and some have hemiplegia or seizures. The enzyme defect has been directly proved in the brain, and the severe brain involvement can be explained by impairment of the glycolytic pathway. The lack of symptoms of brain dysfunction in some patients with PGK deficiency, such as the patients with recurrent myoglobinuria described above, are probably attributable to the presence of sufficient residual enzyme activity to prevent severe energy shortage.

Lafora's disease manifest an accumulation of polyglucosan, in the CNS and PNS as well as in other tissues [1]. Lafora's disease is transmitted as an autosomal recessive trait and is characterized by epilepsy, myoclonus and dementia. Other neurological manifestations include ataxia, dysarthria, spasticity and rigidity. Onset is in adolescence, and death occurs in most patients before 25 years of age.

The pathological hallmark of the disease is the presence in the brain of Lafora bodies: round, basophilic, PAS-positive intracellular inclusions varying in size from small, 'dust-like' bodies less than 3 nm in diameter to large bodies up to 30 nm in diameter. Lafora bodies are typically seen in neuronal perikarya and processes, not in glial cells, and are more abundant in cerebral cortex, substantia nigra, thalamus, globus pallidus and dentate nucleus. Ultrastructural studies have shown that Lafora bodies consist of two components: amorphous electron-dense granules and irregular branched filaments. Linkage analysis in nine families localized the gene responsible for Lafora's disease to chromosome 6q, and the gene product, a tyrosine phosphatase, was called 'laforin'. It has been suggested that laforin may play a role in the cascade of reactions controlling glycogen synthesis and degradation, and that mutations in laforin (documented in patients) may alter the ratio of glycogen synthetase:branching enzyme activities in favor of the former. Indirect support for this hypothesis comes from the observation that polyglucosan accumulates in muscle of patients with PFK deficiency, in whom the increased concentration of glucose-6-phosphate resulting from the enzyme defect may keep an excessive amount of glycogen synthetase in the active form [1].

Another class of carbohydrate and fatty acid metabolism disorders is caused by systemic metabolic defects that affect the brain. **Glucose-6-phosphatase deficiency (glycogenosis type I, Von Gierke's disease)** results in hypoglycemia and excessive intracellular accumulation of glucose-6-phosphate (Fig. 42-1). Hypoglycemia may produce lethargy, coma, seizures and brain damage in gluconeogenic and glycogen synthetase deficiencies [12]. As a result, there is formation of lactic acid, uric acid and lipids. A second form of the disease (type Ib) has been described. The defect in this form involves the glucose-6-phosphate translocation system that is important in facilitating the movement of the substrate into the microsomal compartment for enzymatic conversion to glucose by glucose-6-phosphatase. The clinical features of types Ia and Ib are similar, but normal enzyme activity is present in type Ib. Hepatomegaly, bleeding diathesis and neutropenia are present. The neurological signs result from the chronic hypoglycemia. Recent studies indicate that lactate may be used by the brain as an alternative cerebral metabolic fuel when hypoglycemia is associated with lactic acidosis. Nocturnal intragastric feeding and frequent daytime meals ameliorate most of the clinical and metabolic abnormalities of this condition.

Fructose-1,6-bisphosphatase deficiency, first described by Baker and Winegrad in 1970, has now been reported in approximately 30 cases. It is more common in women and is inherited as an autosomal recessive disorder. Initial manifestations are not strikingly dissimilar from those of glucose-6-phosphatase deficiency. Neonatal hypoglycemia is a common presenting feature, associated with profound metabolic acidosis, irritability or coma, apneic spells, dyspnea, tachycardia, hypotonia and moderate hepatomegaly. Lactate, alanine, uric acid and ketone bodies are elevated in the blood and urine [11]. The enzyme is deficient in liver, kidney, jejunum and leukocytes. Muscle fructose-1,6-bisphosphatase activity is normal.

Fructose-1,6-bisphosphatase is an important rate-limiting step in gluconeogenesis. This gluconeogenic step antagonizes the opposite reaction that forms fructose-1, 6-bisphosphate from fructose-6-phosphate and ATP

(see Ch. 31). A futile cycle exists between these two enzymes, one forming fructose-1,6-bisphosphate and the other disposing of this substrate. Small amounts of fructose-2, 6-bisphosphate also are formed by the PFK reaction. This metabolite stimulates the PFK reaction and inhibits the fructose-1,6-bisphosphatase reaction. This finding nicely explains the subtle interplay between the key rate-limiting step in glycolysis, which is PFK-dependent, and the rate-limiting step in gluconeogenesis catalyzed by fructose-1,6-bisphosphatase.

Phosphoenolpyruvate carboxykinase (PEPCK) deficiency is distinctly rare and even more devastating clinically than deficiencies of glucose-6-phosphatase or fructose-1,6-bisphosphatase. PEPCK activity is almost equally distributed between a cytosolic form and a mitochondrial form. These two forms have similar molecular weights but differ by their kinetic and immunochemical properties. The cytosolic activity is responsive to fasting and various hormonal stimuli. Hypoglycemia is severe and intractable in the absence of PEPCK [12]. A young child with cytosolic PEPCK deficiency had severe cerebral atrophy, optic atrophy and fatty infiltration of liver and kidney.

Pyruvate carboxylase deficiency has been documented in 36 cases [10, 12]. This enzyme is mitochondrial in location and catalyzes the conversion of pyruvate to oxaloacetate in a biotin-dependent manner (Chs 35 and 39). The first report of pyruvate carboxylase deficiency involved an infant with subacute necrotizing encephalomyelopathy, or Leigh's syndrome. Subsequent reports have failed to confirm this causal relationship between pyruvate carboxylase deficiency and the neuropathological features of Leigh's syndrome. Leigh's syndrome has now been assigned to several other biochemical defects, including pyruvate dehydrogenase deficiency, cytochrome-oxidase deficiency, biotinidase deficiency and defects involving complex I and complex V of the respiratory chain.

Most patients with pyruvate-carboxylase deficiency present with failure to thrive, developmental delay, recurrent seizures and metabolic acidosis. Lactate, pyruvate, alanine, β-hydroxybutyrate and acetoacetate concentrations are elevated in blood and urine. Hypoglycemia is not a consistent finding despite the fact that pyruvate carboxylase is the first rate-limiting step in gluconeogenesis.

Sixteen patients had an associated hyperammonemia, citrullinemia and hyperlysinemia. This presentation is the most malignant, with death in early infancy. This French phenotype is commonly associated with the absence of any immunological cross-reacting material (CRM) corresponding to the pyruvate carboxylase apoenzyme protein.

The North American phenotype is associated with the presence of CRM. Possibly as a result, the clinical presentation is less devastating in early infancy, although the outcome is almost invariably fatal in later infancy or early childhood. These patients do not have the associated abnormalities of ammonia metabolism, and the serum aspartic acid concentrations are not as severely depleted. Only one patient has been described with the North American phenotype and a benign clinical syndrome. She has had recurrent episodes of metabolic acidosis requiring hospitalization. Otherwise, her growth and neurological development have been normal.

Prenatal and postnatal diagnoses can be made by enzyme assay of cultured amniocytes, fibroblasts or white blood cells. Treatment remains symptomatic. Sodium bicarbonate is necessary to correct the acidosis. Aspartic acid supplementation will improve the systemic condition but has no effect on the neurological disturbances. Biotin supplementation is of no value.

Biotin-dependent syndromes are manifest in infants, who may present with developmental delay and may demonstrate laboratory abnormalities resulting from deficiencies of the four biotin-dependent carboxylases (see Ch. 39). Three of the carboxylases, located in the mitochondria, are involved in organic acid metabolism. Multiple carboxylase deficiency, when present in the newborn period, is the result of a deficiency of holocarboxylase synthetase, the enzyme that catalyzes the binding of biotin to the apocarboxylase. These infants often die shortly after birth. Older infants gradually develop neurological signs, with developmental delay and seizures associated with alopecia, rash and immunodeficiency. There is a deficiency of biotinidase, the enzyme responsible for the breakdown of biocytin, the lysyl derivative of biotin, to free biotin. Biotinidase deficiency can be recognized at birth by measuring the serum activity. Biotinidase deficiency occurs in 1 in 41,000 live births, and it is eminently treatable by the oral administration of biotin.

Glycogen synthetase deficiency has been described in three families. It caused stunted growth and severe fasting hypoglycemia with ketonuria. Mental retardation was reported in the three children who survived past infancy. The liver was virtually devoid of glycogen and showed fatty degeneration in all cases. In two patients, the brain showed diffuse, nonspecific changes in the white matter, seen as the presence of reactive astrocytes and increased microglia, which were considered secondary to prolonged hypoglycemia or anoxia. Biochemical studies showed that glycogen synthetase activity was markedly decreased in liver but normal in muscle, erythrocytes and leukocytes, suggesting the existence of multiple tissue-specific isoenzymes under separate genetic control. It is not known whether brain glycogen synthetase is different from that in liver.

In liver phosphorylase deficiency (glycogenosis type VI, Hers' disease; Fig. 42-1) and in two genetic forms of phosphorylase kinase deficiency, one of which is X-linked recessive, the other of which is autosomal recessive, hypoglycemia is either absent or mild. Symptoms of brain dysfunction do not usually occur (type VIII, Fig. 42-1) [1].

Fatty acid oxidation defects often produce recurrent disturbances of brain function [4, 8]. Drowsiness, stupor and coma occur during acute metabolic crises and mimic the Reye's syndrome phenotype. The neurological symptoms have been attributed to hypoglycemia, hypoketonemia and the deleterious effects of potentially toxic

organic acids. Hypoglycemia is caused by a continuing demand for glucose by brain and other organs, resulting from the primary biochemical defect of fatty-acid oxidation (Fig. 42-2). Avoidance of catabolic circumstances that require the utilization of fatty acids is the basic principle of treatment. L-carnitine supplementation is recommended for all conditions associated with generalized carnitine deficiency. Some patients may benefit from medium-chain triglyceride supplementation, as discussed previously. Certain forms of ETF-oxidoreductase deficiency respond to riboflavin supplementation. The riboflavin-responsive multiple acyl CoA dehydrogenase deficiency represents the milder form of glutaric aciduria type II.

DISEASES OF MITOCHONDRIAL METABOLISM

Mitochondrial dysfunction produces syndromes involving mainly muscle and the central nervous system. Although some energy can be obtained quickly from glucose or glycogen through anaerobic glycolysis, most of the energy derives from oxidation of carbohydrates and fatty acids in the mitochondria. The common metabolic product of sugars and fats is acetyl-CoA, which enters the Krebs cycle. Oxidation of one molecule of acetyl-CoA results in the reduction of three molecules of NAD and one of FAD. These reducing equivalents flow down a chain of carriers (Fig. 42-3) through a series of oxidation-reduction events. The final hydrogen acceptor is molecular oxygen, and the product is water. The released energy 'charges' the inner mitochondrial membrane, converting the mitochondrion into a veritable biological battery. This oxidation process is coupled to ATP synthesis from ADP and inorganic phosphate (P_i), catalyzed by mitochondrial ATPase [10, 13, 14]. Considering the enormous amount of information collected since 1960 on mitochondrial structure and function, it is surprising that diseases of terminal mitochondrial metabolism, i.e. the Krebs cycle and respiratory chain, have attracted the attention of clinical investigators only recently [10, 13, 14].

Initial clues that some diseases might be due to mitochondrial dysfunction came from electron-microscopic studies of muscle biopsies showing fibers with increased numbers of structurally normal or abnormal mitochondria. These fibers have a 'ragged red' appearance in the modified Gomori trichrome stain. Because the diagnosis was based on mitochondrial changes in muscle biopsies, these disorders were initially labeled mitochondrial myopathies. It soon became apparent, however, that many mitochondrial diseases with ragged red fibers were not confined to skeletal muscle but were multisystem disorders. In these patients, the clinical picture is often dominated by signs and symptoms of muscle and brain dysfunction, probably due to the great dependence of these tissues on oxidative metabolism. This group of disorders, often called mitochondrial encephalomyopathies, includes four more common syndromes (Table 42-1) [10, 13, 14].

The first, **Kearns–Sayre syndrome**, is characterized by childhood onset of progressive external ophthalmoplegia and pigmentary degeneration of the retina. Heart block, cerebellar syndrome or high CSF protein may also appear. Almost all cases are sporadic. The second syndrome, **myoclonus epilepsy with ragged red fibers (MERRF)**, is characterized by myoclonus, ataxia, weakness and generalized seizures. The third syndrome, **mitochondrial myopathy, encephalopathy, lactic acidosis and stroke-like episodes (MELAS)**, affects young children, who show stunted growth, episodic vomiting and headaches, seizures and recurrent cerebral insults resembling strokes and causing hemiparesis, hemianopsia or cortical blindness. The fourth syndrome, **neuropathy, ataxia, retinitis pigmentosa/maternally inherited Leigh's syndrome (NARP/MILS)** comes in two flavors: NARP is usually seen in young adults and is characterized by retinitis pigmentosa, dementia, seizures, ataxia, proximal weakness and sensory neuropathy, whereas MILS affects infants and children (often in the same family) and is a devastating encephalomyopathy with the neuroradiological and neuropathological symmetrical CNS lesions of Leigh's syndrome. Unlike Kearns–Sayre syndrome, MERRF, MELAS and NARP/MILS are transmitted by non-mendelian maternal inheritance. All four conditions are due to mutations in mitochondrial DNA (mtDNA); Kearns–Sayre syndrome is associated with single, large-scale mtDNA deletions; MERRF is typically due to a point mutation (A8334G) in the $tRNA^{Lys}$; MELAS is most commonly due to the A3243G mutation in the $tRNA^{Leu(UUR)}$, whereas NARP/MILS is caused by mutations in the ATPase-6 gene. The different severity of NARP and MILS is due to different mutation loads, much higher in MILS than in NARP [10, 13, 14].

Mitochondrial DNA is inherited maternally. What makes mitochondrial diseases particularly interesting from a genetic point of view is that the mitochondrion has its own DNA (mtDNA) and its own transcription and translation processes. The mtDNA encodes only 13 polypeptides; nuclear DNA (nDNA) controls the synthesis of 90–95% of all mitochondrial proteins. All known mitochondrially encoded polypeptides are located in the inner mitochondrial membrane as subunits of the respiratory chain complexes (Fig. 42-3), including seven subunits of complex I; the apoprotein of cytochrome *b*; the three larger subunits of cytochrome *c* oxidase, also termed complex IV; and two subunits of ATPase, also termed complex V.

In the formation of the zygote, all mitochondria are contributed by the ovum. Therefore, mtDNA is transmitted by maternal inheritance in a vertical, nonmendelian fashion. Strictly maternal transmission of mtDNA has been documented in humans by studies of restriction fragment length polymorphisms (RFLPs) in DNA from platelets. As exemplified by the disorders outlined above,

TABLE 42-1 Clinical features of mitochondrial diseases associated with mtDNA mutations

Boxes highlight typical features of different syndromes, except for maternally inherited Leigh's syndrome (MILS), which is defined on the basis of neuroradiologic or neuropathologic criteria. Pearson's syndrome is a hematological disorder of infancy characterized by sideroblastic anemia and exocrine pancreas dysfunction. –, absent; +, present; Δ-mtDNA, deleted mtDNA; KSS, Kearns–Sayre syndrome; MELAS, mitochondrial encephalomyopathy, lactic acidosis and stroke-like episodes; MERRF, myoclonus epilepsy with ragged-red fibers; MILS, maternally inherited Leigh's syndrome; NARP, neuropathy, ataxia and retinitis pigmentosa.

diseases caused by mutations of mtDNA are also transmitted by maternal inheritance: an affected mother ought to pass the disease to all of her children, were it not for the 'threshold effect', which is described later, but only her daughters can transmit the trait to subsequent generations [10, 13, 14]. Characteristics that distinguish maternal from mendelian inheritance include the following:

1. The number of affected individuals in subsequent generations should be higher than in autosomal dominant disease, again were it not for the 'threshold effect' (see below).
2. Inheritance is maternal, as in X-linked diseases, but children of both sexes are affected.
3. Because there are hundreds or thousands of copies of mtDNA in each cell, the phenotypic expression of a mitochondrially encoded gene depends on the relative proportions of mutant and wild-type mtDNAs within a cell; this is termed the 'threshold effect'.
4. Because mitochondria replicate more often than do nuclei, the relative proportion of mutant and wild-type mtDNAs may change within a cell cycle.
5. At the time of cell division, the proportion of mutant and wild-type mtDNAs in the two daughter cells can shift, thus giving them different genotypes and, possibly, different phenotypes, a phenomenon called mitotic segregation.

As described above, maternal inheritance has been documented in diseases due to point mutations of mtDNA, while most diseases due to mtDNA deletions or duplications are sporadic.

The genetic classification of mitochondrial diseases divides them into three groups. **Defects of mtDNA** include point mutations and deletions or duplications. From a biochemical point of view, these disorders will be associated with dysfunction of the respiratory chain

because all 13 subunits encoded by mtDNA are subunits of respiratory chain complexes. Diseases due to point mutations are transmitted by maternal inheritance, and the number has rapidly increased since the first pathogenic mtDNA mutations were described 16 years ago. The main syndromes include MERRF; MELAS; NARP/MILS (Table 42-1); Leber's hereditary optic neuropathy, a disorder causing blindness in young adult men. Diseases due to deletions or duplications are usually sporadic, for reasons that are not completely clear. They include, besides Kearns–Sayre syndrome (Table 42-1), isolated progressive external ophthalmoplegia and Pearson's syndrome, a usually fatal infantile disorder dominated by sideroblastic anemia and exocrine pancreas dysfunction.

Defects of nuclear DNA also cause mitochondrial diseases. As mentioned above, the vast majority of mitochondrial proteins are encoded by nDNA, synthesized in the cytoplasm and 'imported' into the mitochondria through a complex series of steps. Diseases can be due to mutations in genes encoding respiratory chain subunits, ancillary proteins controlling the proper assembly of the respiratory chain complexes, proteins controlling the importation machinery, or proteins controlling the lipid composition of the inner membrane. All these disorders will be transmitted by mendelian inheritance. From a biochemical point of view, all areas of mitochondrial metabolism can be affected (see below).

Defects of communication between nDNA and mtDNA can also cause mitochondrial diseases. The nDNA controls many functions of the mtDNA, including its replication. It is, therefore, predictable that mutations of nuclear genes controlling these functions could cause alterations in the mtDNA. Two groups of human diseases are due to faulty intergenomic communication [10, 13, 14]. The first is associated with multiple mtDNA deletions and is characterized clinically by ptosis, progressive external ophthalmoplegia (PEO), weakness of limb and respiratory muscles, peripheral neuropathy, parkinsonism and – often – psychiatric disorders. Transmission is more commonly autosomal dominant than recessive. Mutations in four genes have been associated with autosomal dominant PEO syndromes (adenine nucleotide transporter 1, *ANT1*, and *Twinkle*, a helicase), with autosomal dominant or recessive PEO syndromes (polymerase gamma, *POLG*), and with a multisystem disorder called mitochondrial neurogastrointestinal encephalomyopathy, or MNGIE (thymidine phosphorylase, *TP*) [10, 13, 14]. The second group of disorders is associated with mtDNA depletion in one or more tissues, more commonly in muscle (myopathic form) or in liver and brain (hepatocerebral form). Depending on the tissues affected and the severity of the mtDNA decrease, the clinical picture can be a rapidly fatal congenital myopathy, a slightly more benign myopathy of childhood, a fatal hepatopathy or a multisystem disorder. Transmission is autosomal recessive, and two genes have been associated with mtDNA depletion syndromes, deoxyguanosine kinase (*dGK*) and thymidine kinase 2 (*TK2*). Mutations in *dGK* tend to cause the hepatocerebral phenotype and mutations in *TK2* are generally associated with the myopathic variant. However, there are many patients with mtDNA depletion but without mutations in either gene: clearly, more genes are implicated and have to be identified.

The biochemical classification of mitochondrial DNA is based on the five major steps of mitochondrial metabolism. These steps are illustrated in Figure 42-3 and divide mitochondrial diseases into five groups: defects of mitochondrial transport, defects of substrate utilization, defects of the Krebs cycle, defects of the respiratory chain and defects of oxidation–phosphorylation coupling.

All disorders except those in group 5 are due to defects of nDNA and are transmitted by Mendelian inheritance. Disorders of the respiratory chain can be due to defects of nDNA or mtDNA. Usually, mutations of nDNA cause isolated, severe defects of individual respiratory complexes, whereas mutations in mtDNA or defects of intergenomic communication cause variably severe, multiple deficiencies of respiratory chain complexes. The description that follows is based on the biochemical classification.

Defects of mitochondrial transport interfere with the movement of molecules across the inner mitochondrial membrane, which is tightly regulated by specific translocation systems. The carnitine cycle is shown in Figure 42-2 and is responsible for the translocation of acyl-CoA thioesters from the cytosol into the mitochondrial matrix. The carnitine cycle involves four elements: the plasma membrane carnitine transporter system, CPT I, the carnitine–acyl carnitine translocase system in the inner mitochondrial membrane and CPT II. Genetic defects have been described for each of these four steps, as discussed previously [4, 8, 9].

Defects of substrate utilization. Pyruvate dehydrogenase (PDH) deficiency can cause alterations of pyruvate metabolism, as can defects of pyruvate carboxylase, as discussed earlier. Over 200 patients have been described with a disturbance of the PDH complex (PDHC) [15, 16]. The clinical picture includes several phenotypes ranging from a severe, devastating metabolic disease in the neonatal period to a benign, recurrent syndrome in older children. There is considerable overlap clinically and biochemically with other disorders (see below).

The PDHC catalyzes the irreversible conversion of pyruvate to acetyl-CoA (Fig. 42-3) and is dependent on thiamine and lipoic acid as cofactors (see Ch. 35). The complex has five enzymes: three subserving a catalytic function and two subserving a regulatory role. The catalytic components include PDH, E1; dihydrolipoyl transacetylase, E2; and dihydrolipoyl dehydrogenase, E3. The two regulatory enzymes include PDH-specific kinase and phospho-PDH-specific phosphatase. The multienzyme complex contains nine protein subunits, including

protein X. Protein X anchors the E3 component to the E2 core of the complex. The E1α subunit is encoded by a gene on the short arm of the X chromosome and a gene on chromosome 4. The E1β subunit is encoded by a gene on chromosome 3, the E2 component is encoded by a gene on chromosome 11 and the E3 component is encoded by a gene on chromosome 7. Biochemical defects have been documented for the E1α subunit, E2, E3, protein X and the phospho-PDH-specific phosphatase. The great majority of cases involve a mutation defect of the E1α subunit [15, 16]. Both sexes are equally represented despite the location of the E1α-subunit gene on the X chromosome.

The most devastating phenotype of PDH deficiency presents in the newborn period. The majority of patients are male and critically ill with a severe metabolic acidosis. There is an elevated blood or CSF lactate concentration and associated elevations of pyruvate and alanine. These patients have seizures, failure to thrive, optic atrophy, microcephaly and dysmorphic features. Multiple brain abnormalities have been described, including dysmyelination of the cortex, cystic degeneration of the basal ganglia, ectopic olivary nuclei, hydrocephalus and partial or complete agenesis of the corpus callosum. A less devastating phenotype presents in early infancy. These patients demonstrate the histopathological features of Leigh's syndrome. Other patients affected in infancy survive with a chronic neurodegenerative syndrome manifested by mental retardation, microcephaly, recurrent seizures, spasticity, ataxia and dystonia.

Mutations involving the E1α subunit behave clinically like an X-linked dominant condition. These mutations usually are lethal in boys during early infancy. The clinical spectrum in the heterozygous girl is more varied, ranging from a devastating condition in early infancy to a mild chronic encephalopathy with mental retardation. The least symptomatic woman may give birth to affected male and female progeny and pose a significant problem in clinical diagnosis and genetic counseling.

Treatment is largely symptomatic, and the prognosis ranges from dismal to guarded. Thiamine, lipoic acid, ketogenic diet and physostigmine have been tried in different concentrations and doses with equivocal results. Some patients with periodic ataxia resulting from PDHC deficiency may respond to acetazolamide.

Glutaric aciduria type II, which is a defect of β-oxidation, may affect muscle exclusively or in conjunction with other tissues. Glutaric aciduria type II, also termed multiple acyl-CoA dehydrogenase deficiency (Fig. 42-2), usually causes respiratory distress, hypoglycemia, hyperammonemia, systemic carnitine deficiency, nonketotic metabolic acidosis in the neonatal period and death within the first week. A few patients with onset in childhood or adult life showed lipid-storage myopathy, with weakness or premature fatigue [4]. Short-chain acyl-CoA deficiency (Fig. 42-2) was described in one woman with proximal limb weakness and exercise intolerance. Muscle biopsy showed marked accumulation of lipid droplets. Although no other tissues were studied, the defect appeared to be confined to skeletal muscle, suggesting the existence of tissue-specific isozymes [4].

Defects of the Krebs cycle. Fumarase deficiency was reported in children with mitochondrial encephalomyopathy. Usually, there is developmental delay since early infancy, microcephaly, hypotonia and cerebral atrophy, with death in infancy or early childhood. The laboratory hallmark of the disease is the excretion of large amounts of fumaric acid and, to a lesser extent, succinic acid in the urine. The enzyme defect has been found in muscle, liver and cultured skin fibroblasts [16].

Abnormalities of the respiratory chain. These are increasingly identified as the hallmark of 'mitochondrial diseases' or 'mitochondrial encephalomyopathies' [13]. They can be identified on the basis of polarographic studies showing differential impairment in the ability of isolated intact mitochondria to use different substrates. For example, defective respiration with NAD-dependent substrates, such as pyruvate and malate, but normal respiration with FAD-dependent substrates, such as succinate, suggests an isolated defect of complex I (Fig. 42-3). However, defective respiration with both types of substrates in the presence of normal cytochrome c oxidase activity, also termed complex IV, localizes the lesions to complex III (Fig. 42-3). Because frozen muscle is much more commonly available than fresh tissue, electron transport is usually measured through discrete portions of the respiratory chain. Thus, isolated defects of NADH–cytochrome c reductase, or NADH-coenzyme Q (CoQ) reductase suggest a problem within complex I, while a simultaneous defect of NADH and succinate–cytochrome c reductase activities points to a biochemical error in complex III (Fig. 42-3). Isolated defects of complex III can be confirmed by measuring reduced CoQ-cytochrome c reductase activity.

Defects of complex I. Known or presumed nuclear defects of complex I usually affect infants or children. Some have fatal infantile multisystem disorders, characterized by severe congenital lactic acidosis, psychomotor delay, diffuse hypotonia and weakness, cardiopathy, and cardiorespiratory failure. Some have the neuroradiological and neuropathological features of Leigh's syndrome. Interestingly, a handful of mutations in nuclear genes encoding complex I subunits have been identified in these children, making prenatal diagnosis possible for some families [7].

Complex I deficiency due to mtDNA mutations (seven subunits of complex I are encoded by mtDNA) can be divided into encephalomyopathies and myopathies. The most important encephalomyopathy is Leber's hereditary optic neuropathy, characterized by acute or subacute loss of vision due to severe bilateral optic atrophy, with onset usually between 18 and 30 years and marked predominance in men. Three mutations (in *ND1*, *ND4* and *ND6*)

are considered 'primary', i.e. pathogenic in and by themselves. Increased number of mutations in *ND5* have been associated with clinical phenotypes resembling MELAS, Leigh's syndrome, MERRF or overlapping syndromes. As expected, all these disorders are inherited maternally [14].

Myopathies have been described in several sporadic cases with lactic acidosis, cytochrome oxidase (COX)-positive RRF in muscle, and isolated complex I deficiency, and have been attributed to various pathogenic mutations in ND genes. The sporadic nature of these myopathies suggests that the ND mutations are de novo, arising spontaneously in myogenic stem cells after germ-layer differentiation (somatic mutations) [14].

Defects of complex II. These have not been fully characterized in the few reported patients, and the diagnosis has often been based solely on a decrease of succinate–cytochrome *c* reductase activity (Fig. 42-3). However, partial complex II deficiency was documented in muscle and cultured fibroblasts from two sisters with clinical and neuroradiological evidence of Leigh's syndrome, and molecular genetic analysis showed that both patients were homozygous for a point mutation in the flavoprotein subunit of the complex [17]. This was the first documentation of a molecular defect in the nuclear genome associated with a respiratory chain disorder.

Coenzyme Q10 (CoQ10) deficiency. This mitochondrial encephalomyopathy has three main clinical presentations. A predominantly myopathic form is characterized by the triad of exercise intolerance, recurrent myoglobinuria, and CNS involvement. A more frequent ataxic form is dominated by ataxia and cerebellar atrophy, variously associated with weakness, developmental delay, seizures, pyramidal signs, and peripheral neuropathy, often simulating spinocerebellar atrophy. A third presentation with fatal infantile encephalomyopathy and renal involvement, has been described in two families. The biochemical defect (or defects) presumably involve different steps in the biosynthesis of CoQ10, but are still unknown, as are the molecular defects. Diagnosis, however, is important because all patients – and especially those with the myopathic and infantile forms – benefit from CoQ10 supplementation [13, 14].

Defects of complex III. Like defects of complex I, these can be due to nDNA mutations or to mtDNA mutations. The only nuclear defect described thus far does not affect a complex III subunit, but an ancillary protein needed for proper assembly, BCS1L. Mutations in *BCS1L* can cause a Leigh's-syndrome-like disorder or a fatal infantile disease called GRACILE (growth retardation, aminoaciduria, cholestasis, iron overload, lactacidosis, and early death).

Mutations in the only mtDNA-encoded subunit of complex III (cytochrome *b*) can cause multisystem disorders or – more commonly – isolated myopathies, manifested by exercise intolerance with or without exercise-related myoglobinuria. Patients with myopathy are almost invariably sporadic, suggesting that the cytochrome *b* mutations are somatic. Muscle biopsies in these patients show COX-positive RRF and isolated complex III deficiency [18].

Defects of complex IV. These disorders, also termed COX deficiency, have clinical phenotypes that fall into two main groups: one in which myopathy is the predominant or exclusive manifestation and another in which brain dysfunction predominates (Fig. 42-3). In the first group, the most common disorder is fatal infantile myopathy, causing generalized weakness, respiratory insufficiency and death before age 1 year. There is lactic acidosis and renal dysfunction, with glycosuria, phosphaturia and aminoaciduria, also termed DeToni–Fanconi–Debre syndrome. The association of myopathy and cardiopathy in the same patient and myopathy and liver disease in the same family has also been described [14].

In patients with pure myopathy, COX deficiency is confined to skeletal muscle, sparing heart, liver and brain. The amount of immunologically reactive enzyme protein is markedly decreased in muscle by enzyme-linked immunosorbent assay (ELISA) and by immunocytochemistry of frozen sections. Benign infantile mitochondrial myopathy, in contrast, has been described in a few children with severe myopathy and lactic acidosis at birth, who then improve spontaneously and are virtually normal by age 2 years. This condition is due to a reversible COX deficiency. The enzyme activity is markedly decreased, <19% of normal, in muscle biopsies taken soon after birth but returns to normal in the first year of life. Immunocytochemistry and immunotitration show normal amounts of enzyme protein in all muscle biopsies. This finding differs from the virtual lack of CRM in patients with fatal infantile myopathy and may represent a useful prognostic test. The selective involvement of one or more tissues and the reversibility of the muscle defect in the benign form suggest the existence of tissue-specific and developmentally regulated COX isoenzymes in humans [13]. While the molecular bases of both the 'fatal' and the 'benign' myopathies described above remain uncertain, but presumably involve nuclear genes, some patients with exercise intolerance and myoglobinuria have somatic mutations in mtDNA-encoded genes [14].

Subacute necrotizing encephalomyelopathy, also termed Leigh's syndrome, typifies the second group of disorders of complex IV, dominated by involvement of the CNS. Leigh's syndrome usually starts in infancy or childhood and is characterized by psychomotor retardation, brainstem abnormalities and apnea [10, 13, 14]. The pathological hallmark consists of focal, symmetrical necrotic lesions from thalamus to pons, involving the inferior olives and the posterior columns of the spinal cord. Microscopically, these spongy brain lesions show demyelination, vascular proliferation and astrocytosis. In these patients, COX deficiency is generalized, including cultured fibroblasts in most, but not all, cases. This may provide a useful tool for prenatal diagnosis in at least some families. Immunological studies show CRM in all tissues.

Great strides have been made in our understanding of the molecular bases of COX-deficient Leigh's syndrome [13, 14]. As is the case for complex III deficiency, thus far no mutations have been found in genes encoding COX subunits, but several COX-assembly genes have been involved. Most mutations causing typical Leigh's syndrome are in the *SURF1* gene. Mutations in other genes often affect one other tissue besides the brain, such as the heart (*SCO2* and *COX15*), the liver (*SCO1*), or the kidney (*COX10*). Even though there is no effective therapy for these disorders, at least we can now offer prenatal diagnosis to many affected families.

Defects of complex V. The most important disorder is NARP/MILS, an encephalomyopathy already described above, which can present in the same family as Leigh's syndrome in infants or as milder multisystem disorder in young adults (NARP). In fact NARP/MILS is a good example of the importance of the mutation load. When the common mutation (T8993G in the ATPase-6 gene of mtDNA) is present in great abundance (>90%), the phenotype is MILS; when the same mutation is less abundant (about 70%), the phenotype is NARP. Another interesting aspect of the NARP/MILS phenotype is that it can also be caused by a distinct mutation in the same nucleotide (T8993C). Both clinical and biochemical expressions are milder with the T-to-C than with the T-to-G mutation. As expected, ATP production by mitochondria isolated from cultured fibroblasts harboring almost homoplasmic levels of the T89993G mutation was markedly decreased. A few other mutations in the ATPase 6 gene have been associated with Leigh's syndrome or with a similar but milder condition called familial bilateral striatal necrosis.

Mutations in one nuclear gene (*ATP12*), encoding an ATPase assembly protein, have been associated with complex V deficiency in an infant with congenital lactic acidosis and a rapidly fatal disorder affecting brain, liver, heart, and muscle [19].

Defects of oxidation–phosphorylation coupling. The best known example of such a defect is Luft's disease, or nonthyroidal hypermetabolism. Only two patients with this condition have been reported. Family history was noncontributory in both cases. Symptoms started in childhood or early adolescence with fever, heat intolerance, profuse perspiration, resting tachypnea and dyspnea, polydipsia, polyphagia and mild weakness. The basal metabolic rate was markedly increased in both patients, but all tests of thyroid function were normal. Muscle biopsies showed ragged red fibers and proliferation of capillaries. Other tissues were morphologically normal. Studies of oxidative phosphorylation in isolated muscle mitochondria from both patients showed maximal respiratory rate even in the absence of ADP, an indication that respiratory control was lost. Respiration proceeded at a high rate independently of phosphorylation, and energy was lost as heat, causing hypermetabolism and hyperthermia [13, 14].

ACKNOWLEDGMENTS

Some of the work discussed in this chapter was supported by NIH grants NS11766 and HD32062, a grant from the Muscular Dystrophy Association and a laboratory grant from the Colleen Giblin Foundation for Pediatric Neurology Research.

Disorders of Muscle Excitability

Juan M. Pascual

Basil T. Darras

ORGANIZATION OF THE NEUROMUSCULAR JUNCTION 713
Nerve and muscle communicate through neuromuscular junctions 713
Acetylcholine acts as a chemical relay between the electrical potentials of nerve and muscle 714
The fidelity of signal transmission relies on the orchestration of innumerable stochastic molecular events 715

EXCITATION AND CONTRACTION OF THE MUSCLE FIBER 716
The excitable apparatus of muscle is composed of membranous compartments 716
Myofibrils are designed and positioned to produce movement and force 717
Calcium couples muscle membrane excitation to filament contraction 718

GENETIC DISORDERS OF THE NEUROMUSCULAR JUNCTION 719
Congenital myasthenic syndromes impair the operation of the acetylcholine receptor 719

HEREDITARY DISEASES OF MUSCLE MEMBRANES 720
Mutations of the sodium channel cause hyperkalemic periodic paralysis and paramyotonia congenital 720
Hypokalemic periodic paralysis is due to calcium channel mutations 721
Abnormal potassium channels in Andersen's syndrome cause more than periodic paralysis 721
Ribonuclear inclusions are responsible for the multiple manifestations of myotonic dystrophy 722
Congenital myotonia is caused by mutant Cl^- channels 722
Malignant hyperthermia caused by mutant ryanodine receptor calcium release channels 723
Calcium channel mutations may also cause malignant hyperthermia 723
Brody's disease is an unusual disorder of the sarcoplasmic reticulum calcium ATPase 723

IMMUNE DISEASES OF MUSCLE EXCITABILITY 723
Myasthenia gravis is caused by antibodies that promote premature AChR degradation 723
Antibodies against the muscle-specific receptor kinase mimic myasthenia gravis 724
Antibodies cause calcium channel dysfunction in Lambert–Eaton syndrome 724
Potassium channel antibodies in Isaac syndrome cause neuromyotonia 725

TOXINS AND METABOLITES THAT ALTER MUSCULAR EXCITATION 725
Bacterial botulinum toxin blocks presynaptic acetylcholine release 725
Snake, scorpion, spider, fish and snail peptide venoms act on multiple molecular targets at the neuromuscular junction 727
Electrolyte imbalances alter the voltage sensitivity of muscle ion channels 728

ORGANIZATION OF THE NEUROMUSCULAR JUNCTION

Nerve and muscle communicate through neuromuscular junctions. The transmission of the nerve impulse to muscle to generate movement and force takes place at the neuromuscular junction (NMJ), a specialized type of synapse where the nerve action potential triggers a muscle action potential through the intervention of a chemical relay: the release of acetylcholine (ACh). Each motor neuron in the brainstem and spinal cord innervates a larger or smaller group of muscle cells (fibers) – all together constituting the motor unit – whose number depends on the precision of movement and strength of force to which the muscle is accustomed (Fig. 43-1). The entire pre- and postsynaptic apparatus, including the intercellular synaptic space, is contained in a differentiated area of exceeding complexity that only measures about 40 µm in its largest dimension (Fig. 43-2). The neural Schwann cells delimit the surface of the NMJ by contributing a protective enveloping process devoid of myelin and containing specialized membrane proteins such as neural cell adhesion molecule. Entering slightly into the muscle, the nerve endings form boutons that are separated from a highly invaginated region of raised muscle plasma membrane by a synaptic space of 50 nm. The basal lamina of both nerve and muscle, mainly composed of type IV collagen, continues uninterrupted across the synaptic cleft but differentiates at the NMJ by harboring specialized proteins such as acetylcholinesterase (AChE), laminin, agrin

and neuregulins. Presynaptic terminal mitochondria provide ATP for the energetically demanding vesicular ACh turnover process and a fraction of the synaptic vesicles in the terminal are associated with regions of increased membrane density called active or release zones (Fig. 43-3). These zones contain high densities of voltage-gated Ca^{2+} channels of the P/Q type as well as calcium-activated K^+ channels, and are precisely located across from the infoldings of the postsynaptic membrane. Following nerve stimulation, vesicles at these sites fuse with the plasma membrane and release their content of ACh directly over the postsynaptic receptor molecules on the folds below. A significant fraction of synaptic vesicles, however, is directly associated with actin (see Ch. 8) away from the active zones and not available for immediate release. The postsynaptic muscle membrane is also highly specialized. Nicotinic ACh receptors (AChR) cluster in the infoldings and directly associate with 43 kDa rapsyn (receptor-aggregating protein at the synapse). Utrophin – a large protein similar to dystrophin – and α-dystrobrevin are thought to link the AChR complexes to actin filaments and to a much larger network of proteins, many of which are coming to attention as the molecular cause of an increasing number of human myopathies is being determined.

Acetylcholine acts as a chemical relay between the electrical potentials of nerve and muscle. ACh is synthesized in the nerve terminal by choline acetyltransferase (ChAT) from choline and acetyl-CoA – a product of glycolysis and pyruvate oxidation – and, in most regards, this process does not differ from that carried out in central nervous system synapses (see Ch. 11). ACh is released after the arrival of the nerve action potential to the resting terminal, whose potential is maintained by the Na^+,K^+-ATPase. Depolarization leads to activation of Ca^{2+}

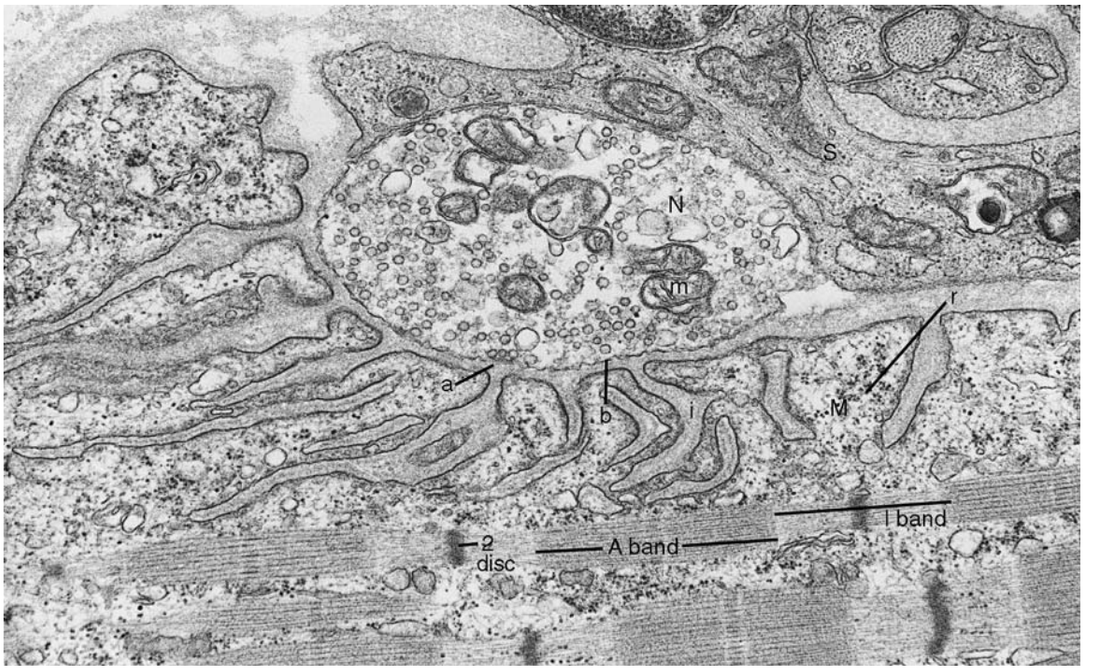

FIGURE 43-2 Photomicrograph of the human neuromuscular junction. In normal muscle, Ach receptors are associated with the terminal expansions of the junctional folds and the architecture of the postjunctional membrane follows closely the distribution of active zones in the presynaptic membrane. *b*, basal lamina; *I*, infoldings; *m*, mitochondria; *M*, myocyte; *N*, nerve terminal; *r*, ribosomes; *s*, synaptic space; *S*, Schwann cell. channels and to a surge of Ca^{2+} entry (see Ch. 22) reaching an impressive concentration of 0.1 mmol/l for a few milliseconds. Later, Ca^{2+} is buffered in the terminal and extruded by the Na^+/Ca^{2+} exchanger, as the opening of voltage-gated K^+ channels also helps restore membrane potential. While still in the cytosol, Ca^{2+} interacts with the sensing vesicular protein synaptotagmin, priming other vesicular proteins for docking against and fusion with the plasma membrane. ACh then is freed to diffuse across the junctional cleft and interact with AChR [1] until it encounters AChE and is hydrolyzed into choline and acetate, later to be recovered by the terminal. AChE exists in a peculiar trimeric conformation composed of three groups of four active globular heads linked by a collagen strand named ColQ. An enzyme of great therapeutic significance, AChE is reversibly blocked by anticholinesterases of medical use, and irreversibly phosphorylated and disabled by organophosphate insecticides, among many other modulators. Following fusion and diffusion of ACh, the vesicular membrane is retrieved by endocytosis of clathrin-coated vesicles and refilled with ACh. While being refilled, vesicles are tethered to actin filaments as mentioned above via synapsin, a vesicular protein that loosens its attachment after Ca^{2+}-dependent phosphorylation by calmodulin kinase. Only then is a vesicle ready for localization near the active zone pending release.

The fidelity of signal transmission relies on the orchestration of innumerable stochastic molecular events. Neuromuscular transmission relies on the generation of a junctional muscle membrane depolarization large enough to sustain the formation of a propagated action potential; the difference between the magnitude of the first parameter and the threshold of the action potential is called the safety factor of neuromuscular transmission. Inexorably, impulse transmission must proceed across multiple conformational changes in the molecules that underlie NMJ excitability. An inherently stochastic (as opposed to a deterministic all-or-nothing) process, normal transmission necessitates a large safety factor in order to operate with fidelity. Among the processes that are nondeterministic, i.e. governed by probability distribution laws, are the opening of voltage-gated Ca^{2+} channels, the number of ACh vesicles released each time, the diffusion of ACh in the cleft, the binding of two ACh molecules to the AChR, the onset of desensitization and closing of the AChR, and the encounter of the neurotransmitter with AChE, to name but a few events for which the probability laws are known. The origin of this stochastic behavior is intrinsic to the molecules that change conformation but is accentuated by the limited dimensions of the NMJ, which includes a relatively small number of molecules. In contrast, an enzymatic reaction taking place, for example,

in solution carried out by an ensemble of many more molecules behaves, as a whole, predictably. The limitation to the size of the NMJ may be due to the large energetic expense associated with its maintenance, particularly when it is subject to frequent use (think, for example, of a flying hummingbird) and, thus, energy may be safely spared by reducing synaptic size as long as the safety factor of transmission remains large. In line with the importance of neuromuscular transmission for the survival of the organism, all key molecular elements of the NMJ are encoded by highly conserved genes whose absence or severe dysfunction is incompatible with life. Instead, diseases of the NMJ tend to shift the probability distribution laws for the different conformations of its key molecules, and may thus be viewed as processes that decrease the safety factor of transmission. This is the central pathophysiological phenomenon of neuromuscular diseases.

EXCITATION AND CONTRACTION OF THE MUSCLE FIBER

The excitable apparatus of muscle is composed of membranous compartments. The muscle cell is surrounded by a plasma membrane that, together with the various connective tissue elements and collagen fibrils, forms the sarcolemma [2]. The interior of the resting cell is maintained at an electrical potential about 80 mV more negative than the exterior by the combined action of pumps and channels in the plasma membrane. Unlike membranes of nerves, muscle membranes have a high conductance (G) to chloride ions in the resting state; G_{Cl^-} accounts for about 70% of the total membrane conductance. Potassium ion conductance accounts for most of the remainder, and the membrane potential is normally close to the Nernst potential for these two ions (see Ch. 6). Asymmetrical concentration gradients for sodium and potassium ions are maintained at the cost of energy by the membrane Na^+,K^+-ATPase. During the generation of a muscle action potential, a rapid and stereotyped membrane depolarization is produced by an increase in sodium ion conductance mediated by voltage-dependent Na^+ channels. The conductance increase is self-limiting and membrane repolarization is assisted by the delayed opening of a potassium ion conductance pathway. Action potentials originating at the NMJ spread in a nondecremental fashion over the entire surface of the muscle. Action potentials traveling on the sarcolemma penetrate the interior of the muscle cell along transverse (T) tubules that are continuous with the outer membrane (Fig. 43-4). These tubules are seen as openings on the surface of the

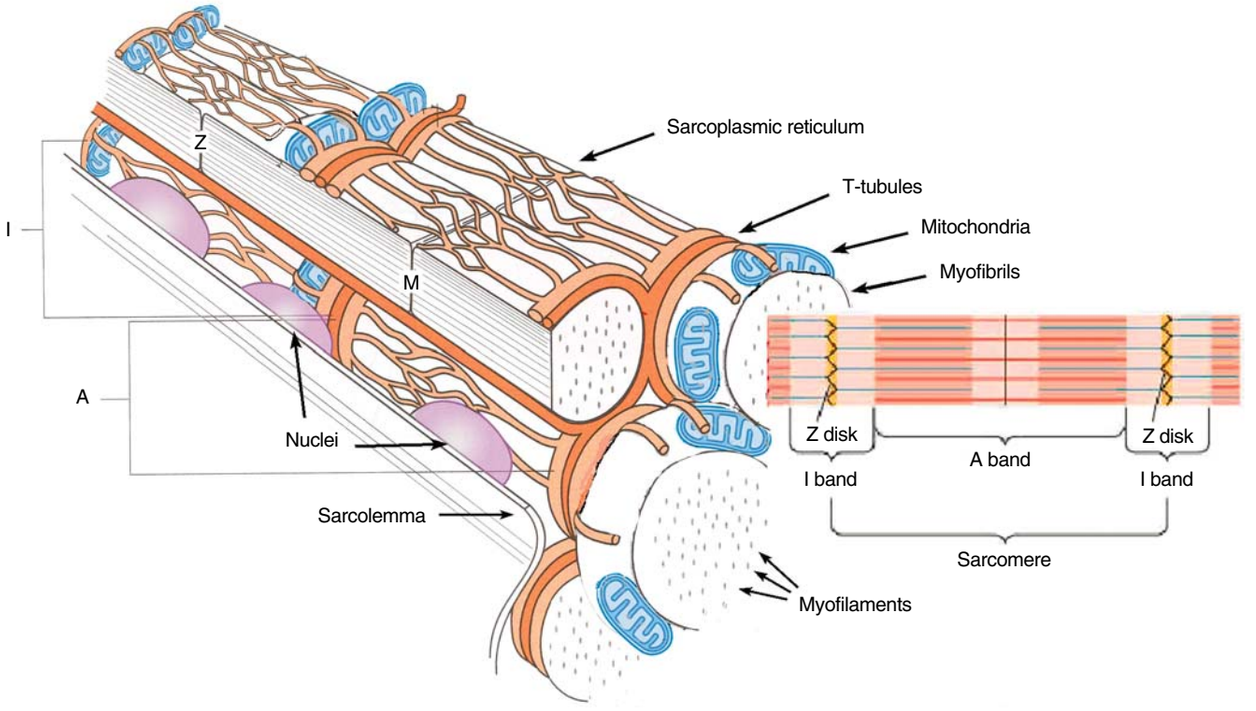

FIGURE 43-4 Cellular and molecular organization of the skeletal myocyte.

muscle cell and the depolarization of this membrane system spreads activity to the center of the fiber. As this T-tubular network courses inward, close associations are formed with specialized terminal elements of the sarcoplasmic reticulum (SR). At the electron microscope level, the structure formed by a single tubule interposed between two terminal SR elements is called a triad. The SR stores Ca^{2+} in relaxed muscle and releases it into the sarcoplasm upon depolarization of the cell membrane and the T-tubular system.

Myofibrils are designed and positioned to produce movement and force. The physiological unit of muscle, the myocyte or fiber, contains repeating structures known as sarcomeres that are separated from each other by dark lines called Z disks. Within each sarcomere, the A and I bands are seen; the A band, lying between two I bands, occupies the center of each sarcomere and is highly birefringent. Within the A band is a central, lighter zone, the H band, and in the center of the H band is the darker M band. The Z disk is at the center of the I band (Fig. 43-4). The difference in birefringence between the A and I bands produces the characteristic striated appearance of voluntary muscle when seen through the light microscope. The repeating optical characteristics of the A and I bands in each sarcomere reflect the regular arrangement of two sets of filaments. The thin filaments have a diameter of ≈180 Å, appear to be attached to the Z bands and are found in the I band and part of the A band. The thick filaments have a diameter of ≈150 Å, occupy the A band and are connected crosswise by material in the M band. In cross section, the thick filaments are arranged in a hexagonal lattice and the thin filaments occupy the centers of the triangles formed by the thick filaments. With the identification of two sets of discontinuous filaments in the sarcomere came the recognition that (1) the two kinds of filaments become cross-linked only on excitation and (2) contraction of muscle does not depend on shortening the length of the filaments but rather on the relative motion of the two sets of filaments, termed the sliding-filament mechanism [3]. Thus, the length of the muscle depends on the length of the sarcomeres and, in turn, variation in sarcomere length is based on variation in the degree of overlap between the thin and thick filaments.

In addition to actin and myosin, other proteins are found in the two sets of filaments. Tropomyosin and a complex of three subunits collectively called troponin are present in the thin filaments and play an important role in the regulation of muscle contraction. Although the proteins constituting the M and the Z bands have not been fully characterized, they include α-actinin and desmin as well as the enzyme creatine kinase, together with other proteins. A continuous elastic network of proteins, such as connectin, surround the actin and myosin filaments, providing muscle with a parallel passive elastic element. Actin forms the backbone of the thin filaments [4]. The thin filaments of muscle are linear polymers of slightly elongated, bilobar actin subunits, each about 4×6 nm, arranged in a helical fashion, with the longer dimension roughly at right angles to the filament axis. Each monomer has a molecular weight of about 42 kDa and contains a single nucleotide binding site. Hydrolysis of ATP to ADP takes place during actin polymerization but is not involved in muscle contraction. A wide variety of proteins interact with actin in both muscle and nonmotile cells. They may affect the polymerization–depolymerization of actin and are involved in the attachment of actin to other cellular structures, including the Z disks in muscle as well as membranes in both muscle and nonmuscle cells.

Myosin, the chief constituent of thick filaments, is a multisubunit protein. It is an asymmetrical molecule of ≈500 kDa with an overall length of ≈150 nm. Its width varies between about 2 and 10 nm. In contrast to actin, myosin consists of several peptide subunits. Each myosin molecule contains two heavy chains of ≈200 kDa; these extend through the length of the molecule. Over most of their length, the two chains are intertwined to form a double α-helical rod; at one end they separate, each forming an elongated globular portion. The two globular portions contain the sites responsible for ATP hydrolysis and interaction with actin. In addition to the two heavy chains, each myosin molecule contains four light chains of ≈20 kDa. These light chains modulate myosin activity and some of them can be phosphorylated by kinases. Myosin molecules form end-to-end aggregates involving the rod-like segments, which then grow into the thick filaments. The polarity of the myosin molecules is reversed on either side of the central portion of the filament. The globular ends of the molecules form projections, termed cross-bridges, on the aggregates that interact with actin. Conformational changes within this region, driven by ATP hydrolysis, provide the force that propels the movement of actin fibrils with respect to the myosin filament (Fig. 43-5). The ATPase activity of myosin itself is stimulated by Ca^{2+} and is low in Mg^{2+}-containing media. The hydrolysis of ATP releases sufficient free energy to induce conformational changes that are converted into cellular movement and, ultimately, mechanical work [4].

Tropomyosin and troponin are proteins located in the thin filaments, and together with Ca^{2+}, they regulate the interaction of actin and myosin (Fig. 43-3) [5]. Tropomyosin is an α-helical protein consisting of two polypeptide chains; its structure is similar to that of the rod portion of myosin. Troponin is a complex of three proteins. If the tropomyosin–troponin complex is present, actin cannot stimulate the ATPase activity of myosin unless the concentration of free Ca^{2+} increases substantially, while a system consisting solely of purified actin and myosin does not exhibit any Ca^{2+} dependence. Thus, the actin–myosin interaction is controlled by Ca^{2+} in the presence of the regulatory troponin–tropomyosin complex [6].

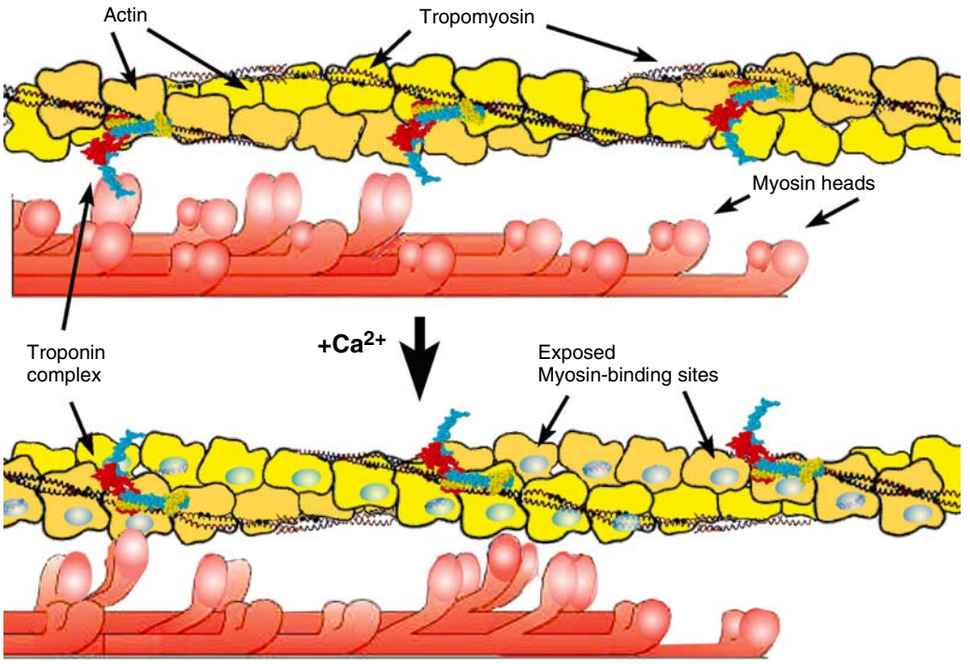

FIGURE 43-5 Myofibrillar apparatus and muscular contraction. Troponin is essential in Ca^{2+} regulation of contraction and is represented as a small, boomerang-shaped trimer. It consists of three subunits (TnT (*yellow*), TnC (*red*) and TnI (*cyan*)) and, together with tropomyosin (drawn as a helicoidal dimeric string), is located in apposition to the actin filament (represented as an *orange-yellow* helical chain with its myosin binding sites in *blue*). Myosin filament heads, represented in the lower part of each panel, possesses ATPase activity. Redrawn from Takeda, S. *et al.* Structure of the core domain of human cardiac troponin in the Ca^{2+}-saturated form, *Nature* 424: 35–41 and Brown J. H. *et al.* Deciphering the design of the tropomyosin molecule, *PNAS* 98: 8496–8501, 2001.

Calcium couples muscle membrane excitation to filament contraction. Important work has focused on the proteins present in the T-tubule/SR junction. One protein, an integral component of the T-tubular membrane, is a form of L-type, dihydropyridine-sensitive, voltage-dependent calcium channel. Another, the ryanodine receptor (RyR), is a large protein associated with the SR membrane in the triad that may couple the conformational changes in the Ca^{2+} channel protein induced by T-tubular depolarization to the Ca^{2+} release from the SR (Fig. 43-6).

The first molecule, the Ca^{2+} channel, is required for coupling at the triad. Skeletal muscle contains higher concentrations of this L-type Ca^{2+} channel that can be accounted for on the basis of measured voltage-dependent Ca^{2+} influx because much of the Ca^{2+} channel protein in the T-tubular membrane does not actively gate calcium ion movement but, rather, acts as a voltage transducer that links depolarization of the T-tubular membrane to Ca^{2+} release through a receptor protein in the SR membrane. The ryanodine receptor mediates sarcoplasmic reticulum Ca^{2+} release. The bar-like structures that connect the terminal elements of the SR with the T-tubular membrane in the triad are formed by a large protein that is the principal pathway for Ca^{2+} release from the SR. This protein, which binds the

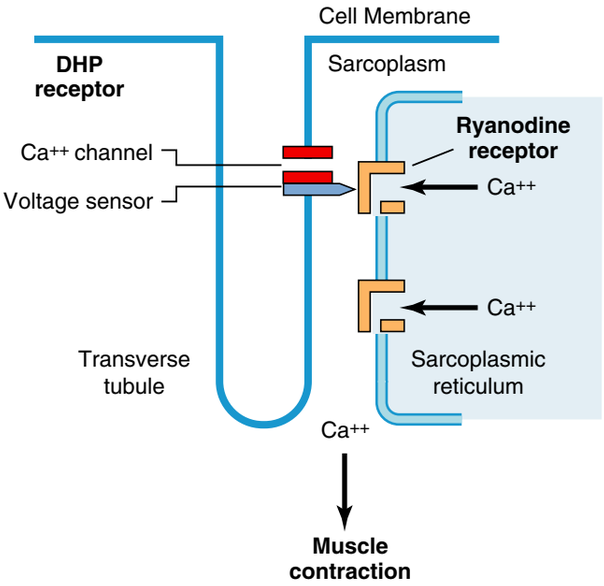

FIGURE 43-6 Molecular physiology of muscle excitation–contraction coupling.

plant alkaloid ryanodine with high affinity, is a huge homotetramer of 565 kDa polypeptide subunits [7].

The purified complex, when incorporated into planar bilayers, exhibits Ca^{2+} channel activity that is modulated by Ca^{2+} itself, Mg^{2+}, and ATP among many other regulators. The manner in which activation of the ryanodine receptor complex is coupled to events at the T-tubular membrane probably involves direct mechanical linkage through a conformational change in the dihydropyridine receptor protein [8]. After diffusion towards the myofibrils, Ca^{2+}reuptake in the sarcoplasmic reticulum allows the relaxation of muscle and the maintenance of a low resting intracellular Ca^{2+} concentration by means of an ATP-dependent Ca^{2+} pump, located in the SR membrane. The free energy of ATP hydrolysis is utilized here for the concentrative uptake of Ca^{2+} into the SR vesicle through a phosphorylated enzyme intermediate (see Ch. 5).

Other SR proteins assist in Ca^{2+} uptake and storage. Phospholamban is prominent in cardiac muscle and slowly contracting muscle, where phosphorylation participates in the control of Ca^{2+}-ATPase and Ca^{2+}-uptake activity. Another protein, calsequestrin, containing numerous low-affinity Ca^{2+}-binding sites, is present in the lumen of the SR and also participates in Ca^{2+} storage. Fast-twitch muscle contains a soluble Ca^{2+}-binding protein, parvalbumin, which is structurally related to troponin-C. Parvalbumin may also regulate the Ca^{2+} concentration in the initial stages of relaxation to facilitate rapid contraction.

The disorders of muscle excitability are best classified according to their cause [9] and are listed in Table 43-1.

TABLE 43-1 Disorders of muscle excitability

Inheritable diseases	
Disorders of the neuromuscular junction: congenital myasthenic syndromes	
Choline acetyltransferase deficiency	MIM 254210
Acetylcholine receptor deficiency	MIM 254210
Rapsyn deficiency	MIM 601592
Slow channel syndrome	MIM 601462
Fast channel syndrome	MIM 254210
Acetylcholinesterase deficiency	MIM 603034
Disorders of the muscle membrane	
Hyperkalemic periodic paralysis	MIM 170500
Paramyotonia congenita	MIM 168300
Hypokalemic periodic paralysis	MIM 170400
Andersen syndrome	MIM 170390
Myotonic dystrophy (Steinert's disease)	MIM 160900
Myotonia congenita (Thomsen's disease and Becker's myotonia)	MIM 160800 and 255700
Malignant hyperthermia	MIM 145600
Brody's disease	MIM 601003
Immunological diseases	
Myasthenia gravis	
Lambert–Eaton syndrome	
Neuromyotonia (Isaac's syndrome)	
Intoxications and metabolic diseases	
Botulism	
Animal envenomations	
Electrolyte imbalances	

Mutations associated with inheritable diseases are numbered in MIM notation as described in: McKusick, V. A. *Mendelian Inheritance in Man. A Catalog of Human Genes and Genetic Disorders*,12th edn. Baltimore: Johns Hopkins University Press, 1998. An updated Internet version is found at: *Online Mendelian Inheritance in Man, OMIM™*. McKusick-Nathans Institute for Genetic Medicine, Johns Hopkins University (Baltimore, MD) and National Center for Biotechnology Information, National Library of Medicine (Bethesda, MD), 2000,: www.ncbi.nlm.nih.gov/omim/.

GENETIC DISORDERS OF THE NEUROMUSCULAR JUNCTION

Congenital myasthenic syndromes impair the operation of the acetylcholine receptor. These disorders result in impaired neuromuscular transmission due to mutations of either presynaptic, synaptic basal lamina-associated or postsynaptic proteins and cause fatigable weakness in specific muscle distribution patterns [10]. Traditionally termed 'congenital myasthenia', they should be differentiated from acquired, immune-mediated myasthenia gravis, and it is recognized that additional types of congenital myasthenic syndrome are likely to be discovered. In fact, in a patient with typical myasthenic symptoms, mutations of *SCN4A* – the gene that encodes the $Na_V1.4$ skeletal muscle sodium channel – leading to enhanced channel inactivation have been found.

Choline acetyltransferase deficiency. The distinguishing clinical feature is sudden episodes of severe respiratory difficulty and oropharyngeal (bulbar) weakness leading to apnea (cessation of respiration) precipitated by infections, fever or excitement, or occurring even spontaneously. In some patients, the disease presents at birth with hypotonia (diminished muscle resistance to mobilization) and severe bulbar and respiratory weakness, requiring ventilatory support that gradually improves through life, but is followed by episodes of apnea attacks and bulbar paralysis later. Other patients are normal at birth and may develop myasthenic symptoms and apneic attacks after infancy or childhood. Muscle action potentials decline abnormally when neuronal impulse flow is increased and recovers slowly, indicating an underlying defect in resynthesis or vesicular packaging of ACh. Several recessive mutations have been identified, all of which decrease the abundance or the efficiency of ChAT. Although still largely unexplained, the selective neuromuscular *versus* CNS involvement in ChAT deficiency may be due to the enzyme rate-limiting characteristics for ACh synthesis at the NMJ.

Acetylcholine receptor deficiency. The degree of disease severity may vary from mild to very severe. In general, patients harboring low-expressor or even homozygous null mutations in the AChR ε subunit may experience

mild symptoms, presumably owing to the compensatory replacement of this peptide by the analogous γ subunit. Conversely, patients with low-expressor mutations in the other non-interchangeable subunits are severely affected, and no patients with null mutations in both alleles of a non-ε subunit have been observed. AChR deficiency results from mutations that cause premature termination of the translational chain by frameshift, by altering splice sites, or by generating stop codons; from point mutations in the promoter region; from chromosomal microdeletion; and even from missense mutations, some of which affect the signal peptide or residues essential for assembly of the AChR. Patients respond moderately well to anti-AChE drugs.

Rapsyn deficiency. These patients manifest AChR deficiency with decreased rapsyn as well as secondary AChR abundance and resulting impaired postsynaptic morphologic development. None of the known rapsyn mutations hinders rapsyn self-association, but all diminish clustering of AChR with this protein. In addition to weakness, some patients manifest striking facial malformations. Patients are treated with anti-AChE drugs and with 3,4-diaminopyridine (3,4-DAP), a blocker of open K^+ channels. 3,4-DAP decreases presynaptic membrane resting conductance, causing hyperpolarization and therefore resetting more Ca^{2+} channels into their closed, non-inactivated state from which they can readily open, increasing Ca^{2+} influx into the terminal and facilitating a compensatory increase in ACh release.

Slow-channel syndrome. Abnormally long-lived openings of mutant AChR channels result in prolonged endplate currents and potentials, which in turn elicit one or more repetitive muscle action potentials of lower amplitude that decrement. The morphologic consequences stem from prolonged activation of the AChR channel that causes cationic overload of the postsynaptic region – the endplate myopathy – with Ca^{2+} accumulation, destruction of the junctional folds, nuclear apoptosis, and vacuolar degeneration of the terminal. Some slow-channel mutations in the transmembrane domain of the AChR render the channel leaky by stabilization of the open state, which is populated even in the absence of ACh. Curiously, some slow-channel mutants can be opened by choline even at the concentrations that are normally present in serum. Quinidine, an open-channel blocker of the AchR, is used for therapy.

Fast-channel syndrome. The clinical features resemble those of autoimmune myasthenia gravis (see below) with variable severity. Conversely to what is found in slow-channel syndrome, the open state of the AChR is destabilized, manifesting as fast dissociation of ACh from the receptor and/or excessively reduced open times. One mutation has also caused multiple congenital joint contractures owing to fetal hypomotility *in utero*. In most cases, the mutant allele causing the kinetic abnormality is accompanied by a null mutation in the second allele, so that the kinetic mutation dominates the phenotype, but homozygous fast-channel mutations also exist. Therapy includes anti-AChE agents and 3,4-DAP.

Acetylcholinesterase deficiency. Inhibition of the AChE results in prolonged exposure of AChR to ACh, leading to prolonged endplate potentials, desensitization of AChR and depolarization block. Endplate myopathy with loss of AChR may result. In most patients, the disease presents in the neonatal period and is highly disabling, but exceptions with mild neonatal onset and severe adult impairment exist. Some patients manifest an excessively slow pupillary response to light. An array of mutations may cause (1) reduced attachment of AChE to ColQ, (2) truncation of the collagen domain rendering it insertion-incompetent, or (3) hindrance of the triple-helical assembly of the collagen domain.

HEREDITARY DISEASES OF MUSCLE MEMBRANES

Mutations of the sodium channel cause hyperkalemic periodic paralysis and paramyotonia congenital. An important group of inherited muscle diseases called the periodic paralyses is characterized by intermittent episodes of skeletal muscle weakness or paralysis that occur in individuals who otherwise appear normal or are just mildly weak between attacks [11]. The periods of paralysis are often associated with changes in serum K+ concentration; while the serum K+ concentration may increase or diminish, the direction of change is usually consistent for a particular family and forms one basis for classifying these diseases as either hyperkalemic or hypokalemic. A variant of periodic paralysis, in which spells of weakness are less frequent and in which a form of muscle hyperexcitability is often seen, is called paramyotonia congenita.

Recordings from muscle fibers isolated from patients during an attack of periodic paralysis have shown that the paralytic episodes are associated with acute depolarization of the sarcolemma. In all forms of periodic paralysis, this depolarization is due to an increase in membrane conductance to Na^+. In the case of hyperkalemic periodic paralysis and paramyotonia congenita, this abnormal conductance can be blocked by tetrodotoxin, a small polar molecule that is highly specific for the voltage-dependent Na^+ channel. Foods with a high K^+ content may trigger an attack, while carbohydrate-rich substances are abortive of the paralytic episode. Single-ion channel recordings in hyperkalemic periodic paralysis have revealed that some of the muscle membrane Na^+ channels show abnormal inactivation kinetics, intermittently entering a mode in which they fail to inactivate. These channels produce a persistent, non-inactivating Na^+ current that in turn produces membrane depolarization. Because normal Na^+ channels enter an inactivated state after depolarization

(see Ch. 6), the net result of long-term depolarization is loss of sarcolemmal excitability and paralysis.

Both hyperkalemic periodic paralysis and paramyotonia are caused by mutation of the adult skeletal muscle Na^+ channel SkM1 gene *SCN4A* on chromosome 17. The hypokalemic form of periodic paralysis, however, is not linked to this Na^+ channel gene (see below). Numerous mutations alter the coding region of the *SCN4A* gene in families with hyperkalemic periodic paralysis or paramyotonia congenita. Although these mutations are distributed through a wide span of the channel coding region, a number of them are clustered in a cytoplasmic linker region known from biophysical studies to control inactivation. Others are located near the cytoplasmic ends of transmembrane domains S5 and S6, and these residues may in fact constitute the binding site for the closing inactivation gate. Mutations in these regions may destabilize this closed conformation, leading to abnormalities in channel inactivation.

Mutants associated with the paramyotonia congenita phenotype show, on the other hand, a marked slowing in the major component of fast inactivation. In some cases, the voltage dependence of the inactivation rate constant, known to biophysicists as τ_h, is markedly reduced as well, and the mutations appear to uncouple the inactivation process from the voltage-dependent channel conformational changes associated with inactivation. In some families with hyperkalemic periodic paralysis, the mutations cause a small, persistent inward Na^+ current in the myocyte that is the result of a shift in channel modal gating. Normal skeletal muscle Na^+ channels can shift between a fast and a slow inactivation gating mode and, usually, the channels are found in the fast inactivation mode. Channels with hyperkalemic periodic paralysis mutations, however, spend a greater percentage of the time in the slow inactivation gating mode, and late openings associated with this slow gating mode contribute to the persistent inward current seen in cells harboring these mutations. Under voltage-clamp conditions at the single-channel level, SkM1 channels with paramyotonia congenita mutations show multiple late openings and prolonged openings after depolarization. These late openings account for the slow inactivation of the Na^+ current observable in the cell. Hyperkalemic periodic paralysis mutations also show multiple late openings at the single-channel level, but these abnormal events are temporally clustered, consistent with an underlying shift in modal gating.

Single-channel conductance is not altered by any of these mutations, but all sodium ion channel mutations in periodic paralysis produce dominant-negative effects. Although some mutant channels only intermittently exhibit abnormal inactivation, this small population of abnormally inactivating channels can modify the behavior of the remaining mutant and normal channels present in the membrane. Unlike the ClC-1 chloride channel mutations in myotonia congenita (see below), which produce dominant-negative effects within a single channel multimer, these Na^+ channel mutations produce dominant-negative effects that reflect the relationship of normal channel inactivation to membrane potential. In either case, the persistent inward current carried by a small population of noninactivating channels, or the prolonged inward current resulting from mutant channels with slowed inactivation rates, results in a slight but long-lasting membrane depolarization. Since the relationship between voltage and inactivation in normal channels is very steep near the resting potential, this slight depolarization can produce inactivation of normal channels. If depolarization is sufficient, too few channels will remain in the noninactivated state to satisfy the requirements for a regenerative action potential and the muscle will become paralyzed.

Hypokalemic periodic paralysis is due to calcium channel mutations. Hypokalemic periodic paralysis, in which serum potassium drops during a paralytic episode, is the most common of the inherited periodic paralyses. Although paralysis is associated with membrane depolarization and increased resting Na^+ conductance, this conductance is not sensitive to tetrodotoxin. This disease is linked to a region of chromosome 1 that encodes the α subunit of the skeletal muscle, dihydropyridine-sensitive Ca^{2+} channel, designated CACNL1A3 [12]. Although this channel in skeletal muscle contains at least five subunits, the channel-forming α subunit has a structure that bears strong sequence homology to the voltage-gated Na^+ channel.

Several mutations have been identified in the Ca^{2+} channel gene in families with hypokalemic periodic paralysis and some of these are in locations where mutations in the homologous Na^+ channel also occur. The pathophysiological mechanism linking these L-type muscle Ca^{2+} channel mutations to the depolarization seen during episodes of weakness in hypokalemic periodic paralysis is less clear. This dihydropyridine-sensitive Ca^{2+} channel is present in the T-tubular membrane at the triadic junction with the terminal elements of the SR. There, it is thought to provide the coupling between T-tubular depolarization and activation of the SR ryanodine-sensitive Ca^{2+} release channel with which it interacts, instead of conducting ionic currents. Perhaps another uncharacterized form of the sarcolemmal Ca^{2+} channel, in which CACNL1A3 is complexed with different accessory subunits, is responsible for the abnormal Na^+ currents seen in this disorder.

Abnormal potassium channels in Andersen's syndrome cause more than periodic paralysis. Andersen's syndrome includes periodic paralysis, prolongation of the electrocardiographic QT interval causing susceptibility to cardiac ventricular arrhythmias, and characteristic physical features including low-set ears, a small jaw and malformation of the digits; it is inherited in an autosomal dominant fashion. The disease is unique due to the combination of both a skeletal and a cardiac muscle phenotype and may be caused by mutations in *KCNJ2*, a gene that encodes the inward rectifier K^+ channel Kir2.1, which is expressed in both cardiac and skeletal muscles. Kir2.1 is an important contributor to the cardiac inward rectifier

K^+ current, I_{K1}, which provides substantial current during the repolarization phase of the cardiac action potential [13]. All KCNJ2 mutations cause a dominant negative effect on channel function and a reduction in I_{K1} prolongs the terminal repolarization phase, rendering the myocardium prone to repetitive ectopic action potentials. Attacks of paralysis can be associated with hypo-, hyper- or normokalemia and, although serum potassium levels during attacks differed among kindreds, they are consistent within an individual kindred. Mutations in Kir2.1 may sufficiently reduce the muscle resting K^+ conductance such that the membrane depolarizes, leading to inactivation of Na^+ channels making them unavailable for initiation and propagation of action potentials.

Ribonuclear inclusions are responsible for the multiple manifestations of myotonic dystrophy. Myotonic dystrophy (DM; Steinert's disease) is a multisystemic disorder that is now recognized as one of the most common forms of muscular dystrophy in adults. In addition to hereditary muscular dystrophy and myotonia (involuntary persistence of muscle contraction), DM causes a constellation of seemingly unrelated clinical features including cardiac conduction defects, cataracts, and endocrine and immunological abnormalities. Two clinical and genetic types of DM exist [14]. The genetic features of DM type 1 (DM1) include variable penetrance, anticipation (a tendency for the disease to worsen in subsequent generations), and a maternal transmission bias for congenital forms despite the location of the causative gene on chromosome 19. The cause of DM1 is a $(CTG)_n$ repeat in the 3-UTR of a protein kinase (DMPK) gene. Type 2 DM, in contrast, predominantly causes pelvic girdle weakness, and is often referred to as proximal myotonic myopathy, ascribed to the genetic locus encoding zinc finger protein 9 on chromosome 3. DM2 is caused by a $(CCTG)_n$ expansion. Nevertheless, all individuals affected by DM1 and DM2 experience weakness, pain and myotonia, and cardiac involvement may lead to conduction defects, arrhythmias and sudden death. Endocrine abnormalities in both DM1 and DM2 result in hyperinsulinemia, hyperglycemia and insulin insensitivity, with type 2 diabetes occurring in each disorder. Testicular failure is also common, with associated hypotestosteronism, elevated follicle-stimulating hormone (FSH) levels and oligospermia. Other serological abnormalities in both disorders include reduced levels of immunoglobulins G and M. The brain is also affected as assessed by magnetic resonance imaging (MRI), but mental retardation is only a feature of DM1.

The unusual multisystemic clinical parallels between DM1 and DM2 suggest a similar pathogenic mechanism. The discovery that DM2 mapped to chromosome 3 and not to the DM1 region of chromosome 19 makes it unlikely that specific gene expression defects cause the common clinical features of the disease. The discovery that a CCTG repeat expansion located on chromosome 3 which is expressed at the RNA (but not at the protein level) causes DM2, and the observation that both CUG and CCUG repeat-containing foci accumulate in affected muscle nuclei suggests that a gain-of-function RNA mechanism underlies the clinical features common to both diseases. This is, in fact, but one of an emerging class of disorders [15]. RNA-binding proteins, including CUG-binding protein (CUG-BP) and *muscleblind* isoforms bind to – being sequestered – or are dysregulated by the repeat-containing RNA transcripts resulting in specific trans-alterations in pre-mRNA splicing. Specific changes in pre-mRNA splicing have been associated with several genes, including the insulin receptor, the chloride channel ClC-1 and cardiac troponin T, and are probably correlated with insulin resistance, myotonia and cardiac abnormalities. For example, CUG-BP, which is elevated in DM1 skeletal muscle, binds to the ClC-1 pre-mRNA, causing an aberrant pattern of ClC-1 splicing. Thus, altered splicing regulation of ClC-1 decreases its abundance in the muscle plasma membrane causing hyperexcitability and leading to the DM feature of myotonia. Further, mutant RNA transcripts bind and sequester transcription factors, leading to the depletion of as much as 90% of several of them, resulting in secondary depletion of proteins such as the chloride channel ClC-1.

Congenital myotonia is caused by mutant Cl^- channels. In two diseases, dominant myotonia congenita (Thomsen's disease) and recessive myotonia congenita (Becker's myotonia), myotonia is the major presenting symptom and often the only abnormality, although the muscles may be overdeveloped (conferring individuals a herculean appearance) in Thomsen's disease. Patients afflicted with these diseases have difficulty relaxing their muscles normally: doorknobs and handshakes are difficult to release, clumsiness is a problem and falls often occur. In both Thomsen's and Becker's myotonia, multiple mutations have been found in chromosome 7 and the sarcolemma exhibits a severe reduction in membrane Cl^- conductance [16]. This locus encodes the ClC-1 skeletal muscle Cl^- channel family, whose members control anion flux in a number of tissues and are closely related in structure, forming dimers of two ClC subunits. The fact that mutations in the gene encoding ClC-1 can produce either dominant or recessive effects is surprising. Mutants that introduce frameshifts of stop codons early in the coding sequence produce a nonfunctional protein product. With one defective gene copy, wild-type channels encoded by the second allele should produce a net Cl^- conductance about 50% of normal. When both gene copies carry the mutation, expression of the functional channels will be very low or absent and, as a recessive disorder, the myotonia can be severe. Point mutations can also lead to the alteration of a single amino acid in the primary structure of an otherwise full-length channel monomer, and channels formed from this protein may not function normally.

The possibility also exists that channels containing even a single mutant subunit may fail to function even though the other subunits are encoded by a normal copy of the gene. Such a dominant-negative effect, which has been demonstrated for a number of myotonia congenita mutations, leads to a dominant transmission of the disease phenotype. Since mixed channels containing different numbers of mutant subunits may have different levels of residual activity, the resulting membrane Cl^- conductance may be more variable and the disease phenotype less severe than in the recessive form of the disease.

Malignant hyperthermia caused by mutant ryanodine receptor calcium release channels. A rare complication of general inhalation anesthesia is a syndrome characterized by muscle stiffness and fever due to a state of elevated skeletal muscle metabolism that occurs in genetically predisposed individuals. If untreated, this syndrome, called malignant hyperthermia (MH), can be rapidly fatal. Although the inheritance pattern of the disease is difficult to trace, it is likely to be transmitted from generation to generation as an autosomal dominant trait. A similar disease occurs in a strain of pigs, and this experimental animal model has proven to be very useful in studying the physiology of the disease. Measurements on isolated muscle from affected pigs or individuals show that the defect is at the level of excitation-contraction coupling. Specifically, the muscles release Ca^{2+} when exposed to caffeine at concentrations much lower than those required for Ca^{2+} release from normal muscle. Once released, this Ca^{2+} produces persistent activation of tropomyosin and sustained contraction, which associates with hypermetabolism. Analysis of the ryanodine receptor (RyR) gene sequence in affected individuals has uncovered several mutations in the coding region of the protein that cosegregates with the MH phenotype [17]. All of the RyR mutations result in amino acid substitutions in the myoplasmic portion of the protein, with the exception of the mutation in the C-terminus, which resides in the luminal/transmembrane region. Functional analysis shows that MH and central core disease – a related myopathy – mutations produce RyR abnormalities that alter the channel kinetics for calcium inactivation and make the channel hyper- and hyposensitive to activating and inactivating ligands, respectively. The deciding factors in determining whether a particular RyR mutation results in MH alone or MH and central core disease are the sensitivity of the RyR mutant proteins to agonists, the degree of abnormal channel-gating caused by the mutation, the extent of decrease in the size of the releasable calcium store and increase in resting concentration of calcium, and the level of compensatory calcium homeostasis achieved by the muscle.

Calcium channel mutations may also cause malignant hyperthermia. At least five loci other than the RyR have been associated with MH, implicating great genetic heterogeneity. One such gene, *CACNA1*, encoding the main subunit of the voltage-gated dihydropyridine receptor, has a confirmed role in MH, so that this type of MH is allelic to hypokalemic periodic paralysis. In contrast to the mutations specific for hypokalemic periodic paralysis, the mutations so far described for MH are situated in the myoplasmic loop connecting repeats III and IV, the function of which is unknown but may serve as a link to RyR.

Brody's disease is an unusual disorder of the sarcoplasmic reticulum calcium ATPase. Brody's disease, a dominant or recessive disorder, is characterized by exercise-induced delay in skeletal muscle relaxation, which is most pronounced in the legs, arms and eyelids. The muscles stiffen during sustained strenuous muscular activities, leading to painless or only mildly painful cramping. Early studies provided evidence for reduced ATP-dependent Ca^{2+} uptake and Ca^{2+}-ATPase activities in the sarcoplasmic reticulum (SERCA) of Brody's disease patients. Several mutations in *ATP2A1*, the gene encoding SERCA1, have been found in families afflicted by the recessive form of the disease, and all have been predicted to truncate SERCA1 [18]. These mutant enzymes would be inactive and degraded *in situ*. The disease may also cosegregate in an autosomal dominant fashion with an apparently balanced constitutional chromosome translocation (2;7)(p11.2;p12.1), providing evidence for another causative locus.

IMMUNE DISEASES OF MUSCLE EXCITABILITY

Myasthenia gravis is caused by antibodies that promote premature AChR degradation. Myasthenia gravis (MG), a frequent disorder of neuromuscular transmission, is an acquired autoimmune disease affecting the AChR on the postsynaptic membrane. Clinically, the disorder is characterized by weakness and abnormal fatigability. Most patients have circulating antibodies against the AChR in their serum and many of them are directed against the main immunogenic region of the receptor, located extracellularly [19]. Patients with MG typically show fluctuating symptoms; weakness and fatigability may be worse in the evenings and usually become more severe with exercise. Weakness may involve only the extraocular muscles, producing diplopia (double vision), or may be so extensive as to cause quadriparesis (weakness of all limbs) and respiratory compromise. Although spontaneous remissions can occur, the untreated disease is often progressive and can eventually lead to death from respiratory failure. The classic electrophysiological observation in MG is a decremental response in the extracellularly recorded compound muscle action potential with

repeated nerve stimulation (Fig. 43-7). The decrease in action potential amplitude is due to a reduction in the number of AChR molecules present in the postsynaptic membrane combined with a pathological alteration in the architecture of the postsynaptic membrane. The density of receptors in the myasthenic postsynaptic membrane may be as low as 20% of normal. In addition, the architecture of the postsynaptic membrane is lost. The distance between pre- and postsynaptic membrane is often increased, and the postsynaptic membrane is highly simplified. The destruction seen at the postsynaptic membrane is mediated by antibodies directed against the AChR. The major effects of anti-AChR antibodies seem to be twofold. First, antibodies cross-link receptor proteins and increase their rates of endocytosis and lysosomal degradation. In the absence of an increased rate of receptor synthesis, this results in a net decrease in receptor density in the postsynaptic membrane. Second, these antibodies target the postsynaptic membrane for complement fixation and activation of the lytic phase of the complement reaction cascade. Although the mechanism of chronic neuromuscular damage in this disease has been defined, the nature of the initial triggering event is unclear. One hypothesis involves the role of muscle-like cells that exist in the thymus gland. These cells express AChRs on their surface membranes. An initial inflammatory response in the thymus may trigger the generation of cross-reacting antibodies that subsequently target AChRs on muscle. This hypothesis would help to explain the beneficial role of the removal of the thymus (thymectomy) as well as that of immunosuppressive steroids in patients with MG. AChE inhibitors and removal of antibodies by plasma filtration are also of therapeutic value. Careful reduction of endplate AChE activity by administration of inhibitors can prolong the action of released ACh sufficiently to increase the amplitude of an abnormally low endplate potential above that required for successful neuromuscular transmission. Excessive inhibition, however, produces long-term postsynaptic depolarization, receptor inactivation and transmission block.

Antibodies against the muscle-specific receptor kinase mimic myasthenia gravis. Another salient antigenic target of the NMJ is the muscle-specific receptor kinase, MuSK. During development, MuSK participates in the orchestration of agrin-dependent clustering of AChR and of other components that make up the postsynaptic architecture of the NMJ. It is unclear how the reaction of this cytoplasmic target with antibodies causes the symptoms of myasthenia in adults. One possibility is that these antibodies bind complement and cause loss of AChR-containing postsynaptic membrane, similar to the action of AChR antibodies. Another possible explanation is that the antibodies do penetrate the postsynaptic cytoplasm and alter the function of MuSK at the NMJ. Exposure of myocytes to plasma containing MuSK antibodies can inhibit agrin-dependent AChR clustering substantially and, in the absence of added agrin, they can cause a modest clustering of AChR, suggesting that they are able to cross-link and activate MuSK on the cell surface. Therefore, it is possible that the antibodies lead to reduced clustering of AChRs and reduced stability of the adult postsynaptic membrane architecture [20].

Antibodies cause calcium channel dysfunction in Lambert–Eaton syndrome. Some patients with cancer, especially small-cell carcinoma of the lung, develop a syndrome of weakness associated with autonomic dysfunction as part

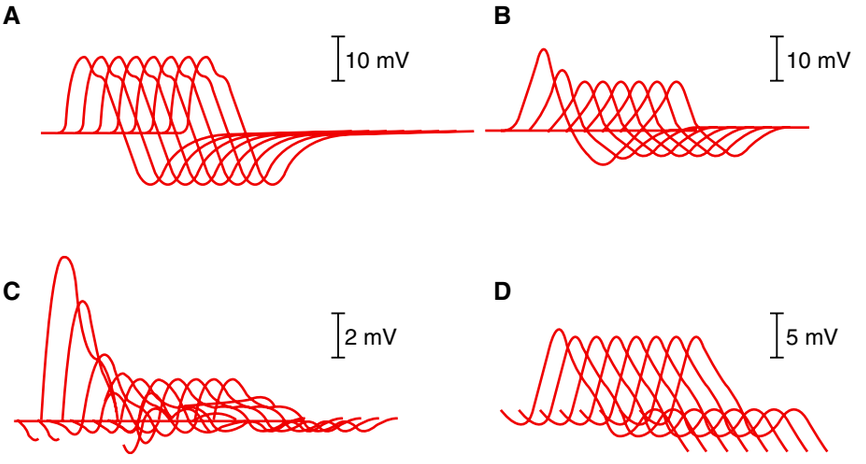

FIGURE 43-7 Block of the acetylcholine receptor in myasthenia gravis. Compound muscle action potentials recorded from the abductor digiti minimi of human subjects during repetitive stimulation of the ulnar nerve at three stimuli per second. (**A**) A recording from a normal individual shows no change in the amplitude of the muscle electrical response during the stimulation interval. (**B**) In a patient with myasthenia gravis, the same stimuli produce a 40% decrement in response amplitude over the first five stimuli, with a slow partial recovery during subsequent stimulation. Similar studies from a patient with severe myasthenia gravis before (**C**) and 2 minutes after (**D**) intravenous administration of 10 mg edrophonium, a short-acting acetylcholinesterase inhibitor. Note the change in amplitude scale between the two recordings and the reversal of the abnormal decrement by edrophonium.

of the Lambert–Eaton myasthenic syndrome (LEMS). Complaints often begin with progressive proximal muscle weakness and fatigue; unlike myasthenia gravis, bulbar involvement is usually mild and respiratory compromise is unusual.

These patients demonstrate a remarkable reduction in the amplitude of the compound muscle action potential produced by single supramaximal stimulus to the motor nerve of a resting muscle. Repeated stimulation of the same nerve, however, results in progressive improvement in response amplitude, often returning to nearly normal levels. These clinical findings are indicative of a defect in presynaptic neurotransmitter release. When analyzed at the cellular level, LEMS is characterized by a reduction of ACh release, often to 10% or less of normal values. Repetitive stimulation causes a progressive increase in ACh release, consistent with the improvement seen in the compound muscle action potential. LEMS, like MG, is an autoimmune disease. The autoantibodies in LEMS are heterogeneous and target a number of presynaptic proteins. Antibodies are most commonly observed against P/Q-type voltage-gated Ca^{2+} channels, but antibodies against L- and N-type channels are also present [21]. Antibodies against the synaptic vesicle protein synaptotagmin have also been identified. The S5–6 loop in the channel α subunit is a particularly active target for LEMS autoantibodies. The large intramembranous particles that form the synaptic active zones are disrupted in the disease. The number of these arrays is reduced, with many particles found instead in irregular aggregates. In small-cell lung carcinomatous cells, voltage-gated Ca^{2+} channels are expressed on their surface, and Ca^{2+} currents in these cells are inhibited by LEMS serum. It seems likely that an immune response against the voltage-gated Ca^{2+} channel population in these tumor cells causes the pathology in LEMS by cross-reaction with similar epitopes present in the presynaptic channels of autonomic and NMJ nerve terminals.

Potassium channel antibodies in Isaac syndrome cause neuromyotonia. Dysfunction of voltage gated K^+ channels is a potential cause of acquired neuronal hyperexcitability disorders, as patients with different point mutations in the potassium channel Kv1.1 can manifest varying combinations of episodic ataxia, neuromyotonia and seizures. Antibodies directed against presynaptic voltage gated K^+ channels have been found in acquired neuromyotonia, also called Isaac's disease, a disorder associated with peripheral nerve hyperactivity that results in muscle twitching (myokymia) and cramps, increased sweating and other autonomic nervous system abnormalities [20]. Approximately 20% of patients with neuromyotonia have an associated thymoma and, occasionally, patients may also experience central nervous system disturbances including insomnia, hallucinations and confusion. Application of the antibodies to the NMJ mimics the electrophysiological effect of 3,4-DAP exposure, with enhanced excitation of muscle owing to pronounced ACh release from hyperpolarized nerve terminals.

TOXINS AND METABOLITES THAT ALTER MUSCULAR EXCITATION

Bacterial botulinum toxin blocks presynaptic acetylcholine release. Botulism is caused by intoxication with an exotoxin with metalloprotease activity synthesized and excreted by bacterial strains from the genus *Clostridium* (*botulinum*, *barati* and *butirycum*). The effect of botulinum toxin on the neuromuscular junction is one of the most potent processes known in biology and recovery from intoxication may persist for months. A dose of 1 ng toxin per kilogram of body weight is lethal to mice. In infancy, the toxin gains access to the neuromuscular junction after bacterial colonization of the gut by *C. botulinum*, whereas food-borne toxin ingestion and wound contamination give rise to more rapid forms of the intoxication. In all its forms, botulism causes a severe and persistent blockade of endplate potentials, rendering the postsynaptic membrane unexcitable after depolarization of the nerve terminal. The neurotoxin greatly reduces the frequency, but not the amplitude, of evoked miniature endplate potentials, indicating that the number of vesicles capable of undergoing fusion and release of ACh is diminished, without affecting the ACh quantum, which indicates an unaltered neurotransmitter synthesis, uptake and storage. In fact, the only structural abnormality of the synapse is an increase in the number of synaptic vesicles near the presynaptic membrane. A structurally related toxin synthesized by *C. tetani* produces tetanus, a process that causes rigid paralysis – often resulting in death from diaphragmatic spasm – due to retrograde transport of this toxin beyond the neuromuscular junction and transcytosis into inhibitory spinal cord interneurons. Another member of this infamous genus, *C. perfringens,* is associated with gas gangrene, an often lethal complication of wound infection in the preantibiotic era.

Seven serotypes (A–G) of botulinum toxin exist. All share a degree of structural homology – different amino acid sequences can be part of each serotype – but differ in potency and duration of action, a phenomenon that has allowed the beneficial use of type A toxin in conditions associated with persistent muscular contraction such as dystonia or spasticity and with excessive autonomic cholinergic activity. At high doses, however, some of the specificity of action is lost and type A toxin may be transported retrogradely, acting on the central nervous system. Botulinum toxins, synthesized as single polypeptides of ≈150 kDa (comprising 1295 amino acids in the case of type A toxin), are encoded in the genome of a bacteriophage virus that infects the bacterium lysogenically [22]. Prior to acquiring its active conformation, the peptide is cleaved into a light (LC) and a heavy (HC) chain that

weigh about 50 and 100 kDa respectively and remain linked via a disulfide bond. The LC domain is a potent zinc endopeptidase designed against specific elements inside the presynaptic nerve terminal, while the HC region contains regions for binding of the toxin to the membrane of the cholinergic motor neuron and for translocation of the LC domain into the terminal. The molecular targets of LC are several synaptic members of the SNARE (soluble NSF (*N*-ethylmaleimide-sensitive fusion protein) attachment protein receptor) family (see Ch. 10), the facilitators of all membrane fusion events in eukaryotic cells.

Upon exposure of the neuromuscular junction to toxin and binding to the neural membrane, a chain of events comprising internalization into synaptic vesicles, translocation into the cytoplasm and inhibition of acetylcholine release unfolds inexorably. Once internalized, the toxin cannot be neutralized by antiserum. The first step of intoxication, involving contact between the carbohydrate-binding, lectin-like HC domain and the terminal membrane, is highly specific. It requires the presence of gangliosides, in particular GD1b, GT1b and GQ1b, together with a protein receptor – possibly synaptotagmin (see Ch. 10) – all embedded and crowded in lipidic rafts that help anchor HC with high affinity. Thus, multivalent binding of HC is accomplished by several near-simultaneous molecular recognition events in a restricted two-dimensional plane taking place between multiple carbohydrate-binding sites on HC and selected sialic-acid-containing gangliosides and glycoproteins. Consequently, the toxin coats the terminal in a punctate distribution and different toxin types bind independently of each other. The presence of the glycosylated portion of synaptotagmin I and II in the synaptic space, however, is contingent upon the fusion of synaptic vesicles with the plasma membrane during neurotransmission and exposure of the luminal aspect of the vesicle to the extracellular medium.

Upon binding, the toxins are internalized via endocytosis and reach vesicular or endosomal compartments that undergo acidification as part of their normal recycling process. Targeting to the appropriate compartment is attributed to the protein receptor present in the endocytic vesicle. The reduction in pH is believed to facilitate a conformational change in the toxin, increasing the exposure of hydrophobic residues on its surface and facilitating its penetration through the membrane to reach the cytosol. Two histidine residues (H551 and H560) lie on a suitably exposed location on botulinum toxin type A, the 'translocation belt' portion of HC, and may therefore be susceptible to titration by pH. The HC domain undergoes conformational changes at low pH *in vitro* and forms somewhat cation-selective channels in artificial membranes of ≈15 Å in diameter as judged from their unitary conductance of 110 pS.

It is thought that LC also experiments a structural change inside the vesicle or the endosome that allows it to translocate via – or next to – the small transmembrane HC channel in an unfolded conformation. This is the least understood event of the intoxication process, as it is very difficult to envision the ≈55×55×62 Å folded, intact LC domain crossing the membrane. Nevertheless, protein-translocating channels are part of the repertoire used by other toxins such as diphtheria and cholera and by the mitochondrial protein import system, the latter with a pore diameter of 13 Å. After translocation and refolding of LC, the toxin is preactivated by proteolysis of a surface-exposed loop accomplishable by a variety of cellular proteases that separate the peptidic continuity after the first 419–449 residues of LC, giving rise to the LC and HC chains proper, and which remain bound by the disulfide bond between C430 and C454 and by noncovalent interactions. Disulfide reduction then releases active LC into the cytosol.

The ultimate localization of LC depends on toxin type, with, for example, type A residing near the plasma membrane and type E remaining in the cytosol, a phenomenon that may explain the differential stability of the toxin isoforms and the persistence of their action. Nevertheless, the LC fragment is always effectively sequestered from the degradative cycle of the terminal. Tyrosines in both LC and HC may be phosphorylated by Src (see Ch. 24), enhancing the stability and proteolytic activity of LC.

The target of LC proteolysis is SNARE proteins, including SNAP25, synaptobrevin and syntaxin, all of which share repeats of a motif that is recognized by LC. The SNARE proteins exist in a complex stabilized by a bundle of tightly packed α-helices, each containing the SNARE motif (distinct from the recognition motif above), and which is disassembled following transmitter release. Binding of LC occurs only after individual SNARE members dissociate and results in their proteolysis at the level of the SNARE motif, preventing reassembly and thus causing impairment of synaptic vesicular release. Residues H222, E223 and H226 form part of the LC active site and are typical of zinc proteases (which display the sequence HEXXH), with H222 and H226 and E261 coordinating zinc and E223 coordinating a water molecule. Additionally, after cleavage, the complex LC-SNAP25 may not dissociate, reentering the otherwise intact SNARE complex and continuing to interfere with neurotransmission.

The long-term effects of botulism are reversible as both nerve and muscle remain alive. The muscle undergoes a transient atrophy with loss of acetylcholinesterase and dispersion of ACh receptors from the endplate over the course of several weeks. During recovery, the release of trophic factors from paralyzed muscle fibers causes enlargement of the endplate, and nerve sprouts develop. The number of endplates per muscle fiber also increases and some muscle fibers may be innervated by more than one motor axon. After axonal sprouting and reformation of functional neuromuscular junctions, the muscle eventually regains its normal size and then redundant sprouts degenerate. The muscle atrophy induced by botulism in animals and humans is therefore largely reversible.

Snake, scorpion, spider, fish and snail peptide venoms act on multiple molecular targets at the neuromuscular junction. β-neurotoxins from the venoms of snakes and scorpions are endowed with phospholipase A_2 (PLA_2) activity. PLA_2 subtypes are essential in phospholipid turnover and in the production of inflammatory mediators (see Ch. 3). PLA_2-directed toxic potency measured as mouse LD_{50} ranges from 1 mg/kg for taipoxin (present in the venom of the Australian snake *Oxyuranus scutellatus*) to 750 mg/kg for pseudexin B (produced by *Pseudechis porphyriacus*), although this wide difference is partly due to toxin pharmacokinetics. There are over 50 neuromuscular toxins with PLA_2 activity and, although their effects differ to some extent, all tend to cause death from respiratory failure due to paralysis of respiratory muscles. This final event may be preceded by hyperexcitability (as in the intoxication with β-bungarotoxins) or by flaccid paralysis of the limbs (after intoxication with crotoxin) that evolves over at least 1 hour, regardless of toxin dose. Muscle use accelerates paralysis and, in the end, the synaptic membrane appears to have experienced massive fusion of ACh vesicles with inhibition of their recycling. ACh release from the nerve terminal, however, undergoes three phases: (1) a short initial phase displaying either decreased or unchanged ACh release, (2) a longer phase (10–30 min) of stimulation of evoked release and (3) complete and irreversible inhibition (30–120 min). In addition, some toxins with PLA_2 activity also inhibit voltage-gated K^+ channels at the synaptic terminal. In the late stage of intoxication, severe alterations of plasma and of synaptic organelle – including mitochondrial – membrane permeability become apparent.

Four types of PLA_2 toxin structure exist. Class I comprises single-chain toxins of ≈14 kDa containing seven disulfide bridges. This class includes agkistrodotoxin from *Agkistrodon* snakes, ammodytoxin from *Vipera ammodytes ammodytes*, caudotoxin from *Bitis caudalis*, notexin from *Notechis scutatus scutatus*, OS toxin from *Oxyuranus scutellatus scutellatus* and pseudexin from *Pseudechis porphyriacus*. Class II includes toxins with two noncovalently linked homologous subunits such as crotoxin and related rattlesnake neurotoxins produced by the genus *Crotalus*. Class III includes heterodimers composed of unrelated subunits, such as the most studied of PLA_2 toxins, β-bungarotoxin. This toxin is manufactured by *Bungarus multicinctus* (together with the ACh-receptor-specific α-bungarotoxin). β-bungarotoxin is similar to dendrotoxin, a neurotoxin that binds to the voltage-gated potassium channels of presynaptic membranes. Class IV toxins comprises noncovalently associated oligomers of homologous subunits and includes taipoxin and paradoxin both of which are heterotrimers. Textilotoxin, produced by *Pseudonaja textilis textilis,* is the most complex of these neurotoxins including five homologous subunits, all of them endowed with PLA_2 activity.

Binding of PLA_2 toxin to the nerve membrane, although selective, is less well understood than that of clostridial toxins. A limited number of high-affinity binding sites exist along with unsaturable low-affinity binding sites. While lipids of the presynaptic membrane may be involved in low-affinity interactions, proteins or glycoproteins are thought to constitute the high-affinity sites. For example, taipoxin may bind the neuronal pentraxin, facilitating its access to the endoplasmic reticulum, where the toxin would be retained via its binding to other specific proteins. But even less well understood is how phospholipid hydrolysis in the endoplasmic reticulum (located in the cellular body) would lead to inhibition of ACh release at the nerve terminal. The structure of the simpler, class I toxin notexin, however, sheds some light into the PLA_2 catalytic mechanism. The toxin is folded into three α-helices with two β-strands and it is both stabilized and activated by Ca^{2+}. The divalent metal binding site consists of the consensus sequence $YGC^{Y}/_{F}CXGG$ and may be occupied, instead of Ca^{2+}, by Sr^{2+}, Ba^{2+} and Zn^{2+}, all of which inhibit PLA_2 activity potently. The toxin also contains a hydrophobic channel that accommodates and secures the fatty acid chains of the phospholipid molecule and places the ester bond to be cleaved into the active site. The activity of the toxin is much higher against membrane-inserted than isolated phospholipids because of the higher efficiency of interfacial catalysis, which depends on the absorption of the enzyme on to the lipid–water interface, facilitating the seamless diffusion of the phospholipid molecule from the membrane to the active site channel.

Elapidae and Hydrophiidae snake α-neurotoxins, in contradistinction, block postsynaptic AChR, inhibiting neuromuscular transmission in a manner analogous to (+)-tubocurare (see Ch. 11). Some 100 α-neurotoxins have been isolated, the most used being α-bungarotoxin, synthesized by the Asian krait *Bungarus multicinctus*. The LD_{50} for these toxins is ≈100 μg/kg in mice. Exposure of humans to low doses of toxin that induce partial blockade of junctional receptors can produce weakness and fatigability that resemble acquired myasthenia gravis. Higher doses can lead to complete neuromuscular block, paralysis, respiratory failure and death.

The α-toxins responsible for the postsynaptic curarimimetic activity are proteins of 7–8 kDa. Structurally, they fall into two groups: long toxins, which comprise 71–74 amino acids and five internal disulfide bonds, and short toxins, with 60–62 amino acids and four internal disulfide bonds. All the α-toxins have about the same equilibrium dissociation constant for the AChR, but they differ markedly in their binding kinetics. The short toxins bind to and dissociate from the AChR five to nine times faster than the long toxins, explaining the near irreversibility of long toxin binding. The stability of the binding of the long α-neurotoxins to the AChR, especially that of α-bungarotoxin, has made them valuable tools for the purification and characterization of the receptor. α-bungarotoxin binds to a site on each α subunit of the AChR that sterically overlaps and interferes with ACh binding at the

interfaces between the two α and the γ and δ subunits. All α-toxins exhibit a high degree of homology and are shaped as concave disks with a small projection at one end. Their elliptical dimensions are approximately 3.8×2.8×1.5 nm, and for the most part, the structure is only a single polypeptide chain thick. The reactive site of the protein is on the concave surface and involves the regions encompassed by residues 32–45 and 49–56 as well as isolated residues from other regions of the molecule.

In contrast with toxins that block neuromuscular transmission, latrotoxins (LTX) cause excessive ACh release and excitation. These toxins are produced by black or brown widow spiders from the genus *Latrodectus* and are directed predominantly against vertebrates (α-LTX), although five homologous insect-specific latrotoxins and one crustacean-specific latrotoxin also coexist in the venom of *Latrodectus mactans tredecimguttans*. This family of toxins may have arisen through a process of gene duplication in the spider. Envenomation by spiders of the genus *Latrodectus* cause lactrodectism, a generalized poisoning syndrome that develops within an hour of being bitten, with pain first localized at regional lymph nodes. Rapidly, generalized muscle cramps and rigidity develop together with hypertension and transient tachycardia followed by bradycardia, profuse sweating and oliguria. A similar envenomation with prominent autonomic nervous system dysfunction is caused by stonefish stings and all these symptoms can be ascribed to hyperexcitability of various nerve terminals. Trachynilysin, a toxin of ≈150 kDa, has been isolated from the venom of the stonefish *Synanceia trachynis* and similar-sized stonustoxin and verructoxin are synthesized by *S. horrida* and *S. verrucosa* respectively. The poisoned neuromuscular junction terminals exhibits enlarged and swollen synaptic boutons depleted of ACh vesicles and containing swollen mitochondria. Exocytosis of synaptic vesicles takes place at active zones and is followed by unaltered vesicular recycling.

Two types of high-affinity LTX receptor have been distinguished in the neuronal membrane on the basis of their Ca^{2+} dependence, with affinity in the nanomolar range. Binding of LTX to the plasmalemma of neuronal cells causes a large influx of Ca^{2+}. After a delay of a few dozens of seconds, LTX induces the formation of long-lasting channels, which are nonselective for cations and display a large conductance of tens of picosiemens, leading to influx of Ca^{2+} and Na^{+} and consequent membrane depolarization. Ion influxes through LTX channels are such that they can well account for the massive neurotransmitter release. However, LTX is capable of inducing neurotransmitter release even in the absence of extracellular Ca^{2+}, provided that the terminal is supplemented with millimolar concentrations of other divalent cations. Unlike the Ca^{2+}-dependent LTX-induced neurotransmitter release, which is mediated via SNARE proteins, LTX may cause Ca^{2+}-independent phospholipase C stimulation, leading to exocytosis. In addition, neurexin Ia and a 120 kDa integral membrane protein associated with the G protein α-subunit (see Ch. 19), syntaxin and synaptotagmin both bind LTX. If these interactions were indeed functional, binding of LTX could activate Ca^{2+} channel/syntaxin complexes coupled to neurexin Ia and to the 120 kDa LTX receptor via a G protein.

LTX consists of 1,381 residues distributed in four different regions: part I is a poorly conserved signal sequence that is removed during toxin maturation, whereas part II is highly conserved and contains two putative membrane-inserting segments, which may account for the channel-forming activity of these neurotoxins; part III is less conserved and includes many ankyrin repeats, suggestive of an adaptor role linking membrane proteins to the cytoskeleton (see Ch. 8). Part IV is of variable size and is not conserved, being removed during maturation and activation of latrotoxin.

Other fish toxins are yet to be characterized, but it appears that all fish venoms act both pre- and postjunctionally to cause depolarization and that the venoms possess cytolytic activity. In contrast, venoms produced by the marine predatory snails of the genus *Conus* are more diverse, the total number of peptides in the venom of a single Conus species ranging from 50 to 200. About 50,000 different *Conus* peptide toxins are estimated to exist, owing to a synthetic strategy that amounts to a combinatorial library scheme [23]. The most prominent venoms belong to the conotoxin type, a class of peptides containing multiple disulfide bonds usually targeted against ion channels. α-conotoxins, produced by the fish-, snail- and worm-hunting marine snails *C. striatus*, *C. magus* and *C. purpurascens*, are competitive antagonists of the AChR with nanomolar affinity. In particular, subtypes α-conotoxin GI and MI inhibit all AChR types from vertebrate muscle without affecting neuronal receptors. *C. purpurascens* also secretes ψ-conotoxin PIIIE, an unrelated noncompetitive AChR antagonist structurally similar to the μ-conotoxins (the potent Na^{+} channel blockers), that probably acts as AChR channel blocker. α-conotoxins bind preferentially to the α:δ subunit interface of the AChR versus the α:γ interface (see Ch. 11) with an affinity difference of 10,000-fold between the two sites in some cases. AChR residues γK34, γS111 and γF172 at the interface with the α subunit confer lower affinity than δS36, δY113 and δI178 at the equivalent α subunit interface.

The overall structure of α-conotoxin GI is triangular, with both the positively charged amino group of the first residue (E1) and the guanidino group of R9 located at two of the corners and a central hydrophobic scaffold held together by the disulfide bonds. Not unexpectedly, conotoxin ψ-conotoxin PIIIE is very differently shaped, as a flat disc with five exposed positive charges that may penetrate the AChR channel pore when its intrinsic electrostatic potential becomes less positive as a result of opening [24].

Electrolyte imbalances alter the voltage sensitivity of muscle ion channels. While the effect of changing ionic concentrations across cellular membranes on membrane

potential and excitability is dictated by the Nernst equation (see Ch. 6), plasmatic electrolyte disturbances affect excitable tissues differently depending on the rate of exchange of the extracellular solution and the mobility of ions across the often narrow intercellular spaces [9]. Hypercalcemia causes divalent metal ionic screening of membrane surface charges and is associated with weakness and fatigability due to muscle dysfunction caused by offsetting of the extracellular potential, to which the voltage sensors of all ion channels are exposed and which can eventually lead to chronic myopathy. Effects on the brain include altered consciousness ranging from apathy to agitation and seizures. Common causes of hypercalcemia are hyperparathyroidism, metastatic disease and vitamin D intoxication. Hypocalcemia, a feature of hypoparathyroidism, malabsorption, vitamin D deficiency and – rarely – thyroid and parathyroid surgery, initially causes numbness of mouth, hands and feet, followed by tetany or spasms in the same distribution. The encephalopathy associated with hypocalcemia is more dramatic, with hallucinations, psychosis and seizures. Effects remote from the cerebral cortex include parkinsonism and chorea (see Ch. 45) and even spinal cord dysfunction. The effects of magnesium electrolyte imbalance resemble those of calcium, except that hypomagnesemia may escape analytical detection because magnesium is predominantly an intracellular ion. Renal tubular acidosis may cause hypomagnesemia, while renal failure commonly causes hypermagnesemia.

Alterations in potassium concentration are worse tolerated because of the fundamental role of potassium in setting resting membrane potential in almost all excitable cells of the organism. Hyperkalemia usually causes cardiac arrhythmia before nerve and muscle dysfunction. The latter abnormalities are manifested as weakness preceded by burning sensation (paresthesia) and are sometimes accompanied by mental changes. Hypokalemia, on the other hand, causes primarily neuromuscular disturbance, with fatigability, weakness of large (proximal) muscles and, ultimately, lysis of the muscle membrane (rhabdomyolysis with release of myoglobin to the plasma). When accompanied by alkalosis, hypokalemia causes tetany.

The neuromuscular junction and muscle are more resistant to changes in sodium concentration, to which they are minimally permeable at rest. In fact, the consequences of sodium disturbance relate instead to the role of this ion in maintaining the osmotic equilibrium between the brain and plasma and range from depression of consciousness, coma and seizures caused by hyponatremia, to brain shrinkage and tearing of superficial blood vessels due to excessive serum osmolarity due to hypernatremia.

Mouse models offer opportunities for discovering disease mechanisms and for testing novel treatment strategies 739

AMYOTROPHIC LATERAL SCLEROSIS IS THE MOST COMMON ADULT ONSET MOTOR NEURON DISEASE

The motor neuron diseases (MND), including amyotrophic lateral sclerosis (ALS), are chronic, progressive illnesses characterized by: severely disabling clinical features involving motor systems (weakness, muscle atrophy and, in ALS, spasticity); relatively selective involvement of lower motor neurons and, in classical ALS, upper motor neurons; disease-related abnormalities associated with, in some instances, the presence of intracellular protein aggregates (inclusions); alterations in axonal transport; and death of motor neurons. Some forms of the disease are inherited as autosomal dominants, others as recessives. In some instances, the presence of specific gene products confer risk. The majority of cases appear to be sporadic. Although symptomatic treatments are available, there are, at present, no effective mechanism-based therapies [1–4]. The MND represent challenges for science and medicine, not because of their prevalence but because of the tragedy of these illnesses for affected individuals, their families and caregivers. Recent research, particularly studies utilizing animal models, has provided new insights into the mechanisms of these disorders, identified potential new targets for therapy and allowed design and testing of treatments.

Before discovery of mutant genes linked to MND, scientists created and studied surrogate models of dysfunction/death of motor neurons [4, 5], including: axotomy models (axonal transection and avulsion); models of neurofilamentous abnormalities of axons induced by exposure to toxins; and spontaneously occurring animal models, such as hereditary canine spinal muscular atrophy (HCSMA), a genetic disease occurring in Brittany spaniels. Although useful for testing hypotheses about pathogenic mechanisms, these models have variable direct relevance to human MND. However, because investigations of these models set the stage and established experimental strategies for later work, we briefly describe studies

Basic Neurochemistry: Molecular, Cellular and Medical Aspects
0-12-088397-X

of several of these disorders as examples of the types of investigations that lead to investigations of the new models, many of which were developed following the exciting discoveries of the roles of mutant genes in MND.

The identification of causative mutations in specific genes in cases of human MND, including familial ALS (fALS) and spinal muscular atrophy (SMA) [6–8], has provided new opportunities, using transgenic and gene targeting approaches, to investigate the molecular participants in disease processes [1, 3]. In autosomal dominant fALS, the mutant proteins often acquire toxic properties that directly or indirectly impact on the functions and viability of neurons [3, 4, 7, 9, 10], and introduction of mutant genes into mice reproduces some features of these diseases [4, 11–13]. In contrast, autosomal recessive diseases, such as SMA, which usually lack the functional protein encoded by the mutant gene (*SMN* – 'survival motor neuron' – in SMA), can often be modeled by gene targeting strategies [1, 4]. Studies of some MND in animals, including progressive motor neuronopathy (PMN) [14], have led to discovery of mutant genes/proteins whose roles in neurons illuminate potential disease mechanisms in humans [14].

In models of MND, therapeutic manipulations, manipulation of expression of selected genes in specific cell populations [15, 16], creation of chimeric animals to test whether abnormalities are cell autonomous [17], administration of trophic factors to prevent trophic cell death [18–20] and testing of a variety of drug therapies [21–24] have been used to try to ameliorate phenotypes and thus provide insights into disease mechanisms and potential treatment strategies [1, 3, 4, 15, 25, 26]. Results of these studies are being used to design novel therapies to be tested in clinical trials in humans.

In this review, we focus on ALS, particularly its genetic variants, and relevant model systems with the belief that understanding these inherited illnesses will help to clarify the mechanisms of the more common sporadic forms of MND. SMA, a major cause of MND in infancy and childhood, is beyond the scope of this chapter and is the subject of several recent reviews [4, 8, 27].

Motor neuron disease is characterized clinically by weakness, muscle atrophy and spasticity. This illness, often termed Lou Gehrig's disease in the United States, is the most common adult-onset form of MND with a prevalence of approximately 2–3 per 100,000 people [1–3, 10, 25, 28]. Each year in the United States, in excess of 5,000 people are diagnosed with ALS. In parts of the United Kingdom, 1 in ≈500 deaths are attributed to some form of MND. The principal clinical signs of ALS include progressive limb weakness, which may be symmetrical or asymmetrical; atrophy of appendicular, bulbar and respiratory muscles; and spasticity [1, 2, 26, 28]. The paralysis/muscle atrophy and spasticity are the result of degeneration of motor neurons in the spinal cord/brain stem and motor cortex respectively. The onset of this illness is typically in the fifth or sixth decade of life; affected individuals usually die within 2–5 years of appearance of symptoms. Both sporadic (sALS) and familial (fALS) forms of illness exist; familial cases make up approximately 5–10% of the total. While the causes of the majority of cases of ALS are yet to be identified, the shared features of the clinical presentations and pathologies occurring in both sporadic and familial cases suggest the existence of some common disease mechanisms.

The pathological processes impact particularly on the spinal and corticospinal motor neurons.

These processes appear to evolve through a series of stages influencing size, shape, content, metabolism and physiology of these cells [28–30]. Years ago, it was observed that proximal axonal segments were swollen with maloriented arrays of neurofilaments (NF) [31, 32]. Similar abnormalities were documented in experimental models [5, 33–37]. Investigations, described below, tested the hypothesis that this type of pathology was the result of defects in axonal transport [5, 38–43] (see Ch. 28 for discussion of axonal transport.). Moreover, it was hypothesized that impairments in transport could also be associated with 'a dying back' phenomenon (i.e. degeneration proceeding retrogradely from distal nerve terminals to proximal cell body), which was hypothesized to be related to impaired delivery of essential constituents to the most distant axons and terminal [5]. In MND, it was hypothesized that these abnormalities become more extensive over time with clinical signs becoming increasingly evident. Moreover, as a part of the dying-back process and discrimination of neurons from targets, retrogradely transported trophic support to neuronal cell bodies is compromised, which, in turn, impacts on the viability of these cells [18, 20, 44]. In ALS, motor neurons show a variety of abnormalities, including chromatolysis (enlargement of cell bodies with dispersal/margination of Nissl substance) and protein aggregates and inclusions, which are often ubiquitinated [28]. Later, neurons may become atrophic. There is wallerian degeneration of motor axons (see Ch. 30). In the final stages, motor neurons exhibit several features of apoptosis (see Ch. 35), which are discussed below [4, 29, 30, 45–47]. Ultimately, the numbers of motor neurons in brainstem nuclei and spinal cord are reduced and there is also a loss of large pyramidal neurons in motor cortex associated with secondary degeneration of the corticospinal tracts [28].

Excitotoxicity (see Chs 15 and 32) has been suggested to be a mechanism by which motor neurons are damaged in ALS [25, 48, 49]. About 60–70% of sporadic ALS patients have a 30–95% reduction in the levels of the astroglial glutamate transporter EAAT2 (excitatory amino acid transporter 2), also termed GLT-1, in motor cortex and spinal cord [25, 48, 49]. Reduction in level of activity of this major glutamate transporter leads to increased extracellular concentrations of glutamate at synapses and evidence of excitotoxicity exists in some patients with ALS.

The mechanisms of cell death are the subject of very active research [29, 30, 45–47, 50–53]. Three variants of cell death have been described: apoptosis or programmed

cell death (PCD); necrosis associated with cytoplasmic swelling and loss of membrane integrity; and autophagy (an intracellular catabolic process that occurs by lysosomal degradation of damaged or expendable organelles). The morphological distinctions between these different forms of cell death are blurred and it has been suggested that the death process may involve a continuum with varying overlapping contributions, particularly of apoptosis and necrosis. In ALS, current evidence indicates that apoptosis plays a role in the degeneration of motor neurons, albeit, perhaps, in a nonclassical form [4, 29, 30, 45–47, 50, 54–56].

Thus, in ALS, motor neuron degeneration evolves over time showing the following: chromatolysis; appearance of inclusions and aggregates; somatodendritic atrophy; and accumulations of vacuoles in mitochondria in dendrites and cell bodies. In late stages, DNA fragmentation is evident and cytochrome *c* and cleaved caspase-3 appear in cytoplasm. The increase in caspase-3 activity and the activation of DNA fragmentation factor endonuclease (DFF-45) leads to the appearance of internucleosomal fragmentation of genomic DNA in cytoplasm, an increase in levels of Bax and Bak and a decrease in levels of Bcl-2 in mitochondrial membrane-enriched fractions derived from selectively vulnerable motor regions [29, 30, 45, 50, 55, 57]. Some investigations support the idea of inappropriate re-emergence of a PCD mechanism involving p53 activation and cytosol-to-mitochondria redistributions of cell death proteins. In this scenario, it has been suggested that death of motor neurons in ALS appears to be linked to a p53-driven, intrinsic mitochondrial caspase-3-dependent apoptotic pathway, possibly involving a Bax channel model [30, 57]. In studies of mouse models of ALS [47, 54, 58–63], there is no clear consensus on the type or mechanism of cell death [30] and some of these issues are discussed below.

Some cases of amyotrophic lateral sclerosis are familial. Approximately 10% of cases of ALS are familial and, in the majority of these cases, the disease is inherited as an autosomal dominant [1, 3, 25]. Several of the genes that cause or confer risk in ALS are reviewed below because the information serves as important background for subsequent discussion of genetically engineered models. In ALS1, mutations in the superoxide dismutase 1 (SOD1) gene occur in ≈5–10% of autosomal dominant cases of fALS. Mutations in dynactin $p150^{glued}$ have been recently linked to autosomal dominant fALS [7] and may, as an allelic variant, serve as a risk factor [64]. In ALS2, autosomal recessive deletion mutations have been identified in *ALS2*, which encodes alsin, a protein that regulates GTPases [65, 66]. In ALS4, a rare autosomal dominant form of juvenile ALS, mutations have been identified in the gene (*SETX*) that encodes senataxin [67], which contains a DNA/RNA helicase domain with homology to other proteins known to have roles in the processing of RNA [68]. Finally, following an observation that deletion of the hypoxia response element in the promoter of the vascular endothelial growth factor (VEGF) gene causes degeneration of motor neurons in mice [69], it has been reported that individuals homozygous for certain haplotypes in the VEGF promoter have an increased risk for ALS [15]. Thus, VEGF, a cytokine involved in angiogenesis but with many other functions, may play a role as a susceptibility gene for ALS [70].

Selected aspects of the genetics of MND are reviewed in greater detail below with the belief that understanding of the biology of some of the proteins encoded by these genes and subsequent generation of mouse models are of value in clarifying the molecular mechanisms of selective dysfunction and death of motor neurons in MND, and, eventually, for identifying targets for new treatments.

Several genes have been shown to cause amyotrophic lateral sclerosis.

Amyotrophic lateral sclerosis 1 is caused by expression of mutant *SOD1*. Approximately 15–20% of patients with autosomal dominant fALS (i.e. ≈2% of all ALS cases) have mutations in the gene (chromosome 21) that encodes cytosolic Cu/Zn SOD1, a 153 amino acid enzyme that, as a homodimer, catalyzes the conversion of O_2^- to O_2 and H_2O_2 [3, 6]. To date, investigators have identified approximately 100 mutations (see on line at: alsod.org), all of which lead to autosomal dominant fALS [3]; the exception is homozygous D90A SOD1, which is inherited as recessive. These mutations are scattered throughout the structure of SOD1 and are not preferentially localized near the active site or the dimer interface. While some fALS SOD1 mutants show reduced enzymatic activities, many mutant proteins retain activity [9, 71]. It is thought that the mutant enzyme causes selective neuronal degeneration through a gain of toxic property [11, 71], consistent with the dominant pattern of inheritance. Supporting this concept are the following observations: $SOD1^{-/-}$ mice do not develop disease [72]; the levels of enzyme activity do not correlate with disease [9]; and, in transgenic mice, increasing wild-type SOD1 activity does not ameliorate the disorder [3, 73]. The presence of aggregates containing mutant SOD1 in affected neurons has generated several hypotheses regarding disease pathogenesis including: the sequestration of essential molecules by mutant proteins in aggregates; damaging mutant peptides are mislocated (i.e. to mitochondria) and cause problems at these sites; malfolded proteins in aggregates are toxic and impact on molecular motor, axonal transport, proteosomal degradation and glutamate transport; and mutant SOD1 participates in aberrant copper chemistry. Some of the potential mechanisms are discussed below.

Amyotrophic lateral sclerosis 2 is linked to mutant alsin. In several families with autosomal recessive juvenile ALS, mutations have been identified in *ALS2 (*chromosome 2), encoding alsin [65, 66]. This illness, which was originally described in a Tunisian kindred, is characterized by spasticity (involvement of upper motor neurons) and weakness/amyotrophy (involvement of lower

motor neurons) [65]. The functions of alsin are not well understood, but the protein has several sequence motifs that have homologies to GTPase regulatory proteins important in cell signaling and in protein trafficking. Alsin appears to be a guanine–-nucleotide exchange factor (GEF) for at least the RAB5 family of GTPases. The *ALS2* mutations are believed to be unstable [74] and it has been hypothesized that loss of functional activities of the GEF domains of alsin could impact on signal transduction pathways, regulation of the cytoskeleton and/or intracellular trafficking [65, 66]. However, at present the mechanisms whereby mutations in this gene cause MND are unknown.

Amyotrophic lateral sclerosis 4 is linked to mutations in a helicase gene. This rare autosomal dominant form of juvenile ALS has been linked to mutations in *SETX* (chromosome 9), encoding senataxin [67], the mammalian ortholog of a yeast RNA helicase [68]. This disease is manifest by distal weakness (beginning at approximately 25 years of age), slow progression and a normal lifespan [75]. There is some evidence of partial denervation of muscle and some affected individuals have signs of involvement of upper motor neurons [75]. Sensation is normal. At autopsy, the number of spinal motor neurons is reduced and swelling of axons occur among a variety of populations of neurons [75]. The corticospinal tract shows evidence of degeneration. Sensory neurons exhibit some mild abnormalities. Senataxin has a helicase domain homologous to that of other proteins known to have roles in the processing of RNA [67, 76–78]. Significantly, recessive mutations in *SETX*, which are believed to result in a truncated protein (loss of function), have also been reported in ataxia–oculomotor apraxia type 2. Interestingly, infantile spinal muscular atrophy with respiratory distress type1, manifest as weakness and difficulty with respiration at age 1–6 months, results from mutations in another helicase gene, which encoded the immunoglobulin M-binding protein (IGH MBP2) on chromosome 11 [79, 80].

Mutant dynactin p150^{glued} causes a form of familial amyotrophic lateral sclerosis. A family with a slowly progressive autosomal dominant lower motor neuron disease (lacking sensory signs) has recently shown linkage to a G59S mutation in the p150^{glued} subunit of dynactin (DCTN1) [7], a motor protein that, along with dynein, plays a role in retrograde axonal transport [81–83]. This inherited disease begins in early adult life with vocal cord paralysis (associated with breathing difficulties), facial weakness and atrophy of muscles in the hands [7]. Subsequently, weakness and atrophy appear in the distal lower extremities. The dynactin complex, which includes p150 and dynamitin, provides a linker between cargos, microtubules and dynein. The mutation in the index family occurs in a motif in the p150^{glued} subunit that binds to microtubules; modeling studies suggest that this mutation impacts on protein structure to create steric hindrance and distortion of the folding of the microtubule binding domain [7]. Consistent with this concept is the observation that the mutant protein binds less well to micro tubules [7]. More recently, heterozygous missense mutations have been described in several familial cases of ALS and one apparently sporadic case; these observations have been interpreted to suggest that variants in the p150 subunit can confer risk in ALS [64].

Taking advantage of the discovery of this fALS-linked mutation in a motor protein, members of our group (Drs Laird, Ackerly, Price, Wong) have recently created a mutant p150^{glued} model of fALS with a robust MND phenotype.

NON-TRANSGENIC, INDUCED MODELS OF MOTOR NEURON DISEASE

Interruption of the communication between the motor neuron cell body and axon by transection, crush or avulsion induces motor neuron injury.

Peripheral nerve axonal injury. These highly reproducible models of neuronal injury, which interrupt anterograde and retrograde transport in axons, are associated with distal wallerian degeneration and retrograde responses of neurons [5, 84–86]. Following axotomy, the proximal and distal stumps become enlarged, with accumulations of membranous elements [86]; shortly thereafter the distal stump begins to undergo wallerian degeneration [86]. The cell bodies of axotomized neurons may show: chromatolysis [84]; alterations in levels of specific mRNAs [87–89]; changes in the synthesis and transport of specific proteins; aberrant distributions of cytoskeletal proteins (i.e. phosphorylated neurofilaments appear in perikarya) [88–91]; and synaptic disconnection [85]. Moreover, by choosing certain experimental parameters (i.e. age of animal, motor or sensory neurons, proximal or distal locations of lesion, nature of the lesion (crush, transection or avulsion)), investigators can study responses associated with regeneration (distal lesions) [86, 88, 91–93] and degeneration (proximal avulsions) [18–20, 94]. Over the years, the axotomy model has provided important information concerning the influence of axonal injury on the expression of genes encoding cytoskeletal proteins, including NF proteins, peripherin, tubulin, etc. [88, 89, 91, 92, 95]. For example, following unilateral crush of the sciatic nerve, sensory neurons exhibit reduced levels of NF gene expression [88]; the amounts of NF proteins entering axons are decreased and a wave of reduced axonal caliber moves down axons at the rate of transport of NF proteins [91]. Following regeneration, the synthesis of NF proteins returns to normal and axonal caliber is restored [88, 91]. These experiments provided the first insights into the role of NF as a determinant of axon caliber [91, 95]. Following axonal injury,

the expression of other genes may be increased (i.e. the levels of β-tubulin and peripherin mRNAs increase following axotomy [96]and levels of p75 NGF-R immunoreactivity transiently reappear in motor neurons [97]. Levels of neurotransmitter-related proteins, including choline acetyltransferase, often decrease after axotomy of motor neurons; when reinnervation occurs, these transmitter-related markers usually return to normal. During outgrowth of regenerating axons, fast transport delivers membranous constituents required for new growth cones and the axolemma [93, 98]. When regeneration is complete, levels of these mRNA return to control values. Fast transport delivers many of the proteins essential for resuming normal functions at the neuromuscular junction.

Proximal axotomies (including rhizotomies) of facial and spinal motor neurons, particularly in young animals, causes death of neurons [18–20, 44, 94]. These models have proved to be very useful for examining the influences of trophic factors on the survival of axotomized motor neurons [18–20, 44, 94]. For example, brain-derived neurotrophic factor (BDNF), a survival factor for motor neurons, is expressed in the local environment and in muscle targets of motor neurons; expression in muscle is upregulated by denervation [18]. (Neurotrophic factors are discussed in Ch. 27.) Significantly, motor neurons express the gene encoding $p145^{trkB}$, a receptor involved in BDNF signal transduction [97] and it is believed that BDNF and phosphorylated TrkB are carried by retrograde axonal transport to motor neurons from skeletal muscles [97, 99]. In the facial nerve axotomy model, human recombinant BDNF, placed in proximity to the proximal stump, reduces cell death as compared to the vehicle-treated group [18, 94, 100]. NT-4/5 has a similar effects on axotomized facial motor neurons [20]. Glial derived neurotrophic factor (GDNF), a member of the TGFβ superfamily, binds to specific receptors and is also a potent trophic factor for motor neurons *in vitro* and *in vivo* [19, 101]. The administration of neurotrophins may have beneficial effects in other models of MND. If delivery problems and biological toxicities can be overcome, trophic approaches may offer potential for treatment and certain types of MND [102, 103].

β,β′-iminodipropionitrile-induced neurofilamentous axonal pathology. Administration of β,β′-iminodipropionitrile (IDPN) produces a pathology in proximal axons [38, 104] similar to that described in ALS [31]. IDPN selectively impairs slow transport, particularly of the three NF proteins [38]; the transport of tubulin and actin are also somewhat slowed, but fast anterograde and retrograde transport appear to be relatively normal. Exposure to IDPN impairs the transport of NF proteins beyond the proximal internodes and the toxin appears to dissociate NF from microtubules [39, 40]. In this model, a relatively selective defect in the transport of NF leads to formation of massive filament-filled proximal axonal swellings and atrophy of distal axons [104]. Secondary to the axonal abnormalities, changes occur in Schwann cells and myelin sheaths [105, 106]. Studies of several toxic neurofilamentous axonopathies, including those induced by IDPN, acrylamide and aluminum, with their highly reproducible pathology, were among the first to be investigated with radiolabeling methods developed in the 1970s. This research demonstrated, for the first time, the roles of impaired axonal transport in generating cytoskeletal axonal abnormalities resembling those identified in ALS [5, 37–43]. Moreover, other investigations were the first to demonstrate that retrograde axonal transport was also important in the disease (i.e. it provided a pathway by which tetanus toxin enters the nervous system [107]). Years after these studies were published, interest in the roles of axonal transport in normal neuronal functions, in the perturbations seen in experimental models (including axotomy, dying back neuropathies and neurodegenerative diseases) and in experimental therapeutics has undergone an extraordinary renaissance [1, 5, 10, 108–112].

Hereditary canine spinal muscular atrophy. This disease of Brittany spaniels, discovered by Dr Linda Cork, manifests as weakness and atrophy of skeletal muscles, with sparing of eye movements and sphincters [34, 113, 114]. Three HCSMA phenotypes have been identified: pups with accelerated disease, produced by mating affected to affected dogs, are tetraplegic by 3–4 months of age; intermediately affected dogs become weak at approximately 6 months of age and are paralyzed at 2–3 years of age; and chronically affected dogs become mildly weak later in life and show very slow rates of progression. Neurofilamentous swellings are abundant in the anterior horns involving proximal axons of motor neurons. Moreover, there are reductions in the size of these cells and, possibly, in the content of transmitter markers [34, 36]. Axonal transport of NF proteins and, to a lesser extent, tubulin are impaired. In ventral roots, axonal diameters are smaller than controls and evidence of axonal degeneration is not conspicuous. The clinical phenotypes, selective involvement of motor neurons and cytoskeletal pathology that occur in HCSMA resembles the abnormalities described in cases of ALS. To date, the genetic basis for the canine disorder has not been defined but it would not be surprising if the mutant gene product impacted on the motor axonal transport.

SELECTED GENETIC MODELS OF RELEVANCE TO AMYOTROPHIC LATERAL SCLEROSIS

Information concerning the functions of some of the genes/proteins implicated in causation of and risk for these illnesses and has been of great value for the generation of mouse models, the study of which has enhanced our understanding of the pathogenesis of ALS and its variants.

Transgenic mice expressing wild type or mutant neurofilament genes develop motor neuron disease and neurofibrillary pathology. Neurofilaments are assembled as obligate heteropolymers from three subunits, including NF-L (68 kDa), NF-M (95 kDa) and NF-H (115 kDa) [115–117]. As described above, NFs are an important determinant of axonal caliber [88, 91, 117, 118]. To determine whether increased NF content or the expression of NF transgene (without or with) mutations can cause disease, investigators have generated a variety of lines of *NF* mice. Approximately twofold overexpression of wild-type mouse NF-L is not associated with an overt phenotype [119] but greater elevations of NF protein leads to accumulations of NF in cell bodies, and accumulations of NF in distended axons and there is evidence of denervation [120]. Animals die within 3–4 weeks of age. Doubling NF-H content by overexpression of wild-type human NF-H results in an similar pathology; however, the onset of signs is later (4–5 months) and the disease progresses more slowly. In this model, axonal transport is impaired [121].

Significantly, mutations in NF genes can cause MND. Mutant *NF-L* mice with a single amino acid substitution at a conserved residue develop clinical signs between 3–4 weeks and 3 months, depending on levels of a mutant NF-L subunit [122]. The mice develop clinical signs, NF axonal swellings, evidence of motor neuron dysfunction (including altered axonal transport) and death, denervation, and muscle atrophy [122]. Thus, perturbations in the biology of NF can cause clinical disease that resembles those features occurring in cases of ALS.

Familial-amyotrophic-lateral-sclerosis-linked mutant *SOD1* mice reproduce many of the clinical and pathological features of amyotrophic lateral sclerosis. SOD1 is normally present in neurons (and other cells) [123]. To attempt to model an inherited form of fALS, investigators have introduced mutant *SOD1* into mice. These mice develop progressive weakness and muscle atrophy as well as cellular abnormalities which closely resemble the features of ALS [11, 12, 124]. For example, the *G37R SOD1* mice, which accumulate three to 12 times the endogenous levels of SOD1 in the spinal cord, develop an MND phenotype [1, 4]. In some lines of mice, high-molecular-weight complexes of mutant SOD1 accumulate in neural tissues [125, 126]; these complexes are rarely found outside the nervous system other than in skeletal muscle [127], suggesting that factors in neural tissues promote the formation or lead to failure of clearance of these complexes. Motor neurons also exhibit SOD1 inclusions, ubiquitin and phosphorylated NF-H immunoreactivities [12, 128, 129]. Aggregates are present in neurons, in some mutant lines of mice, and in glial cells [11, 12, 73, 126, 129]. SOD1, transported with the slow anterograde component [130], accumulates in irregular, swollen, intraparenchymal portions of motor axons and is often associated with vacuolization of mitochondria and disorganized bundles of filaments. Approximately 2–3 months before the appearance of clinical signs, axonal transport appears to be abnormal [131]. The presence of wallerian degeneration correlates with development of weakness [11, 12]. In mutant mice, cleaved products caspase 1 and 3 accumulate in spinal cord (early and late, respectively), followed by evidence of cleavage of caspase 9 [58], suggesting caspase activation. However, more recent studies demonstrated that caspase-1 and caspase-3 activation is not crucial for motor neuron degeneration in mutant SOD1 mice [132]. Investigations have defined a motor-neuron-specific, cell-autonomous death pathway mediated by Fas signaling and involving p38 [54]. Interestingly, embryonic murine motor neurons expressing mutant SOD1 display increased susceptibility to the activation of this pathway (but not to deprivation of trophic factors or to excitotoxic manipulations) [54]. Eventually, in mutant *SOD1* mice, motor neurons degenerate and the anterior horns show reduced number of neurons as well as evidence of local proliferation of glial cells.

Following the discovery that the *SOD1* mutations cause disease independent of levels of dismutase activity [9, 71], several hypotheses were proposed to explain the ways in which mutations lead to abnormalities of motor neurons: mutant SOD1 damages cells by carrying out aberrant copper chemistries; the protein becomes mislocalized, perhaps leading to mitochondrial damage; the mutant protein is improperly folded and shows an increased propensity to aggregate; the aggregates of mutant SOD1 cause toxicity, perhaps because high-molecular-weight complexes sequester molecules critical for viability, deplete chaperones essential for proper protein folding and impair proteosomal degradation processes; the mutant protein, by unknown mechanism alters (reduces) glutamate transport leading to excitotoxicity; and the presence of the mutant enzyme is associated with impaired axonal transport, perhaps by interfering with molecular motors. These hypothetical mechanisms are not mutually exclusive. However, the mechanism whereby the mutant SOD1 gains an adverse property remains to be defined [3, 11] (see below).

Lines of mice with mutant genes encoding motor proteins develop an amyotrophic-lateral-sclerosis-like phenotype. For many years, axonal transport has been suggested to play roles in the pathogenesis of human diseases, including ALS, and in various animal models [5, 38, 41, 107]. As described above, these concepts have been validated in experimental investigations of models of traumatic, toxic and neurodegenerative diseases [37, 38, 41, 107, 110]. In recent studies of mutant SOD1 mice, disruption of transport has been shown to antedate the onset of clinical signs [131]; a similar scenario has long been postulated in ALS [5]. Although the mechanisms leading to impaired transport are not entirely clear, the most obvious consequences of impaired transport are the failure of critical proteins synthesized in the cell body and

destined for the synapses to reach their target(s) at terminals, and/or altered retrograde transport of signals, originating in the periphery, to reach cell bodies [18, 81–83, 99, 103, 133]. Extrapolating from investigations of many models, including those related to mutant motor protein, either or both of these abnormalities could lead to clinical signs and to dysfunction and death of motor neurons.

Compelling evidence in support of roles of impaired transport leading to disease comes from recent studies of the impact of mutations on the properties of motor proteins essential for normal axonal transport. These proteins include: the kinesins and the dyneins, members of two superfamilies of molecular motors, which are responsible for the anterograde and retrograde transport of cargos along microtubules within axons; and dynactin, a large multi-subunit complex, involved in dynein-mediated retrograde transport [81–83, 133]. Selected investigations relevant to these issues are reviewed below.

Mutant dynactin mice. The dynein–dynactin complex is a critical component of fast retrograde transport of vesicles and organelles [81–83]. Dynein is responsible for the minus end movement along microtubules and dynactin has been postulated to enhance the processing and efficiency of the motor with $p150^{glued}$ interacting with dynein and tubulin [134]. The overexpression of the dynactin subunit dynamitin (dynamitin; GenBank number NM 006400) disrupts the dynactin complex (presumably by causing dissociation of dynactin at the junction of the $p150^{glued}$ and Arp1 filament). The *in vivo* result is a mouse model displaying a late-onset MND phenotype, including weakness, trembling, abnormal posture and abnormal gait [134]. These mice exhibit denervation and atrophy of muscles and degeneration of motor neurons.

Mutant dynein mice. Dynein, comprised of heavy, intermediate, light intermediate and light chains [83], is responsible, in conjunction with dynactin complex, for the minus end movement of cargos [81–83]. A late-onset, progressive MND in mice, identified following an *N*-ethyl-*N*-nitrosourea-mediated mutagenesis screen, is linked to mutations in the cytoplasmic dynein heavy chain 1(Dnchc1; GenBank number NM030238) [135]. Heterozygous missense mutations are associated with impaired transport and degeneration of motor neurons.

Mutant *Tbce* mice. Progressive motor neuropathy (PMN), an autosomal recessive murine disease, manifests as weakness beginning within a few weeks of birth [14, 136]. These mice are homozygous for a Trp 524 Gly substitution of *Tbce* (tubulin-specific chaperone E), localized to mouse chromosome 13 [14]. *Tbce* mRNA is present in neurons in the spinal cord. Degenerative changes are conspicuous in motor axons, and ultrastructural studies of peripheral nerves of *PMN* mice disclose reduced numbers of microtubules in these axons. Mutations of the highly conserved Trp524 residue, which appears to influence protein stability, are believed to impact on the biology of tubulin in axons. Transgenic complementation restores the *PMN* mouse line to a normal phenotype [14]. *Tbce* is an ortholog of human *TBCE* and mutations in the human gene are associated with two multiorgan system degeneration syndromes, which are distinct from PMN [14].

A variety of experimental therapeutic strategies have been tested in mutant *SOD1* mice. Lines of mutant *SOD1* mice have been used for pharmacological and 'genetic' therapeutic trials [10, 21, 22, 25, 137–139]. Selected examples of these approaches are briefly described below.

Results obtained during several drug trials have been less than encouraging (vitamin E, selenium, riluzole, gabapentin and D-penicillamine, a copper chelator). Treatment with creatine appear to have modest benefits [138]. Although oral administration of creatine to G93A *SOD1* mice results in a dose-dependent improvement in motor tasks and extended survival, a creatine trial in humans showed no beneficial effects compared to placebo [140]. Minocycline, a second generation tetracycline antimicrobial and anti-inflammatory, which acts as a neuroprotectant by upstream inhibition of the activities of caspase-1, caspase-3, inducible NOS matrix metalloproteinases and p38 mitogen-activated protein kinase (MAPK) and, by reducing cytochrome *c* release, also had a modest effect (i.e. delayed disease onset and prolonged survival) [23, 63]. Because some evidence suggests that several pathogenic pathways converge in ALS, investigators have also turned to combination treatments. Mutant mice received minocycline (which inhibits microglial activation and the pathways described above), riluzole (a glutamate antagonist used to treat patients with ALS) and nimodipine (a voltage-gated calcium channel blocker), beginning in the late preclinical stage. This dietary regimen delays onset, slows progression of weakness and increases survival [22]. Inhibition of inhibitors of intracellular-1β-converting enzyme (ICE) also slows progress of disease in mutant *SOD1* mice; in these studies, a mouse line with a dominant negative mutation of ICE was crossed to mutant *SOD1* mice. The outcome of the mating results in a modest increase in survival [63].

The reasons that outcome studies in mutant mice may not necessarily translate to benefits for humans with ALS are discussed in a recent editorial [21].

As indicated in the discussion of axotomy models, the beneficial influences of trophic factors on motor neurons provide potential therapeutic opportunities. Although previous human trials have been disappointing (for review see [111, 112]), adenoassociated viral (AAv) delivery of insulin-like growth factor (IGF)-1 to muscle prolongs survival in mutant *SOD1* mice [111]. Thus, following intramuscular injection, the retrograde transport of AAV-IGF-1 appears to provide trophic influences to motor neurons.

To test whether increasing or decreasing SOD1 has an impact on disease in the mutant *SOD1* mice, these animals were mated with wild-type *SOD1* or $SOD1^{-/-}$ mice.

Neither elevations nor reductions of SOD1 influence the clinical course or the character of pathology [73].

The molecular mechanisms whereby mutant SOD1 causes selective motor neuron death have not yet been defined. It has been hypothesized that the toxic property of mutant SOD1 may be related to mutation-induced conformational changes in SOD1 that result in aberrant oxidative activities [141]. In this scenario, cell dysfunction and death could be initiated by aberrant oxidative chemistries catalyzed by the copper bound in the active site of mutant SOD1 [141]. Copper within the active site of SOD1 is essential for dismutase activity [16]. However, copper is extremely toxic and there is virtually no free intracellular copper [142, 143]. Instead, copper is delivered to specific proteins by copper chaperones [142, 143]. The copper chaperone for SOD1, termed CCS in mammals and Lys 7 in yeast (where it was discovered), is present within nerve cells, including neurons and astrocytes [144]. CCS binds to SOD1 [142] and delivers copper to the dismutase, where it is bound by specific histidine residues. To determine the role of CCS in copper homeostasis in the nervous system of mammals, mice were generated with targeted disruption of *CCS* alleles ($CCS^{-/-}$ mice). Although $CCS^{-/-}$ mice are viable and possess normal levels of SOD1, the levels of SOD1 activity are markedly reduced as compared to values of control littermates. Metabolic labeling with copper-64 demonstrates that the reduction of SOD1 activity in $CCS^{-/-}$ mice is the result of impaired copper incorporation into SOD1; this effect is specific because no abnormalities are observed in copper uptake, distributions, or incorporation into other cuproenzymes. Consistent with this loss of SOD1 activity, $CCS^{-/-}$ mice exhibit increased sensitivity to paraquat and reduced fertility in females, phenotypes that are characteristic of $SOD1^{-/-}$ mice. Moreover, in $CCS^{-/-}$ mice, as in $SOD1^{-/-}$ mice, motor neurons are more vulnerable to axotomy.

The hypothesis that the toxicity of mutant SOD1 involves aberrant copper chemistry bound to SOD1 has been tested by two approaches: in one set of experiments, mutant *SOD1* mice were crossed to $CCS^{-/-}$ mice (thus preventing delivery of copper to SOD1) [16]; in a second set of experiments, mutant *SOD1* mice also carried mutations in the histidine residues (H46R/H48Q) that disrupt the copper binding site [126]. The $CCS^{-/-}$ mutant *SOD1* mice possess virtually no copper-loaded SOD1 or SOD1 activity [16]. Significantly, these mice exhibit no differences in the onset or progression of disease as compared to mutant *SOD1* mice [16]. Similarly, the mutant *SOD1* mice with the mutated copper binding sites develop pathological features of disease including (fibrillar inclusions) identical to those occurring in mutant *SOD1* mice with the normal histidine residues at these sites [126]. Thus, copper bound within the active site of the enzyme is not essential for mutant SOD1-mediated toxicity. Although proponents of aberrant copper chemistry hypothesis suggest that copper bound elsewhere on SOD1 could be involved in such reactions, the results of these studies are more consistent with the idea that the effects of improper folding/aggregation of mutant SOD1 is a critical feature of disease [126].

To test the role of NF in mutant *SOD1* mice, the latter animals were crossbred to several lines of mice that have altered distributions of NF. The progeny of mutant *SOD1* mice crossed to mice expressing an NF-H-β-galactosidase fusion protein (NF-H-lacZ) [118], which crosslinks NF and prevents their export to axons, show no effect on disease progression. In contrast, mating with $NF\text{-}L^{-/-}$ mice increases the lifespan of mutant *SOD1* mice [145]. However, crosses with mice overexpressing either wild type NF-H or wild type NF-L are associated with slowing of disease progression, increased lifespan and relative sparing of motor neurons [139, 146]. It has been suggested that the common properties shared by these various lines of transgenic mice are the reduced content of assembled NF in the axonal compartment and an increase in NF proteins in cell bodies. Given the varied results, it is uncertain as to the ways by which the distributions of NF influence the mutant *SOD1* phenotype. Some of the observed effects may be related to strains of mice used in the experiments.

Vascular endothelial growth factor (VEGF) (*VEGF*; GenBank number NM 003376) influences the growth and permeability of blood vessels during development and during the response to altered metabolic demands [147]. Importantly, VEGF stimulates survival of motor neurons under certain conditions of stress. Mice homozygous for a targeted disruption of the hypoxia response element (HRE) within the VEGF promoter ($VEGF^{\delta/\delta}$) develop an adult onset progressive MND with clinical and pathological features reminiscent of ALS [15, 69]. $VEGF^{\delta/\delta}$ mice show reduced lower basal levels of VEGF and are unable to regulate VEGF levels in response to tissue hypoxia. It has been hypothesized that reduced perfusion of neurons results in chronic ischemia and/or the loss of VEGF-mediated neuroprotection, and that the impaired response may lead to the degeneration of nerve cells [75, 148]. An inability to regulate levels of VEGF has been reported in mutant *SOD1* mice, and the progeny of crosses of $VEGF^{\delta/\delta}$ mice and mutant *SOD1* mice do not survive as well as mice with mutant *SOD1* alone. Finally, it has been reported that *VEGF* may act as a modifier gene for cases of human ALS [15].

It is not known why mutations in SOD1, an ubiquitously expressed protein, cause selective dysfunction and death of motor neurons. Mutations in *SOD1* do not have obvious impacts on many other cells in CNS or cells in other organs other than possibly skeletal muscle. The question of whether the toxicity of mutant SOD1 is cell autonomous has been tested by selectively expressing mutant *SOD1* in different cell types. Neither restricted expression of mutant *SOD1* to neurons or to astrocytes appears to be sufficient to produce disease [17]. Complex experiments in chimeric mice (with different mixtures of wild-type or mutant SOD1-expressing cells) disclose that motor neuron toxicity can be influenced by expression of wild-type or mutant SOD1 in glial cells. For example,

in the chimeric mice, normal motor neurons develop abnormalities interpreted to be related to the presence of mutant SOD1 in non-neuronal cells. Moreover, when motor neurons accumulate mutant SOD1, the presence of a higher proportion of wild-type SOD1 in non-neuronal cells reduces the incidence of motor neuron death and prolong survival in the chimeric mice. These observations suggest that disease may be result of different populations of cells acting in concert.

It has been hypothesized that individuals with ALS have problems with excessive glutamate at synapses and excitotoxicity related to reduced levels of the glutamate transporter GLT1 (EAAT2) [25, 48, 49]. Using a screen of more than 1000 FDA-approved compounds, investigators discovered that β-lactam antibiotics can stimulate expression of GLT1, via increased transcription of the *GLT1* gene. When animals were treated with the β-lactam ceftriaxone, the levels of GLT1 in the brain increased, as did the biochemical and functional activity parameters of this transporter [24]. Significantly, this antibiotic, which is neuroprotective *in vitro* for models of ischemia and neuronal degeneration, delayed the pathology and increased survival in mutant *SOD1* mice [24].

Mouse models offer opportunities for discovering disease mechanisms and for testing novel treatment strategies. Riluzole is the major drug approved for therapy in human ALS [3, 25]. However, the benefits are modest. Investigators are examining other ways to ameliorate excitotoxicity, possibly by influencing the levels or activity of GLT-1 [24]. Trials with growth factors were truncated because of evidence of complications [25]. Trials of antiaggregation strategies, novel ways to deliver trophic factors, inhibitors of apoptosis, treatment with gene therapy and the use of engineered cells or stem cells are some of the therapeutic approaches for the future [1, 3, 17, 18, 21, 25, 30, 57, 63, 70, 111, 126, 147, 149, 150].

The identification of genes mutated or deleted in the inherited forms of neurodegenerative diseases, including MND, has allowed investigators to create genetically engineered models of these illnesses [1, 3, 17, 18, 21, 30, 57, 63, 70, 111, 126, 147, 149, 150]. Investigations of these mouse models have greatly increased our understanding of the molecular mechanisms of neurodegenerative diseases critical for identifying potential therapeutic targets. These models are of great value for testing a variety of novel therapeutic approaches. Investigations of the pathogeneses of the neurodegenerative diseases, have made spectacular progress over the past few years. We anticipate that knowledge of disease mechanisms will lead to novel treatments for these devastating illnesses.

ACKNOWLEDGMENTS

The authors wish to thank the many colleagues who have worked at JHMI, Drs. David Borchelt, Jack Griffin, Paul Hoffman, Linda Cork, Fiona Laird, Don Cleveland, Michael Lee and Jeffery Rothstein, as well as those at other institutions for their contributions to some of the original work cited in this review and for their helpful discussions. Aspects of this work were supported by grants from the U.S. Public Health Service (5R01NS 1058017, RO1 NS40014, RO1 NS34100) as well as the ALS Association and the Packard Center for ALS.

TAUOPATHIES — OUTLOOK 757

Current concepts of neurodegenerative diseases began to develop a century ago, when the German school of neuropathologists described the salient histological features of what we now know to be the most common of these diseases. In 1907, Alois Alzheimer described the neuritic plaques and neurofibrillary lesions in the disease that was subsequently named after him. In 1911, Alzheimer also described Pick bodies as the characteristic neuropathological lesion of Pick's disease, a form of frontotemporal dementia. In 1912, Friedrich Lewy described the inclusions characteristic of Parkinson's disease, the so-called 'Lewy bodies'. In the 1960s, electron microscopy was used to show that the above inclusions are made of abnormal filaments. At the time, the identification of these lesions was instrumental in establishing the various diseases as discrete entities. However, this work did not establish a role for the lesions in the etiology and pathogenesis of neurodegeneration. Over the past 20 years, a direct correspondence between the formation of the neuropathological lesions and the degenerative process has emerged.

The discovery of this direct relationship was made possible by the merging of two independent lines of research.

Basic Neurochemistry: Molecular, Cellular and Medical Aspects
0-12-088397-X

On the one hand, the biochemical study of the neuropathological lesions led to the identification of their main molecular components. On the other hand, the study of rare, familial forms of Alzheimer's disease, frontotemporal dementia and Parkinson's disease led to the identification of gene defects that cause inherited variants of the different diseases. Remarkably, in these cases, the defective genes have been found to encode or increase the expression of the main components of the neuropathological lesions. It has therefore been established that the basis of the familial forms of these diseases is a toxic property conferred by mutations in the proteins that make up the filamentous lesions. A corollary of this insight is that a similar toxic property may also underlie the much more common, sporadic forms of the diseases.

Lewy bodies, neurofibrillary lesions and Pick bodies are intracellular filamentous inclusions. It is now well established that Lewy bodies are made of the protein α-synuclein and both neurofibrillary lesions and Pick bodies of the microtubule-associated protein tau. Mutations in the α-synuclein gene or an increase in its copy number cause autosomal-dominantly inherited forms of Parkinson's disease and dementia with Lewy bodies. Mutations in the tau gene cause a familial form of frontotemporal dementia. Here we review the evidence implicating α-synuclein and tau in these inherited and a number of sporadic neurodegenerative diseases. Collectively, α-synucleinopathies and tauopathies account for the vast majority of cases of late-onset neurodegenerative disease (Tables 45-1 and 45-2).

TABLE 45-1 α-Synuclein diseases

Idiopathic Parkinson's disease
Dementia with Lewy bodies
Pure autonomic failure
REM sleep behavior disorder
Lewy body dysphagia
Incidental Lewy body disease
Inherited Lewy body diseases
Multiple system atrophy

Alzheimer's disease
Down's syndrome
Progressive supranuclear palsy
Corticobasal degeneration
Pick's disease
Argyrophilic grain disease
Tangle-only dementia
Amyotrophic lateral sclerosis/parkinsonism–dementia complex
Guadeloupean parkinsonism
Frontotemporal dementia and parkinsonism linked to chromosome 17
Postencephalitic parkinsonism
Subacute sclerosing panencephalitis
Niemann–Pick disease type C
Familial British dementia

THE SYNUCLEIN FAMILY

The human synuclein family consists of three members. α-Synuclein, β-synuclein and γ-synuclein range from 127 to 140 amino acids in length, and are 55–62% identical in sequence, with a similar domain organization [1] (Fig. 45-1). They are encoded by three genes located on chromosomes 4q23 (α-synuclein), 5q35 (β-synuclein) and 10q21 (γ-synuclein). More than half of each protein is taken up by six or seven imperfect 11-amino acid repeats with the consensus sequence KTKEGV. This positively charged region is followed by a hydrophobic middle region and a negatively charged region that makes up the carboxy-terminal third of each synuclein. Synucleins are abundant, nervous-system-enriched proteins whose physiological functions are only incompletely understood.

By immunohistochemistry, α- and β-synucleins are concentrated in nerve terminals, with little staining of somata and dendrites. Ultrastructurally, they are found in close proximity to synaptic vesicles. In contrast, γ-synuclein is present throughout nerve cells in many brain regions. In rat, α-synuclein is most abundant throughout telencephalon and diencephalon, with lower levels in more caudal regions. β-Synuclein is distributed fairly evenly throughout the central nervous system, whereas γ-synuclein is most abundant in midbrain, pons and spinal cord, with much lower levels in forebrain areas.

Synucleins are natively unfolded proteins. They have little ordered secondary structure and have only been identified in vertebrates. Experimental studies have shown that α-synuclein can bind to lipid membranes through its amino-terminal repeats, indicating that it may be a lipid-binding protein [2]. It adopts structures rich in α-helical character upon binding to synthetic lipid membranes containing acidic phospholipids. This conformation is taken up by amino acids 1–98, with residues 99–140 being unstructured. In cell lines and primary neurons treated with high fatty acid concentrations, α-synuclein was found to accumulate on phospholipid monolayers surrounding triglyceride-rich droplets. β-Synuclein bound in a similar way, but γ-synuclein failed to bind lipid droplets and remained cytosolic. Accordingly, α-synuclein has been found to bind fatty acids *in vitro*, albeit with a lower affinity than physiological fatty-acid-binding proteins. Both α- and β-synucleins inhibit phospholipase D, suggesting that they may regulate vesicular transport processes. Only little is known about posttranslational modifications of α-synuclein. Serine and tyrosine phosphorylation has been observed in transfected cells, but it remains to be established whether it plays a physiological role in brain. Like some other natively unfolded proteins,

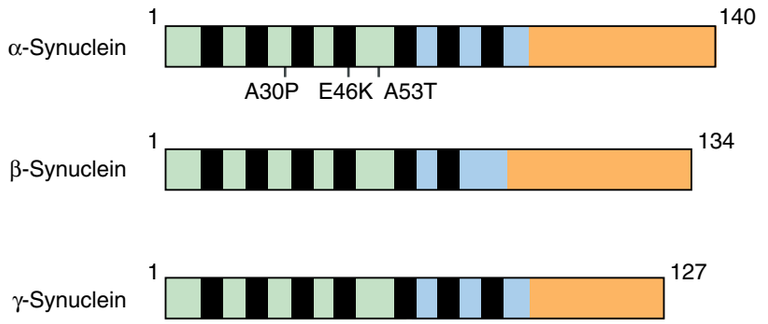

FIGURE 45-1 Schematic diagram of the three human synucleins, which range from 127 to 140 amino acids in length. The amino-terminal repeats are shown as *black* bars. Positively charged regions are indicated in *green*, hydrophobic regions in *blue* and negatively charged regions in *red*. The three known missense mutations (*A30P*, *E46K* and *A53T*) in α-synuclein are shown.

α-synuclein can be degraded by the proteasome in the absence of polyubiquitination.

Inactivation of the α-synuclein gene by homologous recombination results in mice that appear largely normal [3]. Analysis of mice lacking γ-synuclein has similarly failed to reveal any gross abnormalities [4]. In hippocampal slices from mice without α-synuclein, the replenishment of docked vesicles by reserve pool vesicles was slower than in slices from control mice. It suggests a physiological role for α-synuclein in the mobilization of synaptic vesicles.

PARKINSON'S DISEASE AND OTHER LEWY BODY DISEASES

α-Synuclein mutations cause familial Parkinson's disease. In 1990, an autosomal-dominantly inherited form of Parkinson's disease was described in an Italian–American family (the Contursi kindred). It was the first familial form of disease in which Lewy bodies had been shown to be present. In 1997, a missense mutation (A53T) in the α-synuclein gene was identified as the cause of disease in the Contursi kindred [5]. Subsequently, a second mutation (A30P) was identified in a German family with Parkinson's disease. More recently, a third mutation (E46K) was described in a Spanish family with Parkinson's disease and dementia with Lewy bodies. All three missense mutations are located in the repeat region of α-synuclein (Fig. 45-1 and Fig. 45-2).

In addition to changes in the primary structure of α-synuclein, the overexpression of wild-type α-synuclein has been identified as the likely cause of inherited Parkinson's disease–dementia [6] (Fig. 45-2). Thus, duplication or triplication of a 1.6–2.0 Mb region of the long arm of chromosome 4 is responsible for familial forms of disease with abundant and widespread Lewy body pathology. The α-synuclein gene is one of an estimated 17 genes located in this region. Moreover, polymorphic variations in the 5′ non-coding region of the α-synuclein gene have been found to be associated with idiopathic Parkinson's disease in some, but not all, studies. They probably influence the level of α-synuclein expression. Variation in expression levels of α-synuclein may be an important risk factor for the development of Lewy body diseases.

Lewy body filaments are made of α-synuclein. Shortly after the identification of the genetic defect responsible for Parkinson's disease in the Contursi kindred, Lewy bodies and Lewy neurites in the substantia nigra from patients with sporadic Parkinson's disease were shown to be strongly immunoreactive for α-synuclein [7] (Fig. 45-3). Subsequently, Lewy body filaments were found to be

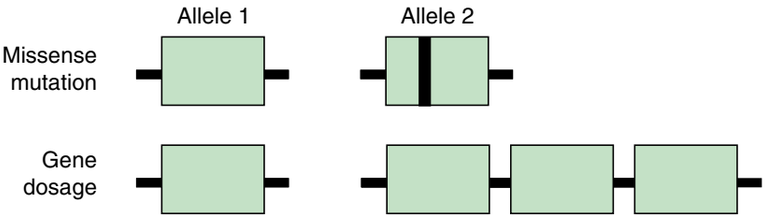

FIGURE 45-2 Missense mutations in the α-synuclein gene and multiplication of the chromosomal region containing the α-synuclein gene cause autosomal-dominantly inherited forms of Parkinson's disease and dementia with Lewy bodies. The α-synuclein gene is shown schematically in *green*.

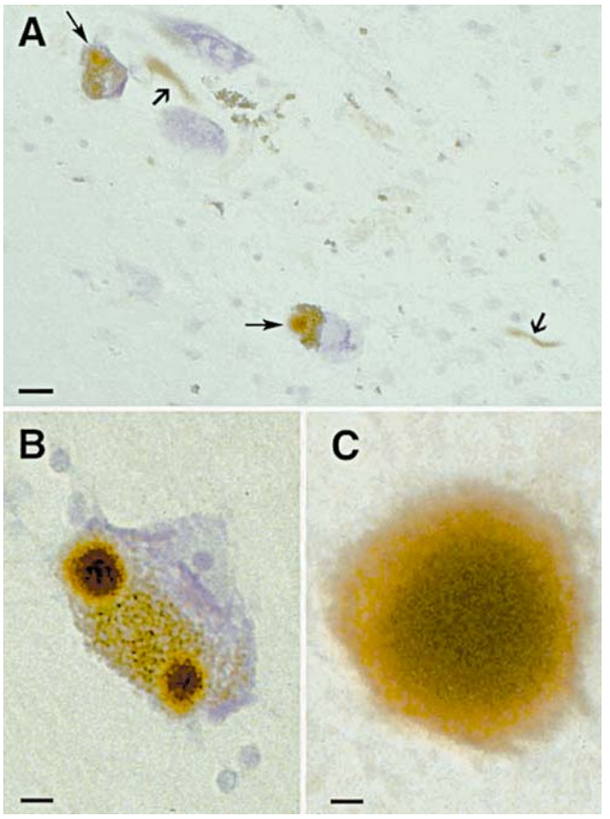

FIGURE 45-3 Substantia nigra from patients with Parkinson's disease immunostained for α-synuclein. (**A**) Two pigmented nerve cells, each containing an α-synuclein-positive Lewy body. Lewy neurites (small arrows) are also immunopositive. Scale bar: 20 μm. (**B**) Pigmented nerve cell with two α-synuclein-positive Lewy bodies. Scale bar: 8 μm. (**C**) α-Synuclein-positive extracellular Lewy body. Scale bar: 4 μm.

decorated by antibodies directed against α-synuclein. The same was true of the Lewy body pathology of dementia with Lewy bodies. This common form of dementia is characterized by large numbers of Lewy bodies and neurites in cortical brain areas, in addition to the substantia nigra.

Filaments associated with Parkinson's disease and dementia with Lewy bodies are unbranched, with a length of 200–600 nm and a width of 5–10 nm. Full-length α-synuclein is present, with its amino- and carboxy-termini being exposed on the filament surface. The core of the filament extends over a stretch of about 70 amino acids that overlaps almost entirely with the lipid-binding region of α-synuclein. Of the three human synucleins, only α-synuclein is associated with the filamentous inclusions of Lewy body diseases.

Prior to this work, ubiquitin staining had been the most sensitive marker of Lewy body pathology. By double-labeling, the number of α-synuclein-positive structures was greater than that stained for ubiquitin, suggesting that the ubiquitination of α-synuclein occurs after assembly. Phosphorylation and nitration are two additional post-translational modifications of filamentous α-synuclein. Phosphorylation at S129 has been documented in Lewy bodies and Lewy neurites and it has been suggested that this may trigger filament assembly [8]. However, it remains to be determined whether phosphorylation at S129 occurs before or after filament assembly in the human brain. Nitration of filamentous α-synuclein was found using antibodies specific for nitrated tyrosine residues. As for ubiquitin, staining for nitrotyrosine was less extensive than staining for α-synuclein, suggesting that nitration of α-synuclein occurs after its assembly into filaments.

Lewy body pathology is also the defining feature of several other, rarer diseases, such as Lewy body dysphagia and pure autonomic failure. In these diseases, Lewy bodies and neurites are largely limited to the enteric and peripheral nervous systems. In Parkinson's disease, Lewy body pathology is also present in the enteric and autonomic nervous systems.

Incidental Lewy body disease describes the presence of small numbers of Lewy bodies and Lewy neurites in the absence of clinical symptoms. It is observed in 5–10% of the general population over the age of 60, and is believed to represent a preclinical form of Lewy body disease. In cases with incidental Lewy body disease, the first α-synuclein-positive structures in the brain form in the dorsal motor nucleus of the glossopharyngeal and vagus nerves, the intermediate reticular zone, the olfactory bulb and the anterior olfactory nucleus [9]. The pathology ascends from vulnerable regions in the medulla oblongata to the pontine tegmentum, midbrain, basal forebrain and cerebral cortex. α-Synuclein deposits may form even earlier in the enteric and peripheral nervous systems, suggesting that Lewy body diseases may originate outside the central nervous system. The first deposits develop in the form of Lewy neurites, suggesting that the filamentous assembly of α-synuclein in axons may precede assembly in cell bodies and dendrites. Incidental Lewy body disease may be at one end of the spectrum of Lewy body diseases, with dementia with Lewy bodies at the other end, and with Lewy body dysphagia, pure autonomic failure and Parkinson's disease in-between. These findings underscore the fact that there is more to Parkinson's disease than the mere degeneration of dopaminergic nerve cells in the substantia nigra.

The Lewy body pathology that is sometimes associated with other neurodegenerative diseases, such as Alzheimer's disease, the parkinsonism–dementia complex of Guam, and neurodegeneration with brain iron accumulation type I, has also been shown to be immunoreactive for α-synuclein. However, it is not an invariable feature of these diseases. Nevertheless, understanding why α-synuclein pathology develops in a proportion of cases in these apparently unrelated conditions, may shed light on the mechanisms operating in diseases defined by the presence of Lewy body pathology.

MULTIPLE SYSTEM ATROPHY

Filamentous α-synuclein deposits characterize this atypical parkinsonian disorder. Lewy body pathology is not generally observed. Instead, glial cytoplasmic inclusions, which consist of filamentous aggregates, are the defining neuropathological feature of multiple system atrophy (Fig. 45-4). They are found mostly in the cytoplasm and, to a lesser extent, the nucleus of oligodendrocytes. Inclusions are also observed in the cytoplasm and nucleus of some nerve cells, and in neuropil threads. The principal brain regions affected are the substantia nigra, striatum, locus coeruleus, pontine nuclei, inferior olives, cerebellum and spinal cord. Typically, nerve cell loss and gliosis are observed. The formation of glial cytoplasmic inclusions may be the primary lesion that will eventually compromise nerve cell function and viability.

Glial cytoplasmic inclusions are strongly immunoreactive for α-synuclein and filaments isolated from the brains of patients with multiple system atrophy are labeled by α-synuclein antibodies [10]. As in dementia with Lewy bodies, assembled α-synuclein is nitrated and phosphorylated at S129, and the number of α-synuclein-positive structures exceeds that stained by anti-ubiquitin antibodies, confirming that the accumulation of α-synuclein precedes ubiquitination. Filament morphologies and their staining characteristics were found to be similar to those of filaments extracted from the brains of patients with Parkinson's disease and dementia with Lewy bodies.

This work revealed an unexpected molecular link between multiple system atrophy and Lewy body diseases. The main difference is that in multiple system atrophy most of the α-synuclein pathology is found in glial cells, whereas in Lewy body diseases most of the pathology is present in nerve cells.

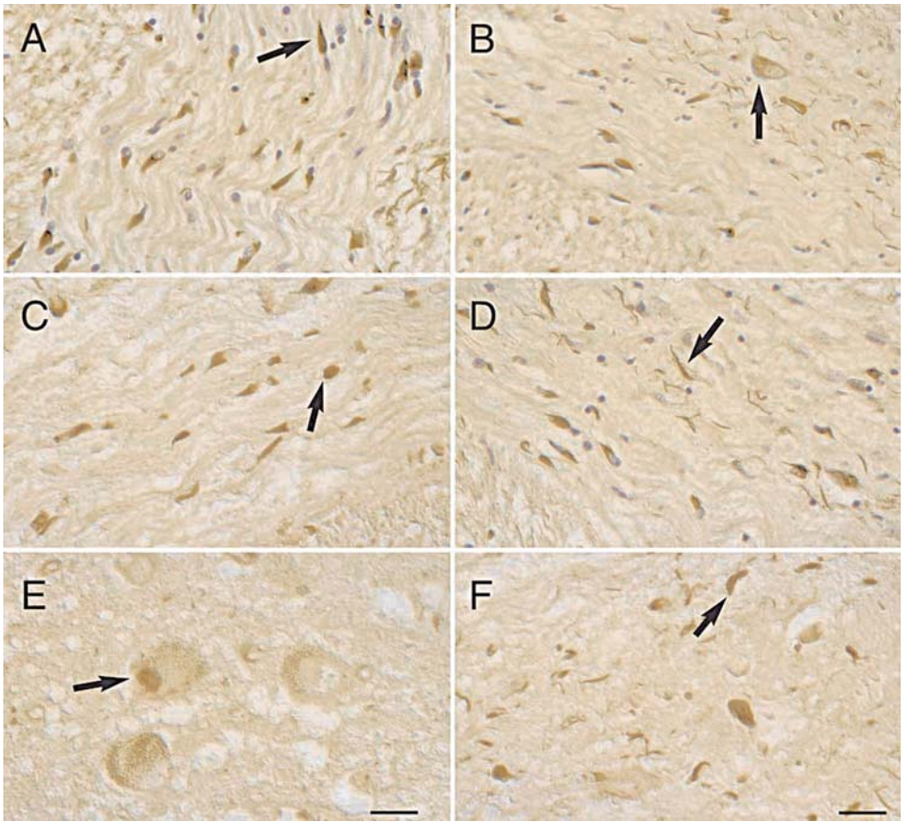

FIGURE 45-4 Brain tissue from patients with multiple system atrophy immunostained for α-synuclein. (**A–D**) α-Synuclein-immunoreactive oligodendrocytes and nerve cells in white matter of pons (**A**, **B**, **D**) and cerebellum (**C**) identified with antibodies recognizing the amino-terminal (**A**, **C**) or the carboxy-terminal (**B**, **D**) region of α-synuclein. (**E**, **F**), α-Synuclein-immunoreactive oligodendrocytes and nerve cells in gray matter of pons (**E**) and frontal cortex (**F**) identified with antibodies recognizing the amino-terminal (**E**) or the carboxy-terminal (**F**) region of α-synuclein. Arrows identify representative examples of each of the characteristic lesions stained for α-synuclein: cytoplasmic oligodendroglial inclusions (**A**, **F**), cytoplasmic nerve cell inclusions (**B**), nuclear oligodendroglial inclusions (**C**), neuropil threads (**D**), and nuclear nerve cell inclusion (**E**). Scale bars: (**E**), 33 μm; (**A–D**, **F**), 50 μm (in **F**).

SYNTHETIC α-SYNUCLEIN FILAMENTS

Recombinant α-synuclein assembles into filaments. They have many of the morphological and ultrastructural characteristics of disease filaments [11, 12] (Fig. 45-5). Assembly is a nucleation-dependent process that occurs through its amino-terminal repeats. The carboxy-terminal region, in contrast, is inhibitory. Assembly is accompanied by the transition from random coil to a β-pleated sheet. By electron diffraction, α-synuclein filaments show a conformation characteristic of amyloid fibers. Under the conditions of these experiments, β- and γ-synucleins failed to assemble, consistent with their absence from the filamentous lesions of the human diseases. When incubated with α-synuclein, β- and γ-synucleins inhibit the fibrillation of α-synuclein, suggesting that they may indirectly influence the pathogenesis of Lewy body diseases and multiple system atrophy.

The E46K and A53T mutations increase the rate of assembly of α-synuclein, indicating that this may be their primary effect. The mechanism of action of the A30P mutation is less clear. One study reported that it causes the accumulation of oligomeric, nonfibrillar α-synuclein, implying that this may be a toxic species. Mutation A30P reduces the binding of α-synuclein to rat brain vesicles, whereas mutation E46K increases lipid binding. Mutation A53T has no significant effect on lipid binding. Many factors have been shown to influence the rate and/or extent of α-synuclein assembly *in vitro*. They include nitration, oxidation, dopamine cytochrome C, polyamines, some pesticides, several di- and trivalent cations and sulfated glycosaminoglycans. Similarly, tau protein has been shown to promote the *in vitro* assembly of α-synuclein. However, the relevance, if any, of these factors for the transition from soluble to filamentous α-synuclein in nerve cells in the brain remains to be established.

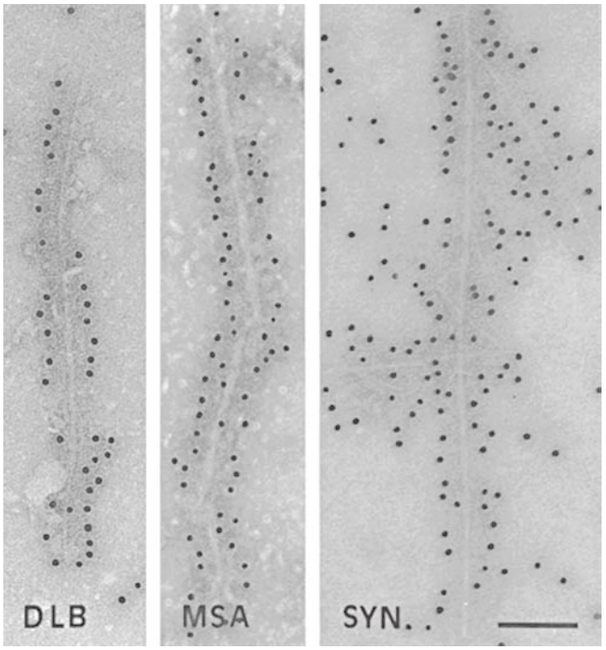

FIGURE 45-5 Filaments extracted from the brains of patients with dementia with Lewy bodies (*DLB*) and multiple system atrophy (*MSA*) or assembled from bacterially expressed human α-synuclein (*SYN*) were decorated by an anti-α-synuclein antibody. The gold particles conjugated to the second antibody appear as black dots. Scale bar: 100 nm.

ANIMAL MODELS OF HUMAN α-SYNUCLEINOPATHIES

Rodents and primates. Mice expressing wild-type and mutant human α-synuclein in nerve cells or glial cells have been shown to develop numerous α-synuclein-immunoreactive cell bodies and processes. However, filament formation and nerve cell loss were a less-consistent feature. One study documented the presence of α-synuclein filaments in brain and spinal cord of mice transgenic for A53T α-synuclein [13]. The formation of inclusions correlated with the appearance of a severe movement disorder [13, 14], suggesting a possible cause-and-effect relationship. A minority of inclusions was ubiquitin-immunoreactive. Signs of Wallerian degeneration were in evidence in ventral roots, but motor neuron numbers were not reduced. A major difference with Parkinson's disease was the absence of significant pathology in dopaminergic nerve cells of the substantia nigra.

Viral vector-mediated gene transfer differs from standard transgenic approaches by being targeted to a defined region of the central nervous system, and by being inducible at any point during the life of the animal. Adeno-associated and lentiviral vectors were used to express human wild-type and mutant α-synuclein in rodent and primate substantia nigra. Lewy-body-like inclusions formed, and a significant proportion of nerve cells degenerated [15]. In the rat, about a quarter of animals were impaired in spontaneous and drug-induced motor behavior.

A neurotoxin model of α-synuclein pathology has been developed in the rat through the chronic administration of the pesticide rotenone, a high-affinity inhibitor of complex I [16]. The rats developed a progressive degeneration of nigrostriatal neurons and Lewy-body-like inclusions that were immunoreactive for α-synuclein and ubiquitin. Behaviorally, they showed bradykinesia, postural instability and resting tremor. Under these conditions, the inhibition of complex I was only partial, indicating that a bioenergetic defect with ATP depletion was probably not involved. Instead, oxidative damage might have played a role, since partial inhibition of complex I by rotenone stimulates the production of reactive oxygen species. It would therefore seem that oxidative stress can lead to the assembly of α-synuclein into filaments.

Flies, worms and yeasts. One of the first reports to describe the overexpression of human α-synuclein made use of *D. melanogaster*, an organism without synucleins [17]. Expression in nerve cells resulted in the formation of filamentous Lewy-body-like inclusions and an age-dependent loss of some dopaminergic nerve cells. The inclusions were α-synuclein- and ubiquitin-positive. The ensuing locomotor defect was reversed by L-DOPA and dopamine agonists. Chaperones modulated these effects. Thus, co-expression of heat shock proteins reduced the toxicity of α-synuclein, whereas a reduction in endogenous chaperones exacerbated nerve cell loss. Overexpression of wild-type and mutant human α-synuclein in *C. elegans* resulted in dopaminergic nerve cell loss and motor deficits, but in the apparent absence of α-synuclein filaments. When expressed in the yeast *S. cerevisiae*, human wild-type and A53T α-synucleins were localized at the plasma membrane, whereas the A30P mutant had a cytosolic distribution, consistent with lipid binding *in vitro* [18]. At 2-fold higher expression levels, inclusions formed and growth was arrested, reminiscent of the gene dosage effects observed in cases of inherited Parkinson's disease–dementia. A genome-wide screen to identify genetic enhancers of α-synuclein toxicity identified genes involved in lipid metabolism and vesicle-mediated transport as the predominant functional class.

α-SYNUCLEINOPATHIES—OUTLOOK

The new work has established that a neurodegenerative pathway leading from soluble to insoluble, filamentous α-synuclein is central to Lewy body diseases and multiple system atrophy. The development of experimental models of α-synucleinopathies has opened the way to the identification of the detailed mechanisms by which the formation of inclusions causes disease. These model systems have also made it possible to identify disease modifiers that may well lead to the development of the first mechanism-based therapies for these diseases. At a conceptual level, it will be important to understand whether α-synuclein has a role to play in disorders, such as autosomal–recessive juvenile forms of parkinsonism caused by mutations in the *Parkin*, *DJ-1* and *PINK-1* genes, or whether there are entirely separate mechanisms by which the dopaminergic nerve cells of the substantia nigra degenerate in Parkinson's disease and in inherited disorders with parkinsonism.

TAU ISOFORMS AND THEIR INTERACTIONS WITH MICROTUBULES

Tau is a microtubule-binding protein that is believed to be important for the assembly and stabilization of microtubules [19]. In nerve cells, tau is normally found in axons, but in the tauopathies it is redistributed to the cell body and dendrites.

Six tau isoforms are expressed in adult human brain. They are produced from a single gene on chromosome 17q21 by alternative mRNA splicing [20] (Fig. 45-6) and differ from one another by the presence or absence of a 29- or 58-amino-acid insert in the amino-terminal half of the protein and by the inclusion, or not, of a 31-amino-acid repeat, encoded by exon 10 of tau in the carboxy-terminal half of the protein. The exclusion of exon 10 leads to the production of three isoforms, each containing three repeats, and its inclusion leads to a further three isoforms, each containing four repeats. The repeats constitute the microtubule-binding region of tau protein, with four-repeat tau being better at promoting microtubule assembly than tau with three repeats. In normal adult human brain, there are similar levels of three-repeat and four-repeat isoforms. In developing human brain, only the shortest tau isoform (three repeats and no amino-terminal inserts) is expressed. In the peripheral nervous system, inclusion of exon 4A in the amino-terminal half results in the expression of high-molecular-weight proteins called *big tau*.

Repeats similar to those in tau are present in the otherwise structurally unrelated high-molecular-weight microtubule-associated proteins MAP2 and MAP4. Repeat sequences are conserved during evolution. Thus, the genomes of *C. elegans* and *D. melanogaster* each encode one protein with tau-like repeats. In all vertebrate species examined, tau is expressed as multiple isoforms that are generated by alternative mRNA splicing. Isoform ratios, however, are not conserved between species. For instance, isoforms with three, four or five repeats are expressed in adult chicken brain, whereas adult rodents only express isoforms with four repeats.

The tau molecule can be subdivided into an amino-terminal domain that projects from the microtubule surface and the carboxy-terminal microtubule-binding domain. Recent structural work has begun to shed light on the way that tau protein interacts with microtubules. When bound to taxol-stabilized microtubules, tau was found to localize along the outer ridges of the microtubule protofilaments. A different conclusion was reached when tau was bound to microtubules in the absence of taxol. The tau repeats were now found to bind to the inner surface of the microtubule, close to the taxol-binding site on β-tubulin. Taxol binds to a site on β-tubulin, where α-tubulin has a conserved extra loop of eight amino acids. Interestingly, this extended loop has significant sequence homology with the tau repeats. Since tubulin cannot have evolved to bind taxol, this work may answer the question of what type of natural substrate binds to this pocket in β-tubulin. In this model, part of the proline-rich region of tau must provide the link between the amino-terminal projection domain on the outside of the microtubule and the repeat motifs on the inside surface. It could thread through one of the holes between protofilaments.

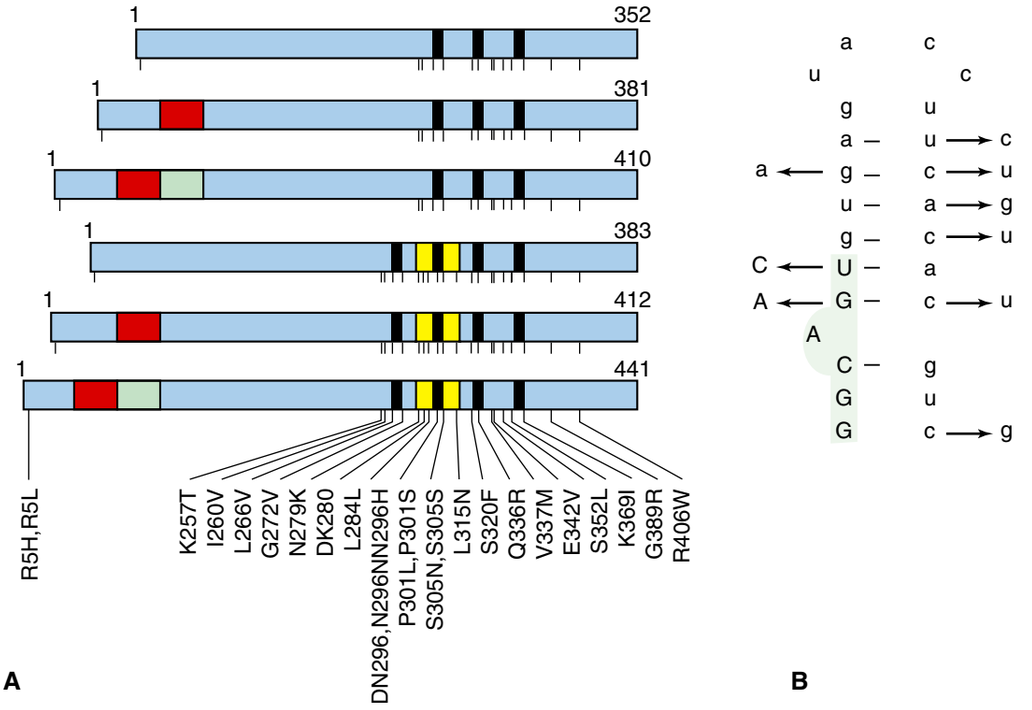

FIGURE 45-6 Mutations in the tau gene in frontotemporal dementia and parkinsonism linked to chromosome 17 (FTDP-17). (**A**) Schematic diagram of the six tau isoforms (352 to 441 amino acids) that are expressed in adult human brain, with mutations in the coding region indicated using the numbering of the 441 amino acid isoform. Twenty missense mutations, two deletion mutations and three silent mutations are shown. The six tau isoforms are produced by alternative mRNA splicing from a single gene. They differ by the presence or absence of three inserts, shown in *red* (encoded by exon 2), *green* (encoded by exon 3) and *yellow* (encoded by exon 10), respectively. (**B**) Stem-loop structure in the pre-mRNA at the boundary between exon 10 and the intron following exon 10. Nine mutations are shown, two of which (*S305N* and *S305S*) are located in exon 10. Exon sequences are shown against a *green background* in *CAPITALS*, with intron sequences being shown in *lower-case* letters.

Tau is a phosphoprotein. Phosphorylation negatively regulates the ability of tau to interact with microtubules [21]. Many of the phosphorylated sites are serine/threonine–prolines, 17 of which are present in the longest human brain tau isoform. Most of these sites flank the microtubule-binding repeats. Proline-directed protein kinases, such as glycogen synthase kinase-3 (GSK3), cyclin-dependent kinase 5 (CDK5), mitogen-activated protein (MAP) kinase and stress-activated protein (SAP) kinases, phosphorylate these sites *in vitro*. Moreover, lithium chloride treatment has been shown to reduce the level of tau phosphorylation in rodent brain, suggesting that GSK3 is a physiological tau kinase. In addition, other sites in tau are phosphorylated *in vitro* by cyclic AMP-dependent protein kinase (PKA), calcium/calmodulin-dependent protein kinase II (CamKII) and microtubule-affinity-regulating kinase (MARK). Some of these sites are located within the repeat region. Protein phosphatase 2A (PP2A) is the major phosphatase activity in brain towards tau phosphorylated by proline-directed and other kinases.

Phosphorylation is developmentally regulated, such that in fetal brain, tau is more heavily phosphorylated than in adult brain. An increase in tau phosphorylation reminiscent of that present during development was observed in the brain of the hibernating ground squirrel. In adult mouse brain, hyperphosphorylation of tau was present following cold-water stress and starvation. Inhibition of PP2A activity rather than activation of protein kinases appeared to be responsible for this hyperphosphorylation of tau.

Inactivation of the tau gene by homologous recombination results in mice that are largely normal [22], indicating that tau is a nonessential protein. This may reflect functional redundancy. Thus, mice doubly deficient in tau and the microtubule-associated protein MAP1B exhibit nervous system defects that are more severe than those in the MAP1B single knockout line.

TAU AND ALZHEIMER'S DISEASE

Abundant neuritic plaques and neurofibrillary lesions define Alzheimer's disease. Plaques are extracellular deposits made of the fibrillar β-amyloid peptide. The paired helical filament (PHF) makes up the bulk of the intraneuronal neurofibrillary pathology of Alzheimer's disease, with the straight filament (SF) being a minority species.

The paired helical filament is made of tau protein. By the early 1990s, it was clear that tau protein is the major component of PHFs and SFs and that all six brain isoforms are present, each full-length and hyperphosphorylated [23–27]. The microtubule-binding repeat region of tau forms the core of the filament, with the amino- and carboxy-terminal regions forming a fuzzy coat around the filament. PHFs and SFs have a cross-β structure characteristic of amyloid fibers. Following assembly, tau is truncated at the amino-terminus, which is necessary for its subsequent ubiquitination. Following the death of neurofibrillary tangle-bearing cells, the pathological material stays around in the extracellular space, in the form of so-called 'ghost tangles' that consist largely of the ubiquitinated repeat region of tau. It thus appears that in Alzheimer's disease the ubiquitination of tau is a late, secondary event.

Filamentous tau is hyperphosphorylated. This is an early event that appears to precede filament assembly. It also renders tau unable to interact with microtubules. Much effort has gone into the mapping of phosphorylation sites and the identification of candidate protein kinases and phosphatases. For sites that are also phosphorylated in normal brain tau, a higher proportion of tau molecules is phosphorylated in filamentous tau. In addition, filamentous tau is phosphorylated at more serine and threonine residues than tau from normal adult brain. Phosphorylation-dependent anti-tau antibodies were instrumental for the study of many phosphorylation sites. In particular, phosphorylation of S214 and S422 was found to be specific for assembled tau.

The mechanisms underlying filament formation in neurons are still unclear, but it is possible that hyperphosphorylation disengages tau from microtubules, thereby increasing the pool of unbound tau, which may be more resistant to degradation and more prone to aggregate than microtubule-bound tau. It suggests that an increased ability of pathological tau to interact with microtubules may be beneficial. This could in principle be achieved by protein kinase inhibitors and/or activation of PP2A. Organic osmolytes, such as trimethylamine *N*-oxide (TMAO) and betaine have been shown to restore the ability of phosphorylated tau to interact with microtubules, probably through a conformational change in tubulin and/or tau. Similarly, the prolyl isomerase Pin1, which binds to phosphothreonine 231 in tau, has been reported to restore the ability of phosphorylated tau to interact with microtubules and to facilitate its dephosphorylation by PP2A.

The development of the neurofibrillary pathology is not random. It follows a stereotyped pattern with regard to affected nerve cell types, cellular layers and brain regions, with little inter-individual variation. This has been used to define six neuropathological stages of Alzheimer's disease [28]. The very first nerve cells in the brain to develop neurofibrillary lesions are located in pre-α layer of the transentorhinal region, thus defining stage I. Stage II shows a more severe involvement of this region, as well as a mild involvement of the pre-α layer of the entorhinal cortex. Patients with this pathology are cognitively unimpaired, indicating that stages I and II may represent clinically silent stages of Alzheimer's disease. Mild impairment of cognitive function becomes apparent in stages III and IV. Stage III is characterized by severe neurofibrillary lesions in the pre-α layers of both entorhinal and transentorhinal regions. During stages III and IV, mild changes are also present in layer I of Ammon's horn of the hippocampus and in a number of subcortical nuclei, such as the basal forebrain magnocellular nuclei and the anterodorsal thalamic nucleus. The major feature of stages V and VI is the massive development of neurofibrillary pathology in isocortical association areas. They meet the criteria for a neuropathological diagnosis of Alzheimer's disease and are found in patients who were severely demented.

The stereotyped nature of the spatial and temporal development of neurofibrillary pathology contrasts with the development of Aβ deposits. They show a density and distribution that are subject to great individual variation. In general, the first Aβ deposits occur in isocortical areas of the frontal, temporal and occipital lobes, where they tend to precede neurofibrillary deposits. This contrasts with the entorhinal and hippocampal regions, where Aβ deposits appear later than the neurofibrillary pathology. These findings are difficult to explain by the amyloid cascade hypothesis for the pathogenesis of Alzheimer's disease, which proposes that the deposition and fibrillization of Aβ peptides to form extracellular plaques is the central event that causes formation of the neurofibrillary pathology and nerve cell loss.

SPORADIC TAUOPATHIES

They include progressive supranuclear palsy, corticobasal degeneration and Pick's disease. Evidence in support of a role for tau protein in neurodegeneration has been provided through the study of these diseases, which exhibit abundant filamentous tau inclusions, in the absence of extracellular amyloid deposits. Clinically, progressive supranuclear palsy leads to supranuclear gaze palsy and postural instability. Neuropathologically, atrophy of the basal ganglia, subthalamus and brainstem are much in evidence. Like progressive supranuclear palsy, corticobasal degeneration is an atypical parkinsonian disorder. It leads to depigmentation of the substantia nigra and an asymmetric frontoparietal atrophy. Pick's disease, by contrast, is a variant of frontotemporal dementia that is characterized by a frontotemporal lobar and limbic atrophy. Other tauopathies include argyrophilic grain disease, parkinsonism–dementia complex of Guam and Guadeloupean parkinsonism.

Filament morphologies differ to some extent between these diseases, but hyperphosphorylation of tau is a common feature. The phosphorylated sites are similar to those seen in Alzheimer's disease. However, the isoform composition in the filaments varies. Like Alzheimer's disease, parkinsonism–dementia complex of Guam is characterized by the presence of all six tau isoforms. In Pick's disease filaments, a relative preponderance of tau isoforms with three repeats is commonly observed. By contrast, filaments from progressive supranuclear palsy, corticobasal degeneration, argyrophilic grain disease and Guadeloupean parkinsonism consist almost entirely of tau isoforms with four repeats. This correlates with the presence of tau inclusions, not only in nerve cells, but also in glial cells, chiefly astrocytes and oligodendrocytes.

MUTATIONS CAUSING TAUOPATHY—THE FTDP-17 SYNDROMES

Frontotemporal dementias occur as familial forms and, more commonly, as sporadic diseases. They are characterized by a remarkably circumscribed atrophy of the frontal and temporal lobes of the cerebral cortex, often with additional, subcortical changes. In 1994, an autosomal-dominantly inherited form of frontotemporal dementia with parkinsonism was linked to chromosome 17q21.2. Subsequently, other forms of frontotemporal dementia were linked to this region, resulting in the denomination 'frontotemporal dementia and parkinsonism linked to chromosome 17' (FTDP-17) for this class of disease. All cases of FTDP-17 have so far shown a filamentous pathology made of hyperphosphorylated tau protein (Fig. 45-7). In 1998, mutations in tau were reported in FTDP-17 patients [29–31]. Since then, more than 30 different mutations have been described in over 80 families with FTDP-17 (Fig. 45-6).

Mutations are either exonic or intronic. Missense, deletion and silent mutations are found in the coding region, with intronic mutations being located close to the splice-donor site of the intron following the alternatively

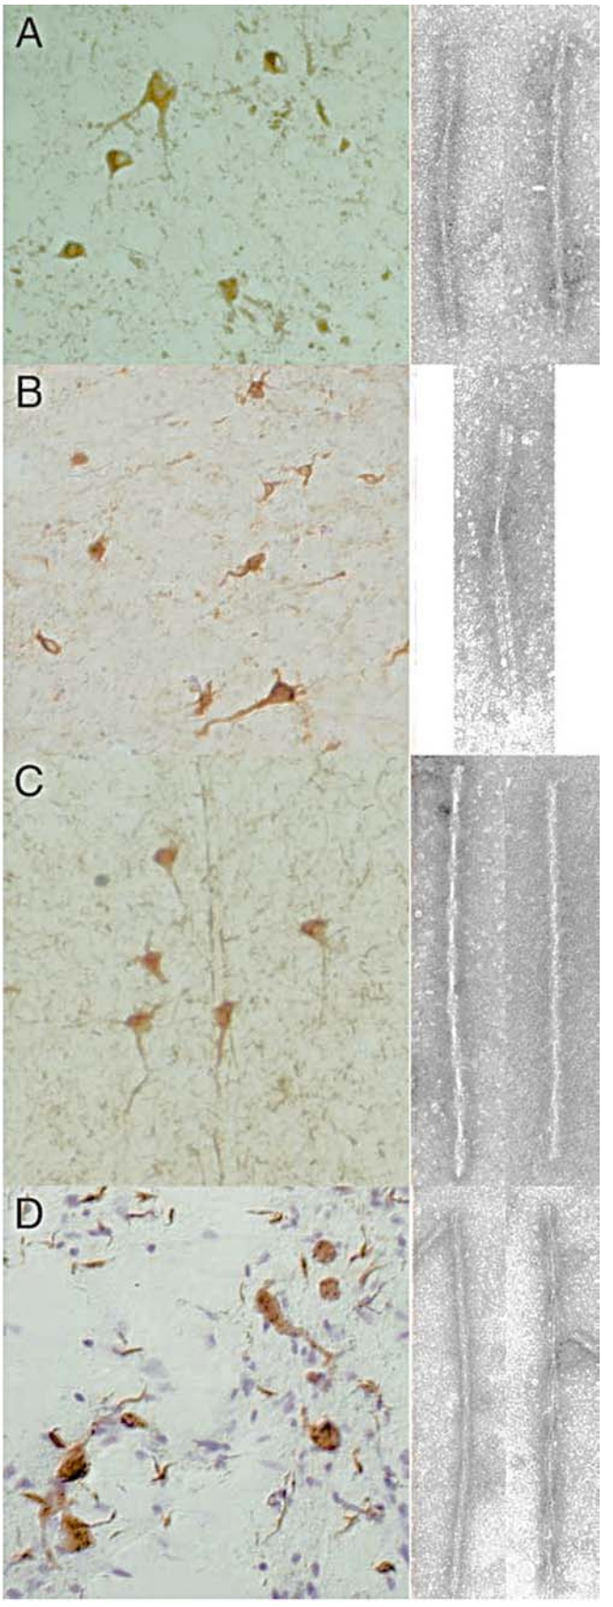

FIGURE 45-7 Pathologies of FTDP-17, as revealed by immunohistochemistry for hyperphosphorylated tau protein and the morphologies of isolated tau filaments. (**A**) The P301L mutation in exon 10 gives rise to a neuronal and glial tau pathology. Filaments consist of narrow twisted ribbons (*left*) as the majority species and rope-like filaments (*right*) as the minority species. (**B**) Mutations in the intron following exon 10 give rise to a neuronal and glial tau pathology. Filaments consist of wide twisted ribbons. (**C**) The V337M mutation in exon 12 gives rise to a neuronal tau pathology. Filaments consist of paired helical filaments (*left*) and straight filaments (*right*), like the tau filaments of Alzheimer's disease. (**D**) The G389R mutation in exon 13 gives rise to a neuronal tau pathology. Filaments consist of straight filaments (*left*) as the majority species and twisted filaments (*right*) as the minority species. The tau pathology resembles that of Pick's disease.

spliced exon 10. Functionally, they fall into two largely nonoverlapping categories — those whose primary effect is at the protein level, and those that influence the alternative splicing of tau pre-mRNA. Most missense mutations reduce the ability of tau protein to interact with microtubules. A number of mutations may cause FTDP-17, at least in part, by promoting the aggregation of tau protein. Most of these mutations lead to the formation of nerve cell inclusions that consist of filaments made of all six brain tau isoforms. Mutations P301L and P301S in exon 10 are exceptions, since they lead to the formation of neuronal and glial inclusions that are made of tau isoforms with four repeats.

The intronic mutations and most coding region mutations in exon 10 increase the splicing of exon 10, thus changing the ratio between three- and four-repeat tau isoforms, resulting in the overproduction of four-repeat tau. This leads to the formation of filaments made of four-repeat tau in both nerve cells and glial cells. Approximately half of the known tau mutations have their primary effect at the RNA level. They affect splicing enhancer or silencer sequences in exon 10 or destabilize a stem-loop structure located at the boundary between exon 10 and the intron that follows it. Thus, to a considerable degree, FTDP-17 is a disease of the alternative mRNA splicing of exon 10 of the tau gene. It follows that a correct ratio of three-repeat to four-repeat tau isoforms is essential for preventing neurodegeneration and dementia in midlife.

RELEVANCE FOR THE SPORADIC TAUOPATHIES

The study of FTDP-17 has established that dysfunction or misregulation of tau protein can cause neurodegeneration and dementia. It follows that tau protein is probably also of central importance in the pathogenesis of diseases, such as Alzheimer's disease, progressive supranuclear palsy, corticobasal degeneration and Pick's disease. This is further underlined by the fact that the aforementioned diseases are partially or completely phenocopied by cases of FTDP-17.

Eight missense mutations in tau have been shown to give rise to a clinical and neuropathological phenotype that is closely related to Pick's disease. The finding that overproduction of four-repeat tau causes disease and leads to the assembly of tau isoforms with only four repeats in nerve cells and glial cells may shed light on the pathogenesis of progressive supranuclear palsy and corticobasal degeneration. Both diseases are characterized by a neuronal and glial tau pathology, with the filaments comprising only four-repeat tau. An association between progressive supranuclear palsy and a dinucleotide repeat polymorphism in the intron between exons 9 and 10 of tau has been described [32]. The alleles at this locus carry 11–15 repeats. The A0 allele, with 11 repeats, has a frequency of over 90% in patients with progressive supranuclear palsy, and about 70% in controls. Subsequently, two common tau haplotypes that differ at the nucleotide level, but not at the level of the protein coding sequence, were identified. Homozygosity of the more common allele H1 predisposes to progressive supranuclear palsy and corticobasal degeneration, but not to Alzheimer's disease or Pick's disease. This work strongly suggests that dysfunction of tau protein is of central importance in progressive supranuclear palsy and corticobasal degeneration, as it is in Pick's disease. Surprisingly, homozygosity for the tau H1 haplotype is also associated with an increased risk of Parkinson's disease, a disorder without significant tau pathology. It remains to be seen whether this association can be explained by the interactions between tau and α-synuclein that have been observed *in vitro*.

SYNTHETIC TAU FILAMENTS

Initial experiments had shown that PHF-like filaments can be assembled *in vitro* from bacterially expressed fragments of tau comprising three repeats. These experiments lent strong support to the view that the repeat region of tau is the only component necessary for the morphological appearance of the PHF. However, they failed to provide insight into filament formation *in vivo*, because the tau filaments were obtained only with truncated tau under nonphysiological conditions. This contrasts with PHFs from Alzheimer's disease brain, which consist of full-length tau protein.

Sulfated glycosaminoglycans induce the assembly of full-length tau into filaments. Assembly of individual three-repeat tau isoforms gave filaments with a typical paired helical filament-like morphology, when incubated with heparin or heparan sulfate, whereas assembly of individual four-repeat tau isoforms gave filaments with a straight appearance [33, 34]. Paired helical-like filaments were decorated by antibodies directed against the amino- and carboxy-termini of tau, but not by an antibody against the microtubule-binding region. A short amino acid sequence (VQIVYK) in the third microtubule-binding repeat of tau has been reported to be essential for heparin-induced filament assembly [35]. Further work revealed that RNA and fatty acids, such as aracidonic acid, can also induce the bulk assembly of full-length recombinant tau into filaments. More recently, α-synuclein was reported to induce tau filament formation, suggesting a direct mechanistic link between the two proteins. These findings were obtained using bacterially expressed, nonphosphorylated tau. The relevance of phosphorylation in these experiments is unclear, with reported effects ranging from no influence to stimulatory and inhibitory effects.

ANIMAL MODELS OF HUMAN TAUOPATHIES

Rodents. Mice expressing wild-type and mutant human tau in nerve cells or glial cells have been found to develop numerous tau-immunoreactive cell bodies and processes. Abundant filaments made of hyperphosphorylated tau protein and neurodegeneration were present in some lines expressing single isoforms of mutant human tau protein [36, 37] (Fig. 45-8 and Fig. 45-9). Hyperphosphorylation of tau appeared to precede filament assembly and an increase in the phosphorylation of soluble tau resulted in increased filament formation [37], suggesting that phosphorylation of tau can drive filament assembly. The presence of extracellular β-amyloid deposits was reported to promote tau filament formation. Filamentous tau deposits were also observed in a mouse line expressing all six wild-type human brain tau isoforms in the absence of endogenous mouse tau [38]. The observed imbalance between levels of three- and four-repeat isoforms may have caused tau pathology in this line. In rodent brain, adeno-associated virus-mediated expression of human P301L tau protein

led to the formation of filamentous deposits made of hyperphosphorylated tau protein.

Loss of function of the prolyl isomerase Pin1 by homologous recombination has been reported to lead to the formation of abundant filaments made of hyperphosphorylated mouse tau and neurodegeneration [39].

Flies and worms. Expression of wild-type and mutant human tau proteins in nerve cells of *D. melanogaster* and *C. elegans* led to a reduced lifespan and the loss of nerve cells, in the apparent absence of tau filaments [40, 41]. Phosphorylation of tau was more extensive in the fly than in the worm. In *Drosophila*, phosphorylation of S262 and S356 in tau by PAR-1 kinase, the fly homologue of MARK, appeared to be necessary for the subsequent phosphorylation at other sites, indicating the existence of a hierarchical and temporally ordered phosphorylation process. Co-expression of human tau with the fly homolog of GSK3-β resulted in accelerated neurodegeneration and the formation of tau-immunoreactive inclusions. In contrast to what has been described in FTDP-17 and mouse models of tauopathies, tau-induced neurodegeneration involved programmed cell death. Taken together, it appears that conformationally altered, nonfilamentous human tau protein is neurotoxic in invertebrates.

TAUOPATHIES — OUTLOOK

It is now well established that a neurodegenerative pathway leading from soluble to insoluble, filamentous tau protein is central to the neurodegenerative process in the human tauopathies. The availability of animal models that exhibit the essential molecular and cellular features

of the human diseases has opened the way to a detailed understanding of the neurodegenerative process and the identification of genetic and pharmacological modifiers. In particular, it will be possible to test the relevance of the hyperphosphorylation of tau. Specific protein kinase inhibitors are widely believed to represent a major class of the drugs of the future. Such compounds may well constitute the first mechanism-based therapies for the human tauopathies.

Neurotransmitters and Disorders of the Basal Ganglia

Thomas Wichmann

Mahlon R. DeLong

ANATOMY AND PHYSIOLOGY OF THE BASAL GANGLIA 761
The basal ganglia are parts of larger circuits 761
Multiple neurotransmitter systems are found in the basal ganglia 762
The basal ganglia are involved in multiple functions 765

DISORDERS THAT INVOLVE BASAL GANGLIA DYSFUNCTION 766
Parkinson's disease (PD) is a hypokinetic movement disorder 766
Huntington's disease is a hyperkinetic movement disorder 771
Wilson's disease is a disease of copper accumulation 773
Dystonia is characterized by sustained muscle contractions 775
Many drugs and toxins induce movement disorders 776

The basal ganglia are a group of subcortical nuclei which are components of modular circuits involved in many cortical functions. They have received considerable attention from basic scientists and clinicians alike because of their prominent involvement in movement disorders, a spectrum of diseases including disorders which are characterized by poverty of movement (hypokinetic disorders), as well as disorders characterized by excess movement (hyperkinetic disorders). It has become clear in recent years that most basal ganglia disorders are not restricted to motor disturbances, but involve cognitive and emotional features as well.

ANATOMY AND PHYSIOLOGY OF THE BASAL GANGLIA

The basal ganglia are parts of larger circuits. The basal ganglia are a group of related subcortical nuclei, including the neostriatum (caudate nucleus and putamen), the ventral striatum, the external and internal segments of the globus pallidus (GPe, GPi, respectively), the subthalamic nucleus (STN), and the substantia nigra pars reticulata and compacta (SNr, SNc, respectively). These structures are components of circuits involving portions of the cerebral cortex, thalamus and brain stem (Fig. 46-1, left). Based on their cortical site of origin, these loops can be grouped into skeletomotor, oculomotor, associative, and limbic based on their connectivity and presumed functions.

Due to its relevance to an understanding of movement disorders, the 'motor circuit' has received the most attention. This circuit is centered on somatosensory, motor and premotor cortices, which send projections to the 'motor portions' of striatum. The connections between the striatum and the basal ganglia output nuclei (GPi/SNr) are organized into direct and indirect pathways [1]. The direct pathway is a monosynaptic projection between striatum and GPi/SNr, while the indirect pathway is a polysynaptic connection that involves intercalated neurons in GPe and STN. Some striatofugal neurons may also collateralize more extensively, reaching GPe, GPi/SNr and STN. Other 'motor'-related inputs to striatum and STN arise from the intralaminar thalamic nuclei, i.e. the centromedian and parafascicular nuclei (CM/Pf).

Basal ganglia output is directed from GPi and SNr to the thalamus. Movement-related basal ganglia output projects from GPi almost exclusively to the ventrolateral nucleus of the thalamus which, in turn, projects to the primary motor cortex, the cortical supplementary motor area, and other premotor cortical areas. Movement-related output from SNr terminates in the ventral anterior and in

the mediodorsal nuclei of thalamus, which, in turn, innervate premotor (and prefrontal) regions of the frontal lobe. GPi and SNr also project to noncholinergic neurons in the pedunculopontine nucleus (PPN) in the brainstem, and to CM/Pf. Additional projections from the SNr reach the superior colliculus. This connection may play a critical role in the control of saccades and orienting head and eye movements.

Multiple neurotransmitter systems are found in the basal ganglia. The basal ganglia contain most of the classical neurotransmitters, and many additional neuropeptides which may participate in the modulation of information transfer in the basal ganglia. Some of the more important systems will be discussed in the following paragraphs.

GABA is the predominant intrinsic transmitter of the basal ganglia. Inhibition and disinhibition are considered to be the most important modes of information transfer in the basal ganglia. Ninety-five percent of all neurons in the striatum are GABAergic medium spiny neurons. These neurons are the striatal output neurons. The medium spiny neurons which give rise to the direct pathway also contain substance P or dynorphin as a co-transmitter, while those striatal output neurons that give rise to the indirect pathway contain enkephalin as a co-transmitter. Most striatal interneurons, as well as neurons in GPe, GPi and SNr are also GABAergic. Because striatal and GPe efferents end in the SNr, GPe and GPi, GABA is found in high concentrations in these nuclei (Fig. 46-2).

Two GABA receptor subtypes have been characterized as GABA-A and GABA-B (see Ch. 16). GABA-A receptors are inhibitory ionotropic receptors (forming a chloride channel whose conductance is rapidly modulated by ligand binding), found mostly on postsynaptic membranes. GABA-B receptors are pre- and postsynaptic G-protein-coupled receptors.

Glutamate. Inputs to the basal ganglia, from the cortex, PPN and CM/Pf, as well as intrinsic projections from the STN, utilize glutamate as a neurotransmitter (Fig. 46-1).

Glutamate receptors are grouped into ionotropic and metabotropic receptors (mGluRs). Ionotropic glutamate receptors, i.e. NMDA, kainate and AMPA receptors, are present throughout the basal ganglia, and are mostly located postsynaptically. They are the primary receptors used for information transfer from cortex to striatum and STN, and STN output. In the striatum, these receptors may be involved learning, through long-term potentiation (LTP) and long term depression (LTD). In addition to the ionotropic glutamate receptors, there are eight different types of metabotropic glutamate receptors (mGluR1–8) which are classified into three groups based on their genetic and pharmacologic properties. These receptors are present at striatal and extrastriatal sites (Ch. 15).

Values are presented as mean ± SEM, *, $p<0.05$. $Thal_a$, anterior thalamus; $Thal_{vl}$, ventral lateral thalamus; $Thal_{va}$, ventral anterior thalamus; $Thal_m$, medial thalamus; $Thal_{cm}$, centromedial thalamus; *STN*, subthalamic nucleus; GP_L, lateral globus pallidus; GP_M, medial globus pallidus; N_{acc}, nucleus accumbens; *Put*, anterior putamen; CN_{cau}, tail of caudate nucleus; CN_{corp}, body of the caudate nucleus; CN_{cap}, head of caudate nucleus; SN_r, substantia nigra pars reticulata; SN_c, substantia nigra pars compacta; G_{pre}, precentral gyrus; G_{post}, postcentral gyrus; *fr Ctx*, frontal cortex.

Acetylcholine. Most of the acetylcholine in the basal ganglia is found in the striatum, as the neurotransmitter of the large spiny interneurons, which account for about 3% of all striatal neurons. Both muscarinic and nicotinic cholinergic receptors are found in the striatum. Postsynaptic muscarinic receptors may inhibit transmitter release from glutamatergic terminals, whereas nicotinic receptor activation may enhance transmitter release.

Dopamine. Dopamine is present in high concentration in the striatum (Fig. 46-2), in densely aborized terminals of projections that originate in the SNc. Neurons in the

ventral tegmental area contribute to the dopamine supply to the ventral striatum as well as the cortex. Perhaps the most important site of extrastriatal dopamine release is the SNr, where the transmitter is released from dendrites of SNc neurons.

Dopamine synthesis in dopaminergic terminals (Fig. 46-3) requires tyrosine hydroxylase (TH) which, in the presence of iron and tetrahydropteridine, oxidizes tyrosine to 3,4-dihydroxyphenylalanine (levodopa, l-DOPA). Levodopa is decarboxylated to dopamine by aromatic amino acid decarboxylase (AADC), an enzyme which requires pyridoxyl phosphate as a coenzyme (see also in Ch. 12).

Dopamine acts on G-protein-coupled receptors belonging to the D1-family of receptors (so-called 'D1-like receptors', or D1LRs, comprised of D1- and D5-receptors), and the D2-family of receptors ('D2-like receptors', or D2LRs comprised of D2-, D3- and D4-receptors). D1LRs stimulate adenylate cyclase activity and, possibly, also phosphoinositide hydrolysis, while D2LRs reduce adenylate cyclase activity. In the striatum, D1LRs are predominately associated with medium spiny neurons of the direct pathway, while D2LRs have been found as autoreceptors on dopaminergic terminals, as heteroreceptors on cholinergic interneurons, and on indirect pathway neurons. In the SNr, D1LRs are located on terminals of the direct pathway projection, while D2LRs appear to function as autoreceptors.

The actions of dopamine are terminated through presynaptic reuptake. Some of the dopamine is then re-incorporated into vesicles, while the rest is metabolized (Fig. 46-3). Dopamine and its O-methyl derivative are both subject to the action of monoamine oxidase (MAO), a flavoprotein present in the outer membrane of the mitochondria. MAO exists in two forms: MAO type A (MAO-A) is predominantly present in catecholaminergic neurons, while MAO type B (MAO-B) predominates in serotonin-containing neurons and in astrocytes. Products of the MAO reaction include the aldehyde corresponding to the amine substrate, hydrogen peroxide and ammonia. Most of the aldehyde undergoes further dehydrogenation to form, in the case of dopamine, DOPAC, which is the substrate for catechol-O-methyltransferase (COMT), to generate homovanillic acid (HVA).

The basal ganglia are involved in multiple functions. The motor circuit of the basal ganglia has received the greatest attention from researchers, because of its perceived involvement in movement disorders. Due to the modular organization of the basal ganglia, many of the findings discussed below for the motor circuit may be applicable to the other circuits as well.

A basic understanding of basal ganglia function can be gleaned from considering the effects of cortical activation on the excitatory (glutamatergic) and inhibitory (GABAergic) projections in the basal ganglia (Fig. 46-1). Voluntary movements appear to be initiated at the cortical level of the motor circuit. Activation of the direct pathway neurons in the striatum will inhibit basal ganglia output neurons, which, in turn, will disinhibit related thalamocortical neurons, and ultimately facilitate movement. In contrast, activation of indirect pathway neurons in the striatum will lead to increased basal ganglia output and, presumably, to suppression of movement. Because most GPi neurons

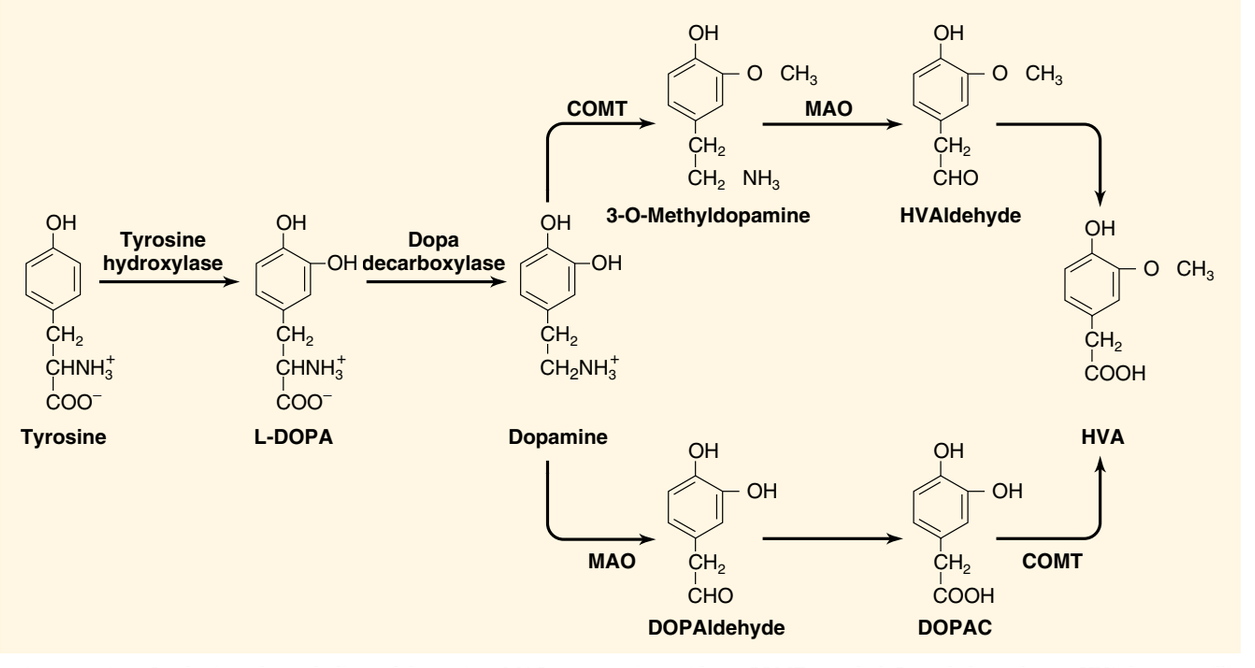

FIGURE 46-3 Synthesis and metabolism of dopamine. *MAO*, monoamine oxidase; *COMT*, catechol-O-methyltransferase; *HVA*, homovanillic acid; *DOPAC*, 3,4-dihydroxyphenylacetic acid.

increase their firing rate with movement, the main role of the basal ganglia motor circuit is to inhibit and to stabilize the activity of the thalamocortical neurons.

The basal ganglia motor circuit may also play a role in the control of the amplitude or velocity of movement, and may focus movements, allowing intended movements to proceed while suppressing other movements (see discussion in ref. [2]). The basal ganglia have also been implicated in self-initiated (internally generated) movements, procedural learning, and movement sequencing [e.g. ref. 3]. Learning may involve modifications of the strength of glutamatergic synapses onto medium spiny neurons in the striatum through dopamine–glutamate interactions which are timed to salient external events. It is thought that phasic dopamine release in the striatum signals whether or not reward-related phenomena in the environment are present. These dopamine signals may affect LTP and LTD at corticostriatal synapses (see also in Ch. 53).

DISORDERS THAT INVOLVE BASAL GANGLIA DYSFUNCTION

Parkinson's disease (PD) is a hypokinetic movement disorder. PD manifests itself in most patients with prominent movement abnormalities, including a 4–6 Hz tremor at rest, muscular rigidity, slowness of movement (bradykinesia), and a failure of movement initiation (akinesia). Many of these signs are initially unilateral, but later progress to involve the opposite side. Depression occurs in up to 50% of patients. PD is a progressive disorder. Non-motor signs and symptoms, such as autonomic insufficiency and disturbances of gait and posture, develop later, along with psychiatric, cognitive and sleep complications.

Between 5 and 24 new cases per 100,000 persons are reported each year (20.5 per 100,000 in the USA). The prevalence of the disease is 57–371 patients per 100,000 persons worldwide (300 per 100,000 for the USA and Canada). With the increasing age of the population, a four-fold increase in the prevalence of PD is expected over the next 20 years. The age of onset differs substantially between patients (average age of onset is 62 years). Young-onset patients commonly suffer from one of the genetic forms of the disease (see below). Males appear to be affected slightly more frequently than females.

Several environmental factors may have an impact on the occurrence of the disease. Living in rural areas, drinking well water, pesticide exposure and head trauma are associated with an increased risk of developing PD, while caffeine consumption, taking nonsteroidal anti-inflammatory medications, and smoking appear to protect from it.

Pathology. The earliest degenerative changes in PD occur in structures outside of the basal ganglia [4], in the olfactory bulb, and brainstem structures, such as the dorsal motor nucleus of vagus, the locus coeruleus and the raphe nuclei. The prominent motor abnormalities in PD appear to arise in large part from degeneration of neurons in the SNc, with resulting loss of dopamine in the basal ganglia. Degenerating dopaminergic cells leave characteristic eosinophilic inclusions in their wake, the so-called Lewy neurites and Lewy bodies. Recent studies have also shown that low-level inflammatory responses may accompany the loss of dopaminergic cells, and may contribute to cell death. Recent imaging studies have suggested that the striatal dopamine concentrations steeply decline, preceding the onset of clinical Parkinsonism, which is usually only seen when more than 70% of striatal dopamine is lost.

In early phases of PD, dopamine loss affects primarily the posterior putamen (the striatal motor area) but later spreads to involve other nigrostriatal regions. In later stages, more widespread dopamine loss and neuronal degeneration in non-dopaminergic systems, such as the locus coeruleus and the raphe nuclei may account for some of the non-motor aspects of PD.

Etiology. Most cases of PD are 'sporadic' and appear to arise from a combination of genetic predisposition and environmental or toxic factors. Purely genetic forms of the disease probably account for less than 10% of cases, but the risk of family members of an affected patient to develop PD is significantly increased even in 'sporadic' PD.

Cells in the SNc are among the most vulnerable cells in the brain due to a relative deficiency in neuroprotective factors, such as the antioxidant glutathione, and because they are exposed to a high level of oxidative stress due to the presence of dopaminergic metabolism and other factors. This environment may render these neurons particularly vulnerable to nonspecific genetic or environmental insults that, by themselves, would not be sufficient to induce cell death in other cells. Interestingly, many of the factors known to be involved in neuronal damage in PD appear to interfere with the cell's ability to eliminate damaged or mutated proteins through the ubiquitin proteasome system [5].

One example of a genetically determined form of parkinsonism, which results directly in degeneration of dopaminergic neurons are mutations of the gene coding for α-synuclein [6]. α-Synuclein is a normal brain protein that is found in synaptic vesicles and membranes along axons and terminals in many neurons. Mutated α-synuclein tends to aggregate as the result of a conformational change of the molecule from its usual unfolded, soluble form into a β-pleated sheath. Aggregated α-synuclein is a prominent component of Lewy bodies.

The mechanism by which the mutated α-synuclein produces toxicity is not clear, but it is thought that the mutated protein forms fibrils, and the oligomers or fibrils formed from this protein exert a toxic gain of function leading to disruption of proteasomal function and the formation of Lewy bodies. However, as evidenced by the

discovery of several families in which triplication of the α-synuclein gene leads to four normal copies of the gene associated with autosomal dominant Parkinson's disease, overproduction of normal α-synuclein may also be causal. Dopaminergic neurons appear particularly sensitive to toxic effects of excessive or fibrillar α-synuclein. Other mutated genes possibly associated with autosomal dominant parkinsonism include UCHL1, NR4A2 and synphilin-1(see ref. [7]).

A number of genetic mutations have been associated with autosomal recessive juvenile Parkinson's disease (ARJP). The most frequent of these is the gene *PARK2*, coding for parkin, which accounts for about half of patients with juvenile onset, below the age of 40. Parkin is an E3 ubiquitin ligase that is necessary for ubiquitination of proteins for their subsequent degradation in proteasomes. Loss of function of the mutated enzyme may result in failure to direct its substrates to the proteasome system for degradation. Of interest is that Lewy bodies are not found in these subjects. Other genes for which there is strong evidence of linkage to ARJP include *DJ-1* (*PARK7*) and *PINK1* (*PARK6*). *DJ-1*, which is translocated to the outer mitochondrial membrane under conditions of oxidative stress, is therefore thought to have a role in protecting neurons from oxidative stress. *PINK1* encodes a putative serine/threonine protein kinase. *PINK1* is located primarily in mitochondria, and evidence from cell cultures suggests that *PINK1* protects cells from stress-induced mitochondrial damage and apoptosis. At present, there is no postmortem neuropathologic information regarding the *DJ-1* and *PINK1* mutations. While the mentioned genetic mutations all lead to parkinsonism with progressive bradykinesia, rigidity, tremor and levodopa-responsiveness, the biochemical processes are different. Key questions related to all of the genetic mutations found are:

- Why is the dopaminergic system so uniquely vulnerable to their effects?
- What are the relationships of Lewy body formation, proteasomal protein degradation and mitochondrial dysfunction to parkinsonism (see ref. [8] for a detailed review).

Animal models. A variety of models can be employed to disturb dopaminergic functions in the brain. Attempts to model parkinsonism by treatment with the dopamine-depleting agent reserpine, or with dopamine-receptor blockers are fairly nonspecific. Models produced by dopaminergic toxins are more faithful reproductions of the pathology of the human disorder. In rodents, injections of 6-hydroxydopamine (6-OHDA) into the SNc, or treatment with mitochondrial complex I inhibitors, such as rotenone or 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) can be used to cause oxidative damage to dopaminergic neurons. Genetic models of parkinsonism in rodents are based on overexpression of α-synuclein. In primates, the most faithful model in terms of behavioral and pathological changes is produced by treatment with MPTP.

Pathophysiology. Metabolic and microelectrode recordings of neuronal activity in animal models of parkinsonism show that spontaneous neuronal discharge in STN, GPi and SNr is increased, as, compared with normal controls, neuronal discharge in GPe is decreased (Fig. 46-4). These results and the known anatomical connections between the different structures have been used to develop a circuit model of parkinsonism (Fig. 46-1, right) in which striatal dopamine loss results in reduced activity in the direct pathway, resulting in disinhibition of the basal ganglia output nuclei. Striatal dopamine loss also results in greater inhibition of GPe, and, consequently, in disinhibition of STN and GPi. The net effect of these changes is an increase in basal ganglia output to brainstem and thalamus, which has been postulated to result in greater inhibition of thalamocortical neurons, and to reduce the responsiveness of brainstem and cortical mechanisms involved in motor control. Brainstem areas such as the PPN may also be involved in the development of akinesia, most likely secondary to excessive inhibitory input from GPi and SNr.

Additional support for this model comes from inactivation studies. For instance, GPi or STN lesions have been shown to reverse all the cardinal motor signs of parkinsonism, presumably by reducing the inhibitory basal ganglia output. However, some results of these lesion studies are not compatible with the simple model shown in Figure 46-1. Thus, surprisingly, lesions of the 'basal ganglia-receiving' areas of the thalamus (VA/VL) do not lead to parkinsonism, and lesions of GPi do not result in excessive movement. These findings suggest that the simple model shown in Figure 46-1(right) may not accurately describe all of the circuit abnormalities in PD.

Other factors that may play a role include specific alterations in information processing, alterations in discharge patterns and changes in the level of synchronization between neighboring neurons. All of these changes have been documented in parkinsonian patients undergoing electrophysiologic recording in the context of neurosurgical treatment of PD, or in animal models of the disorder, but it remains unclear whether there is a causal relationship between any of these abnormalities and the appearance of specific parkinsonian motor signs. The strongest argument for this can be made in the case of a relationship of tremor to the frequently seen oscillatory burst activity in the basal ganglia. However, it has proved to be extremely difficult to identify a single source of oscillatory discharge in the basal ganglia–thalamocortical circuitry.

Within the basal ganglia, abnormal oscillations may arise from changes in local pacemaker networks, through loss of extrastriatal dopamine, or as the result of intrinsic membrane properties of basal ganglia neurons. Increased inhibitory basal ganglia output may also act to induce

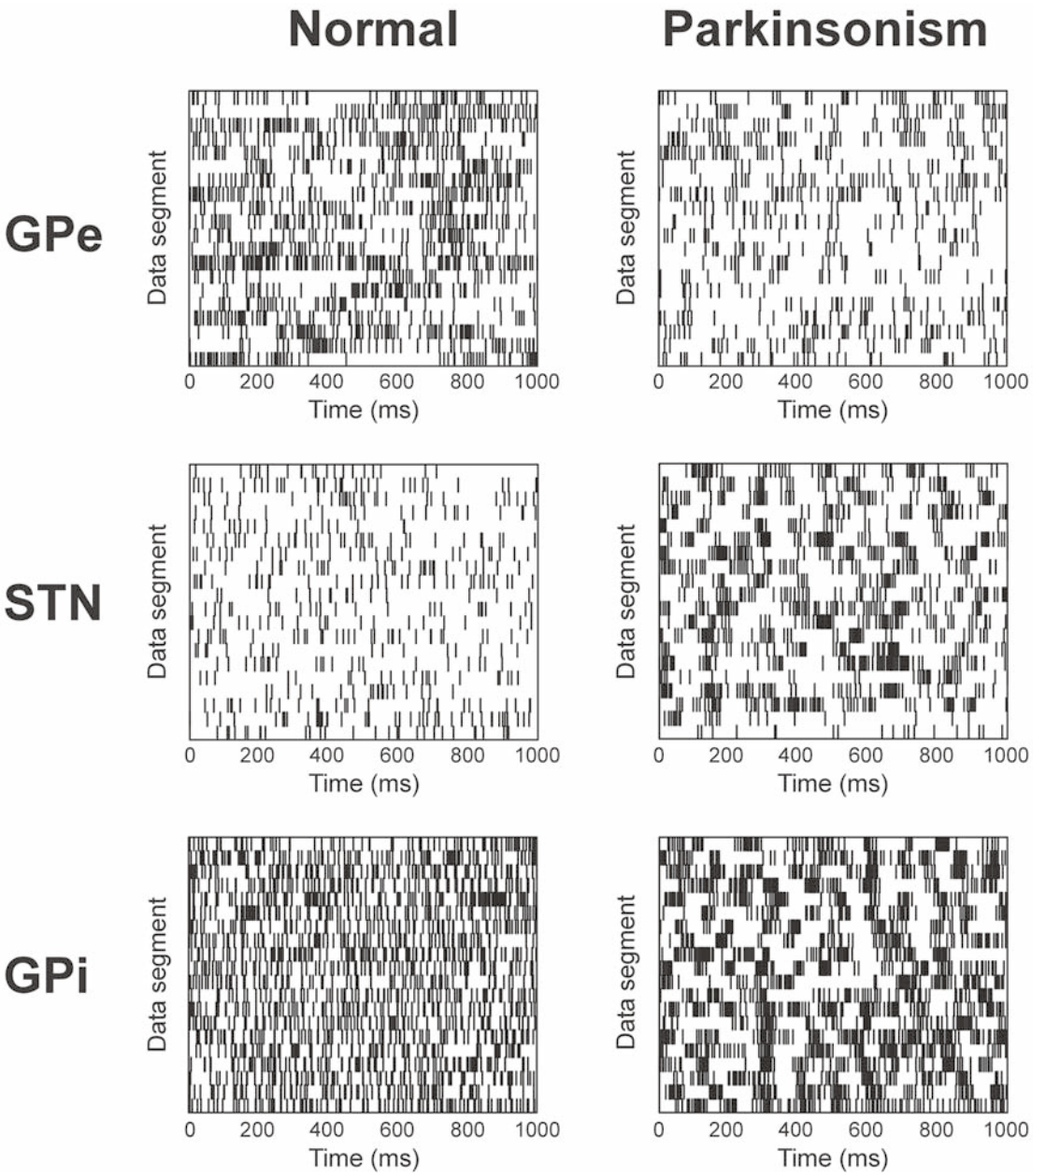

FIGURE 46-4 Activity changes in the basal ganglia in primate parkinsonism. The data are shown as raster diagrams, where each individual line represents a single neuronal discharge. Each diagram shows 20 consecutive 1000 ms segments of data from GPe, STN and GPi. The neuronal activity is reduced in GPe, and increased in STN and GPi. In addition to the rate changes, there are also obvious changes in the firing patterns of neurons in all four structures, with a marked prominence of burstiness and oscillatory discharge patterns in the parkinsonian state.

oscillatory discharge in the thalamus, which may then be transmitted to cortex. Besides tremor, certain aspects of akinesia or bradykinesia may also be related to oscillatory discharge in the basal ganglia. Thus, based on results in patients in whom deep brain stimulation (DBS) leads in the STN were used to record local field potentials from that nucleus, a theory has been proposed according to which the presence of coherent low frequency oscillations (< 30 Hz) in the cortico–basal ganglionic interaction may act to interfere with movement.

Nonoscillatory, phasic activity in the basal ganglia may also be deleterious to normal movement, because it may erroneously signal excessive movement or velocity to precentral motor areas, leading to a slowing or premature arrest of ongoing movements and to greater reliance upon external clues during movement. Any alteration of discharge

in the basal ganglia may also simply introduce noise into thalamic output to the cortex that is detrimental to cortical operations.

Pharmacotherapy. The currently available treatments for PD are symptomatic, and do not alter the course of the disease. The earliest treatment that is still in limited use today, is with the anticholinergic medications, such as trihexiphenidyl or benzotropine. These drugs are useful, particularly for tremor. However, their use is often problematic because of unpleasant side-effects, such as memory disturbances, blurred vision, sedation, dry mouth, or urinary retention, particularly in older patients.

After its introduction in the early 1960s, oral dopamine replacement therapy quickly became the mainstay of treatment of the disorder. The first agent to be introduced was the dopamine precursor levodopa, an amino acid which is metabolized into dopamine both peripherally and centrally. It quickly became apparent that the peripheral conversion into dopamine results in gastrointestinal and autonomic side-effects which significantly limit the usefulness of this agent. This problem was partially remedied by combining levodopa with peripheral blockers of dopa-decarboxylase (carbidopa or benserazide). These combination treatments have had an enormous impact on the outlook for patients with PD, greatly ameliorating many of the clinical features of the disorder and virtually normalizing life expectancy. More recently, blockers of another enzyme which is involved in peripheral metabolism of levodopa, catechol-O-methyl-transferase (COMT), was added to the therapeutic arsenal. The two available COMT-inhibitors, tolcapone and entacapone, are particularly useful in patients who suffer significant motor fluctuations with 'wearing off' of the drug effects, by slowing the metabolism of levodopa. However, problems with liver toxicity forced almost complete withdrawal of tolcapone from the market. The key to the effectiveness of the inhibitors, both carbidopa and entacapone, is that they do not cross the blood–brain barrier, so that their effects are strictly peripheral.

Levodopa therapy has a number of troubling side-effects. The most prevalent short-term problems include nausea and autonomic disturbances, such as orthostatic hypotension, and nausea. However, more troublesome are the development of motor fluctuations (wearing off and failed responses to dosing), drug-induced dyskinesias, and hallucinations. These are the primary reasons why many physicians delay the use of this agent. It also remains a theoretical possibility that levodopa may contribute to the degeneration of dopaminergic cells through free radical production. The results of recent trials suggest, however, that levodopa treatment does not hasten the clinical progression of the disease.

The most important alternatives to levodopa therapy are direct-acting dopamine receptor agonists, such as ropinirole, pramipexole, or pergolide (Fig. 46-5). A number of studies have shown that use of these agents may help to delay the need for use of levodopa/carbidopa. This has prompted the recommendation that dopamine receptor agonists should be used as first-line agents in patients with PD. It appears that these agents may also have a mild neuroprotective effect, which has further bolstered the case for their early use as monotherapy. Because the agonists have a longer half-life than levodopa and carbidopa, they are also often useful in later stages of the disease, when the response to levodopa and carbidopa may become erratic. Another dopamine agonist, apomorphine, has recently reached the market. This agent is only available in injectable form, and has a very short half-life. Its main use is in 'rescue' from episodes of unpredictable worsening in the severity of parkinsonian signs (sudden freezing episodes), sometimes seen in patients with long-standing PD.

The side-effects of agonists are similar to those of levodopa, including nausea, hallucinations and dyskinesias. Although also described for levodopa, recent studies have shown that daytime sedation with sudden 'sleep attacks' is a significant side-effect of these compounds. In addition, pergolide is an ergot derivative, and, like other ergot compounds, may result in ergotism, and may rarely induce cardiac fibrosis and valvular lesions. Ropinirole and pramipexole, both non-ergot compounds, do not have these side-effects.

Neuroprotective treatments. The first controlled clinical trial for neuroprotection in PD evaluated the MAO-B inhibitor selegiline and vitamin E vs. placebo control. Selegiline was selected on the premise that PD might be caused by an (unknown) environmental toxin, akin to MPTP, which requires an MAO-B dependent toxification step [9]. The initial studies with this medication were complicated by the fact that selegiline also has modest symptomatic effects, which were not completely accounted for in the washout phase of these experiments. Although this drug remains in wide use, its neuroprotective benefit remains controversial. It is now thought that mechanisms independent of its MAO-B-blocking actions may contribute to its (rather modest) neuroprotective actions. Initial use of dopamine receptor agonists such as ropinirole or pramipexole appear to be effective in reducing the development of dyskinesias. Coenzyme Q-10, an agent that may help to augment mitochondrial function, has been shown in preliminary trials to slow progression in loss of activities of daily living in PD.

Based on recent insights into the pathogenesis and pathophysiology of PD, a large number of additional compounds have been suggested for neuroprotection in this disease. Drugs that reduce α-synuclein aggregation or inhibit apoptosis (propargylamine, caspase inhibitors), antioxidants (glutathione enhancers, tocopherol, flavonoids), anti-inflammatory drugs (nonsteroidal anti-inflammatory agents, inhibitors of cyclo-oxygenase-2), as well as glutamate receptor antagonists, given in an effort to reduce excitotoxicity, may all serve to provide some level of neuroprotection. In addition, trophic factors and agents to protect mitochondrial function have also been proposed as neuroprotective agents. Conceivably, cocktails of such drugs may

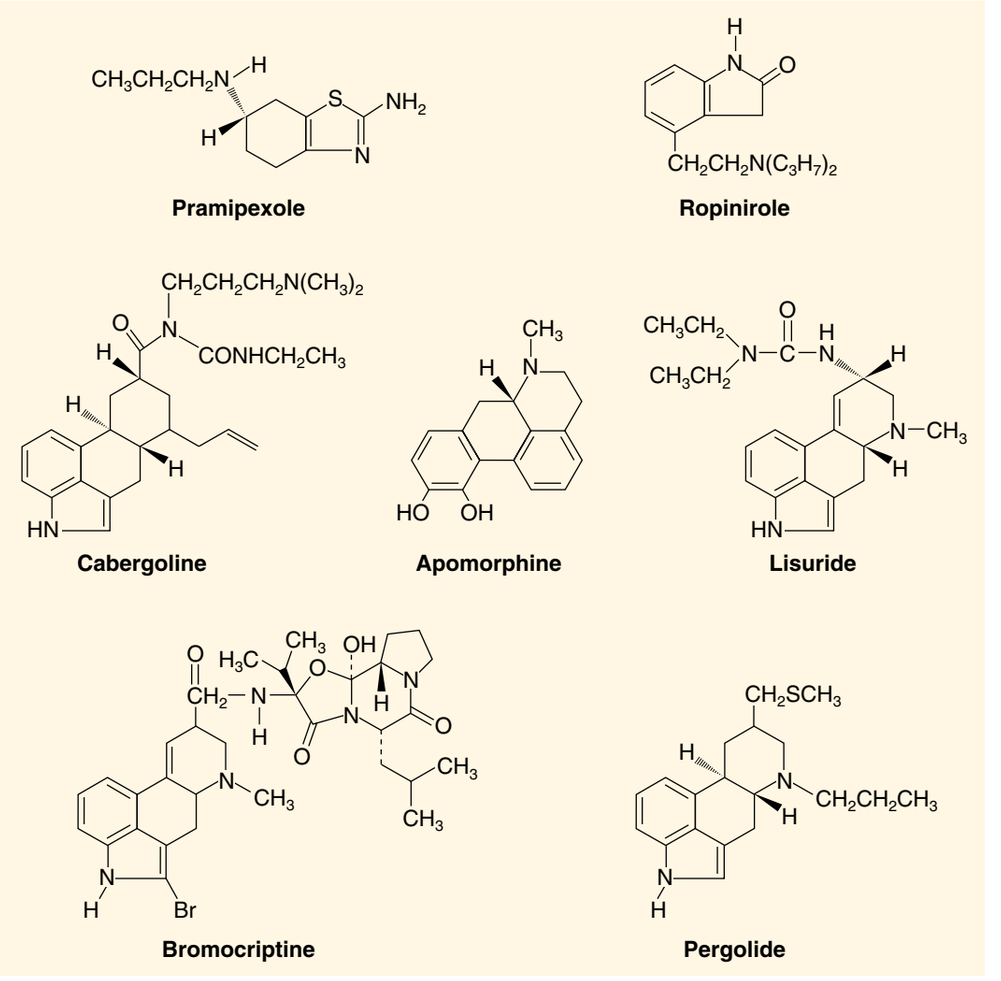

FIGURE 46-5 Chemical structures of dopamine receptor agonists.

be used to provide effects beyond those achievable with single-drug approaches. Finally, in a remarkable series of studies it has been shown, in rodents, that physical exercise can reduce the effects of neurotoxins that induce parkinsonism such as MPTP and 6-OHDA. These effects may be due to exercise-induced production of trophic factors.

Surgical therapy. After 5–10 years, many patients reach a state in which antiparkinsonian drugs are no longer adequate because of the development of intractable motor fluctuations and dyskinesias. For these patients, neurosurgical approaches can be highly beneficial. Neurosurgical procedures were, in fact, widely used in the 1950s and 1960s, but were essentially abandoned with the introduction of levodopa therapy. Following promising results from studies that demonstrated reversal of parkinsonian motor signs through lesioning of the STN in MPTP-treated monkeys [10], there has been renewed interest in surgical treatments of parkinsonism. This was first employed in the form of GPi lesions (pallidotomy) (e.g. ref. [11]). Subsequently, high-frequency deep brain stimulation (DBS) of both the STN and GPi has been shown to reverse parkinsonian signs in a manner similar to ablation. Multiple mechanisms may contribute to these effects, for instance, inhibition of STN neurons through depolarization block, activation of inhibitory afferents, or true activation of STN efferents to the pallidum. Follow-up studies in patients who have been treated with these procedures have demonstrated that although the disease continues to progress in patients with lesions or DBS, patients get significant symptomatic benefit, which may last in excess of five years.

Thalamotomy and thalamic DBS, while effective against parkinsonian tremor, have been largely abandoned since they do not treat akinesia or bradykinesia. Interventions at the level of the STN or GPi are effective against akinesia, bradykinesia rigidity, tremor, as well as disabling drug-induced dyskinesias and dystonia.

Through the use of modern imaging techniques and microelectrode guidance, these procedures have a high success rate and a low incidence of serious complications. Similar to other neurosurgical procedures, they may induce hemorrhage, infection, or cognitive problems (probably due to 'collateral' damage from probe passage through frontal areas), or stroke-like symptoms due to vascular or mechanical damage.

In developed countries, ablative procedures have largely been replaced by DBS, because the latter are equally effective or somewhat superior to ablation, are less invasive, and are reversible and adjustable. In addition, bilateral pallidal lesions have an increased risk of causing speech and swallowing dysfunction, while bilateral DBS procedures can be done without significantly increased risk. However, the stimulators require battery replacements, are prone to mechanical lead difficulties and sometimes require frequent adjustment of stimulation parameters.

One of the persistent paradoxes in basal ganglia research remains that these invasive procedures seem to have very little effect on motor performance in normal animals. Thus, no clear motor deficits and only subtle cognitive side-effects have been demonstrated. Mood disturbances, such as depression or manic episodes have been described particularly after STN DBS procedures, but are also relatively uncommon. It appears that the brain can tolerate or compensate for a lack of basal ganglia function much more readily than for the abnormal basal ganglia output that occurs in PD. In fact, although the mechanism of action of DBS is controversial, it now appears that it may act by replacing the abnormal output of the basal ganglia with a more tolerable pattern of discharge.

New treatment options. A variety of new treatment options are currently under development, and may become available in the near future. Among these are transdermal application of short-acting dopamine agonists. Selective D1-receptor agents, such as dihydrexidine also offer promise. In addition, non-dopaminergic treatments are under development.

One of the most promising treatments in this category is targeting the A2A adenosine receptor (A2ARs). A2ARs are expressed with the greatest abundance in the striatum, but are also found in other nuclei of the basal ganglia. The majority of striatal A2AR receptors appear to be postsynaptic, on dendrites of medium spiny neurons that give rise to the 'indirect' pathway. They may promote GABAergic signaling in these neurons, thus functionally opposing D2-receptor activation. Another important anatomical feature is that many dendrites carrying A2ARs appear to be contacted by glutamatergic terminals, suggesting that A2AR stimulation may facilitate cortical glutamatergic excitatory input to striatopallidal neurons. In parkinsonism, abnormalities of glutamatergic transmission in the striatum have been linked to the development of dyskinesias. Because of these anatomical and pharmacologic features, the use of A2AR antagonists has become a strategy for treating parkinsonism. Experiments in rodents and primates, and preliminary studies in humans, have shown that an A2AR antagonist (KW-6002) potentiates and prolongs the antiparkinsonian response to low-dose levodopa, and attenuates the induction and expression of dyskinesias and other motor response fluctuations that occur in response to dopaminergic stimulation (e.g. ref. [12]).

There is also substantial interest in drugs that target the glutamatergic system. Initial attempts have focused on antagonists that block ionotropic glutamate receptors. Preclinical and clinical studies with these medications (such as MK-801 or remacemide) have yielded mixed results, mostly because of substantial side-effects due to the fact that such glutamate receptors are ubiquitously distributed throughout the central nervous system [13]. More recently, metabotropic glutamate receptors have emerged as potential targets for therapeutic interventions. These compounds have the advantage of being relatively selectively located in specific basal ganglia loci, so that side-effects may be less likely to occur than with the ionotropic glutamate receptor ligands.

Finally, other surgical procedures are also being tested. For instance, there has been a long history of using cell transplants in parkinsonian patients. Initial transplantation studies have focused on the use of dopaminergic adrenal or fetal mesencephalic donor tissues. Owing to the mixed results of recent studies investigating the use of such grafts in parkinsonian patients, these procedures remain experimental. A particular problem that has become apparent is the appearance of transplantation-induced dyskinesias, which may be the result of unregulated dopamine release from the transplanted tissue [14]. Because of ethical and efficacy concerns, it is likely that graft procedures will increasingly rely upon stem cells or encapsulated genetically modified cells, which may offer the opportunity to regulate the graft's dopamine production.

Huntington's disease is a hyperkinetic movement disorder. Huntington's disease was described in 1872 by George Huntington, a general practitioner from Pomeroy, Ohio, who described a Long Island family with a hereditary form of chorea. The term chorea refers to involuntary arrhythmic jerky movements of the limbs. Early in the disease process, the chorea is often a focal phenomenon, and may manifest itself as increased blinking, grimacing, or fidgetiness. Later, it progresses to involve multiple body parts, reaching its maximum within 10 years, when it is gradually replaced by bradykinesia and rigidity, i.e. symptoms reminiscent of PD. Besides the relentless development of chorea, prominent non-motor disturbances such as depression, behavioral disturbances, and cognitive impairments are also seen, and often represent the most significant source of disability for these patients and their families. Many patients have additional, symptoms such as weight loss and autonomic dysfunction.

Men and women are equally affected with a prevalence of 5–10 per 100,000 people [16]. There are distinct geographic

and ethnic differences in the prevalence of Huntington's disease, with the highest prevalence reported in the Western European population. The disease usually manifests itself after the third decade of life, although juvenile cases have been reported. Most patients die as the result of medical complications of the disease, usually 15–20 years after symptom onset.

Pathology and pathophysiology. Pathologic studies have shown widespread neuronal degeneration throughout the cortex, basal ganglia, thalamus and brainstem. Of these, striatal areas seem to be particularly affected [17]. Striatal degeneration first involves enkephalin-containing output neurons, i.e. a group of cells projecting to GPe. This may lead to reduced inhibition of GPe neurons and, subsequently, to increased inhibition of STN neurons, decreased facilitation of GPi output and disinhibition of thalamocortical neurons. Huntington's disease shares the reduction of basal ganglia output to the thalamus with other 'hyperkinetic' disorders, such as hemiballism, a disorder that most often arises from a stroke in the STN. In later stages of Huntington's disease, however, inhibitory striatal output neurons to GPi begin to degenerate, which may result in disinhibition of GPi neurons and development of parkinsonian features.

Striatal degeneration in Huntington's disease goes far beyond the motor portion of this structure. In fact, the earliest and most prominent anatomic and radiologic features of Huntington's disease are in the caudate nucleus. The involvement of basal ganglia–thalamocortical associative and limbic circuits may contribute to the prominent psychiatric and cognitive abnormalities in this disease. Patients also suffer widespread neural degeneration in non-basal-ganglia structures, including cortex, thalamus and brainstem, which may also play a significant role in the disease.

Genetic and molecular aspects of the disease. Huntington's disease results from a mutation of a highly conserved gene on the short arm of chromosome 4 and is transmitted in an autosomal dominant fashion (see ref. [18]). The gene codes for the cytosolic and nuclear protein huntingtin, which is associated with microtubules and synaptic vesicles, and which is widely expressed throughout the nervous system, and in non-neuronal tissues. Huntingtin appears to serve a critical function early in development. It may have a role in axonal transport, and may be involved in processes counterbalancing apoptosis.

Huntington's disease is a prototypical trinucleotide repeat disorder (see also Ch. 39 and **Box 46-1** for disorders due to polyglutamine repeat mutations) [19] in which a short DNA fragment consisting of repeated segments of the trinucleotide sequence CAG greatly expands, resulting in expansion of a polyglutamine sequence in the related gene product. Within a given family, the age of onset of the disease tends to drop from one generation to the next (*anticipation*), at least in part due to further expansion of the CAG repeat sequence.

The process by which expansion of polyglutamine sections within the huntingtin protein results in the neuropathology of Huntington's disease remains unknown, but probably represents a toxic gain of function. Mutated huntingtin tends to form proteolysis-resistant aggregates, probably because of the formation of cross-links between its polyglutamine sections **(Fig. 46-6)**, but it is unclear whether these aggregates are toxic, or whether they simply represent a metabolic end-product. Mutant huntingtin also increases the expression of caspase-1, which may, through caspase-3 activation, trigger apoptosis. Huntingtin may also act to impair proteasomal function and may lead to transcriptional dysregulation. Mutant huntingtin is also associated with changes in activation of various associated proteins, such as huntingtin-associated protein 1 (HAP1), and huntingtin-interacting proteins, which, in turn, may have far-reaching consequences in terms of intracellular transport pathways, the cellular Ca-homeostasis and other phenomena. Finally, problems with mitochondrial energy metabolism have also been identified in Huntington's disease.

Animal models. Early animal models of the disease were directed at mimicking the loss of striatal neurons in Huntington's disease, by injections of neurotoxins into the striatum [20]. Thus, striatal injection of excitatory neurotoxins, such as kainic acid, a rigid analog of glutamate, causes destruction of intrinsic GABA-containing and cholinergic neurons, but spares glia and afferent axons. Affected neurons are those which possess receptors for excitatory amino acid neurotransmitters. Quinolinic acid, a tryptophan metabolite found in brain and other tissues, has a more restricted neurotoxicity, which fairly closely mimics the chemical pathology of early Huntington's disease.

Injections of the neurotoxin 3-nitropropionic acid, an irreversible inhibitor of complex II of the mitochondria respiratory chain, induce selective striatal degeneration similar to that observed in Huntington's disease. Genetically modified animals which express either full-length mutant human huntingtin gene, or sections of the 5′ end of this gene, which contains the CAG expansion, mimic many of the pathologic and some of the behavioral features of the disease.

Symptomatic treatment. The chorea of Huntington's disease responds (partially) to treatment with neuroleptics, which, through blockade of D2 receptors, may help to increase basal ganglia output to more normal levels. Dopamine-depleting agents, such as reserpine or tetrabenazine have also been used. At best, these agents are only moderately effective and they should only be used if the chorea truly interferes with activities of daily living or produces social embarrassment. Neuroleptics and

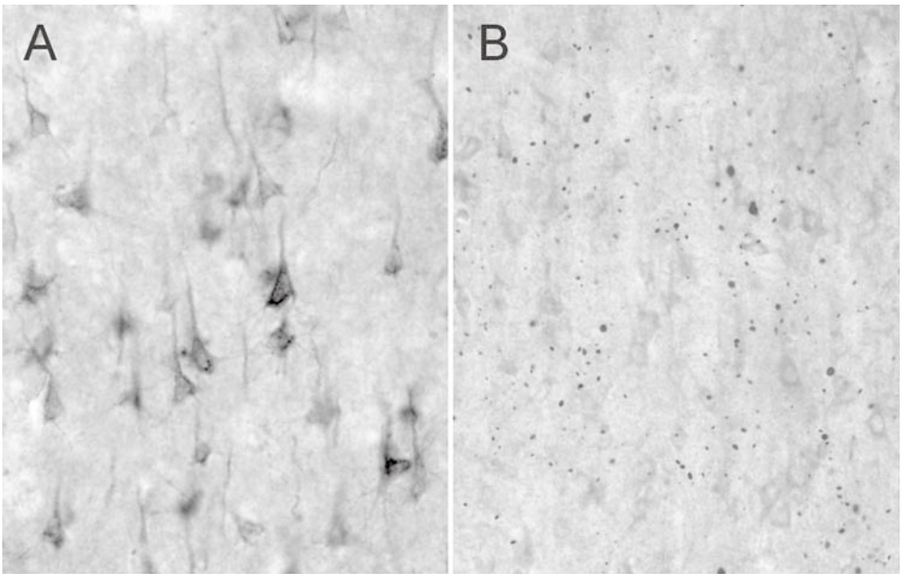

FIGURE 46-6 (**A**) Huntingtin distribution in a normal control in cortex (visualized using an antibody recognizing the internal epitope of the huntingtin molecule). (**B**) Huntingtin aggregates in the cortex of a patient with Huntington's disease (visualized with an antibody recognizing the *N*-terminal epitope of huntingtin). Both images were taken at the same magnification. Courtesy of Dr Claire-Anne Gutekunst (Emory University).

dopamine-depleting agents need to be discontinued in the late akinetic–rigid stage of the disease, because these agents may aggravate parkinsonian symptoms.

Non-motor signs of the disorder are also treatable with symptomatic medications. The frequent mood disorder can be treated with standard antidepressants, including tricyclics (such as amitryptiline) or serotonin reuptake inhibitors (SSRIs, such as fluoxetine or sertraline). This treatment is not without risks in these patients, as it may trigger manic episodes or may even precipitate suicide. Anxiety responds to benzodiazepines, as well as to effective treatment of depression. Long-acting benzodiazepines are favored over short-acting ones because of the lesser abuse potential. Some of the behavioral abnormalities may respond to treatment with the neuroleptics as well. The use of atypical neuroleptics, such as clozapine is preferred over the typical neuroleptics as they may help to control dyskinesias with relatively few extrapyramidal side-effects (Ch. 54).

Finally, it is of utmost importance to provide help with the many social problems these patients and their families and care-givers suffer. At this time there is no proven therapy to prevent the disease; however, genetic testing of patients at risk of the disease, particularly unaffected family members is available. It has been shown that knowing the results of the test helps those at risk of carrying the Huntington gene mutation, regardless of the actual outcome of the test.

Neuroprotective and restorative treatment strategies. Huntington's disease is a disease with a known and testable gene defect, which produces symptoms late in life. This constellation of clinical features makes this disorder an almost ideal candidate for the development of neuroprotective treatments. Various avenues for this have been suggested. Thus, it is known that a continuous influx of the mutant protein is required to maintain inclusions and symptoms, raising the possibility that blockade of the process of polymer formation, which depends on the action of transglutaminases, may be an effective treatment of Huntington's disease. In transgenic mice, use of the competitive transglutaminase inhibitor cystamine extended survival after the appearance of abnormal movements. Various disaccharides (such as trehalose) also inhibit polyglutamine-mediated protein aggregation and may improve motor dysfunction and increase survival in transgenic animals.

Other potential approaches involve the use of anti-apoptotic treatments, such as caspase-1 inhibitors or HDAC inhibitors which may interfere with the transcriptional dysregulation seen in Huntington disease. Both approaches have resulted in encouraging results in animal experiments. The use of growth factors has also been suggested as possible treatment for Huntington's disease.

Finally, cellular transplantation approaches have also been tried. These therapies are aimed at replacing the striatal neurons. However, in view of the widespread pathology, it remains doubtful that this disorder can be treated successfully with these interventions.

Wilson's disease is a disease of copper accumulation. Wilson's disease is an autosomal recessive disorder characterized by the accumulation of copper in liver and brain [21]. Hepatic involvement may result in liver cirrhosis and hepatic cancer. The deposition of copper in the basal ganglia results in a variety of movement disorders, including

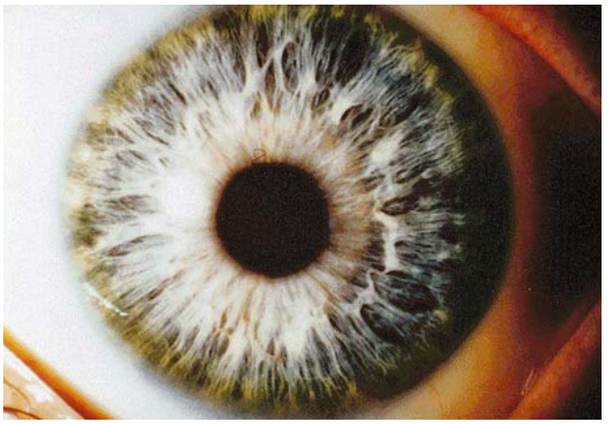

FIGURE 46-7 Kayser–Fleischer ring in a young boy with Wilson's disease. The brown ring at the edge of the cornea is due to corneal copper deposition. Courtesy of Dr Jorge Juncos (Emory University).

tremor, dyskinesias, dystonia and rigidity, as well as behavioral and cognitive abnormalities.

Other organ systems are also involved in the disease. Thus, one of the most striking physical findings in Wilson's disease is the appearance of 'Kayser–Fleischer' rings at the periphery of the cornea. They represent copper deposits, and are seen in about 60% of all patients with Wilson's disease, and in all patients with neurologic manifestations (Fig. 46-7). Less-common signs of the disease are azure lunulae of the fingernails, copper accumulation in joints, resulting in chondrocalcinosis and osteoarthritis, renal hypercalciuria and nephrocalcinosis, perhaps due to a concomitant tubular defect in calcium reabsorption, and cardiomyopathy.

A diagnosis of Wilson's disease should be considered in younger patients presenting with a movement disorder, and in patients of any age who present with a combination of hepatic and neurologic abnormalities. Patients may also first present with behavioral or psychiatric manifestations. The diagnosis should be confirmed by an ophthalmologic assessment to detect Kayser–Fleischer rings, by studies to detect reduced serum levels of the copper-binding protein ceruloplasmin (see below) and elevated urinary copper excretion, and by liver biopsy, if indicated. Imaging techniques such as brain MRI scans to demonstrate basal ganglia abnormalities, cerebral atrophy, and subtle white-matter abnormalities, or echocardiography are also useful.

Several clinically distinct forms of Wilson's disease have been described. Thus, a relatively mild, late-onset form of the disease, has been described in Jewish patients from Eastern Europe. These patients usually present with the neurologic signs of the disease. In contrast, the more common early-onset (childhood) forms of the disease often present first with liver problems, followed by neurologic manifestations.

Molecular, pathophysiologic and genetic aspects. The worldwide prevalence of Wilson disease is estimated to be approximately 3 per 100,000 persons (e.g. ref. [22]). The disease results from mutations within the ATP7B gene on the short arm of chromosome 13 [23, 24]. This gene encodes a protein which appears to be involved in copper transport coupled with the synthesis of ceruloplasmin and other cuproproteins.

Adults require 1–2 mg of copper per day, and eliminate excess copper in bile and feces. Most plasma copper is present in ceruloplasmin. In Wilson's disease, the diminished availability of ceruloplasmin interferes with the function of enzymes that rely on ceruloplasmin as a copper donor (e.g. cytochrome oxidase, tyrosinase and superoxide dismutase). In addition, loss of copper-binding capacity in the serum leads to copper deposition in liver, brain and other organs, resulting in tissue damage. The mechanisms of toxicity are not fully understood, but may involve the formation of hydroxyl radicals via the Fenton reaction, which, in turn initiates a cascade of cellular cytotoxic events, including mitochondrial dysfunction, lipid peroxidation, disruption of calcium ion homeostasis, and cell death.

Animal models. There are several animal models for Wilson's disease which may prove useful for the study of copper metabolism, ceruloplasmin functions, and the pathophysiology of Wilson's disease. One of these models is the Long–Evans Cinnamon rat, a genetically authentic model of Wilson's disease, in which the animals develop hepatitis and liver carcinoma, associated with abnormally high hepatic copper, which can be prevented by treatment with copper-chelating agents. Genetic mouse models have also been studied. Thus, homozygous null mutants for the Wilson's disease gene display a gradual accumulation of copper in liver (resulting in liver cirrhosis), kidney, brain, placenta and lactating mammary glands. However, other features of the phenotype of these animals do not resemble Wilson's disease, but rather suggest a copper-deficiency state. Finally, copper toxicosis, an autosomal recessive disorder in dogs, is also thought to be a genetically faithful model of Wilson's disease.

Treatment. Since the 1950s, the treatment of Wilson's disease has relied on chelating agents [25]. Early attempts to use BAL or EDTA for this purpose were unsuccessful, but penicillamine, triethylene tetramine dihydrochloride (trientine), and tetrathiomolybdate, all in combination with a low-copper diet, have proved to be effective, and result in the urinary excretion of large amounts of copper. The use of penicillamine is complicated by the fact that it may induce a transient worsening of neurologic function due to rapid mobilization of copper, and also has other side-effects, such as the development of nephrosis. Tetrathiomolybdate is an effective alternative with fewer side-effects [26]. In cases in which the dose was rapidly escalated, however, bone marrow suppression or liver function abnormalities have been described.

In addition, treatment with zinc acetate helps to reduce serum copper levels. Zinc acetate is a relatively nontoxic agent which blocks intestinal copper uptake and induces

hepatic metallothionein. It has a slow onset of action compared to penicillamine. Zinc treatment has also been used to prevent the onset of symptoms of Wilson's disease in patients who had been shown to be at risk (for instance, through genetic testing).

In cases in which drug treatment management is not successful, liver transplantation can be used. This is a highly effective treatment to correct the hepatic and metabolic problems, but neurologic symptoms and signs are often irreversible.

Dystonia is characterized by sustained muscle contractions. In patients with dystonia, normal movements are disrupted by cocontraction of agonist and antagonist muscles, and by excessive activation of inappropriate musculature (*overflow*), leading to abnormal postures and slow involuntary twisting movements, which are often associated with movement execution.

Etiology and classification. Dystonia may arise from a variety of disease processes, the majority of which involve the basal ganglia. Dystonia can be classified as a generalized or focal disorder. The most common forms of dystonia are focal in nature (e.g. spasmodic torticollis, blepharospasm, writer's cramp, etc.) and occur in adults, while many of the childhood dystonias are generalized.

Dystonia can also be classified as 'primary' or 'secondary'. In children and young adults, one of the main forms of 'primary' dystonia (i.e. dystonia without a clearly defined pathologic basis) is idiopathic torsion dystonia. The disease is autosomal dominant, occurring with high frequency (1 per 23,000 live births) in Ashkenazi Jews [27]. The penetrance, however, is only 30%. The disorder is caused by a genetic defect in the DYT1 gene on the short arm of chromosome 9 which codes for the ATP-binding protein torsin A. Torsin A is present throughout the brain, but is enriched in SNc neurons, suggesting a tie with dopaminergic transmission. It is located primarily in the nuclear envelope. The disease often begins in childhood or adolescence with involuntary posturing of the limbs, and tends to generalize within a few years.

More than a dozen other determined forms of dystonia have been described. They differ in their mode of inheritance, and the genes involved. A detailed description of these disorders is beyond the scope of this chapter.

Dystonia due to identifiable structural or biochemical abnormalities ('secondary' dystonia) often occurs weeks or months after strokes or other focal lesions, which commonly involve the basal ganglia, but may also involve the thalamus or cerebellum. Dystonia is also seen in children with cerebral palsy and in patients with abnormalities of dopaminergic transmission. For instance, dystonia may develop in the context of Parkinson's disease, either as an early parkinsonian sign, or in response to dopaminergic drugs. A particularly interesting inherited disease results in a combination of dystonia and parkinsonian features at a young age, which responds dramatically to treatment with low-dose levodopa ('dopamine-responsive dystonia'). These patients suffer from a genetic defect of dopamine synthesis, caused by reduced GTP cyclohydrolase activity. This enzyme is rate-limiting in the biosynthesis of tetrahydrobiopterin, a cofactor of the dopamine-synthesizing enzyme tyrosine hydroxylase (see Fig. 40-2).

Pathophysiology. Research into the pathophysiology of primary dystonia has demonstrated that this disorder is associated with widespread loss of inhibition and a loss of specificity in sensorimotor maps at the cortical level. The notion that dystonia may result from aberrant plasticity in susceptible individuals is also indirectly supported by the observation that the beneficial effect of neurosurgical interventions for dystonia, such as pallidotomy or DBS, is typically delayed for several weeks or months.

In cases in which dystonia results from lesions affecting the striatum or its dopaminergic supply, such lesions may affect the affinity or number of dopamine receptors in the unlesioned portion of the striatum, or may lead to reorganization of striatal topography. This will eventually result in altered activity in the basal ganglia output structures. Recent PET studies and results of single-cell recording in human patients with dystonia have suggested a combination of activity changes in the direct and indirect pathways (see below).

Pharmacologic studies suggest that abnormalities in both the indirect and direct pathway contribute to dystonia. Thus, D2LR antagonists have a substantial potential for inducing dystonia, presumably by increasing striatal outflow to GPe via the indirect pathway, whereas D1-receptor antagonists may be beneficial in this regard, presumably by reducing striatal outflow to GPi along the direct pathway. By inference, these data suggest that a relative increase in the activity along the direct pathway (compared to that along the indirect pathway) may strongly contribute to dystonia. Increased activity along the direct pathway may be due to activity changes in feedback loops that regulate GPi activity, for instance the pathway through CM. Interestingly, it has been reported that thalamic lesions were most effective against dystonia if they included the CM nucleus **(Fig. 46-1)**.

Agonist/antagonist co-activation in dystonia may primarily reflect a defect in segregation of 'channels' passing through the basal ganglia output nuclei, i.e. an increased degree of synchronization. The development of dystonia would also depend on the presence of low overall discharge rates in the basal ganglia output nuclei, permitting excess movement. The degree of synchronization is probably determined for the most part by the presence or absence of dopamine in the striatum, but could also be explained by extrastriatal dopamine loss, for instance at the level of the STN. Given the differential effects of dopamine D1 and D2 receptor antagonists in the production of dystonia, the phenomenon of synchronization is likely to be primarily a function of abnormal discharge in the indirect pathway.

Lack of segregation could affect smaller channels within motor subcircuits or could lead to synchronized activity

between different subcircuits. The latter possibility has been favored by the results of recent PET studies in dystonic patients, which have demonstrated widespread changes in the activity of prefrontal areas. Physiologic studies have also provided evidence that dystonia is associated with increased excitability of motor areas (particularly the SMA), probably due to widespread decrease in cortical inhibition.

Treatment. Treatment for dystonia is for the most part symptomatic, except in rare instances where known mechanisms are present and specific therapies are available. The available treatments include support and rehabilitation, pharmacotherapy and, in some cases, functional neurosurgery. Sensory retraining in humans with focal dystonias has resulted in a substantial recovery of function in some patients.

Pharmacotherapy. Anticholinergic drugs, such as trihexyphenidyl, are the most effective forms of treatment for generalized primary dystonia. The use of these medications is often limited by side-effects, such as constipation, dry mouth, blurred vision and urinary retention, as well as impaired short-term memory, confusion and hallucinations. Benzodiazepines, including clonazepam or diazepam, are also effective for dystonia, alone or in combination with anticholinergics. Dosages are raised slowly until benefits are obtained or side-effects, including sedation, ataxia and confusion, prevent further escalation. Baclofen, a GABA-B-receptor agonist, is also effective for treating both focal and generalized dystonia. Relatively high doses are required (60–100 mg); however, side-effects are often limiting. A baclofen pump for intrathecal infusion may be helpful for such cases. Dystonia involving the legs and trunk is most responsive to this form of therapy. Unfortunately, sustained benefits are not the rule, and complications are not infrequent. Dopamine-depleting agents, such as tetrabenazine or reserpine may also be helpful. Dopaminergic drugs are occasionally beneficial in both generalized and focal dystonias, but the most dramatic effects are seen in individuals with DRD, who experience a dramatic and sustained improvement with even a small dose of levodopa. Paradoxically, a fair percentage of patients with generalized dystonia (and craniocervical dystonia) respond to DA *antagonists*, such as haloperidol or pimozide. Sometimes, the combination or 'cocktail' of tetrabenazine, pimozide and trihexyphenidyl is reported to be effective.

In general, the response of focal dystonias to drug treatments with systematically applied drugs is unsatisfactory. However, focal dystonias (or generalized dystonias with prominent focal symptoms) respond dramatically to botulinum toxin injected into the affected muscle groups. The agent acts by preventing fusion of synaptic vesicles with the synaptic membranes in axonal terminals, thereby preventing the release of transmitter into the synaptic cleft. If injected into muscle, this affects mostly cholinergic transmission at neuromuscular junctions, resulting in dose-dependent weakness of the injected muscle. Repeated injections are required every two to five months. A problem with this form of treatment is that some patients develop resistance to the toxin after several injections, usually due to an immune reaction which results in the development of antibodies against the toxin. In these cases, different botulinum toxin serotypes can be used.

Surgical approaches. Prior to the introduction of botulinum toxin, peripheral denervation procedures, such as dorsal or anterior cervical rhizotomy and selective peripheral denervation, were commonly performed, primarily for the treatment of cervical dystonia. These are now performed far less frequently, generally in patients with cervical dystonia who fail botulinum toxin injections. Stereotactic surgery is used primarily for severe generalized dystonia unresponsive to other treatments. In recent years, following the success with PD, pallidotomy and DBS of the pallidum are being used with promising results. The best candidates for surgery appear to be individuals with primary dystonia. Patients with secondary forms of dystonia are less likely to benefit. Bilateral surgery is usually necessary to obtain control of axial dystonia.

Many drugs and toxins induce movement disorders. In addition to MPTP, other drugs that alter the availability of dopamine or that affect its actions at receptors may induce movement disorders with parkinsonian features. Some drugs have an opposite effect, producing hyperactive states with involuntary, abnormal movements. Indeed, an important and distressing adverse effect of levodopa therapy is the development of dyskinesias. Furthermore, the neurons of the basal ganglia and associated structures are uniquely vulnerable to the effects of a variety of toxins, and this sensitivity is a critical factor in the neurological complications that accompany these substances. Generally, toxins produce more extensive neurological damage and a greater variety of clinical deficits than are found in PD. Damage to the nigrostriatal dopaminergic neurons appears to be responsible for the parkinsonian features that occur after exposure to these toxins, whereas involvement of other basal ganglia or associated systems may be responsible for the development of involuntary dyskinesias.

Dopamine depleting agents. Reserpine, a natural alkaloid that blocks vesicular transport of monoamines, depletes stored monoamines, including DA. DA depletion is associated with the emergence of parkinsonism. This effect of reserpine was among the first clues that PD is the result of DA deficiency (see above). Generally, the parkinsonism resulting from reserpine is reversible.

As indicated earlier, α-methyldopa treatment of hypertension sometimes results in the appearance of parkinsonian symptoms. This is presumed to be a consequence of DA depletion by replacement of DA with the relatively inactive false transmitter α-methyldopamine, as well as by inhibition of AADC (Ch. 12).

Dopamine receptor blocking agents. Many of the neuroleptics used in the treatment of schizophrenia frequently produce parkinsonian symptoms as unwanted effects. Neuroleptics block dopamine receptors and their therapeutic effect seems to be related to this action. Although these drugs act on DA systems without distinction, some are more selective. Thioridazine, clozapine and molindone, for example, have electrophysiological effects in the limbic region of the brain but little action in the nigro-striatal area. This selectivity may be related to receptor subtype specificity (see Chs 12 and 54).

Patients who have received neuroleptics for long periods of time may develop a hyperkinetic disorder of the extrapyramidal system characterized by involuntary, purposeless movements affecting many parts of the body. This is known as tardive dyskinesia. Most commonly, these are manifested in a syndrome involving abnormal movements of the tongue, mouth and masticatory muscles. There are also choreoathetoid movements of the extremities. The mechanism by which these symptoms develop remains unknown.

Effects similar to those of the neuroleptics have also been described for other dopamine-blocking agents. Thus, parkinsonism and tardive symptoms may result from use of metoclopramide, a drug which is commonly used to enhance gastric motility, or certain antiemetics, such as perphenazine.

Manganese. A small proportion of miners exposed to manganese dust develop manganism. Manganese is absorbed from the intestine as well as through the pulmonary epithelium, and once in the systemic circulation, it readily enters the brain. After a relatively short interval (months) of exposure to high doses of the dust, the disease is ushered in by psychiatric problems. 'Manganese madness' is characterized by emotional lability, hallucinations, irritability and aggressiveness. When the exposure is to low amounts of manganese, the behavioral changes may be mild and reversible. After more prolonged exposure, behavioral symptoms are replaced by signs of neurological damage. In contrast to PD, the globus pallidus and SNr are the sites of greatest damage; but the striatum, STN, frontal and parietal cortex, cerebellum and hypothalamus may also be involved. Epidemiological studies have shown no risk for the development of PD from drinking of well water rich in manganese. This discrepancy demonstrates the need for further research into the mechanism(s) of manganese-induced movement disorders.

Iron. Iron plays a vital role during development and growth and is an important factor in many metabolic reactions, including protein synthesis as a cofactor of both heme and nonheme enzymes, and in the development of neuronal processes. However, free iron, particularly Fe^{2+}, is highly toxic by virtue of its ability to trigger cellular deleterious effects, including the Fenton reaction, which generates free radical species and lipid peroxidation (Ch. 32). Fe^{3+} (the oxidized form of Fe^{2+}) and total iron are both found in increased concentration in the substantia nigra of patients with PD. It is now clear that exposure to iron does not pose an increased risk for the occurrence of parkinsonism, so that the increase of this metal may be related to some alteration in iron homeostasis.

Carbon disulfide. Carbon disulfide is a volatile, lipid-soluble industrial solvent that enters the body by inhalation or absorption through the skin. The early symptoms of carbon disulfide poisoning resemble those of manganese poisoning; subsequently, neurological deficits are widespread and include peripheral neuropathy as well as encephalopathy with memory loss, incoordination and parkinsonism. Relatively little is known about the pathological changes in humans, but in monkeys exposed to carbon disulfide, damage to the globus pallidus and substantia nigra suggest that similar pathological changes may account for the parkinsonian features of toxicity in humans. Other sulfur compounds, such as sulfuric acid and sulfur hydride, have also been implicated in inducing parkinsonian-like clinical features.

Carbon monoxide. Inhalation of carbon monoxide, which binds avidly to hemoglobin and to cytochromes, is one of the most fatal forms of poisoning. Survivors of acute carbon monoxide poisoning may develop, over several days or weeks, a delayed encephalopathy with memory loss, personality changes and some parkinsonian movement deficits, usually associated with damage to the globus pallidus, which has been reported among the pathological features of this syndrome at autopsy. In spite of all of these detrimental effects, CO is also a putative neurotransmitter (see Ch. 10).

Neurobiology of Alzheimer's Disease

Philip C. Wong

Tong Li

Donald L. Price

ALZHEIMER'S DISEASE IS THE MOST PREVALENT NEURODEGENERATIVE DISORDER 781

The clinical syndrome, ranging from mild cognitive impairment to severe dementia, reflects cellular abnormalities in specific regions of the brain/circuits 782

Advances in laboratory measurements and imaging of amyloid burden in brain will be of value in establishing the diagnosis of Alzheimer's disease (AD) 782

Some cases of familial AD (fAD) are due to mutant genes inherited as autosomal dominants; ApoE4 allele is associated with increased risk 782

Multiple neurotransmitter circuits are damaged by the disease 783

Neuritic plaques, one of the pathological hallmarks of the disease, are composed of swollen neurites, extracellular deposits of Aβ 40–42 peptides, (derived from β- and γ- secretase cleavages of APP) and surrounding astrocytes and microglia 783

Neurofibrillary tangles (NFT) are comprised of bundles of paired helical filaments (PHF) made up of hyperphosphorylated tau 783

Aspartyl proteases carry out the β- and γ-secretase cleavages of APP to generate Aβ peptides 784

Transgenic strategies have been used to create models of Aβ amyloidosis 785

Gene targeting approaches have identified and validated certain genes as targets for therapy 785

Transgenic mouse models are being used to test a variety of novel therapies, including ways of reducing secretase activities and decreasing Aβ burden by Aβ immunotherapy 786

Several of these experimental approaches are moving into clinical trials 787

ALZHEIMER'S DISEASE IS THE MOST PREVALENT NEURODEGENERATIVE DISORDER

Alzheimer's disease (AD), manifesting as progressive memory loss and cognitive impairments [1], affects more than 4 million elderly individuals in the USA [1, 2]. This syndrome results from abnormalities associated with dysfunction and death of specific populations of neurons, particularly those in neural systems involved in memory and cognition [3]. The pathology is characterized by intracellular and extracellular protein aggregates (tau and Aβ related abnormalities) in neurofibrillary tangles (NFT) and neuritic amyloid plaques, respectively [4–6]. Genetic evidence indicates that the inheritance of mutations in several genes causes autosomal dominant familial AD (fAD), while the presence of certain alleles of *ApoE4* are significant risk factors for putative sporadic disease [3, 7, 8].

Due to increased life expectancy and the postwar baby boom, the elderly are the most rapidly growing segment of our society. Thus, over the next several decades, the number of persons with AD in the USA will triple. Because of prevalence, lack of mechanism-based treatments, cost of care, and impact on individuals and caregivers, AD is one of the most challenging diseases in medicine [3, 4, 9, 10]. This review first briefly discusses the clinical syndrome, laboratory tests, genetics, and pathological/biochemical features of the human illness. Subsequently, we describe selected aspects of: the biology of proteins implicated in pathogenesis of disease; the value of transgenic and gene-targeted mouse models; the identification of several therapeutic targets; and results of selected experimental treatments in the models. We demonstrate how information from

Basic Neurochemistry: Molecular, Cellular and Medical Aspects
0-12-088397-X

genetics, pathology, and biochemistry has been used to create models of disease (i.e. mice expressing mutant transgenes). In parallel, we demonstrate how results of targeting genes encoding proteins implicated in disease pathways have provided insights of the roles of these proteins in the pathogenesis of AD and the potential of these proteins as therapeutic targets. The value of these targets for new treatment strategies is being tested in model systems. As safety and efficacy are assured, some of these therapeutic approaches will be increasingly used in human trials [10]. The development of effective new therapies will have a significant impact on the health and care of the elderly.

The clinical syndrome, ranging from mild cognitive impairment to severe dementia, reflects cellular abnormalities in specific regions of the brain/circuits. The disease often initially manifests as a syndrome termed mild cognitive impairment (MCI), which is usually characterized by a memory complaint and impairments on formal testing, intact general cognition, preserved daily activities and absence of overt dementia [11]. MCI is regarded by many as a transitional stage between normal aging and early AD [11–13]. The clinical manifestations of symptomatic AD include increasing difficulties with memory and with other cognitive functions (executive functions, language, attention, judgment, etc.) [1, 6, 12–14]. Some patients develop psychotic symptoms. Over time, mental functions and activities of daily living are increasingly impaired. In the late stages, these individuals become profoundly demented and usually die of intercurrent illnesses.

For a diagnosis, clinicians rely on histories, on physical, neurological and psychiatric examinations, on neuropsychological tests [1, 14], and on laboratory studies [15, 16].

Advances in laboratory measurements and imaging of amyloid burden in brain will be of value in establishing the diagnosis of Alzheimer's disease (AD). In cases of AD, the CSF levels of Aβ peptides are often low, and CSF levels of tau may be higher than in controls [15]. Values vary between individuals and single measures may not be great diagnostic value. Over several examinations, the clinical profile, in concert with laboratory assessments, allows the clinician to make a diagnosis of possible or probable AD [17].

In cases of AD, magnetic resonance imaging (MRI) often discloses regional brain atrophy, particularly involving hippocampus and entorhinal cortex [1, 14], and rates of atrophy which correlate with changes in clinical status and may have predictive value for diagnosis. Positron emission tomography (PET) using [^{18}F]-deoxyglucose or single photon emission computerized tomography (SPECT) commonly demonstrate decreased glucose utilization and early reduction in regional blood flow in the parietal and temporal lobes.

The most exciting recent advance in imaging relevant to AD is the use of PET with the radiolabeled Pittsburgh Compound B (PIB) which demonstrates Aβ amyloid burden *in vivo*. This brain penetrant ^{11}C-labeled uncharged thioflavin derivative binds to Aβ with high affinity [16]. The PET patterns of labeled PIB are interpreted to reflect the Aβ burden in the brain [16]. In comparison with controls, subjects with AD show marked retention of label in several areas of brain that usually accumulate amyloid. This approach should eventually prove useful for enhancing accuracy of diagnosis and should allow assessment of the efficacies of new anti-amyloid therapeutics. Further details of brain imaging are found in Ch. 58.

Some cases of familial AD (fAD) are due to mutant genes inherited as autosomal dominants; ApoE4 allele is associated with increased risk. Genetic risk factors for AD include: mutations in APP (chromosome 21); mutations in *presenilin (PS) 1* (chromosome 14) and *PS2* (chromosome 1); and different susceptibility alleles of *ApoE* (chromosome 19) [3, 7, 8, 18]. Autosomal dominant mutations in APP, PS1, or PS2 usually cause disease earlier than occurs in sporadic cases. The majority of mutations in APP, PS1 and PS2 influence BACE1 and γ-secretase cleavages to increase the levels of all Aβ species or the relative amounts of toxic Aβ 42 [7, 8, 18]. Individuals with trisomy 21 or Down's syndrome (DS) have an extra copy of APP (and other genes) in the putative obligate DS region; these individuals develop AD pathology relatively early in life. The presence of ApoE4 predisposes to later onset AD and some cases of late-onset fAD [19]. Recent research has identified other loci that confer risk [8].

Mutations of APP gene. APP, a type I transmembrane protein existing as several isoforms, is abundant in the nervous system, rich in neurons, and transported anterograde in axons to terminals [20–22]. Its specific functions remain to be defined [7, 23, 24]. APP is cleaved by activities of BACE1 (*β*-site *A*PP *c*leaving *e*nzyme *1*) and the γ-secretase complex, which generate the *N*- and *C*- termini of Aβ peptides, respectively [7, 10, 25–32]. The APPswe mutation, a double mutation involving codons 670 and 671, enhances many-fold the BACE1 cleavage at the *N*-terminus of Aβ; the result is substantial elevation in levels of all Aβ peptides. With APP_{717} mutations, γ-secretase cleavage is altered leading to increased secretion of Aβ 42, which is a more toxic peptide. Thus, some of the APP mutations linked to fAD can change the processing of APP and influence the biology of Aβ by increasing the production of Aβ peptides or the amounts of the more toxic Aβ 42; other mutations may promote local fibril formation.

Mutations of PS1 and PS2 genes. PS1 and PS2, two highly homologous and conserved 43- to 50-kDa multipass transmembrane proteins [3, 7, 33, 34], are involved in Notch1 signaling pathways critical for cell fate decisions [7, 28]. They are endoproteolytically cleaved to form an *N*-terminal 28 kDa fragment and a *C*-terminal 18 kDa fragment [33, 35], both of which (along with several other proteins described below) are critical components of the

γ-secretase complex [7, 27–32, 36]. Nearly 50% of cases of early-onset fAD are linked to approximately 90 different mutations in PS1 [3, 7, 8, 34]. A small number of PS2 mutations cause autosomal dominant fAD in several pedigrees [3, 8]. The majority of abnormalities in PS genes are single amino acid missense mutations that enhance γ-secretase activities and increase the levels of the Aβ 42 peptides.

ApoE alleles. ApoE carries cholesterol and other lipids in the blood. In humans, three alleles exist: ApoE2, ApoE3 and ApoE4 [19]. The ApoE3 allele is most common in the general population (frequency of 0.78), whereas the allelic frequency of ApoE4 is 0.14. However, in clinic-based studies, the ApoE4 allelic frequency in patients with late-onset disease (>65 years of age) is 0.50; thus, the presence of ApoE4 increases the risk for AD [8, 19]. Significant differences exist in the abilities of ApoE isoforms to bind Aβ and these features of the individual protein are hypothesized to differentially influence aggregation, deposition and/or clearance of Aβ by different ApoE isoforms.

Multiple neurotransmitter circuits are damaged by the disease. The clinical signs of AD reflect the distribution of abnormalities among different populations of neurons in brain regions/systems critical for memory, learning, and cognitive performance. Circuits damaged by the disease include: the basal forebrain cholinergic system; hippocampus; entorhinal cortex; limbic cortex; and neocortex [13, 37–39]. Neurodegeneration in these regions/circuits are reflected by: NFT and neurites, related to the presence of cytoskeletal abnormalities, particularly involving conformational alterations in phospho-tau leading to PHF [5]; the presence of neuritic Aβ-containing plaques (sites of synaptic disconnection) in brain regions receiving inputs from these neurons [7, 40]; reductions in both generic and transmitter specific synaptic markers in the target fields of these cells [40]; evidence of death of neurons in these regions [37, 40]; and local glial and inflammatory responses, particularly associated with plaques. Disruption of synaptic communication in these circuits, associated with degeneration of neurons, has profound clinical consequences [40, 41]. Abnormalities that damage the circuits involving the entorhinal cortex, medial temporal cortex, and hippocampus, contribute significantly to memory impairments. Pathology in the neocortex is reflected by deficits in higher cognitive functions, such as disturbances in language, calculation, problem solving, and judgment. Alterations in the basal forebrain cholinergic system may contribute to difficulties in memory, arousal and attention, while involvement of the limbic cortex, amygdala, thalamus, and monoaminergic systems result in behavioral and emotional disturbances [1].

Neuritic plaques, one of the pathological hallmarks of the disease, are composed of swollen neurites, extracellular deposits of Aβ 40–42 peptides, (derived from β- and γ-secretase cleavages of APP) and surrounding astrocytes and microglia. Neuritic Aβ plaques are composed of Aβ deposits of β-pleated sheet peptides surrounded by swollen neurites (nerve terminals). Aβ1–40, 42 and 11–40, 42 amyloid peptides are derived by β- and γ-secretase cleavages of APP to generate Aβ1–40, 42 and 11–40, 42 peptides [3, 7, 26, 42]. These Aβ peptides accumulate in the extracellular space of the neuropil of the neocortex and hippocampus. In neurons, APP is delivered by anterograde axonal transport to terminals [20–22], from which, following β- and γ-secretase cleavages, extracellular monomeric Aβ 40 and 42, 43 peptides are released [7, 21, 36, 43]. Aβ multimers assemble into β sheets, into protofilaments, and into fibrils [44]; these aggregates are birefringent when stained with Congo red or thioflavin dyes and viewed in polarized light or fluorescence illumination, respectively. Considerable debate exists concerning the Aβ species/conformational state exhibiting the greatest toxicity, with plaques, fibrils, protofibrils, or oligomers proposed as principal offenders [44, 45]. It now is believed that multimers, sometimes termed *A*β *d*erived *d*iffusible *l*igands (ADDLs), are the principal toxic entities [41, 42, 45, 46].

In one model, APP and pro-amyloidogenic secretases are transported to terminals and thus neurons are thought to be the major source of APP that gives rise to Aβ [43]. At synapses, BACE1 cleaves APP to form amyloidogenic *C*-terminal derivatives [21], which are then cleaved by γ-secretase to generate Aβ 40, 42, 43 peptides. Released normally at terminals, Aβ may influence synaptic functions [28, 40], perhaps behaving as a modulator depressing activity at excitatory, glutamatergic synapses via the NMDA receptor [24]. With increasing accumulations of Aβ 42 multimers at terminals, synaptic functions, including long term potentiation (LTP, see discussion in Ch. 53), are disrupted [47]. In this scenario, neuritic amyloid plaques, a classical feature of AD, are complex structures representing sites of Aβ-mediated damage to synapses associated with degeneration of neurites and disconnection of terminals from targets. Surrounding plaques are astrocytes and microglia which produce cytokines, chemokines and other factors (including complement components) involved in inflammatory processes (see Inflammation in Ch. 33).

Neurofibrillary tangles (NFT) are comprised of bundles of paired helical filaments (PHF) made up of hyperphosphorylated tau. Tangles are fibrillar intracytoplasmic inclusions in cell bodies/proximal dendrites of affected neurons, while neuropil threads and neurites are predominantly swollen, filament-containing dendrites and distal axons/terminals, respectively [5]. These intracellular lesions are rich in PHF comprised of poorly soluble hyperphosphorylated isoforms of tau, a low-molecular-weight microtubule-associated protein [5]. In human brain, alternative splicing from a single gene leads to formation of six tau isoforms, consisting of three isoforms of three repeat (3-R) tau, and three isoforms of four repeat (4-R) tau, the latter derived by inclusion of exon 10 in the transcript [5, 48]. Normally, tau, synthesized in neuronal cell bodies, is transported anterograde in axons, where it acts, via repeat

regions that interact with tubulin, to stabilize tubulin polymers critical for microtubule assembly and stability [5, 48] (see also axonal transport in Ch. 28). The post-translationally modified tau, which exhibits abnormal conformations, differs somewhat in the different tauopathies: in cases of AD, the PHF are composed of six isoforms of tau; in contrast, the inclusions occurring in cases of progressive supranuclear palsy (PSP) and cortical basal degeneration (CBD)are characterized by 4-R tau, while the inclusions seen in individuals with Pick's disease (PD) are enriched in 3-R tau [5] (see also Tauopathies in Ch. 45).

In one hypothetical model linking Aβ and phosphorylated tau, Aβ42 damages terminals leading to synaptic disconnections which, perhaps preferentially in primates with six isoforms of tau, in turn lead to retrograde signals that ultimately trigger the activation of kinases (or the suppression of phosphatases) whose activities lead to excessive phosphorylation of tau at certain residues. Subsequently, conformational changes in the protein cause the formation of PHF. Since the cytoskeleton is essential for maintaining cell geometry and for the intracellular trafficking and transport of proteins and organelles, disturbances of the cytoskeleton can lead to alterations in axonal transport which, in turn, can compromise the functions and viability of neurons (see Chs 8,9 and 28). Eventually, affected nerve cells die (possibly by apoptosis; apoptosis is discussed in Ch. 35) [37, 49] and extracellular tangles remain as 'tombstones' of the nerve cells destroyed by disease.

Aspartyl proteases carry out the β- and γ-secretase cleavages of APP to generate Aβ peptides. APP is processed by β- and γ-secretase enzymes resulting in release of the ectodomain of APP (APPs), the production of a cytosolic fragment termed *A*PP *i*ntracellular *d*omain (AICD), and the generation of several Aβ peptides. In the CNS, Aβ peptides are generated by sequential endoproteolytic cleavages of neuronal APP by two membrane-bound enzymes: as described below, BACE1 cleaves APP at the Aβ +1 and +11 sites to generate APP–β carboxyl terminal fragments (APP–βCTFs) [26, 50]; while γ-secretase complex cleaves, via regulated intramembranous proteolysis, APP–βCTFs at several sites including Aβ 40, 42, 43 to form these peptides [10, 27, 29–32, 32, 49, 51, 52]. The γ-secretase cleavages of APP–βCTF or αCTF release the AICD, which forms a multimeric complex with Fe 65, a nuclear adaptor protein [23]. It has been suggested that the complex of Fe 65 and Aβ or Fe 65 alone (in a new conformation), enters the nucleus and binds to the histone acetyltransferase, Tip60, to influence gene transcription [23]. This signaling mechanism is analogous to that occurring in the Notch1 pathway following the S3 cleavage of NEXT to produce NICD [28, 31]. In other cells in other organs, APP can also be cleaved endoproteolytically within the Aβ sequence through alternative, nonamyloidogenic pathways involving α-secretase (TACE or *T*NF-*a*lpha *c*onverting *e*nzyme) or BACE2 [30, 53]. The α-secretase and BACE2 cleavages, which occur in non-neural tissues, preclude the formation of Aβ peptides and thus are thought to protect these organs from Aβ amyloidosis [43].

BACE1 and BACE2, encoded by genes on chromosomes 11 and 21, respectively, are transmembrane aspartyl proteases that are directly involved in the cleavages of APP [25, 26, 30, 50, 53, 54]. Analyses of cells and brains from BACE1$^{-/-}$ mice [26, 50] discloses that Aβ 1–40/42 and Aβ 11– 40/42 are not secreted in these samples [26, 50]. BACE1 is demonstrable in the CNS and immunoreactivity is visualized in some synaptic regions. BACE1 preferentially cleaves APP at the +11/+1 sites of Aβ in APP [26] and this enzyme is essential for the generation of Aβ [26, 50]. Significantly, APPswe is cleaved perhaps 100-fold more efficiently at the +1 site than is wild type APP. Thus, the presence of this mutation greatly increases BACE1 cleavage and accounts for the elevation of Aβ species in the presence of this mutation. It has been reported that the expression of BACE1 is increased in certain regions of brain from some cases of sporadic AD [55, 56]. Thus, BACE1 is the principal neuronal β-secretase and is responsible for the critical penultimate pro-amyloidogenic cleavages. Although BACE1 mRNA is present in a variety of tissues (particularly the pancreas), levels of this protein are low in most non-neural tissues. In the pancreas, BACE1 mRNA is high, but the transcript is alternatively spliced to produce a smaller protein incapable of cleaving APP.

BACE2 mRNA, present in a variety of systemic organs, is very low in neural tissues, except for scattered nuclei in the hypothalamus and brainstem. BACE2 activity appears to be virtually undetectable in brain regions involved in AD. BACE2 is responsible for generation of anti-amyloidogenic cleavages at +19/+20 of Aβ [53]. Thus, BACE2, an anti-amyloidogenic enzyme, acts like α-secretase or TACE which cleave between residues 16 and 17 of the Aβ peptide [7, 57].

γ-Secretase, essential for the regulated intramembraneous proteolysis of a variety of transmembrane proteins, is a multiprotein catalytic complex, which includes: PS; Nicastrin (Nct), a type I transmembrane glycoprotein [7, 27, 48, 51]; and Aph-1 and Pen-2, two multipass transmembrane proteins [7, 27–32, 32, 51, 52, 58, 59]. PS1 is isolated with γ-secretase under specific detergent soluble conditions; it is selectively crosslinked or photoaffinity-labeled by transition state inhibitors [60, 61]; substitutions of aspartate residues at D257 in TM 6 and at D385 in TM 7 have been reported to reduce secretion of Aβ and cleavage of Notch1 *in vitro*; PS1$^{-/-}$ cells show decreased levels of secretion of Aβ [27, 29, 51, 62]. Aph-1 and Pen-2 [27, 29, 59] are novel transmembrane proteins: Aph-1 has seven predicted transmembrane domains; and Pen-2 has two predicted transmembrane regions [27, 29].

The functions of these protein and their interactions with each other in the complex and in γ-secretase activity are not yet fully defined. PS1 may: act as an aspartyl protease itself; function as a cofactor critical for the activity of

γ-secretase; or play a role in trafficking of APP or proteins critical for enzyme activity to the proper compartment for γ-secretase cleavage [36, 61, 62]. In one model, Aph-1 and Nct form a pre-complex that interacts with PS; subsequently Pen-2 influences the cleavage of PS into two fragments; all proteins are critical for the activities of γ-secretase complex [51, 52].

Significantly, γ-secretase cleaves both Notch1 and APP [28], generating intracellular peptides termed NICD and AICD [23] which influence transcription [23, 28]. As described above, the AICD interacts with FE65, a cytosolic adapter; this interaction leads to a signal which influences transcription [23, 28]. Results of targeting of PS1, Nct and Aph-1 in mice [51, 52, 63, 64], which are described below, are consistent with the concept that PS1, Nct and Aph-1 [27, 29, 30, 65] are critical components of the γ-secretase complex. The phenotypes of targeted PS1, Nct, and Aph-1 mice are the result of impaired Notch1 signaling.

Transgenic strategies have been used to create models of Aβ amyloidosis. In mice, expression of APPswe or APP_{717} minigenes (with or without mutant PS1) leads to an Aβ amyloidosis in the CNS [66], with the severity of pathology influenced by the nature and levels of the expressed transgene and the specific mutation. Mice expressing both mutant APP and PS1 develop accelerated disease. In these animals, levels of Aβ (particularly Aβ 42) in brain are elevated, and diffuse Aβ deposits and neuritic plaques appear in the hippocampus and cortex. In transgenic mice generated at Johns Hopkins University by Dr David Borchelt [67–69], the pathology evolves in stages: levels of Aβ peptides in brain increase with age; over time, Aβ deposits appear to become increasingly abundant; swollen neurites develop in proximity to these deposits; and neuritic plaques are associated with glial responses. In these mice, aggregated tau and tangles are not detectable. The density of synaptic terminals is reduced and several neurotransmitter markers are decreased; in some settings, these abnormalities appear linked to deficiencies in synaptic transmission [47, 70]. Moreover, some lines of mice show degeneration of subsets of neurons. Although amyloid has been detected *in vivo* by invasive techniques [71], it has proved more difficult to detect Aβ with whole brain imaging.

The paucity of tau abnormalities in these various lines of mutant APP and PS1 mice described above may be related to differences in tau isoforms expressed in this species. Early efforts to express mutant tau transgenes in mice did not lead to striking clinical phenotypes or pathology. More recently, mice overexpressing tau show clinical signs, attributed to degeneration of motor axons [5]. When the prion or Thy1 promoters are used to drive tau_{P301L} (a mutation linked to autosomal dominant frontotemporal dementia with parkinsonism; see Ch. 45), tangles develop in neurons of the brain and spinal cord [72]. Mice expressing APPswe/tau_{P301L} exhibit enhanced tangle-like pathology in limbic system and olfactory cortex [73]. Moreover, when Aβ 42 fibrils are injected into specific brain regions of tau_{P301L} mice, the number of tangles is increased in those neurons projecting to sites of Aβ injection.

A triple transgenic mouse (3×Tg-AD) was created by microinjecting APPswe and tau_{P301L} into single cells derived from monozygous $PS1_{M146V}$ knockin mice [74]. These mice develop age-related plaques and tangles as well as deficits in LTP which appear to antedate overt pathology [74]. However, mice bearing both mutant tau and APP (or APP/PS1) or mutant tau mice injected with Aβ are not fully faithful models of fAD because the presence of the tau mutation alone is associated with the development of tangles.

Finally, learning deficits, problems in object recognition memory, and difficulties in performing tasks to assess spatial reference and working memory, have been identified in some of the lines of mutant mice with high levels of mutant transgene expression [70, 75]. Although these mice do not fully recapitulate the complete phenotype of AD, these animals are very useful subjects for research designed to examine disease mechanisms and to test novel therapies.

Gene targeting approaches have identified and validated certain genes as targets for therapy. To begin to understand the functions of some of the proteins thought to play roles in AD, investigators have targeted in mice a variety of genes encoding these proteins, including APP, *a*myloid *p*recursor *l*ike *p*roteins (APLPs), BACE1, PS1, Nct and Aph-1.

Homozygous $APP^{-/-}$ mice are viable and fertile, but appear to have subtle decreases in locomotor activity and forelimb grip strength. The absence of substantial phenotypes in $APP^{-/-}$ mice is thought to be related to functional redundancy of two amyloid-precursor-like proteins, APLP1 and APLP2, homologous to APP. $APLP2^{-/-}$ mice appear relatively normal, while $APLP1^{-/-}$ mice exhibit a postnatal growth deficit [76]. $APLP1^{-/-}$ mice are viable, but $APP/APLP2^{-/-}$ mice and $APLP1/APLP2^{-/-}$ mice do not survive the perinatal period [76]. These observations support the concept that some redundancy exists between members of this interesting family of proteins [76].

$BACE1^{-/-}$ mice are viable and healthy, have no obvious phenotype or pathology, and can mate successfully [26, 50]. Importantly, cortical neurons cultured from $BACE1^{-/-}$ embryos do not show cleavages at the +1 and +11 sites of Aβ, and the secretion of Aβ peptides is abolished even in the presence of elevated levels of exogenous wt or mutant APP [26]. The brains of $BACE1^{-/-}$ mice appear morphologically normal and Aβ peptides are not produced [26, 50]. These results establish that BACE1 is the neuronal β-secretase required to generate the *N*-termini of Aβ [26]. At present, a consensus has not been reached with regards to other substrates cleaved by BACE1 [30]. Moreover, preliminary behavioral studies of the $BACE1^{-/-}$ mice indicate that these animals show altered performance on some tests

of cognition and emotion. Nevertheless, BACE1 appears to be an outstanding target for development of an anti-amyloidogenic therapy.

PS1$^{-/-}$ mice, in contrast to BACE1$^{-/-}$ mice, do not survive beyond the early postnatal period and show severe developmental abnormalities of the axial skeleton, ribs and spinal ganglia; resembling a partial Notch1$^{-/-}$ phenotype [63, 64], these features occur because PS1 (along with Nct, Aph-1 and Pen-2) are components of the γ-secretase complex that carries out the S3 intramembranous cleavage of Notch1 [27–29, 48, 51, 77, 78]. Without this cleavage, NICD is not released from the plasma membrane and, therefore, the signal does not reach the nucleus to initiate transcriptional processes essential for cell fate decisions. PS2$^{-/-}$ mice are viable and fertile, although they develop age-associated mild pulmonary fibrosis and hemorrhage. Mice lacking PS1 and PS2 die midway through gestation showing a Notch1$^{-/-}$ phenotype.

Nct$^{-/-}$ embryos die by embryonic day 10.5 and exhibit several developmental patterning defects, including abnormal segmentation of somites; the phenotype closely resembles that seen in embryos lacking Notch1 or both PS. Importantly, secretion of Aβ peptides is abolished in Nct$^{-/-}$ fibroblasts, whereas it is reduced by ~50% in NctT$^{+/-}$ cells [51]. The failure to generate Aβ peptides in NctT$^{-/-}$ cells is accompanied by destabilization of the β-secretase complex and by accumulation of APP *C*-terminal fragments. Moreover, analysis of APP trafficking in NctT$^{-/-}$ fibroblasts reveals a significant delay in the rate of APP re-internalization compared with that of control cells.

To determine the contributions of mammalian Aph-1 homologs in formation of functional γ-secretase complexes, we generated Aph-1a$^{-/-}$ mice [52]. As compared to littermate controls, the development of Aph-1a$^{-/-}$ embryos was dramatically retarded by embryonic day 9.5 and exhibited patterning defects that resemble, but are not identical to those of Notch1, Nct or PS$^{-/-}$ embryos. Moreover, in immortalized Aph-1a$^{-/-}$ fibroblasts, the levels of Nct, PS fragments and Pen-2 are dramatically decreased. Consequently, deletion of Aph-1a results in significant reductions in levels of the high molecular weight γ-secretase complex and in the secretion of Aβ. Three murine Aph-1 alleles, termed Aph-1a, Aph-1b and Aph-1c, encode four distinct Aph-1 isoforms: Aph-1aL and Aph-1aS derived from differential splicing of Aph-1a, Aph-1b and Aph-1c [52]. Importantly, complementation analysis reveals that all mammalian Aph-1 isoforms are capable of restoring the levels of Nct, PS and Pen-2 in Aph-1a$^{-/-}$ cells. Taken together, the findings establish that Aph-1a is the major mammalian Aph-1 homolog present in PS-dependent γ-secretase complexes during embryogenesis, and support the view that mammalian Aph-1 isoforms define a set of functional γ-secretase complexes.

Transgenic mouse models are being used to test a variety of novel therapies, including ways of reducing secretase activities and decreasing Aβ burden by Aβ immunotherapy. Many experimental therapeutic efforts have focused on influencing Aβ production (by inhibiting or modulating secretase activities), the aggregation of Aβ, its clearance, and the neurotoxicity of Aβ 42 [9, 10, 79]. Although mutant transgenic mice do not recapitulate the full phenotype of AD, they represent excellent models of Aβ amyloidosis and are highly suitable for identification of therapeutic targets, and for testing new treatments *in vitro*. Because it is not possible to discuss all treatment efforts in transgenic mice here, we focus on a few selected studies to illustrate experimental therapeutic strategies.

BACE1 is the principal β-secretase in neurons *in vitro*, BACE1-deficient neurons fail to secrete Aβ even when co-expressing the APPswe and mutant PS1 genes [25, 26, 36, 43, 50]. Significantly, BACE1$^{-/-}$, APPswe, PS1ΔE9 mice do not develop the Aβ deposits and age-associated abnormalities in working memory that occur in the APPswe, PS1ΔE9 model of Aβ amyloidosis [67]. Similarly, BACE1$^{-/-}$ TG2576 mice appear to be rescued from age dependent memory deficits and physiological abnormalities [80]. These data indicate that BACE1 is a very attractive therapeutic target. However, BACE1$^{-/-}$ mice develop abnormalities in performance of tasks assessing cognition and emotion, which can be rescued if APP is overexpressed in brain. In trials, it will be important to critically examine the influences of BACE1 inhibitors on memory, cognition and emotion.

The γ-secretase complex catalyzes the final cleavage of APP, which liberates the Aβ peptide into the extracellular space (amyloid deposits) [9, 10, 27, 30–32, 51, 52]. As demonstrated by the gene targeting strategies described above, this complex is critically dependent upon the presence of PS1 and 2, Nct, Aph-1a and Pen-2. Because reductions in these components decrease levels of Aβ, γ-secretase activity is a significant target for therapy. Inhibition of γ-secretase decreases production of Aβ in cell-free and cell-based systems and in levels of Aβ mutant mice with Aβ amyloidosis. However, γ-secretase activity is also essential for Notch processing critical for lineage specification and cell growth during embryonic development. Inhibitors could influence these activities. Significantly, LY-411, 575 not only reduced production of Aβ, but it also had profound effects on T and B cell development and on the appearance of intestinal mucosa (proliferation of goblet cells, increased mucin in gut lumen and crypt necrosis). Thus, several adverse effects could occur following inhibition of this enzyme, and it will be important for investigators to be alert for these effects.

Many pharmaceutical and biotechnology companies, and some academic laboratories, are using high throughput screen and molecular modeling strategies to discover compounds that inhibit these enzyme activities [9, 10, 32, 36]. Once lead compounds are identified, medicinal chemists will modify these compounds to enhance efficacy, allow passage through the blood–brain barrier, and reduce any potential toxicities.

Aβ immunotherapy has been used in both prevention and treatment trials in mutant mice. Both Aβ immunization (with Freund's adjuvant) and passive transfer of Aβ antibodies reduce levels of Aβ and plaque burden in

mutant APP and APP/PS1 transgenic mice [79, 81–87]. Efficacy seems to be related to antibody titer. The mechanisms of enhanced clearance are not certain, but two, not mutually exclusive, hypotheses have been suggested:

1. A small amount of Aβ antibody reaches the brain, binds to Aβ peptides, promotes the disassembly of fibrils, and, via the Fc antibody domain, encourages activated microglia to enter the affected region and remove Aβ [86]; and/or
2. Serum antibodies serve as a sink to draw the amyloid peptides from the brain into the circulation, thus changing the equilibrium of Aβ in different compartments and promoting removal of Aβ from the brain [82, 84, 85, 88].

Significantly, immunotherapy in transgenic mice is successful in partially clearing Aβ, in attenuating learning and behavioral deficits in at least two cohorts of mutant APP mice, and in reducing tau abnormalities in the triple transgenic mice [83–85].

Several of these experimental approaches are moving into clinical trials. Presently available therapies for patients include: cholinesterase inhibitors; agents that influence glutamate neurotransmission; neuroprotective and anti-inflammatory approaches; pharmacological agents useful for behavioral disturbances [1]; and statins that reduce brain amyloid burden [89]. However, these approaches do not directly influence the disease process, and new disease-modifying treatments are the major unmet need in AD. In addition to the investigations described, a variety of other treatments are being tested in model systems.

The identification of genes mutated or deleted in the inherited forms of AD has allowed investigators to create *in vivo* and *in vitro* model systems relevant to this illness. In this review, we have emphasized the value of transgenic and gene-targeted models and the lessons they provided for understanding mechanisms of AD, for identifying therapeutic targets and for testing new treatments in models.

First, for illustrative purposes, we focused on studies of the progeny of BACE1$^{-/-}$ mice and mutant APP/PS1 transgenic mice, which provides a dramatic example of the impact of reducing activity of secretases. New models using conditional expression systems, or RNAi silencing, will allow investigators to examine the pathogenesis of diseases and to assess the degrees of irreversibility of the disease processes. The results of these approaches will provide us with a better understanding of the mechanisms that lead to diseases and help us to design new treatments.

Second, we described the successful outcomes of Aβ immunotherapy in mutant mice with Aβ amyloidosis. Unfortunately, in humans, although Phase 1 trials with Aβ peptide and adjuvant vaccination were not associated with any adverse events, Phase 2 trials were suspended because of severe adverse reactions (meningoencephalitis) in a subset of patients [79, 90]. The pathology in a single case, consistent with T-cell meningitis [90], was interpreted to show some clearance of Aβ deposits, yet these regions contained a relatively high density of tangles, neuropil threads and vascular amyloid deposits [90]. In some regions, Aβ immunoreactivity was associated with microglia. T-cells were conspicuous in subarachnoid space and around some vessels [90]. The trial was truncated. The events occurring in this subset of patients illustrate the challenges of extrapolating outcomes in mutant mice to human trials. Interestingly, assessment of cognitive functions in a small subset of patients (30) who received vaccination and booster immunizations, disclosed that patients who generated Aβ antibodies as measured by a new assay, had a slower decline in several functional measures over time [91]. Investigators have continued to pursue the passive immunization approach and attempting to make antigens that do not stimulate T-cell-mediated immunologic attacks [79].

The lines of research described above have greatly enhanced our understanding of AD. We are now on the threshold of implementation of novel treatments, based on an understanding of the neurobiology and biochemistry of the illness. We anticipate that future discoveries will lead to the design of new mechanism-based therapies that can be tested in models of AD, and, eventually, these approaches can be introduced into clinical settings for the benefit of patients with this devastating disease. We are confident that parallel strategies will provide similar benefits for the treatment of other diseases of the nervous system.

ACKNOWLEDGMENTS

The authors wish to thank the many colleagues who have worked at JHMI, as well as those at other institutions for their contributions to some of the original work cited in this review and for their helpful discussions. Aspects of this work were supported by grants from the U.S. Public Health Service (AG05146, NS41438, NS45150, NS049088, AG14248) as well as the Metropolitan Life Foundation, Adler Foundation, Alzheimer's Association, CART Foundation, and Bristol-Myers Squibb Foundation.

CELL DEATH IN PRION DISEASE 801
The mechanism of prion-mediated neurodegeneration is unknown 801
Depletion of neuronal PrP during infection prevents prion neurotoxicity 801

FUTURE PERSPECTIVES 802

INTRODUCTION

The prion diseases are a closely related group of neurodegenerative conditions which affect both humans and animals. They have previously been described as the subacute spongiform encephalopathies, slow virus diseases and transmissible dementias, and include scrapie in sheep, bovine spongiform encephalopathy (BSE) in cattle, and the human prion diseases, Creutzfeldt–Jakob disease (CJD), Gerstmann–Sträussler–Scheinker disease (GSS), fatal familial insomnia (FFI) and kuru. Prion diseases are

Basic Neurochemistry: Molecular, Cellular and Medical Aspects
0-12-088397-X

unique in biology in that they manifest as sporadic, genetic and infectious disorders. Although historically rare in humans, affecting about one person per million worldwide per annum, the appearance of a novel human prion disease, variant CJD (vCJD), and the experimental confirmation that this is caused by the same prion strain as that causing BSE in cattle, has raised the possibility that a major epidemic of vCJD will occur within the U. K. and other European countries as a result of dietary or other exposure to BSE prions. These concerns, together with those of potential iatrogenic transmission of preclinical vCJD via medical and surgical procedures, have led to intense efforts to understand the molecular basis of prion propagation and to develop rational therapies.

PRION DISEASES ARE BIOLOGICALLY UNIQUE

Discovery of the prion protein. The demonstration of transmission of prion disease by inoculation of scrapie brain isolates into sheep, and kuru, CJD and GSS brain isolates into primates, formed the basis for the concept of 'transmissible dementias'; however, the nature of the transmissible agent has been a subject of heated debate for many years. The understandable initial assumption that the agent must be some form of virus was challenged by the failure to directly demonstrate such a virus (or indeed any immunological response to it) and by evidence indicating that the transmissible agent showed remarkable resistance to treatment expected to inactivate nucleic acids. Such findings led to suggestions that the transmissible agent may be devoid of nucleic acid [1], and might be a protein [2]. Subsequently, the progressive enrichment of brain homogenates for prion infectivity resulted in the isolation of a protease resistant sialoglycoprotein, designated the prion protein (PrP), by Prusiner and co-workers in 1982. This protein was the major constituent of infective fractions and was found to accumulate in affected brains and sometimes to form amyloid deposits. The term prion (from ***pro***teinaceous ***in***fectious particle) was proposed by Prusiner to distinguish the infectious pathogen from viruses or viroids. Prions were defined as 'small proteinaceous infectious particles that resist inactivation by procedures which modify nucleic acids' [3].

Prion protein is host encoded. At the time of its isolation, PrP was assumed to be encoded by a gene within the putative slow virus thought to be responsible for these diseases. However, amino-acid sequencing of part of PrP, and the subsequent recovery of cognate cDNA clones using an isocoding mixture of oligonucleotides, led to the realization that PrP was encoded by a single-copy chromosomal gene, rather than by a putative nucleic acid in fractions enriched for scrapie infectivity [4].

Aberrant metabolism of the prion protein is the central feature of prion diseases. It is now clear that the central and unifying hallmark of the prion diseases is the aberrant metabolism of PrP, which exists in at least two conformational states with different physicochemical properties. The normal cellular form of the protein, referred to as PrP^{C}, is a highly conserved cell surface glycosylphosphatidylinositol (GPI)-anchored sialoglycoprotein that is sensitive to protease treatment and soluble in detergents. The disease-associated scrapie isoform, referred to as PrP^{Sc} is found only in prion infected tissue as aggregated material, is partially resistant to protease treatment and insoluble in detergents. Due to its physiochemical properties the precise atomic structure of the infectious particle or prion is still undetermined but considerable evidence argues that prions are composed largely, if not entirely, of an abnormal isoform of PrP. The essential role of host PrP for prion propagation and pathogenesis is demonstrated by the fact that knockout mice lacking the PrP gene ($Prnp^{0/0}$ mice) are entirely resistant to prion infection, and that reintroduction of the murine PrP transgene restores susceptibility to infection [4]. For a comprehensive review of prion disease biology see [5].

ANIMAL PRION DISEASES

Scrapie and BSE. Scrapie is the prototypic prion disease, and has been recognized as an enzootic disease of sheep and goats for more than 250 years. The etiology of natural scrapie has been the subject of intense debate for many years, but it is now clear that it is an infectious disease, for which susceptibility is genetically modulated by the host [6]. Following its discovery in 1985, BSE reached epidemic proportions in cattle within the U. K., with smaller numbers in many other European countries. Epidemiologic studies point to contaminated offal used in the manufacture of meat and bone meal and fed to cattle as the source of prions responsible for BSE, although the nature and source of the original prion contamination remains unknown [7]. The host range of BSE appears to be unusually wide, affecting many other animal species. Foodstuffs contaminated with BSE appear to have caused prion disease in several other animal species in the U. K., including domestic cats, exotic ungulates and captive cats in zoos. In addition to these 'natural' infections, BSE has been experimentally transmitted to a wide variety of species.

Other animal prion diseases. Outbreaks of transmissible mink encephalopathy and chronic wasting disease in captive populations of mink, mule deer and elk in certain regions of the U.S.A. have also been attributed to prion-infected foodstuffs, although the origin of prion infection is unclear [8]. Epidemiological studies suggest lateral transmission as the most plausible explanation for the spread of chronic wasting disease in captive populations

of Rocky Mountain elk. Chronic wasting disease has also been diagnosed in free-ranging mule deer, Rocky Mountain elk and white-tailed deer from north-central Colorado [8].

HUMAN PRION DISEASES

Human prion diseases encompass the three etiological types of prion disease: inherited, sporadic and acquired forms.

Human prion disease most commonly presents with a sporadic etiology. Approximately 85 % of cases of human prion disease occur sporadically as Creutzfeldt–Jakob disease at a rate of roughly one case per million population per year across the world, with an equal incidence in men and women. The etiology of sporadic CJD is unknown, although hypotheses include somatic mutation in the human prion protein gene (*PRNP*), or the spontaneous conversion of PrP^{C} into PrP^{Sc} as a rare stochastic event. Homozygosity at a common coding polymorphism at codon 129 of *PRNP* encoding either methionine or valine predisposes to the development of sporadic CJD [9]. Additionally, a *PRNP* susceptibility haplotype has been identified indicating further genetic susceptibility to sporadic CJD at or near to the *PRNP* locus [5, 10].

Pathogenic mutations in the prion protein gene cause inherited prion disease. Approximately 15% of human prion diseases are associated with autosomal dominant pathogenic mutations in *PRNP* (Fig. 48-1). The identification of one of the pathogenic *PRNP* mutations in a case with neurodegenerative disease allows diagnosis of an inherited prion disease and subclassification according to mutation, and also permits presymptomatic genetic testing in affected families [5, 10, 11]. Over 50 pathogenic mutations have been described in two groups:

1. Point mutations resulting in amino acid substitutions in PrP or, in two cases, production of a stop codon resulting in expression of a truncated PrP;
2. Insertions encoding additional integral copies of an octapeptide repeat present in a tandem array of five copies in the normal protein (Fig. 48-1).

How pathogenic mutations in *PRNP* cause prion disease has yet to be resolved. However, in most cases the mutation is thought to lead to an increased tendency of PrP^{C} to form PrP^{Sc}, although there is evidence to suggest that this may not be solely attributable to decreased thermodynamic stability of mutated PrP^{C}. Experimentally manipulated mutations of the prion gene can lead to spontaneous neurodegeneration without the formation

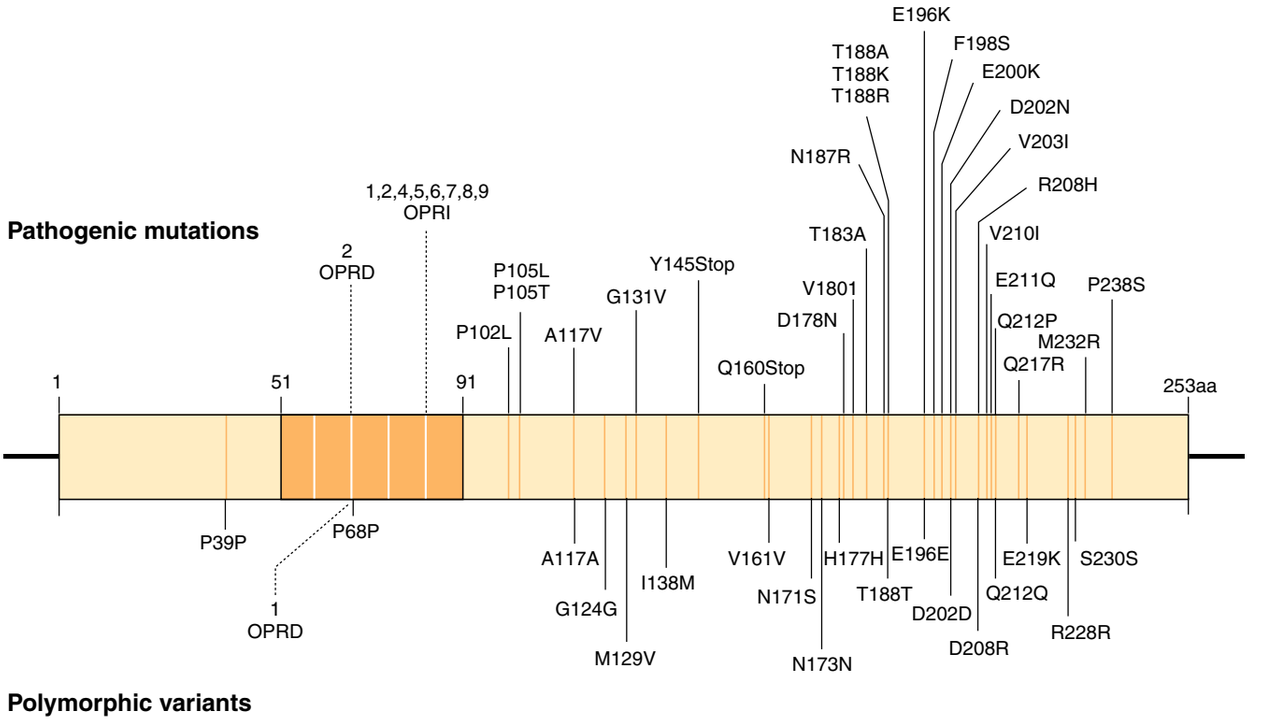

FIGURE 48-1 Pathogenic mutations and polymorphisms in the human prion protein. The pathogenic mutations associated with human prion disease are shown above the human PrP coding sequence. These consist of 1, 2 or 4-9 octapeptide repeat insertions (*ORPI*) within the octapeptide repeat region between codons 51 and 91, a 2-octapeptide repeat deletion (*ORPD*), and various point mutations causing missense or stop amino-acid substitutions. Point mutations are designated by the wild-type amino acid preceding the codon number, followed by the mutant residue, using single-letter amino-acid nomenclature. Polymorphic variants are shown below the PrP coding sequence.

of detectable protease resistant PrP. These findings raise the question of whether all inherited forms of human prion disease invoke disease through the same mechanism, and in this regard it is currently unknown whether all are transmissible by inoculation [5].

Acquired human prion diseases include kuru and variant CJD. Although the human prion diseases are transmissible diseases, acquired forms have, until recently, been confined to rare and unusual situations. The two most frequent causes of iatrogenic CJD occurring through medical procedures have arisen as a result of implantation of dura mater grafts, and treatment with human growth hormone derived from the pituitary glands of human cadavers [12]. Less-frequent incidences of human prion disease have resulted from iatrogenic transmission of CJD during corneal transplantation, contaminated electroencephalographic (EEG) electrode implantation and surgical operations using contaminated instruments or apparatus [12]. The most well-known incidences of acquired prion disease in humans resulting from a dietary origin have been kuru that was transmitted by cannibalism among the Fore linguistic group of the Eastern Highlands in Papua New Guinea [5, 13, 14], and more recently the occurrence of vCJD in the U. K. and other European countries which is causally related to BSE in cattle [5]. Incubation periods of acquired prion diseases in humans can be extremely prolonged, and it remains to be seen if a substantial epidemic of vCJD will occur within the U. K. and elsewhere [15].

Prion protein polymorphism contributes genetic susceptibility to prion disease. *PRNP* codon 129 polymorphism plays a key role in contributing genetic susceptibility to acquired human prion disease [5, 14, 16]. In iatrogenic CJD caused by exposure to contaminated pituitary hormones, *PRNP* codon 129 heterozygotes have a longer mean incubation period [12]. All cases of variant CJD to date have been methionine homozygotes while homozygotes of either allele have an earlier age of onset for kuru [5, 14]. Kuru imposed strong balancing selection on the Fore population essentially eliminating *PRNP* 129 homozygotes. Elderly survivors of the kuru epidemic, who had multiple exposures at mortuary feasts, are, in marked contrast to younger unexposed Fore, predominantly *PRNP* 129 heterozygotes. Worldwide *PRNP* haplotype diversity and coding allele frequencies suggest that kuru-like epidemics imposed strong balancing selection at this locus during the evolution of modern humans [14].

Human prion diseases are clinically heterogeneous. All forms of human prion disease are invariably fatal following clinical onset; however, there is marked phenotypic variability depending upon etiology. Progressive dementia, cerebellar ataxia, pyramidal signs, chorea, myoclonus, extrapyramidal features, pseudobulbar signs, seizures and amyotrophic features are seen in variable combinations. The clinical presentation in classical CJD is a rapidly progressive dementia accompanied by myoclonus, followed by decline to akinetic mutism and death often within 3–4 months. Traditionally, inherited prion diseases have been classified by the presenting clinical syndrome, falling into three main subdivisions of either GSS, CJD or FFI. GSS classically presents as a chronic cerebellar ataxia with pyramidal features, with dementia occurring much later in a clinical course that is typically longer than that seen in classical CJD. FFI is characterized by progressive untreatable insomnia, dysautonomia, dementia and selective thalamic degeneration and is most commonly associated with a missense mutation at codon 178 of *PRNP*, although sporadic FFI with no causative mutation in *PRNP* has been reported. The availability of direct gene markers for inherited prion diseases has enabled identification of highly atypical cases and has widened the known phenotypic range for these disorders.

Some families show remarkable phenotypic variability that can encompass both CJD- and GSS- like cases as well as other cases that do not conform to CJD, GSS or FFI phenotypes. Because of the extensive phenotypic variability seen in inherited prion disease and its ability to mimic other neurodegenerative conditions, notably Alzheimer's disease, prion protein gene analysis should be considered in the investigation of all presenile ataxias and dementias, even in the absence of an apparent family history of neurodegenerative illness. The clinical features of kuru consist of a progressive cerebellar ataxia accompanied by dementia in the later stages and death, which usually occurs within 12 months. Iatrogenic prion disease arising from intracerebral or optic inoculation usually manifests clinically as classical CJD, while those arising from a peripheral route of inoculation, such as pituitary growth hormone commonly present with a progressive ataxia. The early clinical presentation of vCJD resembles kuru more than classical CJD and consists of behavioral and psychiatric disturbances, peripheral sensory disturbance and cerebellar ataxia. For reviews on human prion disease see [5, 10, 17].

PRION DISEASE PATHOLOGY AND PATHOGENESIS

Peripheral pathogenesis involves the lymphoreticular system. Although the pathological consequences of prion infection occur in the central nervous system, and experimental transmission of these diseases is most efficiently accomplished by intracerebral inoculation, most natural infections do not occur by these means. Indeed, administration to sites other than the central nervous system is known to be associated with much longer incubation periods, which may extend to 20 years or more [5, 12]. Experimental evidence suggests that this latent period is associated with clinically silent prion replication in

lymphoreticular tissue, whereas neuroinvasion takes place later. The *M* cells in the intestinal epithelium mediate prion entry from the gastrointestinal lumen into the body, and follicular dendritic cells (FDCs) are thought to be essential for prion replication and for accumulation of disease-associated PrP^{Sc} within secondary lymphoid organs. B-cell deficient mice are resistant to intraperitoneal inoculation with prions probably because of their involvement with FDC maturation and maintenance. The interface between FDCs and sympathetic nerves represents a critical site for the transfer of lymphoid prions into the nervous system; however, the mechanism by which this is achieved remains unknown. Distinct forms of prion disease show differences in lymphoreticular involvement that may be related to the etiology of the disease or to divergent properties of distinct prion strains. For a review of prion disease peripheral pathogenesis see [18].

Prion disease produces characteristic pathology in the central nervous system. The brains of patients or animals with prion disease frequently show no recognizable abnormalities on gross examination at necropsy; however, microscopic examination of the central nervous system typically reveals characteristic histopathologic changes, consisting of neuronal vacuolation and degeneration, which gives the cerebral gray matter a microvacuolated or 'spongiform' appearance, and a reactive proliferation of astroglial cells. For a review see [19]. Although spongiform degeneration is frequently detected, it is not an obligatory neuropathologic feature of prion disease; astrocytic gliosis, although not specific to the prion diseases, is more constantly seen. The lack of an inflammatory response is also an important characteristic. Demonstration of abnormal PrP immunoreactivity, or more specifically biochemical detection of PrP^{Sc} in brain material by immunoblotting techniques is diagnostic of prion disease and some forms of prion disease are characterized by deposition of amyloid plaques composed of insoluble aggregates of PrP [19]. Amyloid plaques are a notable feature of kuru and GSS, but they are less frequently found in the brains of patients with sporadic CJD which typically show a diffuse pattern of abnormal PrP deposition (Fig. 48-2).

The histopathologic features of vCJD are remarkably consistent and distinguish it from other human prion diseases with large numbers of PrP-positive amyloid plaques that differ in morphology from the plaques seen in kuru and GSS, in that the surrounding tissue takes on a microvacuolated appearance, giving the plaques a florid appearance (Fig. 48-2). vCJD is distinct in its pathogenesis from other human prion diseases, as PrP^{Sc} is readily detectable in lymphoreticular tissues in vCJD, and not in classical CJD or inherited cases of human prion disease. Tonsil biopsy is used for antemortem diagnosis of vCJD and, to date, has shown 100% sensitivity and specificity for diagnosis of vCJD at an early clinical stage. The demonstration of extensive lymphoreticular involvement in the peripheral pathogenesis of vCJD raises concerns that iatrogenic transmission of vCJD prions through medical procedures may be a major public health issue [5, 10].

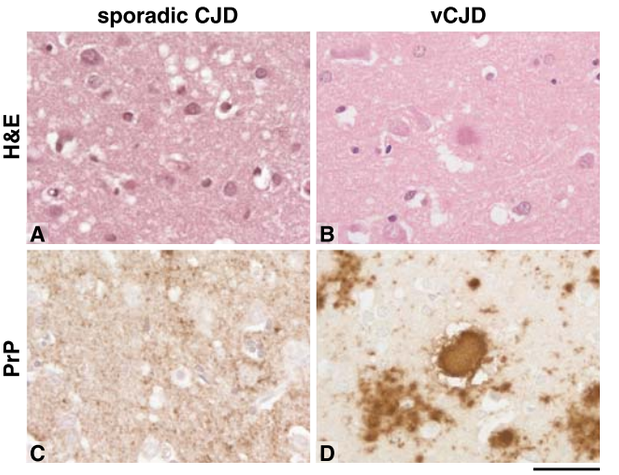

FIGURE 48-2 Prion disease pathology. Serial brain sections from sporadic CJD (**A**, **C**) and vCJD (**B**, **D**) show spongiform neurodegeneration following hematoxylin and eosin staining (*H&E*) and abnormal PrP immunoreactivity following immunohistochemistry using an anti-PrP monoclonal antibody (*PrP*). Abnormal PrP deposition in sporadic CJD most commonly presents as diffuse, synaptic staining, whereas vCJD is distinguished by the presence of florid PrP plaques consisting of a round amyloid core surrounded by a ring of spongiform vacuoles. Scale bar: 50 μm. Figure courtesy of Dr Sebastian Brandner.

THE PROTEIN-ONLY HYPOTHESIS OF PRION PROPAGATION

A wide body of data now supports the idea that infectious prions consist principally or entirely of an abnormal isoform of PrP. Disease associated PrP, designated PrP^{Sc}, is derived from PrP^{C} by a post-translational mechanism and neither amino acid sequencing nor systematic study of known covalent post-translational modifications have shown any consistent differences between PrP^{C} and PrP^{Sc} [5, 20].

Prion propagation involves conversion of PrP^{C} to PrP^{Sc}. The protein-only hypothesis, in its current form, argues that prion propagation occurs through PrP^{Sc} acting to replicate itself with high fidelity by recruiting endogenous PrP^{C}, and that this conversion involves only conformational change [5;20]. However, the underlying molecular events during infection that lead to the conversion of PrP^{C} to PrP^{Sc} and how PrP^{Sc} accumulation leads to neurodegeneration remain poorly defined. The most coherent and general model thus far proposed is that the protein PrP fluctuates between a dominant native state, PrP^{C}, and a series of minor conformations, one or a set of which can self-associate in an ordered manner to produce a stable supramolecular structure, PrP^{Sc}, composed of misfolded

PrP monomers. Once a stable 'seed' structure is formed, PrP can then be recruited leading to an explosive, autocatalytic formation of PrP^{Sc}. Such a mechanism could underlie prion propagation and account for the transmitted, sporadic and inherited etiologies of prion disease. Initiation of a pathogenic self-propagating conversion reaction, with accumulation of aggregated PrP, may be induced by exposure to a 'seed' of aggregated PrP following prion inoculation, or as a rare stochastic conformational change, or as an inevitable consequence of expression of a pathogenic PrP^{C} mutant which is predisposed to form misfolded PrP (Fig. 48-3). Such a system would be extremely sensitive to three factors:

1. Overall PrP^{C} concentration;
2. The equilibrium distribution between the native conformation and the self-associating conformation;
3. Complimentarity between surfaces which come together in the aggregation step.

All three of these predictions from this minimal model are manifest in the etiology of prion disease: an inversely proportional relationship between PrP^{C} expression and prion incubation period in transgenic mice; predisposition by relatively subtle mutations in the protein sequence; and a requirement for molecular homogeneity between PrP^{Sc} and PrP^{C} for efficient prion propagation [4, 5, 20]. It is clear that a full understanding of prion propagation will require knowledge both of the structure of PrP^{C} and PrP^{Sc} and of the mechanism of conversion between them.

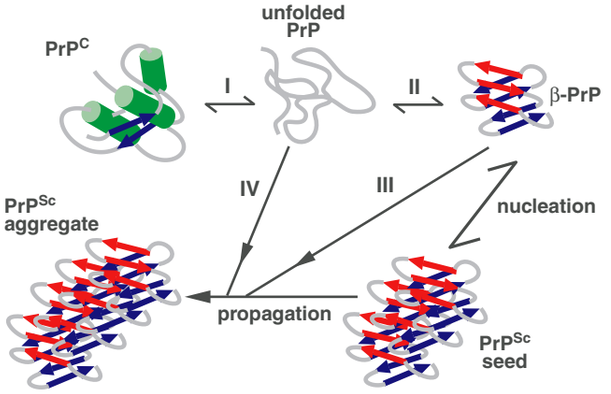

FIGURE 48-3 The protein-only model of prion propagation. The schematic shows a plausible mechanism that could account for prion propagation. α-helical cellular isoforms of prion protein (*PrP^{C}*) proceed via an unfolded state (*I*) to refold into a predominantly β-sheet rich form, *β-PrP* (*II*). Aggregation of β-PrP may form a critical 'seed' of PrP^{Sc} which then propagates, essentially irreversibly, through further recruitment of β-PrP monomers (*III*) or unfolded PrP monomers (*IV*). This mechanism can account for the transmitted, sporadic and inherited etiologies of prion disease. Initiation of a pathogenic self-propagating conversion reaction may be induced by exposure to a 'seed' of PrP^{Sc} following prion inoculation, or as a rare stochastic conformational change in wild-type PrP^{C}, or as an inevitable consequence of expression of a pathogenic PrP^{C} mutant that is predisposed to form β-PrP.

CHARACTERIZATION OF PrP^{C}

PrP^{C} has a predominantly α-helical conformation. The conformation of the cellular isoform of PrP was first established by NMR measurements made on the recombinant mouse protein. Since then, NMR measurements on recombinant hamster and human PrP show that they have essentially the same conformation, and these data have been supported by crystallographic determination of the structure of a human PrP dimer. For reviews see [5, 21, 22]. Following cleavage of an *N*-terminal signal peptide, and removal of a *C*-terminal peptide on addition of a GPI anchor, the mature PrP^{C} species consists of an *N*-terminal region of about 100 amino acids, which is unstructured in the isolated molecule in solution, and a *C*-terminal segment, also around 100 amino acids in length. The *C*-terminal domain is folded into a largely α-helical conformation (three α-helices and a short anti-parallel β-sheet) and stabilized by a single disulfide bond linking helices 2 and 3 (Fig. 48-4). There are two asparagine-linked glycosylation sites (Fig. 48-4). The *N*-terminal region contains a segment of five repeats of an eight-amino acid sequence (the octapeptide-repeat region), expansion of which by insertional mutation leads to inherited prion disease. While unstructured in the isolated molecule, this region contains a tight binding site for a single Cu^{2+} ion, with a second tight Cu^{2+} binding site present upstream of the octa-repeat region but before the structured *C*-terminal domain. Both high affinity Cu^{2+} binding sites can also bind Zn^{2+} ions with binding constants of physiological relevance, and it thus seems likely that the *N*-terminal region of PrP may acquire coordinated structure *in vivo* through coordination of either Cu^{2+} or Zn^{2+} ions [5].

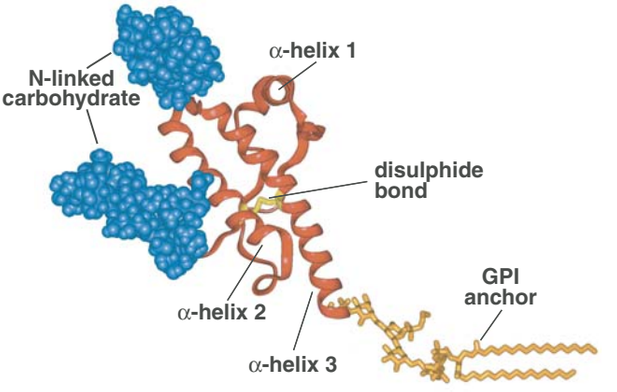

FIGURE 48-4 Model structure of PrP^{C}. The conformation of recombinant mouse PrP (residues 124–231) determined by NMR is shown in *red* ribbon. The single disulfide bridge linking α-helixes 2 and 3 is shown in *yellow*. *N*-linked carbohydrate groups are shown as space-filling structures in *blue*. The glycosylphosphatidylinositol (*GPI*) anchor that attaches PrP to the outer surface of the cell membrane is shown in *gold*.

The structured *C*-terminal domain folds and unfolds reversibly in response to chaotropic denaturants, and it appears there are no populated intermediates in the folding reaction and that the protein displays unusually rapid rates of folding and unfolding (for a review see [5]). These data suggest that PrP^{Sc} is unlikely to be formed from a kinetic folding intermediate, as has been hypothesized in the case of amyloid formation in other systems, and is more likely to be formed from the unfolded state of PrP. Pathogenic mutations in *PRNP* seen in inherited prion diseases may produce disease by destabilizing PrP^{C} which would predispose the molecule to aggregate. Alternatively, a mutation could facilitate the interaction between PrP^{C} and PrP^{Sc} or affect the binding of a ligand or co-protein.

Reverse genetics approaches to studying PrP^{C}. While $Prnp^{0/0}$ mice are completely resistant to prion infection, reconstitution of such mice with PrP transgenes restores susceptibility to prion infection in a species-specific manner, and allows a reverse genetics approach to study structure–function relationships in PrP (for reviews see [4, 23]). Expression of PrP *N*-terminal deletion mutants to residue 106 are tolerated and support prion propagation; however, deletion beyond this leads to severe ataxia and neuronal loss in the granular cell layer of the cerebellum [4]. This has led to the hypothesis that PrP and a structural homologue compete for the same receptor or ligand. An additional gene (*Prnd*) has been discovered downstream of the *Prnp* locus, that encodes a 179-residue protein with between 20% and 24% identity to PrP (depending upon the species), that is a plausible candidate for the putative competitor [4]. PrP in its entirety is unnecessary for prion propagation. Not only can the unstructured *N*-terminal 90 amino acids be deleted, but also the first α-helix, the second β-strand and part of helix 2. In transgenic animals, a 106 amino acid fragment of the protein comprising PrPΔ23–88Δ141–176 conferred susceptibility to and propagation of prions (for a review see [4]).

The function of PrP^{C} remains unknown. PrP is highly conserved among mammals, has been identified in marsupials, birds, amphibians and fish, and may be present in all vertebrates. It is expressed during early embryogenesis and is found in most tissues in the adult with the highest levels of expression in the central nervous system, in particular in association with synaptic membranes. PrP is also widely expressed in cells of the immune system. As a GPI-anchored cell surface glycoprotein, it has been speculated that PrP may have a role in cell adhesion or signaling processes, but its precise cellular function has remained obscure [5, 24]. Newly synthesized PrP^{C} is transported to the cell surface, from which it may cycle via either clathrin-coated vesicles or caveolae-dependent endocytic pathways. A range of PrP^{C} interacting molecules have been identified; however, despite a growing body of evidence suggesting that PrP^{C} may play a role in cell survival through interaction with apoptotic pathways, the *in vivo* relevance of such interactions has yet to be convincingly demonstrated. A role for PrP in copper or zinc metabolism or transport seems possible, and disturbance of this function by the conformational transition from normal to disease related isoforms of PrP may be involved in prion-related neurotoxicity.

PrP knockout mice have subtle abnormalities of synaptic transmission. Mice lacking PrP as a result of gene knockout ($Prnp^{0/0}$ mice) show no gross phenotype; however, these mice are completely resistant to prion disease following inoculation and do not replicate prions [4]. $Prnp^{0/0}$ mice do, however, show subtle abnormalities in synaptic physiology, in circadian rhythms and in sleep (for reviews see [4, 5]). In particular, abnormalities of inhibitory synaptic transmission in hippocampal slices with a reduced amplitude of the maximal inhibitory postsynaptic current have been observed, and this phenotype can be rescued by a reintroduction of a PrP transgene. A second physiological phenotype for $Prnp^{0/0}$ mice manifests as a reduction of slow afterhyperpolarizations evoked by trains of action potentials in hippocampal neurons, and is due to disruption of calcium-activated potassium currents. While the relative normality of $Prnp^{0/0}$ mice was thought to result from effective adaptive changes during development, data from *Prnp* conditional knockout mice suggest this is not the case [25]. These mice undergo ablation of neuronal PrP expression at 9 weeks of age and remain healthy without evidence of neurodegeneration or an overt clinical phenotype. These findings demonstrate that acute loss of neuronal PrP in adulthood is tolerated, and that the pathophysiology of prion diseases is not due to loss of normal PrP function in neurons. Notably, slow afterhyperpolarizations in hippocampal CA1 cells are affected by the conditional knockout of PrP, suggesting that this phenotype is specifically due to the absence of PrP, reflecting loss of a differentiated neuronal function, rather than a developmental deficit arising from congenital knockout of PrP [25].

CHARACTERIZATION OF PrP^{SC}

PrP^{Sc} has a predominantly β-sheet conformation. PrP^{Sc} is extracted from affected brains as highly aggregated, detergent-insoluble, material that is not amenable to high-resolution structural techniques. However, Fourier transform infrared spectroscopic methods show that PrP^{Sc}, in sharp contrast to PrP^{C}, has a high β-sheet content. PrP^{Sc} is covalently indistinguishable from PrP^{C} but can be distinguished from PrP^{C} by its partial resistance to proteolysis and its marked insolubility in detergents (for reviews see [20, 22]). Under conditions in which PrP^{C} exists as a detergent-soluble monomer and is completely degraded by the nonspecific protease, proteinase K, PrP^{Sc} exists in an aggregated form with the *C*-terminal two-thirds of the protein showing marked resistance to proteolytic degradation

leading to the generation of amino terminally truncated fragments of di-, mono- and non-glycosylated PrP (Fig. 48-5). For a particular PrP^{Sc} isoform all three PrP^{Sc} glycoforms show equivalent accessibility to proteinase K and are cleaved at the same point in the *N*-terminus of the protein (Fig. 48-5).

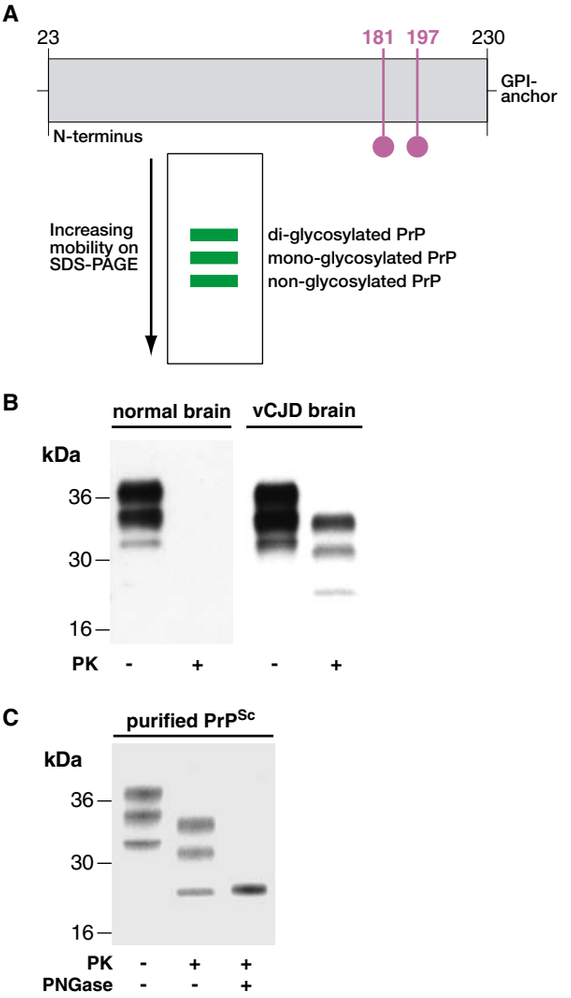

FIGURE 48-5 Western blot analysis of PrP. (**A**) Following cleavage of an *N*-terminal signal peptide, and removal of a *C*-terminal peptide on addition of a GPI anchor, mature human PrP^{C} consists of a 208-residue polypeptide that contains two sites for *N*-linked glycosylation at asparagine residues 181 and 197. PrP^{C} is expressed as di-, mono- and non-glycosylated forms giving rise to three principal PrP bands following sodium dodecyl sulfate polyacrylamine gel electrophoresis (SDS–PAGE). (**B**) Western blot analysis of normal human brain and vCJD brain homogenate before and after treatment with proteinase K (*PK*). PrP^{C} in both normal and vCJD brain is completely degraded by proteinase K, whereas PrP^{Sc} present in vCJD brain shows resistance to proteolytic degradation leading to the generation of amino terminally truncated fragments of di-, mono- and non-glycosylated PrP. (**C**) Western blot analysis of purified PrP^{Sc} from vCJD brain before and after treatment with proteinase K (*PK*) or after consecutive treatment with proteinase K and Peptide-*N*-glycosidase F (*PNGase*). Proteinase K cleaves at the same point in the *N*-terminus of all three PrP^{Sc} glycoforms as removal of *N*-linked carbohydrate with PNGase results in the generation of a single band corresponding to the non-glycosylated proteolytic fragment of PrP^{Sc}.

***In vitro* conversion of PrP^{C} to alternative conformations.** Defining the precise molecular events that occur during the conversion of benign PrP^{C} to the infectious isoform of PrP is of paramount importance, as this process is a prime target for therapeutic intervention. Direct *in vitro* mixing experiments have been performed in an attempt to produce PrP^{Sc}. In such experiments PrP^{Sc} is used as a seed to convert PrP^{C} to a protease resistant form, designated PrP^{Res}. While there are now many examples in the literature of conditions that generate PrP^{Res}, to date such reactions have proved inefficient and have not yet demonstrated *de novo* production of prion infectivity [26]. Despite the obvious limitations of such experiments they may represent an initial step in the generation of the infectious isoform of PrP, which requires additional, as yet unknown, co-factors for the acquisition of infectivity [26]. Seeded conversion has been used successfully to identify compounds that inhibit the *in vitro* generation of PrP^{Res}; however, none of these compounds has yet shown major therapeutic potential for inhibiting prion infectivity *in vivo*. More recently, immunotherapeutic approaches to treating prion disease have shown more promise. For a review of therapeutic approaches to treating prion diseases see [27].

Conversion of recombinant α-PrP to β-PrP as a model of prion propagation. The difficulty in performing structural studies on native PrP^{Sc} has led to attempts to produce soluble β-sheet rich forms of recombinant PrP, which may be amenable to NMR or crystallographic structure determination. Conditions have now been identified in which the PrP polypeptide can be converted between alternative folded conformations representative of PrP^{C} and PrP^{Sc}. At neutral or basic pH PrP adopts an α-helical fold representative of PrP^{C} and this conformation is locked by the presence of the native disulfide bond. Upon reduction of the disulfide bond, PrP^{C} rearranges to a predominantly β-sheet structure. This alternative conformation, designated β-PrP, is only populated at acidic pH with the PrP^{C} conformation predominating at neutral pH. Importantly, β-PrP shares overlapping properties with PrP^{Sc} , including partial resistance to proteolysis and a propensity to aggregate into fibrils [28]. This work suggests β-PrP may be an intermediate on the pathway to formation of PrP^{Sc}, and the conditions required to form β-PrP may be relevant to the conditions PrP^{C} would encounter within the cell during internalization and recycling. The low pH and reducing environment of the endosomal pathway would be a likely candidate, and, although this remains to be demonstrated, there is evidence implicating either late-endosome-like organelles or lysosomes as sites for PrP^{Sc} replication. It remains to be demonstrated whether alternative conformational states of recombinant PrP are sufficient to cause prion disease in an experimental host, or whether other cellular co-factors are also required.

THE MOLECULAR BASIS OF PRION STRAIN DIVERSITY

A major problem for the 'protein-only' hypothesis of prion propagation has been how to explain the existence of multiple isolates, or strains, of prions. Prion strains are distinguished by their biological properties: they produce distinct incubation periods and patterns of neuropathological targeting (so-called lesion profiles) in defined inbred mouse lines. For a review see [29]. As they can be serially propagated in inbred mice with the same *Prnp* genotype, they cannot be encoded by differences in PrP primary structure. Usually, distinct strains of conventional pathogen are explained by differences in their nucleic acid genome. However, in the absence of such a scrapie genome, alternative possibilities must be considered. Weissmann proposed a 'unified hypothesis' where, although the protein alone was argued to be sufficient to account for infectivity, it was proposed that strain characteristics could be encoded by a small cellular nucleic acid, or 'co-prion' [30]. Although this hypothesis leads to the testable prediction that strain characteristics, unlike infectivity, would be sensitive to UV irradiation, no such test has been reported. At the other extreme, the protein-only hypothesis would have to explain how a single polypeptide chain could encode multiple disease phenotypes. Clearly, understanding how a protein-only infectious agent could encode such phenotypic information is of considerable biological interest.

Prion strain diversity may be encoded by PrP itself. Support for the contention that strain specificity may be encoded by PrP itself was provided by study of two distinct strains of transmissible mink encephalopathy prions, which can be serially propagated in hamsters, designated 'hyper' and 'drowsy'. These strains can be distinguished by differing physiochemical properties of the accumulated PrP^{Sc} in the brains of affected hamsters. Following limited proteolysis, strain-specific migration patterns of PrP^{Sc} on western blots are seen, which relate to different *N*-terminal ends of PrP^{Sc} following protease treatment implying differing conformations of PrP^{Sc} [31]. Similarly, different human PrP^{Sc} isoforms have been found to propagate in the brain of patients with phenotypically distinct forms of CJD (for reviews see [5, 10]).

Distinct PrP^{Sc} types are seen in human prion disease. The different fragment sizes seen on western blots, following treatment with proteinase K, suggests that there are several different human PrP^{Sc} conformations, referred to as molecular strain types (Fig. 48-6). These types can be further classified by the ratio of the three PrP bands seen after protease digestion, corresponding to amino-terminally truncated cleavage products generated from di-, mono-, or non-glycosylated PrP^{Sc}. Four types of human PrP^{Sc} have now been commonly identified using molecular strain typing [5, 10, 32] (Fig. 48-6), although much greater

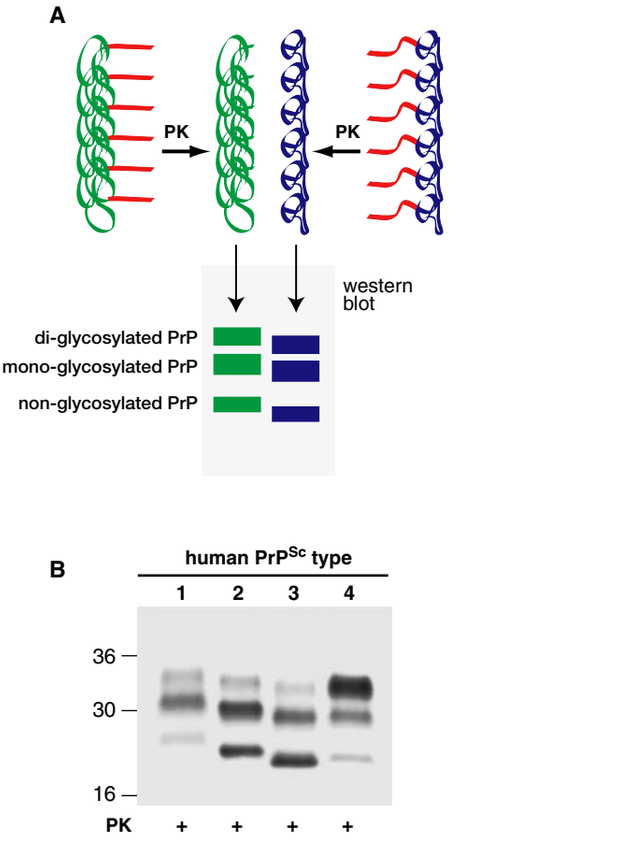

FIGURE 48-6 Molecular analysis of PrP^{Sc} isoforms. (**A**) The schematic demonstrates the principle of molecular stain typing of PrP^{Sc} isoforms by limited proteolytic digestion and western blotting. Two distinct aggregates of PrP^{Sc} with differing conformations (shown in *green* or *blue*) present different accessibilities to proteinase K within the *N*-terminal region of the protein (shown in *red*). Disparity in the most *C*-terminal scissile bond accessible to proteinase K results in a different mobility of *C*-terminal PrP^{Sc} proteolytic fragments generated from of di-, mono- and non-glycosylated PrP^{Sc} that can be visualized by western blotting. (**B**) Western blot showing proteinase K digestion products from distinct human PrP^{Sc} conformers designated PrP^{Sc} types 1–4. PrP^{Sc} types 1–3 are seen in the brain of classical forms of CJD (either sporadic or iatrogenic CJD), PrP^{Sc} type 4 is uniquely seen in vCJD brain and differs markedly in the proportions of di- and mono-glycosylated glycoforms.

heterogeneity seems likely [10]. Sporadic and iatrogenic CJD are associated with PrP^{Sc} types 1–3, while type 4 PrP^{Sc} is uniquely associated with vCJD, and is characterized by a fragment size and glycoform ratio that is distinct from PrP^{Sc} types 1–3, but similar to PrP^{Sc} seen in BSE and BSE when transmitted to several other species. PrP^{Sc} types 1 and 2 associated with clinically distinct subtypes of sporadic CJD have different *N*-terminal conformations determined by metal-ion binding, and such post-translational modification of PrP through coordination of copper and zinc ions provides a mechanism for the generation of multiple PrP^{Sc} conformers [10]. Polymorphism at *PRNP* residue 129 appears to place constraints upon the propagation of distinct PrP^{Sc} types in humans [5, 10], and it has

now become clear that prion strain selection and the propagation of distinct PrP^{Sc} types may be crucially influenced by other genetic loci of the host genome [33–35].

The hypothesis that alternative conformations or assembly states of PrP^{Sc} provide the molecular substrate for clinicopathological heterogeneity seen in human prion diseases (and that this relates to the existence of distinct human prion strains) has been strongly supported by transmission experiments to conventional and transgenic mice. Transgenic mice expressing human PrP with either valine or methionine at residue 129 have shown that this polymorphism constrains both the propagation of distinct human PrP^{Sc} conformers and the occurrence of associated patterns of neuropathology [5, 35]. These data strongly support the 'protein-only' hypothesis of infectivity, by suggesting that prion strain variation is encoded by a combination of PrP conformation and glycosylation [5]. These data also provide a molecular basis for *PRNP* codon 129 as a major locus influencing both prion disease susceptibility and phenotype in humans [5, 14].

Molecular strain typing facilitates investigation of prion disease etiology. The identification of strain-specific PrP^{Sc} structural properties now allows an etiology-based classification of human prion disease by typing of the infectious agent itself. Molecular strain typing of prion isolates is being applied in the molecular diagnosis of sporadic and variant CJD, and to produce a new classification of human prion diseases with implications for epidemiological studies investigating the etiologies of sporadic CJD and BSE-related human prion disease [5, 35]. Stratification of all human prion disease cases by PrP^{Sc} type will enable rapid recognition of any change in relative frequencies of particular PrP^{Sc} sub-types in relation to either BSE exposure patterns or iatrogenic sources of vCJD prions. Such methods allow strain typing to be performed in days rather than the 1–2 years required for classical biological strain typing. This technique may also be applicable to determining whether BSE has been transmitted to other species, thereby posing a threat to human health [5].

PRION TRANSMISSION BARRIERS

Prion transmission between species is limited by a barrier. A 'species barrier' restricts transmission of prion disease between different mammalian species. On primary passage of prions from species A to species B, usually not all inoculated animals of species B develop disease, and those that do have much longer and more variable incubation periods than those that are seen with transmission of prions within the same species. On second passage of infectivity to further animals of the species B, transmission parameters resemble within-species transmissions, with most if not all animals developing the disease with short and consistent incubation periods. Species barriers can therefore be quantified by measuring the fall in mean incubation period on primary and second passage, or, perhaps more rigorously, by a comparative titration study. The effect of a very substantial species barrier is that few, if any, animals succumb to clinical prion disease at all on primary passage, and then at incubation periods approaching the natural lifespan of the species concerned [5, 36].

Both PrP sequence and prion strain type influence prion transmission barriers. Early studies of the molecular basis of the species barrier argued that it principally resided in differences in PrP primary structure between the species from which the inoculum was derived and the inoculated host. However, it has been clear for many years that prion strain type also has a crucial effect on species barriers. For example, the natural transmission of BSE to a wide variety of hosts, and the subsequent demonstration that transmission of BSE from these different species (all with varied PrP primary amino acid sequences) to mice results in the maintenance of a 'BSE-like' strain, provides a key example of where effects from a prion strain appear more important than PrP primary sequence homology to such barriers [37]. Similarly, following transmission to transgenic mice expressing only human PrP there is disparity in the behavior of sporadic or vCJD prions that have originated in humans expressing wild-type PrP of identical primary sequence. Whereas sporadic CJD prions have transmission characteristics consistent with the complete absence of a species barrier, vCJD prions have transmission properties that are completely distinct from other human prions but closely similar to those of cattle BSE, and that are consistent with the presence of a barrier [5, 35]. The term 'species barrier' does not seem appropriate to describe such effects and the general term 'transmission barrier' now seems more preferable [5, 15, 36].

A conformational selection model of prion transmission barriers. Recently, a conformational selection model of prion transmission barriers has been proposed that encompasses contributions from both PrP sequence and strain-specific PrP^{Sc} structural properties [5, 15, 36]. Both PrP amino-acid sequence and strain type will affect the three-dimensional structure of glycosylated PrP, which will presumably, in turn, affect the efficiency of the protein–protein interactions thought to determine prion propagation. Mammalian PrP genes are highly conserved, and presumably only a restricted number of different PrP^{Sc} conformations (that are highly stable and can therefore be serially propagated) will be permissible thermodynamically, and will constitute the range of prion strains seen. PrP glycosylation may be important in stabilizing particular PrP^{Sc} conformations. While a significant number of different PrP^{Sc} conformations may be possible among the range of mammalian PrPs, only a subset of these would be allowable for a given single mammalian PrP sequence. Substantial overlap between the favored conformations for PrP^{Sc} derived from species A and species B might

therefore result in relatively easy transmission of prion diseases between these two species, while two species with no preferred PrP^{Sc} conformations in common would have a large barrier to transmission (and indeed transmission would necessitate a change of strain type). According to such a model of a prion transmission barrier, BSE may represent a thermodynamically highly favored PrP^{Sc} conformation that is permissive for PrP expressed in a wide range of different species, accounting for the remarkable promiscuity of this strain in mammals [5,36]. Contribution of other components to the species barrier are possible, and may involve interacting co-factors that mediate the efficiency of prion propagation, although no such factors have yet been convincingly identified [26].

Subclinical forms of prion disease pose a risk to public health. Recent data have further challenged our understanding of prion transmission barriers. The assessment of species barriers has historically relied on the development of a clinical disease in inoculated animals; however, during infection with prion diseases, infectious titres in the brain rise progressively throughout prolonged, clinically silent, incubation periods. Therefore, asymptomatic animals can have significant infectious titres in the brain and other tissues. However, subclinical forms of prion infection that are distinct from preclinical forms have now been recognized, in which animals become asymptomatic carriers of infectivity and do not develop clinical disease during a normal lifespan. Such carrier states are well recognized in other infectious diseases. The high incidence of subclinical prion infection seen in BSE- and vCJD-inoculated transgenic mice expressing human PrP [35], together with other recent data demonstrating extensive subclinical prion infection in other rodent models of prion disease [36], indicate that current definitions of transmission barriers (conventionally assessed on the basis of occurrence of clinical disease in inoculated animals), must be re-assessed.

Subclinical or carrier states of prion disease have major implications for public health, most notably iatrogenic transmission from apparently healthy individuals. The existence of subclinical prion infections also raise the possibility that other species (such as sheep, pigs and poultry), exposed to BSE prions by contaminated feed, might be able to develop subclinical carrier states. Given that BSE prions are pathogenic in a wide variety of species, and that the strain characteristics of BSE prions are retained upon transmission to new species, it must be considered possible, if not probable, that BSE in animals other than cattle will retain pathogenicity for humans.

CELL DEATH IN PRION DISEASE

The precise structure of the infectious agent and the cause of neuronal cell death in prion disease remain unclear. The current working hypothesis is that an abnormal isoform of PrP is the infectious agent. To date, the most highly enriched preparations contain one infectious unit per 10^5 PrP monomers; however, it is unclear whether this indicates that a large aggregate is necessary for infectivity, or at the other extreme, whether only a single one of these PrP^{Sc} molecules is actually infectious. The relationship of PrP^{Sc} molecules to infectivity could simply, however, relate to the rapid clearance of prions from the brain known to occur on intracerebral challenge.

The mechanism of prion-mediated neurodegeneration is unknown. Various hypotheses have been proposed to explain the mechanism of spongiform change and neuronal cell loss [38]. These have included direct neurotoxic effects from a region of the prion protein encompassing residues 106–126 (although this is controversial), to increased oxidative stress in neurones as a result of PrP^{C} depletion, which has been proposed to function as an antioxidant molecule. It has also been suggested that PrP^{C} plays a role in regulating apoptosis, with disturbance of normal cellular levels of PrP during infection leading to cell death. Although PrP^{C} expression is required for susceptibility to the disease, a number of observations argue that PrP^{Sc} and indeed prions (whether or not they are identical) may not themselves be highly neurotoxic. Prion diseases in which PrP^{Sc} is barely or not detectable have been described, and different strains of prions are known to differ in their degree of protease resistance [5]. Mice with reduced levels of PrP^{C} expression have extremely high levels of PrP^{Sc} and prions in the brain, and yet remain well for several months after their wild-type counterparts succumb. Conversely, transgenic mice, with high levels of murine PrP^{C}, have short incubation periods and yet produce low levels of PrP^{Sc} after inoculation with mouse prions [4]. In addition, wild-type brain grafts producing high levels of PrP^{Sc} do not damage adjacent tissue in $Prnp^{0/0}$ mice [38]. The demonstration that animals with subclinical prion infection can harbor high levels of prion infectivity and detectable PrP^{Sc} without exhibiting any clinical signs of prion disease challenges our understanding of the pathogenic mechanisms involved in these diseases [5, 36].

Depletion of neuronal PrP during infection prevents prion neurotoxicity. While the requirement for PrP to mediate neurodegeneration in prion disease remains absolute, conditional knockout of PrP indicates that prion neurodegeneration is unlikely to be related to gross loss of PrP^{C} function in neurons [25]. Based upon existing data it is possible to hypothesize that the neurotoxic prion molecule may not be PrP^{Sc} itself, but a toxic-intermediate that is produced in the process of conversion of PrP^{C} to PrP^{Sc}, with PrP^{Sc}, present as highly aggregated material, being a relatively inert end-product [5, 36]. The steady-state level of such a toxic monomeric or oligomeric PrP intermediate, designated PrP^{L} (for lethal), could determine the rate of neurodegeneration. Subclinical prion infection states may

generate the toxic intermediate at extremely low levels below the threshold required for neurotoxicity [5, 36].

Recently, direct support for this hypothesis has been demonstrated by depleting endogenous neuronal PrP^{C} in mice with established neuroinvasive prion infection. This depletion of PrP^{C} reverses early spongiform change and prevents neuronal loss and progression to clinical prion disease despite the accumulation of extraneuronal PrP^{Sc} to levels seen in terminally ill wild-type mice [39]. These data establish that propagation of non-neuronal PrP^{Sc} is not pathogenic, but arresting the continued conversion of PrP^{C} to PrP^{Sc} within neurons during scrapie infection prevents prion neurotoxicity.

FUTURE PERSPECTIVES

Prion diseases appear to be disorders of protein conformation, and elucidating their precise molecular mechanisms may be of far wider pathological significance. It is of considerable interest that many of the commoner neurodegenerative diseases, such as Alzheimer's disease, Parkinson's disease and Huntington's disease are also associated with abnormal protein aggregates. The apparent ability of a single polypeptide chain to encode information and specify distinctive phenotypes is unprecedented, and it seems unlikely that evolution will not have used this mechanism in many other ways. While the protein-only hypothesis of prion propagation is supported by compelling experimental data, and now appears also able to encompass the phenomenon of prion strain diversity, the goal of producing prions *in vitro* remains. Success in producing disease in experimental animals that can be serially propagated following inoculation with PrP^{Sc}-like forms derived from recombinant PrP would not only prove the protein-only hypothesis, but would provide an essential model by which the mechanism of prion propagation could be understood in molecular detail.

PHYSIOLOGICAL BACKGROUND

The eye is a remarkable photosensor that can detect a single photon and transmit its signal to the brain. In the vertebrate eye the receptors for light are the visual, or photoreceptor, cells of the retina. Each visual cell comprises two principal parts: the outer segment, which contains light-absorbing visual pigments, and the inner segment, which contains the nucleus, mitochondria, endoplasmic reticulum, and other subcellular organelles and which metabolically supports the functions of the outer segment (Fig. 49-1). The segments are connected by the ciliary process, or cilium. The inner segments of visual cells have terminals that synapse with horizontal cells and bipolar cells. The bipolar cells, in turn, form synapses with ganglion and amacrine cells.

Light-absorbing pigments differentiate rod cells for black–white vision and three types of cone cells for color vision. Visual cells are of two types. Rod cells, which have elongated outer segments, contain rhodopsin, with a light wavelength for maximal absorption (λ_{max}) of ~500 nm, the visual pigment responsible for dim-light vision, also termed black-and-white or scotopic vision. Cone cells, possessing cone-shaped outer segments, are the photoreceptors for daylight vision, also termed color or photopic vision. In the human retina, there are three types of cone cells, each containing one of three pigments: λ_{max} = 420, 530 and 560 nm. According to one estimate, the human eye contains 120 million rod cells in the peripheral region of the retina and 6.5 million cone cells concentrated mainly in the central, or foveal, region.

Absorption of light causes *inhibition* of vertebrate photoreceptor cells, which then initiate programs of responses among retinal neurons. The plasma membrane of each

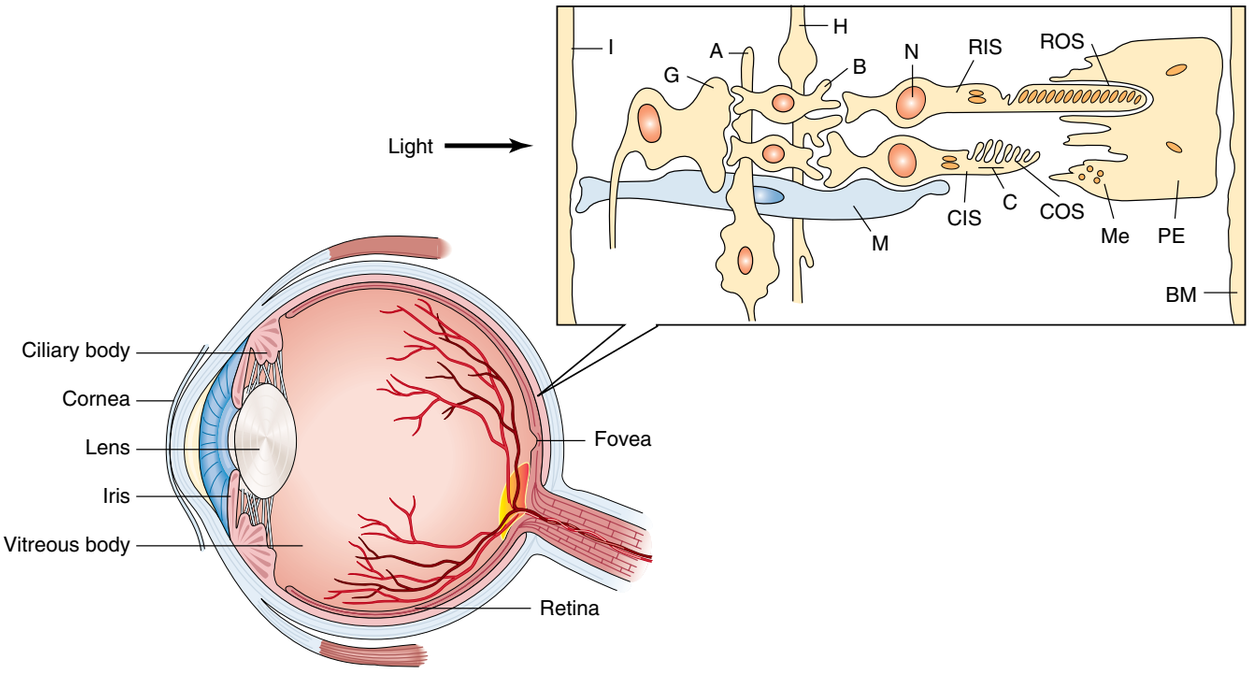

FIGURE 49-1 The vertebrate retina: *A*, amacrine cell; *B*, bipolar cell; *BM*, Bruch's membrane; *C*, ciliary process (cilium); *CIS*, cone inner segment; *COS*, cone outer segment; *G*, ganglion cell; *H*, horizontal cell; *I*, inner limiting membrane; *M*, Muller cell (glial cell); *Me*, melanin granule; *MC*, mitochondrion; *N*, nucleus; *PE*, retinal pigmented epithelium; *RIS*, rod inner segment; *ROS*, rod outer segment.

rod outer segment possesses several thousand cation channels through which Na^+, Ca^{2+} and Mg^{2+} enter the cell at a rate of about 30,000 cations per channel per second *in the dark*. Na^+ accounts for more than 80% of this current. The plasma membrane of the rod inner segment has ATP-dependent Na^+/K^+ pumps that pump Na^+ out of the cell. Thus, in the dark the plasma membrane of the vertebrate rod cell shows a membrane potential of about 40 mV (inside negative) and is depolarized. Photoreception by the visual pigment rhodopsin triggers an enzymatic cascade that leads to closure of the cation channel and, due to a resultant decrease in intracellular Na^+, hyperpolarizes the membrane. Therefore, 'visual excitation' in the vertebrate photoreceptor means hyperpolarization of the visual cell plasma membrane caused by inhibition of its conductance. The neurotransmitter, glutamate, released continuously in the dark at the synaptic terminal of a visual cell, is thus inhibited by light. The retina, which is part of the CNS, contains numerous neurotransmitters, including acetylcholine, dopamine, GABA, glycine, glutamate, and neuropeptides and their receptors [1–3]. Glutamate is released by photoreceptors, as well as bipolar cells and ganglion cells. Ionotropic glutamate receptors account for most of the fast excitatory synaptic transmission in the retina. Bipolar cells have both ionotropic and metabotropic glutamate receptors. Half of the amacrine cells release the inhibitory neurotransmitters, glycine and GABA, whereas the ganglion cells and bipolar cells express receptors for both glycine and GABA. Amacrine cells are diverse and some also release acetylcholine, dopamine, or serotonin. These cells also contain various neuropeptides, including substance P, enkephalin, glucagon, somatostatin, neurotensin, neuropeptide Y, vasoactive intestinal peptide and cholecytokinin, which co-localize with other neurotransmitter substances and function as neuromodulators. The effects of neuromodulators generally are slower and last longer than those of neurotransmitters.

Retinal responses to different light frequencies are encoded in the retina and conveyed to the thalamus and visual cortex. Absorption of photons by visual cells triggers a series of events that result in a particular pattern of retinal stimulation and, eventually, stimulation of cerebral neurons. In dim-light vision, the magnitude of the neural response in rod cells is directly related to the perception of brightness. In color vision, absorption of light by at least two cone cell pigments with different absorption maxima is essential to discriminate color. The ratio of the magnitudes of the induced photoresponses determines the color perceived. The arrays of visual signals generated by the photoreceptor cells and programmed by retinal neurons, principally bipolar cells, are transmitted to the lateral geniculate bodies via ganglion cell axons, which make up the optic nerves and tracts. Impulses are conveyed by the geniculocalcarine radiations to the visual cortex of the brain, where the signals representing light intensity and wavelength are decoded separately by different neurons. The coding and decoding of visual signals,

an important area of neurophysiology, is not covered here. This chapter deals primarily with the structure and function of photoreceptors and the molecular events that take place after photon absorption by the visual cells [4–6].

PHOTORECEPTOR MEMBRANES AND VISUAL PIGMENTS

Rod outer segment membranes are arranged in stacks of disks containing rhodopsin. The outer segment of a rod cell consists of a stack of 1,000–2,000 disks encased in a sack of plasma membrane. It is presumed that the disks are formed by evagination of the plasma membrane in the proximal region of the outer segment, followed by fusion of two adjacent evaginates and detachment from the plasma membrane. This is probably controlled by the ciliary process. This repeated evagination and disk formation greatly increases the area of membrane within each rod cell. This increases the amount of visual pigment, a transmembrane protein, in each cell. As new disks are formed, older disks are pushed toward the apex of the outer segment. Disks that eventually reach the apex are shed from the tip and phagocytized by the pigmented epithelial cells. In higher-order animals, rod-disk shedding follows a circadian rhythm: shedding occurs soon after the onset of light [7]. The life cycle of a single disk may last from a few days to months, depending on the species. Disk membrane components, such as proteins, carbohydrates and lipids, are synthesized in the inner segment and transported to the basal region of the ciliary process, where membrane assembly occurs. In contrast to rod disks, cone disks generally remain contiguous with the plasma membrane, and shedding occurs in the dark rather than in the light.

Rod outer segment membranes, which are comprised of >95% disk membranes and <5% plasma membrane, consist of 60% protein and 40% phospholipids. In vertebrate photoreceptors, phosphatidylethanolamine and phosphatidylcholine account for about 80% of the phospholipids. High concentrations of polyunsaturated fatty acids make rod membranes as fluid as olive oil at physiological temperatures, allowing the integral membrane protein rhodopsin to rotate freely and diffuse within the membrane. This fluidity may be important in allowing photoactivated rhodopsin to collide quickly with so many molecules of the peripheral membrane proteins, such as G protein and rhodopsin kinase. The most abundant polyunsaturated fatty acid is docosahexaenoic acid, consisting of 22 carbons and six unsaturated bonds, linked to the middle carbon of the glycerol moiety of phospholipids.

Rhodopsin is a transmembrane protein linked to 11-*cis*-retinal, which, on photoabsorption, decomposes to opsin and all-*trans*-retinal. Rhodopsin has a molecular weight of about 40,000. Its *C*-terminus is exposed on the cytoplasmic surface of the disk, and its sugar-containing *N*-terminal sequence is exposed on the intraluminal surface. Half of the mass is embedded in the hydrophobic region of the membrane lipid bilayer, with the remaining half distributed equally on both sides of the membrane. The primary structures of about 100 visual pigment proteins of different species are known, including human rhodopsin and cone pigments (Fig. 49-2). Based on their amino acid sequences, these pigments have been grouped into five distinct molecular subfamilies [5]. All visual pigments possess seven segments of hydrophobic sequences separated by segments of hydrophilic sequences. The seven hydrophobic sequences, designated helices 1–7 (see bovine rhodopsin shown as an example in Fig. 49-3), are α-helical and form a bundle that spans the membrane. The cytoplasmic sequence between the end of helix 7 and cysteine-322 forms a short helix (helix 8). Near the *N*-terminus, two sugar moieties, each composed of three mannoses and three *N*-acetylglucosamines, are linked to asparagine-2 and asparagine-15 in bovine rhodopsin, whereas near the *C*-terminus cysteine-322 and cysteine-323 carry palmitoyl groups which probably penetrate the membrane, thereby forming an additional polypeptide loop. The *C*-terminal sequence contains three phosphorylatable serine residues (Ser-334, -338, -343). All of the rod and cone opsins are members of the G-protein coupled receptor (GPRC) family ([8] and Ch. 10). A three-dimensional structure of bovine rhodopsin has been determined by x-ray crystallography [8, 9].

The chromophore, 11-*cis*-retinal, is linked to the α-amino group of lysine-296 in helix 7 via a protonated Schiff base. Protonated Schiff bases usually absorb light maximally at around 440 nm, but the λ_{max} of rhodopsin is near 500 nm. This 60 nm 'red shift' of the λ_{max} can be explained by the strength of interaction of the positive charge of the protonated Schiff base with a counter-ion. The more distant the counter-ion is from the Schiff base, the greater is the red shift. In the case of rhodopsin, the counter-ion is the carboxylate group of glutamic acid-113 (Fig. 49-3). When the helices are bundled together, the acidic residue in helix 3 moves to the vicinity of the chromophore in helix 7 and donates the necessary negative charge. On absorption of light, rhodopsin decomposes to the opsin protein and all-*trans*-retinal. The reaction occurs through several spectrally distinct intermediates (Fig. 49-4). Formation of bathorhodopsin involves photoisomerization of the 11-*cis*-retinylidene chromophore to a constrained all-*trans* form and, at physiological temperature, occurs within a few picoseconds after light absorption. Bathorhodopsin then undergoes thermal relaxation, giving rise first to lumirhodopsin and then to metarhodopsin I. Current evidence suggests that the formation of metarhodopsin II is of particular significance because this intermediate transmits the photosignal to a G protein.

Bleached rhodopsin must be regenerated to maintain normal vision. Regeneration occurs by several mechanisms. The major pathway occurs in the retinal pigmented

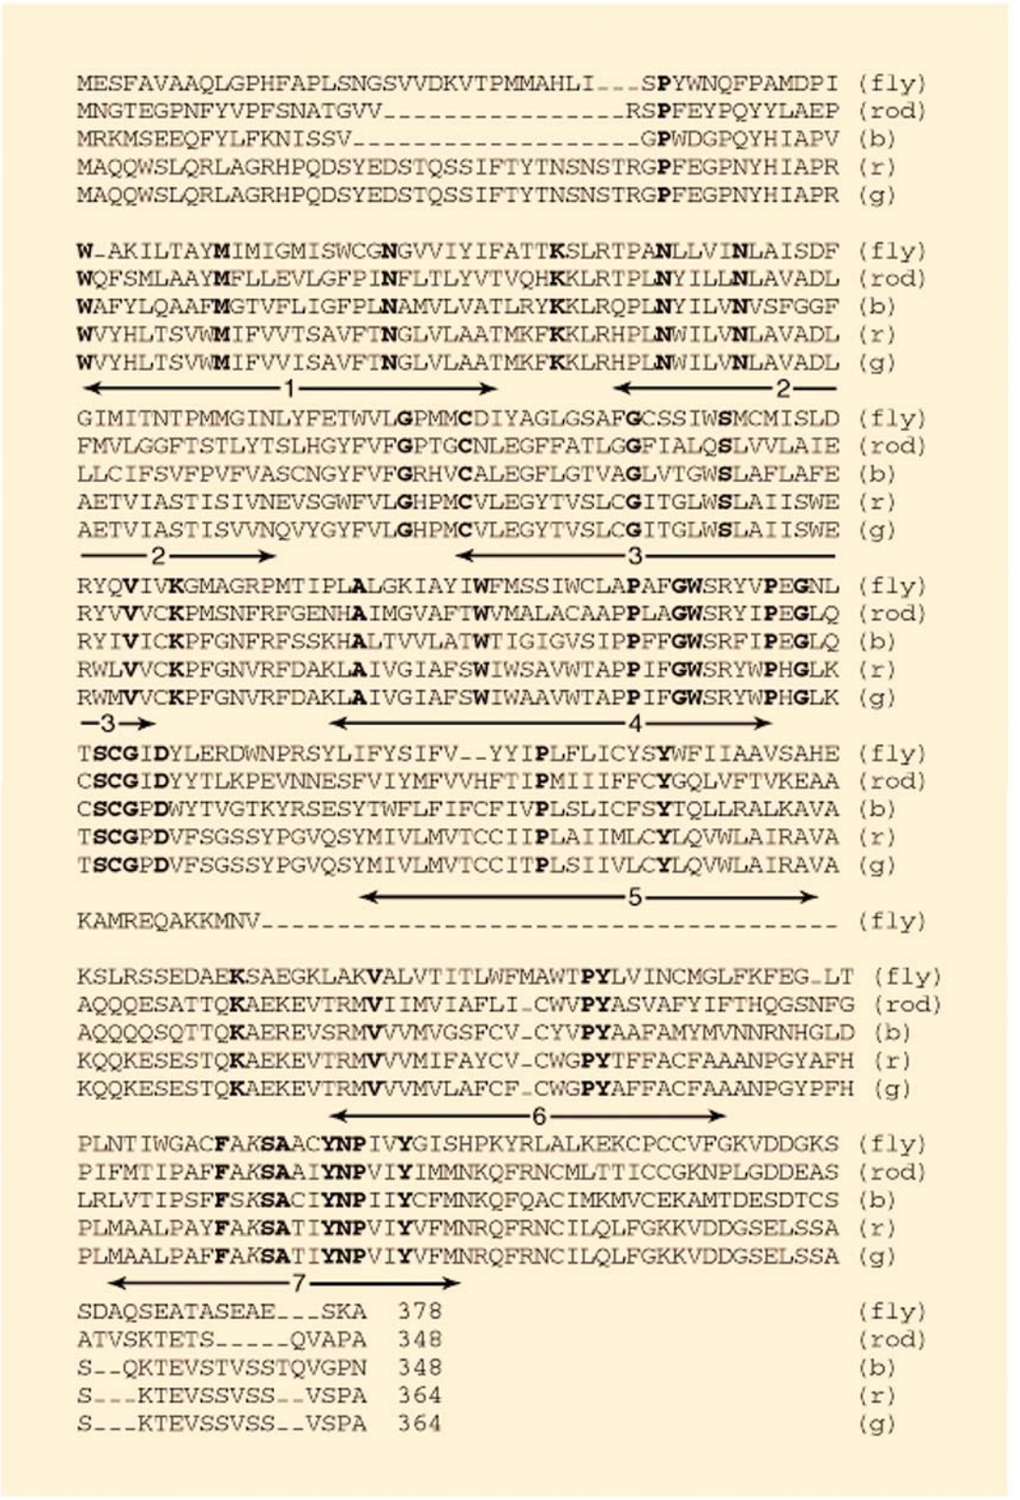

FIGURE 49-2 The primary structures of visual pigments. The fly sequence is from *Drosophila*. All other sequences are human. The lower three are the sequences of cone pigments deduced from cDNA sequences: *b*, blue-sensitive; *r*, red-sensitive; and *g*, green-sensitive. Residues identical in all sequences are shown in **boldface**. Gaps necessary to maintain the alignment are connected by *dashed lines*. The transmembrane segments shown in Figure 49-3 are indicated by the *numbered arrows* below the corresponding sequences. The lysine to which retinal is linked to form the chromophore is indicated as *K* near the center of transmembrane segment 7.

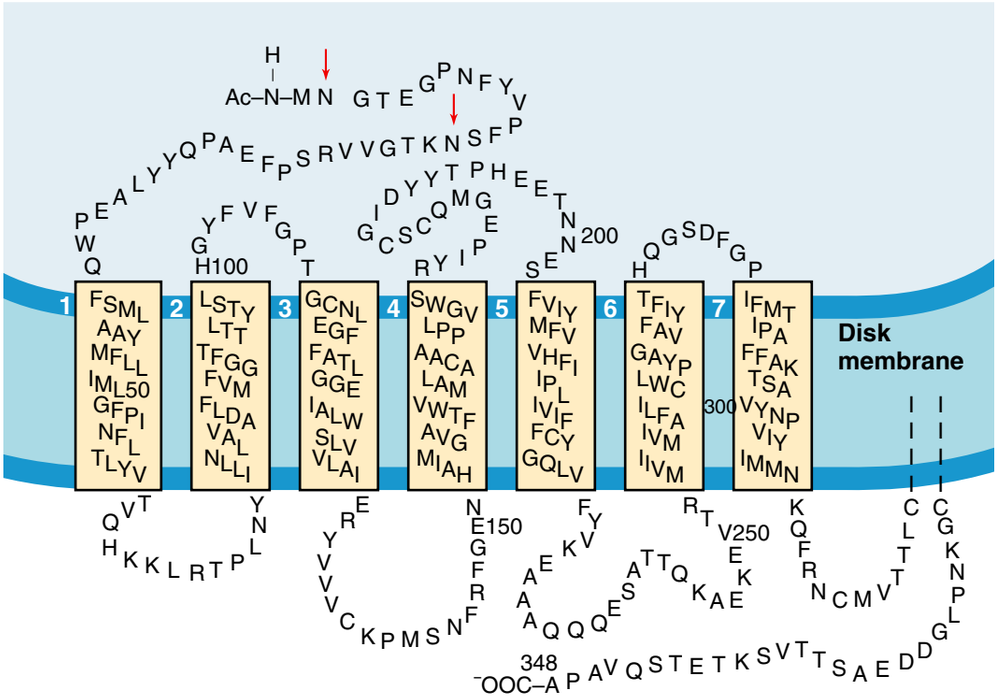

FIGURE 49-3 Proposed transmembrane disposition of bovine rhodopsin. Sugar moieties at asparagine-2 and asparagine-15 are shown with *red arrows*. Palmitoyl groups at cysteine-322 and cysteine-323 are indicated with *broken lines*. Hydroxyamino acid residues that may be phosphorylated by rhodopsin kinase are clustered in a *C*-terminal domain of the molecule.

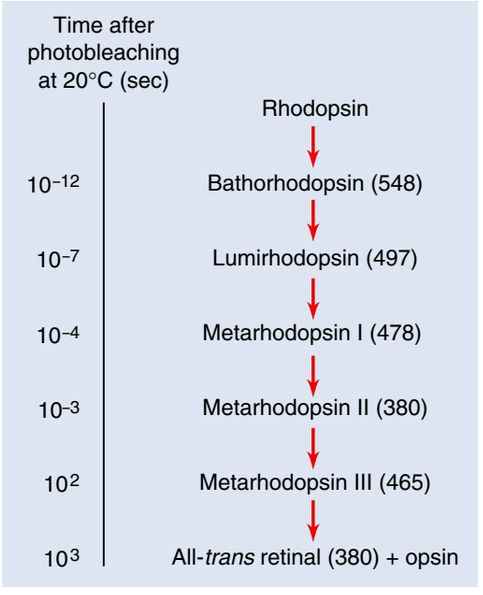

FIGURE 49-4 Intermediates formed after photic bleaching of vertebrate rhodopsin. Numbers in parentheses are wavelengths of light (in nanometers) absorbed maximally by the individual intermediates.

epithelium and involves isomerization of all-*trans*- to 11-*cis*-retinal, followed by transport of 11-*cis*-retinal to the outer segment where it is recombined with opsin [10]. All-*trans*-retinol produced by reduction of retinal in the outer segment is transported to retinal pigmented epithelium. The pigmented epithelium contains the enzyme, lecithin:retinal acyltransferase, that reversibly transfers acyl group (primarily palmityl) from lecithin to all-*trans*-retinol forming all-*trans* esters. According to a current hypothesis, in the pigmented epithelium all-*trans*-retinyl esters bind to a carrier protein called RPE65, and this complex interacts with an isomerohydrolase to produce and quickly hydrolyze the ester to form 11-*cis*-retinol [11]. The free energy of hydrolysis of the ester is coupled to drive the isomerization process. Shuttling of retinoids between the photoreceptor and pigmented epithelium may involve several additional retinoid-binding proteins. A second regeneration mechanism involves photoconversion of thermal intermediates, such as the *meta*-rhodopsins, to rhodopsin. For example, regeneration of squid rhodopsin occurs mainly by photoisomerization of opsin-linked retinal at pH 10 and subsequent dark adaptation [12]. In a third mechanism, the photoisomerization to the 11-*cis* form may take place in the rod outer segment membrane after all-*trans*-retinal has formed complexes with phospholipids. For example, all-*trans*-*N*-retinylidene

phosphatidylethanolamine is photoisomerized to the 11-*cis* form within the disk membrane and reacts with opsin [13].

Cone-cell pigments contain different opsins that have high sequence homology. The primary structures of the three human cone pigments were deduced from analysis of the genomic and complementary DNA clones encoding them [14] (Fig. 49-2). These cone-pigment sequences have >41% identity with rhodopsin. In the case of red and green pigments only 15 of the 364 residues are different. Genetic analysis locates the human rhodopsin gene on chromosome 3 and the blue pigment gene on chromosome 7. Although none of the human cone pigments has been isolated in pure form, the chicken cone pigment, iodopsin, has been purified and characterized [15]. Iodopsin (λ_{max} 571 nm) forms batho-iodopsin on light absorption at −196°C. This intermediate reverts back to iodopsin on warming and, if illuminated by 600 nm light at −183°C, iodopsin is converted to lumiiodopsin, which thermally decays to *meta*-iodopsin I and *meta*-iodopsin II. Cone pigments respond to light faster and, after bleaching, regenerate faster than rhodopsin.

PHOTOTRANSDUCTION

Light absorption by rhodopsin leads to closure of Na^+-conductance channels via a chemical messenger system. Light is known to close the cation channels on the outer segment plasma membrane and to induce hyperpolarization of the membrane within 100 ms. The magnitude of light response reaches a maximum by absorption of several hundred photons per rod cell. Below the saturation light intensity, the relationship between the magnitude of light response *(I)* and the energy of irradiating light *(A)* is given by

$$I = I_{max} A/(A + K)$$

Where I_{max} is the magnitude of response at the saturation light intensity and K is light energy required for 50% of the maximum response [16]. This equation has the same form as the Michaelis–Menten equation of enzyme kinetics. By analogy to enzyme kinetics, we may assume that rhodopsin reacts with light to form a photoactivated rhodopsin, probably *meta*-rhodopsin II, which, in turn, gives rise to an intracellular messenger, X, that links the photochemical reaction of rhodopsin to the plasma membrane channels. It is logical to postulate such a messenger, because the disk membrane, where rhodopsin is localized, is not continuous with the plasma membrane that contains the cation channels. The messenger must satisfy at least two properties. First, its concentration in the outer segment cytoplasm must change rapidly on light irradiation and return to the original value after light is turned off. Second, the messenger must mimic the effect of light when introduced into the outer segment cytoplasm in the dark.

A G-protein/cGMP system in outer segments is responsive to photoactivated rhodopsin. Exposure of an outer segment membrane fragment to cGMP in patch-clamp experiments increases its Na^+-conductance in the dark [17]. This effect is reversible. The concentration of cGMP in dark-adapted rod outer segments is high and decreases rapidly when the rod is irradiated at low Ca^{2+}. The decrease of cGMP is proportional to the log of light intensity. These results suggested that cGMP is messenger X . The crucial evidence for this cGMP hypothesis of vertebrate phototransduction is that the cation channel is, in fact, kept open by cGMP and closes when cGMP is hydrolyzed in light. It should be noted that the amount of messenger X that is expected to 'accumulate' in light is represented by the amount of cGMP hydrolyzed. Several components that participate include rhodopsin, G protein (transducin), arrestin, phosphodiesterase, rhodopsin kinase, guanylate cyclase, guanylate cyclase activating protein, and cGMP-gated cation channel. Relevant properties of these components are described below (see also ref. [5]).

Photoactivated rhodopsin (R*) activates a G protein which in turn mediates activation of a cGMP phosphodiesterase (PDE) (Fig. 49-5). A single R* molecule, before it is inactivated, may produce hundreds of active G protein molecules but this is the rate-limiting step in rod vision. Rhodopsin has an ERY motif in helix 3 at the cytoplasmic surface (Fig. 49-3), that is thought to be involved in the interaction with G proteins because most G-protein-coupled receptors contain the homologous DRY sequence at this location [9]. The polypeptide loops between helices 3 and 4 and helices 5 and 6 and a cytoplasmic loop (helix 8) between helix 7 and the palmitoyl anchors are probably also involved in G-protein binding. The rod G-protein, transducin, consists of three subunits α, β and γ, with GDP bound to the α subunit in the inactive form. R* catalyzes exchange of GTP for GDP, and the G_α-GTP thus formed dissociates from $G_{\beta\gamma}$, which remains membrane-bound. Rods and cones express distinct G proteins. Two GTP-activated G complexes are required to activate one phosphodiesterase molecule by forming a PDE-$\alpha\beta\gamma_2$ complex by successively dissociating two G-protein γ subunits. In the case of rods, PDEα and PDEβ designate two different isoforms expressed in these cells — sometimes called PDE6A and PDE6B, *not* to be confused with the G-protein subunits. Cones appear to express a single phosphodiesterase isoform, 'cone PDEβ'or PDE6C (see Table 21-1, Fig. 21-6). A single PDE molecule may hydrolyze 10^5–10^6 cGMP molecules during the lifetime of one R*. Because of this large gain, the cGMP hypothesis is also called the cGMP cascade hypothesis.

Visual pigment kinases belong to the G-protein-coupled receptor kinase (GRK) family ([18], Ch. 23). Rhodopsin kinase or RK and cone-pigment kinase are designated GRK1 and GRK7, respectively. The catalytic site of RK is located in the middle of the polypeptide chain and is highly conserved. The kinase also has an ATP binding sequence, GXGXXGX and a GRK-specific signature sequence, D (L/M)G. At high

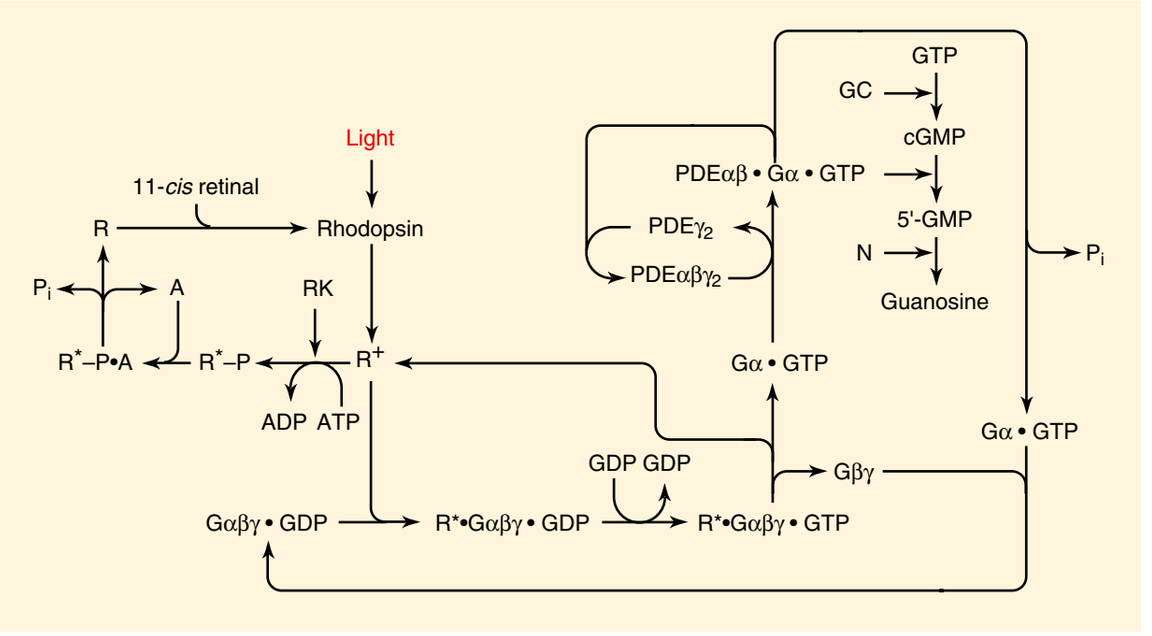

FIGURE 49-5 Light-elicited biochemical reactions leading to cGMP hydrolysis: *Gαβγ*, guanine nucleotide-binding protein (transducin); *PDEβγ2*, phosphodiesterase; *GC*, guanylyl cyclase; *N*,5′-nucleotidase; *P*$_i$, inorganic phosphate; *RK*, rhodopsin kinase; *R**, photoactivated rhodopsin; *R*, inactive form of rhodopsin; *A*, arrestin. cGMP binds to the cation channel protein of the plasma membrane and opens the channel.

levels of photobleaching where 20–40% of rhodopsin is converted to R*, RK phosphorylates only one serine residue (Ser^{343}, Ser^{338} or Ser^{334} at the *C*-terminal sequence of R*. At low bleaching levels (<1% R*), multiple sites appear to be phosphorylated. Phosphorylation of R* partially inhibits its ability to activate G protein, whereas binding of R* with arrestin, a 48 kDa protein blocks binding of G protein to R*. In the rods, cGMP is steadily synthesized by guanylate cyclase (GC) and hydrolyzed by PDE. Retinal GCs are members of the membrane-bound GC family (Ch. 21) and two forms, GC-E (ret GC-1) and GC-F (ret GC-2), are present in both rods and cones [19, 20]. GC functions as a dimer. Two GC activating proteins are known which have three Ca^{2+}-binding EF hands [21]. They activate GC at low Ca^{2+} and inhibit GC at high Ca^{2+}. The cyclic-nucleotide-gated (CNG) cation channel of rods is a tetrameric complex composed of three CNGA1 subunits and one CNGB1 subunit [22]. While the homomeric channel formed by CNGA1 subunits is opened by cGMP, CNGB1 subunits do not form functional channels and are considered to have modulatory roles including inhibition of the channel by Ca^{2+}-calmodulin. Cone channels are more permeable to Ca^{2+} than rod channels and little affected by Ca^{2+}-calmodulin. Even after the closure of CNG channels, cation concentrations in the outer segment continue to change due to a $Na^+/Ca^{2+}/K^+$ exchange protein located in the plasma membrane. The exchanger exists as a dimer. It exchanges four Na^+ (inward) for one Ca^{2+} and one K^+ (outward) and becomes inactive at low Ca^{2+} concentrations (see Ch. 5). The rate of exchange is faster in cones than in rods.

Although abundant evidence supports the cGMP cascade hypothesis for vertebrate vision, whether cGMP plays a key role in invertebrate vision remains controversial. Because invertebrate visual cells depolarize in light, a rise in cGMP is expected upon light absorption. However, light does not increase cGMP in invertebrate photoreceptors [23]. A mechanism proposed for invertebrate phototransduction involves light-stimulated hydrolysis of phosphatidyl inositol 4,5-biophosphate (PIP_2). Reception of an external signal by a variety of receptors is known to evoke hydrolysis of PIP_2 to diacylglycerol (DAG) and inositol-1,4,5-triphosphate (IP_3) by activating phospholipase C. In this mechanism, both IP_3 and DAG can serve as intracellular messengers. IP_3 increases intracellular Ca^{2+}, and DAG stimulates protein kinase C. Injection of IP_3 into Limulus ventral photoreceptors in the dark mimics the light effect, evoking membrane depolarization without latency and an increase in intracellular Ca^{2+} [24].

Visual photoreceptors have an ability to adapt to a wide range of light intensities. The retina can respond to a broad range of light intensities due to its property of adaptation. Light adaptation (or background adaptation) refers to photosensitivity changes observed in background illumination that causes only a low level of pigment bleaching. On the other hand, photoreceptor desensitization by high light intensities, that produce significant amounts of

bleached pigment, is called bleaching adaptation. Changes in intracellular Ca^{2+} play an important role in both types of adaptation in rods and cones. In background light adaptation, GC modulation by Ca^{2+} is important for photoregulation at low light intensities, while PDE modulation by Ca^{2+} plays a dominant role in photosensitivity regulation at high light intensities. In bleaching adaptation, low levels of fully bleached pigments (i.e. decay products of R*) activate G protein, and consequently PDE regulation seems to be responsible for changes in light sensitivity. The recovery process from bleaching adaptation is known as dark adaptation and is important for resetting the photoreceptor systems. As described above and in Fig. 49-5, R* is inactivated by phosphorylation and binding of arrestin and releases all-*trans*-retinal. During dark adaptation, the opsin protein is dephosphorylated, dissociated from arrestin, and reconjugated with 11-*cis*-retinal. GTP bound to the α-subunit of G protein is hydrolyzed to GDP, a reaction probably accelerated *in vivo* by a GTPase accelerating protein. The Gα subunit then dissociates from PDE-αβ and reassociates with G protein βγ subunits. PDE-αβ becomes inactive by association with its inhibitory γ subunits.

COLOR BLINDNESS

Red–green color blindness is explained by unequal intragenic recombination between a pair of X chromosomes. The blue pigment gene is located on chromosome 7, whereas both red and green pigment genes reside on the X chromosome [14]. Amino-acid sequences of the three cone pigments of human retina (Fig. 49-2) indicate that red and green pigments are very similar, showing 96% homology, but blue pigment differs more. Peculiarly, in color normals each X chromosome has one red pigment gene and either one, two or three green pigment genes. A hypothesis to explain the variability of the green pigment gene is that the red pigment gene occurs upstream of the 5′ end of the green pigment gene, and a pair of homologous red–green gene arrangements has undergone unequal recombinations during evolution. Red–green color blindness is explained by abnormalities in the unequal intragenic recombination as described below.

Approximately 8% of Caucasian men inherit a color abnormality: one type, dichromats, require only two primary wavelengths to match all colors. Another type, anomalous trichromats, require three primary wavelengths but make color matches different from the normal. Loss of one of the three color pigments or systems explains dichromats, while a shift in the spectral sensitivity of one of the three pigments or systems may be responsible for anomalous trichromatism. Blue cone abnormalities are inherited as autosomal traits and are rare. Therefore, abnormalities in the red and green cone systems have been most extensively studied. From psychophysical studies, defects in the red and green cone systems are mapped to two tightly linked loci on the X chromosome which are most likely the loci of red and green pigment genes.

What are the underlying genetic mechanisms that produce dichromats and anomalous trichromats? Nathans [25] hypothesizes that visual abnormalities are caused by alterations in red and green pigment genes by unequal intragenic recombination. Red and green pigment genes are similar and tightly linked on the X chromosome, as described above. If, during the development of ova and sperm cells, a pair of chromosomes joins by crossing over in the region encoding red and green pigments and breaks between the two genes of one of the chromosomes, one chromosome may lose the green pigment gene and the other chromosome may have two. However, breaking within a gene may result in a hybrid gene composed of part of the green pigment gene and part of the red pigment gene. If the X chromosome lacking the green pigment gene is inherited, the carrier is a true dichromat. Depending on the location of breakpoints, a variety of hybrid genes are generated; a man with a hybrid gene producing a nonfunctional pigment similar to the normal pigment will be a dichromat. However, the carriers of hybrid genes producing pigments with spectral sensitivities intermediate between those of red and green pigments will be anomalous trichromats.

RETINITIS PIGMENTOSA

Mutations in rhodopsin and other photoreceptor proteins are linked to retinitis pigmentosa. Retinitis pigmentosa (RP) is a group of inherited retinopathies that affects about 1 in 4,000 humans [26]. RP may be classified into four types: autosomal dominant (19%), autosomal recessive (19%), X-linked (8%) and allied diseases (54%). RP is characterized by loss of night vision in the early stage, followed by loss of peripheral vision. Chromosomal loci for numerous RP genes have been mapped and mutations characterized [27].

The first gene suspected to be linked to dominant-type RP was located on the long arm of chromosome 3, and its mutant product was found to be a rhodopsin: replacement of proline 23 by histidine [26]. About 100 point mutations within the rhodopsin gene have so far been reported, including mutations causing autosomal recessive RP and congenital stationary night blindness. Another gene of dominant-type RP, localized on the short arm of chromosome 6, was recently identified to be peripherin, a structural protein with a M_r of 35,000, present in the rim of disks of rod outer segments [28]. A defect in the peripherin gene is involved in a hereditary retinopathy of the mouse, termed 'retinal degeneration slow', or rds [29]. In another form of mouse retinopathy, rd, a defect is in the β subunit of cGMP-PDE [30]. Mutations in an oxygen-regulated photoreceptor protein called RP1 cause nearly 10% of autosomal dominant RP [31]. Up to 15% of X-linked RP is accounted for by mutations in RP2 gene [32]. RP2 protein is a dual-acylated protein that has sequence similarity to a tubulin-specific chaperone cofactor. These findings suggest that defects causing photoreceptor degenerations in

different forms of RP could be in any structural and functional proteins associated with rod outer segments. Very little is known about how mutations in these proteins bring about degenerations of the rod cells. It is possible that various elements released into the subretinal space via the retinal vasculature normally protect the photoreceptors and that mutations forfeit the protection. In RCS rats, a strain with inherited retinal dystrophy, in which the ability of the retinal pigmented epithelium to phagocytize photoreceptor outer segments is impaired, subretinal or intravitreal injection of basic fibroblast growth factor causes a significant delay in retinal degeneration [33].

Choroideremia can be classified, broadly, as an X-linked form of RP. A study of lymphoblasts from subjects with this disorder has disclosed deficient activity of geranylgeranyl transferase [34]. This enzyme catalyzes the transfer of geranylgeranyl groups to guanine nucleotide-binding proteins. This modification is necessary for these proteins to participate in membrane fusion processes. Both the biogenesis of photoreceptor disks and their subsequent phagocytosis by the pigmented epithelial cells involve very active membrane fusion and turnover. Thus, it is quite possible that the pathology of RP may arise from an enzyme deficiency of this type.

AGE-RELATED MACULAR DEGENERATION

Age-related macular degeneration (AMD) is a common cause of central vision impairment in the elderly, affecting more than 11 million people in the U. S. A.. A juvenile form of macular degeneration, called Stargardt's disease, is caused by mutations in a gene encoding an ATP-binding cassette transporter (ABCR, see Ch. 5) expressed in the retina. Environmental factors, such as cigarette smoking and diet, as well as genetic factors contribute to age-related degeneration. In order to examine whether ABCR mutations are associated with the disease, 167 unrelated patients were screened [35]. Alterations in the ABCR gene were found among as many as 16% of patients. Age-related macular degeneration is clinically subdivided into 'dry' and 'wet' forms. The dry form is characterized by the accumulation of cellular debris, called drusen, in and under the retinal pigmented epithelium, and the wet form involves choroidal neovascularization. ABCR gene mutations were found to be more frequent among patients with dry than among those with wet macular degeneration. There is evidence suggesting that ABCR transports retinal (or *N*-retinylidene phosphatidylethanolamine (NRPE)) from the luminal side to the cytosolic side of the disk membrane [36]. NRPE is produced by photobleaching of rhodopsin in the outer segment [13]. If the ABCR protein is defective and not able to transport the retinoid across the disk membrane, its buildup may become toxic and cause retinal degeneration. Beside the genetic risk, environmental and metabolic factors also contribute to AMD. The retinal pigmented epithelial cells of aged human eyes accumulate a compound formed by condensation of NRPE with a second molecule of all-*trans*-retinal and hydrolysis of the adduct by phospholipase D. The compound, designated A2E [37], makes RPE cells sensitive to blue light that induces oxidative stress and cell apoptosis. A possible role of A2E in the pathogenesis of dry form of AMD has been suggested [38].

Molecular Biology of Olfaction and Taste

Steven D. Munger

OLFACTION 817
The mammalian olfactory system possesses enormous discriminatory power 817
The initial events in olfaction occur in a specialized olfactory neurepithelium 818
Odor discrimination could involve a very large number of different odorant receptors, each specific for one or a small set of odorants 818
The information generated by hundreds of different receptor types must be organized to achieve a high level of olfactory discrimination 820
Zonal expression of olfactory receptors 821
Convergence of sensory neurons onto a few glomeruli in the olfactory bulb 821
The sensitivity of the olfactory system is likely to derive from the capacity of the olfactory transduction apparatus to effectively amplify and rapidly terminate signals 821
Odorant recognition initiates a second-messenger cascade leading to the depolarization of the neuron and the generation of action potentials 821
Negative-feedback processes mediate adaptation of the olfactory transduction apparatus to prolonged or repetitive stimulation 823
Alternative second-messenger pathways may be at work in olfactory transduction 823
The vomeronasal organ is an accessory chemosensing system that plays a major role in the detection of conspecific chemical cues, also known as pheromones 824
Chemosensory neurons of the vomeronasal system are narrowly tuned to specific chemical cues, and utilize a unique mechanism of sensory transduction 824

TASTE 825
Multiple senses, including taste, contribute to our total perception of food 825
Taste receptor cells are organized into taste buds 825
Sensory afferents within three cranial nerves innervate the taste buds 826
Information coding of taste is not strictly according to a labeled line 826
Taste cells have multiple types of ion channels 826
Salts and acids are transduced by direct interaction with ion channels 826
Taste cells contain receptors, G proteins and second-messenger-effector enzymes 827
Gustducin is a taste-cell-specific G protein closely related to the transducins 827
Sweet, bitter and umami taste involve receptor-coupled second-messenger pathways that are differentially expressed across the gustatory epithelium 827

The mammalian olfactory and taste (gustatory) systems are extraordinarily accomplished in the detection of odor, pheromone and taste stimuli that may number in the millions [1]. Utilizing a number of specialized cells, a vast array of chemosensory receptors, and highly regulated signal transduction mechanisms, the olfactory and taste systems are able to specifically encode a range of chemically diverse stimuli so that quality food can be identified, predators can be avoided, and appropriate mating partners can be found. Enormous strides have been made in understanding the molecular mechanisms that underlie olfaction and taste in vertebrates. The application of innovative experimental techniques, as well as the availability of several sequenced genomes, has allowed for the identification and characterization of molecules involved in the initial events in perception in these two sensory systems, and has provided fresh insight into the processes by which olfactory and gustatory discriminations are achieved.

OLFACTION

The mammalian olfactory system possesses enormous discriminatory power. It is claimed that humans can perceive many thousands of different odorous molecules, termed odorants. Even slight alterations in the structure of an odorant can lead to profound changes in perceived odor quality. One commonly cited example is carvone, whose L- and D-stereoisomers are perceived as spearmint and caraway, respectively. However, more subtle molecular alterations can also generate striking changes in perception.

The fine discriminatory power of the mammalian olfactory system is likely to derive from information-processing events that occur at several distinct anatomical

Basic Neurochemistry: Molecular, Cellular and Medical Aspects
0-12-088397-X

sites [2]: the olfactory epithelium of the nasal cavity, where odors are first sensed by olfactory sensory neurons; the olfactory bulb, where information received from the sensory neurons is first processed; and the cortex, where information received from the olfactory bulb is thought to be further refined to allow for the discrimination of thousands of different odors.

The initial events in olfaction occur in a specialized olfactory neurepithelium. In mammals, this structure lines the posterior nasal cavity. The olfactory epithelium contains three predominant cell types: the olfactory sensory neuron (OSN); the supporting, or sustentacular, cell; and the basal cell (Fig. 50-1). OSNs turn over throughout life. They are continuously replaced from progenitor populations within the basal cells. Two morphologically distinguishable types of dividing basal cell have been identified in mammals, the horizontal basal cell and the globose basal cell. There is evidence for both basal cell types containing multipotent precursor cell populations, although the precise lineage relationships of the cells of the olfactory epithelium remain controversial.

The OSN is a bipolar cell that extends a single dendrite to the apical surface of the epithelium. From the dendritic terminus, numerous nonmotile cilia project into the layer of mucus that lines the nasal cavity. The cilia contain the molecular machinery of olfactory transduction, which includes receptors, synthetic enzymes and ion channels. The details of signal generation, adaptation and propagation will be discussed in a later section.

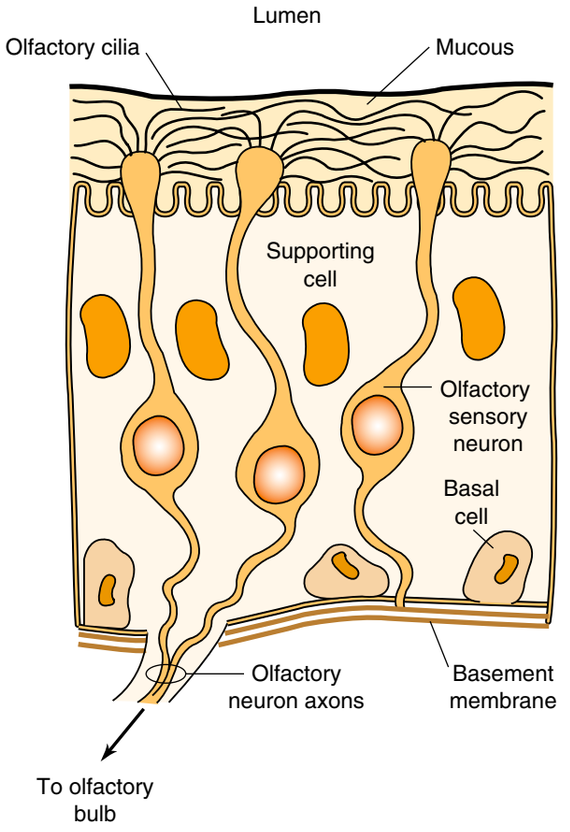

FIGURE 50-1 A schematic diagram of the olfactory epithelium. The initial events in odor perception occur in the olfactory epithelium of the nasal cavity. Odorants interact with specific odorant receptors on the lumenal cilia of olfactory sensory neurons. The signals generated by the initial binding events are transmitted along olfactory neuron axons to the olfactory bulb of the brain.

Each OSN projects an unbranched axon to the olfactory bulb, where it forms synapses within specialized regions of neuropil, called glomeruli. OSNs form synapses with both projection neurons and local interneurons. The major output neurons of the bulb, the mitral and tufted cells, project to higher olfactory areas in the brain, including the olfactory cortex. Bulbar interneurons, such as periglomerular cells and granule cells, help to shape sensory input and bulbar output in several ways, including creating an interglomerular center-surround inhibitory network that may enhance some features of odor signals [3].

Electrophysiological experiments demonstrate that most OSNs recognize multiple odorants. It is thought that the patterns of axonal convergence in the olfactory bulb by OSNs that recognize different odorants might constitute elementary odor codes. It is not clear how many different types of odorant receptor would be required to accurately encode a single odorant, nor is it obvious how narrowly or broadly tuned they might be or how their expression might be organized to achieve a high level of sensory discrimination.

Odor discrimination could involve a very large number of different odorant receptors, each specific for one or a small set of odorants. At the other extreme, there could be a relatively small number of different odorant receptors (ORs), each of low specificity and capable of interacting with a wide assortment of different odorous ligands. Individual OSNs could each express only a single OR type or multiple different odorant receptors.

The identification and cloning of genes encoding ORs has made it possible to begin to answer these questions. Nearly 15 years ago, Buck and Axel made a seminal discovery when they identified the first members of a large multigene family in mammals encoding hundreds of diverse ORs [4]. ORs are members of the G-protein-coupled receptor (GPCR) superfamily, and share with them a number of stereotypical motifs, including an apparent seven transmembrane domain topology. However, ORs share unique sequence motifs not seen in other GPCRs, and which, along with their expression in OSNs, help to define them as a unique group of receptor proteins [5].

Analyses of the human and mouse genomes has revealed ~350 functional OR genes in humans (with an equivalent number of OR pseudogenes) and ~1,200 in mice [6–9], making this the largest mammalian gene family. OR genes are found in clusters within the genome on nearly every chromosome, suggesting a large number of local tandem duplications during evolution [9]. While the accepted numbers of OR genes may change in the coming years with greater analysis of the genomes and of OR transcripts, it is clear even today that the large number of

mammalian ORs has enormous implications for the way odorants are detected and encoded by the olfactory system.

Olfactory receptors can be grouped based on conservation of protein sequences. First, mammalian olfactory receptor genes can be divided into two phylogenetic classes (Fig. 50-2). Class I genes are more ancient, and are more closely related to those found in fish. Class II genes are an evolutionarily more recent family, and appear restricted to terrestrial vertebrates. It is reasonable to hypothesize that these two phylogenetic classes of OR subserve different olfactory roles, and this possibility is a focus of current interest to both neurobiologists and evolutionary biologists. Second, OR genes can be further divided into subfamilies based on sequence similarity (Fig. 50-2). Members of a subfamily exhibit a sequence conservation of >40% amino-acid identity [8], as compared to 37% average amino-acid similarity across the OR family [1]. It is tempting to propose that the members of divergent subfamilies recognize different structural classes of odorants. The highly related members of a subfamily might either recognize the same odorants, or detect subtle differences between structurally related odorants.

A striking feature of ORs is that some regions or the protein are highly variable, while others are relatively conserved. As seen in Figure 50-3 [5], transmembrane domain 4 (TM4), TM5 and parts of TM3 are highly variable across the OR repertoire. As it would be expected that variation in amino-acid sequence would be a hallmark of a ligand-binding pocket, enabling divergent ORs to recognize

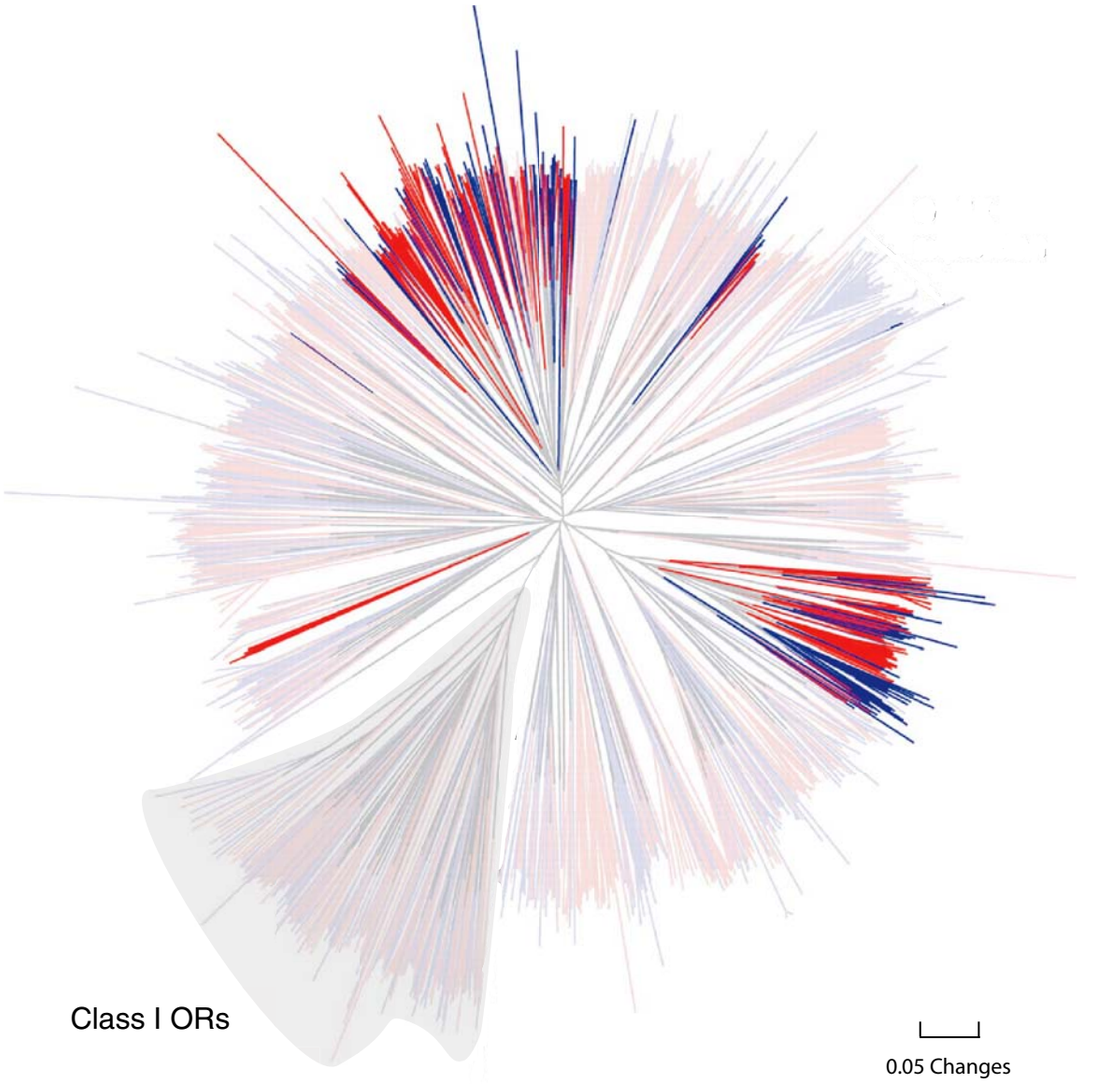

FIGURE 50-2 Phylogenetic relationships between human and mouse OR genes. This unrooted tree represents all full-length mouse and human OR proteins. Class I ORs, which most closely resemble those found in fish and amphibians, are *shaded*. Class II ORs are restricted to the mammalian lineage and are *unshaded*. Human sequences are colored *blue* and mouse sequences *red*. Human and mouse sequences found in syntenic genomic locations on human chromosome 11 and mouse chromosome 2 are highlighted in *darker colors*. Clustering of these receptors on the tree support their identification as orthologous groups. Clustering of human (*blue*) or mouse (*red*) receptors within clusters suggests that the OR gene repertoire has arisen largely through gene duplication. Modified from [71], with permission.

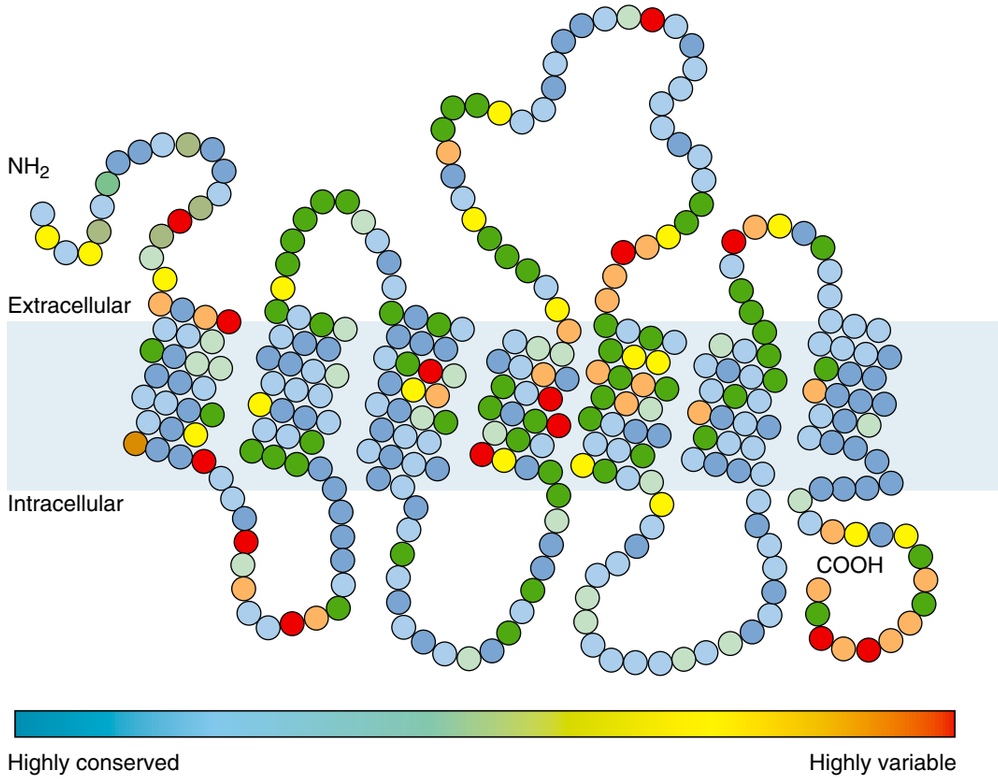

FIGURE 50-3 Amino acid sequence conservation across mammalian odorant receptors. ORs pass through the plasma membrane (*blue box*) seven times, with the *N*-terminus located extracellularly and the *C*-terminus intracellularly. The degree of conservation of each amino acid in this consensus OR is indicated by a colored ball, with *dark blue* being most highly conserved and *red* most highly variable. Modified from [5], with permission.

chemically diverse odorants, these regions have been proposed as the site of ligand interaction [4]. This idea is further supported by two observations: (1) many odorants are hydrophobic, and are likely to partition within the plane of the lipid bilayer, and (2) many other Class A GPCRs, which include the ORs along with rhodopsin (Ch. 49), the β-adrenergic receptor (Ch. 12), and many others, have a ligand-binding pocket formed by the transmembrane helices.

Unfortunately, technical hurdles have slowed progress on pairing individual receptors with their cognate odor ligands, making a systematic structure–function analysis of ORs problematic. Using a number of approaches, such as viral-mediated overexpression of individual receptors *in vivo*, isolation of receptor cDNAs from single olfactory neurons with characterized responses to a panel of odors, or the coupling of expressed receptors to endogenous cellular signaling pathways in heterologous cells, researchers have identified ligands for only a small number of receptors [1]. However, even this small number has revealed some important features of OR function. First, ORs can have a broad receptive range; that is, they respond to more than one odorant, and often to odorants of more than one chemical class (e.g. aldehydes vs. alcohols). Second, more than one OR can be activated by the same odorant. For example, it is estimated that up to 55 ORs in the mouse genome can respond to the aliphatic aldehyde octanol [10]. Third, not every OR activated by a particular odor responds with the same efficacy to that odor. Together, these observations indicate a repertoire of ORs with overlapping odorant profiles. The idea that the identity of an individual odor is encoded by several differentially tuned ORs has been called a combinatorial odor code [11]. As will be discussed in a later section, studies of odor coding in the olfactory bulb largely support this model.

The information generated by hundreds of different receptor types must be organized to achieve a high level of olfactory discrimination. The visual, auditory (Chs 49 and 51) and somatosensory systems localize environmental information in space and possess neural topographical maps of that spatial information. The olfactory system does not perceptually localize environmental information in external space. However, it could use spatial determinants within the nervous system to encode information. If so, topographical maps or spatial codes for odors might be evident within the olfactory epithelium or olfactory bulb. For example, olfactory neurons that express a particular odorant receptor gene, and therefore recognize the same odorants, might be clustered in one region of the olfactory epithelium or might all form synapses at a

discrete site in the olfactory bulb. On the other hand, neurons that express the same odorant receptor gene could be broadly distributed in the olfactory epithelium or form synapses at many different bulbar sites, encoding information by a nontopographical strategy. The identification of olfactory receptors has provided an important tool for dissecting how olfactory information is coded in neural space.

Zonal expression of olfactory receptors. In the olfactory epithelium, different OR genes are expressed within restricted anatomical zones [12, 13]. These zones exhibit bilateral symmetry in the two nasal cavities and are virtually identical across individuals. Within each zone, many different members of the OR gene family are expressed. However, each individual gene may be expressed only within a single zone. Although the zonal assignment of each gene seems to be strictly regulated, though perhaps not absolute, within each zone neurons that express a particular receptor gene are broadly distributed. It thus appears that when an olfactory neuron or its progenitor chooses which odorant-receptor gene(s) to express, it is restricted to a single zonal gene set but may choose a receptor gene or set of genes to express from among the zonal set via a stochastic mechanism. Recently, *cis*-acting regulatory elements have been identified near one OR gene cluster that participates in this choice [14]. This work and others [15] also suggest a poorly understood negative feedback mechanism for a phenomenon that is accepted, but not proven: in most circumstances, OSNs express only one OR gene.

Convergence of sensory neurons onto a few glomeruli in the olfactory bulb. The odorant receptor expression zones in the olfactory epithelium exhibit a pronounced dorsal–ventral and medial–lateral organization. Interestingly, the axonal projection from the olfactory epithelium to the olfactory bulb is also organized along the dorsal–ventral and medial–lateral axes [16]. Comparisons of the locations of the expression zones with the topography of projections between the olfactory epithelium and olfactory bulb indicate that the organization of odorant receptor gene expression in the epithelium is preserved in the axonal projection to the olfactory bulb. Indeed, the map is even more specific than this. Axons from olfactory sensory neurons expressing the same receptor gene converge on just a few glomeruli in the bulb, usually two [17–19]. Thus, it appears that all of the cells expressing a particular receptor are somehow targeted to just a few among approximately 1,900 glomeruli in the mouse olfactory bulb. Interestingly, the olfactory receptor itself seems to play a critical role in this specific pattern of axonal targeting, although whether this is a direct or indirect role is unclear.

These results suggest that an initial organization of olfactory sensory information occurs in the olfactory epithelium, and that this organization is maintained in the patterns of signals transmitted to the olfactory bulb. This conclusion is consistent with the observation that responses in mitral cells to odors applied to the epithelium are narrowly tuned and that sensitivity to particular types of odor, determined by either functional group or carbon chain length, is spatially organized in the bulb [20]. Thus, the organization of receptors into broad zones in the epithelium is further refined in the bulb, where receptors find common targets.

This pattern of organization in the bulb argues that the glomerulus, not the receptor, is the fundamental unit of olfactory coding. Given the overlapping odor specificities of individual olfactory receptors, one would then expect that an individual odor would activate more than just one or two glomeruli, an expectation that has been supported by a number of functional studies. It is now believed that some version of a combinatorial code for odors is present in the bulb, where the identity of a particular odorant is represented by the pattern of glomerular activity in the whole bulb. As more researchers turn their focus to higher brain centers, such as the olfactory cortex, it will be interesting to see the extent to which the glomerular pattern of odor activity is maintained.

The sensitivity of the olfactory system is likely to derive from the capacity of the olfactory transduction apparatus to effectively amplify and rapidly terminate signals. The olfactory system responds to extremely low concentrations of odorants and has a fast recovery of perceptual sensitivity. In recent years, significant advances have been made in the understanding of the signal-transduction events that take place when an olfactory sensory neuron is exposed to an odorant. Although olfactory perception is believed to be extremely sensitive, the degree of sensitivity is controversial [2]. Human olfactory thresholds of 10^{-11} M have been measured by psychophysical methods. In such studies, however, the actual concentration of odorant at the odorant receptor cannot be known definitively. Due to factors such as odor molecule interactions, diffusion, adsorption into mucus, and anatomical structures which may trap and concentrate odor molecules, these estimates could be as much as two to four orders of magnitude too low. It can be shown from the law of mass action that with significant amplification mechanisms, such that occupation of only a few receptors would be sufficient to elicit a response, thresholds as much as five or six orders of magnitude lower than the K_d can be attained. Thus, K_d values of 10^{-6} could, in theory, produce threshold responses at odor concentrations as low as 10^{-11}, permitting the olfactory system to maintain the broad specificity seen in physiological recordings, and the high threshold sensitivity measured in psychophysical experiments. Several amplification mechanisms that could serve this purpose are described below.

Odorant recognition initiates a second-messenger cascade leading to the depolarization of the neuron and the generation of action potentials. Stimulation of single OSNs with odorants causes the membrane to depolarize,

leading to the generation of action potentials (Fig 50-4). Underlying the initial depolarization is the influx of cations through a conductance in the specialized cilia extending from the distal end of the cell. The biochemical elements coupling odorant receptor binding to the opening of a cation channel are now understood in some detail [2, 21]. A consensus view is presented in Figure 50-5.

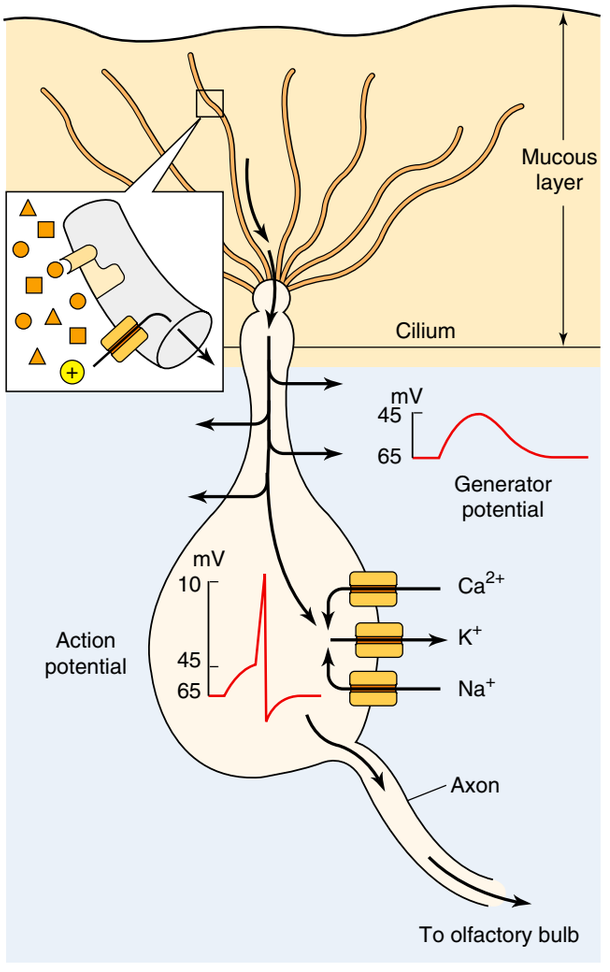

FIGURE 50-4 Schematic drawing of an olfactory neuron showing the single bipolar morphology, with a single thick dendrite ending in a knob-like swelling and an unbranched axon projecting from the proximal soma centrally to the olfactory bulb. The cell is highly compartmentalized into transduction and signaling regions. Transduction occurs in the cilia, which extend from the distal dendritic knob into the mucous layer. A receptor-coupled second-messenger system (see Fig. 50-5) results in the opening of a cation-selective channel in the ciliary membrane. The influx of cations depolarizes the cell membrane from its resting level near −65 to −45 mV, in a graded manner. This depolarization spreads by passive current flow through the dendrite to the soma. A depolarization that reaches −45 mV is sufficient to activate voltage-gated Na^+ channels and initiate impulse generation. This Na^+ current along with several varieties of voltage-dependent K^+ currents and a small Ca^{2+} current produce one or more action potentials that are propagated down the axon to the brain.

The second-messenger cascade of olfactory transduction is a classic cyclic nucleotide-based system with some interesting modifications. A G protein (Ch. 19) that is likely to couple odorant receptors to other intracellular elements of the cascade, $G\alpha_{olf}$, has been identified [22]. An isoform of $G\alpha_s$, it is highly enriched in OSN cilia. Deletion of this gene in mice abolishes nearly all odor responses in OSNs and odor-mediated behaviors, confirming its central role in olfactory transduction. Since $G\alpha_{olf}$ can interact with GPCRs other than odorant receptors, it has been proposed that the existence of a separate gene for $G\alpha_{olf}$ may, in some manner, permit the specific and high level of expression of this protein observed in olfactory neurons.

OSNs also contain an adenylyl cyclase isoform (Ch. 21), type III (ACIII) that is highly enriched in olfactory cilia [23]. An important characteristic of this isozyme is that, when expressed in a mammalian cell line, its basal activity is extremely low, while in its stimulated state it has a catalytic rate higher than other known cyclases. These properties could confer a high signal-to-noise ratio on the system, being quiescent in the absence of stimulus but able to rapidly generate large amounts of cAMP upon odor exposure. Deletion of the gene encoding ACIII elicits a general anosmia in mice [24]. ACIII is also inhibited by Ca^{2+}, providing an opportunity for negative feedback upon intracellular elevations of this signaling molecule.

In 1987, Nakamura and Gold [25] recorded a cAMP-activated conductance from OSN cilia. This was the final link between the biochemical cascade and the electrical signal. It was subsequently determined that the channel responsible is comprised of three distinct olfactory-specific subunits, CNGA2, CNGA4 and CNGB1b; all are members of the cyclic-nucleotide-gated (CNG) channel family (Ch. 21) that also contains the cGMP-activated channel found in photoreceptors. These channels are homologous with voltage-sensitive channels, such as K^+ and Ca^{2+} channels [26]. CNGA2 is obligatory for channel function both *in vitro* and *in vivo*, while CNGA4 and CNGB1b serve important modulatory roles [26]. The olfactory CNG channel is selective for cations; is sensitive to both cAMP, with a K_d of 20 μM, AND cGMP WITH A K_d of 5 μM; requires at least three molecules of cyclic nucleotide to bind for activation, and is required for odor signaling in OSNs [26, 27].

The activation of tens to hundreds of these channels and the subsequent influx of cations, including both Na^+ and Ca^{2+}, leads to depolarization of the cell membrane. Olfactory neurons have one additional level of amplification that is rather unusual. A Ca^{2+}-activated Cl^- conductance is also present on the cilia and is opened during the odor response by the Ca^{2+} ions flowing into the cilia through the cAMP-gated channel [28]; this channel has not been cloned. Curiously, olfactory neurons maintain a very high intracellular Cl^- concentration, perhaps as high as 125 mM, so that the driving force for Cl^- ions is outward and, therefore, further depolarizes the cell. This additional current may be important for preserving ionic

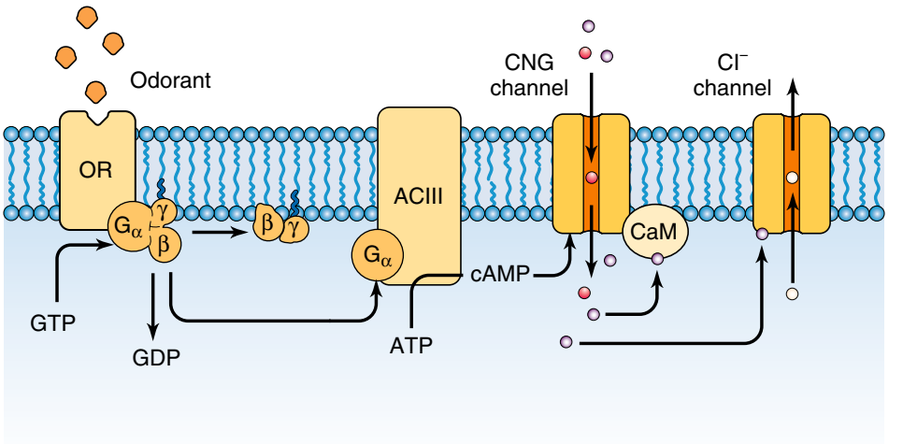

FIGURE 50-5 A model for the transduction of odors in OSNs. The individual steps are detailed in the text. Note that several feedback loops modulate the odor response, including inhibition of the CNG channel by Ca^{2+} ions (*purple balls*) that permeate the channel, and a Ca^{2+}/calmodulin (CaM)-mediated desensitization of the channel that underlies rapid odor adaptation. Several other mechanisms, including phosphodiesterase-mediated hydrolysis of the second messenger, cAMP, and phosphorylation of the OR by various kinases, have also been described.

driving forces across a membrane in a compartment that is not highly regulated, that is, the mucus. Changing ion concentrations in the mucus could affect the driving forces on ions, so the olfactory neuron supplies its own driving force by maintaining a high intracellular concentration of Cl^-.

This pathway provides several amplification steps between odorant binding and signal generation. Due to the electrically compact structure of the cell, it is possible for the activation of only a few tens of channels to drive the membrane to the threshold for action-potential generation. Thus, it is theoretically possible that the limit of olfactory detection is a single molecule, although this has not yet been conclusively demonstrated.

Negative-feedback processes mediate adaptation of the olfactory transduction apparatus to prolonged or repetitive stimulation. Upon application of a sustained odor stimulus to an olfactory neuron, the current response is transient, falling back to baseline within 4–5 s. The termination of a response in the continued presence of agonist is characteristic of many signaling systems, and is variously known as adaptation or desensitization, depending on the putative site of the off mechanism. Typically, a negative-feedback process is at work such that accumulation of a product of the agonist response serves to turn off an upstream link in the signal-generating cascade. In the olfactory neuron, two feedback messengers have been identified, and, as might be expected, they are Ca^{2+} and cyclic nucleotides.

The cyclic-nucleotide-gated channel is permeable to cations, especially Ca^{2+}. Thus, increased channel activation results in influx of Ca^{2+} and a transient rise in the intracellular Ca^{2+} concentration. Intracellular Ca^{2+} concentrations of 1–3 μM have been found to lead to a decrease in the open probability of the ion channel, even in the presence of high concentrations of cAMP [29]. Mediated by the intermediate Ca^{2+}-binding protein calmodulin, this Ca^{2+}-dependent desensitization of the channel accounts for virtually all short-term adaptation, and is dependent on the presence of the CNGA4 subunit, which increases the kinetics of Ca^{2+}/calmodulin-mediated desensitization of the native channel nearly 70-fold [30]. This is an attractive mechanism for mediating a rapid but short-lasting form of adaptation since it is dependent on the influx of Ca^{2+} during the response to an odor.

Other mechanisms have also been implicated in odor adaptation, including cAMP-dependent phosphorylation of ciliary proteins via protein kinase A; G-protein-receptor kinase activity (GRK3), possibly via phosphorylation of the OR; Ca^{2+}/calmodulin kinase II (CaMKII) phosphorylation of ACIII; cGMP; and carbon monoxide [31]. These latter three mechanisms have been particularly linked to longer-lasting forms of adaptation, on the order of tens of seconds (for CaMKII) or minutes (CO/cGMP). Together with the short-term adaptation described above, these various molecular mechanisms provide the OSN with a number of ways to fine-tune odor responses over time.

Alternative second-messenger pathways may be at work in olfactory transduction. The role of cAMP in olfactory transduction is well established. Are there alternative pathways, such as those involving phospholipids and Ca^{2+}? Several groups have reported that certain odorants can elicit an increase in the phosphoinositde second messenger inositol 1,4,5,-trisphosphate (IP_3) (Ch. 20). However, there is no clear evidence that IP_3 directly mediates an electrical response in OSNs, nor is there a clear rationale for two parallel excitatory odor transduction cascades. However, more recent data support the idea that phosphoinositides or enzymes related to their metabolism may play a modulatory role, shaping the OSN output by

interactions with the cAMP-signaling cascade or the CNG channel [32]. It should be noted, however, that among invertebrates there is good evidence that IP_3, as well as cAMP, play important roles in olfactory signal transduction.

There is one small subset of cells in the main olfactory epithelium that clearly does not utilize a cAMP-dependent transduction cascade. These cells, which may represent less than 0.1% of the ciliated neurons in the epithelium, do not express G_{olf}, ACIII or CNGA2. They do, however, express components of a putative cGMP signaling mechanism: a transmembrane isoform of guanylyl cyclase called GC-D (Ch. 21); a splice variant of the cGMP-sensitive channel subunit CNGA3, the principal subunit found in cone photoreceptors; and cGMP-sensitive phosphodiesterase 2A [21]. These cells, which project their axons to the caudal olfactory bulb, terminating in ~9 'necklace' glomeruli, are of unknown chemosensory function.

The vomeronasal organ is an accessory chemosensing system that plays a major role in the detection of conspecific chemical cues, also known as pheromones. These cues are important in rearing, territorial, courtship and, in particular, sexual behaviors. The vomeronasal organ (VNO) is separate from the main epithelium in mammals, comprising a thin epithelial tissue within a bony capsule in the lateral wall of the nasal cavity. It is probably vestigial in humans. The VNO epithelium contains at least two populations of microvillar chemosensory neurons; one is in the more apical aspects of the epithelium, while the other lies in the more basal region. These two populations of vomeronasal neurons (VNs) are defined by the differential expression of several genes. For example, the apical VNs express the G-protein subunit $G\alpha_{i2}$, while the basal neurons express $G\alpha_o$. Apical and basal VNs also express different putative chemosensory receptors, the V1Rs and V2Rs, respectively. There are ~150 V1Rs, and a similar number of V2Rs. These receptors, while both GPCRs, are otherwise unrelated to each other: V1Rs are Class A GPCRs, while V2Rs are members of Class C (similar to metabotropic glutamate receptors; Ch. 15)(Fig. 50-6). They also bear no sequence homology to ORs. Although the V1Rs have been linked to pheromone responses, only a single V1R, and no V2R, has been paired with a cognate ligand [1]. The basal VNs also specifically express several major histocompatibility complex class Ib genes. While their specific function is still unclear, they do appear to play an important role in V2R trafficking to, or stabilization in, the plasma membrane [33].

Chemosensory neurons of the vomeronasal system are narrowly tuned to specific chemical cues, and utilize a unique mechanism of sensory transduction. Pheromones, odorants released by one member of a species that elicit behavioral or hormonal changes in another member, have been identified in a number of mammals, and are often found in urine. Leinders-Zufall and colleagues first demonstrated the specific activation of VNs by odorants with pheromone properties in mice [34]. In doing so, two unique properties of VNs were identified that functionally differentiate them from OSNs. First, VNs are extremely sensitive to their ligands, with activation thresholds as low as 10^{-11} M. Second, in contrast to the broadly tuned OSNs, VNs are highly selective, seemingly responsive to only single stimuli even at high stimulus concentrations. These properties suggest a different coding strategy for these two types of olfactory neurons: broadly tuned OSNs that can respond to novel odorants, and narrowly tuned, highly sensitive VNs that specifically respond to conspecific odorants of particular behavioral relevance.

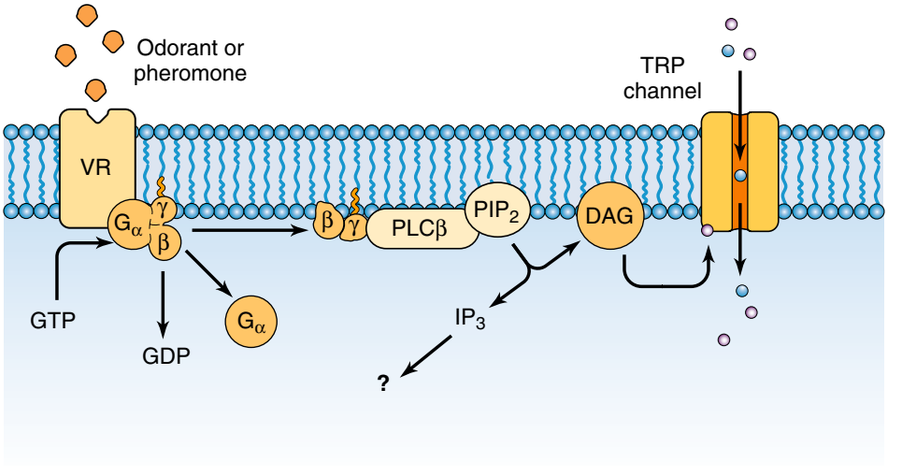

FIGURE 50-6 A model for chemosensory transduction in vomeronasal sensory neurons. The individual steps are detailed in the text. In contrast to the transduction cascade in OSNs, the mechanism of vomeronasal transduction is less well characterized. Vomeronasal neurons express either V1R or V2R receptors and either $G\alpha_{i2}$ or $G\alpha_o$, respectively. The TRPC2 channel subunit is expressed in all vomeronasal neurons, and may be part of a multimeric channel complex. Ca^{2+} ions are represented as *purple balls*, Na^+ ions as *blue balls. VR*, vomeronasal receptor (V1R or V2R); *PIP_2*, phosphatidylinositol 4,5-bishphosphate; *IP_3*, inositol 1,4,5-trisphosphate; *DAG*, diacylglycerol.

The biochemical cascade responsible for the transduction of VN stimuli is not fully understood. However, recent findings implicate a phospholipid signaling pathway at work in both VN populations (Fig. 50-6). All VNs express an ion channel subunit, TRPC2, that is a member of the transient receptor potential (TRP) family [35]. The essential role of TRPC2 in VN function, and the critical role of VNs in some pheromone-dependent behaviors, was conclusively demonstrated when the *Trpc2* gene was deleted in mice: VN activity in response to pheromones was nearly or completely abolished, and null mice exhibited altered sexual and social behaviors [36, 37]. The native VN channel containing TRPC2 is directly gated by the lipid messenger diacylglyerol in a pheromone-dependent manner [38]. However, the activation of vomeronasal receptors has still not been directly linked to diacylglycerol production via any G protein or phospholipase isoforms.

TASTE

Multiple senses, including taste, contribute to our total perception of food. Our perception of the flavor of food is a complex experience based upon multiple senses: taste *per se*, which includes sweet, sour, salty and bitter; olfaction, which includes aromas; touch, also termed 'mouth feel', that is, texture and fat content; and thermoreception and nociception caused by pungent spices and irritants. Taste proper is commonly divided into four categories of primary stimuli: sweet, sour, salty and bitter. One other primary taste quality, termed umami (the taste of L-glutamate), is still somewhat controversial. Mixtures of these primaries can mimic the tastes of more complex foods.

The chemical complexity of taste stimuli suggests that taste receptor cells utilize multiple molecular mechanisms to detect and distinguish among these compounds. Our sense of taste can detect and discriminate various ionic stimuli, for example, Na^+ as salty, H^+ as sour, sugars as sweet and alkaloids as bitter. While a number of recent studies have begun to identify the molecular players in taste transduction, the relative inaccessibility of the sensory cells, the diversity of sensory cell across the epithelium, and a number of functional and anatomical differences between animal models, even amongst rodents, mean that the mechanisms of taste transduction are still poorly understood.

Taste receptor cells are organized into taste buds. The chemical detection of taste stimuli resides in specialized epithelial cells, taste receptor cells (TRCs), which in vertebrates are present as ovoid clusters, or taste buds, each containing 50 to 100 cells (Fig. 50-7). The taste buds are embedded within the nonsensory lingual epithelium of the tongue, and they are housed within connective tissue specializations called papillae, which in humans are fungiform, foliate and circumvallate. Taste buds are also found in the palate, pharynx and upper portion of the esophagus.

The taste bud is a polarized structure with a narrow apical opening, termed the taste pore, and basolateral synapses with afferent nerve fibers. Solutes in the oral cavity make contact with the apical membranes of the TRCs via the taste pore. There is a significant amount of lateral connectedness between taste cells within a bud: both electrical synapses between TRCs and chemical synapses between TRCs and Merkel-like basal cells have been demonstrated to occur [39]. Furthermore, there are symmetrical synapses between TRCs and Merkel-like basal cells [39]. In addition, these basal cells synapse with the afferent nerve fiber, suggesting that they may function in effect as interneurons [39]. The extensive lateral interconnections

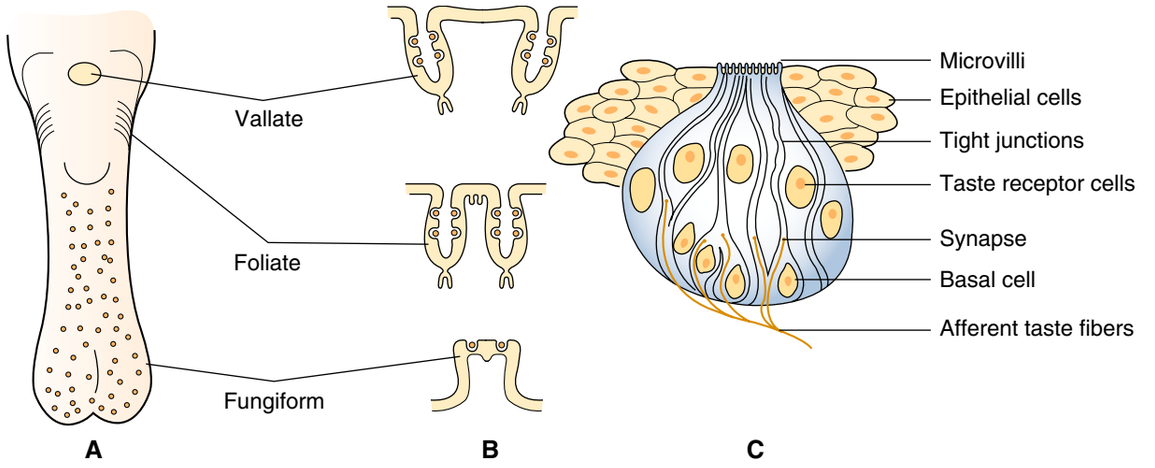

FIGURE 50-7 Rat tongue, taste papillae and taste buds. (**A**) Surface of the rat tongue showing location of the taste papillae. (**B**) Cross-section of the three main types of taste papillae: fungiform, foliate and vallate. (**C**) The taste bud contains 50–100 taste cells, including receptor cells and basal cells.

within a bud along with the branching of afferent fibers to synapse with several receptor cells within a given bud, suggest that much signal processing occurs peripherally within the taste bud itself.

Sensory afferents within three cranial nerves innervate the taste buds. The sensory fibers that innervate the taste buds travel in cranial nerves VII, IX and X. The chorda tympani carries fibers from VII to innervate taste buds on the anterior portion of the tongue, within the fungiform papillae and the anterior foliate papillae. The lingual branch of the glossopharyngeal nerve (IX) innervates buds within the circumvallate papillae and the posterior foliate papillae, while the superior laryngeal branch of the vagus (X) innervates taste buds of the epiglottis and the esophagus. These nerves relay taste information both to forebrain taste areas and to local circuits involved in oromotor reflexes.

Information coding of taste is not strictly according to a labeled line. Two different models have been proposed to account for information coding in the gustatory system: (1) labeled line and (2) across-fiber pattern code. The labeled-line model predicts that individual TRCs will respond to only a single taste quality; separate afferent pathways then transmit information about each taste quality to the gustatory cortex via the medulla and the thalamus. Thus, in the labeled-line model, the function of any one neuron in an afferent pathway is to signal its particular encoded taste quality. The across-fiber pattern-coding model proposes that individual taste cells respond to multiple taste qualities. Information about taste quality is then transmitted to the brain by afferent fibers that have broadly overlapping response spectra. Thus, the code for a particular quality is determined by the pattern of activity across all of the afferent nerve fibers, rather than by activity in any single nerve fiber.

Experimental results suggest that gustatory information coding utilizes both types of mechanisms. For example, single chorda tympani fibers respond to multiple taste qualities, such as salt and sour or sour and bitter, although they will often show a preferential response for a single taste quality. This implies that while some type of pattern-recognition processing must occur in taste coding, there is likely also some specificity of inputs from cells in the taste buds. Recent molecular biological experiments support this more nuanced view of taste processing. For example, *in vivo* expression in TRCs that normally express sweet taste receptors of a non-native receptor responsive to a synthetic ligand, results in mice that prefer the taste of this previously 'tasteless' stimulus [40].

Taste cells have multiple types of ion channels. TRCs are electrically excitable and capable of generating action-potentials: voltage-dependent channels for Na^+, Ca^{2+} and K^+, similar to those in neurons, have been detected in vertebrate TRCs. The surface distribution of these channels may reflect differences in their functional activities, but the consequences of this are not well understood. Ion channels also play more direct roles in the transduction of salts and acids [41]. These ionic stimuli can either directly enter taste cells via channels in the apical membranes, or can modulate the activity of channels. Interestingly, some ions can diffuse through the tight junctions of the taste epithelium to interact with channels in the basolateral membranes of the TRCs, the so-called paracellular taste pathway.

Salts and acids are transduced by direct interaction with ion channels. Salt taste in mammals is mediated, at least in part, by a voltage-independent, amiloride-blockable, apical Na^+ channel. Micromolar concentrations of amiloride block this Na^+ conductance in isolated taste cells and reduce Na^+ salt stimulation of gustatory nerve fibers [42]. The presumed mechanism for taste cell response to salt is direct influx of Na^+ through this amiloride-blockable channel, leading to taste-cell depolarization, action-potential generation and neurotransmitter release. These Na^+ channels share a number of physiological and pharmacological properties with ENaC channels. Members of the degenerin (DEG)/ENaC ion channel superfamily, ENaCs are commonly found in epithelial cells involved in solute transport, such as renal epithelial cells. DEG/ENaC family members display a common topology, including two putative transmembrane helices, a large extracellular loop and a smaller pore-forming loop (Fig. 50-8). Although α, β and γ subunits of the ENaC channel have been localized to the apical membranes of TRCs (ENaCs function as heteroligomeric complexes), they have still not been definitively linked to salt taste. Furthermore, other mechanisms must contribute to the transduction of Na^+ taste, since about 20% of the afferent nerve response to NaCl is

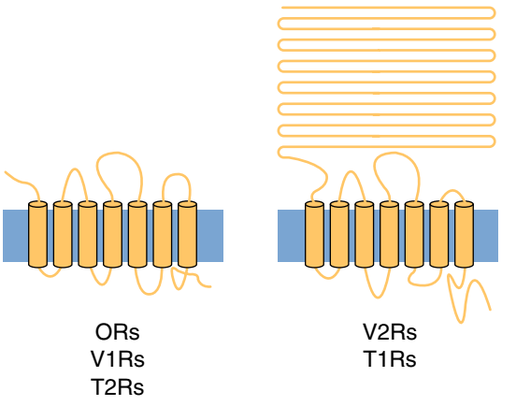

FIGURE 50-8 Topology of GPCR-type chemosensory receptors. Chemosensory receptors are found in two major GPCR classes: Class A (rhodopsin-like) and Class C (mGluR-like). ORs, V1R vomeronasal receptors and T2R bitter taste receptors are all Class A, though they share no amino-acid sequence. V2R vomeronasal receptors and T1R taste receptors are Class C GPCRs, and have the long, extracellular *N*-terminus stereotypical of that class. V2Rs and T1Rs also exhibit no amino-acid sequence similarity.

amiloride-insensitive. One of these mechanisms is believed to involve permeation of Na^+ through the tight junctions that connect taste cells at the apex of the taste bud; the Na^+ presumably enters taste cells through basolateral Na^+ channels [43]. Recently, a TRPV1-like channel has been implicated in amiloride-insensitive salt taste in mice [44].

Sour taste is a function of the acidity of a solution, depending primarily on the proton concentration and to a lesser extent on the particular anion involved. As with salty taste, sour taste is perceived as a result of the direct interaction of protons with ion channels of taste cells. Sour stimuli can depolarize TRCs by either activating cation channels or directly permeating ion channels. Several mechanisms have been found to contribute to sour transduction. As for salt taste, DEG/ENaC channels may be involved in sour taste transduction. For example, in hamsters, protons enter the cell through an amiloride-sensitive Na^+ channel; in the absence of Na^+, protons permeate the channel, depolarizing taste receptor cells [45]. Clearly, other mechanisms must be involved or we could not distinguish salts from acids. ASICs (acid sensing ion channels) and MDEG1/BnaC1 (mammalian degenerin-1/brain-type sodium channel-1) are directly activated by protons and are expressed in taste tissue. Other mechanisms of acid transduction could include proton permeation of the tight junctions at the apex of the taste bud or acidification of potassium channels. The basolateral targets of protons have not been identified.

Taste cells contain receptors, G proteins and second-messenger-effector enzymes. Research on the biochemistry and molecular biology of taste has long lagged behind that on vision or olfaction, because of the relative inaccessibility of taste receptor cells and the lack of high-affinity ligands specific for taste receptors. However, more recently, significant progress has been made in identifying important players in the transduction of sweet, umami and bitter taste. It is now clear that these tastants are transduced predominantly, if not exclusively, by G-protein-coupled, second-messenger cascades.

Gustducin is a taste-cell-specific G protein closely related to the transducins. The first heterotrimeric G protein subunit to be implicated in taste transduction was α-gustducin. This novel G protein α subunit was first cloned from rat taste tissue [46] and is expressed in about 25–30% of TRCs of the circumvallate, foliate and fungiform papillae [47]. Gustducin is most closely related to the transducins (Ch. 49), the rod-and-cone-photoreceptor G proteins, which have also been found in taste cells. Gustducin has been implicated in the transduction of bitter tasting stimuli through the activation of a phosphodiesterase [47]. In TRCs, α-gustducin associates with the G protein $\beta\gamma$ subunits $G\beta_3$ and $G\gamma_{13}$. Interestingly, these subunits activate a phosphoinositide-mediated signaling pathway through phospholipase C-β_2 (PLCβ_2) [48]. PLCβ_2 is also critical for the transduction of bitter tastants both *in vitro* [48] and *in vivo* [49]. It remains unclear whether a cyclic nucleotide cascade may contribute to the transduction of bitter tastants through the modulation of phophoinositide signaling, or via a more direct mechanism.

Gustducin plays a role in sweet and umami taste, as well. As expected, gustducin null mice, in which the gene encoding gustducin has been deleted by gene targeting, exhibit normal responses to salts and acids but reduced responses to bitter stimuli [50]. Surprisingly, these null mice also had reduced responses to sweet and umami stimuli [50, 51]. Highlighting the fact that taste transduction mechanisms may subtly vary across the gustatory epithelium (see below), gustducin is important for umami detection from anterior, but not posterior taste buds. Further studies will be required to determine the precise role of gustducin in the sweet transduction cascade.

Sweet, bitter and umami taste involve receptor-coupled second-messenger pathways that are differentially expressed across the gustatory epithelium. Though sweet and bitter transduction may share some common downstream signaling mechanisms, it was hypothesized that each must utilize different groups of receptor proteins. Though the first taste-specific GPCRs were identified several years ago [52], for many years they remained orphan receptors (i.e. their physiological ligands were unknown). Now called T1R1 and T1R2, these receptors are Class C GPCRs and contain a large extracellular *N*-terminus that is thought to contain the ligand-binding domain (Fig. 50-8). Recently, several groups have utilized a combination of molecular biological and genetic approaches to identify the gene encoding a third T1R, T1R3 [53–59]. The T1Rs are differentially distributed across the gustatory epithelium: T1R1 and T1R2 are expressed in distinct populations of TRCs (T1R1 is found predominantly on the anterior tongue and T1R2 mostly on the posterior tongue), but are always coexpressed with T1R3. This differential pattern of expression suggested varied functions of T1R1 and T1R2, a possibility born out by subsequent *in vitro* and *in vivo* studies (see below).

Certain mutations in the mouse *Tas1r3* gene (which encodes T1R3) correlate with a reduced sensitivity to sweet compounds, including saccharin and many natural sugars [60]. The identification of *Tas1r3* as the saccharin-sensitivity gene *Sac* provided the first evidence that the T1Rs might be involved in sweet taste. The T1Rs function as heteromeric receptors (probably dimers), with T1R2 and T1R3 combining to form a receptor for sweet-tasting compounds including sugars, sweeteners, and some D-amino acids [55] (T1R3 can also form homomeric receptors responsive to high concentrations of natural sugars). In contrast, T1R1/T1R3 heteromers are insensitive to sweet-tasting stimuli but do respond to umami stimuli, including many L-amino acids [61, 62]. Furthermore, T1R1/T1R3 responses are potentiated by 5′-ribonucleotides, a characteristic of umami taste. Although it is now accepted that the T1Rs are essential for normal sweet and umami

taste sensitivity in mammals, some studies have implicated T1R-independent mechanisms, as well [63,64]. Resolution of this controversy awaits further experimentation.

A distinct receptor family is involved in the detection of bitter tastants. Bitter agents are very structurally diverse, suggesting multiplicity of receptors and/or multiplicity of detection pathways. Many bitter compounds are lipophilic and membrane-permeant, and may act on intracellular or integral membrane targets. However, it is clear that GPCRs play a central role in the detection of bitter stimuli. The T2R family comprises ~30 Class A GPCRs (Fig. 50-8) whose genes (the *Tas2rs*) were first identified based on their proximity to known genetic loci involved in bitter taste [65]. Subsequent *in vitro* experiments have paired several of these receptors to a number of bitter ligands [1], confirming the role of T2Rs in bitter taste. Unlike the T1Rs, which show a somewhat differential pattern of expression, it appears that T2R-containing TRCs express most, if not all, of the *Tas2r* genes. This overlapping pattern of expression is consistent with bitter-taste behavior, as animals do a poor job of discriminating bitter compounds and may be more dependent on high taste-sensitivity to these compounds, which are often toxic.

How T1Rs and T2Rs are coupled to intracellular signaling cascades is still unclear, but a model for the major molecular players is presented in Figure 50-9. Gustducin is critical for bitter, sweet and umami taste, but is unlikely to account for all T1R or T2R-mediated signaling as gustducin knockout animals retain residual taste responses [50]. Other G-protein isoforms have been implicated in taste, including transducin, $G\beta_3$ and $G\gamma_{13}$, more may play a role, as well [47].

Both cyclic-nucleotide and phosphoinositide-second-messenger signaling mechanisms have been implicated in bitter, sweet and umami taste [47]. The strongest evidence supports a role of PLCβ2 in the transduction of stimuli of these three taste qualities. Deletion of the gene encoding PLCβ2 from mice abolishes behavioral responses to bitter, sweet or umami stimuli, while restoration of PLCβ2 expression in only T2R-expressing cells rescues bitter taste alone [49].

In many cells, phosphoinositide signaling leads to an elevation in intracellular calcium levels through the release of calcium from intracellular stores in response to IP_3-dependent gating of channels in the endoplasmic epithelium (Ch. 20). It is not known if IP_3 plays a critical role in TRC transduction, but such a role would be consistent with recent findings that a Ca^{2+}-activated cation channel, TRPM5, is essential for normal sweet, bitter and umami taste function [49, 66–69].

Many textbooks continue to state incorrectly that taste sensitivities are strictly localized on the gustatory epithelium. However, there is some regionalization of sensitivity that is consistent with the observation that taste receptors and intracellular signaling components are differentially localized across the gustatory epithelium [70] (Fig. 50-10). For example, gustducin is only expressed in a subset of TRCs, although it is found across the epithelium. ENaC is heavily expressed in the anterior tongue and palate, but at lower levels in the posterior tongue. Gustducin is implicated in umami detection from the anterior, but not the posterior tongue. A number of gustducin-expressing cells do not express TRPM5. These differential patterns of expression highlight the functional and molecular

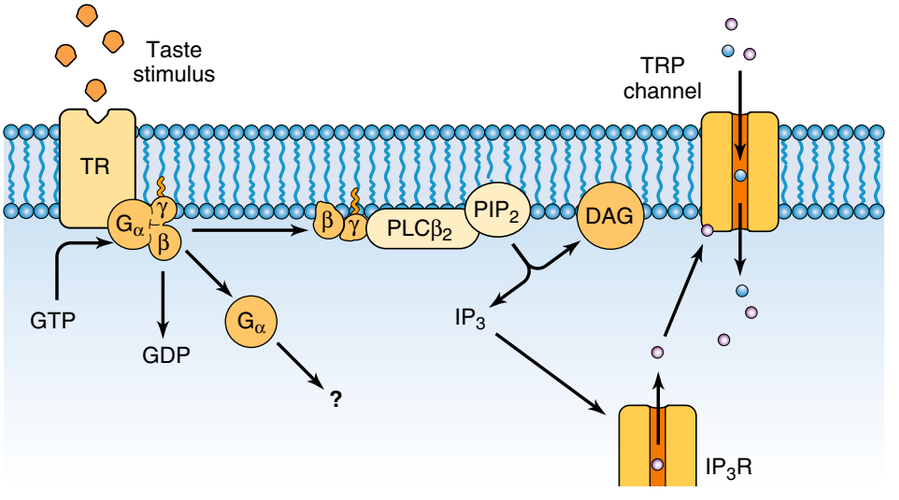

FIGURE 50-9 A model for the major signaling mechanisms for the transduction of bitter, sweet and umami stimuli. The individual steps are detailed in the text. Note that stimuli of each of these taste qualities interact with GPCRs: bitter stimuli with T2Rs and sweet and umami stimuli with T1Rs. α-gustducin has been implicated in the transduction of all three types of stimuli, but other α-subunits may couple to T1Rs and T2Rs in some TRC subpopulations (e.g. Fig. 50-10). PLCβ2 and the Ca^{2+}-activated TRP channel subunit TRPM5 are essential for normal bitter, sweet and umami taste, but other mechanisms may play some role as well. For example, some bitter stimuli may diffuse through the plasma membrane to activate intracellular proteins directly, and cyclic nucleotide-dependent signaling has been implicated in both bitter and sweet taste [47, 70]. The role of IP_3 and the IP_3R in the stimulus-dependent increase in intracellular Ca^{2+} as depicted is speculative.

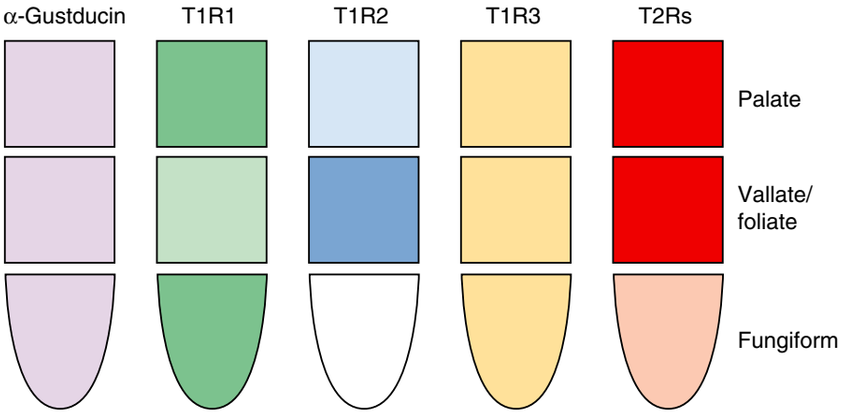

FIGURE 50-10 Many taste transduction elements are differentially expressed across the gustatory epithelium. Three areas of epithelium are represented: the anterior tongue (with fungiform papillae), the posterior tongue (with vallate and foliate papillae) and the soft palate. *Darker colors* represent relatively greater numbers of TRCs expressing that protein. It is important to note that within a given region, only a subset of TRCs will express a given protein. For example, α-gustducin is expressed in 20–30% of TRCs, and α-gustducin is co-expressed with T2Rs but is found in only subsets of T1R-expressing TRCs. The specifics of these expression patterns also probably vary between species. Modified from [70], with permission.

complexity of taste transduction. A major effort in taste transduction research over the coming years will focus on understanding how subtle differences in transduction mechanisms across TRC subpopulations may have an impact on taste function.

ACKNOWLEDGMENTS

Molecular Biology of Hearing and Balance

Peter G. Gillespie

GENERAL FEATURES OF MECHANORECEPTORS 833
Mechanotransduction is of great utility for all organisms 833
A unified model for mechanotransduction allows comparison of mechanoreceptors from many organisms and cell types 833

MODEL SYSTEMS 834
Genes responsible for touch detection in *C. elegans* have been identified and suggest a model for mechanical transduction 834
Polymodal sensory neurons in *C. elegans* are also mechanoreceptors 835
Drosophila bristle receptors and chordotonal organs are surface mechanoreceptors 835
Insect mechanoreceptors and hair cells share evolutionary relationships 835

HAIR CELLS 835
Hair cells are the sensory cells of the auditory and vestibular systems 835
Hair cells are exposed to unusual extracellular fluids and potentials 836
Mechanical transduction depends on activation of ion channels linked to extracellular and intracellular structures 836
Some of the molecules responsible for hair-cell transduction have been identified 838

DEAFNESS 839
The 'deafness gene' approach has proven fruitful for finding genes important to the auditory system 839
A variety of genes have been identified, including a set of genes that apparently interact with each other in the auditory and visual systems 839
The surprise is that genes clearly involved in mechanotransduction have not yet been identified by the deafness-gene approach 839

CONCLUSIONS 840

Hair cells are specialized mechanoreceptors located in the inner ear; these cells transduce mechanical forces transmitted by sound and head movement, and permit an organism to sense features of the external world. Well-characterized biophysically, a molecular description of hair-cell transduction has finally begun to emerge. Although many key molecules remain to be identified, striking molecular and functional correspondences between vertebrate hair cells and invertebrate mechanoreceptors have indicated that some types of mechanoreceptors probably share a common ancestor. The continued application of genetic, molecular, biological and biophysical approaches should lead to a more thorough understanding of this critical sensory cell.

GENERAL FEATURES OF MECHANORECEPTORS

Mechanotransduction is of great utility for all organisms. Most multicellular organisms exploit mechanoreceptors — specialized cells that detect external mechanical forces — to help construct their internal view of the external world. The senses of hearing, balance and touch all rely on mechanoreceptors, as do the proprioceptive sensations that tell an organism how it is situated in the environment. Mechanoreception is probably one of the most ancient of the senses.

A unified model for mechanotransduction allows comparison of mechanoreceptors from many organisms and cell types. Mechanoreceptors nearly universally use ion channels for transducing sensory information. Mechanoreceptors are either neurons or are neuroepithelial cells with synapses, and the currency of the nervous system is the membrane potential. Opening an ion channel allows a cell quickly and extensively to modulate its membrane potential, and hence neurotransmitter release, the final step in mechanoreception at the cellular level.

Ion channels open or close upon relative movement of internal domains, movements that can be elicited by

Basic Neurochemistry: Molecular, Cellular and Medical Aspects

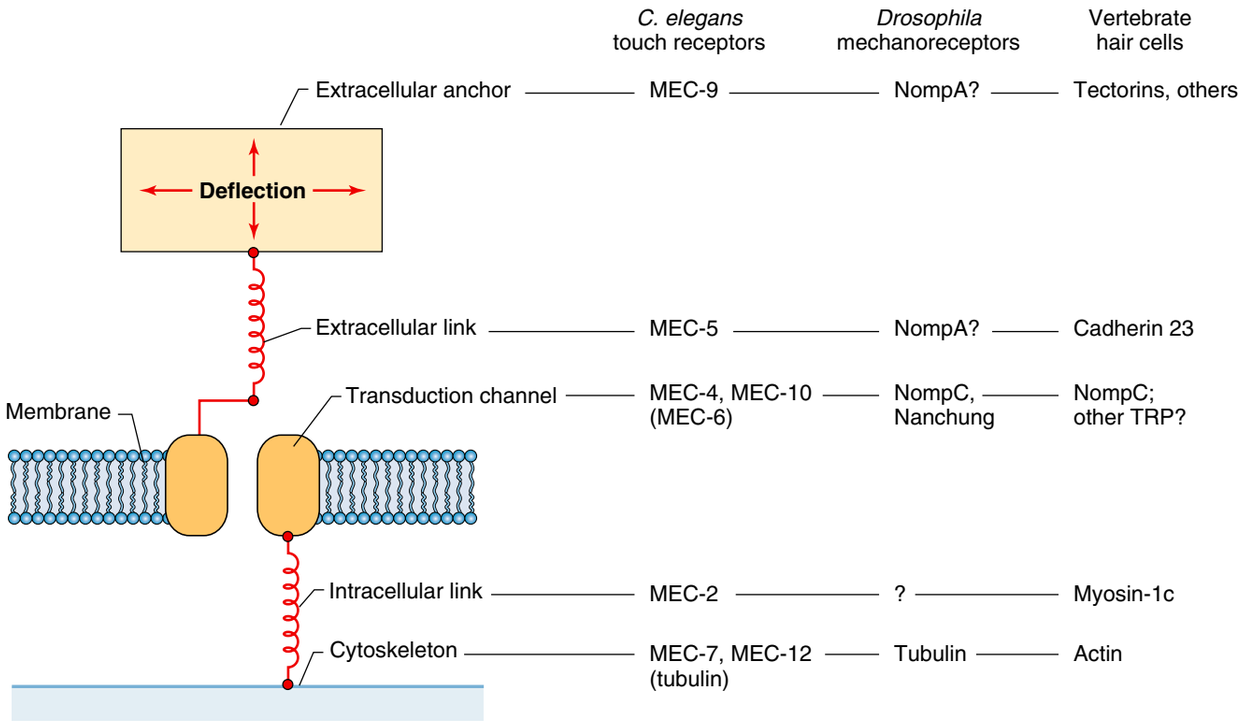

FIGURE 51-1 General model for mechanotransduction. **Left**, a transduction channel, embedded in the plasma membrane, is anchored mechanically to the cytoskeleton and to an extracellular structure that can move relative to the cell. Movements of the extracellular structure relative to the cytoskeleton cause tension to develop throughout the system, which is delivered to the gate of the channel. Increased gating tension causes channels to open. **Right**, candidate proteins are named from the best-characterized mechanoreceptor systems for each of the elements indicated on the left.

voltage, ligand binding, or force (see Ion Channels in Ch. 6). How can force influence domain movements within ion channels? In some cases, domains can be moved by tension within the plasma membrane. Bacterial osmosensors are thought to work this way; as membrane tension increases, the channels gate to reduce tension [1]. However, most mechanoreceptors apparently do not sense membrane tension. Instead, independent investigation of hair cells, worm touch receptors and fly bristles have converged on a single general model for how transduction channels are gated (Fig. 51-1). In this model, the ion channel is anchored on both sides of the membrane. The intracellular anchor is the cytoskeleton, actin in the case of hair cells and microtubules in the case of characterized mechanoreceptors in worms and flies. The extracellular anchor varies substantially from cell type to cell type. The critical feature of this model is that external forces cause a net displacement of the two anchors; the force is transmitted to the channel, and net domain movement is triggered [1].

MODEL SYSTEMS

Understanding the general features of mechanoreceptors has been greatly assisted by the use of model systems. Genetically tractable organisms like *Caenorhabditis elegans* and *Drosophila melanogaster* have permitted a much more thorough inventory of the parts required for mechanotransduction than is possible in most vertebrates; the recent ascent of the zebrafish *Danio rerio* as a model has extended the advantages of a genetic organism to vertebrate mechanotransduction.

Genes responsible for touch detection in *C. elegans* have been identified and suggest a model for mechanical transduction. Worms like *C. elegans* respond to a gentle touch on the nose by turning away. Mechanical deformation of the worm's cuticle stimulates specific cells (six body-touch sensory neurons), which transmit sensory information to neural circuits that control locomotion. Genetic experiments have revealed ~12 genes involved in this response, and the identities of these genes have suggested a specific molecular model for the transduction apparatus (reviewed in [2]). Extracellular matrix molecules (MEC-5, MEC-9) presumably are mechanically connected to ion channels formed by MEC-4 and MEC-10 subunits, which belong to the DEG/ENaC family of channels. MEC-6 also contributes to this channel complex. These ion channels are connected (probably by MEC-2) to an underlying microtubule network, which consists of unique 15-protofilament microtubules (tubulin subunits encoded by the *mec-7* and *mec-12* genes). Movement of the cuticle relative to the microtubule

network mechanically stimulates the transduction channel, which admits cations that depolarize the cell. Recent work has shown that excitation of the mechanosensory neurons leads rapidly to Ca^{2+} influx, apparently through MEC-4-type channels, which can be detected in live worms subject to touch stimuli [3]. Although direct mechanical gating of the DEG/ENaC channels has not been observed in intact neurons or cultured cells, the preponderance of the evidence supports this model.

Is this system relevant for hair cells? It does not appear so. Indeed, there appear to be at least two broad classes of mechanoreceptors, one like those of *C. elegans* touch neurons that rely on DEG/ENaC channels, and another class that apparently relies on *transient receptor potential* (TRP) channels. As we will see later, circumstantial evidence suggests that hair cells use TRP channels. Other mechanoreceptors in vertebrates may be related to *C. elegans* touch cells.

Polymodal sensory neurons in *C. elegans* are also mechanoreceptors. Polymodal sensory neurons in *C. elegans* seem to fall into the TRP class of mechanoreceptors as they apparently rely on several TRP channels for mechanosensation [4]. These sensory neurons respond to nose touch, hyperosmolarity and volatile repellents by triggering a backward response in the worm; the OSM-9 and OCR-2 channels apparently mediate these responses, and the pathways differ for each sensory modality. However, little is known about the transduction mechanism in these cells.

***Drosophila* bristle receptors and chordotonal organs are surface mechanoreceptors.** These surface mechanoreceptors on insects have been studied for many years. Progress on identifying molecules responsible for insect mechanoreception received a big boost in 1994, when Kernan *et al.* developed a screen for mechanoreceptor mutants in *Drosophila* [5]. They identified several dozen mutants that were deficient in mechanoreception and, with the assistance of their colleagues, have begun to identify them.

The most important molecules so far identified from this screen include a likely transduction channel, an extracellular molecule that could gate channels, and several molecules known to be important for axonemal structure and function. Although the set of molecules is less complete than that identified for *C. elegans* touch receptors, the diversity of mechanotransduction in *Drosophila* and the apparent similarity of these receptors to those in vertebrates, including hair cells (see below), demonstrates the significance of this model system.

The protein NompC is a TRP channel and appears to be the major transduction channel in fly bristles [6]. Bristle mechanotransduction resembles hair-cell transduction remarkably in its speed, polarity and adaptation [6], suggesting the possibility of a close evolutionary relationship between these mechanoreceptors. NompC is not the only bristle transduction channel, however, as a residual transduction current remains in *nompC* null flies. Moreover, NompC plays a relatively small role in fly hearing [7], where the TRP channel *nanchung* is essential [8]. These results have intensified the search for TRP channels that could mediate transduction in hair cells, as discussed below.

The gene *nompA* encodes a multi-domain extracellular protein that is expressed by support cells that cradle the mechanically sensitive neuron [9]. NompA is localized to the dendritic cap, which is covers the mechanically sensitive outer segment of the neuron. NompA is a good candidate for a protein that couples mechanically sensitive channels to external stimuli.

nompB is the gene for a protein involved in intraflagellar transport, the basic mechanism by which axonemal structures like mechanoreceptor dendrites are maintained by the cell [10]. We certainly expect that this screen will identify genes like *nompB*, just as deafness screens have identified proteins thought to be involved in hair-cell structural integrity.

Insect mechanoreceptors and hair cells share evolutionary relationships. In flies, the proneural gene *atonal* controls development of mechanoreceptors; *Math1* plays a similar role in mice. Indeed, *atonal* can fully substitute for *Math1* in mice and *Math1* can fully substitute for *atonal* in flies [11], suggesting that these two disparate systems might share a common genetic program used for development. As another example, as we will discuss later, *Drosophila* bristle mechanoreceptors and zebrafish hair cells each rely on the TRP channel NompC for mechanotransduction.

HAIR CELLS

Hair cells are the sensory cells of the auditory and vestibular systems. Hair cells are the sensory cells of the internal ear, essential for the senses of sound and balance. The hair cell's transduction apparatus, the molecular machinery that converts forces and displacements into electrical responses, can respond to mechanical stimuli of less than 1 nm in amplitude, and of tens or even hundreds of kilohertz in frequency. Indeed, our hearing is ultimately limited by Brownian motion of water molecules impinging on the transduction apparatus.

Even though well-characterized at a biophysical level, the mechanical transduction mechanism of hair cells is still not fully understood in molecular terms. This discrepancy is in part due to the extreme scarcity of hair cells; instead of the millions or even hundreds of millions of receptor cells that the olfactory and visual systems possess, only a few tens of thousands of hair cells are found in the internal ears of most vertebrate species. The small number of hair cells and the direct transduction mechanism has greatly impeded molecular biological and

biochemical characterization. Consequently, molecular description of hair-cell transduction has lagged well behind description of vision and olfaction.

Hair cells are neuroepithelial cells; their large basolateral surface includes synaptic contacts with afferent and efferent nerve fibers, while the mechanically sensitive hair bundle is located on their apical surface. The hair bundle is an ensemble of 30–300 actin-filled stereocilia and a single axonemal kinocilium (Fig. 51-2). The kinocilium, present during development in all hair cells, degenerates in those cells sensitive to high auditory frequencies. Stereocilia range in height from 1 µm, for very high frequency auditory detection, to 50 µm or more, in some vestibular systems. Stereocilia contain hundreds of cross-linked actin filaments throughout their length; as the stereocilium approaches the apical surface of the hair cell, that number systematically declines to a dozen or two. Stereocilia are thus mechanically stiff throughout most of their length, but are flexible at the insertion point. Stereocilia do not flex independently, however, as they are cross-linked together by a variety of linkages, including ankle links, lateral links and tip links.

The consequence of the mechanical properties of the stereocilia and their interconnection by flexible linkages is that, when the bundle is deflected by a mechanical stimulus, the bundle moves as a whole. Moreover, individual stereocilia slide with respect to each other, a movement that underlies mechanical transduction (Fig. 51-3).

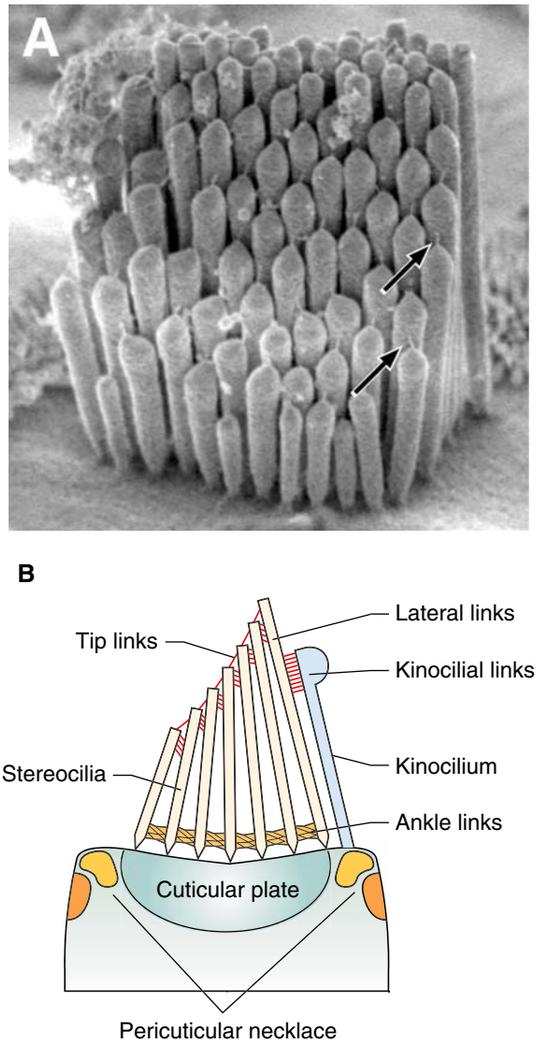

FIGURE 51-2 Hair-bundle structure. (**A**). The hair bundle, consisting of ~100 stereocilia, protrudes from the apical surface of this chicken-cochlea hair cell. Deflection of the bundle towards the taller stereocilia imparts tension onto tip links (indicated by *arrows*), which gate transduction channels. (**B**) Schematic depiction of a hair bundle. Actin-rich structures (e.g. stereocilia and cuticular plate) are indicated in *red*. The axonemal kinocilium, a microtubule-based cilium, is indicated in *blue*. The pericuticular necklace, a location of membrane vesicles bearing proteins targeted to the bundle, is indicated in *green*. Links between the stereocilia and between the tallest stereocilia and the kinocilium are also indicated.

Hair cells are exposed to unusual extracellular fluids and potentials. The apical surfaces of hair cells are exposed to an unusual extracellular fluid called endolymph. Endolymph is relatively similar in ionic composition to cytoplasm: it is high in K^+ (~150 mM), low in Na^+ (~2 mM), and relatively low in Ca^{2+} (~100 µM). Endolymph may have evolved to separate from hair cells the energy expenditure required to remove ions from hair cells. Normally, an excitatory cell like a neuron must pump out all of the ions that entered during an excitatory response (see Ch. 5). The ear separates this pumping task away from the hair cell. K^+, the major current-carrying ion, enters hair cells down an electrical gradient (hair cells are typically −60 mV) through transduction channels; when channels are closed, however, K^+ readily leaves through basolateral K^+ channels down the normal K^+ electrochemical gradient. The energy expenditure required for transduction is thus passed on to the stria vascularis cells, which, via the Na/K-ATPase, establish the high K^+ concentration in the endolymph.

The endolymphatic compartment of the auditory system is at an elevated potential (about +80 mV); this endocochlear potential increases the driving force on K^+ yet more, producing additional transduction current. Some mutations that cause deafness affect either K^+ levels in the endolymph or the endolymphatic potential itself.

Mechanical transduction depends on activation of ion channels linked to extracellular and intracellular structures. A comprehensive model for hair-cell transduction has emerged, derived primarily from biophysical and morphological investigations. Residing in the mechanoreceptive organelle of a hair cell, the hair bundle, the transduction apparatus consists of at least three components: the *transduction channel*, a mechanically gated ion channel; the *tip link*, an extracellular filament that transmits force to the channel's gate; and the *adaptation motor*,

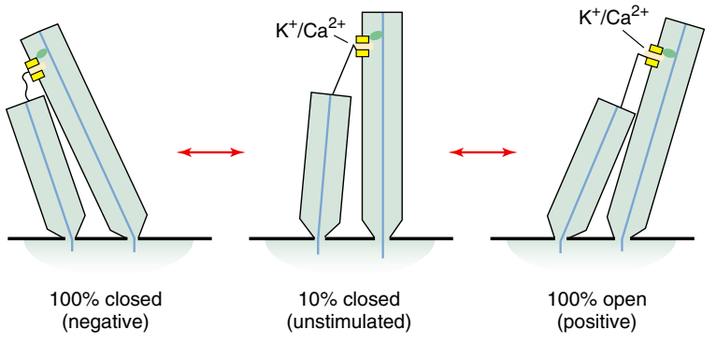

FIGURE 51-3 Hair-cell transduction. Only two stereocilia out of a bundle are shown. The transduction channel (*yellow*) is gated by the tip link. At rest, channels spend ~10% of the time open. An excitatory deflection moves the bundle towards the taller stereocilia; increased tension in the tip link leads to channel opening and entry of K^+ and Ca^{2+}. Moving the bundle towards the shorter stereocilia is inhibitory; this movement causes tension in the tip link to drop, and the channels then close.

a mechanism that maintains an optimal tension in the tip link so that the channel can respond to displacements of atomic dimensions (Fig. 51-3). The tip link is probably connected in series with the *gating spring*, an elastic element through which stimulus energy can affect the transduction channel. Although highly specialized for the internal ear, the channel, gating spring, and adaptation mechanism are likely to be general requirements for any mechanical transduction apparatus; detailed characterization of the transduction apparatus of the hair cell may therefore eventually illuminate other transduction systems.

In this model, deflection of the hair bundle in the excitatory direction — towards the tallest stereocilia — causes a shorter stereocilia to slide down its neighbor's side, stretching the gating spring. Tension in the gating spring is transmitted to the transduction channel, which responds by increasing the frequency and the duration of the openings.

Transduction channels do not remain open, even if a deflection is maintained; using two independent processes, the hair cell adapts to a sustained mechanical stimulus [12]. Rapid channel reclosure (sometimes called fast adaptation) occurs on a time-scale of a few milliseconds or less; Ca^{2+} entering open transduction channels binds to a site on or nearby the channel, causing the channel to close (Fig. 51-4). Because closing channels exert a negative-directed force on the hair bundle, the fast adaptation mechanism can mechanically amplify an input; if the negative force occurs during the negative phase of a sinusoidal stimulus, the forces add and bundle movement is enhanced.

A slower mechanism, operating on a time-scale of tens of milliseconds, adjusts the transduction apparatus so that the open probability at rest is optimal and fast adaptation is enhanced. Slow adaptation is mediated by a cluster of myosin molecules [13]; the myosins exert a resting tension, but the oppositely directed force in a stimulus overcomes the resting tension, dragging the myosin complex down the stereocilium (Fig. 51-5). As the motors descend the stereocilium, tension in the gating spring is reduced, and the transduction channels close. When the bundle is moved in the negative direction, reducing tension in the gating spring and hence tension applied to the motors, the adaptation motor climbs the actin of the stereocilium until the motors generate enough tension in the gating spring to stall themselves (Fig. 51-5).

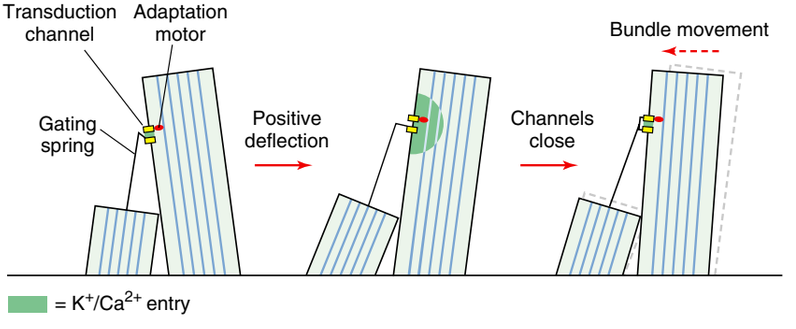

FIGURE 51-4 Fast adaptation by hair cells. After a positive (excitatory) deflection, Ca^{2+} enters transduction channels, binds to a site at the channel, yanking the channel shut. The movement of the channel's gate increases tension in the tip link, and the bundle is moved in the negative direction.

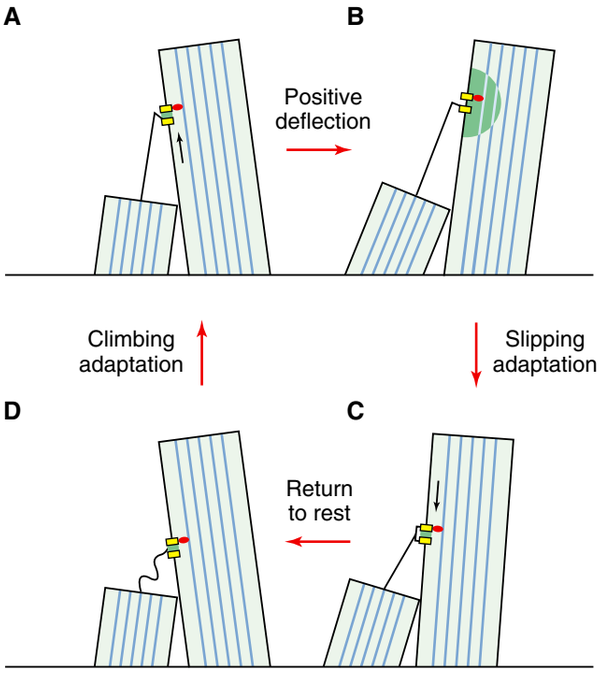

FIGURE 51-5 Slow adaptation by hair cells. (**A**) . Resting hair bundle. (**B**) An excitatory deflection lets in Ca^{2+} (*green*) and increases the tension felt by the motor (*blue*). (**C**) The adaptation motor responds to Ca^{2+} and high force by slipping towards the base of the stereocilium (*black arrow*). (**D**) When the bundle is returned to rest, gating spring tension is low and the motor can climb towards the tips of the stereocilia (*black arrow* in **A**).

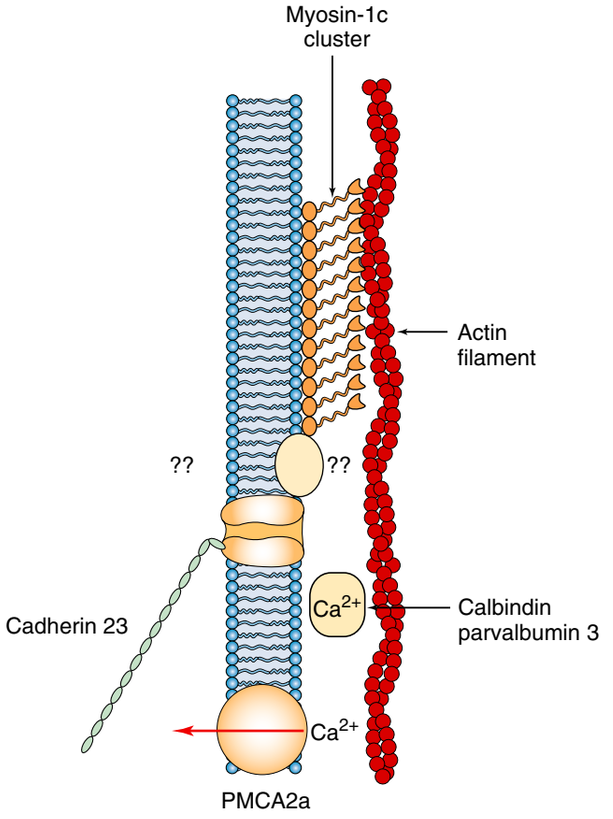

FIGURE 51-6 Molecules of the hair-cell transduction apparatus. Known molecules participating in transduction in hair cells are shown. Actin filaments, cross-linked by fimbrin and espin (not shown), are the substrate for slow adaptation. A cluster of myosin-1c molecules makes up the adaptation motor and is connected by an unknown molecule or molecules (*green oval*) to the transduction channel (*yellow*). The channel may be NompC in flies and fish but apparently is not in mammals. The channel is gated, perhaps directly, by cadherin-23, which makes up part of the tip link. Ca^{2+}, entering through open transduction channels, modulates fast and slow adaptation; it is rapidly buffered by mobile Ca^{2+} buffers including calbindin and paravalbumin 3. Ca^{2+} is eventually pumped out of the stereocilia by the Ca^{2+} pump *PMCA2a*.

Some of the molecules responsible for hair-cell transduction have been identified. A few key molecules, some already described, have been identified as part of the transduction complex (Fig. 51-6). Myosin molecules clearly play essential roles, and hair cells express a variety of myosin isoforms. Because it is located at the tips of the stereocilia, near the tip-link anchors, myosin-1c is the best candidate for the adaptation motor. Selective inhibition of a sensitized myosin-1c mutant with an ADP analog proved that this myosin participates in adaptation [14], although contribution by other myosins has yet to be ruled out. For example, mice with near-null mutations in myosin-7a have defects in auditory transduction that are consistent with alterations in the adaptation machinery, suggesting a central role for this myosin too [15].

Although mice with mutations in the myosin-6, -7a, and 15a genes are deaf, these isozymes apparently mediate essential hair-cell functions besides adaptation. Myosin-7a may play an important role in bundle integrity, as mice and fish with no functional myosin-7a protein have highly disheveled bundles.

Myosin-6 is an unusual isoform as it moves in the opposite direction along actin filaments, as compared to all other well-characterized myosins. Myosin-6 is located near the base of the hair bundle, and could play a role in anchoring the apical membrane to prevent fusion along the stereocilia shafts [16] or it may affect the forces applied to stereocilia actin filaments [17].

Myosin-15a is located at stereocilia tips and apparently controls the rate of actin filament growth [18]; stereocilia with more myosin-15a grow faster than those with lesser amounts of the myosin. Hair cells with no functional myosin-15a protein grow stereocilia that are very short and stubby, indicating that myosin-15a is important for actin filament elongation but not in the specification of the positions of the stereocilia.

Recent experiments have suggested that the tip link, a complex of two or three braided glycoprotein filaments [19], may be made in part from cadherin-23, a Ca^{2+}-dependent cell-adhesion molecule [20]. Moreover, cadherin-23 can interact directly or indirectly with myosin-1c, suggesting that these two molecules form part of the transduction complex in hair cells [20].

Although the transduction channel has attracted much attention, it too has yet to be identified. This channel passes cations, including Ca^{2+}, and can be inhibited by aminoglycoside antibiotics and amiloride derivatives. Unless controlled by tension applied through the gating spring, the channel remains shut. Most researchers in the field feel that the transduction channel belongs to the TRP channel family. TRP channels are remarkably diverse in structure and function and include many channels central for sensory function, including those involved in vision, pheromone sensing, temperature detection, and mechanical responsiveness. Indeed, TRP channels have been shown to be important in insects for mechanotransduction. In the fly, the TRP channel NompC plays a predominant role in the bristles and a lesser role in the auditory system. At least one TRP channel of the TRPV family, *nanchung*, is essential for fly hearing.

Are any of these TRP channels found in hair cells? The answer is yes for NompC, although the details are unexpected. NompC is found in zebrafish hair cells, where it has been shown to be essential for transduction [21]. Surprisingly enough, however, NompC has yet to be identified in mammalian genomes. This suggests the possibility that NompC is just one of several channel subunits required, and that other TRP channels could contribute to the transduction channel in mammals. Although several TRPV channels have been localized to hair cells in mammals, gene knockouts suggest that these channels do not play a role in transduction.

As both fast and slow adaptation mechanisms are regulated by Ca^{2+}, the stereocilia mechanisms that control the free concentration of this ion also play central roles in transduction. Entering Ca^{2+} is thought to be buffered very rapidly by the mobile buffers parvalbumin 3, calbindin, and calretinin [22, 23]. Even before bound Ca^{2+} can diffuse out of stereocilia, it is pumped back out into the endolymph by isoform 2a of the plasma-membrane Ca^{2+}-ATPase (PMCA2) [24, 25] (see also Ca^{2+} transport in Ch. 5).

DEAFNESS

About 1 in 1,000 children are born deaf, and another 1 in 1,000 develop deafness by adolescence. Although some deafness can arise during development due to external sources, much deafness in children is due to mutations in specific genes. As many forms of deafness are nonsyndromic — there is no other associated abnormality — identification of the responsible genes can lead to characterization of proteins that are essential for the auditory system (and often the vestibular system, as well).

The 'deafness gene' approach has proven fruitful for finding genes important to the auditory system. The genes responsible for ~20 recessive and ~20 dominant nonsyndromic deafness syndromes have been identified in humans, and similar numbers have been identified in mice [26]. Because some genes are associated with both recessive and dominant syndromes, and because most genes identified in humans have also been identified in mice, this tally corresponds to about 30 different genes.

The identified genes code for a variety of proteins, including transcription factors that are important for inner-ear development, cytoskeleton proteins that are responsible for the specialized architecture of hair cells, extracellular matrix molecules that make up some of the specialized acellular structures of the inner ear, and still others whose function is not yet clear.

A variety of genes have been identified, including a set of genes that apparently interact with each other in the auditory and visual systems. An example of a gene important for transduction that was identified in this manner was PMCA2. The deaf mouse *deafwaddler* was shown to have a mutation in the PMCA2 gene, which is called *Atp2b2* [27]; knockout of this gene also leads to deafness [28]. These results demonstrate that the Ca^{2+}-pumping activity of stereocilia is essential for auditory (and vestibular function), and reinforce the central role played by this ion in hair cell function.

Usher syndrome is a deafness–blindness syndrome that is caused by mutations in a number of genes [29]. Usher syndrome is divided into three classes depending on the severity of the phenotype; Usher I produces profound deafness and vestibular dysfunction, as well as adolescent blindness; in Usher II, deafness is less profound . User III is less common; in these patients, hearing and vision loss develop progressively, and vestibular dysfunction is variable.

Of the seven mapped genes underlying Usher I, five have been identified. These included cadherin-23 and myosin-7a, both described above, harmonin and SANS, both scaffold proteins, and protocadherin-15, another member of the cadherin superfamily. Biochemical evidence and phenotypic similarity suggests that these proteins may assemble into a complex [29], although conclusive evidence for such a complex is lacking.

Usher II is caused by mutations in at least four genes; only one, usherin, has been identified. Usherin is an extracellular matrix protein of unknown function; it is found in basement membranes in the eye and ear (and in other tissues as well). Similarly, at least two genes underlie Usher III, but only one (clarin-1) has been cloned. The function of clarin-1 is unknown.

The surprise is that genes clearly involved in mechanotransduction have not yet been identified by the deafness-gene approach. Clearly disruption of hair-cell function at many levels can lead to deafness, so it is expected that deafness genes include those involved in inner-ear development, in ion balance in the endolymph, and in structural integrity of hair cells. Examination of deafness genes in zebrafish has been particularly thorough, however, and

investigators using this system have several useful assays that allow them to focus only on those mutants that clearly have consequences for transduction [30].

However, the deafness-gene approach has not been successful in identifying either known (e.g. myosin-1c) or unknown (e.g. the transduction channel) components of the transduction apparatus in fish, mouse, or human. This is surprising, as the genetic approach relies on few assumptions about the nature of the systems studied. Perhaps the lesson here is that some of the important molecules for transduction play essential roles elsewhere in the organism during development; given the widespread expression of Myo1c, this presumption seems reasonable.

CONCLUSIONS

Although only a relatively small number of hair-bundle proteins have been identified, many of these clearly play important roles for transduction and bundle structure. The increasing speed of identification of important proteins suggests that a thorough accounting of the major transduction proteins for hair cells should not be too far off. The next and more interesting phase of characterization of hair-cell transduction will then ensue, determining how these molecules interact and how the hair cell assembles them during development and following normal protein turnover, in order to make a remarkably sensitive transduction apparatus.

Activation and adaptation behaviors may be mediated by hormones 856
Enhancement of neuronal atrophy and cell loss during aging by severe and prolonged psychosocial stress are examples of allostatic load 856

INTRODUCTION

The brain undergoes changes in its chemistry and structure in response to changes in the environment. Circulating hormones of the adrenals, thyroid and gonads play an important role in this adaptation because the endocrine system is controlled by the brain through the pituitary gland (Fig. 52-1). This control allows environmental signals to regulate hormonal secretion. Furthermore, circulating hormones act on the brain as well as on other tissues and organs of the body to modify their structure and chemistry via two mechanisms: (i) intracellular receptors that bind to DNA and alter gene expression and (ii) cell-surface receptors that modulate ion channels and second-messenger systems.

Hormonal actions occur during sensitive periods in development, in adult life during natural endocrine cycles and in response to experience as well as during the aging process (see Ch. 30). As a result of their fundamental actions on cellular processes and genomic activity and of the control of their secretion by environmental signals, steroid and thyroid hormone actions on the brain provide unique insights into the plasticity of the brain and behavior (see also Ch. 50).

Basic Neurochemistry: Molecular, Cellular and Medical Aspects

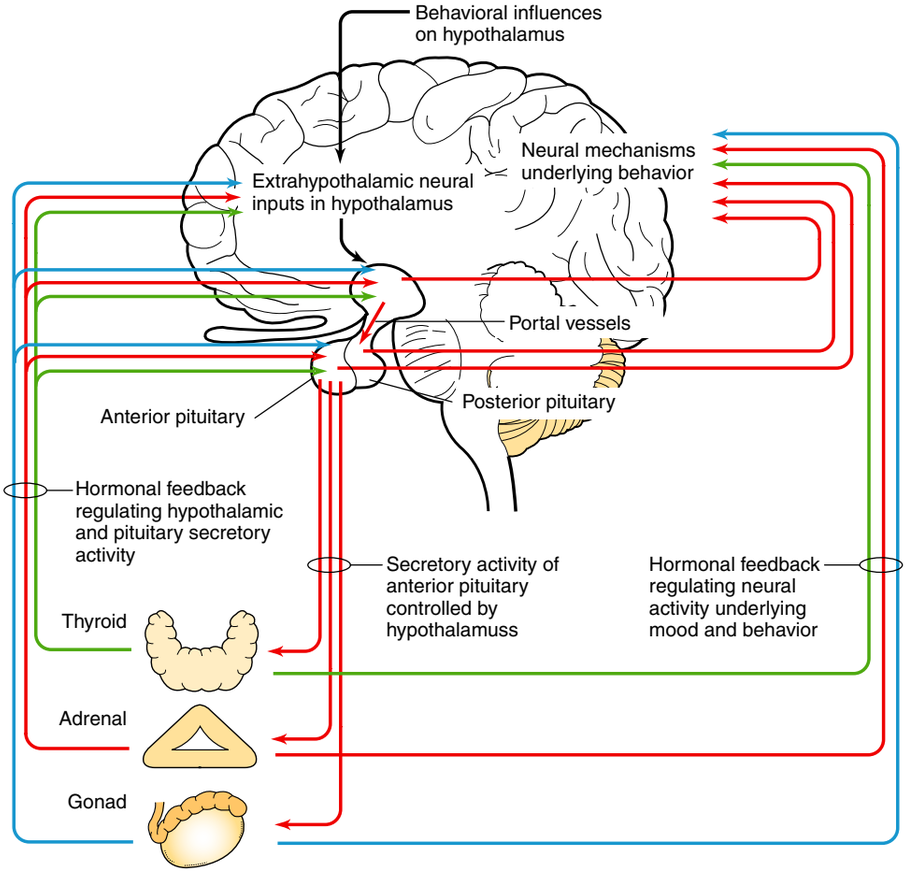

FIGURE 52-1 Schematic representation of possible and known reciprocal interactions among hypothalamic, pituitary, thyroid, adrenal and gonadal hormones.

Awareness of endocrine influences on brain function is as old as endocrinology itself. In 1849, Berthold described striking behavioral changes resulting from castration of roosters, and the reversal of these changes after testes had been transplanted into the castrated animals (see [1]). Nearly 100 years later, Beach published *Hormones and Behavior* (see [1]), which has served to instruct generations of investigators and to motivate them to explore in depth the interactions of hormones and brain. Spectacular growth of the field of neuroendocrinology (see also Ch 18) offers the present generation of neurobiologists unparalleled opportunities to explore with great sophistication the influence of neural activity on endocrine secretion, and the effect of hormones, in turn, on neural activity and behavior.

This chapter focuses on the neurochemical and molecular aspects of the influences of hormones on the nervous system and behavior, after first considering the chemical signals, behavioral events and underlying neural activity that regulate hormonal secretion.

BEHAVIORAL CONTROL OF HORMONAL SECRETION

The hypothalamic releasing factors regulate release of the anterior pituitary trophic hormones. As summarized in Figure 52-1, the releasing factors are produced in various neuronal groups within the hypothalamus and are transported to the median eminence for release into the portal circulation to the anterior pituitary. Neurons in the hypothalamus also produce the hormones oxytocin and vasopressin, which are released by the posterior pituitary into the blood. Therefore, it is not surprising that behavior and experience, which influence the hypothalamus, sometimes alter the secretion of these hypothalamic releasing factors and hormones.

Secretion of pituitary hormones is responsive to behavior and effects of experience. Consider, for example, the phenomenon of lactation, in which the sucking stimulus to the nipple triggers the release of oxytocin,

which facilitates milk ejection, and of prolactin, which helps the mammary gland to replenish the supply of milk [2]. The phenomenon of stress also illustrates the behavioral and emotional control of anterior pituitary hormone secretion. Conditions associated with tissue injury and surgical trauma, as well as the so-called psychic stresses of fear, novelty and even joy, can activate the release of adrenocorticotropic hormone (ACTH), which in turn stimulates the secretion of adrenal glucocorticoids [2]. The behavioral, emotional stimuli are mediated by neural pathways that can be modified readily by learning.

In the female rabbit, copulation activates spinal reflex pathways that stimulate the secretion of luteinizing hormone (LH), which leads to ovulation [3]. In the male rabbit, copulation also activates the secretion of LH and increases plasma testosterone [3]. Social stimuli also modify gonadotropin secretion. Olfactory cues between female mice can interrupt normal estrous cycles and lead to pseudopregnancies or to periods of prolonged diestrus, termed the Lee–Boot effect; olfactory cues from male mice can shorten the estrous cycle and either cause rapid attainment of estrus, termed the Whitten effect, or terminate pregnancy in a newly impregnated mouse, termed the Bruce effect [3]. In male rhesus monkeys, sudden, decisive defeat by other males leads to prolonged reduction in plasma testosterone, which can be reversed in the defeated male by the introduction of a female companion [3]. In men, the anticipation of sexual intercourse has been reported to increase beard growth, a process under the control of circulating androgen [3].

Hormones secreted in response to behavioral signals act in turn on the brain and on other tissues. Functional changes caused by hormones secreted in response to behavioral signals include modifications of behavior. With the sex hormones, these changes strengthen and guide the reproductive process. Thus, aggressive encounters between male birds or mammals in defense of territory during the mating period stimulate gonadotropin and testosterone secretion. Increases in these hormones further increase readiness for sexual activity by enhancing supplies of sperm and seminal fluid. This analysis was taken further by Lehrman (see [1]), who showed that among doves the behavioral sequence of courtship, mating, nest building and parenting involves complex behavioral interplay between the partners that triggers further hormonal secretion, which leads to the next phase of behavior and hormonal secretion.

Regarding the adrenal steroids, the behavioral activation of hormonal secretion in stress is part of a mechanism for restoring homeostatic balance. For example, an encounter with a predator may require rapid evasive action, in which neural activity and rapidly mobilized hormones such as epinephrine play a role. Adrenal steroid secretion is slower, reaching a peak minutes after the stressful event, and therefore is not expected to play a role in coping with the immediate situation. If the evasive action is successful and the animal survives, it will have to re-establish homeostasis; presumably, it also will learn from the experience to minimize the chances of another such encounter. Adrenal steroids facilitate such long-term adaptation; that is, they facilitate the acquisition as well as extinction of a conditioned avoidance response [4]. Suppose an animal has learned to avoid a certain place where previously it was punished; adrenals facilitate this learning in order to help 'keep it out of trouble'. Yet, if the animal later discovers that being in that place no longer results in punishment, and if that place also contains a food or water supply, it is in the best interest of the animal to extinguish the avoidance response in order to take advantage of the available food or water. Adrenal steroids have, in fact, been found to facilitate such extinction and, thus, can be said to facilitate a form of behavioral adaptation [4]. Adrenal steroids also appear to play a role in both selective attention and consolidation of a variety of learned information related to episodes or events in daily life [4]. Another aspect of adaptation in which stress-induced secretion of adrenal steroids participates, concerns the ability of the organism to cope with repeated stressful events through a variety of neurochemical changes [5].

Besides stress, adrenal steroids are secreted in varying amounts according to the time of day, and in this capacity they perform an important role in coordinating daily activity and sleep patterns with food-seeking and processing of information [5]. In nocturnally active animals, such as the rat, adrenal steroids are secreted at the end of the light period prior to onset of darkness. In humans and monkeys, adrenal steroid secretion precedes waking in the morning to begin daily activity. In both rats and primates, adrenal steroid secretion precedes the waking period, and appears to contribute, during waking, to optimal synaptic efficacy in the hippocampus for long-term potentiation, a correlate of learning. It is this aspect of adrenal steroid action that contributes to enhanced attention and improved retention of episodic memories [6] (see Ch. 50). Moreover, adrenal steroid elevation prior to waking also increases food-seeking behavior and enhances appetite for carbohydrates [5].

Cyclic changes in hormonal secretion, which are under the control of daily and seasonal light–dark rhythms, are important not only for the adrenals but for the gonads as well. Estrous cycles, menstrual cycles and seasonal breeding patterns represent adaptations of individual species to climatic conditions of the environment [1]. The feedback actions of gonadal and adrenal hormones, which are secreted in response to rhythmic output of hypothalamic and pituitary hormones, prime or activate the nervous system to perform the appropriate behavioral responses. It is important to stress that hormones themselves do not cause behaviors; rather, hormones induce chemical changes in particular sets of neurons, making certain behavioral outcomes more likely as a result of the strengthening or weakening of particular neural pathways.

CLASSIFICATION OF HORMONAL EFFECTS

Hormonal actions on target neurons are classified in terms of cellular mechanisms of action. Hormones act either via cell-surface or intracellular receptors. Peptide hormones and amino-acid derivatives, such as epinephrine, act on cell-surface receptors that do such things as open ion-channels, cause rapid electrical responses and facilitate exocytosis of hormones or neurotransmitters. Alternatively, they activate second-messenger systems at the cell membrane, such as those involving cAMP, Ca^{2+}/calmodulin or phosphoinositides (see Chs 20 and 24), which leads to phosphorylation of proteins inside various parts of the target cell (Fig. 52-2A). Steroid hormones and thyroid hormone, on the other hand, act on intracellular receptors in cell nuclei to regulate gene expression and protein synthesis (Fig. 52-2B). Steroid hormones can also affect cell-surface events via receptors at or near the cell surface.

The various modes of hormonal action summarized in Figure 52-2 may be distinguished from each other by time course. The fastest effects, in both latency and duration, are those involving direct opening of ion channels and stimulation of exocytosis. Intermediate effects involve phosphorylation of enzymes, ion channels, receptors or structural proteins, which may last for minutes or even hours. The slowest and most enduring effects are those that alter gene expression and lead to induction or repression of enzyme or receptor proteins, growth responses and even the structural remodeling of tissues.

As summarized in Figure 52-3, steroid/thyroid hormone receptors bind to other proteins as well as to DNA [7–9]. In the simplest type of action (Fig. 52-3A), the steroid/thyroid hormone receptor becomes activated after the hormone binds to it; activation results in conformational changes that include shedding of other proteins, such as heat-shock proteins, and exposing the DNA-binding domain. The receptor then binds to the specific sequence of DNA, called a 'hormone-response element' or enhancer, located on the coding strand of DNA; this enhances transcription by permitting other transcription factors as well as the RNA polymerase to bind to the promoter region [7]. A second scheme (Fig. 52-3B) is for the hormone receptor to bind with high affinity to another protein transcription factor, in this case the c-fos-c-jun complex, removing both protein complexes from binding to DNA [7]. Such a result also blocks the enhancement of transcription by either agent, although it also could reduce inhibitory effects produced by the hormone receptor through the scheme shown in Figure 52-3C. A variant on this theme, not shown in the figure, is 'squelching' in which multiple transcription factors compete with each other for a limited supply of soluble ligands that enhance their activities [7]. A third scheme, shown in Figure 52-3C, is for the steroid receptor to compete with another transcription factor for binding sites in the promoter regions. These other factors may be COUP or the cAMP-dependent transcription factors that bind to the adapter protein-1 (AP-1) response element. The result of this competition is inhibition of transcription since, in this situation, the other transcription factor enhances transcription, whereas the hormone receptor does not do so when it binds to the coding DNA strand [7].

As we have noted, second-messenger systems, through phosphorylation of nuclear proteins, can influence gene expression. There is evidence that even the classical steroid

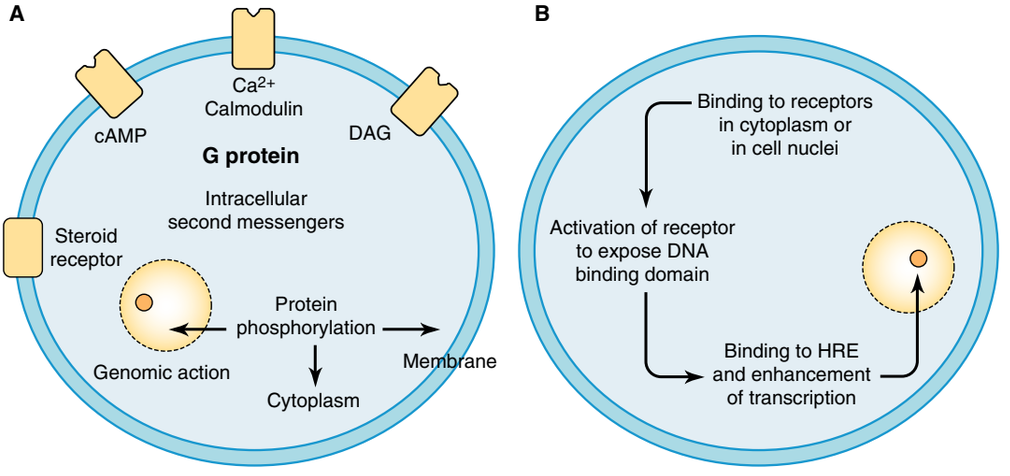

FIGURE 52-2 There are two modes of hormonal action. (**A**) Activation of cell-surface receptors and coupled second-messenger systems, with a variety of intracellular consequences. (**B**) Entry of hormone into the target cell, binding to and activation of an intracellular receptor and binding of the receptor-hormone complex to specific DNA sequences to activate or repress gene expression. *DAG*, diacylglycerol; *HRE*, hormone-response element.

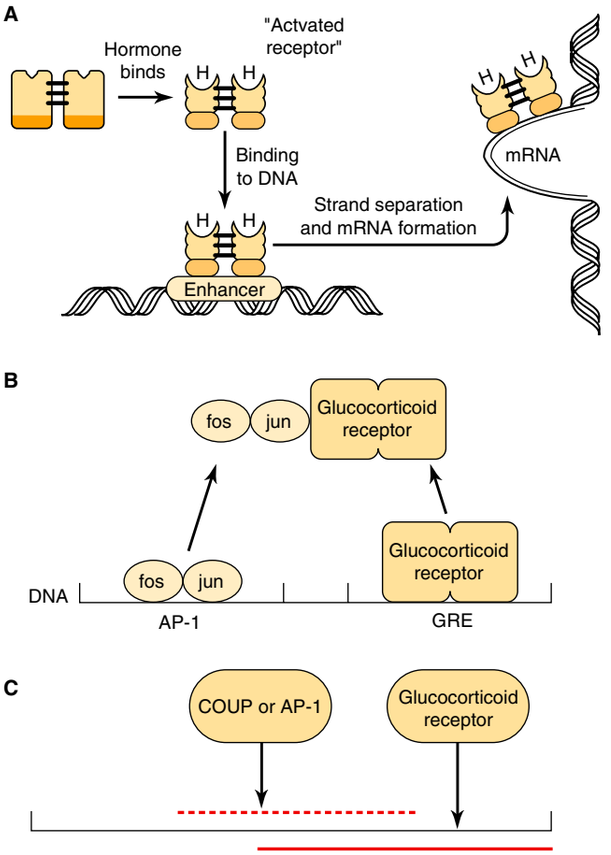

FIGURE 52-3 Intracellular receptors mediate at least three distinct types of actions on gene expression. (**A**) Binding of the hormone-receptor complex to a hormone-response element, a DNA sequence that is placed in a position where receptor binding to it can enhance unwinding of the double helix and attachment of other transcription factors. (**B**) Binding of the steroid receptor to another protein transcription factor, for example, the fos-jun complex through protein–protein interactions, removing both transcription factors from binding to DNA. *GRE*, glucocorticoid response element. (**C**) Binding of the hormone receptor to a hormone-response element located in the middle of a site for binding of another transcription factor-response element, such as the adaptor protein-1 (AP-1) or chicken ovalbumin upstream promoter-transcription factor (COUP sites), resulting in inhibition of transcription normally activated by transcription factors acting on these response elements (see [6–8]).

receptors are subject to regulation by phosphorylation and that phosphorylations promoted by a neurotransmitter such as dopamine (Ch. 12) are able to cause nuclear translocation of a steroid receptor in the absence of the steroid [7].

So far, the best understood examples of genomic regulation of neuronal function stem from the actions of gonadal and adrenal steroids and thyroid hormone, and many of these actions are involved in the plasticity of behavior that results from hormonal secretion, such as changes in aggressive and reproductive behavior and adaptation to repeated stress. In fact, hormonal actions that involve the genome are pervasive throughout the life cycle.

We can distinguish four major types of hormonal actions on the nervous system: (i) developmental actions, such as those involved in sexual differentiation and the effects of thyroid hormone and retinoic acid; (ii) reversible, and often cyclical, effects on the structure and function of neurons and glial cells that underlie corresponding cyclical changes in behavior, such as in reproduction and the daily rhythms of sleep and waking; (iii) experiential effects involving environmentally induced changes in hormonal secretion that evoke adaptive or maladaptive changes in the brain, as in stress; and (iv) effects that protect neurons or potentiate damage and lead to cell death.

It will be seen below that, in addition to genomic actions, there are nongenomic effects of steroids that modulate neurotransmitter release as well as ion traffic across the cell membrane, and do so frequently in coordination with genomic actions.

BIOCHEMISTRY OF STEROID AND THYROID HORMONE ACTIONS

Steroid hormones are divided into six classes, based on physiological effects: estrogens, androgens, progestins, glucocorticoids, mineralocorticoids and vitamin D. As shown in Figures 52-2 and 52-3, steroid hormone action on the brain and on other target tissues involves intracellular receptor sites that interact with the genome [1]. There are also important metabolic transformations of certain steroids, occurring in the nervous system, that either generate more active metabolites or result in the production of less active steroids. Such transformations are particularly important for the actions of androgens, of lesser importance for estrogens and progestins, and of practically no importance for glucocorticoids and mineralocorticoids. For vitamin D, the principal transformation to an active metabolite occurs in the kidney and liver [8]. Some metabolites, such as allopregnanolone and allotetrahydrodeoxycorticosterone, produce nongenomic effects on the $GABA_A$ receptor.

Some steroid hormones are converted in the brain to more active products that interact with receptors. The brain, like the seminal vesicles, is able to reduce testosterone to 5α-dihydrotestosterone (DHT); and, like the placenta, the brain aromatizes testosterone to estradiol (Fig. 52-4). Neither conversion occurs equally in all brain regions. The aromatization reaction is discussed below. Regional distribution of 5α-reductase activity toward testosterone in rat brain reveals that the highest activity is found in the midbrain and brainstem, intermediate activity is found in the hypothalamus and thalamus, and the lowest activity is found in the cerebral cortex [1]. The pituitary has higher 5α-reductase activity than any region of the brain, and its activity is subject to changes as

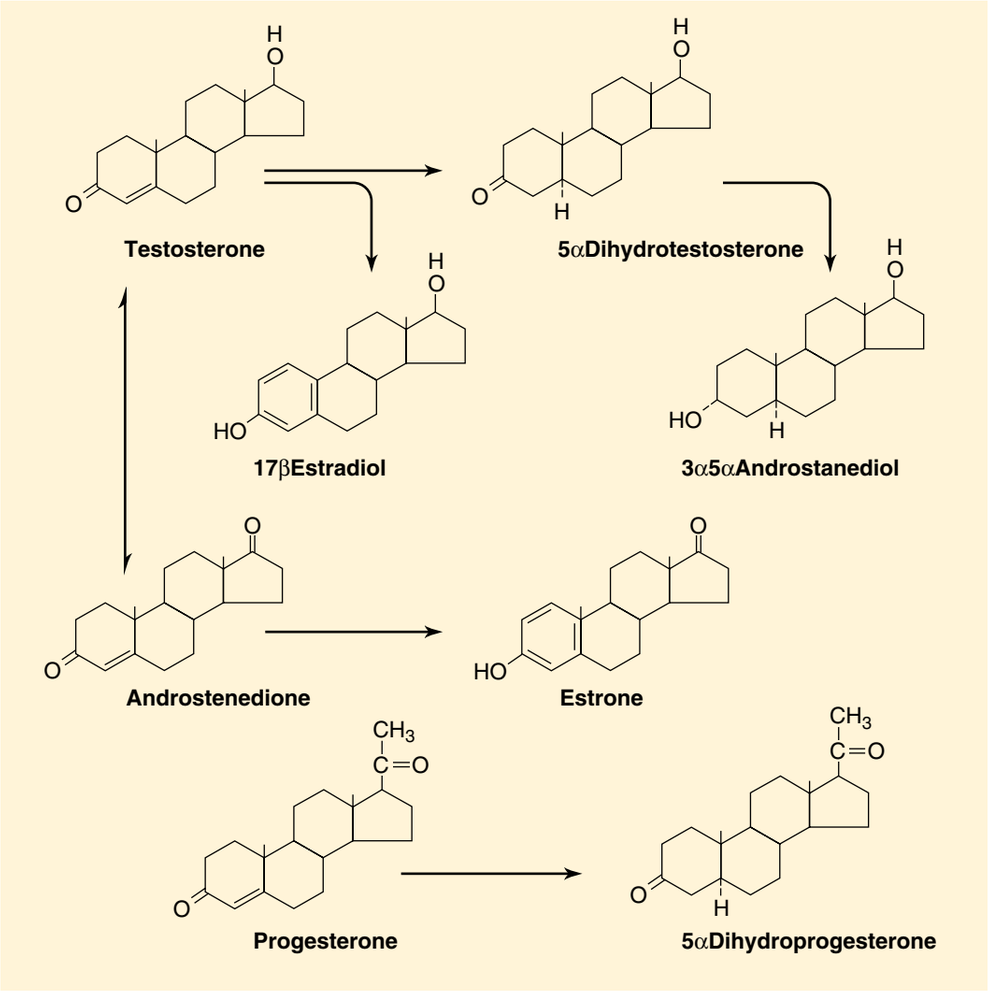

FIGURE 52-4 Some steroid transformations that are carried out by neural tissue.

a result of gonadectomy, hormone replacement and postnatal age [1]. 5α-DHT has been implicated in the hypothalamus and pituitary as a potent regulator of gonadotropin secretion, but it is relatively inactive toward male rat sexual behavior [1, 3]. Labeled metabolites with Rf values of 5α-DHT have been detected in extracts of hypothalamic and pituitary tissue after [^{3}H]-testosterone administration in both adult and newborn rats. It is interesting that progesterone inhibits 5α-reductase activity toward [^{3}H]testosterone and that [^{3}H]progesterone is converted to [^{3}H]5α-dihydroprogesterone (Fig. 52-4). Progesterone competition for 5α-reductase may explain some of the antiandrogenicity of this steroid [1]. 5β-DHT is a metabolite of testosterone formed in the avian CNS, as is 5α-DHT. 5β-DHT is inactive toward sexual behavior and is believed to represent an inactivation pathway for testosterone.

The aromatization of testosterone to form estradiol, and of androstenedione to form estrone (Fig. 52-4), has been described in brain tissue *in vitro* and *in vivo* [1, 9]. Aromatization is higher in hypothalamus and limbic structures than in cerebral cortex or pituitary gland, and, in noncastrated animals, it is higher in the male than in the female brain. Aromatization has been found in reptile and amphibian brain as well as in mammalian brain [1]. The capacity to aromatize testosterone and related androgens, therefore, may be a general property of vertebrate brains. The functional role of aromatization has been studied most extensively in the rat. Male sexual behavior is facilitated by estradiol [1], and testosterone facilitation of male sexual behavior can be blocked by a steroidal inhibitor of aromatization [1, 3]. There are indications that a similar situation exists in birds, amphibians and reptiles; that is, testosterone and estradiol can stimulate male and female heterotypical sexual behavior. Curiously, not all mammals are like the rat; for example, male sexual behavior of guinea pig and rhesus monkey is restored by the nonaromatizable androgen DHT [1, 3].

Both aromatization and 5α-reductase are regulated by gonadal steroids. In mammals such as the rat, it is principally the neural aromatase activity that is upregulated by androgens acting via neural androgen receptors [1].

In birds, both neural aromatase and 5α-reductase are induced by testosterone, and this regulation provides a way by which androgens can regulate CNS hormone sensitivity without regulating receptor number [1].

Both estrogens and glucocorticoids appear to act on brain cells without first being metabolized because both [^{3}H]estradiol and [^{3}H]corticosterone are recovered unchanged from their cell nuclear binding sites in brain [3]. However, estradiol is subject to conversion to the catechol estrogen 2-hydroxyestradiol, and this metabolite is both a moderately potent estrogen via intracellular estrogen receptors, as well as an agent capable of interacting with cell-surface receptors such as those for catecholamines, albeit at fairly high concentrations [7] (see Ch. 12). Glucocorticoids are inactivated by the enzyme 11-hydroxysteroid-dehydrogenase-2 (e.g. cortisol is converted to cortisone) and cortisone is re-activated to cortisol by the enzyme 11-hydroxysteroid-dehydrogenase-1 [10]. Organs such as the liver and brain have the ability to carry out this reactivation, which can lead to obesity via the liver and cognitive impairment via the brain [11].

Vitamin D, prior to acting in the brain, is converted to an active metabolite, 1,25-dihydroxy vitamin D_3, by enzymes in the liver and kidney [8] (see Fig. 52-5). The nervous system is also capable of cleaving the side chain from cholesterol to generate the same initial series of steroids [8] that are produced by the adrenals and gonads, namely, pregnenolone, dehydroepiandrosterone and progesterone (Fig. 52-6). In addition, neural tissue converts progesterone via reduction of the delta 4–5 double bond and reduction of the 3 keto group to 3,5α-pregnanolone, which is active on the chloride channel of the $GABA_A$ receptor [12] (Fig. 52-7). Glial cells are believed to be the primary sites of both cholesterol side-chain cleavage and generation of pregnanolone from progesterone [12]. There is also now evidence that the brain is capable of generating testosterone and estradiol from cholesterol via a process that is enhanced by excitatory neurotransmission [9].

While steroids generated in the brain have been referred to as 'neurosteroids', another useful term is 'neuroactive steroids' to refer to all steroids that affect brain function via any mechanism and irrespective of site of formation. The term neuroactive steroid also has been used to describe neuroactive steroid drugs.

Genomic receptors for steroid hormones have been clearly identified in the nervous system. The detection of intracellular, DNA-binding steroid receptors became possible with the introduction of tritium-labeled steroid hormones of high specific radioactivity: 20–25 Ci/mmol at each labeled position. The limited number of these sites had escaped detection using steroids labeled with ^{14}C at a much lower specific radioactivity. Tritium labeling also permitted histological localization of steroid receptors because the high spatial resolution of ^{3}H, 1–2 μm in light-microscopic autoradiography, allows cellular and even cell nuclear localization of the radioactivity.

Cell fractionation procedures were fundamental to the biochemical identification of steroid and thyroid hormone receptors in brain as well as in other tissues. Isolation of highly purified cell nuclei from small amounts of tissue from discrete brain regions generally is accomplished with the aid of a nonionic detergent, such as Triton X-100 [7].

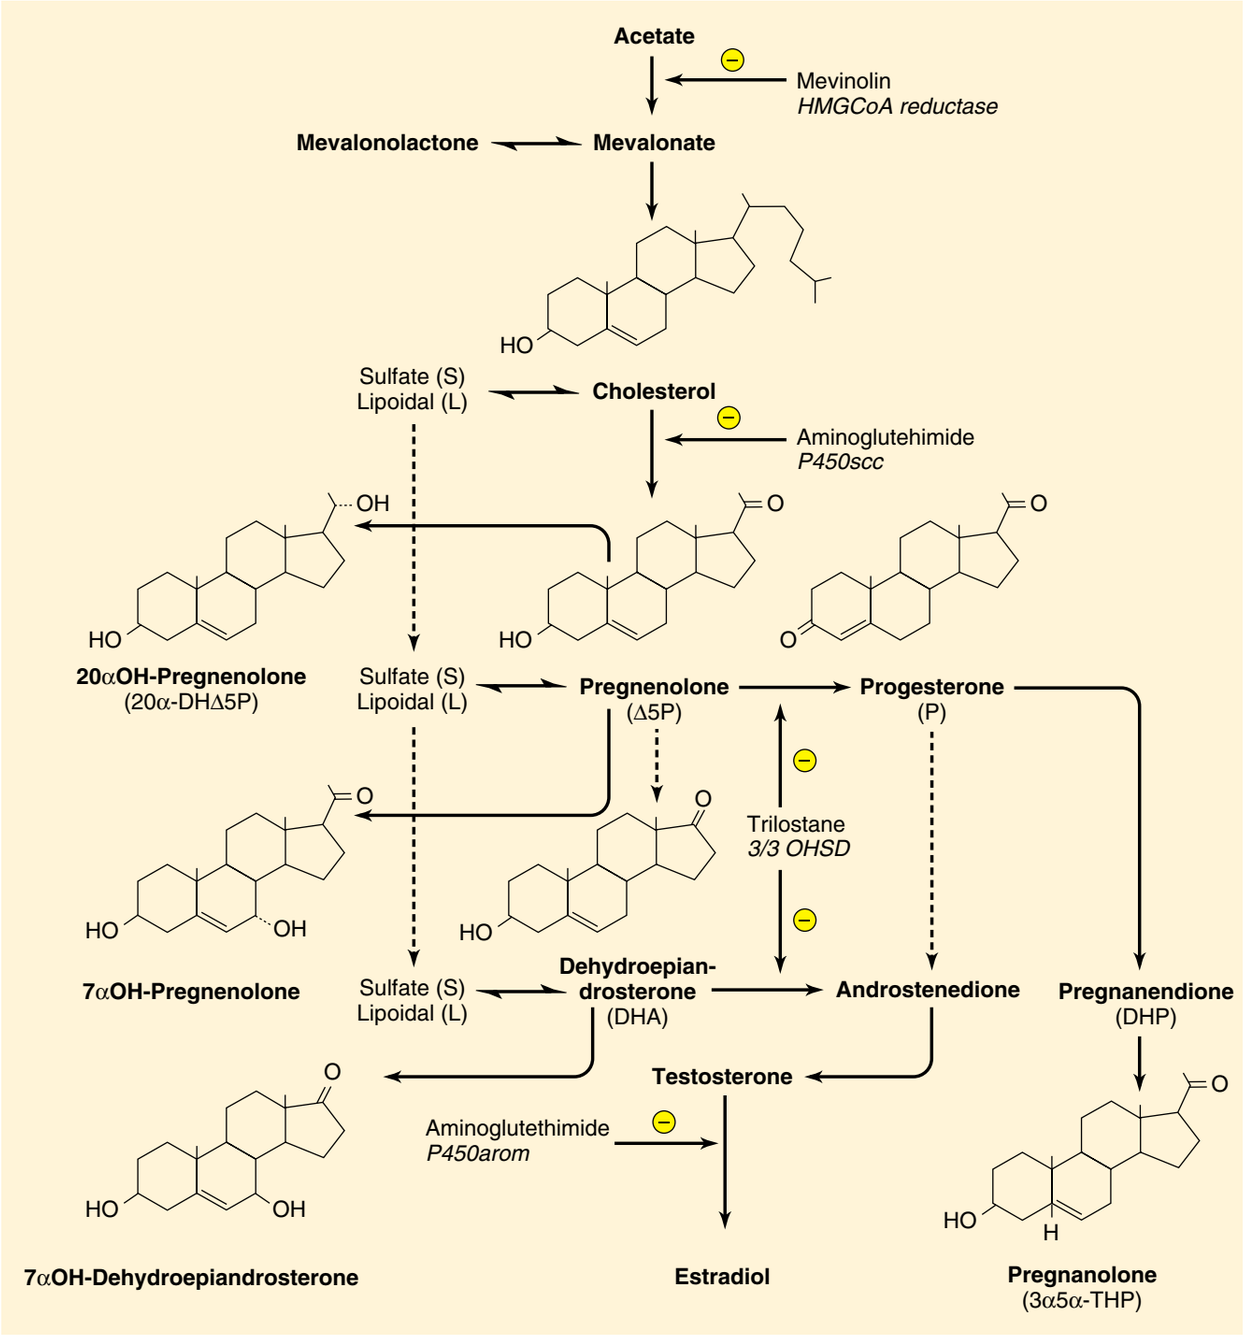

FIGURE 52-6 Biosynthesis/metabolism of steroids in the CNS. The conversion of delta5P to dehydroepiandrosterone (DHA) is postulated but not demonstrated. D5P and DHA inhibit and 3α,5α-THP potentiates $GABA_A$ receptor function, as summarized in Figure 52-7. *Solid arrows* indicate demonstrated pathways; *dotted arrows* indicate possible pathways. Metabolic inhibitors of enzymes are indicated by ⊖. (Redrawn from [12], with permission.)

Cytosolic fractions of brain tissue, prepared by centrifugation of homogenates at 105,000 g for 60 min, contain the soluble steroid-hormone-binding proteins, and a variety of methods intended to separate bound from unbound steroid have been used for measuring their binding activity [3, 7]. The most commonly employed are gel filtration chromatography and sucrose-density-gradient centrifugation. Dextran-coated charcoal or Sephadex LH20 are frequently used because they effectively absorb unbound steroid and leave intact the complexes between steroid and putative receptor. Other methods, such as gel electrophoresis and precipitation of putative receptor material with protamine sulfate, have more restricted uses.

The objective of such studies is to measure the affinity, capacity and specificity of the hormone–receptor interaction [3, 7]. Measurements of affinity and capacity are

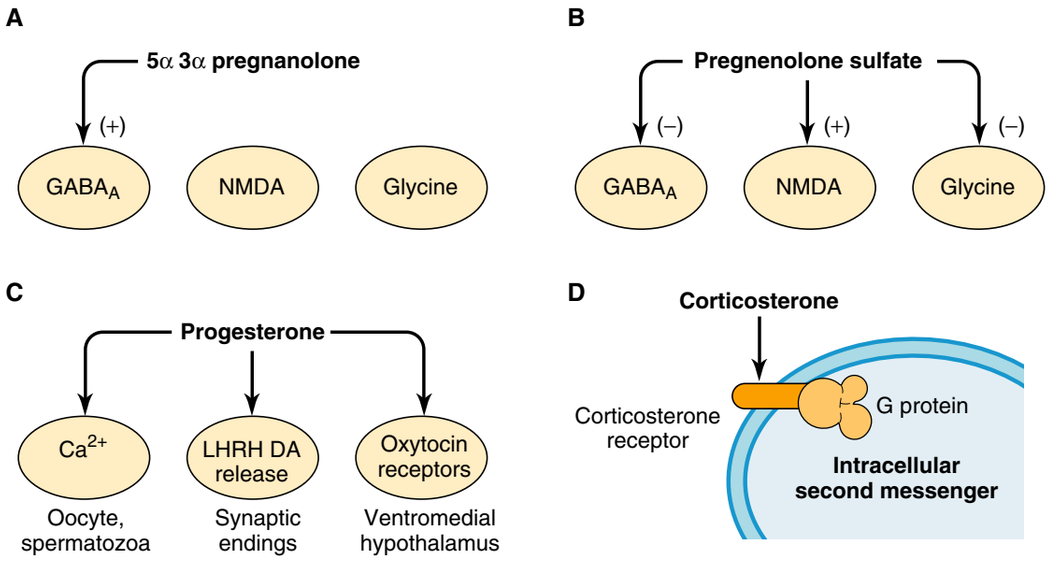

FIGURE 52-7 Schematic summary of four ways in which steroids affect cell-surface-mediated events and neuronal activity by nongenomic mechanisms. (**A**) Activation of $GABA_A$ receptor by 5α3α-pregnanolone. (**B**) Activation of NMDA receptor and inhibition of $GABA_A$ and glycine receptors by pregnenolone sulfate. (**C**) Activation of Ca^{2+} mobilization in oocytes and spermatozoa by progesterone; the same is postulated to happen in certain synaptic endings and may be involved in the rapid, direct effect of progesterone on the oxytocin receptor. (**D**) Corticosterone binds to a cell surface receptor linked to a G protein, and presumably through it to a second-messenger system, in some brain cells. *DA*, dopamine; *LHRH*, luteinizing hormone releasing hormone; *NMDA*, *N*-methyl-D-aspartate.

accomplished with equilibrium binding analysis. Specificity is based on competition between the labeled and various unlabeled ligands for binding sites.

Because the nervous system is highly heterogeneous from the standpoint of many neurochemical characteristics, including steroid and thyroid hormone receptors, the most useful techniques for mapping these receptors have been histochemical. Steroid autoradiography was the first such method. With purification of receptors and generation of antibodies, immunocytochemistry has been added as a tool. Cloning of steroid and thyroid receptors has opened the way to mapping of receptor mRNAs via *in situ* hybridization histochemistry.

Several criteria determine whether a steroid-hormone-binding site is a putative receptor. First, the steroid-hormone-binding site must be present in hormone-responsive tissues or brain regions, and absent from nonresponsive ones. Second, it should bind steroids that are either active agonists or effective antagonists of the hormone effect, and should not bind steroids that are inactive in either sense.

Understanding of the intracellular localization of steroid receptors has gone through a number of phases, beginning with the view that receptors translocated from cytoplasm to nucleus in the presence of hormone. Indeed, with the exception of thyroid hormone receptors, which are exclusively nuclear in location, cell fractionation studies have revealed that in the absence of hormone, steroid receptors are extracted in the soluble or cytosolic fraction. However, when steroid is present in the cell, many occupied receptors are retained by purified cell nuclei. Histological procedures, such as immunocytochemistry, have confirmed the largely nuclear localization of occupied receptors, but they also have revealed a nuclear localization of receptors in the absence of hormone in the tissue. This is true for estrogen, progestin and androgen receptors, but the mineralocorticoid and glucocorticoid receptors show a cytoplasmic localization in the absence of hormone. Thus, steroid receptors may exist in nuclei in a loose association that is disrupted during cell fractionation. This is not an uncommon situation for many constituents of cell nuclei [7].

At the same time, there is evidence for membrane-associated steroid receptors that are coupled to second messenger systems (see below).

INTRACELLULAR STEROID RECEPTORS: PROPERTIES AND TOPOGRAPHY

Steroid hormone receptors are phosphoproteins that have a DNA-binding domain and a steroid-binding domain. All steroid receptors have a molecular weight of 55,000–120,000. The state of phosphorylation appears to influence functional activity.

Estradiol. The first neuroactive steroid receptor type to be recognized was that for estradiol [3]. *In vivo* uptake of [^{3}H]estradiol, and binding to cell nuclei isolated from hypothalamus, pituitary and other brain regions, revealed steroid specificity closely resembling that of the uterus, where steroid receptors were first discovered [3]. Cytosolic estrogen receptors isolated from pituitary and brain tissue closely resemble those found in uterus and mammary tissue. A hallmark of the estrogen receptor is its existence

as an aggregate of subunits that dissociate during steroid-induced transformation to the DNA-binding nuclear form of the receptor. This part of the estrogen-receptor complex was cloned from human breast cancer cells and consists of a 65- to 70-kDa hormone and DNA-binding subunit [7]. The dissociation constant of estradiol binding is approximately 0.2–nM.

Estrogen receptors are found in the adult pituitary, hypothalamus, preoptic area and amygdala. They are principally in neurons, although glial cells also may express these receptors in some brain regions [13]. The developing rat brain expresses estrogen receptors in cerebral cortex and hippocampus, but these receptors largely disappear as the brain matures [13–15]. A second form of the estrogen receptor, the β-estrogen receptor, is similar to the α form in affinity and specificity but different in tissue distribution [16].

Progesterone receptors in brain were detected using the synthetic progestin R5020 (promegestrone; 17α, 21-dimethyl-19-nor-pregna-4,9-diene-3,20-dione), which has a high affinity for the progestin receptor, with a K_d of 0.4 nM [7]. The progestin receptor, cloned from chick oviduct, consists of a steroid- and DNA-binding subunit of 108 kDa, although one 79-kDa subunit has also been described [7]. Progestin receptors with similar properties are found in pituitary, reproductive tract and most estrogen receptor-containing brain regions; these receptors are inducible by estrogen treatment [7]. There are also progestin receptor sites in brain areas lacking estrogen receptors, such as the cerebral cortex of the rat; these receptors are not induced by estradiol treatment. Nevertheless, such receptors resemble those induced by estradiol [21]. Another inducer of progestin receptors in brain is testosterone, which works through its conversion to estradiol via aromatization [7]. Progesterone acts rapidly to induce feminine sexual behavior, termed lordosis, in female rats that have been primed with estradiol to induce progestin receptors [7]. The principal site of estradiol and progesterone action is the ventromedial nucleus of the hypothalamus [17].

Androgen receptors have a steroid-binding subunit estimated to be 120 kDa [7]. The estimated K_d for active androgens is approximately 1–2 nM [3]. Androgen receptors are widely distributed in brain and pituitary tissue, although the highest concentrations are found in hypothalamus, preoptic area and limbic brain tissue [18]. Androgen receptors are deficient in the androgen-insensitivity (Tfm) mutation, and animals with this mutation show defects in sexual behavior, juvenile rough-and-tumble play behavior and certain aspects of neuroendocrine function, thus indicating the actions of testosterone that are mediated by androgen receptors, as opposed to those mediated by aromatization of testosterone to estradiol (see above) and estrogen receptors [14, 15].

Glucocorticoid. Adrenal steroid receptors have been subdivided into two categories, one of which is the classical glucocorticoid receptor [7, 19]. This receptor, cloned from human and rat sources, consists of a steroid- and DNA-binding subunit of 95 kDa [7, 19]. Such receptors, which have dissociation constants of 4–5 nM for glucocorticoids, are widely distributed across brain regions and are found in neurons and glial cells [7, 19].

Mineralocorticoid. The other type of glucocorticoid receptor is similar to the mineralocorticoid receptor originally described in the kidney [7, 19]. In the brain, receptors of this type bind the glucocorticoid corticosterone with high affinity, having a K_d of approximately 1 nM, and they are responsible for the high uptake of tracer levels of [^{3}H]corticosterone by the hippocampus [7, 19]. These corticosterone receptors, which are found in high concentrations in the hippocampus but are also widely distributed in other brain regions at lower concentrations, may be involved in mediating the effects of diurnally varying concentrations of corticosterone [5, 7, 19]. Uptake of [^{3}H]aldosterone by brain tissues reveals two types of binding sites: those in the hippocampus, which can be occupied preferentially by corticosterone, and those more diffusely distributed in the brain, which appear to retain [^{3}H] aldosterone preferentially in the presence of the normally higher concentrations of corticosterone [7]. The reasons for this selectivity of an enzyme, 11β-hydroxysteroid dehydrogenase, are that, at least in the kidney-collecting tubules, it converts corticosterone to an inactive metabolite and allows aldosterone access to the mineralocorticoid receptors [10].

Vitamin D is a steroid hormone, production of which by the body requires the action of light. Therefore, it is often necessary to provide some vitamin D in the diet [8] (see Ch. 33). Moreover, vitamin D is converted by the kidney and liver to the active metabolite 1,25-dihydroxyvitamin D3 (Fig. 52-5) [8]. Vitamin D3 receptors consist of a hormone- and DNA-binding subunit of 55 kDa [7, 18]. Receptor sites for 1,25-dihydroxyvitamin D3 are found in pituitary and brain, especially in the forebrain, hindbrain and spinal cord neurons [8]. In the brain, one site containing vitamin D3 receptors, the bed nucleus of the stria terminalis, responds to exogenous 1,25-dihydroxyvitamin D3 with an induction of choline acetyltransferase, even though the calcium-binding protein that is regulated by vitamin D3 in the intestine is not regulated by this hormone in the brain [8].

MEMBRANE STEROID RECEPTORS AND SIGNALING PATHWAYS

The known rapid effects of some steroid hormones on neuronal excitability are difficult to explain solely in terms

of genomic actions [20]. Instead, some type of membrane receptor interaction is inferred. Indeed, several types of interaction between neuroactive steroids and neural membranes have been described. Direct binding assays have revealed membrane sites for glucocorticoids and gonadal steroids and one instance of a membrane receptor coupled to a G protein (Fig. 52-7). Additionally, indirect binding assay results have implied interaction of the catechol estrogens with dopamine and with adrenergic receptors [7]. Moreover, studies with specific antibodies at the electron microscope level have revealed estrogen receptors in dendrites, presynaptic terminals and glial cell processes [21], and a membrane receptor for progesterone has been cloned from oocytes [22]. Finally, deletion of the nuclear vitamin-D receptor deprives cells of rapid membrane actions of vitamin D, indicating that this receptor may serve a dual function [23].

Progesterone produces direct membrane effects [16]. These include actions that promote maturation of spermatozoa as well as oocytes and facilitation of the release of neurotransmitters such as dopamine and LH-releasing hormone (LHRH) (Fig. 52-7). Membrane actions of progesterone also activate oxytocin receptors in the hypothalamus in a way that enables oxytocin to turn on sexual behavior in the estrogen-primed female rat [3].

Estradiol activates a variety of signaling pathways via membrane-associated receptors in many cell types [20]. In neurons, rapid actions of estradiol stimulate translation of a key protein, PSD-95, involved in synapse formation [24].

There are now indications for the interaction of progesterone metabolites with the Cl^- channel of the $GABA_A$ receptor (Fig. 52-7). The A-ring-reduced steroids, especially those with the 5α,3α configuration, are particularly active on the $GABA_A$ receptor [12]. By facilitating chloride-channel opening, these steroids produce anesthetic, anxiolytic and sedative–hypnotic effects (see Ch. 16).

Another neurosteroid (Fig. 52-6), pregnenolone sulfate (PS), produces effects that in many ways antagonize those of the steroids that open the $GABA_A$ receptor Cl^- channel [12]. PS in micromolar concentrations inhibits the $GABA_A$ receptor and the inhibitory glycine receptor, and facilitates activity of the excitatory *N*-methyl-D-aspartate (NMDA) receptor (Fig. 52-7). It is unclear, however, whether these effects are physiologically relevant, since the PS concentration needed to produce them is rather high. However, PS is produced locally in the brain and may reach sufficiently high concentrations in some compartments within the nervous system.

None of these findings undermines the importance of the intracellular genomic actions of steroids. Rather, they increase the richness of the cellular actions of steroid hormones and raise the possibility that there may be connections between genomic and nongenomic actions of steroids. For example, genomic action may induce receptors that mediate nongenomic effects. Moreover, the activation of oxytocin receptors by progesterone is dependent on the ability of estrogen priming to induce the formation of new oxytocin receptors via a genomic mechanism; these receptors are then transported along dendrites to sites where the progesterone action occurs at the membrane level [3].

BIOCHEMISTRY OF THYROID HORMONE ACTIONS ON BRAIN

Like steroid hormones, thyroid hormones interact with receptors to alter genomic activity and affect the synthesis of specific proteins during development [25–28]. As with testosterone and progesterone, metabolic transformation of thyroxine (T_4) is critical to its action [25–28]. Moreover, as with steroid hormones, thyroid hormones alter brain functions in adult life in ways that both resemble and differ from their action during development [25–28].

The initial step after cellular uptake of T_4 is metabolic transformation to 3,5,3′-tri-iodothyronine (T_3) (Fig. 52-8), which interacts with cytosolic and nuclear receptors, as well as with synaptosomal membrane binding sites of unknown function [25]. Cytosolic receptors are proteins of 70 kDa that do not appear to undergo translocation to cell nuclei, nor do they appear to be nuclear proteins that have leaked out of cell nuclei during cell rupture; nuclear receptors are proteins of 50 70 kDa that have both DNA- and hormone-binding domains [25, 26, 28].

Nuclear T_3 receptors are present in higher levels during neural development than they are in adult life [28]. In human fetal brain, nuclear T_3 receptors increase in concentration from 10 weeks of gestation to the sixteenth week, when neuroblast multiplication is high [25, 28]. Glial cells, as well as neurons, contain nuclear T_3 receptors [25, 28]. Functionally, many neurons develop prior to the appearance of significant T_3 receptor levels and, therefore, appear to be independent of large-scale thyroid influence [25–28]. Other neurons, such as those in the cortex and cerebellum, show a more profound dependence on thyroid function [25]. Although thyroid hormone affects the

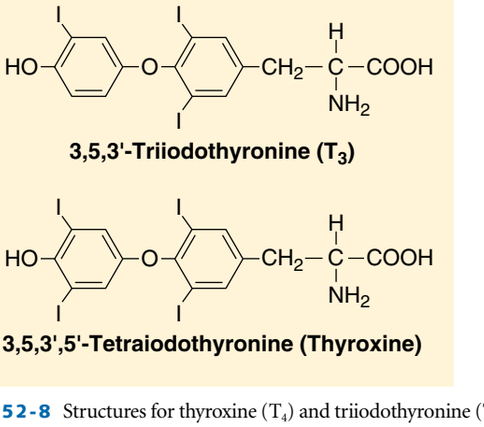

FIGURE 52-8 Structures for thyroxine (T_4) and triiodothyronine (T_3).

number of replicating cells in the external granular layer of the developing cerebellum, it is not possible to conclude that T_3 directly affects the mechanism of cell replication [25]. Rather, the most pronounced effect of hypothyroidism is a hypoplastic neuropil, with shortened dendrites and fewer spines. It has been shown that a major effect of T_3 involves development of the neuronal cytoskeleton [25–28]. Proteins, such as microtubule-associated protein (MAP2) and tau (see Ch. 27), which are polymorphic and affect microtubular assembly, are differentially affected by T_3 absence or excess [25, 28].

Developmentally, thyroid hormones interact with sex hormones such that hypothyroidism prolongs the critical period for testosterone-induced defeminization (see below) [3]; in contrast, the hyperthyroid state prematurely terminates the sensitivity to testosterone [3]. Undoubtedly, an important link in these and other effects is synapse formation. Hypothyroidism increases synaptic density, at least transiently [3]. Interesting parallels with synapse formation are reported for learning behavior in rats; neonatal hypothyroidism impairs learning ability, whereas hyperthyroidism accelerates learning initially, followed by a decline later in life [3].

The adult brain is endowed with nuclear as well as cytosolic and membrane T_3 receptors that have been visualized by autoradiography and studied biochemically [30–33]. Both neurons and neuropil are labeled by [125I]T_3, and the labeling is selective across brain regions. Functionally, one of the most prominent features of neural action of thyroid hormone in adulthood is subsensitivity to norepinephrine as a result of a hypothyroid state [27]. These changes may be reflections of loss of dendritic spines in at least some neurons of the adult brain. Clinically, thyroid hormone deficiency increases the probability of depressive illness, whereas thyroid excess increases the probability of mania (Ch. 52) in susceptible individuals [27].

DIVERSITY OF STEROID-HORMONE ACTIONS ON THE BRAIN

Steroid-hormone effects on the brain link the environment surrounding the organism with the genome of target brain cells through the process of variable genomic activity [3, 7, 29]. By this we mean that an organism experiences light, dark, heat, cold, fear and sexual arousal. These experiences influence hormonal secretion, and these hormones in turn act on the genome of receptor-containing brain cells to alter their functional state. The genome of brain cells, like that of other cells of the body, is continually active from embryonic life until death and continually responsive to intra- and extracellular signals. This activity can be seen from the high rates of RNA metabolism in neurons. The differential influence of steroid hormones on variable genomic activity is evident from studies showing rapid and brain region-specific induction of ribosomal and mRNA, as well as changes in cell nuclear diameter and chromatin and structure [1, 17]. However, variable genomic activity changes qualitatively with the state of differentiation of the target cells: embryonic neurons show growth responses that result in permanent changes in circuitry, whereas adult neurons show impermanent responses. Under other circumstances, the same hormonal signals can promote damage and even neuronal loss; under still other conditions, adult neurons can be stimulated by treatment with hormones to grow and repair the damage.

During development, steroid-hormone receptors become evident in target neurons of the brain. These receptors appear within several days of final cell division [14, 15]. Whether some receptors are also present in dividing neuronal precursors is not clear. After they have appeared, these receptors mediate a variety of developmental actions. For example, glucocorticoids direct differentiation of adrenergic/cholinergic neurons of the autonomic nervous system to develop in the adrenergic direction [7]. Glucocorticoids also increase the number of epinephrine-containing, small, intensely fluorescent cells, often referred to as SIF, in autonomic ganglia and are required for the normal postnatal ontogeny of serotonin neurons in the forebrain [7]. These effects may not all be direct but may involve hormonal modulation of growth factors produced by other cells surrounding the developing neurons.

Gonadal hormones, however, are involved in sexual differentiation of the reproductive tract and brain [1, 14, 15]. Mammals, among which animals have X and Y chromosomes, undergo sexual differentiation under the impetus of testosterone secreted by the testes during a period of perinatal life; in humans, this period is in midgestation, while in rats it is from the end of gestation into neonatal life. Key features of sexual behavior in birds are determined in the reverse manner, in keeping with the fact that the female has the chromosomal heterogeneity: females produce either estradiol or testosterone, either of which feminizes the brain, which otherwise would develop a masculine pattern in the absence of gonadal steroids [1, 15].

As for the mechanisms of sexual differentiation, we must consider the metabolism of the hormone receptor types involved and the primary-receptor-mediated events. Testosterone, as noted above, is a prohormone that is converted into either 5α-DHT or estradiol within the brain; these products exert effects on brain sexual differentiation via androgen and estrogen receptors, respectively [14, 15]. Masculinization of sexual and aggressive behavior involves either 5α-DHT alone or a combination of 5α-DHT and estradiol acting on different cells. Besides masculinization, there is in some mammals a process of defeminization, in which feminine responses that would develop in the absence of testosterone are suppressed by its presence during the critical period. Conversion to estradiol appears to be involved in this process [14, 15]. Progesterone plays no major role in brain sexual differentiation, but it does have the ability to antagonize actions at both androgen and

estrogen receptors and, thus, can moderate the degree of masculinization and defeminization.

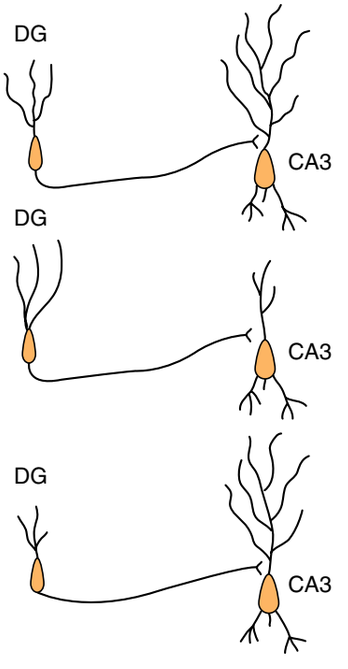
As to the primary developmental actions of testosterone, growth and differentiation appear to be involved. Testosterone or estradiol stimulates outgrowth of neurites from developing hypothalamic neurons that contain estrogen receptors [14, 15]. This is believed to be one of the principal aspects of testosterone action that increases the number and the size of neurons within specific hypothalamic nuclei in males, compared to females [1, 14, 15]. 5α-DHT may have a similar effect on androgen-sensitive neurons. Differentiation of target neurons also occurs; in adult brain tissue, hormones like estradiol can evoke responses that differ between adult male and female rats [1, 14,1 5].

Because of new research with genetic manipulations, there are other aspects of sexual differentiation that must now be incorporated into our thinking. First is that female sexual differentiation depends in part on aromatization of androgens, since knockout of the aromatase gene deprives the female of a number of normal sociosexual behavior patterns in adult life [30]. Second, is that genetic sex plays a role in brain and body sexual differentiation; more specifically, genes on the Y chromosome are believed to contribute to sex differences in the midbrain dopaminergic system, among other brain regions [31].

The response of neural tissue to damage involves some degree of structural plasticity, as in development. Collateral growth and reinnervation of vacant synaptic sites is facilitated in some cases by steroid hormones [32]. In the hypothalamus, estrogen treatment after knife cuts that destroy certain inputs promotes increases in the number of synapses. In the hippocampus, glucocorticoid treatment promotes homotypical sprouting of serotonin fibers to replace damaged serotonin input. It has also been noted that androgens enhance the regrowth of the severed hypoglossal nerve [32]. One interpretation of these steroid effects is that injury reactivates programs of steroid-responsive genomic activity that normally operate during the phase of synaptogenesis in early development [32].

Estrogens are also neuroprotective against ischemic damage [13], and aromatization of androgens to estrogens plays a role even in females, where knockout of the aromatase gene increases the vulnerability of female mice to stroke damage by a process that is prevented by estradiol administration [33].

Another aspect of neuroprotection by steroids is stabilization of neurons against death and replacement. In the dentate gyrus of both the neonate and the adult rat, neurons are born and die; rates of both birth and death are increased by adrenalectomy, and these increases are prevented by low doses of adrenal steroids acting via mineralocorticoid receptors [34] (Fig. 52-9). Regulation of the turnover rate of dentate gyrus neurons may provide the hippocampal formation of the adult with the potential to increase and decrease its volume and functional capacity, as occurs in relation to seasonal or other long-term changes in the environment. This process also occurs in the developing dentate gyrus [34].



CA3 pyramidal neurons receive the mossy fiber input from the granule neurons of the dentate gyrus. This connection is part of the 3-cell circuit of the hippocampus that is believed to be involved in learning and memory.

Chronic corticosterone treatment or repeated restraint stress promotes atrophy of apical dendrites of CA3 pyramidal neurons.

Adrenalectomy causes neurons of the dentate gyrus to die and to be replaced by new neurons, whereas pyramidal neurons are unaffected. Low levels of adrenal steroids prevent this and stabilize the dentate granule neuron population; they do this via Type I adrenal steroid receptors.

FIGURE 52-9 Summary of estrogen effects on the ventromedial nuclei related to its activation of female sexual behavior in the rat. *DG*, dentate gyrus. (From [41], with permission.)

Activation and adaptation behaviors may be mediated by hormones. Hormonal secretion by the adrenals and gonads is controlled by endogenous oscillators that can be entrained by environmental cues such as light and dark. The actions of cyclically secreted hormones on behavior and brain function are referred to as activational effects. In addition to the cyclic mode, there is another mode of secretion initiated by such experiences as stress, fear and aggressive and sexual encounters. In this case, actions of adrenal steroid hormones secreted in response to experience lead to adaptive brain responses, which help the animal cope with stressful situations [5, 19, 29]. The activational and adaptational effects are largely reversible and involve a variety of neurochemical changes, most of which appear to be initiated at the genomic level. For example, estradiol is secreted cyclically during the estrous cycle in the female rat and triggers the surge of LH, which induces a surge of progesterone from the ovary. Progesterone, in turn, stimulates sexual responsiveness to the male rat [1].

Estradiol action to promote feminine sexual behavior in the rat involves a cascade of induced protein synthesis in specific hypothalamic neurons accompanied by morphological changes indicative of increased genomic activity [1, 17, 35]. Among the induced proteins are receptors for progesterone (see above), crucial for activating sexual behavior; receptors for acetylcholine and oxytocin that are active in enabling the hypothalamic neurons to respond to afferent input; proteins that are axonally transported from the hypothalamus to the midbrain, where they may be involved in neurotransmission; and structural proteins that contribute to formation of new synapses that come and go during the estrous cycle [1, 17, 35] (Fig. 52-9).

Estradiol also induces synapses in the hippocampus and this contributes to enhanced capacity for learning and memory that is dependent on the hippocampus [13]. Estradiol exerts many other nonreproductive actions on the brain, such as fine motor coordination, seizure susceptibility, mood, protection from ischemic damage. Many of these actions occur in brain regions that show little, if any, nuclear estrogen receptors, and it seems likely that the nongenomic estrogen receptor described above may be involved [13].

Adrenal steroids secreted in the diurnal cycle are responsible for reversibly activating exploratory activity, food-seeking behavior, carbohydrate appetite and synaptic efficacy [4–6]. These appear to do so by acting on the hippocampus, where there are many mineralocorticoid and glucocorticoid receptors (see above). Adaptational effects of adrenal steroids that result from stress appear to operate via the classical glucocorticoid receptor found not only in hippocampus but also in other brain regions [19, 29]. Changes in synaptic vesicle proteins, high-affinity GABA transport, neurotransmitter-stimulated cAMP formation and central serotonin and noradrenergic sensitivity accompany repeated glucocorticoid elevations [7, 19, 29]. One view of these changes induced by glucocorticoids is that they counter-regulate some of the immediate and persistent neural effects of stress and are, therefore, part of the mechanism of adaptation [4–6, 7, 19, 29, 36]. This and other aspects of adaptation protect the organism; without adrenal secretions, the body probably would not survive many events in daily life.

The price of adaptation often includes some wear and tear and damage, called allostatic load [36]. Allostasis, meaning to achieve stability through change, is another word to describe adaptation. The wear and tear is the result of the inefficiency or overactivity of allostatic systems, including those like the adrenal cortex and autonomic nervous system, which respond to challenge and promote adaptation. This takes three forms: (i) repeated activation by many stressful events; (ii) failing to shut off after the challenge is over; and (iii) inability to be activated adequately, allowing other systems that are normally counter-regulated to become overactive, for example, inflammatory cytokines. In each of these situations, there is a cumulative as well as an immediate effect on many organs, including the heart and brain, as well as on the immune system.

Enhancement of neuronal atrophy and cell loss during aging by severe and prolonged psychosocial stress are examples of allostatic load. Repeated psychosocial stress in primates and rodents causes pathological changes in various body organs, including neuronal loss in the hippocampus [37]. Shorter exposure of rats to restraint stress, psychosocial stress or corticosterone causes atrophy of neurons in the hippocampus, particularly in the CA3 region, which receives heavy input from the dentate gyrus mossy fiber system (Fig. 52-10). The mossy fiber input is also responsible for kainic-acid- and seizure-induced damage of the CA3 region and strongly suggests the importance of excitatory amino acids [37].

Indeed, the stress-induced atrophy is blocked by NMDA receptor blockers and by an anticonvulsant drug, phenytoin. The presence of elevated glucocorticoids at the time of hypoxic damage or kainic-acid lesions (Chs 34 and 35) to the brain potentiates the necrosis produced by these treatments, especially in the hippocampus. Adrenalectomy reduces such damage and retards loss of neurons with age [37]. Thus, adrenal steroids operate in conjunction with neural excitability to produce damage, and it has been suggested that they do so by compromising the ability of the brain to obtain nutrients to support ATP generation [37].

Yet, the effect of repeated stress on the hippocampus is reversible if the stress is terminated after 3 weeks in rats, and it is best referred to as 'adaptive plasticity', since other brain areas, such as the amygdala, show a growth response to repeated stress [38].

The concept of allostatic load implies that there is a paradox in the actions of adrenal steroids: they exert protection in the short run and have the potential to cause damage in the long run if the allostatic, that is, the adaptation-promoting, responses are not managed efficiently.

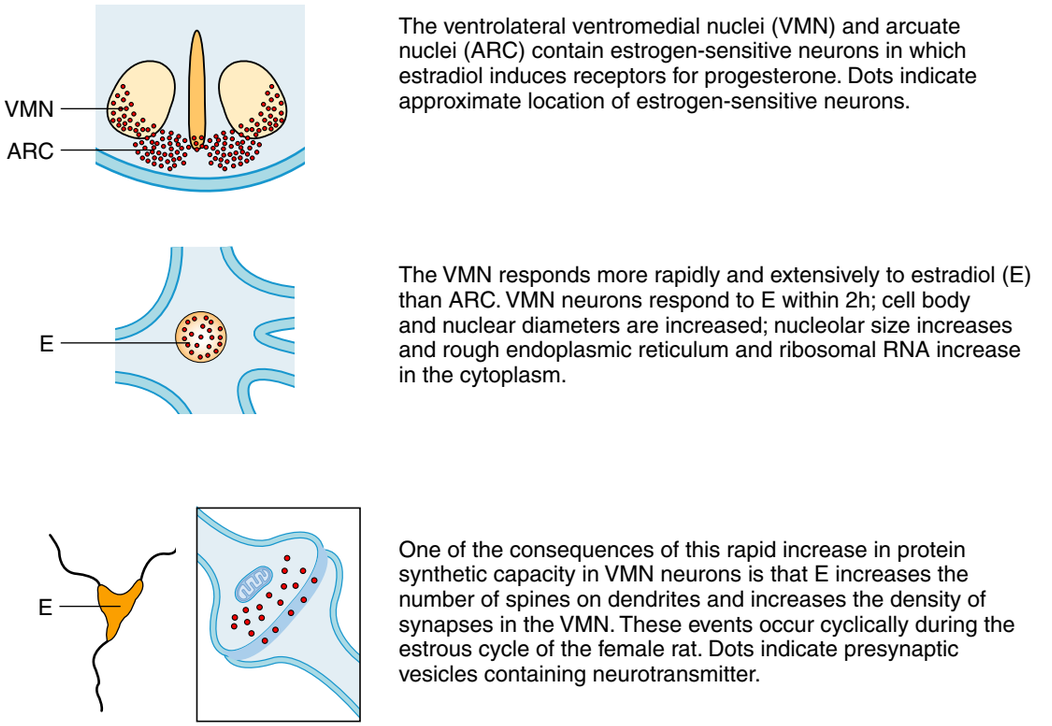


FIGURE 52-10 Summary of adrenal steroid effects on neurons of the hippocampus, illustrating their ability to protect and stabilize the population of the dentate granule neurons and to potentiate damage caused by excitatory amino-acid release upon pyramidal neurons. *E*, estrogen. (From [41], with permission.)

'Good stress' is therefore the efficient management of an allostatic response, whereas 'bad stress', or being 'stressed-out', involves the persistence or otherwise inefficient operation of these normally adaptive responses.

Stressful early life events, involving abuse or neglect, can have a life-long influence on the stress response, and lead to elevated levels of allostatic load for the lifespan. Overactivity of the stress hormone axis has been linked to prenatal stress or poor maternal care in rodent models, and this overactivity contributes to increased rates of brain and body aging [39].

There are gradients of health status across income and education (referred to as 'socioecomic status' or 'SES') that are not explained by access to health care or other simple explanations [40]. Therefore, it may be of great relevance in the future to understand the role of such factors as sense of control, helplessness, persistent fear and anxiety, diet, exercise, and the impact of the living and social (e.g. family and work) environments in regulating the allostatic systems; these factors could cause allostatic systems to operate inefficiently and lead to an acceleration of genetic predispositions towards disease.

FUTURE DIRECTIONS AND CHALLENGES 872

BRIEF HISTORY OF MEMORY RESEARCH IN HUMANS

The ability to learn and to remember is one of the most fundamental features of the brain. Understanding how learning and memory work is important, because what we learn and what we remember determine, to a great extent, what we are and who we are. Memory, not merely facial and physical appearance, defines an individual, as everyone who has known someone with Alzheimer's disease understands all too well. Furthermore, the impact of learning and memory reaches far beyond the individual, and they form the very foundation for transmitting knowledge through generations, consequently, serving as the major forces in driving cultural and social evolution.

By definition, learning is the acquisition of new information, whereas memory is the retention of acquired information. Driven by knowledge obtained by scientists before them, various disciples of neuroscience over the course of the past 100 years have learned more about various components of learning and memory, whether at the molecular level of synapses or at the systems level of brain circuitry. The concept of memory of mind has existed since the time of Aristotle. It is only during the past 50 years or so that scientists have begun to unravel some of the anatomical and cellular bases underlying such a complex mental process.

Most neuroscientists regard the ideas and observations of Santiago Ramon Y Cajal at the end of 19th century as the beginning of the cellular exploration of just how memory is retained in the brain. Upon his original observation of synaptic conjunction between neurons, he immediately entertained the idea that the modification of these conjunctions could form the anatomical basis responsible for the persistence of memory.

Basic Neurochemistry: Molecular, Cellular and Medical Aspects
0-12-088397-X

The Penfield studies were a breakthrough in human functional brain mapping. So where should we look for such changes? The answer to this seemingly simple question lies at the core of modern neuroscience. Scientists must first find out where memories reside in the brain. A breakthrough was made in the mid 1950s by Wilder Penfield who had the opportunity to stimulate the cortical surface of over 1,000 of epileptic patients in the course of neurosurgery for removing epileptic tissue [1]. Since the brain does not have pain receptors, the operation only needs local anesthesia on the scalp and the patients remained fully conscious during surgery. Some patients reported that they were hearing voices and music, or seeing images and having other mental perceptions uniquely when electrical stimulation was delivered to a brain area known as the temporal lobe (Fig. 53-1). Those electrical stimulation-triggered mental experiences often had dream-like qualities, which suggested that they reflected flashbacks to past experiences.

Further studies have shown that electrical activation of specific limbic structures within the temporal lobe system, such as the hippocampus and amygdala (Fig. 53-1), are capable of generating experiential responses [2]. These fascinating reports were the first indications that the temporal lobe system may play a crucial role in representing memories and thoughts. In fact, we now know that memories are processed in many regions of the brain, far beyond the temporal lobe system [3]. Many studies suggest that memory is both distributed and localized. In other words, no single memory center exists in the brain, but rather memory is encoded along many pathways in the brain by a set of specific circuits.

Amnesia patients showed the role of temporal lobe in memory. Almost at the same time of Penfield's studies, Brenda Milner of the Montreal Neurological Institute examined a patient, known by his initials as H. M., who had undergone bilateral surgical removal of the temporal lobe (medial temporal cortex, amygdala, and two-thirds of the hippocampus). The surgery was apparently a success in terms of relieving his severe epilepsy, but left him with a devastating loss of ability to form memories [4]. For example, although H. M. recognized his childhood pictures and remembered well childhood events, he had trouble recalling major personal and social events that had taken place a couple of years before his operation. This inability to remember things that happened several years preceding the surgery is called *retrograde amnesia.*

More strikingly, in H. M.'s case, the surgery also produced severe *anterograde amnesia* — the inability to form new memories about events, places and people he encountered after the operation. For example, H.M would not recognize Dr Milner following the surgery, even though she had been examining him very frequently for more than 40 years. His anterograde amnesia was so severe that H. M. could not even recognize current photos of himself, despite the fact that he viewed himself in a mirror every morning.

Interestingly, H. M. preserved his ability to form short-term memory. For example, with rehearsal and as long as he was not interrupted, he could remember for several minutes a string of six-digit numbers. His intact short-term memory suggests that the temporal lobe is crucial for the conversion of new memory into long-term memory, a process termed *memory consolidation.* Even more amazingly, H. M. exhibited normal learning and memory for perceptual–motor tasks such as mirror-drawing (to learn to draw pictures by looking at his hand in a mirror) despite his inability to remember the repeated daily learning sessions. Thus, it seemed clear that H. M.'s ability to learn and retain new motor skills and procedural operations remained intact.

H. M. was the first human case in which specific amnesia could be linked to selective regions of the brain. Since then, many patients have been identified as having selective lesions to the temporal lobe system, especially within the hippocampus. They have exhibited amnesias similar to H. M.'s. For example, *amnesic patient*, R. B, who had a specific lesion in the CA1 region of hippocampus, showed profound loss of ability to form new memories of people, places, and events [5]. R. B. also lost memories regarding public and personal events that he had experienced two

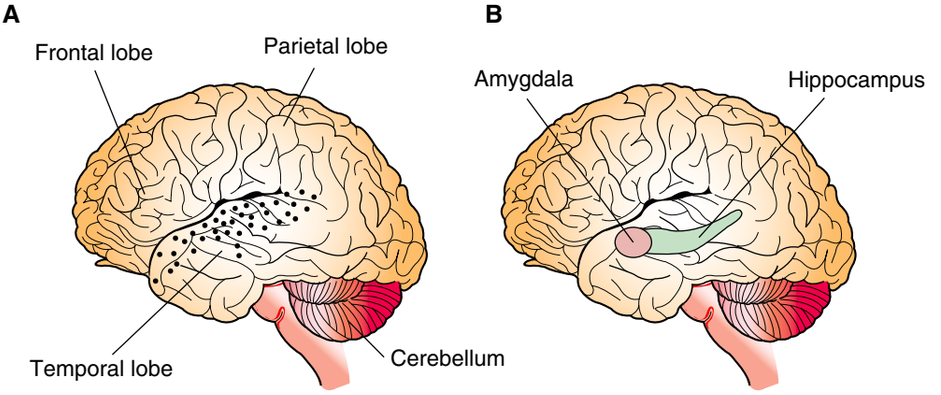

FIGURE 53-1 Illustrative drawing of the temporal lobe system in the human brain. (**A**) Anatomical sites, marked by *black dots*, within the temporal lobe where electrical stimulation evoked experiential responses in Penfield's patients. (**B**) The location of the hippocampus and amygdala inside the temporal lobe.

years before his CA1 lesion. Such clinical observations have established the view that the hippocampus system is critically involved in memory processes.

DIVISIONS OF MEMORY

Declarative memory vs. procedural memory. Based on the types of memory selectively affected in such amnesic patients, memory can be divided into two major classes: declarative memory and procedural memory.

Declarative memory, also termed *explicit memory*, is memory of places, events, facts and people, and is dependent on the temporal lobe system. Retrieval of these memories requires conscious recollection. This type of memory tends to form easily and be forgotten easily.

Declarative memory can be divided further into two subclasses: episodic memory and semantic memory. *Episodic memory* refers to memory of episodic events that contain what, where and when information. This is the major type of memory encoded in our daily life. *Semantic memory* refers to memory of facts and knowledge that are no longer ascribable to any particular occasion in life (without necessarily remembering where and when the person acquires it). Thus, semantic memory, created through either single or repeated experience, represents a more abstract generalization of experience that may give rise to concepts and categorization. Lesions in the temporal lobe, such as the hippocampus, are known to greatly impair patients' ability to learn new facts, concepts, vocabulary and knowledge about the world.

Procedural memory, also termed *nondeclarative memory* or *implicit memory,* is the counterpart of declarative memory and encompasses a variety of perceptual–motor learning skills and mental operations. This type of memory does not depend on the structural integrity of the temporal lobe system. For example, H. M. showed good ability to reduce the time required for completing a ten-choice tactile maze after 80 trials, despite the fact that he never remembered the correct sequence of turns during the maze test. Actually, amnesic patients with temporal lobe lesions retain other learning capacities such as classical conditioning (such as eye-blink conditioning), habituation, sensitization, priming (the facilitation of performance by prior exposure to words) and mental operations such as how to put together a jigsaw puzzle and use of numbers. It should be mentioned that priming is a short-lived phenomenon, whereas learned motor skills (such as how to ride a bike) can endure for a long time. Currently, the brain regions involved in encoding procedural memory are not clear, at least in humans. In rodents, lesion studies suggest that the striatum may be engaged.

Short-term memory vs. long-term memory. The classification of memories into declarative memory and nondeclarative memory is based on the anatomy of the temporal lobe system. However, memory is often classified temporally: *short-term memory* has a time course of the order of seconds to hours, whereas *long-term memory* has a time course of weeks, months and years. The basis for temporal division of the memory process is revealed by observations that newly formed memories (short-term memories) are more vulnerable to interferences and disruptions. For example, if someone involved in a car accident lapses into a coma from head trauma, he or she very likely will not remember the events leading up to and including the accident on regaining consciousness,. Similarly, someone who receives electroconvulsive treatment will lose memories of events immediately preceding the convulsion. However, these same treatments have no effects on old memories which were generated long ago (long-term memories). These phenomena have led to the notion that memories are initially created in a much more labile status, and are gradually converted into a more stable state (*memory consolidation*). As we recall from the cases of H. M. and R. B., those patients exhibited severe impairment in the formation of new long-term memories while preserving old long-term memories as well as intact short-term memories. These clinical studies, together with lesions in laboratory animals, clearly suggest that the hippocampal system is crucial for helping the brain to convert short-term memory into long-term memory.

MOLECULAR MECHANISMS OF LEARNING

Hebb's rule, long-term potentiation (LTP) and experimental models of synaptic plasticity. By knowing the neurobiological classifications of memory as well as identifying some of the brain regions crucial for the memory process, you may want to ask the next question: 'How is memory formed and stored in those brain regions?' As mentioned in the introduction, the idea that changes in synaptic efficacy are important can be traced back to Cajal 100 years ago, when he showed that networks of neurons are linked with each other at the specialized junctions that Sherrington called synapses. Cajal was the first to hypothesize that modification of the physical structures of individual signaling units, i.e. synapses, may account for the cellular event of memory storage.

The foundations for exploring the molecular and cellular mechanisms of learning and memory were laid in 1949, when Canadian psychologist Donald O. Hebb came up with a simple yet profound idea to explain how memory is represented and stored in the brain. According to Hebb's postulate [6]:

> 'When an axon of cell A is near enough to excite a cell B and repeatedly or persistently takes part in firing it, some growth process or metabolic change takes place in one or both cells such that A's efficiency, as one of the cells firing B, is increased.'

These 49 words have formed what now is known as *Hebb's Learning Rule*. Although some minor modifications have been required over the years, the essence of Hebb's rule remains unchanged: a memory is produced by coincident neural activity; when two connected nerve cells are active simultaneously, the strength of their synaptic connection increases; this confers a basis for the persistence of memory.

To understand whether the brain actually uses 'coincidence-detection' logic to modify synaptic efficacy and store information, one needs to know where to look for such synaptic changes. As we recall from the pioneering studies made by Dr Brenda Milner, the hippocampus and its nearby structures are crucial for the formation of memories about facts, people, and events. In the 1970s, Timothy Bliss and Terji Lomo observed that the perforant-dendate gyrus pathway in the anesthetized rabbit hippocampus exhibits increased synaptic responses after a train of high-frequency stimulation. The increase in synaptic transmission, as often measured by either the amplitude or slope of the EPSP, can last for hours *in vitro* and days and weeks *in vivo*. This phenomenon is called *long-term potentiation* (LTP) (see also relation to glutamate receptors in Ch. 15) [7]. Later studies by many scientists have shown that high-frequency stimulation of every pathway within the hippocampus, including the CA3–CA1 Schaffer-collateral pathway, can produce LTP (Fig. 53-2). In fact, we now know that LTP exists in many animal species and in many brain regions including the neocortex, amygdale, and striatum. Moreover, LTP occurs in several distinct forms.

A series of investigations suggests that LTP generally possesses four basic characteristics: (1) temporal specificity; (2) cooperativity, (3) associativity, and (4) input-specificity. *Temporal specificity* means that the strengthening of synaptic efficacy requires the presynaptic cell(s) to fire *before* the postsynaptic cell. This temporal requirement resembles the temporal feature of associative Pavlov conditioning in which the conditioned stimulus (e.g. a bell-ring) must precede the unconditioned stimulus (e.g. food) if the conditioning is to be successful. *Cooperativity* refers to the fact that many synapses are required to produce enough depolarization to induce LTP: activation of a single synapse can rarely trigger a spike in the brain. Because of variations in the internal states of many synapses, LTP induction thresholds are not fixed, and often require different intensities and patterns of tetanic stimulation. *Associativity* refers to the special scenario in which strong activation of one set of synapses can facilitate LTP induction at a set of recently and weakly activated adjacent synapses of the same postsynaptic cell. Finally, *input-specificity* of LTP means that potentiation is only induced at the synapses receiving stimulation, and not at unstimulated synapses on the same cell. This property is crucial since it guarantees the specificity of altered connections, and may also increase the capacity of individual neurons to process and store information.

The NMDA receptor in the hippocampus induces LTP. What molecular machinery controls these forms of synaptic plasticity? One of the most studied brain regions is the CA1 region of the hippocampus: the CA1 region is not only crucial for memory formation (profound amnesia in patient R. B with selective CA1 lesion), but also exhibits a well-organized laminar structure ideal for electrophysiological recording.

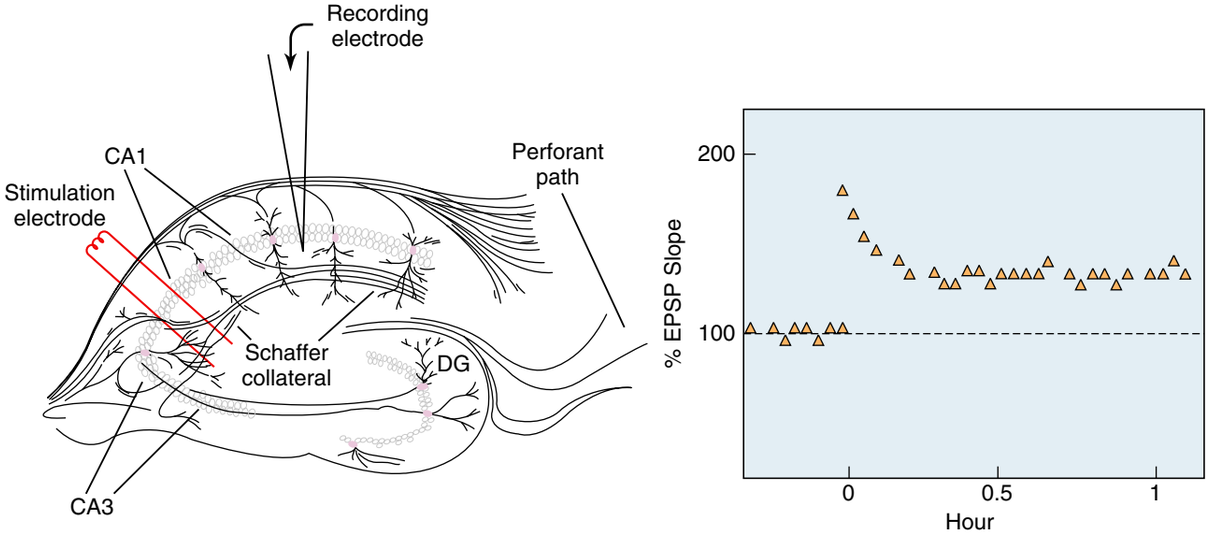

FIGURE 53-2 A drawing of the major pathways and synaptic plasticity of the hippocampus. The hippocampus is made of three major synaptic pathways (the left panel). The first one is called the *perforant*-pathway which transfers information from the entorhinal cortex to the granule cells of the dentate gyrus. The second relay is from the dentate gyrus to the CA3 pyramidal cell, and is called the *mossy-fiber* pathway. The third pathway is from the CA3 cells to CA1 pyramidal cells, termed the *Schaffer collateral* pathway. This pathway is one of the most studied systems *in vitro*. Long-term potentiation, as measured by the increase in EPSPs of CA1 cells in response to stimulation of the CA3 axon bundle, is induced by the high-frequency stimulation in the Schaffer-collateral pathway (the right panel). This increased potentiation can last for several hours *in vitro* and days and weeks *in vivo*.

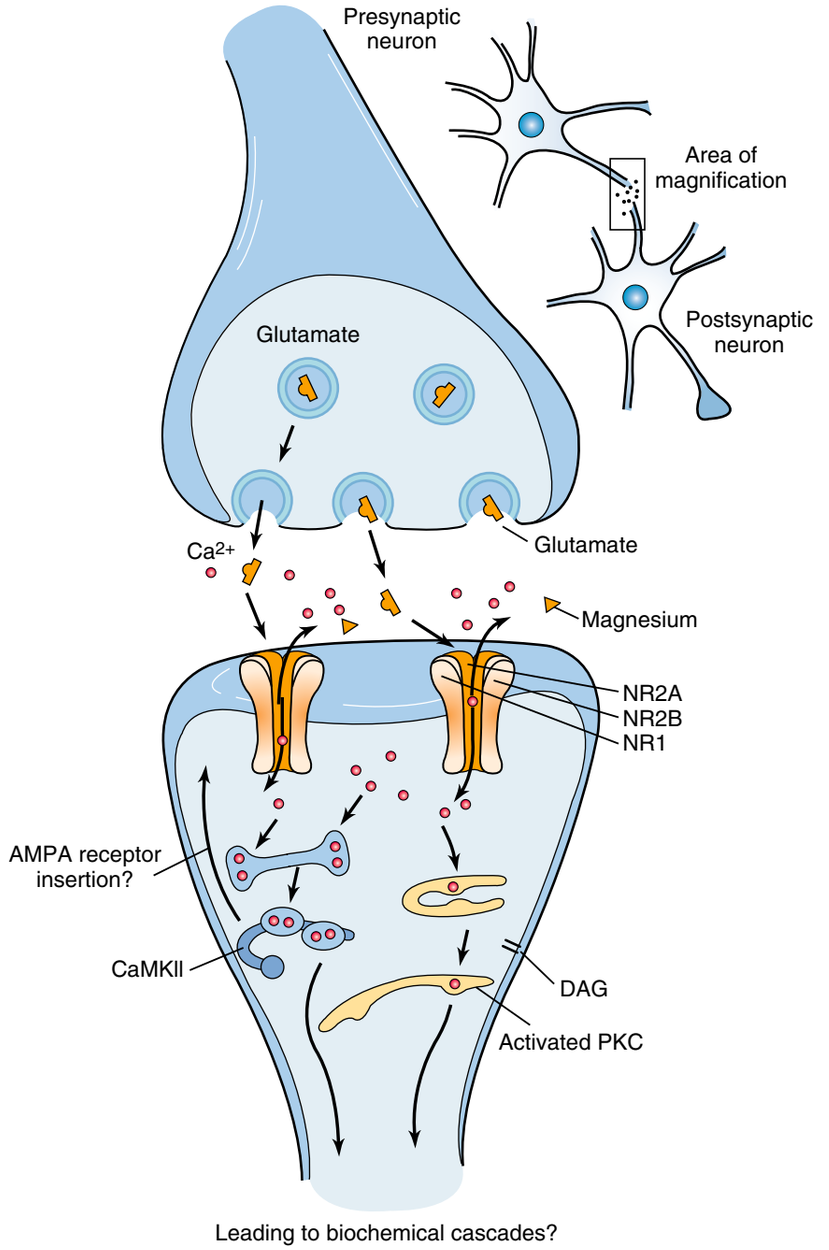

FIGURE 53-3 An illustration of a synapse between the presynaptic and postsynaptic neurons. The glutamate released from presynaptic terminals activates both AMPA and NMDA receptors. While the AMPA receptor is responsible for basal synaptic transmission, the NMDA receptor acts like the volume controller regulating the efficacy of synaptic transmission. Synaptic transmission is enhanced if the NMDA receptor detects the co-activity of the presynaptic (release and binding of glutamate) and postsynaptic neuron (enough depolarization to expel Mg^{2+} from the channel pore). When such a coincidence event occurs, the NMDA receptor is activated, which opens the channel pore and allows Na^{+} and Ca^{2+} to rush in and K^{+} to rush out. The influx of Ca^{2+} then activates biochemical cascades that eventually strengthen the synapse. It is believed that some of these kinases bind directly to the *C*-terminus of the NR2B subunit, allowing efficient signal detection and amplification (see also Ch. 15).

It is well-established that the *induction mechanism of LTP* at the CA3–CA1 synapse of the Schaffer collateral pathway requires postsynaptic activation of the NMDA receptors (Ch. 15). The NMDA receptor seems to be a perfect cellular device to detect the synaptic coincidence between pre-synaptic and post-synaptic neurons, and to associate two events at the cellular level [8].

What is the molecular underpinning for the coincidence-detector property of the NMDA receptor? The NMDA receptor is a channel protein that sits in the postsynaptic membrane (Fig. 53-3). The electrical stimulation of a pre-synaptic cell releases glutamate which binds to the post-synaptic AMPA and NMDA receptors. Glutamate binding to the NMDA receptor alone is not sufficient to activate

the channel because, at the usual resting membrane potential, the Mg^{2+} blocks the pore of the NMDA receptor, thereby preventing the channel from opening. The relief of the Mg^{2+} blockade comes when the postsynaptic cell is sufficiently depolarized by the repetitive activations of the AMPA receptor, which cause Na^+ influx and consequently increase EPSP. Thus, the opening of the NMDA receptors is both ligand-dependent (release and binding of glutamate) and voltage-dependent (the depolarization of postsynaptic cell). Because the NMDA receptor is permeable not only to Na^+ and K^+ but also to Ca^{2+}, calcium influx into a dendritic spine triggers activation of protein kinases which initiate a cascade of biochemical events (Fig. 53-3). These biochemical cascades are believed to modify synaptic strength. Thus, the NMDA receptor is a gating switch for the induction of synaptic plasticity.

Thus, the mechanistic properties of the NMDA receptor can help account for the properties of temporal specificity, cooperativity, and associativity of LTP. They can also explain why both high-frequency stimulation (100 Hz) and pairing low-frequency stimulation with postsynaptic depolarization can induce LTP. The occurrence of presynaptic activity followed by postsynaptic activity determines a temporal sequence and specificity. To generate sufficient depolarization in the postsynaptic cell to expel Mg^{2+} from NMDAR channels usually requires cooperative depolarization at many synapses. Moreover, the requirement of postsynaptic depolarization also underlies associativity since the depolarization caused by the strongly activated synapses can relieve the Mg^{2+} blockade of the NMDA receptors on weakly activated synapses.

Molecular mechanisms underlying the early- and late-phase expressions of LTP. While opening the NMDA receptors is crucial for coincidence-detection, the sensitivity and robustness of coincidence-detection is not solely determined by the opening time-window. It is dependent on at least three other features: summation of the opening duration, the peak amplitude and proper intracellular signal transduction.

Among many signaling molecules involved in the relevant biochemical cascades, Ca^{2+}/calmodulin-dependent protein kinase II (CaMKII) plays a key role in mediating the early-phase expression of LTP [9]. Ca^{2+} entry through NMDA receptors promotes binding of calcium/calmodulin to CaMKII, which causes physical translocation of α-CaMKII to post-synaptic density zones (PSD) by binding to the *C*-terminus of the NMDA receptor NR2B subunits at synapses (Fig. 53-3). Autophosphorylation at Thr^{286} of α-CaMKII further enhances the Ca^{2+}/CaM binding affinity with the CaMKII and prolongs the association of the CaMKII holoenzyme at PSDs. It is believed that the activated CaMKII at the PSD zone is responsible for potentiating synapses, probably by causing synaptic insertion of AMPA receptors and/or increasing their single channel conductance. Several other kinases, such as PKC and MAP kinase, may also be involved in the expression of LTP. This phosphorylation-dependent modification of synaptic potentiation is believed to be capable of supporting LTP for 1–3 h. This period is termed *the early phase of LTP*.

For maintaining synaptic potentiation beyond the initial three hours, protein kinase A(PKA) and ERK pathways may be involved. This is termed *late-phase LTP* and appears to require gene transcription and protein synthesis [10]. At the level of transcription, it has been further hypothesized [11] that the phosphorylation of the nuclear transcription factor, CREB (*c*AMP *R*esponse *E*lement-*B*inding protein), is the key regulator for turning on gene expression. Initial analyses indicated that the CREB manipulations seemed to be correlated with changes in long-term memory. Since then, the role of CREB as a central switch for the long-term plasticity and memory formation has been promoted as a central dogma in neuroscience.

However, a series of recent crucial experiments have begun to question the scientific validity of this view. For example, the original 'transcription requirement for the late phase LTP' experiments could not be reproduced. Also, the transgenic fly overexpressing the dCREB2-a transgene originally reported to produce enhanced long-term memory (touted as 'photographic memories') actually carries a mutation that produces a translational reading-frame shift with the consequent formation of a stop codon at predicted amino-acid position 79. Overexpression of a *corrected* dCREB2-a transgene failed to show any enhancement of LTM [12]. Furthermore, it turns out that the original CREB global knockout mice did not delete all forms of CREB isoforms and their performance of memory tasks may be due to developmental abnormalities. Moreover, once crossed to different genetic background their memory deficits disappeared or were greatly alleviated.

Most importantly, later genetic experiments, using conditional knockout technique to delete all forms of CREB in either the entire forebrain or hippocampus, showed that these conditional knockout mice have normal hippocampal early- and late-phase LTP, and normal performance in hippocampal-dependent memory tasks [13]. Therefore, those newer findings cast significant doubt on the role of CREB as a central switch for long-term plasticity.

While gene transcription may still provide a mechanism for laying down long-term synaptic plasticity, the complex morphological specialization and large number of synapses would require that newly synthesized proteins are selectively transported to the activated synapses without altering the function of the other synapses in the neuron. One hypothesis to deal with this issue is that synaptic plasticity may be partially mediated via local production of new proteins only at specific subsets of synapses or individual spines (translational control) [14]. Another hypothesis is that the activated synapses may create some types of 'synaptic tagging' signals by which the newly synthesized proteins can find their ways to the supposed sites [15]. So far, the molecular identities of 'synaptic tagging' remain unclear (but see ref. [16]).

Although the exact molecular basis underlying long-term plasticity is not clear, the general consensus has been that structural plasticity is a fundamental property of

neurons, and that it is a component of mechanisms for storing long-term memories (both Ramon y Cajal (in 1893) and Taniz (in 1893) put forward the idea that changes in dendritic spine number and morphology may provide a cellular basis for memory storage). The search for relationships between structural changes and LTP is complicated by the difficulty in identifying and tracking changes at synapses which have been activated by electrode stimulation to undergo LTP. In order to increase the chance of detecting any learning-induced subtle structural change, researchers have employed a behavioral model known as *the enriched environment paradigm*. In this model, animals are raised in, or allowed to explore daily, a large space containing a variety of toys, exercise wheels, small houses and tunnels. This paradigm has yielded consistent improvements in learning and memory functions as well as increases in dendritic spines and synapses.

Other forms of synaptic plasticity include long-term depression (LTD) and NMDA-receptor-independent LTP. In addition to its ability to produce LTP, a synapse also possesses the ability to decrease its synaptic efficacy. For instance, it has been shown that low-frequency (~1 Hz) stimulation of the hippocampal Schaffer-collateral pathway for 15 min. produces decreased ESPS responses at CA3–CA1 synapses. This type of synaptic plasticity can last at least one hour, and is called *long-term depression* (LTD) (see glutamate transmission in Ch. 15). Similar to the typical form of LTP at the CA1 region, the induction of LTD also requires NMDA receptor activation [17]. Pharmacological studies suggest that, in contrast to the involvement of α-CaMKII in the expression of LTP, Ca^{2+}/calmodulin-dependent phosphatase (see Ch. 23) plays a major role in the expression of LTD. It is interesting to note that although both LTP and LTD induction are dependent on the activation of the NMDA receptor and Ca^{2+} influx, experiments indicate that differential levels of Ca^{2+} influx distinguish which of these signaling pathways will be activated. High Ca^{2+} influx, produced by tetanic stimulation, leads to activation of CaMKII-mediated cascades, whereas lower Ca^{2+} elevation, produced by low-frequency stimulation, favors activation of protein phosphatase cascades (see Ch. 22).

It is now known that synapses in other regions can produce the NMDA-receptor-independent LTD following the same low-frequency stimulation. This, in fact, was true of the first reported case of LTD: the original observation of synaptic weakening after stimulation was made by Masao Ito and his colleagues who recorded in the cerebellum. In the cerebellar cortex Purkinje cells receive input from two major pathways, namely, climbing fibers from the inferior olive nuclei of the brain stem, and the parallel fiber of the cerebellar granule cells. Interestingly, a single climbing fiber makes hundreds of excitatory synapses on a Purkinje cell, whereas a single parallel fiber makes only one synapse (but a single Purkinje cell receives as many as 100,000 passing parallel fibers). Ito and his colleagues found that the parallel-fiber–Pukinje synapses become weaker after the low-frequency pairing of climbing fiber stimulation with stimulation of the parallel fibers. It is now known that induction of this *cerebellar LTD* requires activation of metabotrophic glutamate receptors (mGluR). This type of glutamate receptor is coupled to G proteins that activate phospholipase C. The activation of this enzyme leads to the production of a second messenger, diacylglycerol (DAG) which in turn activates protein kinase C (Ch. 15).

Like NMDA-receptor-independent LTD, at least two types of LTP can occur independently of NMDA receptor activation. First, in the CA1 Schaffer-collateral pathway and some pathways in the visual cortex, extremely-high-frequency stimulation (200–250 Hz) can lead to slow development, over 20–30 min. after stimulation, of synaptic potentiation that is dependent on the activation of voltage-gated calcium channels (VGCC) ([18] and Ch. 6). Thus, this form of plasticity is also known as *the voltage-gated calcium-channel-dependent LTP*, or VGCC–LTP. Another interesting feature of VGCC–LTP is that in contrast to the synaptic localization of the NMDA receptors, voltage-gated calcium channels are situated at the base, or around the base, of dendritic spines. This suggests that this type of LTP may be able to spread to nearby synapses.

A second type of NMDA-receptor-independent LTP exists in the mossy-fiber pathway at the dentate granule cell-to-CA3 pyramidal cell synapse [19]. This form of LTP, termed *mossy fiber-CA3 LTP*, is believed to involve PKA activation in the presynaptic cell which leads to increased neurotransmitter release. However, the exact induction mechanism is not yet clear.

Despite the various exceptions described above, NMDA-receptor-dependent forms (both LTP and LTD) are the most prevalent CNS forms of synaptic plasticity. The pivotal role of the NMDA receptors in synaptic plasticity is also highlighted by the peculiar fact that the effect of NMDA receptor blockade on the induction of LTP and LTD is one of few things that most LTP laboratories can agree on. This contrasts with more variable results of blocking downstream molecules. In a sense, this is not entirely surprising since even a slight variation in experimental protocols (e.g. short tetanus, long tetanus, repeated tetanus, theta-burst, slice incubation temperature, etc) can often result in LTP with different magnitudes, decay and shapes, reflecting activation or recruitment of different molecular downstream pathways.

Initial evidence linking Hebb's coincidence detection rule to learning and memory. As the unique receptor in the brain with the coincidence-detection property, the NMDA receptor is an ideal candidate to gate the formation of memory at the synaptic level. Early observations demonstrated that infusion of NMDA receptor blockers into brain ventricles resulted in animals' poor performance in the hidden-platform water maze. At first, this seemed to provide evidence for the role of hippocampal LTP in memory formation. Unfortunately, careful analyses revealed that poor performances in the water maze tests

were probably due to drug-induced side-effects such as sensorimotor disturbances.

The first crucial experimental test for the role of Hebb's rule in learning and memory came in mid 1990s as a result of development of *conditional gene knockout technology* [20]. This region-specific gene knockout technique allows the NR1 gene, which encodes the core subunit of the NMDA receptor, to be selectively deleted in excitatory pyramidal neurons in the CA1 region [21] (Fig. 53-4). This second-generation knockout technique is based on the Cre/loxP recombination system, a trick employed for millions of years by a virus that infects bacteria. This new method overcomes many shortcomings of the first-generation gene knockout, which deletes the gene of interest in every tissue and during embryonic development. Therefore, the conditional gene knockout can allow researchers to avoid developmental abnormalities and the tissue nonspecificity associated with global gene knockout. Using this brain-region-specific knockout method, mutant mice were engineered, in which NMDA receptors were selectively and post-developmentally absent in the CA1 region of the hippocampus. These mice lacked NMDA-receptor-dependent forms of LTP and LTD at the CA1–CA3 synapse, and did not learn and remember well in a variety of spatial and nonspatial tasks that were dependent on the hippocampus [21, 22]. This series of experiments strongly suggest the important role of CA1 NMDA receptors in controlling the formation of hippocampal-dependent learning and memory. Intriguingly, daily exposures of these CA1-specific NR1 mice to enriched environments can significantly alleviate some of those learning and memory deficits [22]. Later studies showed that daily enrichment produces significant changes in the expression of several hundred genes, as well as an increase in dendritic spines in the brains of those mutant mice. This suggests that environmental enrichment is capable of compensating the hippocampal deficits in the CA1-specific knockout mice. However, it is interesting to note that similar enrichment seems to be incapable of rescuing the memory deficits in the forebrain-specific NMDA-receptor knockout, suggesting that the enrichment may exert its effects through a cortical NMDA-receptor-mediated mechanism.

While the conditional gene knockout experiments are supportive of a role for the NMDA receptors in memory, they are less than fully conclusive in linking the synaptic coincidence-detection feature of the NMDA receptor to memory formation. Like all 'loss-of-function' studies, CA1-specific gene-knockout experiments could, in theory, produce memory impairment via a mechanism independent of the coincidence-detection function of the NMDA receptor. For example, one may argue that the physical absence of the NMDA receptor channels may cause subtle structural reconfiguration at the synapse, thereby altering normal synaptic transmission. Therefore, the 'memory impairment' in CA1-specific NR1 knockout mice does not allow a firm conclusion that the coincidence-detection function of NMDA receptors controls learning and memory processes at the cellular level.

Genetic engineering of 'smart mice' is a more stringent test of Hebb's rule. In seeking a more stringent test of Hebb's rule for learning and memory, a somewhat unconventional design was devised: if Hebb's prediction were correct, his rule implies that enhancing the coincidence-detection feature of the NMDA receptor might serve as a theoretical basis to genetically engineer '*smart mice*' with superior learning and memory functions. If such a 'memory enhancement' experiment worked, it would offer far more convincing evidence that the NMDA receptor is Hebb's gating switch for memory formation. Among several advantages, this is a 'gain-of-function' approach that relies on fine-tuning a particular channel property of the NMDA receptor, rather than the earlier sledgehammer approach of knocking out the entire receptor function. In 1999, researchers reported just such 'gain-of-function' experiments [23].

To do this, they focused on the molecular composition and channel biophysics of the NMDA receptor. At the molecular level, NMDA receptors are believed to be tetrameric complexes consisting of the NR1 subunit and NR2

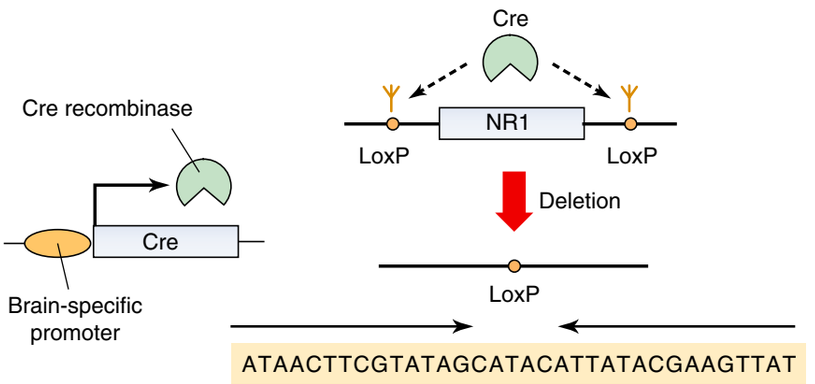

FIGURE 53-4 The strategy for achieving brain-region-specific gene knockout. This second-generation genetic technique employs a trick used by bateriophage to infect host cells: the Cre/loxP recombination system. The Cre recombinase acts like a DNA scissor which cuts specifically at the loxP sites. By expressing the Cre gene in a specific region of the brain, any gene flanked by loxP sites, which are inserted by embryonic cell homologous recombination, can be deleted. The bottom picture illustrates the efficient deletion restricted to the CA1 region of the mouse hippocampus.

or NR3 subunits (see Fig. 53-3 and Ch.15). The core component is the NR1 subunit, deletion of which leads to complete loss of the NMDA receptor function, as in the memory-deficient CA1-specific NR1 knockout mice. But the NR1 subunit needs to associate with different partners, because these other subunits determine and regulate many of the coincidence-detection features such as channel gating and Mg^{2+} dependency.

Among NR2 subunits, NR2A and NR2B are particularly important because they are the main subunits available for association with NR1 to form channels in cortex and hippocampus, the primary regions for learning and memory. Coincidently, these two subunits impart strong Mg^{2+} dependency, a feature ideal for coincidence-detection. Interestingly, the NR2C and NR2D, which exhibit greatly reduced Mg^{2+} dependency (and are thereby less suitable for coincidence function), are mainly expressed in the cerebellar granule cells and interneurons in the midbrain regions, respectively. In addition, the NMDAR complex contains many other modulation sites for fine-tuning the channel properties. For example, some neurosteroids can selectively potentiate NR2A- and NR2B-containing NMDA receptors, whereas they inhibit NR2C- or NR2D-containing NMDA receptors [24].

Integration of this knowledge with two other phenomena contributed to the design of this test:

1. In species ranging from birds to rodents to primates, the NMDA receptor almost invariably stays open longer in young animals than in adults;
2. The molecular composition of NMDA receptors in brains exhibits dynamic changes as a function of age.

During the transition from juvenile to adult, there is a gradual switch from NR2B to NR2A as the preferred partner for NR1 in the cortex and hippocampus. Moreover, it is known from *in vitro* studies that NR2B prolongs the duration of channel opening, whereas NR2A shortens it [25].

Therefore, researchers reasoned that the natural switch with age of NR1's partner could explain why the NMDA receptor in adult brain has a much narrower window of time for cellular association to occur, and it might explain why adult animals find it harder to learn and register new information [26]. So a copy of the NR2B gene was linked to a forebrain-specific promoter that increases NR2B's expression in the adult mouse forebrain (Fig. 53-5A), thereby counteracting the natural decline of the NR2B expression in the adult.

As a result of making more NR2B as a partner for NR1 in the adult cortex and hippocampus, the NMDA receptor underwent a subtle but significant change: instead of staying open for about 130 ms, as does the NR2A-containing NMDA receptor in the normal adult brain, these transgenic NMDA channels now opened for about 230 ms, in form of NR2B-containing receptor. Thus the transgenic channels retain some juvenile receptor properties which make them better at detecting synaptic coincidence and forming stronger synaptic connections between co-activated cells. The performance of these genetically modified mice was tested in a variety of situations that addressed different aspects of learning and memory. They found that these NR2B transgenic animals (nicknamed *Doogie*) learn faster, remember longer, and outperform wild-type littermates in at least six different behavioral tests [23] (Fig. 53-5B).

Recently, other research groups have independently confirmed these findings [27], and further shown that upregulation of NR2B expression at synapses can be obtained by over-expressing KIF-17, a kinesin motor protein for transporting NR2B protein from soma to dendrites. This procedure also enhances learning and memory in mice [28]. Together, these 'smart mice' experiments substantially validate Hebb's theory, by clearly demonstrating that NMDA-receptor-mediated coincidence-detection serves as a common cellular mechanism underlying learning and memory in brain. These experiments also confirm that the change in the molecular ratio of NR2A:NR2B at the onset of sexual maturity is a genetic basis for the gradual cognitive declines in adulthood. Perhaps Hamlet had a different meaning in mind when he declaimed '2B or not 2B that is the question'.

Experimentally induced LTP may be disassociated from memory function. While the evidence for the coincidence-detector function of the NMDA receptor in learning and memory is consistent, correlations between experimental LTP and specific learning and memory functions remain controversial. Although many gene knockout studies have correlated deficiency in hippocampal LTP with decreases in learning and memory, there are major exceptions to this simplistic relationship between LTP and memory. For example, in mutant mice lacking the PSD-95 gene, enhanced LTP is associated with impaired performance in the water maze [29]; in contrast, glutamate-receptor-type-A (GluR-A or GluR1) knockout mice have an impaired LTP (induced by 100 Hz ×1 s tetanus), but perform normally in the hidden-platform water maze [30]. Thus, analyses of correlations between LTP and memory formation have not given researchers a simple 'Yes-or-No' answer. This may not be entirely surprising, since evaluations of LTP mostly depend on artificial-induction in brain slices. Not only are such measurements prone to variations of experimental protocols and incubation conditions, but also LTP, as a form of an artificially induced phenomenon, is unlikely to capture all hallmark features of actual synaptic mechanisms elicited by natural learning conditions.

MOLECULAR MECHANISMS OF MEMORY CONSOLIDATION AND STORAGE

Retrograde amnesia and post-learning consolidation occur in the hippocampus. Researchers have sought to understand the biological mechanisms underlying the formation of long-term memory since Muller and

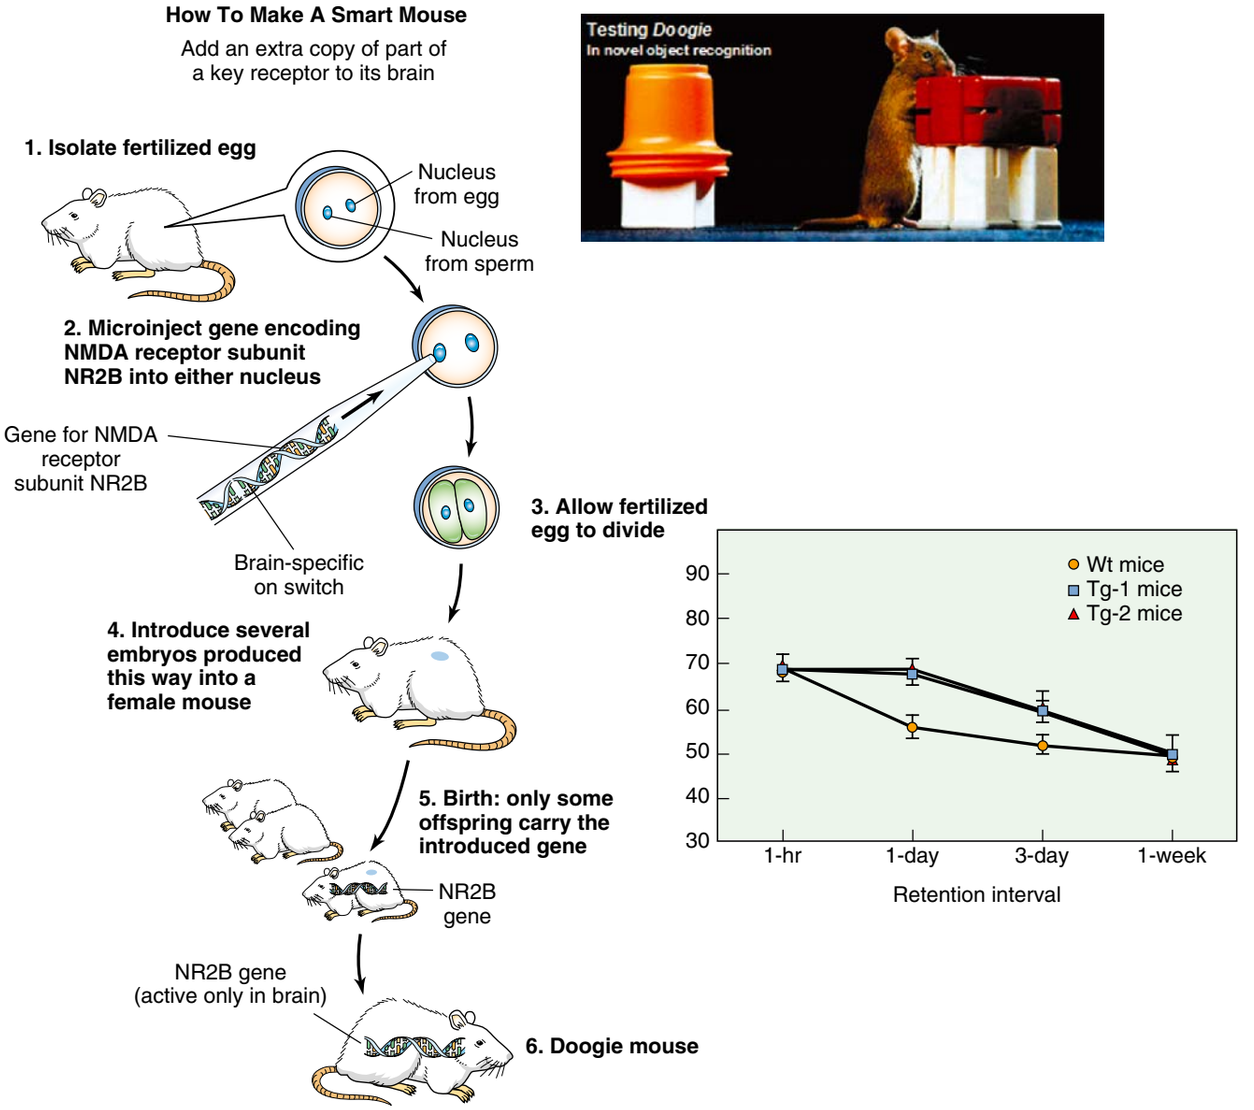

FIGURE 53-5 The procedure to make 'smart mice' through the transgenic microinjection technique. A genetically engineered smart mouse is performing the novel object recognition task. This task allows researchers to measure the amount of time the animal spent on exploring either the old toy (in *orange* on the left) or new one (the *red* one on the right). If the mouse remembers the old toy, he tends to spend more time playing with the new one. The graph shows that transgenic NR2B mice are capable of remembering for at least three days, whereas the wild-type littermates retain the memory for only one day. This task assesses only one type of memory. In other tests, the transgenic mice also showed greater learning ability (modified from Tsien, J. Z. *Scientific American,* 282: 62–68, 2000).

Pilzecker at the turn of 20th century [31]. Recall from the previous sections, that studies of amnesiac patients and experimental animals have revealed two effects of hippocampal lesion: *anterograde amnesia* (lost ability to form new memories) and *retrograde amnesia* (loss of recently formed memories). The later effect suggests that the hippocampus is involved in the conversion of short-term memory into long-lasting memory even long after learning has occurred. This post-learning process is termed *memory consolidation.* Memory consolidation requires the hippocampus to continue its engagement for an additional period of time after learning — estimated to be a couple of weeks in rodents, and up to one or two years in humans. Those observations have led to the general notion that the memory process is not an instant and unitary, but rather a gradual and continuous process which can be divided into four distinct temporal stages: acquisition (learning), consolidation, storage, and retrieval. However, analysis of molecular mechanisms underlying each memory stage has not been an easy task, since precise temporal control of molecular functions has been lacking.

A dominant view is that long-term memory is ultimately expressed in the form of changes in synaptic structure, resulting from a learning-triggered molecular cascade consisting of receptor activation, transient changes in protein phosphorylation levels, new protein synthesis, and new gene expression. This '*single cascade hypothesis*' has guided many experimental designs as well as conceptual thinking in the past decades [11]. However, emerging evidence suggests that the single cascade hypothesis is insufficient to account for the formation and consolidation of long-term memory in the mammalian brain. First, the time scales for a molecular cascade and memory consolidation do not match each other. A single molecular cascade typically operates on the timescale of minutes to hours, whereas the hippocampus-mediated consolidation of long-term memories operates on the timescale of week(s) in rodents and years in humans [5, 32, 33]. Second, although protein synthesis inhibitors seem to produce long-term memory deficits (often tested within a day or days of training), spontaneous recovery or reminder-induced recovery of memory over the period of a week or weeks has been reported in animals initially thought to be amnesic [34]. Finally, individual synaptic receptor and structural protein molecules have relatively short lifetimes, in brain as in other organs. For example, a recent study shows that synaptic NMDA receptors are degraded within 5 days in brains of freely behaving mice. Such turnover rates of synaptic receptors and their associated signaling and structural proteins would inevitably lead to deleterious drifts in synaptic efficacy, thereby destabilizing the stored memory traces, in the absence of restorative mechanisms. Thus, the observed metabolic turnovers of synaptic proteins raise a fundamental question: how can the structural changes at synapses, as envisioned by the Hebb's biochemical cascade, sustain memories over long periods of time in spite of such dynamic turnover?

Synaptic re-entry reinforcement (SRR) is a candidate cellular process for consolidating and storing memory traces. To address this question, the third-generation knockout technique has been developed to allow manipulation of gene function in an inducible, reversible, and region specific manner (Fig. 53-6). This technique allows one to genetically engineer a strain of mice in which the NMDA receptors can be selectively switched on and off in the CA1 region during various stages of the memory process in freely behaving mice. This has been employed to demonstrate that NMDAR are required not only during learning, but also during the initial post-training week(s). This reveals that memory consolidation is a continuous process and dependent on multiple rounds of NMDAR reactivations because those synaptic changes (or synaptic memory traces) created by initial learning can be repeatedly reinforced (Fig. 53-7A). This molecular reactivation process, known as *synaptic re-entry reinforcement (SRR)*, may form the crucial mechanism underlying consolidation of recently acquired memories [35].

Computational analysis has been further illustrated by repeatedly reinforcing synaptic traces via SRR mechanism within the relevant hippocampal circuits; coherent reactivations of hippocampal neurons may also act as a '*coincidence-regenerator*' to provide coordinated input that drives the collective reactivations of cortical neurons previously corresponding to different sensory modules (Fig. 53-7B). Such collective reactivations of cortical neurons consequently permit the SRR-process-based synaptic consolidation of cortical memories. Indeed, experiments demonstrate that activation of the hippocampus triggers the re-entrance of activity specifically into the deep layer of the entorhinal cortex [36]. Such re-entrance activations would result in the progressive strengthening of cortical memory traces through reactivation of cortical NMDA receptors. Once these cortical traces are fully consolidated and stabilized via cortical SRR into remote memory status, the hippocampus itself becomes dispensable for the retrieval of these cortically stored remote memories. In the absence of SRR, hippocampal memory traces could not remain stable in face of synaptic turnovers. As a result, it would be difficult for the hippocampus to maintain its ability to provide coherent output to drive the cortical neurons to reactivate together, thereby preventing the consolidation and binding of cortical memories spanning multiple sensory modules.

Consistent with the requirement of NMDA-receptor-reactivation for memory consolidation, it has been found that memory consolidation is also dependent on reactivations of CaMKII, the key intracellular mediator for the NMDA receptor activation, during the first post-learning week (see CaMKII in Chs. 15, 23). Using *inducible protein knockout technique* (Fig. 53-8), it was shown that mice with either the normal or higher level of CaMKII activity can learn and consolidate fear memories equally well. However, switching back-and-forth between two different levels of CaMKII activity within the first post-learning week severely disrupts synaptic consolidation of 1-month long-term fear memories. In other words, memory consolidation needs to occur at the same level of CaMKII activity as the one used during learning. Interestingly, the similar alterations in the CaMKII expression level during the second, third and fourth post-training weeks were no longer capable of disrupting memory consolidation. This shows that memory consolidation has a critical time-period during which precise reactivation of NMDA-receptor-mediated cascades is required. Additional experiments suggest that the SRR process appears not to be restricted to the consolidation of hippocampal-dependent memory, but is also required for the consolidation of hippocampal-independent memory. Therefore, synaptic re-entry reinforcement may present a common off-line mechanism for memory consolidation at both synaptic and systems levels in the brain.

Mechanistically speaking, SRR-mediated off-line strengthening of synaptic connections requires only pair-wise reactivation between two activated neurons. Thus, this synaptic reactivation feature is different from the reactivation of memory at the cognitive level. Although the SRR

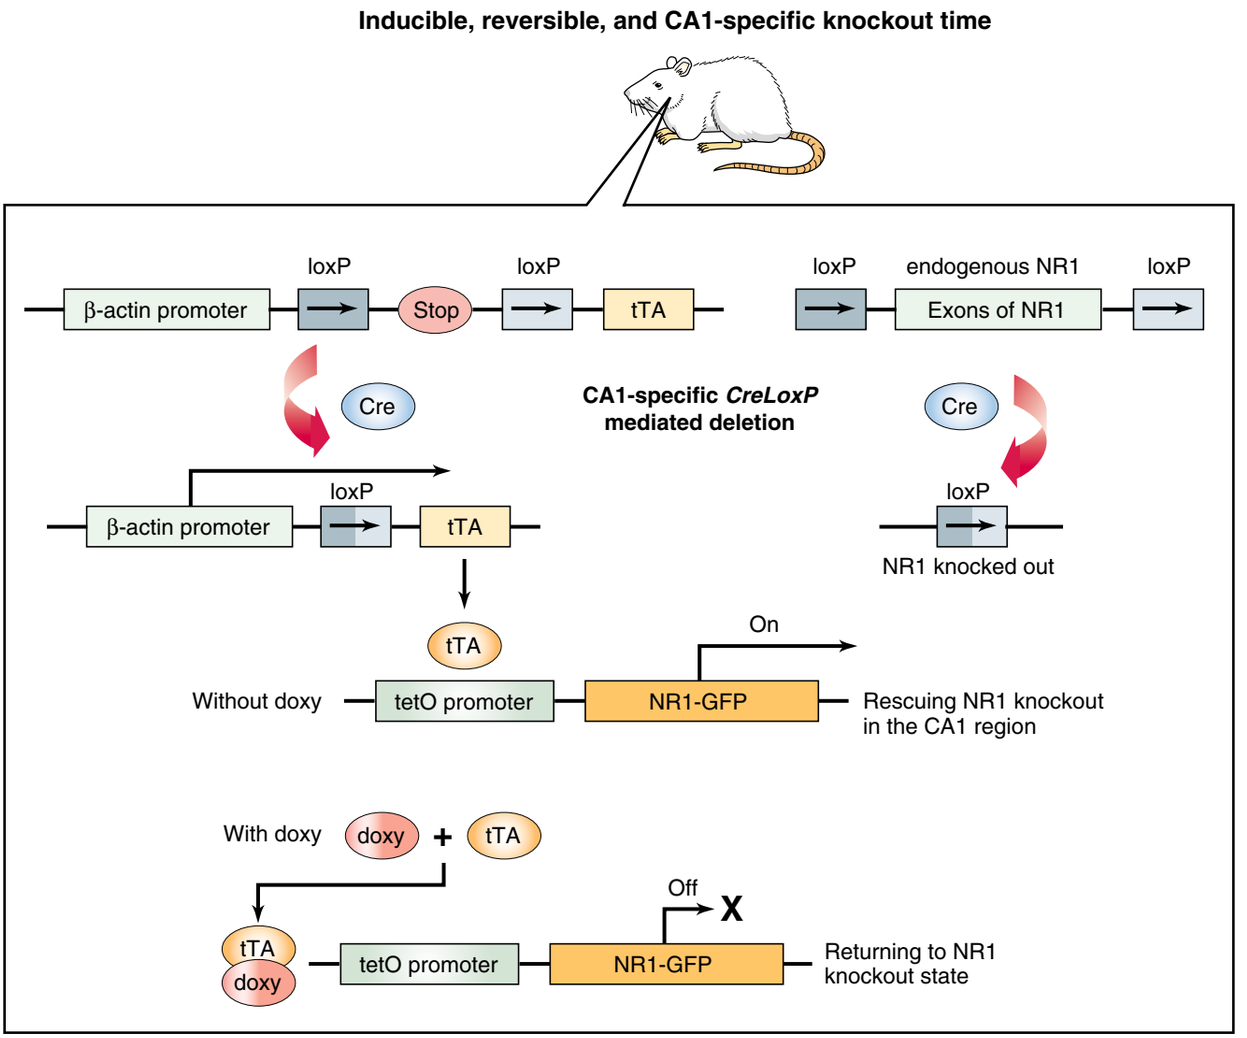

FIGURE 53-6 The strategy for making the inducible, reversible, and region-specific gene knockout. Through a series of genetic engineering techniques, any gene can be knocked out in inducible, reversible and region-specific manner. This third-generation knockout method employs both the tetracycline-based transactivator (tTA) gene expression system and the Cre/loxP recombination system. In the inducible knockout mice, expression of the tTA transgene in the CA1 neurons is achieved by the Cre/loxP-mediated deletion of the 'STOP' sequence, which then allows the expression of the NR1-green fluorescence protein (*NR1-GFP*) fusion protein in these neurons, thereby rescuing the knockout of floxed endogenous NR1 gene in CA1. Feeding the mice with doxy, a tetracycline analog compound pulling tTA off the tetO promoter, will switch off NR1-GFP transgene expression, and return the CA1 cells to the NMDA receptor knockout state. On the other hand, the withdrawal of doxy from their food or drinking water will restore NR1-GFP expression, thereby reversing NMDA receptor function (modified from Shimizu, E. *et al. Science* 290: 1170–1174, 2000).

process was initially proposed to describe the consolidation of long-term memory traces, most recent evidence shows that a similar process also seems to be required for long-term storage of remote memories in the brain [37]. Furthermore, the time necessary for detrimental manifestation of synaptic drift, in the absence of the NMDA receptors, has been estimated to be about one month. This suggests that the brain may use the SRR process to counteract cumulative synaptic drift caused by metabolic turnovers of synaptic proteins, and thereby to dynamically preserve brain stability.

When and how does the SRR process occur — a role for sleep? Currently, it is not clear what triggers the SRR process and when SRR usually takes place. We can only entertain a couple of ideas at this stage. One conceivable triggering mechanism could be that conscious recall can initiate the SRR process. This is consistent with common experience, where the more frequently a particular event is recalled, the better and longer it will be remembered. Another triggering mechanism could be the subconscious reactivation of the brain network. This could most likely be achieved during sleep, because various sleep states are

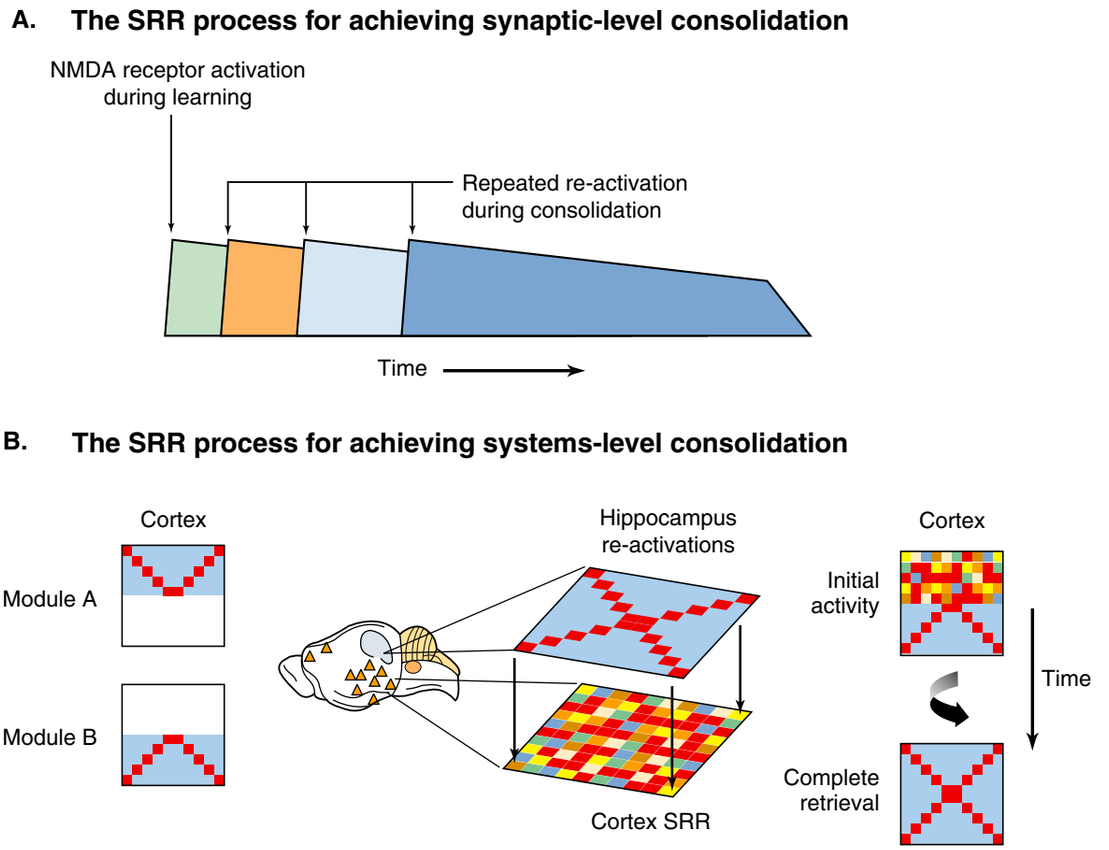

FIGURE 53-7 The synaptic re-entry reinforcement model for the consolidation of long-term memory. (**A**) Re-activations of the NMDA receptor during the consolidation period trigger the repeated reinforcements of hippocampal synaptic modifications initiated by original learning. The molecular reactivations strengthen the synaptic connections between neurons involved in the learning. (**B**) Re-activations of the hippocampus also serve as the coincidence-regenerator for co-activating the cortical neurons belonging to different sensory modules, resulting in the SRR-based strengthening of cortical synaptic efficacies, primarily between cortical modules *A* and *B*, as well as within each module. Once fully consolidated, the cortically stored memories across all modules can be retrieved by partial cues.

known to produce high levels of synchronized neuronal activity across many brain regions. For instance, recent studies show that learning-induced correlations in the firing of hippocampal place cells reappear during sleep [38]. Such a coordinated reactivation of these neurons suggests the existence of a natural condition in which NMDA receptors can be reactivated, thus reinforcing the synaptic connections between them. It is important to point out that the cellular re-activation producing SRR during subconscious consolidation is not the same as the conscious re-activation of memory traces — in the sense that it does not require sequential activation of coding assemblies at the circuitry level. In theory, consolidating synapses only require pair-wise coreactivation between the connected neurons to maintain their existing synaptic efficacy.

Clearance of outdated memory traces in the hippocampus — a role for adult neurogenesis? What happens to memory traces left behind in the hippocampus after long-term memories have been stored in the cortex? It has been estimated that the hippocampus may have limited storage capacity. For instance, there are only roughly 200,000–300,000 CA3 and 300,000–400,000 CA1 pyramidal cells and 700,000–1,000,000 granule cells in rodent hippocampus. It is conceivable that continued accumulation of outdated memory traces in the hippocampus could overload the system over time, eventually disabling the ability of hippocampal functioning in memory consolidation. So how might the hippocampus deal with this overloading problem?

A possible answer comes unexpectedly from experiments originally aimed at investigating the role of the presenilin-1 gene, whose mutations lead to familial early-onset Alzheimer's disease. This type of Alzheimer's disease is known to be the most aggressive form that can cause severe memory loss and dementia in patients as early as in their 30s. Recent studies have shown that forebrain-specific

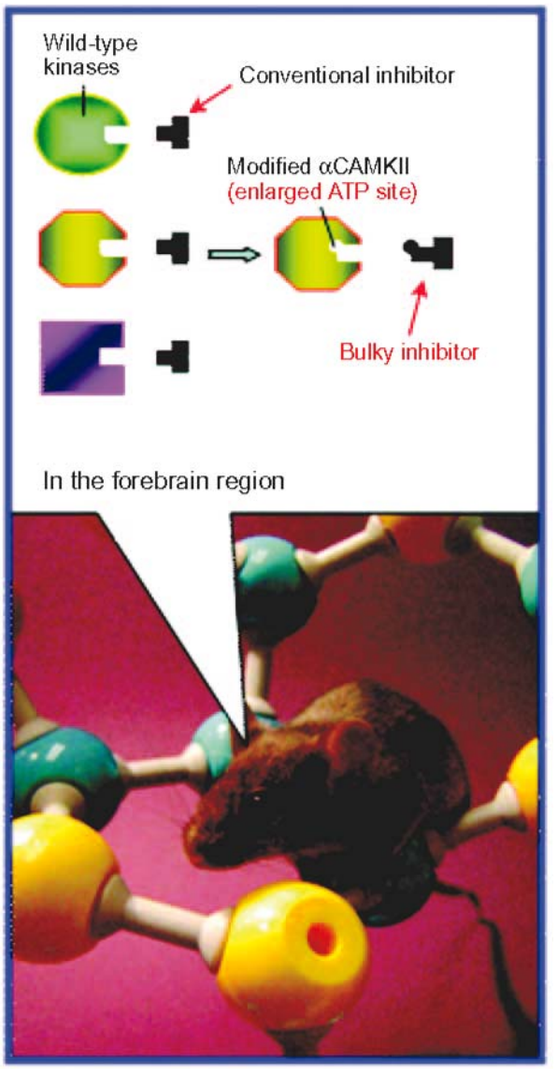

FIGURE 53-8 Inducible protein knockout strategy. This fourth-generation genetic knockout technique is based on the 'bump-and-hole' strategy (Wang, H. *et al. Proc. Natl Acad. Sci. USA*, 100: 4287–4292, 2003). The ATP-binding pocket of a protein kinase (e.g. aCaMKII) is enlarged such that a bulky inhibitor can be rationally designed to fit only the enlarged pocket and not the unmodified pocket of all other wild-type kinases. This protein knockout method offers superior temporal resolution that allows the knockout of protein function *in vivo* within several minutes, in comparison to the relatively slow inducible gene knockout, which intrinsically relies on the complete turnovers of the existing protein before phenotypic manifestation.

knockout of the presenilin-1 gene results in a pronounced deficiency in enrichment-induced adult neurogenesis in the dentate gyrus [39]. Deficient neurogenesis in the dentate gyrus is associated with impaired clearance of outdated memory traces from the hippocampus. This suggests that adult neurogenesis in the dentate gyrus plays a role in periodic clearance of outdated hippocampal memory traces after cortical memory consolidation, thereby ensuring that the hippocampus is continuously able to process new memories.

Adult neurogenesis refers to the phenomenon of continued proliferation of some progenitor cells in the olfactory bulb and the dentate gyrus of the hippocampus into neurons throughout adulthood. This capability is one of the mysteries of neuroscience, since nearly all neurons in the brain stop dividing shortly after birth. But some cells in these two regions retain this property even in adulthood. Moreover, although this phenomenon is preserved across many mammalian species, ranging from rodents to monkeys to humans, nobody knows the actual function of adult neurogenesis.

The proposed '*neurogenesis-memory clearance hypothesis*' is attractive because addition and removal of adult-born neurons in local network architecture could gradually destabilize the stored memory traces. Also, adult-generated neurons within the dentate gyrus, the upstream location in the hippocampus, potentially can amplify the 'destabilization' effects. Coincidently, these newborn neurons are short-lived, typically with a life-span of three weeks in rodents [40], which seems to correlate well with the duration of hippocampal dependence of declarative memories.

FUTURE DIRECTIONS AND CHALLENGES

As we can see from the above, over the past century scientists have made tremendous progress in understanding the molecular and cellular bases of learning and memory. Through a series of genetically engineered mice, some of the central molecular components of learning and memory have been assembled. Now we know that the NMDA receptor is a molecule with major responsibility for memory acquisition, consolidation, and storage. This memory switch is activated during learning and then needs to be reactivated for consolidating newly formed memories as well as for chronic storage of remote memories. However, many fundamental questions still remain. What is a memory trace? What is the organizing principle that the brain uses to achieve its real-time encoding of memory? How is memory retrieved? Can the stored memory be selectively erased through experimental manipulation? With new and exciting technologies emerging at the horizon, it is safe to predict that many new discoveries will be made in the coming years and decades.

From the history of the advance of sciences, it is often the case that our human quest to understand nature unexpectedly creates knowledge and technology that will have profound impact, and potentially unpredictable consequences for society and civilization. Neuroscience is no exception to this rule. For example, the genetic experiments, which were designed to test the predictions of Hebb's rule, have resulted in the creation of smart '*Doogie*' mice. While there is clearly a giant, perhaps even an impossible, gap in leaping from mice to human beings, it has already triggered widespread discussion of many issues: 'Where do all those revolutionary genetic technologies lead us?'

'Should people use genetic manipulations in human embryos to correct gene mutations which would otherwise lead to Alzheimer's disease or learning disability?' 'If so, is it ethical to use the same procedure to improve cognitive function in persons who are healthy but with low intellectual ability?' 'How should society define *normal*?' 'Where should we draw a line between moral compassion and unethical obsession?'

Although some may think these questions are premature; unfortunately, avoiding or ignoring these issues would not be a wise or lasting strategy. History has shown that scientists bear a particular burden and responsibility for directly engaging in public education and policy, because the scientific ignorance of citizens and policy-makers will not be in the long-term interest of either the scientific community or society in general.

The Neurochemistry of Schizophrenia

Joseph T. Coyle

CLINICAL ASPECTS OF SCHIZOPHRENIA 875
Schizophrenia is a severe, chronic, disabling mental disorder 875
Schizophrenia is characterized by three partially independent symptom clusters 875
Schizophrenia is a disorder of complex genetics 876
Current treatment of schizophrenia relies on atypical antipsychotic drugs 876

BRAIN IMAGING 878
Brain imaging studies provide unequivocal evidence that schizophrenia is a disease of brain 878
Functional imaging studies have consistently shown cortico–limbic abnormalities in schizophrenia 878

CELLULAR AND MOLECULAR STUDIES 880
The dopamine hypothesis has dominated schizophrenia research for over 40 years 880
Hypofunction of NMDA receptors may contribute to the endophenotype of schizophrenia 880
GABAergic neurons are also implicated in schizophrenia 882
The cholinergic system has also been implicated in schizophrenia 883
Some intracellular signal transduction molecules are reduced in schizophrenia 883
Proteins involved in the fundamental structure and function of neurons are decreased in schizophrenia 883
Glia may play a role in schizophrenia 884

CONCLUSION 884

CLINICAL ASPECTS OF SCHIZOPHRENIA

Schizophrenia is a severe, chronic disabling mental disorder. Schizophrenia affects approximately 1% of the population worldwide. Symptomatic onset occurs in late adolescence and early adulthood in males and somewhat later in females, who tend to be somewhat less severely affected. It is estimated to be the seventh most costly medical illness to society in terms of cost of care and loss of productivity, because less than 30% of affected individuals experience complete remission after its symptomatic onset at the beginning of their productive lives.

The conceptualization of schizophrenia as a specific disorder occurred at the turn of the last century. The German psychiatrist, Amil Kraepelin, identified a group of psychotic patients characterized by the onset of symptoms in early adulthood, impaired cognition and poor outcomes, which he labeled *dementia praecox*. The term *schizophrenia* was introduced a decade later by Eugen Bleuler, who characterized the splitting ('schizo') of affect (i.e. emotional tone) from cognition. He further identified four characteristic symptoms: autism, ambivalence, blunted affect and disturbances of volition. While these early clinicians readily accepted that schizophrenia was a brain disorder with heritable vulnerabilities, this biological conceptualization of the disorder was eclipsed by the rise of psychoanalysis in the 1930s, and the dominance for the next half century of its theoretical conceptualization that intra-psychic conflicts are the cause of psychiatric disorders. Thus, until recently, many clinicians viewed schizophrenia as a consequence of pathologic maternal child interactions and deviant family communication.

This chapter will review the compelling evidence that schizophrenia is a brain disorder with a high degree of heritability. It will draw upon four major research strategies that have transformed our understanding of this disorder: neuropsychopharmacology, brain imaging, genetics and postmortem studies of the brains of individuals affected with schizophrenia. Over the last decade, the convergence of findings from these different approaches is pointing to plausible, final common pathways accounting for the pathophysiology of schizophrenia.

Schizophrenia is characterized by three partially independent symptom clusters. These symptom clusters are designated: *positive symptoms, negative symptoms and cognitive impairments* [1]. The positive symptoms are the most dramatic and are manifestations of psychosis.

Basic Neurochemistry: Molecular, Cellular and Medical Aspects
0-12-088397-X

They include hallucinations, typically auditory in nature wherein the individual hears voices commenting on their thoughts or actions, and delusions, which often are of a paranoid nature. The patients feel that they are being persecuted and neutral life-events take on special meaning to support this belief. More bizarre delusional experiences are common, such as the feeling that their mind or body is being controlled by someone else or that thoughts are being inserted or withdrawn from their mind. Cognitive processes can become quite disorganized, resulting in loose associations with tangential thinking, illogical reasoning and emotional states inconsistent with thought content.

The positive symptoms are the most responsive to antipsychotic medications, such as chlorpromazine or haloperidol. Initially, these drugs were thought to be specific for schizophrenia. However, psychosis is not unique to schizophrenia, and frequently occurs in bipolar disorder and in severe major depressive disorder in which paranoid delusions and auditory hallucinations are not uncommon (see Ch. 55). Furthermore, in spite of early hopes based on the efficacy of antipsychotic drugs in treating the positive symptoms, few patients are restored to their previous level of function with the typical antipsychotic medications [2].

The more enduring and disabling components of the disorder that remain after effective treatment of the positive symptoms are the negative symptoms and cognitive impairments. The term 'negative' refers to a loss or deficit, and includes the blunting of affect, social incompetence and the loss of initiative. The cognitive impairments, which are associated with a modest reduction in IQ, disrupt problem-solving abilities, verbal declarative memory, delayed word recall and verbal fluency. While clearly disabling, the cognitive deficits do not become as severe as those associated with dementia or delirium. The degree of cognitive impairment correlates with the severity of negative symptoms. Neither correlates well with positive symptoms.

Retrospective and prospective studies of children who are at genetic high-risk for schizophrenia indicate that subtle abnormalities in cognitive function and attention, social oddness and motor clumsiness are often present years before the onset of psychosis [3]. These observations on the developmental aspects of schizophrenia, as well as the enduring nature of the negative symptoms and cognitive impairments over the lifetime of the schizophrenic patient, has led to the conceptualization of these symptoms as the *endophenotype* of schizophrenia — i.e. the core symptomatic features — with psychosis viewed as a secondary phenomenon. The variation in symptomatic features of schizophrenia across individuals, and the common nature of the disorder, strongly suggest that there will probably be multiple causes that result in the phenotype.

Schizophrenia is a disorder of complex genetics. Adoption, twin and family studies carried out over the last 40 years have provided compelling evidence for the heritability of schizophrenia [4]. Meta-analysis of the twin studies indicates a concordance rate of approximately 50% in identical twins if one twin is affected, which is 5-fold greater than the concordance rate in fraternal twins or siblings. The absence of complete concordance in identical twins points to additional epigenetic factors, which can transform genotype to phenotype. Perinatal insults such as second trimester viral infection and anoxia at birth figure prominently as environmental factors influencing the risk of schizophrenia. Findings from family studies support the role of complex genetics. The risk of developing schizophrenia in first-degree relatives of a proband is approximately 10%, which is 10-fold greater than the risk in the general population. In second-degree relatives the risk falls to 3%. Based upon a multigroup model, evidence supports substantial additive genetic effects, indicating that the heritable liability to develop schizophrenia is approximately 80%. The pattern of distribution of schizophrenic symptoms within affected families, with a rapid falling off of concordance from that in identical twins to first-degree relatives to second-degree relatives, is consistent with complex genetics in which many genes of small effect interact to contribute to the phenotype.

The family environment, such as communicational deviancy, is unlikely to contribute to risk, because adoption studies indicate that the risk for schizophrenia in offspring of schizophrenics (i.e. first degree relatives) is unchanged by being adopted into and raised in a family without schizophrenia. Nevertheless, adverse family environments characterized by high levels of expressed emotions negatively affect the course of schizophrenia for those who are already symptomatic.

Meta-analysis of the 20 genome-wide scans for linkage to schizophrenia has identified loci on 16 of the autosomes at which susceptibility genes are likely located[5]. Thus far, there is no evidence for autosomal dominant/recessive Mendelian-like genes that would account for schizophrenia. Potential risk genes will be discussed in the section **Cellular and Molecular Studies**.

Current treatment of schizophrenia relies on atypical antipsychotic drugs. The antipsychotic efficacy of chlorpromazine for the treatment of schizophrenia was discovered serendipitously by Laborit, Delay and Denicker in France in 1953, following the observation of the peculiar calming and poikilothermic effects of chlorpromazine in experimental animals[6]. In the early 1960s, placebo-controlled double-blind studies demonstrated that chlorpromazine was superior to placebo and the sedative phenobarbital in reducing psychosis in schizophrenic patients. A number of other effective antipsychotic drugs were subsequently discovered over the next 30 years on the basis of animal behavioral screens. These screens, we now know, selected for the drug's ability to block dopamine D2 receptors, as shown by their ability to prevent apomorphine-induced vomiting in dogs and amphetamine-induced hyperactivity in rodents (dopamine

receptors are discussed in detail in Ch. 12). In 1963 Arvid Carlsson was the first to propose that antipsychotic drugs exert their therapeutic effects by blocking dopamine receptors, based on the observations that these drugs cause Parkinsonian side-effects, which were known to be associated with loss of striatal dopamine, and that these drugs also increased the turnover of dopamine in the striatum[7] (see also Ch. 46).

Fifteen years later with the development of radio-ligand binding assays, the dopamine D2 receptor was identified by the specific, high-affinity binding of [^{3}H]haloperidol to brain membranes that displayed the requisite regional and pharmacologic characteristics for a dopamine receptor distinct from the dopamine receptor-associated adenylyl cyclase activity (D1 receptor, see Chs 12 and 21). Furthermore, a compelling correlation between the affinity of antipsychotic drugs, regardless of structural class, for the D2 receptor, and their clinical potency was demonstrated. Abuse of stimulants like amphetamine, which releases dopamine, was known to cause psychotic symptoms, especially paranoid delusions, similar to those observed in schizophrenia. Given the antipsychotic effects of these D2 blocking drugs in schizophrenia, the *dopamine hypothesis* was articulated, in which schizophrenia was proposed to be caused by excessive dopaminergic neurotransmission [9].

The typical antipsychotic drugs, which for 50 years have been the mainstay of treatment of schizophrenia, as well as of psychosis that occurs secondary to bipolar disorder and major depressive disorder, affect primarily the positive symptoms[10]. The behavioral symptoms, such as agitation or profound withdrawal, that accompany psychosis, respond to the antipsychotic drugs within a period of hours to days after the initiation of treatment. The cognitive aspects of psychosis, such as the delusions and hallucinations, however, tend to resolve more slowly. In fact, for many patients the hallucinations and delusions may persist but lose their emotional salience and intrusiveness. The positive symptoms tend to wax and wane over time, are exacerbated by stress, and generally become less prominent as the patient becomes older.

Among the commonly used typical antipsychotic drugs are chlorpromazine, haloperidol, fluphenazine, molindone and thioridazine [10]. In spite of their structural heterogeneity, there is no evidence that they differ in efficacy in the treatment of psychosis, although they do differ in their clinical potency and in their side-effect profiles. A major limitation of the typical antipsychotic drugs is the high risk of extrapyramidal side-effects due to a blockade of striatal dopamine D2 receptors. Manifestations of these include extrapyramidal or Parkinson's-disease-like syndrome, characterized by bradykinesia, tremor and rigidity. The associated mask-like face and 'zombie-like' gait are stigmatizing for patients (see also Ch. 46). Younger patients are particularly prone to the development of dystonic reactions, with cramping of tongue, neck or back muscles causing grotesque posturing. *Akathisia* causes a sense of inner tension that is relieved only by movement (i.e. pacing). As akathisia is quite uncomfortable, and it is a major cause of noncompliance in taking antipsychotics. Finally, with long-term use of the antipsychotics, a relatively irreversible neurologic syndrome can occur known as *tardive dyskinesia,* which is characterized by writhing movements of the tongue and choreiform movements of the extremities. These movements persist long after the discontinuation of the antipsychotic drugs.

Additional side-effects, reflecting the various degrees of muscarinic receptor antagonist actions of the antipsychotic drugs, result in dry mouth and constipation. α-Adrenergic receptor antagonism is associated with hypotension, tachycardia and impotence. Histamine H1 antagonism contributes to sedation. Needless to say, this panoply of side-effects has been associated with real problems in compliance with medication, resulting in discontinuation of therapy and recurrence of psychosis.

Because of the problems with compliance and stigma, neuropharmacologists have long sought antipsychotic drugs that are devoid of neurologic side-effects. The first such agent identified was clozapine[11]. It does not produce catalepsy in rodents, nor does it cause acute extrapyramidal side-effects or tardive dyskinesia in humans. Furthermore, low doses of clozapine have been used effectively in Parkinson's disease to treat psychotic symptoms induced by dopamine replacement therapy without exacerbating the underlying neurologic symptoms (Ch. 46). The clinical use of clozapine has been limited because of a 1% risk of a fatal hematologic complication known as *agranulocytosis.* To avoid this complication, patients receiving clozapine are subject to regular hematologic tests to identify those at risk. Clozapine has been found to be particularly effective in treating a subgroup of schizophrenic patients who respond poorly to typical antipsychotic drugs, in whom it reduces negative symptoms, improves cognition and is associated with a marked reduction in suicide (the lifetime risk for suicide in schizophrenia is 10%).

Deciphering the mechanism of action of clozapine has been difficult because clozapine and its metabolites interact with several neurotransmitter receptors aside from the D2 receptor, including the dopamine D4 receptor that is predominantly expressed in cortico–limbic regions, muscarinic receptors, α-adrenergic receptors, histamine receptors and the serotonin 5-HT_{2A} receptor (see also Chs 11–14). Since blockade of the 5-HT_{2A} receptor appears to mitigate against extrapyramidal symptoms resulting from D2 receptor blockade, a number of effective antipsychotic drugs have been developed which have dual D2 and 5-HT_{2A} antagonism; these include risperidone, olanzapine, quetiapine and ziprasidone. Since these newer agents have a lower propensity for causing extrapyramidal symptoms, they have been designated 'atypical antipsychotic drugs'. Because of their low risk for neurologic side-effects and their possibly greater efficacy than typical antipsychotic drugs, the second generation of atypical antipsychotic drugs have largely replaced the typical antipsychotic drugs in the management of schizophrenia.

Nevertheless, some atypical antipsychotic drugs, such as clozapine and olanzapine, have been linked to substantial weight gain, hyperlipidemia and type II diabetes, a new range of medically serious side-effects.

Extrapyramidal side-effects generally appear with blockade of dopamine D2 receptors in excess of 80%, whereas clinical efficacy in treating psychosis is associated with 60–70% D2 receptor blockade [12]. Recently, a partial agonist for the D2 receptor known as aripiprazole has been developed, which results in approximately 70% antagonism/30% agonism at the D2 receptor. It is an effective antipsychotic, has low risk for extrapyramidal symptoms, and does not cause elevated levels of prolactin as do the full antagonists at D2 receptors.

BRAIN IMAGING

Brain imaging studies provide unequivocal evidence that schizophrenia is a disease of brain. Brain imaging exploits three different strategies:

- Morphometric analysis utilizing computer assisted tomography (CAT) or magnetic resonance imaging (MRI) to reveal brain structure;
- Functional brain imaging, which monitors blood flow or glucose utilization through Positron Emission Tomography (PET) or functional (f) MRI;
- Measurement of brain neurochemical features by means of PET ligand binding studies or MRI spectroscopy (MRS), which can quantify chemicals of high concentration in the brain.

These methodologies are discussed in Chapter 58.

The first report of cortical volume loss in schizophrenia must be credited to Alois Alzheimer, who is most noteworthy for his clinical and neuropathologic description of the primary dementia that bears his name (Ch. 47). However, the unequivocal proof of his initial observations awaited the application of CAT scanning and quantitative morphometric MRI nearly 100 years later. Initial findings to support this inference came from CAT scans documenting an increase in the size of the lateral ventricles in schizophrenia. MRI studies that exploit sophisticated statistical analyses demonstrate unequivocally reduced volume of the cerebral cortex that is unevenly distributed and affects predominantly the frontal cortex and temporal lobe [13]. Segmentation studies indicate that these effects are borne predominantly by the gray matter, although some reductions in white matter volume have been demonstrated. Magnetic tensor imaging studies also indicate disruption of axon terminals in the cerebral cortex in schizophrenia.

The reduction in cortical volume observed in schizophrenia is substantially less than that found in the adult onset primary dementias such as Alzheimer's disease and Huntington's disease. A subject of controversy has been whether the reduction in cortical volume in schizophrenia is the result of developmental cortical hypoplasia or of a progressive cortical atrophic process after development. Studies of patients in the earliest stages of schizophrenia do indicate cortical volume reduction as well as functional abnormalities. Nevertheless, prospective studies have revealed increases in ventricular volume, progressive loss in cortical volume and progressive impairments in cortical function in a substantial portion of, but not all, subjects with schizophrenia [14]. Notably, the degree of cortical volume reduction correlates with the severity of cognitive impairments and negative symptoms in patients suffering from chronic schizophrenia.

Magnetic resonance spectroscopy has provided compelling evidence of significant persistent neurochemical abnormalities in the brains of individuals with schizophrenia. *N*-acetyl-aspartate (NAA), an amino acid of poorly understood function, is concentrated in neurons, including their somata, axons and dendrites, and appears to be a marker of neuronal functional status. A number of studies have demonstrated small but highly significant reductions in the levels of NAA in the prefrontal cortex, temporal lobe and hippocampal formation in schizophrenia. Levels of NAA in prefrontal cortex correlate negatively with symptom severity [15]. Furthermore, NAA deficits in the hippocampal formation and in the dorsolateral prefrontal cortex correlate with working memory impairments. In contrast, the level of glutamine, a precursor to the neurotransmitter glutamate, has been reported to be elevated in the anterior cingulate cortex and in the thalamus in never-treated patients with schizophrenia. ^{31}Phosphorus MRS studies have consistently shown membrane phospholipid abnormalities in individuals with schizophrenia [16]. Thus, glycerophospho-ethanolamine has been found to be decreased in the anterior cingulate, prefrontal cortex and thalamus in schizophrenia. There have been consistent reports of a decrease in phosphomonoester and an increase in phosphodiester in prefrontal cortex, These membrane lipids are discussed in Chapters 2 and 3.

Functional imaging studies have consistently shown cortico–limbic abnormalities in schizophrenia. Two non-invasive brain imaging techniques have been used to understand neural function in schizophrenia: surface electroencephalographic recordings, such as the event-related potentials (ERP); and brain hemodynamic activity, as measured by ^{15}O regional cerebral blood flow by positron emission tomography (PET) or blood oxygen level desaturation (BOLD) measured with fMRI (Ch. 58).

Electroencephalography allows real-time measurement of neural activity with millisecond temporal resolution. When coupled with the repeated presentation of a stimulus, the electroencephalograms can be averaged to produce an event-related potential (ERP), whose components develop and resolve within tens or hundreds of milliseconds. These potentials are designated by the millisecond lag between presentation of the stimulus and the appearance of the ERP, with the P50 (i.e. potential at 50 ms after

the stimulus) and P300 being the subject of most study in schizophrenia. The P300 ERP is smaller in amplitude and longer in latency in patients with schizophrenia as compared with controls [17]. The latency is increased with the duration of disease, although the P300 amplitude is unaffected by the severity of symptoms or antipsychotic medications. The P50 is a measure of sensory gating. The subjects receive two brief auditory stimuli separated by 400 ms. In normal subjects, a negative wave at 50 ms after the second stimulus is suppressed, whereas this is not the case in subjects with schizophrenia. An allelic variant in the promoter region of the α7 nicotinic receptor gene (CHRNA7), which has been linked to schizophrenia, is associated with abnormal P50 potential [18]. Notably, the atypical antipsychotic, clozapine, corrects this abnormality in schizophrenic patients, whereas other typical and atypical antipsychotic drugs do not. In a related task, *pre-pulse inhibition* (PPI), there is a warning auditory stimulus followed by a loud noise, causing a startle response. After a few experiences, normal subjects recognize the low volume warning stimulus and suppress the startle response, whereas schizophrenics fail to suppress the startle response.

Early functional imaging studies performed in subjects at rest suggested that blood flow was reduced somewhat in the frontal cortex in patients with schizophrenia. However, when subjects with schizophrenia are compared with normal subjects while performing cognitive tasks that require the engagement of the frontal cortex, such as the Wisconsin Card Sort Task, robust differences between controls and the patients are observed [19]. Similarly, when patients with schizophrenia are compared with controls using a difficult memory-recall task, patients perform more poorly than the controls and also exhibit little increase in blood flow to the hippocampus [20]. Measurement of the absolute blood flow to the hippocampus indicated a significantly elevated blood flow at rest in the schizophrenic subjects, suggesting that the failure to activate reflected a 'ceiling effect'. Functional imaging during the performance of cognitive tasks, such as word recognition, demonstrates regions of reduced blood-flow (such as the dorsolateral prefrontal cortex and paralimbic regions) in schizophrenic subjects as compared with controls, but also areas of increased blood flow (such as the anterior prefrontal cortices) in comparison with controls, indicating that schizophrenic subjects engage alternative neuronal systems in their attempts to perform such tasks.

One of the most prominent positive symptoms in schizophrenia is the auditory hallucinations that are perceived as distinct voices emanating from outside the individual. Regional cerebral-blood-flow studies in patients experiencing auditory hallucinations reveal activation of the associational auditory cortex during the episodes of hallucinations, but not in their absence. One theory holds that auditory hallucinations occur as a consequence of the inability of individuals with schizophrenia to monitor effectively their inner speech. fMRI studies suggest that this monitoring function requires activation of the temporal, parietal and parahippocampal cortices. Schizophrenic subjects exhibit much lower activation of these regions when generating inner speech.

PET studies are helpful in measuring trace markers, such as receptors and transporters in the brains of living subjects. Because antipsychotic drugs all block dopamine D2 receptors, the status of forebrain dopaminergic systems has been of particular interest with regard to schizophrenia research. Quantitating dopamine transporters (DAT), a marker thought to be an index of dopaminergic terminal density, with [^{123} I]β-CIT has revealed no apparent difference in DAT density in schizophrenic subjects as compared with controls. Most evidence indicates no difference in the density of D2 receptors in the striatum in schizophrenic subjects as compared with controls in PET scanning studies. Investigators have exploited the PET ligand [^{11}C]raclopride, which has high specificity but low affinity for the D2 receptor, to monitor endogenous dopamine release through its displacement of the ligand from the D2 receptor [21]. Challenge with D-amphetamine, which releases endogenous dopamine, causes a greater displacement of [^{11}C]raclopride in schizophrenic subjects than controls. Consistent with this finding, several studies using [^{18}F] or [^{11}C]DOPA have documented an increased incorporation of the dopamine precursor in the striatum in schizophrenic subjects as compared with controls, suggesting an increased turnover of dopamine, indicating increased dopamine release in schizophrenic subjects. Hypofunction of NMDA subtype of glutamate receptors has also been hypothesized as a core feature of schizophrenia (see NMDA receptors in Ch. 15). Studies of striatal D2 receptor occupancy with [11C]raclopride show that normal subjects receiving the NMDA receptor antagonist ketamine exhibit a more robust release of dopamine than subjects naive to ketamine, replicating the findings from schizophrenic subjects.

A modification of the dopamine hypothesis proposes that dopaminergic neurotransmission is impaired in the prefrontal cortex, although elevated in subcortical regions [22]. Studies with ligands for the dopamine D1 receptor have revealed an increase in the density of these receptors in the frontal subcortical region, which correlates with the severity of negative symptoms. This finding comports with the modified dopamine hypothesis that dopaminergic function is reduced in the frontal cortex, which would provoke D1 upregulation in subcortical regions.

In summary, brain imaging studies have provided compelling evidence of structural, neurochemical and functional abnormalities in the cerebral cortex, limbic system and thalamus in patients suffering from schizophrenia. The structural abnormalities, primarily loss of gray matter in discrete cortical regions and in the thalamus, correlate with the impairments in the cognitive functions associated with these regions. Finally, these cognitive impairments correlate with regionally specific abnormalities in neural processing. These findings provide a solid

foundation for inferring neurochemical abnormalities in the brains of individuals with schizophrenia.

CELLULAR AND MOLECULAR STUDIES

The dopamine hypothesis has dominated schizophrenia research for over 40 years. Given the current evidence that schizophrenia is a highly heritable disorder with complex genetics involving multiple genes of small or modest effects interacting to produce the phenotype, it is now clear that dysfunction of a single neural system will be unlikely to account for the pathophysiology of the disorder. Rather, the emerging evidence from postmortem studies, in the context of the accumulating genetic findings, is that there are a number of neural systems that can be affected in schizophrenia but that none appear to be affected in all cases. Postmortem tissue studies have become much more comprehensive with the introduction of DNA-micro-array analyses capable of measuring up to 30,000 transcripts. Cellular specificity has also been markedly improved, with the use of laser-capture single-cell analysis as well as *in situ* hybridization. The extensive array of antibodies against specific proteins augurs well for proteomic strategies to measure proteins, as well as their posttranslational modifications such as their phosphorylation state. Finally, informatics methodology identifies interrelationships among proteins that reveal families of proteins involved in common functional or structural roles. Freeware, such as Expression Analysis Systemic Explorer (EASE), available through the NIH Database for Annotation, Visualization and Integrated Discovery (DAVID), facilitates such analyses. This strategy assists in linking seemingly isolated abnormalities in gene or protein expression that may be involved in related functions such as myelinization or mitochondrial oxidative metabolism [23].

Despite the ability to measure dopamine, its metabolite homovanillic acid (HVA) and other presynaptic markers for dopaminergic neurons in the striatum and cortico–limbic regions for 40 years, most postmortem findings of dopaminergic markers in schizophrenia have been inconsistent and largely negative. The only reproducible finding is that antipsychotic drugs increase cerebrospinal fluid (CSF) and plasma HVA, consistent with preclinical studies demonstrating that D2 blockade causes an increase in dopamine turnover.

The dopamine receptors, so designated by the sequence of their discovery, consist of DA1, which is positively coupled to adenylyl cyclase, and DA2, which is negatively coupled to adenylyl cyclase[8] (Ch. 12). Cloning strategies yielded three additional DA receptors: D3 and D4, which are D2-like, and D5, which is D1-like. Given the remarkable correlation of D2 receptor affinity and clinical potency of antipsychotic drugs, perhaps it is surprising to note that over a generation of studies have revealed no consistent evidence of alterations in D2 receptor as measured by ligand binding, receptor autoradiography and *in situ* hybridization in brains from schizophrenic patients, who were untreated or not recently treated with antipsychotic drugs (to avoid the confounding effects of D2 antagonists on D2 expression). D3 receptors are concentrated in the ventral striatum and their expression is regulated by brain-derived neurotrophic factor (BDNF). Studies to determine alterations of expression of D3 receptors in schizophrenia have been largely inconclusive. However, results of studies analyzing the serine-9-glycine polymorphism of the D3 receptor suggest that the glycine-9 allele may confer susceptibility to tardive dyskinesia.

The D4 receptor differs from D2 and D3 receptors by exhibiting a disproportionately high affinity for the atypical antipsychotic clozapine, as well as for some other antipsychotic drugs. The D4 receptor is relatively enriched in cortico–limbic regions including the hippocampus in humans, but is expressed at very low levels in the striatum. While receptor autoradiographic techniques that measured indirectly D4 receptor density suggested an increase in the striatum in schizophrenia, PCR and *in situ* hybridization studies have not revealed consistent alterations in D4 receptors in striatum or in most areas of cortex in schizophrenia. The D1 receptors, for which antipsychotic drugs have a highly variable affinity, are highly expressed in frontal cortex and they play an important role in cognitive functions.

Since the ventral-tegmental-area (VTA) cortical-dopaminergic fibers express negligible amounts of dopamine transporter (DAT), the inactivation of extracellular dopamine occurs primarily through catabolism by catechol-*O*-methyltransferase (COMT) (see Ch. 12). In this regard, a common allelic variant of COMT, valine-158-methionine, is associated with substantial differences in COMT activity, as the valine allele is much more temperature sensitive, resulting in lower enzymatic activity than the methionine allele [24]. Cognitive testing in normal subjects matched for IQ demonstrates that those with the least active COMT genotype (valine–valine), which would enhance cortical dopaminergic neurotransmission, perform best on a task that requires prefrontal cortical function as compared with those with the methionine allele. Schizophrenics with higher activity genotypes for COMT exhibit greater impairments in cognitive functioning, suggesting that this may be a risk gene for the disorder. These genotype differences have been confirmed in postmortem studies.

Hypofunction of NMDA receptors may contribute to the endophenotype of schizophrenia. The hypothesis that hypofunction of a subpopulation of NMDA receptors contributes to the pathophysiology of schizophrenia has gained considerable support over the last decade (**see Fig. 54-1**). The dissociative anesthetics including phencyclidine (PCP) and ketamine when introduced clinically 40 years ago were noted to produce a syndrome that was difficult to distinguish from schizophrenia. These agents act as non-competitive open-channel blockers of the NMDA receptor.

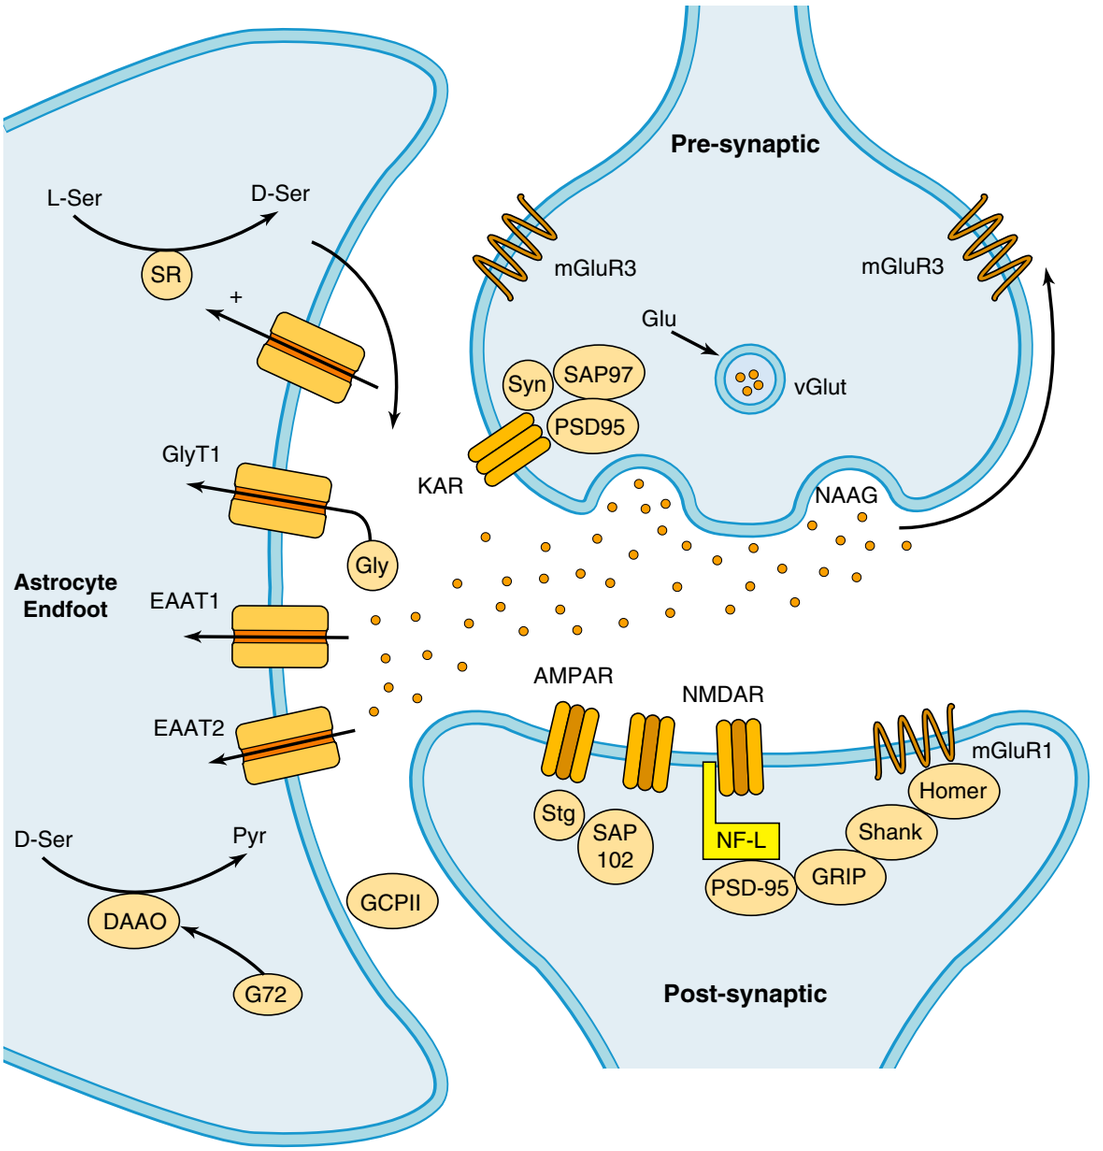

FIGURE 54-1 Schematic relationship of the tripartite glutamatergic synapse. This synapse consists of a presynaptic glutamatergic bouton, the postsynaptic spine and the astrocytic endfoot. Presynaptic mGluR3 receptors inhibit the release of glutamate and are selectively activated by *N*-acetyl aspartyl glutamate (*NAAG*). Presynaptic kainic acid receptors (*KAR*) regulate glutamate release. Postsynaptic AMPA receptors (*AMPAR*) and NMDA receptors (*NMDAR*) generate the excitatory postsynaptic currents when activated by glutamate. The astrocyte expresses two types of Na^+-dependent glutamate transporters (*EAAT1* and *EAAT 2*), a glycine transporter (*GlyT1*), which maintains subsaturating concentrations of glycine at the synaptic NMDA receptor, Serine Racemase (*SR*), which synthesizes D-serine (*ser*), Glutamate Carboxypeptidase II (*GCPII*), which hydolyzes NAAG, and D-Amino-Acid Oxidase (*DAAO*), which degrades D-serine. The receptors are associated with a variety of structural proteins that anchor them in the synapse including *PSD-95* (Post-Synaptic Density, kDa 95), Stargazin (*STG*), *SAP-97* and *SAP -102* (Synapse Associated Protein, kDa 97 and 102), Syntenin (*SYN*), Glutamate Receptor Interacting Protein (*GRIP*) and Neurofilament Light protein (*NF-L*). Adapted from Coyle *et al.* [26] and Meador-Woodruff *et al.* [29].

Controlled clinical investigations with careful titration of doses in normal subjects demonstrate that ketamine produces negative symptoms, such as withdrawal and the subtle cognitive impairments associated with schizophrenia [25]. As is the case for schizophrenia, these symptoms occur without clouding of consciousness or frank dementia. Positive symptoms with auditory hallucinations and fully formed delusions do not typically occur with acute administration of ketamine to normal subjects, but do occur with chronic abuse. Furthermore, low-dose ketamine produces several physiologic abnormalities associated with schizophrenia, such as abnormal eye-tracking, enhanced subcortical-dopamine-release, impaired prepulse inhibition, hypofrontality and abnormal event-related potentials.

In vivo dialysis studies indicate that acute blockade of the NMDA receptor in experimental animals results in a disinhibition of forebrain dopamine-release, suggesting that dopamine-mediated psychosis could be secondary to a more primary defect in cortical glutamatergic signaling.

Postmortem studies combined with genetic findings have generated compelling evidence that disruption in the modulation of subtypes of NMDA receptors contribute to psychopathology in schizophrenia [26]. Glutamate carboxy peptidase II (GCPII) degrades the neuropeptide *N*-acetyl-aspartyl-glutamate (NAAG), which is co-localized and released by glutamatergic neurons as well as other neuronal systems (cholinergic motor neurons, noradrenergic locus coeruleus neurons). NAAG is an agonist at the mGluR3 receptor, which reduces glutamate release, and a reversible glycine antagonist at hippocampal NMDA receptors (see Ch. 15). Postmortem studies with cohorts from three different brain banks have documented significant reductions in its enzyme activity, and in its mRNA levels in frontal and temporal cortex and in hippocampus. A translocation associated with schizophrenia affects a locus on chromosome 11q13 in close proximity to the gene encoding GCP II.

D-serine is a full agonist at the glycine modulatory site on the NMDA receptor and its levels are determined by the catabolic enzyme D-amino acid oxidase (DAAO) since the levels of the former are inversely correlated with the activity of the latter. A mutation in a protein designated *G72*, which results in robust activation of DAAO, has been described in two genetic studies of schizophrenia [27]. Single-nucleotide polymorphisms (SNPs) of DAAO have been associated with increased risk for schizophrenia. The levels of D-serine in plasma, which appears to come primarily from the CNS, are decreased in schizophrenics. Kynurenic acid is another endogenous antagonist of the glycine modulatory site on the NMDA receptor. The levels of kynurenic acid are significantly elevated in prefrontal cortex but not motor cortex in schizophrenic patients as compared with controls, which appears to be unrelated to antipsychotic drug exposure. Tryptophan-2,3-dioxygenase, an upstream enzyme in kynurenic acid synthesis, is also up-regulated in frontal cortex in schizophrenia [28]. Notably, double-blind placebo-controlled clinical trials of agents that directly or indirectly enhance NMDA receptor function at the glycine modulatory site show significantly reduced negative symptoms and enhanced cognitive function in patients with chronic schizophrenia.

NMDA receptors are anchored in the postsynaptic density (PSD95, 95 kDa), a complex with which over 80 proteins have been associated (see Ch. 15). Postmortem studies have examined the expression of the subunits of the NMDA receptors as well as components of the PSD [29]. In one study in the thalamus, the NR1 and NR2B subunits were decreased in schizophrenia and PSD95, SAP102 (Synapse Associated Protein kDa 102) and NF-L (Neurofilament-Light), components of the PSD, were also significantly reduced with the latter reduction also found in bipolar disorder. Similarly, other studies have shown significant reductions in the expression of SAP97 (Synapse Associated Protein, kDa 97), SAP102 and PSD95 in the prefrontal cortex in schizophrenia [30]. Decreased phosphorylation of NR1 at serine 97, which impairs NMDA receptor function, has been found in prefrontal cortex in two cohorts of schizophrenic subjects. That the postsynaptic density complex may be an important target for the pathophysiology of schizophrenia is reinforced by the highly significant association of SNPs for distobrevin and dysbinden, two proteins in the PSD complex, with the risk for schizophrenia. Notably, dysbinden expression is reduced in prefrontal cortex.

Nitric oxide (NO) synthesis in brain is, in part, driven by NMDA receptor activation through Ca^{2+}/calmodulin-dependent activation of NO-synthase [23]. Several studies suggest that NO interacting with NMDA receptor thiols causes inhibition of the receptor. In this regard, it is noteworthy that arginine, the substrate for NO-synthase, is elevated threefold, and the expression of endothelial and inducible NO-synthase are significantly elevated in the frontal cortex in schizophrenia. While these alterations would be expected to associate with oxidative stress, which promotes DNA damage and apoptosis, DNA fragmentation is found to be markedly reduced in prefrontal cortex in schizophrenic subjects as compared with both controls and bipolar subjects.

It is important to note that other components of the glutamatergic signaling system are also affected. For example, the glutamate transporters, Excitatory Acid Amino Acid Transporters 1 and 2 are elevated in the thalamus, which should further compromise glutamatergic neurotransmission [29] (see also Chs. 5 and 15). Consistent reductions in kainic acid receptor have been documented by ligand binding, *in situ* hybridization of subunits and DNA microarray studies in the prefrontal cortex and hippocampus [31]. SNPs for the mGluR3 receptor gene, which down-regulates glutamate release, have been linked to the risk for schizophrenia in three different studies, although the effects on its expression or function remain unclear at present.

Neuregulins are cell–cell signaling proteins that are ligands for the tyrosine kinase receptor of the Erb family [32]. At least three separate studies have associated allelic variants of neuregulin 1 and the risk for schizophrenia. Neuregulin has complex effects on glial differentiation, astrocyte function and synapse stabilization (Ch. 25). Postmortem studies have revealed reductions in neuregulin expression in cortex in schizophrenia. Mice homozygous for a null mutation of neuregulin or its ErbB4 receptor display hyperactivity that responds to clozapine and exhibit reduced numbers of NMDA receptors. Individually and in concert, these alterations would attenuate NMDA receptor function in schizophrenia.

GABAergic neurons are also implicated in schizophrenia. Early postmortem neurochemical studies suggested reductions in presynaptic markers for the GABAergic neurons, such as glutamatic acid decarboxalase (GAD) activity, in prefrontal cortex in schizophrenic subjects

[33]. However, the validity of these findings was undermined by the finding that agonal events, such as anoxia and a slow death, to which schizophrenics in particular are prone, can markedly reduce the activity of GAD independent of diagnosis. Later studies profitably took advantage of more discrete anatomical analyses of GABAergic interneurons in the frontal cortex and hippocampal formation. Disruption in the migration of these neurons in frontal cortex, a process occurring during the second trimester, has been noted in a subpopulation of patients with schizophrenia. Several studies have shown reduced expression of GAD67, and immunohistochemical studies have shown reduced GABA transporter (GAT) staining on the GABAergic 'cartridges' from Chandelier neurons synapsing on pyramidal cell dendrites. Consistent with this is the finding of decreased GAT mRNA in these intermediate level GABAergic interneurons in prefrontal cortex. In support of a discrete reduction in GABAergic innervation, increased ligand binding for the GABA-A receptor has also been noted in the same sector, consistent with denervation supersensitivity. GABAergic neurons that co-express calbindin appear to be more affected. Most of these findings have been confirmed in different laboratories using different sources for brain material (see Ch. 16 for further discussion of GABA transmission and transporters).

Whether the concerted reduction in the function and the number of a subpopulation of cortico–limbic GABAergic neurons is primary or secondary to some other process in schizophrenia remains to be determined, although thus far no putative candidate gene, with the exception of reelin, has been directly associated with GABAergic neurons [34]. Several groups have demonstrated a significant reduction in the levels of reelin in schizophrenia, a high-affinity peptide ligand for integrin receptors. The reelin–integrin system modulates early cortical development, especially neuronal migration. Notably, reelin is expressed by virtually all GABAergic neurons throughout life.

There are data that suggest a link between the hypothesized NMDA receptor hypofunction and the cortical GABAergic abnormalities. Electrophysiologic evidence suggests that limbic GABAergic interneurons may be differentially more sensitive to NMDA receptor antagonists than those located on pyramidal neurons. The expression of NMDA NR2 B-subunit is reduced on GAD67, expressing GABAergic interneurons in prefrontal cortex in schizophrenia. Furthermore, chronic treatment with the noncompetitive NMDA receptor antagonist dizocilpine (MK801) results in down-regulation in the expression of GAD67 and GAT and up-regulation of GABA-A receptors in rat cortex, mirroring the alterations in these parameters observed in the cortex in schizophrenic subjects.

The cholinergic system has also been implicated in schizophrenia. Cigarette smoking is remarkably prevalent among patients suffering from schizophrenia. Speculating that this may reflect a form of self-medication, Freedman and colleagues demonstrated that nicotine improved the sensory gating abnormalities that occurs in the P50 potential in schizophrenia [18]. Further studies also revealed similar P50 abnormalities in many first-degree relatives of schizophrenic probands, suggesting that the gating abnormality may be a heritable risk factor for schizophrenia. Subsequent linkage studies identified a locus on 15q13 that was associated with increased risk for schizophrenia. This region contains the gene for the α7 nicotinic receptor (CHRNA7), a subtype of nicotinic receptor with intriguing parallels to the NMDA receptor because of its calcium ion conductance, sensitivity to kynurenic acid inhibition and involvement in neuroplasticity (see also Ch.12). An allelic variant in the promoter region of CHRNA7 is associated with P50 abnormalities and results in reduced expression of α7 receptors. This allele has been documented in some patients with schizophrenia.

Some intracellular signal transduction molecules are reduced in schizophrenia. The release of neurotransmitters is regulated by a family of proteins that coordinate vesicular trafficking (see Ch. 9). Of these, the expression of complexin I and II appears to be decreased in prefrontal cortex and subfields of the hippocampal formation, and the ratio of complexin I to complexin II is elevated in the hippocampus [35]. SNAP-25 (Synaptosomal Associated Protein, kDa 25) has inconsistently been found to be down-regulated in both these regions. Synapsin expression is also reduced, but more robust decrements have been observed in bipolar disorder (Ch. 55).

Regulators of G-protein signaling (RGS) comprise a large family of modulators of synaptic neurotransmission. RGS4 has been implicated in schizophrenia in part because its gene is located at 1q21-22, a locus associated with high risk for the disorder [4]. The expression of RGS4 has been shown to be consistently down-regulated in prefrontal cortex in schizophrenia. The AKT (phosphatidylinositide 3-kinase, PI3K) and glycogen synthase kinase-3β (GSK3β) are downstream components of the neuregulin and wingless (Wnt) signaling pathways. GSK3β is an important kinase for tau phosphorylation in brain, thereby regulating tau function. GSK3β is itself regulated via the Wnt proteins and several other kinases that phosphorylate it on the ser-9 residue, which inhibits its kinase activity (see Fig. 55-1 and legend for further details). Association studies have implicated the neuregulin gene at 8p12 as a risk gene for schizophrenia. Postmortem studies have revealed decreased levels of AKT1 protein and reduced phosphorylation of serine 9 on GSK3β as well as decreased GSK3β expression in frontal cortex and hippocampus in schizophrenia [36].

Proteins involved in the fundamental structure and function of neurons are decreased in schizophrenia. Several postmortem studies have identified consistent reductions in the expression of mitochondrial associated genes involved in oxidative metabolism, such as cytochrome oxidase and cytochrome C reductase [23]. Reduced oxidative metabolism is consistent with evidence of increased brain lactate,

documented with MRS and postmortem measures, as well as decreased brain pH observed in postmortem studies in schizophrenia Morphologic studies have also shown a decreased number of mitochondria in both frontal cortex and striatum.

Robust decreases in the expression of the various proteasome subunits and ubiquitin-conjugating enzymes have been described in prefrontal cortex in schizophrenia. Neuronal ubiquitin and proteasomes play an important role in the assembly, function and plasticity of the synapse. Structural proteins including tubulin and α-spectrin also show decreased expression in prefrontal cortex.

Glia may play a role in schizophrenia. Disruption in myelin is a novel pathophysiologic mechanism recently identified in schizophrenia [37]. The results of imaging studies strongly suggest abnormalities in myelin tracks, with reduction in the total white-matter volume in whole brain, significant decreases in myelin or axonal membrane integrity as seen with magnetization transfer ratio, and decreased anisotropy in cortical regions indicative of myelin disruption, as documented by the diffusion tension imaging. DNA microarray studies have repeatedly shown reduced levels of mRNA encoding proteins associated with oligodendroglia and myelinization [38]. In several cases, these findings have been confirmed using quantitative RT-PCR. Among these are mRNAs for *myelin associated glycoprotein* (MAG), *myelin lymphocyte protein* (MAL), the neuregulin receptor *ErbB3* and *transferrin*. See Myelin Formation, Structure and Biochemistry, Chapter 4. The genes encoding these proteins are located at loci on the human genome that have been associated with heritable risk for schizophrenia. It should be noted that down-regulation of the expression of several of these genes has also been observed in postmortem cortex from individuals with bipolar disorder. This suggests that these myelin abnormalities may account for features such as psychosis that are shared between schizophrenia and bipolar disorder. Nevertheless, the unexpected implication of myelin dysfunction in schizophrenia speaks to the power of microarray technology for surveying efficiently an extraordinary large number of gene transcripts in tissue.

Although the apparent number of glial fibrillary acidic protein (GFAP) positive astrocytes are unchanged in schizophrenia, the expression of GFAP is reduced in prefrontal cortex. While reduction in glial numbers has been associated primarily with affective disorders, reduced numbers of astrocytes have been reported for the anterior cingulate cortex in schizophrenia [39]. Both the activities and the protein levels of glutamine synthetase and glutamate dehydrogenase, astrocyte-associated enzymes, are altered in prefrontal cortex in schizophrenia.

CONCLUSION

Our understanding of the pathophysiology of schizophrenia has advanced remarkably over the last decade through the combined use of *in vivo* imaging techniques, genetic studies and neurochemical (in the broadest sense) analyses of postmortem brain. Interdigitating the findings from these different methods of analysis indicates that the disorder is highly heritable and involves interactions of multiple genes, each producing a small effect, which in total probably affect several functional domains. Aside from dopamine, which may be central to psychosis, the glutamatergic, GABAergic and cholinergic neurotransmitter systems are credible participants. As several of the affected proteins modulating NMDA receptor function are expressed in astrocytes and multiple candidate genes, and their products are involved in myelinization, non-neuronal cell types may also be important participants in the pathophysiology of schizophrenia. A major challenge for the future will be disentangling those alterations in gene expression that are primary from those that are secondary, and relating these alterations in a meaningful way to the symptoms of schizophrenia. These advances will provide the hope for developing more effective treatments that will probably be unrelated to the dopaminergic system, which has dominated pharmacotherapy of schizophrenia for the last 50 years.

MOOD DISORDERS 888

Three common diagnoses comprise the major mood disorders 888

Mood disorders are recurrent in about 80% of cases 888

Both genetic and non-genetic factors play roles in the transmission of mood disorders 888

Major depressive and bipolar disorders arise from the interactions between the susceptibility genes and environmental factors 888

NEUROTRANSMITTER AND NEUROPEPTIDE SYSTEMS ARE IMPLICATED IN THE PATHOPHYSIOLOGY OF BIPOLAR AND MAJOR DEPRESSIVE DISORDERS 889

The serotonergic system has long been thought to play a role in major depression and bipolar disorders, although the exact mechanisms are yet to be determined 889

The catecholamine hypothesis of depression proposed that major symptoms of the disorder are explained by a deficiency in noradrenalin or its receptors 891

Altered dopaminergic system function has been implicated in major depression 892

There might be an increased ratio of cholinergic to adrenergic activity in depression, and the reverse in mania 892

The antidepressant effects reported for some drugs that antagonize NMDA receptors suggest a role for the glutamatergic system in depressive disorders 892

Reduced GABAergic activity may play a role in depression 892

The cortical–hypothalamic–pituitary–adrenal axis has been implicated in major depression 893

Thyroid dysfunction may produce depression 893

Depression has been associated with disorders of various neuropeptides 893

ABNORMALITIES OF SLEEP RHYTHMS IN MOOD DISORDERS 894

NEUROANATOMICAL AND NEUROPATHOLOGICAL CORRELATES OF MOOD DISORDERS 894

STRESS, GLUCOCORTICOIDS AND NEUROPLASTICITY IN THE PATHOLOGY OF MOOD DISORDERS 895

INTRACELLULAR SIGNALING PATHWAYS INTEGRATE ENVIRONMENTAL AND GENETIC CUES INVOLVED IN MOOD 895

Abnormalities in G protein subunits/cAMP signaling pathway have been observed in bipolar disorder 897

Protein kinase C (PKC) exists as a family of closely related kinase subspecies with a heterogeneous distribution in the brain 897

A crucial kinase that functions as an intermediary in numerous intracellular signaling pathways is the enzyme glycogen synthase kinase-3 (GSK-3) 898

Activation of the HPA axis appears to play a critical role in mediating hippocampal atrophy 898

INTRACELLULAR CALCIUM SIGNALING STUDIES IN BIPOLAR DISORDER 899

ANXIETY DISORDERS 899

Animal models of fear and anxiety have primarily used the rat, the mouse and, to a lesser extent, non-human primates 899

Transgenic and knockout mice are employed to investigate the genetics of anxiety 900

Neurotransmitters and neuropeptides have been implicated in fear and anxiety 901

INTRACELLULAR TARGETS FOR ANXIETY DISORDERS 904

FUTURE DIRECTIONS AND THE DEVELOPMENT OF NOVEL THERAPEUTICS 905

Basic Neurochemistry: Molecular, Cellular and Medical Aspects

Mood and anxiety disorders are common, severe, chronic, and often life-threatening illnesses. There is a growing appreciation that, far from being diseases with purely psychological manifestations, severe mood and anxiety disorders are systemic diseases with deleterious effects on multiple organ systems. The emerging evidence suggests that the combination of genetics, and various stressors ultimately determines individual responsiveness to mood and anxiety disorders. In this chapter, we review emerging evidence for the involvement of critical neurotransmitter and cellular plasticity cascades, and discuss their implications, not only for changing existing conceptualizations regarding the pathophysiology of these disorders, but also for the strategic development of improved therapeutics.

MOOD DISORDERS

Three common diagnoses comprise the major mood disorders. The most common mood disorder diagnoses are:

1. major depressive disorder, also known as unipolar depression,
2. dysthymia, a less severe but more chronic form of depression akin to a mood trait, and
3. bipolar disorders, or manic-depression, characterized by both depressive episodes and episodes of mania and hypomania.

Epidemiological surveys report yearly mood disorder prevalence rates in the U.S.A. of 5.1–11.1% of the population. By subtype, yearly prevalence rates are 4.5–10.1% for a major depressive episode, 4–8.9% for major depressive disorder, 0.5–1.3 % for bipolar I, and 0.2% for bipolar II disorder [1]. Women have higher rates of major depressive disorder, approximately twice that of men, whereas bipolar disorder is equally prevalent in men and women [1]. Globally, major depression is the leading cause of disease burden among females aged 5 years and above. Individuals with a mood disorder have greater overall mortality risk, including higher risk of death by unnatural causes. Much of the excess mortality amongst individuals with mood disorders is attributable to higher rates of suicide. Approximately 60% of all suicides occur in relation to mood disorders [2]. Lifetime mortality due to suicide in discharged hospital populations is approximately 20% in bipolar disorder, and 15% in major depressive disorder. A diagnosis of mood disorder also carries an elevated risk for nonfatal suicide attempts, with epidemiological studies documenting lifetime rates of suicide attempt of 29.2% in bipolar disorder, 15.9% in major depressive disorder, and 4.2% in all other DSM III Axis I disorders [3].

Mood disorders are recurrent in about 80% of cases. The reason most likely lies in genetic and developmental effects having created a neurobiological diathesis for recurrent episodes of major depression or mania. It is of note that the clinical picture of major depression varies greatly from episode to episode within the same patient [4]. The pleomorphic nature of recurrent mood disorders implies that there is a super-family of mood disorders with a potentially common set of causal genes and environmental causes. The specific manifestation of an episode of a mood disorder must therefore be sensitive to state-dependent factors, and pathophysiology should reflect both a common trait-dependent component and a more variable state-dependent component. An example of the former is the serotonin system abnormality observed during and between episodes, brought on by acute tryptophan depletion or fenfluramine challenge. An example of the latter is dysregulation of the hypothalamic–pituitary–adrenal axis (see Ch. 52), or regional alterations in brain glucose metabolism as seen on positron emission tomography [5] (see also Ch. 58).

Both genetic and nongenetic factors play roles in the transmission of mood disorders. The familial nature of mood disorders is well established. Studies over the past 20 years have consistently documented higher rates of mood disorder in the relatives of individuals with major depression and bipolar disorder than in relatives of healthy controls [6, 7]. The familial aggregation of mood disorders is the outcome of both genetic and environmental factors.

The heritability of bipolar and major depressive disorders has been demonstrated in twin and adoption studies. In twin studies, monozygotic twins have two- to three-fold higher concordance for major depressive disorder than dizygotic twins [7], and four- to eight-fold higher concordance in bipolar disorder [6]. A higher concordance rate indicates that genetic factors play a role over and above shared environmental factors. Shared environment may be greater for monozygotic twins than for dizygotic twins, and the confound of shared environment can be avoided by adoption studies. In studies of depressed adoptees, higher rates of depression are observed in biological parents than adoptive parents, indicating a genetic component underlying the familial transmission of mood disorders. Genetic factors are estimated to account for 37– 75% of the liability for major depressive disorder [8] and 60–85% of liability for bipolar disorder [6].

Major depressive and bipolar disorders arise from the interactions between the susceptibility genes and environmental factors. Parental psychopathology contributes to the transmission of mood disorders to offspring both by transmission of susceptibility genes and through environmental effects. Parental mood disorder might result in adverse childrearing practices and environments, with greater exposure to stressors such as childhood abuse, marital discord in parents, impoverished parenting due to parental illness, substance misuse, poverty, and early separation from a parent due to loss or departure [9]. Deficient parenting by depressed parents, particularly maternal interaction with children, has also been associated with mood disorders in children (see Beardslee *et al.* [9] for a review). Such adverse child-rearing environments can

precipitate onset of depressive disorders in children and adolescents with a genetic susceptibility [10], or may interfere with treatment response.

Genetic studies have examined a number of candidate genes in association and linkage studies with inconclusive, but suggestive, results. In bipolar disorder, genetic studies have tentatively implicated chromosomes 18, 11 and X (for a review see Johansson *et al.* [11]). There have been fewer studies of major depressive disorder and results remain inconclusive. A less-well-defined clinical phenotype may be one reason. Linkage analyses of families with major depression have not observed a significant linkage to any of the genetic markers examined, with the possible exception of gamma-aminobutyric acid (GABA) A receptor $\alpha 5$ subunit gene [12]. With respect to candidate genes, association studies of the promoter regions of the norepinephrine transporter gene, the dopamine D2 receptor gene, and the serotonin transporter gene have not found consistent differences between individuals with major depression and healthy controls. One large postmortem study of the 5-HTTLPR polymorphism of the serotonin transporter found more heterozygotes in major depression; however, this relationship did not explain the lower transporter binding which has been observed in the prefrontal cortex, anterior cingulate, and brainstem raphe nuclei [13]. It is possible such an effect is present but obscured by regulatory effects at nerve terminals, such as rate of transporter internalization, which is influenced by the intrasynaptic level of serotonin.

A major obstacle faced by studies in psychiatric genetics is uncertainty over the degree of the biological heterogeneity encompassed within any particular psychiatric diagnoses. For example, we have reported that the pattern of symptoms and signs of major depressive episodes can vary considerably from episode to episode [4]. This implies that, although within an individual patient with a constant genetic makeup, successive episodes of major depression may vary in terms of the most prominent clinical features, the fact they all occur within a single patient suggests they are part of a single, super-family of major depression [4]. Thus, although the clinical phenotype may vary, the genetic underpinnings must be the same.

The interaction of environmental factors with genetic susceptibility in the development of mood disorders also complicates genetic studies. For example, Caspi *et al.* [10], found that childhood maltreatment favored the onset of major depressive episodes and responses to life events in individuals harboring the short allele of the promoter region of the serotonin transporter gene; while those individuals carrying the long allele of this gene, which is more highly expressed, were more resistant to the development of major depressive episodes in the context of a past history of adverse childhood experiences or in response to recent life events in adulthood. Replication of these potentially important findings is required because, in general, replication of results in genetic studies has proven difficult. This is due to factors such as environment–gene interaction, the likelihood that the same clinical phenotypes are informed by multiple genes and gene combinations, and the low power of sample sizes in most studies to date.

NEUROTRANSMITTER AND NEUROPEPTIDE SYSTEMS ARE IMPLICATED IN THE PATHOPHYSIOLOGY OF BIPOLAR AND MAJOR DEPRESSIVE DISORDERS

The serotonergic system has long been thought to play a role in major depression and bipolar disorders, although the exact mechanisms are yet to be determined.

In 1969, the indoleamine hypothesis of depression was proposed [14], wherein the vulnerability to either depression or mania was related to low serotonergic activity, attributable to either less serotonin release, or fewer serotonin receptors, or impaired serotonin receptor-mediated signal transduction. Prange *et al.* [15] formulated a permissive hypothesis of serotonin function in bipolar disorder, in which a deficit in central serotonergic neurotransmission permits the expression of bipolar disorder, and both the manic and depressive phases of bipolar disorder are characterized by low central serotonergic neurotransmission. Studies of the serotonergic system over the last 30 years, have reinforced its role in mood disorders, and have identified additional associations with suicidal behavior, impulsivity, aggression, eating disorders, obsessive–compulsive disorder, anxiety disorders, personality disorders, seasonal changes in mood and behavior and alcohol misuse disorders (see also Addiction, Ch. 56). The serotonergic system also plays a role in the regulation of a range of basic biological functions, including sleep, appetite, circadian rhythm, and cognition. These functions are often disrupted in episodes of major depression.

Serotonergic function has been investigated by using multiple methods. Assaying the major metabolite of serotonin, 5-hydroxyindoleacetic acid (5-HIAA) in cerebrospinal fluid (CSF) has been widely used (Ch. 13). This method assumes that CSF 5-HIAA is related to brain serotonin activity. This premise is supported by the rostral–caudal concentration gradient of CSF 5-HIAA and the observation in postmortem studies that CSF 5-HIAA correlates with levels of 5-HIAA in prefrontal cortex [16], both of which suggest that CSF 5-HIAA is a reasonable index of prefrontal serotonin turnover .

Some, but not all, studies observe low CSF 5-HIAA in major depressive episodes. Numerous studies, though not all, have also reported no difference between patients with mania or depression in CSF 5-HIAA levels, consistent with both Prange *et al.*'s [15] permissive hypothesis for bipolar disorders and the indoleamine hypothesis.

This implies that CSF 5-HIAA is low in both manic and depressive states and thus is not a mood-state-dependent effect. Moreover, the level of CSF 5-HIAA generally does not correlate with severity of depression. There is an independent association between lower levels of CSF 5-HIAA and serious suicidal behavior in depressed patients [17]. A history of serious suicide attempts rather than severity of depression distinguishes depressed patients with lower CSF 5-HIAA. Low CSF 5-HIAA is also related to lifetime aggressive behavior, and has been shown to predict both future suicide and pathological aggression. This may be due to low serotonin input into the ventral prefrontal cortex and anterior cingulate gyrus, resulting in less behavioral inhibition and thus a greater likelihood of suicide or violence.

Platelets are more accessible for study than CSF, and share many properties with central serotonin neurons, including uptake, storage, and release of serotonin, some serotonin receptors, and serotonin transporter binding sites. Platelets have been used as a peripheral model for serotonin neurons in studies of serotonin function in mood disorders. Ligands such as [^{3}H]imipramine and [^{3}H]paroxetine bind to the serotonin transporter on the presynaptic nerve terminal and in the platelet. Over 20 years ago, lower platelet [^{3}H]imipramine and [^{3}H]paroxetine binding were first observed in depressed patients [18]; however, no difference in platelet [^{3}H]imipramine binding has been observed in manic patients compared with healthy controls [19]. Suicidal behavior has been associated with higher platelet 5-HT_{2A} binding [20], and aggressive behaviors related to higher platelet serotonin content [21]. Serotonin receptors are discussed in detail in Ch. 13.

Hormonal response to the serotonin releasing-agent/uptake-inhibitor fenfluramine, and other related direct and indirect serotonin agonists, have also been examined in mood disorder research as an indicator of central serotonin system function. A release of serotonin from raphe nuclei projections to the hypothalamus causes the release of prolactin, cortisol and adrenocorticotropic hormone (ACTH, see Ch. 52). Thus, prolactin response is an index of central serotonin responsivity. Using this method one can measure net serotonin transmission, including elements of presynaptic and postsynaptic serotonergic functioning, which is not possible in cerebrospinal fluid and platelet studies. A blunted prolactin response to fenfluramine, indicating less serotonin release and/or serotonin 5-HT_{1A} or 5-HT_{2A} receptor signal transduction, in depressed patients has been reported [22] but not in all studies. Discrepancies between studies may be due to differences in the composition of study populations; for example, the proportion of patients with suicidal behavior or certain personality traits in study samples [22, 23]. Depressed patients who have made high lethality suicide attempts show lower prolactin response to fenfluramine than those who have made low-lethality suicide attempts [23]. Depressed patients who experience anger attacks have significantly blunted prolactin response to fenfluramine compared to patients without anger attacks [24], and in personality-disorder patients reduced prolactin response to fenfluramine correlated with ratings of impulsive aggression [22].

Another method of studying the serotonergic system has been through depletion of serotonin by either inhibition of tryptophan hydroxylase (TPH), the rate-limiting biosynthetic enzyme for serotonin, with parachlorophenylalanine (PCPA), or acute tryptophan depletion. These studies have demonstrated that, in long-term-remitted medication-free depressed patients, depression recurs after serotonin or tryptophan depletion. An elevated rate of induction of depression by acute tryptophan depletion has also been observed in the relatives of mood-disorder patients, consistent with familial serotonin hypofunction. Similarly, a transient return of depressed symptoms following acute serotonin or tryptophan depletion occurs in patients who have responded to selective serotonin reuptake inhibitors (SSRIs), indicating that the antidepressant effect of this class of medications is dependent on a continuous enhancement of serotonergic function.

Medications, such as SSRIs, that block the serotonin transporter site and selectively inhibit reuptake of serotonin, have proven to be effective antidepressants. Some antidepressant drugs act specifically at one or another of the serotonin receptor subtypes, for example buspirone and gepirone are 5-HT_{1A} receptor agonists. Fewer 5-HT_{1A} receptors have been implicated in the pathophysiological mechanism of depression and anxiety. In positron emission tomography (PET) studies of the regional 5-HT_{1A} receptor binding potential, that compare depressed subjects with primary, recurrent, familial mood disorders with healthy controls, mean 5-HT_{1A} receptor binding potential has been reported as lower in the midbrain raphe and mesial hippocampus [25]. Single positron emission tomographic study [SPECT) studies have also found less brainstem serotonin transporter binding sites in depressed patients [26]. Postmortem studies have confirmed this effect in the brainstem, and have extended it to the prefrontal cortex [13].

The role of 5-HT_{2A} receptors has been examined in postmortem and imaging studies. In postmortem studies of suicide victims, both with and without depressive diagnoses, there is evidence that 5-HT_{2A} receptors are up-regulated in the dorsal prefrontal cortex (areas 8 and 9) in suicide, but remain unchanged in the rostral pole of the prefrontal cortex (area 10) (see [27] for a review). Imaging studies of 5-HT_{2A} receptor binding in depressed subjects have reported conflicting results, with some observing increased 5-HT_{2A} receptor binding in the prefrontal cortex, others reporting a decrease in binding potential in the cingulate, insular, and inferior frontal cortex, and others observing no alterations [27]. The variation in results is possibly explained by the effects of antidepressant medications which have been shown to downregulate 5-HT_{2A} receptor binding across widespread areas of the

prefrontal cortex [28]. There is disagreement about 5-HT_{2A} receptor binding in medication-free depressed subjects in imaging [29], and postmortem studies [30]. The cause of higher 5-HT_{2A} receptor binding in depression is unclear, but animal studies show that stress can up-regulate 5-HT_{2A} receptor binding.

Given the heritability of major depressive disorders, a genetic contribution to serotonergic dysfunction seems likely. Animal studies have demonstrated that CSF 5-HIAA levels are partly under genetic control [31]. As noted above, linkage and association studies of candidate genes related to the serotonin system are numerous. In one such study, Mann *et al.* [13] assayed prefrontal cortical (PFC) serotonin transporter binding in postmortem brain from major depression and suicide victims and examined the relationship to the functional 5-HTTLPR allele in the promoter region. Lower binding to the serotonin transporter (5-HTT) throughout the PFC of subjects with a history of a major depressive episode was observed, and the 5-HTTLPR genotype was associated with major depression, but not with suicide or 5-HTT binding. The authors consider that a diffuse reduction of transporter binding in the PFC of individuals with major depression may be indicative of a widespread impairment of serotonergic function. It was unrelated to genotype at the level of the cortex, although Heinz *et al.* [32] reported a relationship in the brainstem using SPECT.

Studies of serotonin function in major depression suggest both hypofunction and accompanying compensatory alterations to increase serotonergic activity. A role for serotonergic system underactivity in the pathogenesis of depression is suggested by findings such as lower serotonin and 5-HIAA levels in postmortem brainstem, relapse of depression with acute depletion of tryptophan, fewer serotonin transporter sites in prefrontal cortex, fewer postsynaptic 5-HT_{1A} receptors, and the antidepressant properties of medications that enhance serotonergic transmission. Conversely, reports of more 5-HT_{2A} receptor binding in the frontal cortex of depressed individuals who committed suicide, fewer brainstem 5-HT_{1A} autoreceptors, and fewer serotonin transporters in the cortex, would be consistent with homeostatic changes designed to increase deficient serotonergic transmission in major depression. Future investigations of serotonergic activity in mood disorders will need to further differentiate primary pathogenesis from such compensatory changes.

There is evidence for the contribution of serotonin dysfunction to mania, and in the mechanism of action of mood stabilizers [19], however, specific data on the serotonergic system and mania are fewer and variable. Moreover, altered functioning of other neurotransmitters in mania such as norepinephrine, dopamine, acetylcholine, and GABA, and their interaction with serotonin, are also likely to be involved in the pathogenesis of mood disorders. Differences in these neurotransmitter systems possibly underlie differences in the pathogenesis of depressive and manic episodes.

The catecholamine hypothesis of depression proposed that major symptoms of the disorder are explained by a deficiency in noradrenalin or its receptors. Early evidence that the noradrenergic system is crucial in the pathophysiology of depression appeared in the mid-1950s, when a number of patients became profoundly depressed when treated for hypertension with tetrabenazine and reserpine, which deplete cathecholamines in the central and peripheral nervous system [33]. More recently, evidence of the role of the noradrenergic system in depressive disorders is seen in the effect of α-methyl-*p*-tyrosine (AMPT), which induces more biochemically specific catecholamine depletion by inhibiting tyrosine hydroxylase, the rate-limiting step in catecholamine synthesis (details of synthesis are given in Ch. 12). AMPT has negligible effects on mood in healthy subjects, but produces a return of depressive symptoms in recovered depression patients treated with noradrenalin reuptake inhibitors.

Multiple lines of investigation provide evidence for a role of the noradrenergic system in depressive disorder, although considerable variability in findings indicate that much remains to be learned regarding specific mechanisms. The noradrenalin metabolite, 3-methoxy-4-hydroxyphenylglycol (MHPG), has been investigated in plasma, urine and CSF studies. Early studies of urinary MHPG reported lower levels in depressed patients compared with controls and higher MHPG levels in manic states in bipolar patients. However, subsequent studies have shown considerable variability in MHPG levels in patients with depression [34]. These inconsistencies may in part be due to the low contribution of CNS catecholamines to urinary metabolite levels.

Investigators have sought more accurate measures of brain noradrenalin activity by measuring CSF metabolite levels. Again, significant heterogeneity of results appears in studies of major depressive disorder. For example, of six studies of CSF noradrenalin metabolites, three found higher levels in depression, one found lower levels, and two reported no difference [34]. Studies of bipolar disorder have yielded somewhat more consistency, with bipolar type I patients generally showing lower levels of noradrenalin metabolites in the depressed state; however, results also vary [35]. While there is some contribution from the spinal cord, most MHPG comes from the brain. The observation in rodents that lower CNS noradrenergic activity is associated with greater sympathetic nervous system (SNS) activity suggests that mood disorders may be characterized by lower CNS noradrenergic activity and greater SNS activity. Thus, CSF MHPG levels in mood disorders may reflect the balance of changes in brain and SNS noradrenergic activity.

Noradrenalin turnover is decreased with antidepressant treatment. This is a compensatory effect of elevated intrasynaptic noradrenalin causing feedback inhibition of tyrosine hydroxylase. This effect has been consistently observed with noradrenergic-specific antidepressants, as expected, but has also been reported with serotonergic-specific

agents, and with ECT [36]. The former effect may be due to the action of the raphe serotonergic neurons on activity of locus coeruleus noradrenergic neurons.

Receptor studies also provide evidence of noradrenergic anomalies in mood disorders. No consistent changes in α_1-adrenergic receptor numbers have been observed in unmedicated depressed patients; however, downregulation and hyposensitivity of β-adrenergic, and possibly α_2-adrenergic, receptors have been reported [37]. Antidepressant treatment decreased the number of α_2 and β_1-adrenergic receptors and increased the density of α_1-adrenergic receptors in animal studies [37]. α_2-adrenergic receptors can also be studied indirectly through challenge with the α_2-receptor agonist clonidine, which induces growth hormone secretion, primarily through an action on postsynaptic receptors. Following clonidine challenge, attenuated growth hormone secretion, indicating decreased responsiveness of postsynaptic α_2-adrenergic receptors, has been observed in depressed patients [38]. Elevated plasma cortisol levels have been observed in depressed patients following administration of yohimbine, an α_2-adrenergic receptor agonist, likewise indicating subsensitivity of postsynaptic α_2-adrenergic receptors [39].

Postmortem brain studies offer further evidence of noradrenergic abnormality in depression, finding greater cortical norepinephrine, and less high-affinity β_1-adrenergic receptor binding. More tyrosine hydroxylase in the locus coeruleus (LC) may result from depletion of stores of NE, and that may thereby trigger a compensatory increase in NE synthesis. There are fewer noradrenergic neurons reported in depressed suicides [40], which may indicate a lower functional reserve of the noradrenergic system in suicide and/or major depression. Thus, there is greater likelihood of noradrenergic depletion in the face of severe or prolonged stress, such as the stress of a depressive illness. Noradrenergic response to stress in adulthood appears to be greater in those with an adverse experience in childhood, potentially putting them at greater risk in adulthood for norepinephrine depletion because of fewer noradrenergic neurons, and therefore for major depression [41].

There is ample support for the hypothesis of noradrenergic system dysfunction in depression; however, the inconsistencies in findings rule out any simple model of increased or decreased noradrenergic activity. It is important to determine which noradrenergic system abnormalities relate specifically to the pathogenesis of mood disorders, and which are related to nonspecific effects of stress, homeostatic mechanisms, or comorbid psychopathology. More work is needed on the mood-state-dependence of noradrenergic function.

Altered dopaminergic system function has been implicated in major depression. Patients with major depression have been reported to have lower CSF levels of the dopamine metabolite homovanillic acid (HVA) compared to nondepressed controls, with more severely depressed patients having still lower CSF HVA levels (see [42] for a summary). By increasing the sensitivity of CSF HVA as a measure of CNS dopamine turnover through using probenecid to block the transport of HVA from the CSF, researchers found lower CSF HVA in patients with depression, particularly in a subgroup of patients with psychomotor retardation [43]. However, not all studies have observed lower CSF HVA in patients with depression. In other measures of dopaminergic activity, lower serum dopamine β-hydroxylase activity, higher plasma dopamine and HVA concentrations have been observed in psychotically depressed patients compared with nonpsychotic depressed patients [44]. Adding support to the hypothesis that the dopaminergic system is implicated in depressive disorders are the antidepressant properties of dopamine-releasing stimulants methylphenidate and dextroamphetamine, which are useful in the treatment of depression.

There might be an increased ratio of cholinergic to adrenergic activity in depression, and the reverse in mania. This concept was proposed by Janowsky *et al.* [45]. More recently, Poland *et al.* [46] suggested that cholinergic hyperactivity could contribute to depression. Further support for over-activity of the cholinergic system in the pathogenesis of depression is offered by such findings as:

- Cholinergic input reduces rapid eye movement sleep (REM) latency, and decreased REM latency is seen in depression;
- The anticholinergic properties of some antidepressants;
- In some cases mania is reduced and depression induced by lecithin, an acetylcholine precursor;
- Following abrupt withdrawal of anticholinergic medications cholinergic rebound can cause a relapse of depression [37].

The antidepressant effects reported for some drugs that antagonize NMDA receptors suggest a role for the glutamatergic system in depressive disorders. Lower glucose uptake, as indicated by PET imaging studies of the prefrontal cortex in depression using the glucose analogue [^{18}F]-FDG, could reflect lower glutamate–glutamine turnover as a result of lower glutamatergic activity in the cortex [47]. Morphometric studies of pyramidal cells in neocortex and magnetic resonance spectroscopic analysis of glutamate will help clarify the state of the glutamatergic system in mood disorders.

Reduced GABAergic activity may play a role in depression. In depressed patients, magnetic resonance spectroscopy studies have observed lower GABA levels in occipital cortex, and lower CSF and plasma concentrations of GABA have also been reported [48]. We have found that low CSF GABA may be inversely proportional to severity of anxiety and depression in major depression. Lamotrigine enhances GABAergic activity, and has demonstrated antidepressant prophylactic effects, preventing recurrent

depressions in bipolar disorders [49]. Anticonvulsant mood-stabilizers acting by enhancing GABAergic function suggest GABA plays a role in mood stability, and a GABA deficiency may favor mood swings. These pathophysiological contributions of GABA and therapeutic effects of GABAergic medications in mood disorders may also be mediated via effects on other neurotransmitter systems [37].

The cortical–hypothalamic–pituitary–adrenal axis has been implicated in major depression. Multiple methods of measuring cortical–hypothalamic–pituitary–adrenal axis activity have provided evidence of altered function in patients with major depression, including: elevated corticotropin-releasing factor (CRF) concentrations in CSF ; blunted cortical–adrenocorticotropic hormone (ACTH) and β-endorphin responses after intravenous CRF administration; lower CRF binding in frontal cortex; pituitary gland enlargement; adrenal gland enlargement; hypercortisolemia and elevated CSF cortisol concentrations; blunted plasma glucocorticoid, ACTH, and β-endorphin nonsuppression after dexamethasone administration; higher urinary free cortisol concentrations; elevated 5-hydroxytryptophan-induced cortisol secretion; higher ACTH-induced cortisol secretion; and higher ACTH and cortisol responses to CRF after dexamethasone pretreatment.

In depressed patients, cortical–hypothalamic–pituitary–adrenal axis hyperactivity can be explained by the hypersecretion of CRF, and secondary pituitary and adrenal gland hypertrophy. Impaired negative feedback at various CNS sites, including the hippocampus and pituitary are also likely to contribute. Downregulation of hippocampal mineralocorticoid receptors and expression is reported in depressed suicides [50]. In bipolar disorder, hyperactivity of the cortical–hypothalamic–pituitary–adrenal axis has been observed [51]. This increase in cortical–hypothalamic–pituitary–adrenal axis activity has also been observed in mixed mood states, mania and in depression in rapid-cycling patients. Partial reversal of HPA overactivity is associated with treatment and recovery from depression.

Thyroid dysfunction may produce depression. Approximately 5–10% of individuals evaluated for depression have previously undetected or subclinical thyroid dysfunction [52]. Jackson [53] suggests that most patients with depression, although generally viewed as chemically euthyroid, have altered thyroid function, including slight elevation of the serum thyroxine (T4), loss of the nocturnal TSH rise, and blunted thyrotropin (TSH) response to thyrotropin-releasing-hormone (TRH) stimulation. A down-regulation of TRH receptors in the pituitary in response to the increased levels of TRH secreted into the hypophyseal-portal circulation might explain the blunting of the TSH response to TRH challenge.

Bipolar disorder patients have shown abnormalities of the hypothalamic–pituitary-thyroid axis, demonstrated by an exaggerated TSH response to TRH and elevated basal plasma concentrations of TSH [54]. In contrast, a blunted TSH response to TRH, the presence of antithyroid microsomal or antithyroglobulin antibodies [55], and a blunted or absent nocturnal surge in levels of plasma TSH [56], have also been observed in patients with bipolar disorder.

Depression has been associated with disorders of various neuropeptides.

Growth hormone. Mood disorders have been related to alterations in the activity of the growth-hormone axis. A blunted growth-hormone response to clonidine, an α_2 receptor agonist, has been consistently found in depression. Increased growth-hormone secretion during the day and decreased nocturnal growth-hormone secretion have also been observed in depressed patients. Depressed patients have lower CSF concentrations of somatostatin, compared to those with schizophrenia and normal controls. While lower CSF somatostatin is a state-dependent marker of depression, it occurs in a number of unrelated nonpsychiatric conditions, and thus appears to be relatively nonspecific.

Brain-derived neurotrophic factor. Brain growth and development is affected by multiple neurochemical factors, including thyroid hormones, somatostatin, growth hormone, and brain-derived neurotrophic factor (BDNF). BDNF, a major neurotrophic factor in the brain, is critical to the survival and guidance of neurons during development, and is also required for the survival and function of neurons in the adult brain [57]. For example, it has been shown to play a critical role in long-term potentiation, a cellular model of learning and memory, thus influencing plasticity [58].

Antidepressant treatment has, in recent studies, been shown to upregulate the cyclic adenosine monophosphate (cAMP) response element binding protein (CREB) cascade and expression of BDNF [59]. This upregulation of CREB and BDNF raises the possibility that antidepressant treatment could oppose the cell death pathway, possibly via increased expression of the oncogene *Bcl-2*. Studies are necessary to determine if antidepressant treatment increases *Bcl-2* expression. Increased expression of *Bcl-2* in brain and cultured cells, and inhibition of apoptosis of cultured cerebellar granule neurons have been reported with lithium treatment [57]. Mice lacking the BDNF TrkB receptor fail to show behavioral and neurogenic responses to antidepressants.

Substance P, an undecapeptide, is abundant both in the periphery and in the central nervous system. It is usually co-localized with one of the classical neurotransmitters, most commonly serotonin. Substance P is thought to have a role in the regulation of pain, asthma, psoriasis, inflammatory bowel disease and, in the CNS, emesis, migraine, schizophrenia, depression and anxiety. The substance-P-preferring receptor neurokinin-1 has been focused on most intensively in drug development, and existing

preclinical and clinical literature is suggestive, but not conclusive, of a role for substance P and neurokinin-1 receptors in the pathophysiology of depression and/or anxiety disorders. Originally studied as potential analgesic compounds, recent evidence suggests that neurokinin-1 receptor antagonists may possess antidepressant and anxiolytic properties. If confirmed by further controlled clinical studies, this will represent a mechanism of action distinct from all existing antidepressant agents. Evidence of impaired substance-P-mediated neurotransmission in depression is lacking, and CSF studies of substance P in depressed subjects are not in agreement.

ABNORMALITIES OF SLEEP RHYTHMS IN MOOD DISORDERS

Disturbances of sleep are typical of mood disorders, and belong to the core symptoms of major depression. More than 90% of depressed patients complain of impaired sleep quality [60]. Typically, patients suffer from difficulties in falling asleep, frequent nocturnal awakenings, and early morning awakening. Not only is insomnia a typical symptom of depression but, studies suggest, conversely, insomnia may be an independent risk factor for depression. In bipolar disorders sleep loss may also be a risk factor for the development of mania. Hypersomnia is less typical for depression [61] and, in contrast to insomnia, may be related to certain subtypes of depression, such as seasonal affective disorder (SAD).

Polysomnographic sleep research has demonstrated that besides disturbances of sleep continuity in depression, sleep disturbance is also characterized by a reduction of slow-wave sleep and a disinhibition of REM sleep, with a shortening of REM latency, a prolongation of the first REM period, and increased REM density [62]. Most effective antidepressant agents suppress REM sleep , and depressive symptoms are at least transiently alleviated by manipulations of the sleep–wake cycle, such as sleep deprivation or a phase advance of the sleep period [63]. Thus, there appears to be a bidirectional relationship between sleep, sleep alterations and mood.

NEUROANATOMICAL AND NEUROPATHOLOGICAL CORRELATES OF MOOD DISORDERS

Neuroimaging technology provides opportunities for elucidating the anatomic correlates of mood disorders. Neuroimaging studies of major depression have identified structural and functional abnormalities in multiple areas of the orbital and medial prefrontal cortex, hippocampus, amygdala, and related parts of the striatum and thalamus [25, 64]. Neuromorphology and neuromorphometry in primary mood disorders, and localization of pathology in major depressive episodes arising secondary to cerebral lesions, have been assessed with structural magnetic resonance imaging (MRI). See Hastings *et al.* [65] and Lochhead *et al.* [66] for reviews on structural imaging findings in major depressive disorder and bipolar disorders, respectively. Briefly, although the specific structure affected may vary between studies and between patients, there is a convergence of findings from structural imaging studies implicating a circuit involving the anterior cingulate, ventral striatum, pallidum, thalamus and hippocampus. There has been no clear evidence of global atrophy in mood disorders, although there are reports that patients with major depression have smaller basal ganglia, cerebellum, and possibly frontal lobe, perhaps indicating local atrophy. Bipolar disorder is associated with smaller cerebellum, possibly smaller temporal lobe, and changes in the hippocampus. Bipolar and elderly major depression patients both show increased subcortical white matter and periventricular hyperintensities. Lesions in these selected brain regions caused by injuries, such as anterior tumors or stroke, can be involved in the pathogenesis of mood disorders. The aging process may also contribute to the emergence of depression by causing lesions in these areas.

The emergence of functional neuroimaging methods permits the study of patients across the course of their illness. Functional imaging tools such as positron emission tomography (PET), functional magnetic resonance imaging (fMRI), and single photon emission computed tomography (SPECT), allow *in vivo* characterization of neurophysiologic and/or receptor pharmacologic correlates of normal and pathologic emotional states, chronic or recurrent illness, and treatment response and resistance (see detailed discussion in Ch. 58).

Functional neuroimaging findings have consistently observed prefrontal lobe dysfunction, indicated by lower blood flow and glucose metabolism, in mood disorders. There is evidence of abnormalities in basal ganglia, temporal lobe and related limbic structures, that accompany or are independent of structural changes. Major depressive disorder is primarily associated with dysfunction in the prefrontal cortex and basal ganglia, while bipolar depression appears to be associated with dysfunction in the temporal lobe, in addition to these other areas (see Blumberg *et al.* [67], Soares and Mann. [64] for reviews). Some of these functional abnormalities appear mood-state-dependent and are located in regions where cerebral blood flow increases during normal and some pathologic emotional states. Such neurophysiologic differences between depressives and control subjects may thus indicate areas where physiologic activity changes to mediate, or respond to, the emotional, behavioral and cognitive manifestations of major depressive episodes.

Other abnormalities are more trait-like, and persist following symptom remission. They are found in orbital and medial prefrontal cortex areas where postmortem studies have also documented reductions in cortex volume and histopathologic changes in primary mood disorders [68]. Evidence from brain mapping, lesion analysis and electrophysiologic studies of humans and experimental

animals, suggests that these areas appear to modulate emotional behavior and stress responses. Thus, it is hypothesized that dysfunction involving these regions plays a role in the pathogenesis of depressive symptoms. Taken together, these findings implicate interconnected neural circuits in which pathologic patterns of neurotransmission may result in the emotional, cognitive, motivational and behavioral manifestations of primary and secondary mood disorders.

Well-characterized postmortem human brain tissue banks permit study of the brain changes in mood disorders, and such findings can then be correlated with those of functional neuroimaging studies [68]. *In vivo* neuroimaging data, delimiting areas where gray matter volume is abnormal and characterizing the clinical conditions under which such abnormalities are evident, are beginning to also guide postmortem studies of mood disorders.

The development of selective ligands for neuroreceptor imaging provides expanding capabilities for noninvasive quantitation of *in vivo* receptor binding and neurotransmitter function. For example, PET and SPECT studies have yielded important information regarding the role of serotonergic receptors in the pathogenesis of mood disorders (see above). Such studies will facilitate a more complete characterization of the neurotransmitter abnormalities suggested by studies of postmortem tissue, body fluids, and neuroendocrine function. Combining PET and SPECT technology with genotyping functional polymorphisms in serotonin receptor genes, allows for more precise characterization of potentially important biological intermediate endophenotypes that are more sensitive indices of the pathology of mood disorders. Repeated studies in different mood states, and examination of familial and developmental effects using such methods, will help understand the pathophysiology of mood disorders; and will perhaps provide useful biomarkers for measuring and monitoring treatment effects.

STRESS, GLUCOCORTICOIDS AND NEUROPLASTICITY IN THE PATHOLOGY OF MOOD DISORDERS

The potential hyperactivation of the HPA axis in mood disorders has been revisited in recent years, in large part due to the growing recognition of the specific brain areas in which atrophy (loss), a neuroplastic event, may be present in many patients. To what extent these findings of atrophy represent the sequelae of the biochemical changes (for example, in glucocorticoid levels) accompanying repeated affective episodes, remains to be fully elucidated.

This suggestion receives support from the observation that chronic stress or glucocorticoid administration has been demonstrated to produce atrophy and death of vulnerable hippocampal neurons in rodents and primates. Furthermore, MRI studies have revealed reduced hippocampal volumes in patients with Cushing's disease and post-traumatic stress disorder (PTSD), conditions associated with hypercortisolemia. One of the most consistent effects of stress on cellular morphology is atrophy of hippocampal neurons. This atrophy is observed in the CA3 pyramidal neurons, but not in other hippocampal cell groups [69, 70] (i.e. CA1 pyramidal and dentate gyrus granule neurons). Atrophy of CA3 pyramidal neurons also occurs upon exposure to high levels of glucocorticoids, suggesting that activation of the HPA axis probably plays a major role in mediating the stress-induced atrophy. In addition, long-term exposure to stress (i.e. for several months) has also been associated with loss of hippocampal neurons in the CA3 pyramidal cell layer [69, 70].

Thus, it is possible that recurrent mood disorders, as in the case of bipolar disorder, may lower the threshold for cell death and/or atrophy in response to a variety of other physiological (e.g. normal aging) and pathological (e.g. ischemic) events, and thereby contribute to a variety of deleterious health-related effects.

INTRACELLULAR SIGNALING PATHWAYS INTEGRATE ENVIRONMENTAL AND GENETIC CUES INVOLVED IN MOOD

Recent neurobiological research into the pathophysiology and treatment of mood disorders has moved from a focus on neurotransmitters and cell surface receptors to intracellular signaling cascades. Multicomponent cellular signaling pathways interact at various levels, thereby forming complex signaling networks which allow the cell to: (a) receive internal and external cues, (b) process these cues, and (c) respond to information [71–73]. These signaling networks facilitate the integration of signals across multiple timescales, assist in the generation of distinct outputs depending on input strength and duration, and regulate intricate feed-forward and feedback loops [71–73]. Given their widespread and crucial role in the integration and fine-tuning of physiologic processes, it is not surprising that abnormalities in signaling pathways have now been identified in a variety of human diseases. Furthermore, signaling pathways represent major targets for a number of hormones, including glucocorticoids, thyroid hormones and gonadal steroids. The biochemical effects of these signaling pathways may play a role in mediating certain clinical manifestations of altered hormonal levels in mood-disorder subjects, e.g. the frequent onset of bipolar disorder in puberty, triggering of episodes in the postpartum period, association of depression and potentially rapid cycling with hypothyroidism, and triggering of mood episodes in response to exogenous glucocorticoids.

Complex signaling networks may be especially important in the CNS, where they 'weigh' and integrate diverse neuronal signals and then transmit them to effectors, thereby forming the basis of a complex information processing network. See Figure 55-1 for details of these

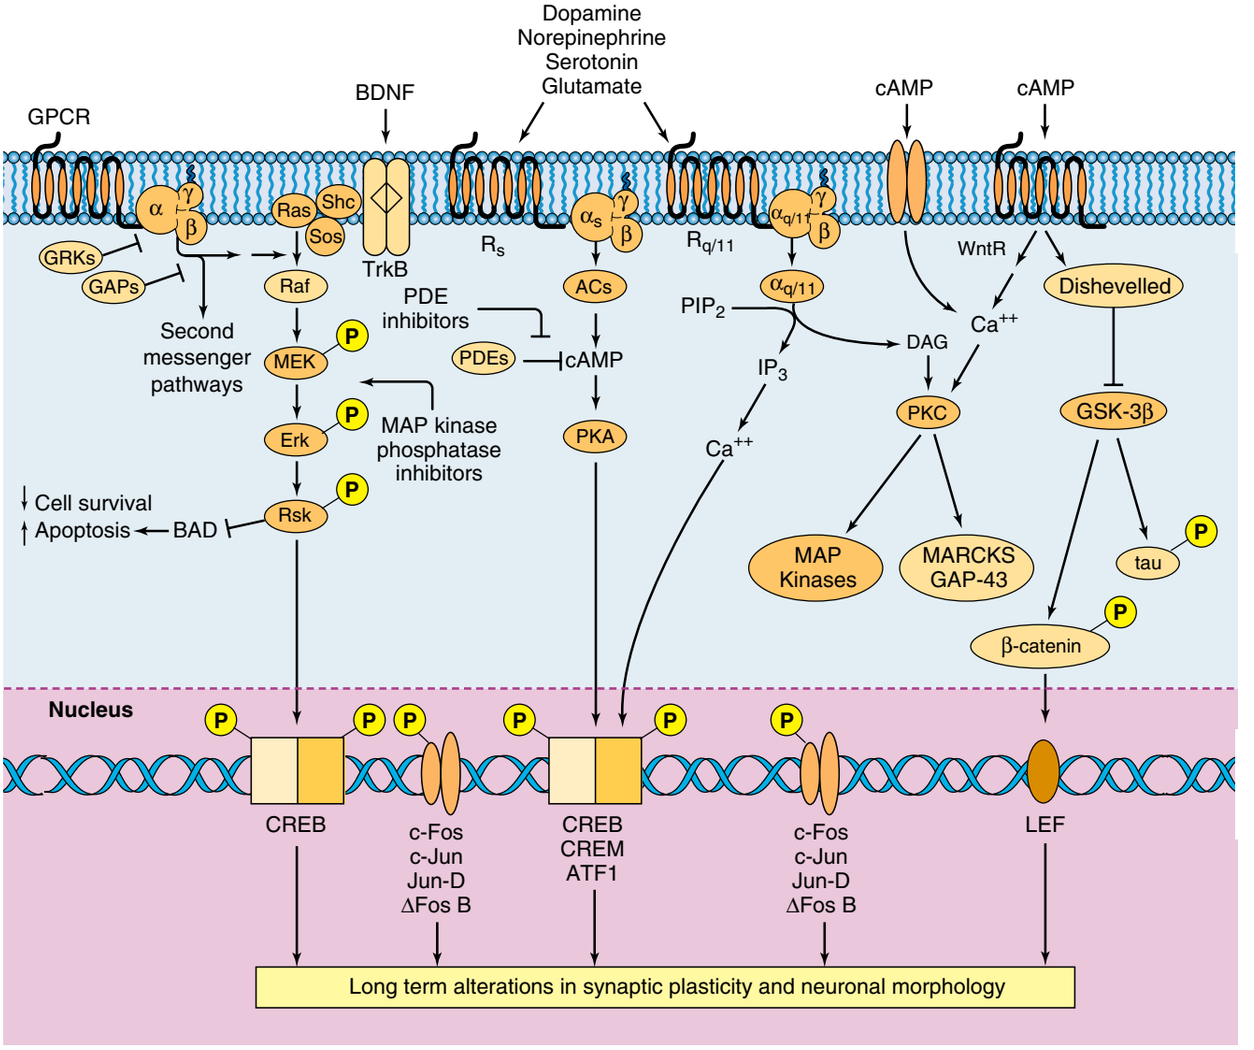

FIGURE 55-1 Major intracellular signaling pathways involved in neural and behavioral plasticity. The figure depicts some of the major intracellular signaling pathways involved in neural and behavioral plasticity. Cell-surface receptors transduce extracellular signals such as neurotransmitters and neuropeptides into the interior of the cell. Most neurotransmitters and neuropeptides communicate with other cells by activating seven transmembrane spanning G-protein-coupled receptors (*GPCRs*). As their name implies, GPCRs activate selected G proteins, which are composed of α and βγ subunits (Ch. 19). Two families of proteins turn off the GPCR signal, and may therefore represent attractive targets for new medication development. G-protein-coupled receptor kinases (*GRKs*) phosphorylate GPCRs and thereby uncouple them from their respective G proteins. GTPase activating proteins (*GAPs*, also called RGS or regulators of G-protein-signaling proteins) accelerate the G-protein turn-off reaction (an intrinsic GTPase activity). Two major signaling cascades activated by GPCRs are the *cAMP* generating second messenger system (Ch. 21), and the phosphoinositide (*PI*) system (Ch. 20). cAMP activates protein kinase A (*PKA*), a pathway which has been implicated in the therapeutic effects of antidepressants. Among the potential targets for the development of new antidepressants are certain phosphodiesterases (*PDEs*). PDEs catalyze the breakdown of cAMP; thus PDE inhibitors would be expected to sustain the cAMP signal, and may represent an antidepressant augmenting strategy. Activation of receptors coupled to PI hydrolysis results in the breakdown of phosphoinositide 4,5-biphosphate (PIP_2) into two second messengers — inositol 4,5-trisphosphate (IP_3) and diacylglycerol (*DAG*). IP_3 mobilizes Ca^{2+} from intracellular stores (Ch. 22), whereas DAG is an endogenous activator of protein kinase C (*PKC*), which is also directly activated by Ca^{2+}. PKC, PKA and other Ca^{2+}-dependent kinases directly or indirectly activate several important transcription factors, including *CREB*, *CREM*, *ATF-1*, *c-Fos*, *c-Jun*, *Jun-D*, and *ΔFos B* (Ch. 26). Endogenous growth factors such as brain-derived neurotrophic factor (*BDNF*) utilize different types of signaling pathways (Ch. 27). BDNF binds to and activates its tyrosine kinase receptor (*TrkB*); this facilitates the recruitment of other proteins (*SHC*, *SOS*), which results in the activation of the ERK-MAP kinase cascade (via sequential activation of *Ras*, *Raf*, *MEK*, *Erk*, and *Rsk*). In addition to regulating several transcription factors, the ERK-MAP kinase casade, via Rsk, down-regulates BAD, a pro-apoptotic protein. Enhancement of the ERK-MAP kinase cascade may have effects similar to those of endogenous neurotrophic factors; one potential strategy is to utilize inhibitors of MAP kinase phosphatases (which would inhibit the turn-off reaction) as potential drugs with neurotrophic properties. In addition to utilizing GPCRs, many neurotransmitters (e.g. glutamate and GABA) produce their responses via ligand-gated ion channels (see detailed discussions in Chs. 15 and 16). Although these responses are very rapid, they also bring about more stable changes via regulation of gene transcription. One pathway gaining increasing recent attention in adult mammalian neurobiology is the *Wnt* signaling pathway. Wnts are a group of glycoproteins active in development, but now known to play important roles in the mature brain.

Continued

potential pathways. The high degree of complexity generated by these signaling networks may be one mechanism by which neurons acquire the flexibility for generating the wide range of responses observed in the nervous system. These pathways are thus undoubtedly involved in regulating such diverse vegetative functions as mood, appetite and wakefulness, and are therefore likely to be involved in the pathophysiology of mood disorder.

Abnormalities in G protein subunits/cAMP signaling pathway have been observed in bipolar disorder. Postmortem brain studies in bipolar patients show increased levels of the stimulatory G protein ($G\forall_s$) accompanied by increases in postreceptor-stimulated adenylyl cyclase (AC) activity in bipolar disorder. These observations are further supported by a study showing increased agonist-activated [^{35}S]GTP(S binding to G protein $\forall_s$ subunits in the frontal cortical membranes of bipolar disorder patients [74]. Several studies have also found elevated $G\forall_s$ protein levels and mRNA levels in peripheral circulating cells in bipolar disorder, although the dependency of this finding on clinical state remains unclear. However, there is at present no evidence to suggest that the alterations in the levels of $G\forall_s$ are due to a mutation in the $G\forall_s$ gene itself. There are numerous transcriptional and post-transcriptional mechanisms which regulate the levels of G protein subunits (see Ch. 26), and the elevated levels of $G\forall_s$ could potentially represent the indirect sequelae of alterations in any one of these other biochemical pathways.

There is growing consensus that the ability of a 'simple' monovalent cation like lithium to treat multiple aspects of an illness as complex as bipolar disorder arises from its major effects on intracellular signaling pathways, rather than on any single neurotransmitter system *per se*. Although it appears that the lithium ion (at therapeutic concentrations) does not directly affect G protein function, there is considerable evidence that chronic lithium administration affects G protein function [75, 76]. It might be postulated that these G-protein effects of lithium, which would theoretically attenuate excessive signaling through multiple pathways, probably contribute to lithium's long term prophylactic efficacy in protecting susceptible individuals from spontaneous cyclic affective episodes induced by stress and drugs (e.g. antidepressants and stimulants).

Protein kinase C (PKC) exists as a family of closely related kinase subspecies with a heterogeneous distribution in the brain. These kinases have particularly high levels in presynaptic nerve terminals and, together with other kinases, appear to play a crucial role in the regulation of synaptic plasticity and various forms of learning and memory. PKC is one of the major intracellular mediators of signals generated upon external stimulation of cells via a variety of neurotransmitter receptors that induce the hydrolysis of various membrane phospholipids; these neurotransmitter receptors include muscarinic M1, M3, and M5 receptors, noradrenergic $\forall_1$ receptors, metabotropic glutamatergic receptors and serotonergic $5HT_{2A}$ receptors.

To date, there have only been a limited number of studies directly examining PKC in bipolar disorders [77]. Although undoubtedly an oversimplification, particulate (membrane) PKC is sometimes viewed as the more active form of PKC, and thus an examination of the subcellular partitioning of this enzyme can be used as an index of the degree of activation. Friedman *et al.* [78] investigated PKC activity and PKC translocation in response to serotonin in platelets obtained from bipolar-disorder patients before and during lithium treatment. They reported that the ratios of platelet-membrane-bound to cytosolic PKC activities were elevated in the manic patients. In addition, serotonin-elicited platelet PKC translocation was found to be enhanced in those patients. With respect to brain tissue, Wang and Friedman [74] measured PKC isozyme levels, activity and translocation in postmortem brain tissue from patients with bipolar disorder, and reported increased PKC activity and translocation in the brains of bipolar patients compared with controls, effects which were accompanied by elevated levels of selected PKC isozymes in cortices of bipolar disorder patients.

Evidence accumulating from various laboratories has clearly demonstrated that lithium, at therapeutically relevant concentrations, exerts significant effects on the PKC signaling cascade. Current data suggest that chronic lithium attenuates PKC activity, and down-regulates the expression of PKC isozymes $\forall$ in the frontal cortex and hippocampus [79, 80]. Chronic lithium has also been demonstrated to dramatically reduce the hippocampal levels of a major PKC substrate, myristoylated-alanine-rich C kinase substrate (MARCKS), which has been implicated in regulating long-term neuroplastic events.

Although these effects of lithium on PKC isozymes and MARCKS are striking, a major problem inherent in neuropharmacologic research is the difficulty in attributing therapeutic relevance to any observed biochemical finding. It is thus noteworthy that the structurally dissimilar

FIGURE 55-1—cont'd Binding of Wnts to the Wnt receptor (*WntR*) activates an intermediary protein, Disheveled, which regulates a glycogen synthase kinase (*GSK*-3β). GSK-3βexerts many cellular effects; it regulates cytoskeletal proteins, including *tau*, and plays an important role in determining cell survival/cell death decisions. GSK-3β has recently been identified as a target for Li^+'s actions. GSK-3β also regulates phosphorylation of β-*catenin*, a protein that when dephosphorylated acts as a transcription factor at LEF (lymphoid enhancer factor) sites. *CREB*, cAMP response element binding protein; R_q and R_o, extracellular GPCRs coupled to stimulation or inhibition of adenylyl cyclases (ACs), respectively. *Rq/11*, GPCR coupled to activation of phospholipase C (PLC), *MARCKS*, myristoylated-alanine-rich C kinase substrate, a protein associated with several neuroplastic events. Modified and reproduced, with permission from Payne, J. L. *et al.* Cellular biology of bipolar disorder. In *Neurobiology of Mental Illness*, Charney, D. S. and Nestler E. J. (eds). Oxford University Press, 2004.

antimanic agent valproate (VPA) produces effects very similar to those of lithium on PKC ∀ and on isozymes and MARCKS protein [79, 80]. Interestingly, lithium and VPA appear to bring about their effects on the PKC signaling pathway by distinct mechanisms. These biochemical observations are consistent with the clinical observations that some patients show preferential response to one or the other of the agents, and that one often observes additive therapeutic effects in patients when the two agents are co-administered.

In view of the pivotal role of the PKC signaling pathway in the regulation of neuronal excitability, neurotransmitter release, and long-term synaptic events, it was postulated that the attenuation of PKC activity may play a role in the antimanic effects of lithium and VPA. In a pilot study it was found that tamoxifen, a nonsteroidal anti-estrogen drug known to be a PKC inhibitor at higher concentrations, may possess antimanic efficacy [81]. Clearly, these results have to be considered preliminary, due to the small sample size thus far. However, in view of the preliminary data suggesting the involvement of the PKC signaling system in the pathophysiology of bipolar disorder, these results suggest that PKC inhibitors may be very useful agents in the treatment of mania. Larger double-blind, placebo-controlled studies of tamoxifen and of novel selective PKC inhibitors in the treatment of mania are warranted.

A crucial kinase that functions as an intermediary in numerous intracellular signaling pathways is the enzyme glycogen synthase kinase-3 (GSK-3). Given the evidence noted thus far of the importance of intracellular signaling pathways in bipolar disorders, GSK-3 may therefore play an important role in bipolar disorder research [82, 83]. GSK-3, a highly conserved enzyme in evolution, is found in two nearly identical isoforms (variations) in mammals, α and β. This enzyme was first discovered (and named) based on its ability to phosphorylate, and thereby inactivate, the enzyme glycogen synthase, an action that leads to a decrease in the synthesis of glycogen. GSK-3 is unique among kinases in that it is generally constitutively active, and thus most intracellular signals to GSK-3 inactivate this enzyme by phosphorylating it on its serine-9 residue, or, possibly, by inhibiting a putative phosphatase. Signals deactivating GSK-3 arise from insulin stimulation, numerous growth factors (e.g. phosphoinisitide [PI] 3-kinase), and developmental signals. A number of endogenous growth factors (e.g. nerve-growth factor and brain-derived neurotrophic factor [BDNF]) use the PI-3-kinase signaling cascade as a major effector system. Thus, growth factors may bring about many of their neurotrophic and/or neuroprotective effects, at least in part, by GSK-3 inhibition. GSK-3 phosphorylates — and thereby inactivates — many transcription factors, and modulates the function of cytoskeletal proteins such as the Alzheimer's disease protein tau (another name for GSK-3 is tau kinase). Inhibition of GSK-3 thus results in the release of this inhibition, and activation of multiple cellular targets.

Rapidly increasing evidence suggests that GSK-3 plays an important role in regulating neuroplasticity and cellular resilience. Studies have suggested that changes in GSK-3 mediated MAP-1B (a cytoskeletal protein) phosphorylation are associated with the loss and/or unbundling of stable axonal microtubules. Furthermore, GSK-3 inhibition results in the accumulation of synapsin I, a protein involved in synaptic vesicle docking and release of growth-cone-like areas.

In addition to its putative role in regulating synapse formation and axonal growth, there is considerable excitement regarding the role of GSK-3 in regulating cell death (apoptosis) in mature neuronal tissue, and the development of GSK-3 inhibitors as novel therapeutic agents for bipolar disorder and classical neurodegenerative diseases. Although it was initially reported that GSK-3 activity was required for β-amyloid-induced neurotoxicity in primary hippocampal neurons, this observation was not followed-up until very recently. More-current studies have demonstrated that GSK-3 may regulate cell death beyond its role in β-amyloid-induced toxicity. For example, GSK-3 overexpression induces apoptosis in cultured cells, which is prevented by dominant negative mutants. Furthermore, the expression of FRAT-1, a protein that inhibits GSK-3, also rescues primary sympathetic neurons from cell death induced by PI-3-kinase inhibition.

Activation of the HPA axis appears to play a critical role in mediating hippocampal atrophy. In addition to directly causing neuronal atrophy, stress and glucocorticoids also appear to reduce cellular resilience, thereby making certain neurons more vulnerable to other insults, such as ischemia, hypoglycemia, and excitatory amino-acid toxicity (see Ch. 32). The reduction in the resilience of hippocampal neurons may also reflect the propensity for various stressors to decrease the expression of BDNF in this region [84]. BDNF and other neurotrophic factors are necessary for the survival and function of neurons, implying that a sustained reduction of these factors could affect neuronal viability. Increasing evidence suggests that neurotrophic factors inhibit cell death cascades by (in large part) activating the mitogen activated protein (MAP) kinase signaling cascade, and up-regulating major cell survival proteins such as bcl-2 [85].

Bcl-2 is now recognized as a major neuroprotective protein, since bcl-2 overexpression protects neurons against diverse insults, including ischemia, the neurotoxic agent methyl-phenyl-tetrahydropyridine (MPTP), β-amyloid, free radicals, excessive glutamate and growth factor deprivation [86]. Accumulating data suggest that bcl-2 is not only neuroprotective, but also exerts neurotrophic effects and promotes neurite sprouting, neurite outgrowth and axonal regeneration [86]. If enhanced bcl-2 expression appears to be capable of offsetting the potentially deleterious consequences of stress-induced neuronal endangerment, then pharmacologically induced upregulation of bcl-2 may have considerable utility. Overall, it is clear

that the neurotrophic factor/MAP kinase/bcl-2 signaling cascade plays a critical role in cell survival in the CNS, and that there is a fine balance maintained between the levels and activities of cell survival and cell death factors. Modest changes in this signaling cascade or in the levels of the bcl-2 family of proteins (potentially due to genetic, illness, or insult-related factors) may therefore profoundly affect cellular viability.

Interestingly, pretreatment with pramipexole, a dopaminergic agonist agent, increased bcl-2 and inhibited methylphenylpyridinium-induced apoptosis in human neuroblastoma SH-SY5Y cells, and treatment of rats for 4 days with pramipexole markedly increased bcl-2 immunoreactivity in neuronal dendritic processes in both cerebral cortex and hippocampus. Our group recently demonstrated the antidepressant efficacy of this agent in a double-blind placebo-controlled study, in bipolar II depressed patients on therapeutic levels of lithium or valproate [87].

INTRACELLULAR CALCIUM SIGNALING STUDIES IN BIPOLAR DISORDER

Calcium ions play a critical role in regulating the synthesis and release of neurotransmitters, in neuronal excitability, and in long-term neuroplastic events, and it is thus not surprising that a number of studies have investigated intracellular Ca^{2+} in peripheral cells, particularly in bipolar disorder.

Impaired regulation of Ca^{2+} cascades has been found as the most reproducible biological measure abnormality described in bipolar disorder research. For this reason, mechanisms involved in Ca^{2+} regulation have been postulated to underlie aspects of the pathophysiology of bipolar disorder. To date, approximately 15 studies have consistently revealed elevations in basal intracellular Ca^{2+} levels in platelets, lymphocytes or neutrophils of patients with bipolar disorder. By contrast, there are only four negative studies. Although this may represent (in part) the phenomenon of publication bias, the elevation in basal Ca^{2+} represents one of the most replicated findings in bipolar disorder research. Higher platelet intracellular Ca^{2+} elevations have also been found in patients with bipolar disorder in response to stimulation with thrombin, platelet activator factor (PAF), serotonin, dopamine and thapsigargin. In lymphocytes, the same higher elevations were observed when the cells were stimulated with phytohemaglutinin, concavalin A, thrombin and (as in platelets) with thapsigargin and serotonin.

However, a few caveats to these positive studies should be noted. There is considerable evidence that a variety of circulatory factors may influence the activity of blood cells and elements, and bipolar disorder patients are known to have numerous neurohormonal abnormalities (such as catecholamine and cortisol level abnormalities). Furthermore, many of these studies did not employ an extensive medication washout period, raising the possibility that the elevations of Ca^{2+} in circulating cells are simply secondary manifestations. Yet, in an elegant series of studies, Epstein–Barr-virus-immortalized B lymphoblasts (BLCL) were grown in culture (away from the patients' confounding circulatory environment) for weeks. These studies found that even in the immortalized lymphoblasts, patients with bipolar disorder showed elevated basal Ca^{2+} concentrations compared with healthy subjects or patients with other psychiatric disorders. In an extension of these studies, these investigators examined the components of the storage-operated Ca^{2+} entry (SOCE), and found a reduction in the mRNA expression of the TRPC7 (TRPM2) gene (whose gene product is implicated in SOCE functioning), in BLCLs from a subgroup of bipolar disorder I patients [88].

The regulation of free intracellular Ca^{2+} is a complex, multi-faceted process (see Chs. 5 and 22), and the abnormalities observed in bipolar disorder could arise from abnormalities at a variety of levels. Ongoing studies should serve to delineate the specific regulatory sites at which the impairment occurs in bipolar disorder.

ANXIETY DISORDERS

The development of mild forms of anxiety and neurovegetative and/or cognitive responses to stress may represent an adaptive evolutionary step against environmentally (external) or self-triggered (internal) threats, but maladaptive reactions have also emerged in human evolution. Thus, anxiety disorders are maladaptive conditions in which disproportionate responses to stress, or even self-evoked responses, are displayed. Anxiety disorders are one of the most frequent psychiatric illnesses, and have a lifetime prevalence of 15– 20% [1, 89]. The most common presentations are generalized anxiety disorder, with a lifetime prevalence rate of close to 5% [1, 89]; social anxiety disorder, with very variable lifetime prevalence rates ranging from 2 to 14% [90]; panic disorder, with rates from 2 to 4% [1, 89]; and post-traumatic stress disorder (PTSD), with a prevalence rate close to 8%. Specific phobias, acute stress and obsessive–compulsive behavior are other clinical presentations of anxiety disorders.

Animal models of fear and anxiety have primarily used the rat, the mouse and, to a lesser extent, nonhuman primates. It is not particularly difficult to evoke or measure anxiety in these species. However, difficulties arise when one attempts to define exactly how a stimulus and resultant behavioral response are related to human behavior, i.e. when a mouse exhibits freezing behavior to an unfamiliar and threatening cue, what is the human equivalent? Or, similarly, what stimulus could one present to a rat to best model the anxiety-inducing-experience of

public speaking? The unique set of symptoms and physiological markers associated with each anxiety disorder makes the development of truly specific models difficult. There is also the extremely important distinction between models which simply measure the anxious response of normal animals exposed to pharmacological or other manipulations, as might be used to screen drugs or genes, and those which attempt to create a pathological model of abnormal behavior.

There are three generally accepted criteria for validating animal models for human psychiatric disorders: face validity, construct validity, and predictive validity. Face validity refers to the outward appearance of the model, i.e. does the animal's behavior adequately reflect the human behavior being modeled? In this dimension, anxiety models have a clear advantage over other psychiatric models; it is usually quite apparent if an animal is frightened, whereas it is a much more difficult to assess whether an animal is displaying psychotic-like or depressive-like behavior, for example.

Construct validity refers to the fundamental causality and etiology for the behavior. Again, animal models of anxiety perform relatively well in this regard; the purpose and underlying anatomical and neurochemical substrates of anxiety are well conserved. However, although the general modeling of fear and anxiety has both face and construct validity, models of specific disorders are much more meager in these respects.

Predictive validity is the ability of a model to predict the effect that pharmacological or other manipulations will have on the condition being modeled. This criterion can present a real difficulty, in that drug development is often dictated by animal models. For example, if a given model only detects a subset of effective compounds (i.e. those belonging to a specific chemical class), then useful candidates will be discarded long before clinical trials, and the flaw in the model's predictive validity will not be discovered. Thus, the possibility that a model will yield false negatives cannot be ruled out.

Currently, a wide variety of methods are employed to measure animal anxiety. In rodents, the most commonly used measures employ these animals' natural fear of brightly lit, open spaces. Measures may include exploratory behavior and social behaviors (in the social interaction test), with the expectation that such behaviors will decrease as anxiety increases. Advantages of these methods, including light–dark exploration and open-field tests, lie primarily in their ease of use. These models have had great predictive validity for benzodiazepines and barbiturates, but have been only marginally successful in detecting the serotonergic and noradrenergic anxiolytics (anti-anxiety drugs). These methods are also currently enjoying great popularity in the behavioral testing of transgenic and knockout mice (mice with genes added or removed, respectively).

In operant conflict models, animals are trained to respond for a reward, such as food. The reward is subsequently paired with a punishment (e.g. foot shock), causing a reduction in response frequency. The degree to which the animal ceases to respond is thought to reflect its anxiety about receiving punishment. The predictive validity of this method is somewhat better than the elevated-plus-maze and social interaction measures, in that chronic administration of antidepressants or serotonin $(5\text{-HT})_{1A}$ partial agonists results in an anxiolytic effect, at least in rats. Furthermore, the requirement for chronic treatment with these drugs appears to be preserved in this model. However, the long training periods and specialized equipment required for this technique makes it impractical for many laboratories.

Ultrasonic vocalizations are emitted by rat pups (under the age of 14 days) when they are isolated from their mother, and are thought to reflect anxiety. This measure has proven sensitive to both anxiolytic and anxiogenic manipulation of GABA neurotransmission. However, the early developmental window used is problematic, in that chronic drug administration probably results in a variety of compensatory changes not seen in adulthood, and may alter development of relevant brain systems. Indeed, in contrast to the clinical situation, the antidepressant clomipramine has acute, but not chronic, anxiolytic efficacy in this model.

Nonhuman primates offer another, although clearly much more difficult, avenue to investigate fear and anxiety [91]. The interspecies variation in neurobiology and behavior is substantially reduced compared with rodents. A variety of measures to test anxiety have been developed, using stressors such as social isolation, conspecific (of the same species) intruders, extraspecific (human or predator) threat, and pharmacological anxiogenesis. These models have demonstrated validity, and may be especially valuable in the later stages of preclinical drug development.

Animal models thus allow us to study the biology of anxiety behavior, and the manipulation of that behavior through environmental, pharmacological and genetic mechanisms. However, the ability of these models to adequately replicate the character and diversity of human anxiety disorders is far from clear. Given the rapid advancement of techniques for probing human brain function *in vivo*, we will increasingly be able to discern disorder-specific biology, and thereby develop more valid animal models.

Transgenic and knockout mice are employed to investigate the genetics of anxiety. The recent ability to manipulate the genome of mice — either through adding a gene (transgenic) or removing a gene (knockout) — has enabled an entirely novel type of study: relating a particular gene directly with a particular behavior. Using these genomic manipulation strategies in animals, a large number of genes have been implicated, to some degree, in the pathophysiology of anxiety in humans.

In principle, the knowledge that can be gained by genome manipulation is impressive. Given sufficient knowledge

about both the gene and the behavior(s) in question, it is possible to simultaneously investigate in a 'top-down' and 'bottom-up' fashion; in other words, one may proceed upward from the gene function level to the cell biology and physiology level (bottom-up), or proceed downward from the behavioral to systems and circuit-level neuroscience (top-down). In this way, one may aggressively approach from two different directions the complex problem that is the relationship between genes and behavior (see also Learning and Memory, Ch. 53).

However, genes and behaviors cannot be associated on a simplistic, one-to-one basis; the true relationship between a gene and a behavior is probably closer to chaos theory's 'sensitive dependence on initial conditions'. For example, there is presumably no gene for language; there are a number of genes which pattern the embryonic brain in such a way as to facilitate, and allow the physiological processes necessary for, language acquisition. In a similar regard, no single gene has been found to code for a human psychiatric condition. It is more likely that susceptibility genes interact with developmental factors, both day-to-day and profound environmental events, epigenetic DNA modifications, and possibly entirely stochastic mechanisms, eventually leading to the development of normal and abnormal human behaviors.

Although many difficulties exist in the interpretation of knockout and transgenic studies, one of the most troubling is the relative role of immediate versus developmental and adaptive effects. Many knockout gene studies have been interpreted in much the same way as a pharmacological manipulation, assuming that the only difference between the wild versus the experimental animal is the presence or absence of a specific protein. In truth, the actual effect of a gene knockout can be far-reaching and highly complex. Given the universality of homeostatic regulation in biology, from the intracellular to the organism level, it is almost inevitable that adaptations will occur in the chronic absence of a particular gene. Furthermore, the consequences of developmental absence are almost certainly even more profound. The recent use of *conditional knockouts*, in which gene expression is only altered in particular anatomical regions and/or during particular times, has illustrated this point quite clearly and has simultaneously offered a solution. Perhaps the most relevant example to the field of anxiety comes from genetic studies of the 5-HT_{1A} receptor.

The 5-HT_{1A} receptor, as a target of many useful anxiolytic agonists, has been studied more than any other gene in the context of anxiety research. As might be expected, most knockout studies have reported increased anxiety-like behavior in the mutant animals. Seemingly, these data support a very simple, pharmacological view-that 5-HT_{1A} activation counteracts anxiety. However, the recent work of Gross and colleagues has placed this interpretation in doubt [122]. Using a knockout/rescue approach with regional and temporal specificity, it was demonstrated that the anxiety-related effect of the 5-HT_{1A} receptor knockout was actually developmental. Specifically, 5-HT_{1A} receptor expression limited to the hippocampus and cortex during early postnatal development was sufficient to counteract the anxious phenotype of the mutant, even though the receptor was still absent in adulthood. Thus, pharmacological, genetic, and developmental effects of the 5-HT_{1A} receptor on anxiety appear to be distinguishable. In conclusion, although there is no debating the usefulness of genetic manipulation, the interpretation of behavioral genetics studies must be thoughtful and cautious.

There are undoubtedly many developmental insults, genetic and otherwise, that can alter the expression of anxiety-related behaviors. The dissection of a gene's role in anxiety must include the acute, adaptive, compensatory, and developmental effects. For further discussion of the genetic approaches to animal anxiety, the reader is referred to several recent reviews [92–94].

Neurotransmitters and neuropeptides have been implicated in fear and anxiety. Much of our knowledge of the human neural substrates of fear and anxiety is derived from pioneering work using cat and rodent models. As techniques have advanced, our understanding of the anatomy, neurochemistry and physiology of these responses has progressed. In particular, the development of functional imaging techniques has allowed us to confirm that observations made in a number of animal species may also apply to humans.

The fear response necessarily begins with perception. Most sensory information is relayed via the thalamus to the sensory cortices, which are responsible for recognition and cognitive appraisal of a threat. Two exceptions to this pathway are olfactory input, which may reach the amygdala and entorhinal cortex directly, and visceral organ input, which proceeds from nuclei in the brainstem to the locus ceruleus (LC). The LC appears to have several roles that are important in the regulation of anxiety. On one level, noradrenergic efferents appear to have a key role in regulating the peripheral sympathetic response; LC firing appears necessary for the generation of a physiological response to anxiogenic stimuli. Additionally, the LC, perhaps as a mediator of sensory information in the cortex-to-thalamus pathway, also plays a role in directing attention towards salient, threatening stimuli. Notably, there is evidence that the release of corticotrophin releasing hormone (CRH) in the LC is necessary for the enhanced firing seen in high-anxiety conditions.

The amygdala is perhaps the best-studied, and most strongly implicated, brain structure in anxiety and fear. Electrical stimulation of the amygdala produces fear-like behavioral and physiological responses in animals, and increases the suggestive experience of fear in human subjects. Additionally, amygdala stimulation leads to corticosterone secretion and HPA-axis activation in animals, probably via outputs to the hypothalamus and the bed nucleus of the stria terminalis. It has been suggested

that the amygdala may represent a sort of 'master switch' of fear, which projects to a variety of areas. This unitary-mediator hypothesis explains the constellation of behavioral and physiological responses that concur so consistently.

Multiple studies suggest that particular pharmacological agents often provoke symptoms of anxiety in susceptible individuals. These agents can be generally classified into two categories: (a) those that reduce available oxygen, and appear to act on peripheral areas, and (b) those that directly manipulate neurotransmitter systems. A number of pharmacological agents have been noted to increase anxiety (generally measured as panic symptoms in patients with panic disorder) in susceptible individuals.

In one sense, these findings provide important clues in understanding the underlying neurobiology of anxiety disorders. However, the broad spectrum of agents that can produce anxiety symptoms makes it difficult to define one system, or pathway, in the brain most responsible for anxiety. It is possible, however, to broadly define the targets of compounds that may have general mechanisms of action. In this regard, carbon dioxide, sodium lactate and bicarbonate fall into the first category — all act peripherally, resulting in increased respiration, heart rate, and other signs of sympathetic nervous system activity. These mechanisms of action helped form a hypothesis in which patients with anxiety disorders may interpret physiological changes (such as increased heart rate, increased respiration, etc) as more serious than they really are, and thus the patients respond with increasing anxiety.

It may be that any peripherally adverse stimulus — especially one that stimulates sympathetic activity — thus has the potential to activate brain areas of prime importance in the formation of anxiety symptoms. As a result of pharmacological challenge studies, biochemical assays, neuroimaging and studies of animal models, a number of centrally acting neurotransmitters, and their relevant neural circuits, are implicated in anxiety. These neurotransmitters include norepinephrine, serotonin, GABA, neuropeptide Y, cholecystokin and substance P.

Noradrenergic systems. Preclinical studies using pharmacological manipulation and electrical stimulation have suggested the involvement of norepinephrine and the LC in anxiety- and fear-like behaviors. The strongest human evidence comes from studies of the anxiogenic and anxiolytic properties of centrally acting selective noradrenergic drugs, some of which exert these actions by increasing LC activity. The selective β-agonist isoproterenol induces anxiety and panic attacks in some patients. However, directly attributing the effects of isoproterenol to enhanced central β-adrenergic receptor throughput is problematic, because this drug does not appear to cross the blood–brain barrier. NE receptors are discussed in Ch. 12.

More direct evidence of noradrenergic effects comes from studies using the α2 antagonist, yohimbine. α2 adrenergic receptors are known to be present on the cell bodies and terminals of norepinephrine neurons, where they regulate the firing rate and amount of norepinephrine released per nerve impulse respectively. Thus, blockade of α2 receptors has been clearly established to increase the firing on LC norepinephrine neurons, as well as norepinephrine release. In patients with panic disorder, yohimbine increases anxiety and the frequency of panic attacks compared with controls, effects which have been attributed to enhanced LC firing and norepinephrine release [95, 96]. Consistent with the behavioral data are neurobiological data showing that yohimbine increases cardiovascular responses and plasma MHPG and cortisol in panic patients relative to control subjects. Yohimbine has also been reported to produce a decrease in frontal blood flow in this patient population, effects which were not seen in control subjects.

Additional pharmacologic support for the role of the LC norepinephrine system in mediating anxiety symptoms comes from studies using clonidine, a centrally active α2 receptor agonist, which decreases LC firing and norepinephrine release. Thus, clonidine has been shown to have some efficacy in the treatment of anxiety and in both spontaneous and induced panic disorder. Interestingly, the beneficial effects of clonidine subside over time, perhaps due to desensitization of the α2 receptor with continued stimulation by a direct agonist. Furthermore, clonidine administration results in a greater degree of hypotension and larger reductions in plasma MHPG in patients with panic disorder relative to control subjects, raising the possibility of altered α2 receptor sensitivity in panic disorder. Consistent with such a contention, norepinephrine and its metabolites measured in urine, blood and CSF are elevated in panic disorder, PTSD, specific phobias, social anxiety and GAD, suggesting a dysregulation of the central and peripheral norepinephrine systems.

It has been postulated that the inhibitory inputs from the frontal cortex to limbic regions may be disrupted in anxiety disorders, resulting in unrestrained amygdala activity, which results in an increase in anxiety. In this context, yohimbine decreases metabolism in the cortical brain areas in PTSD patients, whereas in control subjects cerebral metabolism is increased. Additionally, as mentioned, functional studies in panic disorder suggest an abnormal blood flow following administration of agents that result in panic symptoms. In addition to yohimbine [97], these studies have also been performed with lactate infusion. These findings in the cortex are consistent with the model by which cortical input to the amygdala provides a 'top down' inhibition that is lacking in patients with anxiety disorders — and functions as a contributor to anxiety in patients. Also consistent with these data is the general finding that while low levels of anxiety increase cortical metabolism in humans, high levels of anxiety have been shown to decrease it [98, 99]. Thus, abnormal cerebral metabolism in anxiety may allow for abnormal amygdala activity. In this regard, recent preclinical work in rats has shown that stimulating specific areas of the medial PFC can increase the extinction of fear responses [100].

Serotonergic systems. Evidence on several levels implicates the serotonergic system in the treatment of anxiety, although not conclusively. The raphe nuclei presumably play an important role in the serotonergic aspects of fear and anxiety. An excitatory projection from the LC to the dorsal raphe may be important in the serotonin release observed in the PFC, amygdala, and hypothalamus in response to anxiogenic stimuli. Additionally, projections from the dorsal raphe also extend to and inhibit the LC, suggesting a possible negative-feedback mechanism. Chronic, but not acute, SSRI administration suppresses LC firing in rats. The medial raphe may also have some opposing effects; there is some evidence that output from this nucleus to the dorsal hippocampus acts to increase stress resistance [101], whereas LC projections to the medial raphe suppress its firing.

A number of medications used in the treatment of anxiety have effects on serotonin neurotransmission (Ch. 13). These medications include tricyclic antidepressant medications, SSRIs, and monoamine oxidase inhibitors (MAOIs). However, because these medications take weeks to exert their full anxiolytic effects, it is unlikely that blocking the reuptake (and thus increasing synaptic levels) of either serotonin or norepinephrine selectively is responsible for their anxiolytic properties — rather it is suspected that the therapeutic effects are due to changes in gene expression, protein levels, and eventually changes in synaptic connections between neurons.

In spite of the large number of medications that target serotonin neurotransmission, consistent evidence implicating serotonin neurotransmission in the pathophysiology of anxiety is lacking. As reviewed in refs [102] and [103], markers of the density and/or activity of serotonin reuptake transporters has been found to be increased, unchanged or decreased in panic disorders, depending on the study and experimental conditions. Furthermore, the application of pharmacological challenges to patients with anxiety disorders has been almost equally ambiguous. Thus, responses to serotonin precursors (such as L-tryptophan and 5-hydroxytryptophan) do not appear to be different between control subjects and those with panic disorder, or to be anxiogenic. Challenges with other more direct serotonin agonists are also inconclusive. In this regard, the 5-HT-releasing agent fenfluramine has been reported to be anxiogenic and produce greater increases in plasma prolactin and cortisol in patients with panic disorder compared with control subjects. The 5-HT agonist m-chlorophenyl-piperazine (mCPP) has been shown to increase anxiety and plasma cortisol in some studies of panic-disorder patients compared with control subjects. Tryptophan depletion in anxiety disorders has also not been generally informative. Indirect evidence also implicates serotonergic dysfunction in PTSD, but more work needs to be done [102, 103].

GABA. The GABA system is the primary target for the acute treatment of anxiety. The benzodiazepines (BDZs) function by binding to a potentiator site on the GABA-A receptor, increasing the amplitude and duration of inhibitory postsynaptic currents in response to GABA binding (see Ch. 16). Unfortunately, the BDZs have significant negative side-effects, including sedation, cognitive impairment and addictive liability. Our growing understanding of the GABA system may enable us to design more tolerable medications.

The GABA-A receptor displays enormous heterogeneity; it is composed of a combination of five subunits, of which there are at least 18 subtypes. The various receptors display variation in functional pharmacology, hinting at the multiple, finely tuned roles that inhibitory neurotransmission plays in brain function. The majority of GABA-A receptors in the brain are targets of diazepam and other BDZs. For this reason, there has been considerable interest in determining if the desirable and undesirable effects of BDZs might be based on the differing receptor subtypes.

Much work has been focused in this direction, particularly using gene knockout technology. For instance, mutation of the BDZ-binding site of the GABA-A ∀-1 subunit in mice blocks the sedative, anticonvulsive, and amnesic, but not the anxiolytic, effects of diazepam. In contrast, the ∀-2 subunit (expressed highly in the cortex and hippocampus) is necessary for diazepam anxiolysis and myorelaxation. Thus, there is now optimism that an ∀-2 selective ligand will soon provide effective, acute treatment of anxiety disorders without the unfavorable side-effects profile of current BDZs. A compound with this preferential affinity has already been demonstrated to exert fewer sedative and depressant effects than diazepam in rat behavioral studies.

It is believed that novel medications under development will specifically target subtypes of GABA receptors, resulting in medications that are more specific for anxiety, and that have fewer side-effects. Current GABAergic drugs exert their actions almost immediately upon initiation of treatment, and there is optimism that novel medications of this class will also have immediate effects, thereby circumventing one of the primary problems of many current anxiolytic drugs, namely the delay in onset of action. For more on the pharmacology of benzodiazepines, see [104].

CRH and stress axes. The HPA axis is a major pathway by which stress exerts its effects on the brain and the rest of the body. The HPA axis is also believed to be relevant to development of anxiety and anxiety disorders [105]. In the HPA axis pathway, the lateral ventricular nucleus of the hypothalamus releases CRH, which stimulates the production of ACTH by the pituitary gland. This hormone (ACTH) stimulatesthe production of cortisol by the adrenal gland. Cortisol is considered a primary stress hormone of the body, having varied effects on metabolism, neurovegetative behaviors of organisms, and on functions of neurons and neuronal systems. A primary receptor for cortisol — the glucocorticoid receptor — is localized to many brain regions important in the stress response, including a high density of receptors in the hippocampus.

CRH and its receptors have generated increasing interest as a target for medications. In addition to the pituitary, CRH receptors have been localized to the cortex, the nuclei of the amygdala, the LC, and regions of the hypothalamus. It has also been reported that CRH increases LC activity, and that local injection of CRH into the LC increases behavioral responses consistent with increased anxiety [105]. Furthermore, CRH antagonists have been repeatedly shown to have anxiolytic effects in animal models.

Supporting the notion of an overactivation of the HPA axis in anxiety, are a number of clinical studies suggesting that patients with PTSD have a smaller hippocampal volume than matched control subjects, a finding that is consistent with what has been observed in animal models of stress. To date, no quantitative neuro-imaging studies have been performed in panic disorder, phobic disorder or generalized anxiety disorder — but a single study does suggest the presence of abnormalities in the temporal lobe in panic disorder [103, 106]. Studies also suggest an increase in cortisol release in response to stress in PTSD and panic disorder. Furthermore, a generally consistent finding is a chronic increase of CRH in patients with anxiety. Additional studies suggest changes in other mediators of the HPA axis, but these are generally less consistent.

A great deal of effort has gone into the development of antagonists to the type 1 and 2 CRH receptors, because CRH agonism has proven anxiogenic in a variety of animal models, and CRH antagonists have demonstrated anxiolytic properties in rodent and primate studies, and even in a preliminary clinical study for depression [107]. Drugs targeting the CRH family of ligands and receptors are perhaps the most promising new class of anxiolytics and antidepressants. The orally active CRH antagonist, antalarmin, significantly reduces fear and anxiety responses in nonhuman primates and may be a candidate for further development. Several pharmaceutical companies have developed substituted-pyrimidine small-molecule CRH antagonists [108]. Clinical trials are underway to examine the efficacy of these treatments in depression, and it is likely that complementary trials for the treatment of anxiety will also be undertaken. Targeting glucocorticoid receptors may also represent a possible mechanism to prevent stress-mediated neuronal plasticity changes.

Thus, the evidence that stress, and the stress hormone corticosterone, may cause changes in hippocampal structure, hippocampal connections, and changes in gene and protein expression, suggest that viable targets of anxiolytic agents are cellular signaling pathways involved in neuroplasticity and the maintenance of cellular resilience.

Neuropeptide Y (NPY) and its receptors may also be important in the regulation of anxiety and stress. NPY is synthesized in the arcuate nucleus, which receives LC input. In a number of rodent models, NPY administration has anxiolytic and, at somewhat higher doses, sedative effects. Likewise, NPY antagonizes CRH-induced stress responses, and suppresses LC firing when injected into the brainstem. There is some evidence to suggest that NPY is low under unstressed conditions, but is stimulated as a counteradaptation to stress. Additionally, NPY projections to the central amygdala, the nucleus accumbens, septum, periaqueductal gray (PAG), hippocampus and other regions, may also be involved in NPY anxiolysis. As our understanding of the differing roles played by the various NPY receptors improves, NPY receptor agonists are likely to become a goal of anxiolytic development [109].

Cholecytokinin (CCK) is another neuropeptide with importance to anxiety disorder research. CCK-B receptor agonists reportedly have an anxiogenic effect in animals, and are anxio- and panico-genic in normal subjects and panic disorder patients (patients are more sensitive). Likewise, suppression of CCK-B receptor expression or pharmacological antagonism blocks the acquisition of conditioned-fear response. However, CCK antagonists have yet to succeed in clinical trials [110]. Nevertheless, the CCK system remains an attractive target for drug development, particularly for panic disorders.

Substance P. The neuropeptide substance P (Sub P) binds to the neurokinin-1 receptor (NK-1; also known as tachykinin-1 receptor). Although originally targeted as a nociceptive pathway, antagonists of this receptor may exert anxiolytic and antidepressant effects. There is also evidence for an anxiolytic effect of Sub P when it is injected into the cholinergic nucleus basalis magnocellularis, suggesting region-specific effects. Furthermore, NK-1 activation in the hypothalamus inhibits CRH secretion. Several NK-1 antagonists appear anxiolytic in animal studies, and in a preliminary clinical trial, the antagonist MK-869 was found to be as effective as paroxetine in treating anxiety and depression. For additional discussion about the potential usefulness of NK-1 antagonists, see [111].

INTRACELLULAR TARGETS FOR ANXIETY DISORDERS

Whereas genetic and pharmacological studies have focused predominantly on the receptors, transporters and metabolic enzymes of neurotransmitters already implicated in anxiety, there also exists a more diverse group of gene knockouts with anxiety-related phenotypes. A number of animal studies have investigated anxiety-like behavior in knockouts of key intracellular signaling enzymes, including calcium/calmodulin-dependent protein kinase-II (CaMK-II) α, adenylate cyclase type VIII, and PKC ε and γ. These studies raise the possibility that pharmacological manipulation of signaling cascades within cells might be exploited in the development of new anxiolytics.

Studies of PKC and anxiety provide a particularly good example. The knockout of either the ε or γ isoform confers resistance to anxiety and potentiates the action of benzodiazepines. Furthermore, PKC inhibition may have

anxiolytic effects in humans; in a study of psychosocial functioning in women on long-term tamoxifen, which possesses both PKC- and estrogen-inhibiting properties, there was a statistical trend towards reduced anxiety in the treatment group. Likewise, valproic acid, an anticonvulsant and mood stabilizer that reduces expression of several PKC isoforms, may have efficacy in the treatment of panic disorder [112] and PTSD [113]. The specific roles of PKC isozymes in anxiety behavior require study, but specific inhibitors may someday serve as anxiolytics or anxiolytic-potentiators.

Inositol, the building block of the phosphoinositide intracellular signaling pathway, has been examined as a potential anxiolytic. In clinical trials, inositol has reported to be effective in both panic disorder [114, 115] and depression [116], and animal data are also favorable. Because of inositol's status as a dietary supplement, there is little financial backing for studies of its efficacy and safety. The mechanism of action of inositol is not entirely clear, but it is believed to facilitate phosphoinositide-signaling-coupled neurotransmission.

FUTURE DIRECTIONS AND THE DEVELOPMENT OF NOVEL THERAPEUTICS

This chapter describes neurobiological findings that are generating considerable scientific excitement about the development of novel agents for the treatment of mood and anxiety disorders. Most notably, there is a considerable body of evidence — both conceptually and experimentally — suggesting that impairments in neuroplasticity and cellular resilience are demonstrable in certain mood and anxiety disorders. Thus, in addition to a variety of neurochemical changes, many patients also have pronounced structural alterations (e.g. reduced spine density, neurite retraction, overall neuropil reductions, and/or volumetric changes on neuroimaging measures) in critical neuronal circuits. Therefore, for these disorders, optimal treatment may only be attained by providing both trophic and neurochemical support. The trophic support would enhance and maintain normal synaptic connectivity, thereby allowing the chemical signal to reinstate the optimal functioning of critical circuits necessary for normal affective functioning. It is thus noteworthy that many novel strategies currently being investigated for these disorders — including CRH antagonists, GR antagonists, glutamatergic agents, and phosphodiesterase inhibitors — can be conceptualized as 'plasticity enhancers', which would be expected to exert trophic effects in addition to their effects on specific neurochemical systems.

It is hoped that our ever-expanding knowledge of the neurobiology of anxiety and anxiety disorders will yield entirely new pharmacological approaches to the treatment of these disorders. Despite some concerns with their validity, animal models continue to provide a useful screening mechanism for the development of novel anxiolytics. There are presently a number of promising new targets for anxiety disorders, and a new generation of drugs directed at some of these may come to market in the coming years. Traditionally, the neurochemical systems targeted in the treatment of anxiety disorders have been GABA, serotonin, and norepinephrine. Continuing the development of drugs modulating these transmitters will probably yield modestly more effective and/or better-tolerated medications. However, the results achieved with more innovative targets mentioned above promise both markedly better drugs and a more sophisticated understanding of pathological anxiety. Nongenetic mechanisms of gene regulation, termed epigenetic, probably play a role in the formation of cellular memory and the modulation of neural circuitry. The interplay of transcription factors interacting with covalent DNA modifications is probably involved in modulating how previous experience may regulate subsequent behavioral responses. In conclusion, emerging results from a variety of clinical and preclinical experimental and naturalistic paradigms suggest that a reconceptualization about the pathophysiology, course and optimal long-term treatment of severe mood and anxiety disorders may be warranted. An increasing number of strategies are being investigated to develop small-molecule agents to enhance cellular plasticity; this progress holds much promise for the development of novel therapeutics for the long-term treatment of these devastating disorders.

Addiction

Marina E. Wolf

GENERAL PRINCIPLES 911
Addiction is characterized by compulsive drug use, despite severe negative consequences 911
Many forces may drive compulsive drug use 912

NEURONAL CIRCUITRY OF ADDICTION 912
Natural reinforcers and drugs of abuse use similar circuits 912
The neuronal circuitry underlying drug craving has been intensely studied to develop strategies for preventing relapse 912

OPIATES 914
Opiates are drugs derived from opium, including morphine and heroin 914
There are three classical opioid receptor types, μ, δ, and κ 914
Chronic opiate treatment results in complex adaptations in opioid receptor signaling 915
Upregulation of the cAMP second-messenger pathway is a well-established molecular adaptation 916
Endogenous opioid systems are an integral part of the reward circuitry 916

PSYCHOMOTOR STIMULANTS 916
This drug class includes cocaine and amphetamine derivatives 916
Transporters for dopamine (DAT), serotonin (SERT) and norepinephrine (NET) are the initial targets for psychomotor stimulants 916
Cocaine and amphetamines produce neuronal adaptations by repeatedly elevating monoamine levels 917
Dopamine receptor signaling through the PKA pathway mediates many effects of psychomotor stimulants 918

CANNABINOIDS (MARIJUANA) 919
Marijuana and hashish are derivatives of the cannabis sativa plant 919
Cannabinoid effects in the CNS are mediated by the CB1 receptor 919
Endocannabinoids are endogenous ligands for the CB1 receptor 919
Endocannabinoids serve as retrograde messengers 920
There are many similarities between endogenous opioid and cannabinoid systems 921

NICOTINE 921
Nicotine is responsible for the highly addictive properties of tobacco products 921
Nicotine is an agonist at the nicotinic acetylcholine receptor (nAChR) 921
The ventral tegmental area (VTA) is a critical site for nicotine action 921

ETHANOL, SEDATIVES AND ANXIOLYTICS 922
Alcoholism is a chronic relapsing disorder 922
Ethanol interacts directly with ligand-gated and voltage-gated ion channels 922
Multiple neuronal systems contribute to the reinforcing effects of ethanol 922
There is a need for improved therapies for alcoholism 922
Barbiturates and benzodiazepines are used to treat anxiety 922

HALLUCINOGENS AND DISSOCIATIVE DRUGS 923
Hallucinogens produce an altered state of consciousness 923
Phencyclidine (PCP) is a dissociative drug 923

ADDICTION AND NEURONAL PLASTICITY SHARE COMMON CELLULAR MECHANISMS 923
Addiction may result from inappropriate neuronal plasticity 923
Studies of behavioral sensitization have linked addiction to long-term potentiation (LTP) 924
Drugs of abuse have profound effects on transcription factors and gene expression 924
Persistent adaptations may involve changes in the structure of dendrites and dendritic spines 924

GENERAL PRINCIPLES

Addiction is characterized by compulsive drug use, despite severe negative consequences. It follows a chronic course, with periods of abstinence followed by relapse. Vulnerability to relapse can persist even after years of abstinence, suggesting that long-lasting and perhaps permanent neurobiological changes underlie addiction. There are tremendous individual differences in vulnerability, reflecting both genetic and environmental influences, and many people experiment with potentially addictive drugs without progressing to compulsive use. Nevertheless, substance abuse accounts for more deaths, illnesses and disabilities than any other preventable health condition. Approximately one in four of all deaths in the U.S.A. are attributable to the use of alcohol, nicotine or illicit drugs [1].

Long-term drug exposure produces many physiological and behavioral changes that contribute to addiction. *Tolerance* is the need for increasing doses of a drug to

Basic Neurochemistry: Molecular, Cellular and Medical Aspects
0-12-088397-X

achieve the same effect. *Sensitization* refers to the enhancement of drug responses as a result of repeated drug exposure. For a given drug, it is possible for certain effects to show tolerance and others to show sensitization. *Dependence* is an adapted physiological state of cells or systems that develops to compensate for excessive stimulation by a drug. When drug intake stops, unmasking of this adapted state leads to a *withdrawal syndrome* that may have somatic (physical) components as well as affective and motivational components.

Many forces may drive compulsive drug use. The incentive-sensitization theory of addiction proposes that sensitization occurs in the neural systems that attribute incentive salience to drugs and drug-associated cues [2]. Drug 'wanting' sensitizes, even though drug 'liking' typically shows tolerance. Alternatively, addiction has been characterized as a spiraling cycle of hedonic dysregulation driven by many factors but with an important role ascribed to negative affective states that occur during periods of drug abstinence [3]. Other theories emphasize the role of learning in addiction, based on the ability of drugs to facilitate some forms of learning and trigger neuroadaptations also seen in learning. Abnormally strong forms of learning are proposed to underlie habitual behaviors associated with addiction [4–6]. Finally, drugs may produce dysregulation of cortical systems that normally exert inhibitory control over behavior, leading to poor decision-making and impulsivity, which in turn drive compulsive pursuit of drugs [7]. These theories are not mutually exclusive. Different factors may contribute at different times in the cycle of addiction.

NEURONAL CIRCUITRY OF ADDICTION

Natural reinforcers and drugs of abuse use similar circuits. Drugs of abuse — like food, drink and sex — are reinforcing. That is, they 'stamp in' or 'reinforce' learned associations, such that behaviors associated with obtaining the reinforcer tend to be repeated. Different drug classes have different initial targets in brain (Fig. 56-1). However, a common mechanism underlying the reinforcing actions of most addictive drugs — and those of natural reinforcers — is activation of mesocorticolimbic dopamine neurons (Ch. 12). These neurons originate in the ventral tegmental area (VTA) of the midbrain and project to cortical and limbic target regions (Fig. 56-2). Elevation of dopamine levels in one of these target regions, the nucleus accumbens, is particularly important for reinforcement. The nucleus accumbens serves as an interface between limbic and cortical regions important for motivation, and motor circuits responsible for execution of motivated behaviors. Dopamine neurons in the substantia nigra, which project primarily to dorsal striatum, are also important, particularly in the learning and performance of habitual behaviors associated with addiction.

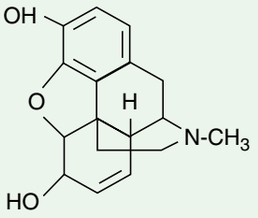
The exact role of dopamine in reinforcement remains an active area of research [8–10]. According to the incentive-sensitization theory of addiction (above), dopamine signals the incentive salience attributed to drugs and drug associated cues, causing them to be 'wanted' [2]. Another influential theory holds that activation of dopamine neurons is important in learning and predicting the likelihood of reward when an animal is presented with reward-related stimuli [11]. Thus, a normal function of dopamine may be to enable reward-related stimuli to shape behavior, and so promote the learning of adaptive behaviors that enable survival.

While dopamine neurons are activated to a modest degree by natural rewards, drugs of abuse produce a much stronger elevation in dopamine levels that may not be subject to normal regulatory mechanisms. For example, dopamine released by natural rewards will be removed from the synapse by the dopamine transporter. However, cocaine works by blocking this transporter, so cocaine produces larger and more prolonged increases in dopamine levels. Other drugs activate dopamine neurons through indirect mechanisms depicted in Figure 56-3. The unregulated release of dopamine initiates compensatory changes in dopamine-receptive neurons that lead to a chain reaction of molecular and cellular adaptations throughout the circuits depicted in Figure 56-2. A major challenge is to understand the relationship between these adaptations and the behavioral changes that characterize addiction. One reason for the difficulty is the sheer number of adaptations that have been described, encompassing signal transduction, gene expression and structural changes. Further complicating the picture, some adaptations reduce drug responsiveness, favoring homeostasis, while others increase drug responsiveness in a feed-forward manner. The molecular and cellular adaptations that underlie addiction are discussed in more detail in subsequent sections of this chapter.

The neuronal circuitry underlying drug craving has been intensely studied to develop strategies for preventing relapse. Drug craving in human addicts, and the reinstatement of drug-seeking behavior in animal models of relapse, can be triggered by three types of stimuli: cues associated with prior drug use (such as drug paraphernalia), re-exposure to a low dose of drug and exposure to stress. Animal studies have shown that these stimuli trigger reinstatement of drug-seeking through distinct but overlapping neuronal circuits [12]. For example, the basolateral amygdala is critical for the ability of conditioned cues to maintain and reinstate drug-seeking behavior [13, 14]. Cocaine-primed reinstatement requires activation of glutamate projections from the prefrontal cortex to the nucleus accumbens [12]. Stress-induced reinstatement involves brain corticotrophin-releasing factor (CRF) and norepinephrine systems [15]. Stress also contributes to other aspects of addiction. For example, stress increases the rate at which rats will learn to

A. Opiates

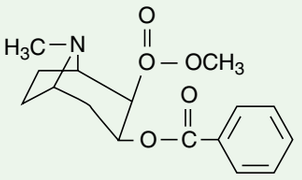
Morphine



Primary target: μ opioid receptor

B. Psychostimulants

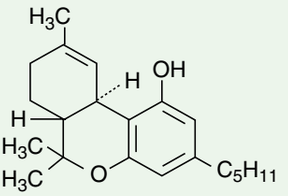
Cocaine



Primary target:
Monoamine transporters

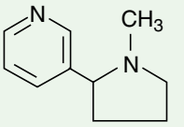
C. Cannabinoids

Δ^9-tetrahydrocannabinol



Primary target:
Cannabinoid CB1 receptor

D. Nicotine



Primary target:
Nicotinic acetylcholine receptor

E. Alcohol

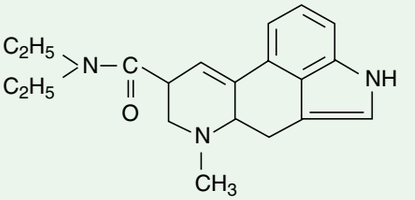
Ethanol

$H_3C - CH_2 - OH$

Primary target:
Ligand gated and voltage gated ion channels

F. Hallucinogens

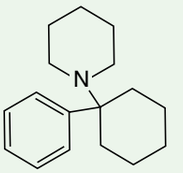
Lysergic acid diethylamine



Primary target:
Serotonin receptors

G. Dissociative Drugs

Phencyclidine



Primary target:
NMDA receptor

self-administer addictive drugs [16]. After chronic administration of many drugs of abuse, including heroin, cocaine and ethanol, there are profound adaptations in brain, hypothalamic and pituitary stress systems. These adaptations contribute importantly to dependence and withdrawal [17].

Functional imaging studies (Ch. 58) in human addicts have found that cue-elicited craving is associated with activation of the amygdala, the anterior cingulate cortex, the orbitofrontal cortex, and the dorsolateral prefrontal cortex [18]. Activation of other regions has been reported less consistently. The amygdala is critical for associative

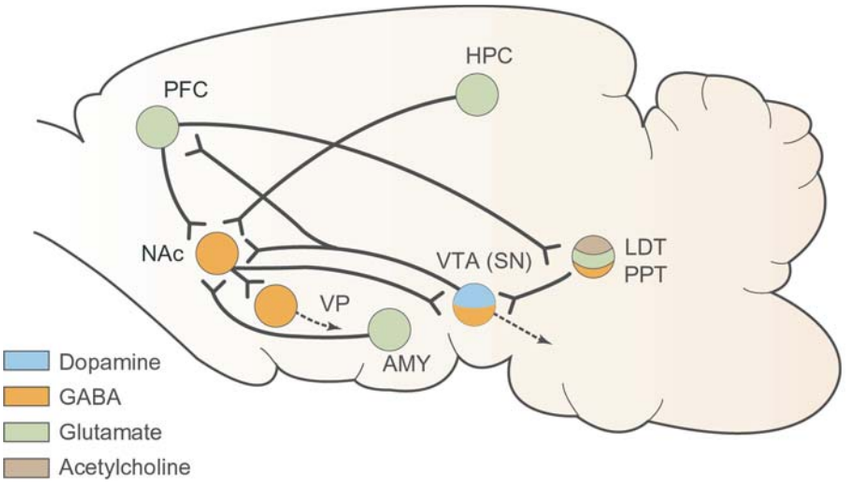

FIGURE 56-2 The mesocorticolimbic dopamine system and associated circuits. The ventral tegmental area (*VTA*) contains both dopamine and GABA neurons that innervate the nucleus accumbens (*NAc*), prefrontal cortex (*PFC*) and other forebrain targets not shown. Nucleus accumbens neurons, which use GABA as their transmitter, receive glutamate inputs from the PFC, amygdala (*AMY*), hippocampus (*HPC*), and thalamus (not shown). These glutamate inputs convey information important for goal-directed behaviors. NAc neurons integrate this information, and then transmit it to brain regions important for execution of these behaviors, including the ventral pallidum (*VP*), VTA and substantia nigra (*SN*), as well as other motor regions (*dashed arrows*). The prefrontal cortex influences this circuitry at many levels by sending descending glutamate projections to many targets, including the NAc, VTA, SN, pedunculopontine tegmental nucleus (*PPT*) and laterodorsal tegmental nucleus (*LDT*). The PPT and LDT send mixed cholinergic, glutamate and GABA projections to the VTA and SN, that exert an important regulatory influence on dopamine and GABA cells in the latter regions.

learning related to reward, while the three cortical areas are important for decision-making based on integration of cognitive and motivationally relevant information. Disruption of these circuits in addicts may be associated with alterations in dopamine transmission [10].

Overall, the results of functional imaging studies are consistent with results obtained using animal models, and both underscore the importance of conditioned responses and cognitive dysfunction in drug craving. Compulsive drug use may reflect a combination of an increase in motivation to take a drug, driven by enhanced responsiveness of memory and motivational circuits to drugs or drug-associated cues, and a decrease in the ability to exert inhibitory control and exercise appropriate judgment, due to alterations in executive function.

OPIATES

Opiates are drugs derived from opium, including morphine and heroin. Opium, extracted from poppy plants, has been used for recreational and medicinal purposes for thousands of years. Morphine was identified as the active pharmacological ingredient of opium in the early 1800s. Heroin was synthesized from morphine in the late 1800s in an attempt to develop a nonaddicting cough suppressant. Opioid is a more inclusive term that includes opiates, as well as endogenous, or naturally occurring, opioid peptides. These include the enkephalins, endorphins, dynorphins and endomorphins (see Ch. 18).

Acutely, opiates produce analgesia, autonomic inhibition and an intense 'high'. Prolonged use leads to tolerance and dependence, and to craving and withdrawal symptoms when drug use is terminated. Withdrawal symptoms include anxiety, nausea, insomnia, hot and cold flashes, muscle aches, perspiration, and diarrhea. Opiate actions in spinal cord and brain stem are important for analgesic effects, autonomic effects, and physical withdrawal symptoms. Opiate effects on the mesocorticolimbic system are important for acute rewarding effects, some psychological withdrawal symptoms, and craving.

There are three classical opioid receptor types, μ, δ, and κ. The μ-opioid receptor is responsible for the reinforcing effects of heroin and morphine. Morphine is relatively selective for μ receptors. Endorphins and enkephalins bind to μ and δ receptors, while dynorphin binds selectively to κ-opioid receptors. Endomorphins are another class of potential endogenous opioid peptide with high affinity and selectivity for μ receptors. The N/OFQ receptor, cloned in 1994, has high structural homology with classical opioid receptors, but very low affinity for conventional opioid ligands. Orphanin (nociceptin) is the endogenous ligand for the N/OFQ receptor, and may modulate opioid effects.

Opioid receptors generally mediate neuronal inhibition. They couple to G_i or G_o, and produce inhibition of Ca^{2+} channels and opening of K^+ channels. They also inhibit adenylyl cyclase. Through this and other downstream signaling pathways, opioid receptors modulate

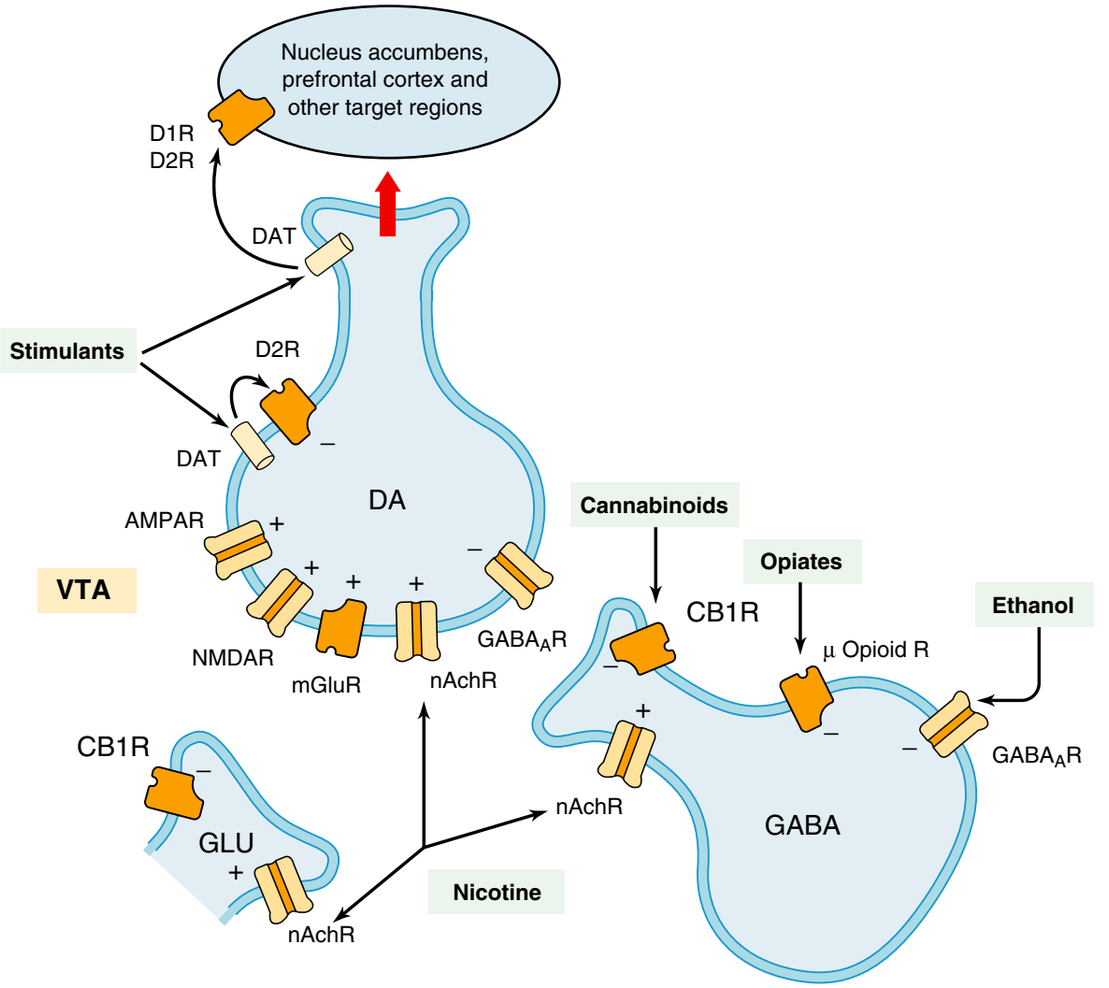

FIGURE 56-3 All reinforcing drugs increase dopamine transmission in the mesocorticolimbic dopamine system, but they use different mechanisms. Opiates, ethanol and cannabinoids decrease GABA transmission in the ventral tegmental area (*VTA*), thereby disinhibiting dopamine neurons. Psychomotor stimulants interact with the DA transporter (*DAT*) to elevate extracellular dopamine levels. Nicotine excites dopamine cells directly and promotes glutamate release from glutamate nerve terminals in the VTA.

synaptic plasticity and gene expression [19]. Recent work has shown that opioid receptors interact to form homodimers and hetero-dimers. This generates signaling units with different pharmacology and signaling ability compared to the cloned receptor subtypes [20]. The significance of this finding is only beginning to be explored, but it may contribute to the pharmacological diversity of opioid receptors, and has exciting implications for drug design.

The reinforcing effects of opiate drugs involve a number of neuronal pathways [21]. In the VTA, opiates stimulate μ-opioid receptors on GABA neurons that synapse on dopamine neurons. This inhibits the GABA neurons, leading to disinhibition of the dopamine neurons and enhanced dopamine release in the nucleus accumbens and other target areas (Fig. 56-3). Opiates also exert dopamine-independent effects in the nucleus accumbens by activating μ-opioid receptors on nucleus accumbens neurons themselves. The relative contribution of these two mechanisms to the reinforcing effects of opiates remains unclear. There is increasing evidence that endogenous cannabinoid systems are also important in mediating the rewarding effects of opiates, and vice versa.

Chronic opiate treatment results in complex adaptations in opioid receptor signaling. Much has been learned from studies on mechanisms of tolerance to the analgesic effects of opiates. This is a major clinical problem, as it means that ever-escalating doses are required for the treatment of chronic pain. The classic view was that tolerance reflects a decrease in functional opioid receptors via desensitization and internalization. Desensitization occurs when receptors are uncoupled from G proteins as a result of phosphorylation by G-protein-coupled receptor

kinases (GRKs) and arrestin binding (Ch. 19). These events also lead to internalization of opioid receptors by promoting their association with clathrin-coated pits. However, the paradoxical observation that morphine produces tolerance but does not promote efficient receptor internalization has led to a re-evaluation of this view and prompted exciting research on opioid receptor regulation [22]. Although much remains to be learned, one possibility is that lack of internalization promotes tolerance because it is associated with abnormally sustained signaling and resultant adaptations in the target cell and downstream circuits. A key element of this theory is that different agonists direct opioid receptors towards different signaling and trafficking pathways. Understanding the rules governing the function of ligand–receptor complexes may help in the development of opiates that are effective analgesics but have reduced liability to cause tolerance and dependence.

Upregulation of the cAMP second-messenger pathway is a well-established molecular adaptation. It occurs in many brain regions after chronic administration of opiates and other drugs of abuse. The locus coeruleus (LC) has been a useful model system for studying upregulation of the cAMP pathway [23]. Located in the brain stem, the LC is the largest cluster of norepinephrine-containing neurons in the brain and normally participates in regulation of autonomic function and attentional states. Acutely, opiates suppress the activity of LC neurons via G_i-coupled receptors that inhibit adenylyl cyclase activity (Chs 19 and 21). Chronic opiate administration leads to compensatory upregulation of specific subtypes of adenylyl cyclase and specific subunits of protein kinase A. The transcription factor CREB plays a critical role in this adaptive response. Upregulation of the cAMP pathway increases the excitability of LC neurons, enabling them to fire at normal rates despite the continued presence of opiates. When opiates are withdrawn, upregulation of the cAMP pathway is no longer opposed by inhibitory effects of opiates, leading to a dramatic rebound activation of LC neurons that contributes to somatic withdrawal symptoms. Of course, upregulation of the cAMP pathway is only one of many cellular mechanisms contributing to adaptive changes in the LC and other regions after chronic opiate administration [19].

The nucleus accumbens is another brain region in which the cAMP pathway is upregulated by chronic administration of opiates. This leads to increased transcription of CREB-regulated proteins, including dynorphin, the endogenous ligand for the κ-opioid receptor. Dynorphin stimulates presynaptic κ-opioid receptors on dopamine nerve terminals, inhibiting dopamine release. In the presence of opiates, this effect of dynorphin may serve as a homeostatic adaptation that diminishes drug responsiveness by reducing activation of the dopaminergic system. However, once opiates are no longer present, decreased dopamine release may contribute to the anhedonia and dysphoria that characterize the early phase of opiate withdrawal.

There are two main treatments for the opiate withdrawal syndrome. One is replacement therapy with methadone or other μ agonists that have a longer half-life than heroin or morphine, and produce mild stimulation rather than euphoria. They also produce cross-tolerance to heroin, lessening heroin's effect if patients relapse. Withdrawal is also treated with the α_2 agonist clonidine, which inhibits LC neurons, thus counteracting autonomic effects of opiate withdrawal — such as nausea, vomiting, cramps, sweating, tachycardia and hypertension — that are due in part to loss of opiate inhibition of LC neurons.

Endogenous opioid systems are an integral part of the reward circuitry. As such, they contribute to adaptations that underlie addiction to many drug classes. For example, interactions of endorphins and enkephalins with μ and δ receptors contribute to reinforcing effects of cocaine and ethanol through mechanisms involving activation of mesolimbic dopamine transmission. Dynorphin is upregulated by other drugs of abuse, e.g. cocaine, and its interaction with κ-opioid receptors produces aversive states that oppose reinforcement by decreasing mesolimbic dopamine transmission (see above). Naltrexone, a nonspecific opioid receptor antagonist, is approved in the U.S.A. for the treatment of individuals with alcohol dependence. It appears to block some of the reinforcing properties of alcohol, and reduces rates of relapse to alcohol drinking.

PSYCHOMOTOR STIMULANTS

This drug class includes cocaine and amphetamine derivatives. Low-to-moderate doses lead to increased activity, talkativeness and feelings of euphoria and general well-being, along with decreases in fatigue and in food intake. Repetitive motor activity (stereotyped behavior) is produced by higher doses, and very high doses can produce convulsions, hyperthermia, coma and death. Stimulants have some therapeutic uses. For example, amphetamine is used to treat narcolepsy, and methylphenidate (Ritalin) is used in the treatment of children with attention deficit hyperactivity disorder. Because repeated administration of stimulants can produce sensitization of their reinforcing effects, there is concern that long-term childhood exposure to methylphenidate may increase vulnerability to drugs of abuse later in life. However, some studies suggest that methylphenidate may have protective effects [24].

Transporters for dopamine (DAT), serotonin (SERT) and norepinephrine (NET) are the initial targets for psychomotor stimulants. By interacting with these transporters (Chs 12 and 13), psychomotor stimulants increase extracellular levels of monoamine neurotransmitters. Cocaine is a monoamine uptake inhibitor. The reinforcing effects of cocaine correlate best with its binding potency at the DAT. However, experiments with monoamine transporter-deficient mice suggest that cocaine actions at

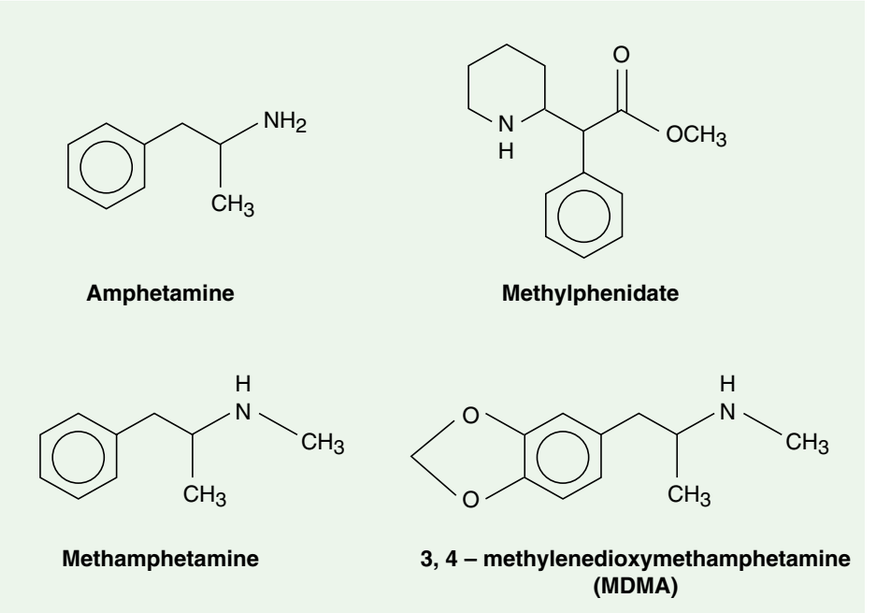

FIGURE 56-4 Amphetamine and other important stimulants.

the SERT and NET are also important for its reinforcing effects [25]. Amphetamine and other important stimulants are shown in Figure 56-4. These drugs interact with DAT, SERT and NET with varying relative affinities. Some, like methylphenidate, appear to block uptake in a manner similar to cocaine, while others, including amphetamine itself, are transported substrates. Through the latter mechanism they promote monoamine efflux by reverse transport via a process known as exchange diffusion [26]. The amphetamines are also lipophilic weak bases and likely transported substrates of the synaptic vesicle monoamine transporters (VMAT). Once inside the vesicles, they collapse the vesicular pH gradient that drives dopamine uptake into synaptic vesicles (Chs 5, 12). This promotes redistribution of dopamine from vesicles to the cytosol, making more dopamine available for reverse transport [26]. In addition, amphetamine elevates cytosolic monoamine levels by inhibiting monoamine oxidase and stimulating tyrosine hydroxylase. Recent studies suggest that amphetamine and cocaine can also cause DAT internalization, a novel mechanism for reducing DAT function.

In experimental animals, repeated exposure to high doses of some psychomotor stimulants produces long-term decreases in markers for the integrity of dopamine and serotonin nerve terminals [27]. This involves a neurodegenerative process mediated by free radicals and oxidative stress [28]. In rats, high-dose amphetamine preferentially damages dopamine terminals, methamphetamine damages serotonin and dopamine terminals, and 3,4-methylenedioxymethamphetamine (MDMA) preferentially damages serotonin neurons. MDMA is the major constituent of the street drug ecstasy. The important and controversial questions are whether similar neurotoxic changes occur in the human brain at the lower doses used by humans, whether these doses produce functional impairment (detected in behavioral or brain imaging studies), whether functional changes are attributable to neurotoxicity versus other mechanisms, and whether any observed changes are reversible. The answers depend on the stimulant in question. There is emerging evidence that methamphetamine has long-term effects on motor, cognitive and motivational function that are associated with reductions in DAT levels and brain metabolism; some effects recover and others persist, even after 12–17 months of abstinence [29]. In MDMA users, there is some evidence for mild impairments of memory and cognition [30], but no strong evidence linking these impairments to neurotoxicity.

Cocaine and amphetamines produce neuronal adaptations by repeatedly elevating monoamine levels. The resulting overstimulation of monoamine receptors, located on target neurons postsynaptic to monoamine nerve terminals, leads to a complex cascade of downstream changes that involves many brain regions and transmitter systems. Many adaptations have been characterized that are associated with behavioral sensitization, an animal model of addiction [2]. During repeated drug administration, behavioral responses to psychomotor stimulants gradually intensify or 'sensitize', including responses that provide an index of motivation for drug-taking. For example, a sensitized rat will work harder to obtain drugs in a self-administration experiment [31]. Sensitization persists for months after discontinuing drug exposure, reminiscent of the persistence of vulnerability to relapse in recovering addicts. Although sensitization is

best characterized for psychomotor stimulants, most drugs of abuse produce sensitization and cross-sensitization occurs across drug classes.

The dopamine system itself undergoes complex adaptations during behavioral sensitization to psychomotor stimulants [32, 33]. During the first few days after discontinuing drug administration, the firing rate of dopamine neurons increases due to transient changes in regulatory mechanisms in the VTA, including the development of LTP at excitatory synapses onto dopamine neurons. Adaptations in the VTA dissipate with longer withdrawal times, giving way to more persistent adaptations in the nucleus accumbens and other forebrain regions, some of which increase the responsiveness of the dopamine system to subsequent drug exposure. For example, there are alterations in Ca^{2+} signaling within dopamine nerve terminals that allow more dopamine to be released by depolarizing stimuli and psychomotor stimulants. There are also alterations in postsynaptic dopamine receptor signaling (see next section).

Stimulant-induced changes in glutamate transmission have received considerable attention in recent years [32, 33]. In part, this is due to glutamate's central role in plasticity and the recognition that addiction is a form of plasticity, a topic considered in the last section of this chapter. However, the focus on glutamate also reflects the fact that postsynaptic neurons in most dopamine-innervated brain regions are co-regulated by convergent dopamine and glutamate inputs, with dopamine serving a neuromodulatory role. Glutamate transmission in the nucleus accumbens is the critical mediator of cocaine-seeking behavior in rats [12].

Dopamine receptor signaling through the PKA pathway mediates many effects of psychomotor stimulants. Dopamine receptors can be divided into two major families, based on pharmacology and signal transduction mechanisms, the D1-like receptors (D1 and D5) and the D2-like receptors (D2, D3 and D4) (Ch. 12). This section will focus on D1 and D2 receptors. D1 receptors are positively coupled to adenylyl cyclase, while D2 receptors are negatively coupled to adenylyl cyclase. In addition, both receptors influence other signaling mechanisms. Both serve as postsynaptic receptors in the nucleus accumbens, dorsal striatum, amygdala, prefrontal cortex and other dopamine innervated regions. D2 receptors also serve as presynaptic autoreceptors. Both D1 and D2 receptors mediate psychomotor stimulant actions, but D1 receptor signaling through the cAMP-dependent protein kinase (PKA) pathway may be more important for persistent drug effects (Fig. 56-5).

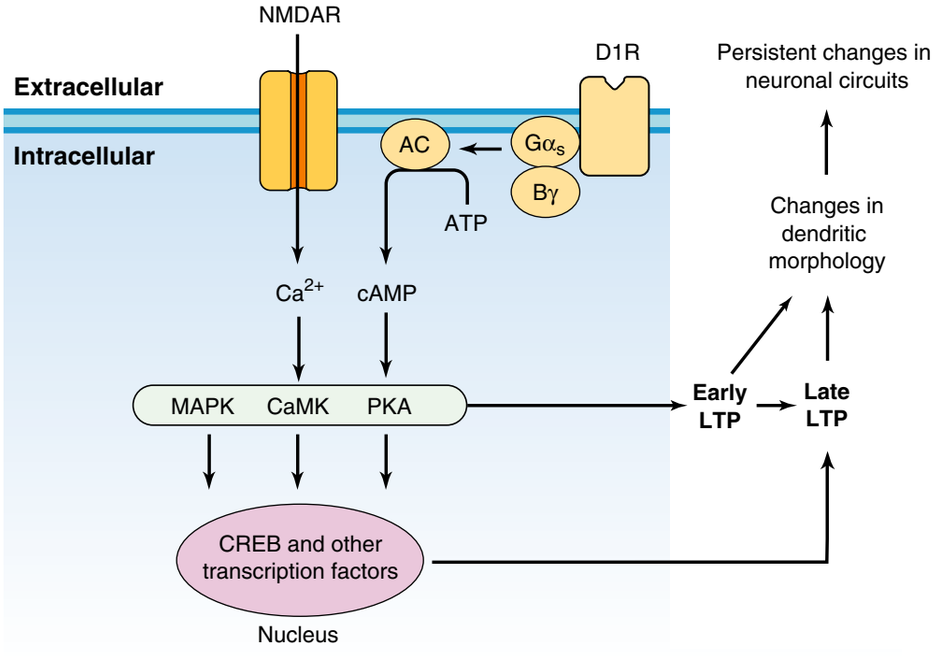

FIGURE 56-5 The D1 receptor–PKA signaling pathway influences neuronal excitability by regulating ion channels and receptors in the membrane (see text) and influences gene expression by activating transcription factors such as CREB. Note that some effects of this pathway are mediated indirectly by DARPP-32, a potent inhibitor of protein phosphatase-1 that is involved in many aspects of addiction (see Ch. 23). There is considerable cross-talk between the D1 receptor–PKA signaling pathway and other receptors located in dopamine-receptive neurons, for example, NMDA, AMPA, mGluR, D2 dopamine, serotonin, adenosine, opiate and $GABA_A$ receptors. The NMDA receptor plays an important role in activating Ca^{2+}-dependent signaling pathways. Convergent activation of cAMP and Ca^{2+} signaling pathways is necessary for some responses, e.g. CREB activation. The same cascades are critical for activity-dependent forms of plasticity such as LTP. During the early component of LTP, which requires activation of several protein kinases, synaptic strength is increased by mechanisms that include the synaptic insertion of new glutamate receptors. This is followed by a later more persistent component of LTP that requires protein synthesis. Over time, morphological changes occur in the postsynaptic density, perhaps related to the insertion of new glutamate receptors. Ultimately, dendritic spines and even presynaptic terminals undergo complex remodeling, leading to persistent changes in the activity of neuronal circuits. The ability of addictive drugs to influence the same signaling pathways that mediate LTP may explain their ability to produce persistent structural and functional changes in neuronal pathways related to motivation and reward (see Fig. 56-7).

Through this pathway, dopamine regulates the phosphorylation state of many important proteins that influence neuronal excitability on different time scales. For example, D1 receptors can exert rapid effects on neuronal excitability via PKA phosphorylation of ligand- and voltage-gated ion channels, including NMDA receptors, AMPA receptors, Na^+ channels and Ca^{2+} channels. D1 receptors exert longer lasting effects by regulating transcription factors such as CREB (Ch. 26).

Repeated cocaine administration, like repeated morphine administration, leads to upregulation of the cAMP–CREB pathway in the nucleus accumbens [23]. The resulting changes in gene expression and cellular biochemistry have yet to be fully characterized, but one consequence is CREB induction of dynorphin, which serves a homeostatic function by decreasing dopamine release (see Opiates above). It is important to keep in mind that repeated stimulant exposure produces adaptations in dopamine receptive neurons in addition to those related to D1 receptor–PKA signaling, and that convergent activation of PKA and Ca^{2+} signaling may be necessary for the recruitment of mechanisms that enable synaptic and structural plasticity (Fig. 56-5). Finally, although this section has focused on the role of dopamine receptors, serotonin and norepinephrine receptors are also important mediators of stimulant effects in both naïve and drug-experienced animals.

CANNABINOIDS (MARIJUANA)

Marijuana and hashish are derivatives of the cannabis sativa plant. Although cannabinoids have been used for centuries for recreational and therapeutic purposes, dramatic advances in cannabinoid neurobiology have occurred since 1990 [34–37]. This is attributable to the cloning of cannabinoid receptors and the discovery of endogenous cannabinoids, termed endocannabinoids.

Marijuana's major effect in humans is a mildly euphoric and relaxing 'high'. Other effects include increased appetite, and apparently reversible cognitive impairments related to attention and memory. Less common effects are anxiety, paranoia and panic. The psychoactive component of cannabis is Δ^9-tetrahydrocannabinol (THC). Tolerance develops to most effects of marijuana, but it disappears rapidly. Very few people seek treatment for marijuana addiction, and withdrawal symptoms are rare. However, a mild withdrawal syndrome has been observed in users who suddenly stop after heavy, daily marijuana use and in experimental animals treated chronically with THC and then administered a cannabinoid receptor antagonist (precipitated withdrawal). Cannabinoid withdrawal, like opioid withdrawal, is associated with upregulation of the cAMP pathway. But this occurs mainly in the cerebellum, accounting in part for much milder symptoms. Cannabinoids also have therapeutic potential. Marijuana is used for the treatment of nausea produced by cancer chemotherapy, and wasting syndrome caused by AIDS. Cannabinoid agonists and antagonists are being considered for use in a number of conditions, including movement disorders, eating disorders, and even for drug and alcohol addiction (see below).

Cannabinoid effects in the CNS are mediated by the CB1 receptor. This G_i/G_o-protein-coupled receptor was cloned in 1990. Its counterpart in the periphery, CB2, was cloned three years later. The brain may contain other undiscovered cannabinoid receptors. CB1 is by far the most abundant G-protein-coupled receptor in the mammalian brain. It is highly expressed in the basal ganglia, cerebellum, hippocampus, cortex and brain stem. Accordingly, cannabinoids modulate motor activity, motivation, learning, memory, and pain processing. Many CB1 receptors are located presynaptically on GABA and glutamate nerve terminals, where they decrease GABA or glutamate release by inhibiting Ca^{2+} currents and altering K^+ channel gating. Presynaptic CB1 receptors inhibit the release of other transmitters as well. CB1 receptors are also coupled to inhibition of adenylyl cyclase and activation of the MAP kinase/ERK pathway, as well as other protein kinase signaling cascades that regulate gene expression (see Part 3, Intracellular Signaling). Like other GPCRs, CB1 receptors undergo agonist-induced desensitization involving G-protein uncoupling in response to phosphorylation by GRKs and receptor internalization.

Cannabinoids share with other drugs of abuse the ability to increase the firing rate of VTA dopamine neurons and increase dopamine release in the nucleus accumbens. One mechanism involves stimulation of presynaptic CB1 receptors on GABA nerve terminals in the VTA, leading to decreased GABA release and disinhibition of dopamine neurons (Fig. 56-3). CB1 receptors in other locations, including the nucleus accumbens, may also contribute to reinforcing effects of cannabinoids. Endogenous opioid systems play a role in cannabinoid effects on dopamine release and, more generally, in the reinforcing effects of cannabinoids, as opioid antagonists block cannabinoid self-administration in animals.

Endocannabinoids are endogenous ligands for the CB1 receptor. The best established are anandamide (*N*-arachidonoylethanolamine) and 2-AG (2-arachidonoylglycerol). Others may also exist. Pathways involved in the formation and inactivation of anandamide and 2-AG are shown in Figure 56-6. Some steps in their formation are Ca^{2+}-dependent. This explains the ability of neuronal depolarization, which increases postsynaptic intracellular Ca^{2+} levels, to stimulate endocannabinoid formation and release. Some neurotransmitter receptors (e.g. the D2 dopamine receptor) also stimulate endocannabinoid formation, probably by modulating postsynaptic Ca^{2+} levels or signaling pathways (e.g. PLC) that regulate endocannabinoid formation.

Endocannabinoids are derived from lipids, making them different from classical and peptide transmitters in several important respects. The latter are stored in vesicles after their synthesis and released by exocytosis in response

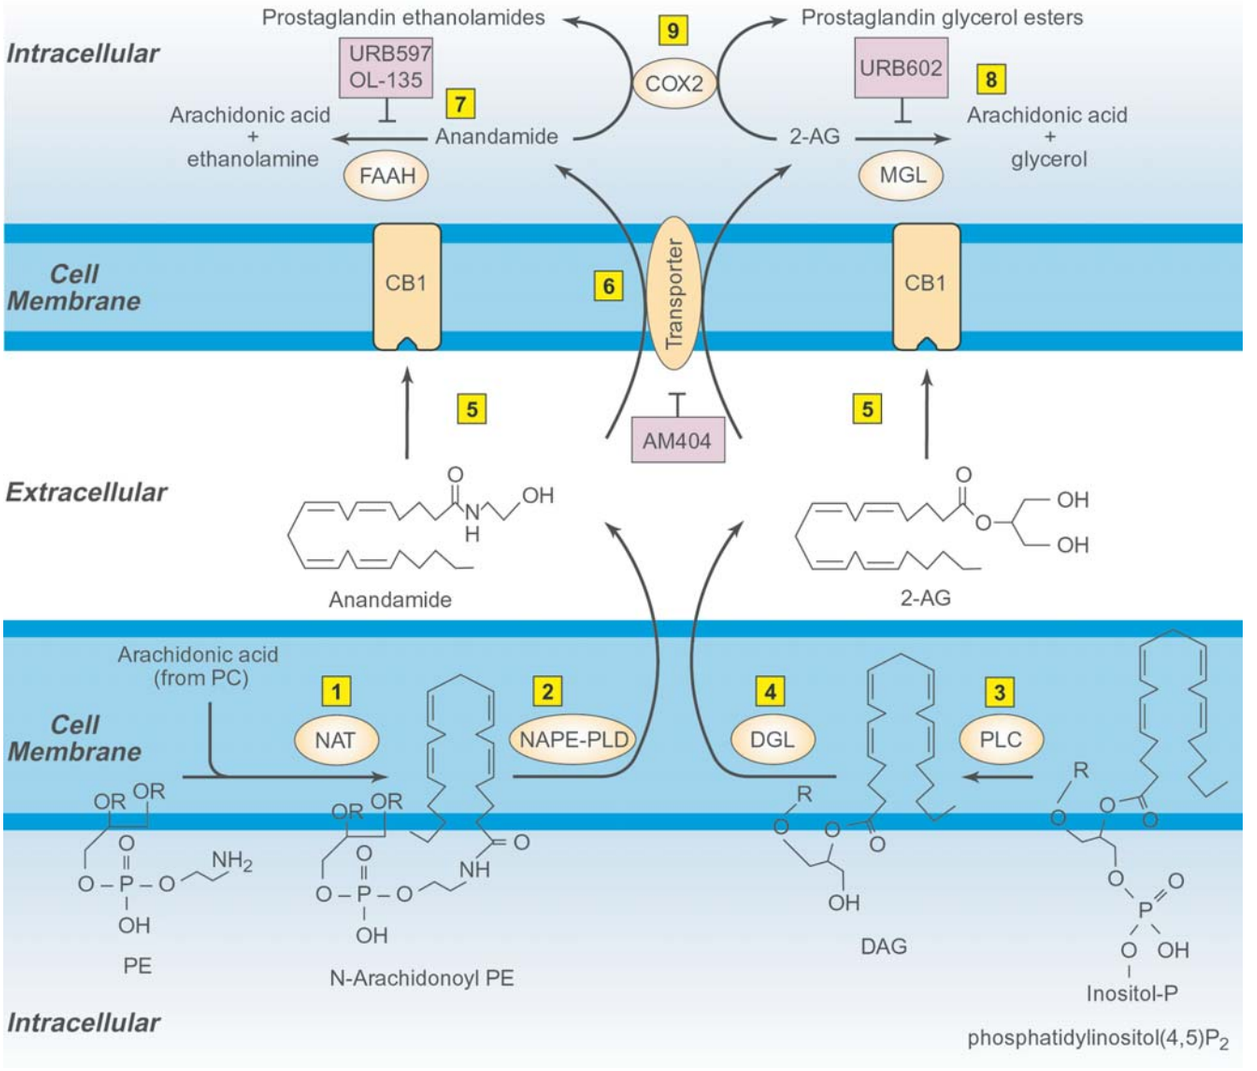

FIGURE 56-6 Formation and inactivation of the endocannabinoids anandamide and 2-AG. (**1**) *N*-arachidonoyl phosphatidylethanolamine (*N*-arachidonoyl PE), required for synthesis of anandamide, may be formed by *N*-acyl transferase (*NAT*), which transfers an arachidonate moiety, derived from the sn-1 position of phospholipids such as phosphatidylcholine (*PC*), to the primary amino group of PE. (**2**) Anandamide is generated from the hydrolysis of *N*-arachidonoyl PE, catalyzed by *N*-acylphosphatidylethanolamine-hydrolyzing phospholipase D (*NAPE-PLD*). (**3**) Phospholipase C (*PLC*) catalyzes the hydrolysis of phosphatidylinositol (4,5)-bisphosphate (PtdIns(4,5)P_2) to diacylglycerol (*DAG*) and inositol (1,4,5)-triphosphate. (**4**) DAG lipase (*DGL*) catalyzes the formation of 2-AG from DAG. An alternative pathway for 2-AG formation involves the formation of a 2-arachidonoyl-lysophospholipid such as lyso-PI (catalyzed by phospholipase A1) followed by its hydrolysis to 2-AG (catalyzed by lyso-PLC) (see Piomelli [36]). (**5**) Anandamide and 2-AG are agonists at the CB1 receptor. (**6**) Anandamide and 2-AG are removed from the extracellular space by carrier-mediated transport, which is inhibited by AM404. (**7**) Anandamide is hydrolyzed by a membrane-bound fatty acid amidohydrolase (*FAAH*), which is inhibited by URB597 and OL-135. (**8**) 2-AG is hydrolyzed by monoacylglycerol lipase (*MGL*). MGL is inhibited by URB602. (**9**) Anandamide and 2-AG are converted to prostaglandin ethanolamides and glycerol esters, respectively, by cyclooxygenase-2 (COX-2). Abbreviations: *AA*, arachidonic acid; *R*, fatty acid group.

to action potential invasion of the nerve terminal. In contrast, endocannabinoids are produced 'on demand' when neuronal activity or occupation of membrane receptors leads to cleavage of membrane lipid precursors. Cannabinoid release is poorly understood, but it is not vesicular. Their hydrophobic nature raises questions about how they cross the extracellular space. It is possible that this is facilitated by extracellular lipid-binding 'carrier' proteins.

Endocannabinoids serve as retrograde messengers. They are released by postsynaptic neurons and act on presynaptic CB1 receptors on neighboring nerve terminals. Retrograde signaling by endocannabinoids is essential for many forms of synaptic plasticity that are initiated by postsynaptic depolarization and increased postsynaptic intracellular Ca^{2+}, but expressed as a presynaptic decrease in the probability of transmitter release. Examples include some forms of long-term depression (LTD; see Ch. 53) at GABA

synapses in the hippocampus and the amygdala, and at glutamate synapses in the striatum and nucleus accumbens. Marijuana may alter normal endocannabinoid-mediated synaptic effects, perhaps leading to abnormal synaptic plasticity. This may be related to the short-term disruption of memory and learning associated with marijuana use, and to motivational and rewarding effects of marijuana.

There are many similarities between endogenous opioid and cannabinoid systems. Both CB1 and μ-opioid receptors are G_i/G_o-coupled receptors that share some signaling mechanisms and cellular effects, such as presynaptic inhibition. Both opioids and cannabinoids produce analgesic and rewarding effects. Finally, both systems are integral components of the reward circuitry and thus participate in responses to other drug classes. For example, in animals, blockade of endocannabinoid transmission attenuates reinstatement of cocaine- and heroin-seeking behavior and decreases motivation for alcohol consumption. It is likely that the mechanism involves CB1 receptor-mediated modulation of synaptic transmission and synaptic plasticity in reward-related brain regions such as the VTA, nucleus accumbens, dorsal striatum and amygdala. It is possible that drugs targeting endocannabinoid transmission may be useful in treating some aspects of addiction.

NICOTINE

Nicotine is responsible for the highly addictive properties of tobacco products. Addiction occurs in 30% of those who experiment with tobacco products, and more than 80% of those who attempt to quit smoking will relapse within a year. Withdrawal from nicotine produces a syndrome characterized by nicotine craving as well as dysphoria, anxiety, irritability, restlessness and increased appetite. It is treated with nicotine replacement therapies, such as nicotine gum and patches, and/or with buproprion, a drug that is classified as an antidepressant but has multiple and complex effects in brain. Buproprion reduces craving in some smokers. Nicotine addiction has been reviewed recently at cellular and systems levels [38–41].

Nicotine is an agonist at the nicotinic acetylcholine receptor (nAChR). Activation of this receptor depolarizes target cells (see Ch. 11). nAChRs are composed of five subunits surrounding a central ion-channel pore. Twelve different nicotinic receptor subunits are expressed in the nervous system (α2–α10 and β2–β4). Of these, a subset is expressed in the VTA (α3–α7 and β2–β4). It is thought that α7 receptors form homomeric receptors; α3, α4 and α6 form heteromeric channels with β2 or β4; and α5 and β3 can associate with other α/β pairs. Studies in knockout mice implicate several subunits in the ability of nicotine to modulate dopamine neurons (α4, α6, α7, β2, β3) but suggest that β2-containing receptors play a critical role in reinforcement, as β2-subunit knockout mice do not self-administer nicotine.

nAChRs exist in three basic conformational states: closed, open and desensitized. There are both short- and longer-lasting desensitized states. The extent to which desensitization occurs depends on the subunit composition of the nAChR, as well as the concentration and duration of agonist exposure. For example, prolonged exposure to low agonist concentrations, such as occurs during smoking, can induce receptor desensitization. Cycles of receptor activation and desensitization contribute to smoking behavior. For example, the first cigarette of the day may be perceived as the most pleasurable because high-affinity nAChRs are still available for activation. These include the β2-containing receptors on dopamine and GABA cells of the VTA, which are readily desensitized during smoking (see below). With long-term nicotine exposure, the number of nAChRs is upregulated, probably as a homeostatic response to nAChR desensitization. This may contribute to agitation and withdrawal symptoms through increased nAChR transmission. Additional cigarettes may 'medicate' the smoker by desensitizing these excess receptors.

The ventral tegmental area (VTA) is a critical site for nicotine action. Intra-VTA nicotine is sufficient to produce behavioral effects, whereas injections outside the VTA are not effective. Activation of dopamine transmission by nicotine is important for its reinforcing effects in drug-experienced animals. For example, nicotine self-administration is reduced by blocking dopamine transmission in the nucleus accumbens. Complicating the picture, however, is evidence implicating dopamine activation in aversive effects of intra-VTA nicotine in naïve animals. Brain regions connected to the VTA also play important roles in nicotine's actions, notably the pedunculopontine tegmental nucleus and the adjacent laterodorsal tegmental nucleus (see Fig. 56-2). These regions send cholinergic (as well as glutamate and GABA) projections to the VTA that are important regulators of dopamine cell activity. Thus, the acetylcholine system, along with endogenous opioid and cannabinoid systems, can be considered part of the natural reward circuitry. In this context, it is not surprising that nAChR transmission is implicated in the reinforcing effects of other drug classes, including psychomotor stimulants and ethanol.

Within the VTA, nicotine exerts its effects via nAChRs located on dopamine neurons, GABA neurons and glutamate nerve terminals. Dopamine and GABA neurons of the VTA express β2-containing receptors, which include α4 as well as other subunits. α7-containing receptors are expressed by glutamate nerve terminals in the VTA, and by a subset of dopamine and GABA neurons. Differential desensitization of nAChRs is important for nicotine's action in the VTA. While β2 receptors on the dopamine cells and GABA cells desensitize readily in response to a

smoker's nicotine levels, the α7 receptors on glutamate terminals desensitize to a lesser extent and continue to promote glutamate release, which now excites the dopamine cells even more effectively due to the decrease in inhibitory GABA synaptic inputs. This enables sustained activation of dopamine transmission. Furthermore, by enhancing glutamate release, presynaptic α7 receptors in the VTA can produce LTP at excitatory synapses onto dopamine neurons. This further enhances the firing of dopamine neurons. nAChRs also influence synaptic plasticity in other regions, including the striatum and hippocampus.

ETHANOL, SEDATIVES AND ANXIOLYTICS

Alcoholism is a chronic relapsing disorder. The risk of alcoholism depends on interactions between genetic, environmental and neurobiological factors. Historically, ethanol's actions were attributed to nonspecific disruption of the lipid bilayer of neurons. It is now recognized that ethanol has specific targets, and that effects of long-term ethanol exposure are due to neuroadaptations as well as neurotoxicity [42–45].

The symptoms of mild ethanol intoxication vary among individuals, ranging from stimulation to sleepiness. At higher doses, sedating effects increase. Intoxicating doses impair memory, judgment, reaction time and self-control. After repeated exposure, tolerance can be substantial. Alcoholics may attain very high blood alcohol levels without appearing grossly sedated. Heavy use inevitably leads to physical dependence. The severity of the ethanol withdrawal syndrome depends on the degree of dependence and the number of prior withdrawal episodes. Symptoms can include tachycardia, sweating, tremor, hypertension, anxiety and agitation, and can progress to include perceptual changes, confusion, seizures and, in some cases, other life-threatening complications. The severity of these symptoms is one factor that contributes to the resumption of alcohol consumption early in withdrawal. However, the major problem in the treatment of alcohol dependence in humans is continued vulnerability to relapse even after prolonged withdrawal periods.

Ethanol interacts directly with ligand-gated and voltage-gated ion channels. This is important both for acute effects and long-term adaptations. Ethanol interacts with a wide range of ion channels, including $GABA_A$, NMDA, glycine, nACh and 5-HT3 receptors and voltage-gated calcium channels. Most attention has focused on ethanol's ability to act as a positive allosteric modulator of $GABA_A$ receptors and a negative allosteric modulator of NMDA receptors. Ethanol inhibits ion flux through the NMDA receptor channel by binding to a hydrophobic pocket distinct from other modulatory sites of the NMDA receptor. During long-term ethanol exposure, there are compensatory changes in the expression of ethanol-responsive ion channels and receptors. NMDA receptors are upregulated, while $GABA_A$ receptors are downregulated. This results in increased neuronal excitability during acute withdrawal, when ethanol is no longer present to decrease NMDA receptor function and enhance GABA transmission. The increase in glutamate tone may contribute to withdrawal-related seizures and neurotoxicity. Different mechanisms may come into play during protracted ethanol withdrawal.

Multiple neuronal systems contribute to the reinforcing effects of ethanol. Activation of dopamine neurons is most important for reinforcing effects associated with ethanol's mild stimulant actions. In the VTA, $GABA_A$ receptors are predominantly located on GABA neurons. By enhancing $GABA_A$ receptor transmission in VTA, ethanol inhibits these GABA neurons, thus disinhibiting the dopamine neurons (Fig. 56-3). Ethanol also directly excites dopamine neurons by decreasing a potassium conductance. After chronic ethanol exposure, adaptations develop in the mesolimbic dopamine system to offset excitatory effects of ethanol, such that withdrawal from chronic ethanol leads to decreased dopamine cell activity and extracellular dopamine levels in the nucleus accumbens. This may contribute to dysphoria. There is also an important role for endogenous opioid systems in ethanol addiction. Antagonists of μ and δ opioid receptors decrease ethanol consumption and reinforcement. One locus for opioid effects is the nucleus accumbens. Opioids influence ethanol reinforcement through both dopamine-dependent and dopamine-independent actions in the nucleus accumbens. Other transmitters (e.g. endocannabinoids and neuropeptide Y) and other brain regions (e.g. the extended amygdala) may also contribute to ethanol action.

There is a need for improved therapies for alcoholism. Disulfiram is used to help prevent relapse, but compliance is often low. Disulfiram inhibits aldehyde dehydrogenase, an enzyme involved in alcohol metabolism, resulting in the buildup of acetaldehyde when alcohol is consumed. This produces unpleasant effects such as tachycardia, nausea and anxiety. The opioid antagonist naltrexone is used to decrease alcohol consumption and craving, based on the role of opioid receptors in the reinforcing effects of ethanol (above). Acamprosate, a newer drug used currently in Europe to maintain abstinence, may produce therapeutic effects via modulation of NMDA receptor function, although $GABA_B$ receptors and voltage-dependent Ca^{2+} channels may also be involved.

Barbiturates and benzodiazepines are used to treat anxiety. Sedatives such as the barbiturates were commonly

used until the introduction of benzodiazepines in the early 1960s. Both of these drug classes have abuse liability, although less than stimulants and opiates. There is cross-tolerance and cross-dependence among ethanol, barbiturates and benzodiazepines, as all are positive allosteric modulators of $GABA_A$ receptors, and produce downregulation of $GABA_A$ receptors after chronic treatment. Accordingly, benzodiazepines are commonly used, both in the clinic and on the street, to treat symptoms of alcohol withdrawal.

HALLUCINOGENS AND DISSOCIATIVE DRUGS

Hallucinogens produce an altered state of consciousness. Users may experience perceptual distortions and sometimes hallucinations, mood changes (ranging from elation to depression or paranoia) and intense arousal. High doses can elicit a 'mystical–religious' experience, accounting for the important role of naturally occurring hallucinogens, such as mescaline (the psychoactive component of peyote), in religion and philosophy in early cultures. Hallucinogen use tends to be episodic and limited, not chronic or compulsive, so these drugs are not associated with drug dependence or addiction. Nevertheless, there can be serious adverse consequences, including accidents due to impaired judgment and 'bad trips' characterized by severe anxiety. Psychotic reactions have been reported in a small proportion of users. In addition, flashbacks which resemble the original LSD experience occur in a small proportion of former users. This is termed hallucinogen persisting perception disorder (HPPD).

Two categories of hallucinogens can be defined based on chemical structure: the tryptamines, which include LSD, and the phenethylamines, which include mescaline and MDMA. MDMA is discussed in the section on Psychomotor Stimulants above. This section will focus on LSD, the most-potent hallucinogenic drug [46]. Based on structural similarity between tryptamines and serotonin, interactions between LSD and serotonin systems have been suspected since the 1950s. The hallucinogenic properties of LSD are now attributed mainly to its partial agonist effects at $5\text{-}HT2_A$ receptors. However, LSD's mechanism still remains puzzling, because its high *in vivo* potency is not predicted from its receptor affinity or intrinsic activity at known signaling pathways. A possible explanation is related to the realization that different agonists can activate different signaling pathways through the same receptor (agonist-directed signaling). Perhaps LSD produces a unique pattern of activation of 5-HT2 receptor signaling pathways. It is also possible that other monoamine receptors contribute to LSD's actions. At the neuronal systems level, frontal cortex and thalamus are important sites of LSD action. Modulation of glutamate transmission in these regions probably underlies distortions in perceptual and cognitive function. Effects of LSD on neurons of the locus coeruleus, an important region for gating of sensory inputs, may contribute to enhanced sensory experiences after LSD.

Phencyclidine (PCP) is a dissociative drug. PCP and ketamine were developed in the 1950s as general anesthetics for surgery. They were discontinued because patients sometimes became delusional during recovery from anesthesia. PCP became a drug of abuse in the 1970s. It is classified as a dissociative drug because it distorts perception and produces feelings of dissociation from reality. Its effects can be powerfully euphoric as well as dysphoric. Notably, PCP mimics both negative symptoms (e.g. apathy and social withdrawal) and positive symptoms (e.g. delusions, paranoia and hallucinations) of schizophrenia. Tolerance and withdrawal have not been well studied in humans. Long-term users of PCP report problems with memory, thinking and mood. PCP overdose is associated with dangerous physical complications.

PCP is a noncompetitive antagonist of NMDA-type glutamate receptors. It binds to a site within the open NMDA receptor ion channel (Ch. 15). Because PCP mimics schizophrenic symptoms, the discovery that it blocks glutamate transmission was a major impetus for the development of glutamate-based theories of schizophrenia (see Ch. 54). Although PCP is a weak dopamine-uptake inhibitor, its reinforcing effects in rat self-administration models reflect NMDA receptor blockade, not an increase in dopamine transmission. However, PCP can activate dopamine neurons indirectly, by blocking NMDA receptors that influence dopamine neurons. Similarly, other transmitter systems are influenced by PCP via pathways 'downstream' of NMDA receptor blockade. Thus, the pharmacology of PCP action in animal models of addiction is complex. Very high doses of PCP and other noncompetitive NMDA receptor antagonists produce neurodegeneration in animal models.

ADDICTION AND NEURONAL PLASTICITY SHARE COMMON CELLULAR MECHANISMS

Addiction may result from inappropriate neuronal plasticity. As discussed in earlier sections of this chapter, drugs of abuse activate the same neuronal pathways as natural reinforcers. However, they do so in a strong and unregulated manner that is hypothesized to lead to abnormal engagement of learning and memory mechanisms, ultimately producing abnormal plasticity in neuronal circuits involved in motivation and decision-making. As a result, the addict becomes narrowly focused on compulsive, habitual behaviors associated with the addictive

substance. Many features of addiction are consistent with this hypothesis, such as the important role of learned associations in triggering drug craving and the activation of learning and memory circuits during craving. However, the strongest support for this hypothesis has come from studies showing that drugs of abuse can influence synaptic plasticity and its underlying mechanisms.

Studies of behavioral sensitization have linked addiction to long-term potentiation (LTP). Behavioral sensitization is an animal model for the intensification of drug craving (see Psychomotor Stimulants above). Work in the late 1980s and early 1990s showed that glutamate transmission is required for the development of behavioral sensitization [32], suggesting a parallel between sensitization and LTP, which also requires glutamate transmission for its induction (see Ch. 53). This was important for shifting addiction research towards an emphasis on plasticity and learning mechanisms. Many studies have now demonstrated that common signaling pathways are activated by drugs of abuse and learning [6]. For example, the MAP kinase/ERK pathway, critical for learning and memory, is increasingly implicated in plasticity related to addiction. In addition, recent years have witnessed an explosion of research demonstrating that drugs of abuse influence LTP and long-term depression (LTD) in neuronal pathways related to addiction [47, 48]. For example, the development of behavioral sensitization to cocaine is correlated with LTP at excitatory synapses onto dopamine neurons of the VTA. This provides a transient increase in excitatory drive to the dopamine neurons, triggering downstream adaptations in nucleus accumbens and other forebrain regions. Other drugs of abuse (amphetamine, nicotine, ethanol and morphine) and stress have in common with cocaine the ability to produce LTP in VTA dopamine neurons [49]. This commonality may explain cross-sensitization between drug classes, and between stress and drugs. Cannabinoids and nicotine may influence LTP directly, through mechanisms described in previous sections. Psychomotor stimulants may do so indirectly through their effects on protein kinases and other signaling molecules involved in LTP [47]. While these and other findings strongly suggest that LTP participates in the cascade that leads to addiction, LTP is not permanent. An important goal of current research, considered in the next two sections of this chapter, is to understand how relatively short-lived adaptations such as LTP may lead to the long-lasting, and perhaps permanent, behavioral abnormalities that are associated with addiction.

Drugs of abuse have profound effects on transcription factors and gene expression. These effects are clearly important for long-lasting changes in brain function. Two transcription factors strongly implicated in addiction are CREB and ΔFosB [23]. CREB is important for learning and memory and is activated by phosphorylation. Addictive drugs influence many of the signal transduction pathways that regulate its phosphorylation state (see Ch. 26). ΔFosB isoforms are highly stable products of the *fosB* gene that accumulate in nucleus accumbens and dorsal striatal neurons during chronic drug treatment, enabling novel patterns of gene expression. Changes in gene expression initiated by these transcription factors contribute to 'sensitizing' adaptations that promote drug-taking as well as 'compensatory' adaptations that oppose drug-taking (e.g. dynorphin upregulation, see Opiates above). However, CREB and ΔFosB levels return to normal following weeks or months of drug withdrawal, so these transcription factors are not directly responsible for maintaining more persistent changes associated with addiction.

Persistent adaptations may involve changes in the structure of dendrites and dendritic spines. Dendritic spines are the postsynaptic contact site for most excitatory synapses in the brain. Structural changes in dendrites and spines were originally described after experience-dependent forms of plasticity, such as exposure to an enriched environment, and in association with LTP. It is now appreciated that structural plasticity also occurs after repeated exposure to psychomotor stimulants, nicotine and morphine [50]. For example, both cocaine and amphetamine increase spine density and dendritic branching in the nucleus accumbens and prefrontal cortex (Fig. 56-7). These structural changes, which are among the most long-lasting adaptations reported in response to repeated drug exposure, may initiated by some of the more transient adaptations discussed in previous sections. For example, ΔFosB may partly mediate cocaine-induced increases in spine density in the nucleus accumbens [23]. Drugs of abuse may initiate synaptic remodeling through their effects on LTP (Fig. 56-5). This is based on evidence that LTP is an initial trigger for activity-dependent changes in the structure of synapses (Ch. 53).

An important challenge is to understand the relationship between neuronal plasticity in identified pathways and specific behavioral alterations that underlie addiction. For example, plasticity in specific pathways presumably explains how drug-associated cues acquire a heightened ability to control behavior in drug addicts. If we identify the pathways that are rewired, and understand the pharmacology of systems that regulate these pathways, perhaps pharmacological treatments can be devised to reduce craving and relapse.

ACKNOWLEDGMENTS

I thank David Lovinger, David Sulzer, Eric Nestler, John Dani, Daniel McGehee, Terry Robinson, Bryan Yamamoto, Susan Sesack and Daniele Piomelli for their help in preparing this chapter. I regret that I was able to cite only a limited number of important studies.

INTRODUCTION: THE PAIN PATHWAY 927

PRIMARY SENSORY NEURONS 928
Sensory detection of a noxious stimulus is known as nociception 928
Primary sensory neurons sense pain and convey it to the spinal cord 928
The molecules that transduce noxious heat or cold are members of the transient receptor potential (TRP) receptor family 929
Receptors that transduce mechanical stimuli are members of the Degenerin family 930
Several molecules participate in chemical stimulus detection 930
Sodium channels are key in conveying nociceptive information from the periphery to the CNS 930

DORSAL HORN 930
The dorsal horn acts as a gate, regulating the flow of peripheral activity 930
The dorsal horn is the first site of synaptic transfer in the nociceptive pathway 931

THE BRAIN 931
Nociceptive information is integrated in the brain 931
Descending systems modify the spinal processing of nociceptive input 931
Endogenous opioids and opioid receptors inhibit pain responses 932

CLINICAL PAIN 932
Clinical pain is characterized by the presence of spontaneous pain or hypersensitivity to pain-provoking stimuli 932

INFLAMMATORY PAIN 933
Inflammatory pain results from changes both in primary sensory and dorsal horn neurons 933
Peripheral sensitization lowers nociceptor activation threshold 933
Central sensitization results in hyper-responsive dorsal horn neurons 933
Prostanoids are key modulators of inflammatory pain 934

NEUROPATHIC PAIN 935
A broad variety of diseases may cause neuropathic pain 935
Injured axons may develop spontaneous and repetitive firing known as ectopic activity 935
Sensory neurons transform their phenotype 936
Spinal disinhibition allows more nociceptive signal input 936
Peripheral nerve injury provokes a marked neuroimmune reaction 937

CONCLUSION 937

INTRODUCTION: THE PAIN PATHWAY

The neural pathway responsible for the sensation of pain begins with high-threshold primary sensory neurons, called nociceptors because they are receptive only to noxious peripheral stimuli. Nociceptors have cell bodies outside the central nervous system (CNS) in dorsal root ganglia (DRG) and peripheral axons that innervate the surface and deep tissues of the body. The central axons of nociceptors enter the CNS and synapse on second order neurons within the spinal cord (Fig. 57-1). Some second-order neurons send outputs that activate flexor motor neurons to produce a brisk withdrawal response (the flexion reflex), and others elicit the sensation of pain by projecting to the somatosensory cortex via the thalamus [1]. The dysphoric, unpleasant aspect of pain is generated by pathways that also originate in the spinal cord and activate the prefrontal cortex, amygdala and nucleus accumbens, and is accompanied by changes in autonomic function, sleep-cycle and mood [2].

Basic Neurochemistry: Molecular, Cellular and Medical Aspects

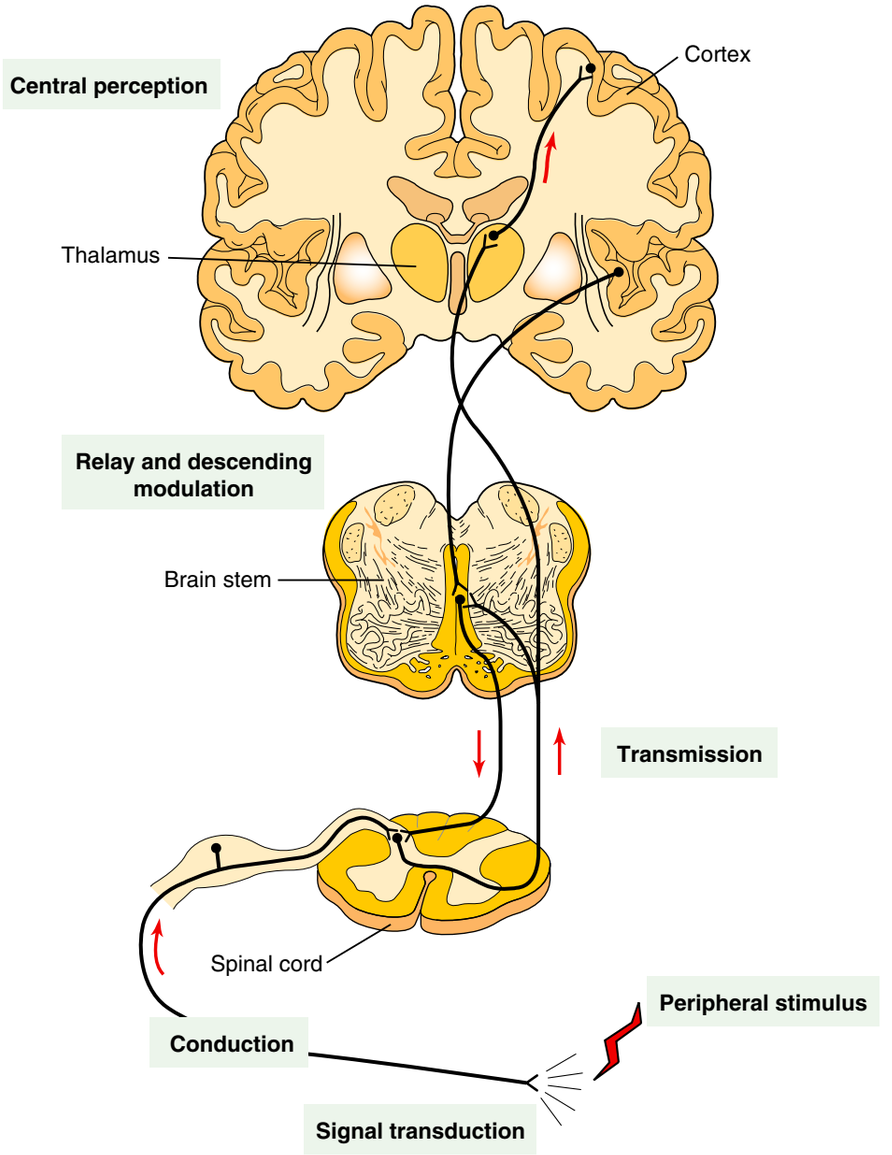

FIGURE 57-1 A diagrammatic representation of the major neural pathway responsible for pain.

In this chapter we highlight the mechanisms and neurochemical basis for nociceptive pain as well as the pain that occurs clinically after tissue injury (inflammatory pain) or nerve damage (neuropathic pain).

PRIMARY SENSORY NEURONS

Sensory detection of a noxious stimulus is known as nociception. The perception of such a stimulus, nociceptive pain, is essentially the 'ouch pain' we experience in response to a pinprick or touching a hot or very cold object. Nociceptive pain is an important physiological protective mechanism that warns of impending tissue injury, and activates reflex and sensory responses to avoid it.

Primary sensory neurons sense pain and convey it to the spinal cord. Nociceptors have unmyelinated (C fiber) or thinly myelinated (Aδ) axons, while the low-threshold Aβ-fiber mechanoreceptors involved in tactile and proprioceptive perception have large myelinated sensory neurons (Table 57-1). The peripheral terminals of primary sensory neurons convert changes in the environment into neuronal activity by transducing mechanical (Ch. 51), thermal or chemical stimuli into ion fluxes across their

TABLE 57-1 Classification of primary afferents

	Fibre class	Role	Activation threshold	Conduction velocity	Cell body diameter	Cell count in dorsal root ganglia
Large calibre myelinated	Aα	Proprioception	Low	Fast	Large (>40 μm)	20%
	Aβ	Touch	Low	Fast	Large (>40 μm)	20%
Medium calibre myelinated	Aδ	Nociception	High	Medium	Medium (25–40 μm)	5%
Small calibre unmyelinated	C	Nociception	High	Slow	Small (<25 μm)	>70%

membrane, producing a generator potential [3]. This transduction is mediated by specialized receptor ion channels that are located on the nociceptor terminal and determine the threshold and specificity of a sensory neuron's response (Fig. 57-2). While some nociceptors are unimodal, activated only by a mechanical, thermal or chemical stimulus, most are polymodal activated by a variety of these intense stimuli. Nociception involves detection of high and low temperature extremes, mechanical stimuli, the presence of chemicals released by damaged cells and extrinsic chemical irritants (Fig. 57-2). Some nociceptors have such a high threshold that they cannot normally be activated by noninjurious stimuli (silent nociceptors).

The molecules that transduce noxious heat or cold are members of the transient receptor potential (TRP) receptor family. TRP proteins (Table 57-2) form tetrameric nonselective cation channels within the plasma membrane, allowing sodium and calcium ion influx [4]. The TRPV3 channel is activated at temperatures between 31 and 39°C, TRPV1 at 43°C, and TRPV2 at 52–55°C. The heat pain threshold in humans is 43°C, suggesting that TRPV1 has a particular role in its determination. TRPV1 and TRPV3 are expressed in C fibers as well as in Aδ fibers, while TRPV2 is found only in Aδ fibers. TRPV1 is activated by capsaicin, the pungent ingredient in chili peppers, giving these fruits their characteristic hot taste. TRPV4 has an activation temperature below 27°C and may play a role in innocuous heat (warm) perception. TRPV3 and 4 channels are localized in skin keratinocytes, suggesting that they act in a paracrine fashion, detecting change in temperature in the epidermis and then, by releasing an intermediary signaling molecule such as ATP, activate sensory fibers through purinoreceptors [5].

The TRPM8 channel is activated by temperatures between 28°C and 8°C and by menthol, producing the cooling effect of this compound. TRPA1 is also activated by noxious cold (<18°C) and by pungent isothiocyanate compounds in horseradish (wasabi) and mustard, as well as cinnamaldehyde (the active ingredient of cinnamon). Temperature detection over the entire physiological range is likely to be achieved by combined actions of the TRPs, with some functional specificity achieved by mixing TRP subunits to produce heteromeric channels [5].

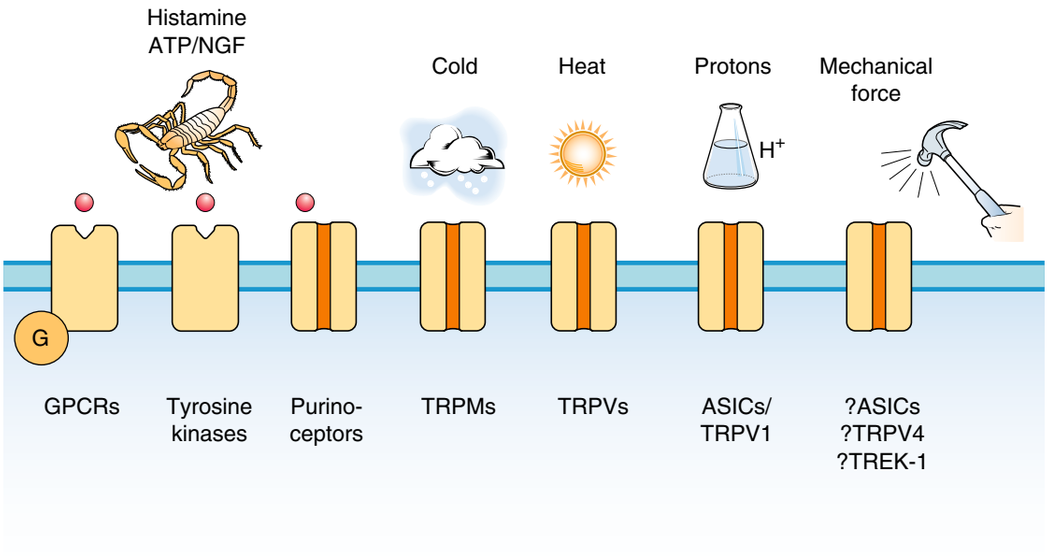

FIGURE 57-2 Noxious chemical, thermal and mechanical stimuli activate specific high-threshold receptors and ion channels that lead to inward currents in the peripheral terminals of nociceptors.

TABLE 57-2 Transient receptor potential channels

Subtype	Other names	Threshold (°C)	Other activating stimuli	Channel selectivity (P_{Ca}/P_{Na})	Chromasomal location	Tissue localization
TRPV1	VR1	>43	Capsaicin, anandamide, PIP_2 extracellular H^+, 2APB	10 ($P_{Mg}/P_{Na}\approx5$)	17p13	DRG
TRPV2	VRL1	>53	2APB	3	17p11	DRG, CNS
TRPV3		>30	Insulin growth factor-1, 2APB	-10	17p13	DRG, keratinocytes, CNS
TRPV4	OTRPC4	>27	Hypotonicity, phorbol esters, anandamide	6	12p24	Keratinocytes, muscle, kidney, CNS
TRPM8		<25	Menthol, icilin	1-3	2q37	DRG
TRPA1	ANKTM1	>18	Icilin, mustard oil	1.4 $P_{Ca}\approx P_{Mg}$	8q13	DRG, fibroblasts

Receptors that transduce mechanical stimuli are members of the Degenerin family. Analysis of mutant *C. elegans* responses to light touch led to the detection of several mechano-sensory abnormal or *mec* genes. These genes, MEC-4 and MEC-10, are members of the Degenerin (DEG) receptor family, and form a hetero-tetrameric nonselective cation channel that is gated by mechanical tension. DEG channels are tethered to a specialized extracellular matrix around the touch-sensitive cell. In addition, the channel is anchored inside the cell to a microtubule network via accessory proteins. A mechanical shearing movement of these two scaffolding structures relative to one another provides the energy needed for DEG channel gating [6]. DEG genes show significant homology with mammalian acid-sensing ion channels (ASIC) and amiloride-sensitive epithelial Na^+ channels (ENaCs). One of these, DRASIC, is expressed only in DRG neurons. While ASIC2- and ASIC3-null mutant mice display deficits in mechanosensation, their specific role in mechanotransduction in sensory neurons remains controversial, and it is possible that another channel is responsible, such as one of the stretch-sensitive TRP channels or the TREK-1 potassium channel [6].

Several molecules participate in chemical stimulus detection. Histamine released from mast cells directly stimulates a small subset of C-fiber sensory neurons through its Gq-linked H1 GPCR receptor to contribute to the initiation of itch sensation. Direct tissue damage results in the release of protons and high concentrations of ATP from injured cells. Protons directly depolarize primary afferents through the ASIC channels. ASIC3 for example, mediates the intense pain associated with cardiac ischemia (angina). ATP acts both on ligand-gated P2X2 and P2X3 channels and the P2Y2 GPCR to activate nociceptors. ATP is released from damaged cells and acts as an efficient tissue injury detector. P2X3 is also involved in detecting bladder distension, since ATP is released from the urothelium of the distended bladder and activates P2X3 receptors on sensory neuron terminals [7].

Sodium channels are key in conveying nociceptive information from the periphery to the CNS. Voltage-gated sodium-ion channels (VGSC) allow Na^+ ion influx in response to local membrane depolarization, such as the generator potential in the peripheral terminals of nociceptors. These ions determine the excitability of the membrane and mediate the propagation of action potentials from peripheral terminals to the CNS. They consist of a large α subunit (~250 kDa) and one or more accessory β subunits (33–36 kDa) (Table 57-3) [8]. Nociceptor neurons express a number of VGSC α subunits, including some found only in these cells (Na_V 1.8 and 1.9). Local anesthetics are nonselective sodium-channel blockers, and specific blockade of sensory-neuron-specific sodium channels could lead to analgesics with potentially few if any side-effects.

The sodium channel α subunit spans the membrane 24 times. These transmembrane domains are split into four groups, each with six spanning segments. The four structurally homologous domains (I–IV) come together to form a membrane-spanning pore; in addition, domain IV contains a voltage sensor and domain III an ion selectivity filter [9]. The fourth spanning segment (S4) of each domain plays the pivotal role in channel opening. These regions possess multiple positively charged residues and undergo conformational change in response to depolarization. A single aromatic amino-acid within domain I confers binding and sensitivity to the puffer-fish toxin tetrodotoxin (TTX). The sensory neuron specific channels Na_V1.8 and 1.9 are TTX resistant. Sodium channel β subunits target and anchor the channels to the plasma membrane, they consist of a single transmembrane region and are glycosylated on the *N*-terminal extracellular domain. These glycoproteins accelerate inactivation kinetics and shift the voltage dependence of steady-state inactivation.

DORSAL HORN

The dorsal horn acts as a gate, regulating the flow of peripheral activity. In 1965 Melzack and Wall launched the spinal gate-control theory, arguing that pain represents the outcome of a balance of excitatory and inhibitory influences operating on the dorsal horn of the spinal cord. Forty years later, much has changed, particularly the realization that nociceptive pain is the expression of activation of a highly specialized and specific sensory

TABLE 57-3 Sodium channels

α-Subunit type	Other names	TTX sensitivity (nM)	Activation threshold	Inactivation rate	Chromasomal location	Tissue localization
$Na_v1.1$	Brain I	-	Low	Fast	2q24	CNS, DRG, motor neurons
$Na_v1.2$	Brain IIA	18	Low	Fast	2q23-24	CNS
$Na_v1.3$	Brain III	15	Low	Fast	2q24	Embryonic nervous system, adult CNS, injury induced DRG/CNS
$Na_v1.14$	SkM1	5	Low	Fast	17q23-25	Skeletal muscle
$Na_v1.5$	H1	1,800	Low	Medium	3p21	Heart, embryonic DRG
$Na_v1.6$	SCP6, PN4	1	Low	Fast	12q13	DRG, motor neurons, CNS
$Na_v1.7$	PN1	2	Low	Fast	2q24	Mostly DRG, some CNS (all cells)
$Na_v1.8$	SNS, PN3	>100,000	High	Slow	3p22-24	Exclusively DRG (80% small cells, 20% large cells)
$Na_v1.9$	NaN, SNS2, PN5	39,000	Low	Noninactivating	3p21-24	Almost exclusively DRG (small cells only)
β-Subunit type			**Chromasomal location**			**Tissue localization**
$Na_vβ1.1$			19q13			CNS, muscle
$Na_vβ1.2$			11q23			CNS
$Na_vβ1.3$			11q24			CNS
$Na_vβ1.4$			11q23			mainly DRG, CNS and muscle

pathway, not of changing patterns of activity in large and small afferents. Nevertheless, it is increasingly clear that both inflammatory and neuropathic pain reflect major alterations in excitation and inhibition in the spinal cord, some transient and some persistent. It is the balance of these positive and negative influences which determines the degree of information that is relayed to higher centers and therefore defines the level of perceived pain.

The dorsal horn is the first site of synaptic transfer in the nociceptive pathway. Aδ- and C-fiber nociceptors in common with most neurons in the CNS utilize glutamate as their fast transmitter (Fig. 57-3). Glutamate binds to ionotropic AMPA and NMDA receptors, as well as to metabotropic glutamate receptors expressed by dorsal horn neurons. The AMPA receptors produce fast excitatory postsynaptic potentials that signal the onset, duration, intensity and location of peripheral noxious stimuli. More intense or sustained C-fiber nociceptor activation results in the release of neuropeptide neuromodulators (substance P and calcitonin gene-related peptide or CGRP) that produce slow synaptic potentials via NK1, CGRP1 and CGRP2 receptors. The latter receptors , by temporal and spatial summation, can generate a sustained postsynaptic depolarization. This depolarization removes the voltage-dependent block by Mg^{2+} of NMDA receptor ion channels (see Ch. 15), thereby producing a short-latency, short-lasting activity-dependent increase in responsiveness called *windup*. In windup, the response to successive repeated noxious stimuli gets bigger with repetition [10].

The release of transmitters from C fibers is mediated by presynaptic, voltage-gated *N*-type calcium channels (Ca(V)2.2). Omega conotoxins found in mollusks that block these channels have an analgesic action when given locally into the spinal cord. Voltage-gated calcium channels (VGCC) comprise pore-forming α subunits plus accessory α2δ and β subunits. A class of novel anticonvulsants that bind to the α2δ subunits (gabapentin and pregabalin) have analgesic activity and modulate transmitter release (Fig. 57-3). Transmitter release is also regulated by presynaptic inhibition produced by the transmitter GABA G-protein-coupled receptors, acting on $GABA_A$ ion channels and $GABA_B$ GPCRs (see also Ch. 16). Other presynaptic inhibitory GPCRs (see Ch. 19) include the cannabinoid CB1 receptor and the three opioid μ, δ and κ GPCRs (MOR, DOR and KOR; discussed in detail in Ch. 56). GABA also produces postsynaptic inhibition, as does glycine, which acts mainly on GlyR α3 containing receptors [1] (Fig. 57-3). Inhibitory circuits are activated either tonically or phasically in response to afferent and descending inputs from the brainstem, and thereby control the transfer of output from the spinal cord [12].

THE BRAIN

Nociceptive information is integrated in the brain. Nociceptive signals reach the brain through spinal projections to the brainstem, hypothalamus, thalamus and ventral forebrain. Two major ascending pathways convey nociceptive signals from the dorsal horn to the thalamus; these are the lateral and the medial (or anterior) spinothalamic tracts (STT). The majority of STT neurons project to the contralateral thalamus. Direct spinobulbar terminations are concentrated in the parabrachial nucleus, midbrain periaqueductal gray (PAG), reticular formation and catecholaminergic nuclei of the brainstem. Functional imaging in humans shows that the primary (S1) and secondary (S2) somatosensory cortex, the insula, anterior cingulate gyrus and prefrontal cortices are all activated in association with the sensation of pain [13].

Descending systems modify the spinal processing of nociceptive input. Supraspinal control of nociceptive signaling is relayed through the PAG, which integrates input from a number of sources: the frontal cortex, insula,

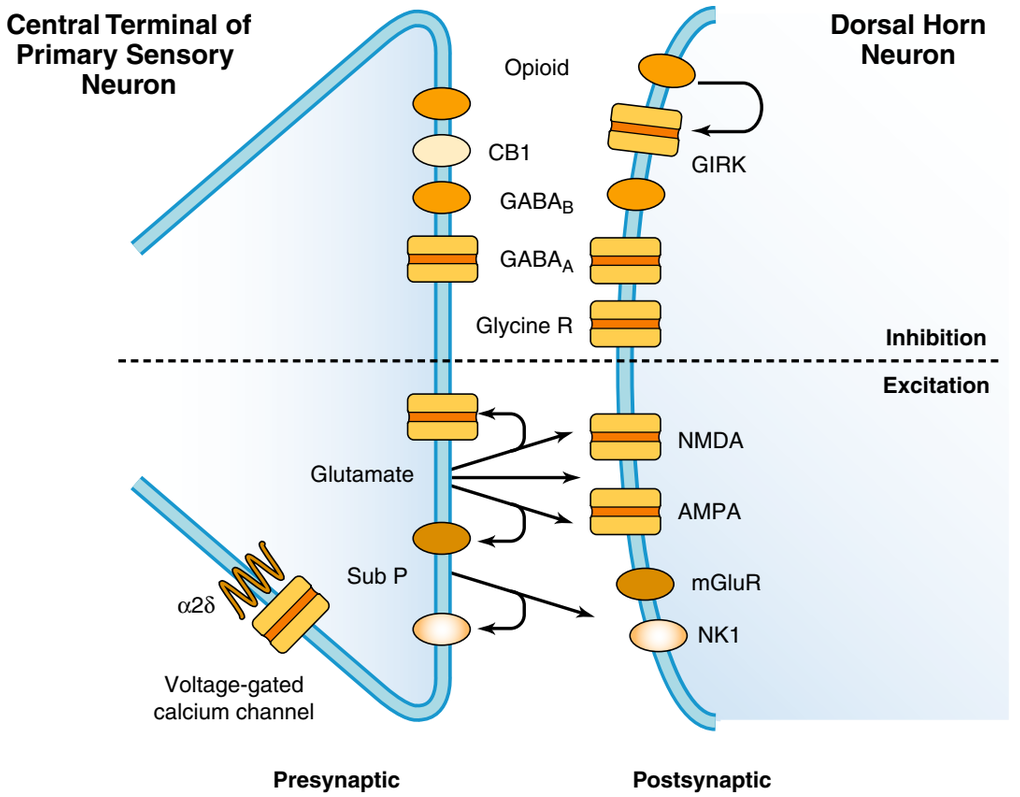

FIGURE 57-3 Transmission between primary sensory and dorsal horn neurons is subject to pre- and postsynaptic excitatory and inhibitory influences.

amygdala, hypothalamus and brainstem nuclei. The PAG does not project directly to the dorsal horn, but rather via the rostral ventromedial medulla (RVM) and the pontomesencephalic noradrenergic nuclei. The RVM is the major source of descending serotonergic input (Ch. 13) that modulates nociceptive transmission in the spinal cord [14].

Endogenous opioids and opioid receptors inhibit pain responses. The DRG, spinal dorsal horn, PAG, RVM, and the amygdala are rich in opioid G-protein-coupled receptors. Local injection of morphine into each of these areas produces analgesia. Opioid receptors (a) decrease the release of transmitters presynaptically by reducing calcium ion influx, and (b) hyperpolarize postsynaptic neurons by opening G-protein-coupled inward-rectifying potassium channels (GIRKs). Five endogenous ligands for the MOR and DOR receptors have been identified: leucine (leu)-enkephalin, methionine (met)-enkephalin, β-endorphin, and endomorphins I and II. A sixth endogenous opioid peptide, dynorphin, binds with high affinity to KOR. Orphanin is a 17-amino-acid neuropeptide similar to dynorphin and acts on the opioid-receptor-like receptor 1. The precursor molecule of orphanin, pronociceptin, gives rise to another peptide with analgesic effects, nocistatin. Neurons synthesizing endogenous opioid peptides are present along the neuraxis and in the DRG. It is still not clear what activates release of the endogenous opioids, such as in life-threatening stress situations (fight or flight) and the placebo reaction, which can produce effective analgesia. MOR agonists such as morphine produce powerful analgesia because they act on multiple sites. However, the role of opiates as analgesics is complicated by tolerance, side-effects such as sedation and nausea, and because of their euphoric actions, a high potential for abuse [15]. Further details concerning peptides and opioids and their receptors are found in Chapters 18 and 56.

CLINICAL PAIN

Clinical pain is characterized by the presence of spontaneous pain or hypersensitivity to pain-provoking stimuli. Hypersensitivity includes pain produced by low-intensity stimuli that normally only elicit an innocuous sensation (*allodynia*), or an exaggerated response to a noxious stimulus (*hyperalgesia*). There are two distinct forms of clinical pain, the pain that occurs after tissue injury or inflammatory diseases (*inflammatory pain*) and the pain associated with a lesion or disease of the nervous system (*neuropathic pain*). Although the mechanisms responsible for the initiation and maintenance of these pains differ, they are both characterized by heightened

pain sensitivity, with a reduction in threshold and increased responsiveness. Unlike nociceptive pain, which reflects short-lasting activation of a specific sensory pathway, *clinical pain* is generally long-lasting and the consequence of a remarkable plasticity of the nervous system due to post-translational changes and altered trafficking of receptor ion channels, altered transcription, neuron loss and novel synaptic inputs [16].

INFLAMMATORY PAIN

Inflammatory pain results from changes both in primary sensory and dorsal horn neurons. The alterations in primary sensory neurons fall into two broad categories: (a) a reduction in threshold and an increase in the response of the peripheral terminals of nociceptors (*peripheral sensitization*), and (b) an alteration in transmitter content modifying synaptic input to the spinal cord. In the dorsal horn, peripheral inflammation results in an increase in membrane excitability and synaptic efficacy, which is the phenomenon of *central sensitization* [12].

Peripheral sensitization lowers nociceptor activation threshold. Tissue damage and peripheral inflammation result in the release and production of inflammatory mediators, including cytokines, chemokines, growth factors, kinins and prostanoids that sensitize the nerve terminal rather than directly activating it [17]. Prostaglandins and inflammation are discussed in Ch. 33. Such sensitizers include bradykinin acting through B1 and B2 GPCRs, prostanoids (notably prostaglandin E2) that bind to four EP GPCRs, and nerve growth factor (NGF) via the membrane tyrosine kinase, trkA receptor. These receptors activate intracellular signal pathways that converge on calcium-dependent protein kinase C (PKC) and cAMP-dependent protein kinase A (PKA) (see Ch. 6). Two major substrates for these kinases are the TRPV1 heat sensor and the $Na_V1.8$ sodium channel. Phosphorylation of TRPV1 reduces the temperature at which it is activated and this is responsible for heat hypersensitivity after sunburn, while phosphorylation of $Na_V1.8$ alters its kinetics, increasing the excitability of the membrane and thereby the responsiveness of the terminal. TRPV1 is also sensitized by phosphatidylinositol-4,5-bisphosphate (PIP2) hydrolysis after phospholipase C activation and by protons. Peripheral sensitization is restricted to the site of tissue damage (zone of primary hyperalgesia).

NGF, in addition to its direct sensitizing action in the peripheral terminal, is retrogradely transported to the cell body, where, via the ERK MAPK and CREB pathways, it increases expression of substance P (sub P), CGRP, BDNF, ASIC and $Na_V1.8$, and produces an increase in TRPV1 translation. $Na_V1.8$, ASIC and TRPV1 are shipped to the periphery, where their increased levels further augment peripheral sensitivity. After peripheral inflammation, substance P and BDNF are expressed in low threshold myelinated Aβ fibers (normally they are expressed only in C fibers) and this phenotypic switch contributes to an altered synaptic drive to the dorsal horn [16].

Central sensitization results in hyper-responsive dorsal horn neurons. Second-order sensory neurons in the dorsal horn respond to high-level nociceptive input with an increase in excitability that outlasts the stimulus and that is termed *central sensitization* [10]. Glutamate receptors play a critical role in central sensitization (Fig. 57-4). Normally, glutamate released from primary afferent terminals only activates AMPA and mGluRs on dorsal horn neurons, because the NMDA receptor ion channel is blocked by a magnesium ion, preventing influx of sodium and calcium ions (see Ch. 15). Synaptic input through AMPA receptors and activation of NK_1 by substance P lead to membrane depolarization, the opening of voltage-gated calcium channels, and a rise in intracellular calcium, which triggers a phosphorylation cascade within dorsal horn neurons involving the ERK MAPK, protein kinase A (PKA), calcium-calmodulin-dependent protein kinase II and protein kinase C (PKC) (Ch. 24). Downstream of PKC, cell adhesion kinase β (CAKβ) and Src are also activated. Src and Fyn, phosphorylate serine and tyrosine residues on the NMDA receptor (Ch. 23). As a consequence, the magnesium block is removed and channel-open time is increased, and therefore synaptic-released glutamate acting on the NMDA receptor provides a powerful additional source of postsynaptic activation. NMDA-receptor activation itself allows calcium ion influx into the cell that further augments signal transduction within the dorsal horn neuron. ERK activation also leads to phosphorylation of A-type potassium channel Kv4.2, which increases membrane excitability. Apart from a change in ligand- and voltage-gated ion-channel properties induced by these activity-dependent post-translation changes, the intracellular kinase cascades also increase the trafficking of AMPA and NMDA receptors from a cytosolic site to the synaptic membrane (see trafficking in Ch. 9). Synaptic efficacy increases, and previously subthreshold inputs now drive the postsynaptic neuron — the dorsal horn cell is thereby sensitized and hyper-responsive — representing a central mechanism that plays the major role in establishing post-injury pain hypersensitivity.

Features of central sensitization are pain in response to normally innocuous tactile stimuli, and the spread of pain sensitivity beyond the site of tissue injury. Central sensitization plays a major role in acute post-traumatic pain, and also in migraine, neuropathic pain (see below) and some diffuse chronic pain syndromes, such as fibromyalgia and irritable bowel syndrome. In these conditions, which have no detectable peripheral trigger, an autonomous central sensitization may be the pathology, increasing the gain in neuronal activity in the CNS and thereby producing abnormal responses to normal inputs.

The activity-dependent changes in dorsal horn that constitute acute or immediate central sensitization are

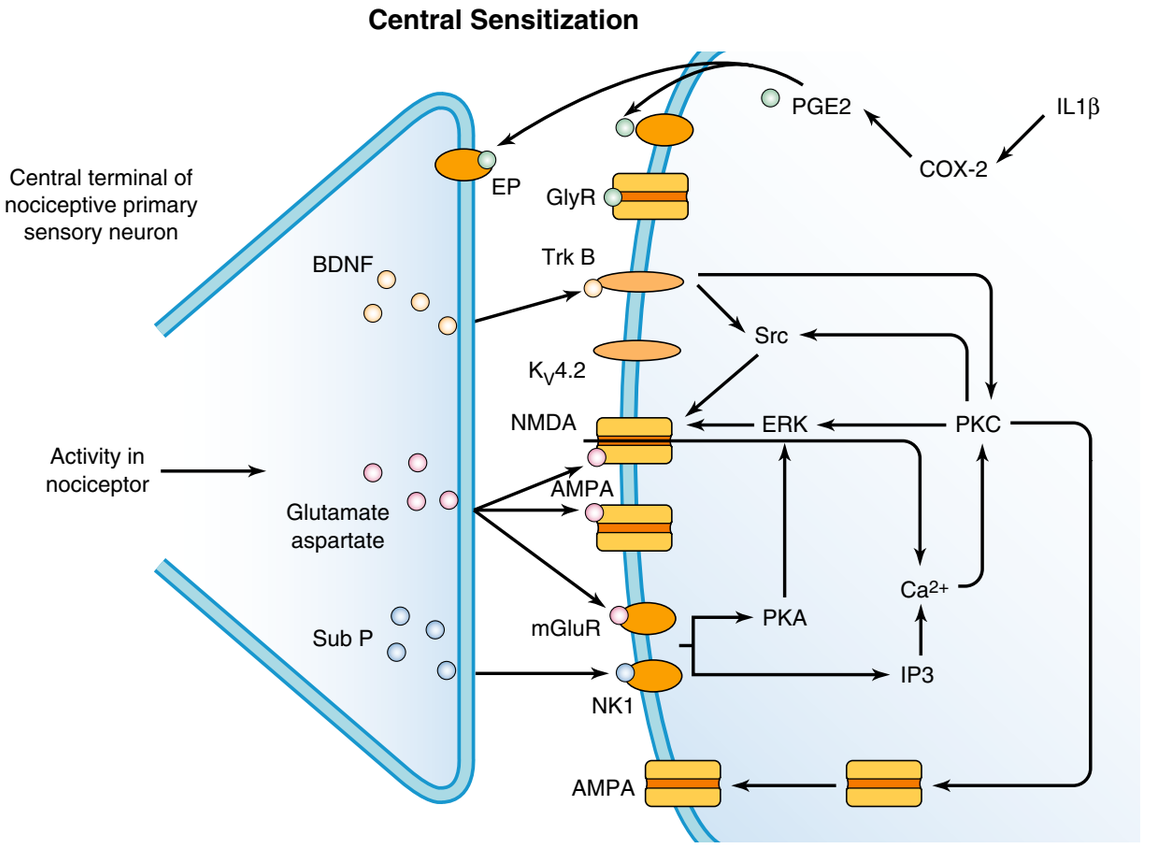

FIGURE 57-4 High levels of activity in nociceptors induce long-lasting increases in the excitability of postsynaptic dorsal horn neurons, the phenomenon of central sensitization. Initially, these are the result of post-translational processing with phosphorylation of ion channels and receptors, altering receptor kinetics as well as trafficking to the membrane. Later transcriptional changes contribute to the sustained excitability, including induction of COX-2 leading to PGE2 production.

induced within minutes, and typically last for an hour or so. However, transcription-dependent changes then kick in and produce alterations in excitability that can last for several days. These include increased expression of the sodium channel $Na_V1.3$, the NK1 receptor, dynorphin and COX-2 in spinal neurons [18]. PGE2 produced as a result of central COX-2 induction results in an increase in transmitter release, a direct depolarization of dorsal horn neurons and a blockade of glycine receptors. All of these result in a marked increase in neuronal excitability. Altered transcription results from increased expression or activation of transcription factors, or the removal of transcription repressors, driven by some of the same signal transduction pathways, such as the MAPKs, that drive the post-translational changes that underlie central sensitization [10]. Some of these transcription-dependent changes are activity-dependent, driven by synaptic input and restricted to localized regions of the spinal cord (e.g. dynorphin). Others are mediated by humoral signals initiated by peripheral inflammation and central cytokine production (e.g. COX-2) and are much more widespread (see Ch. 33).

Prostanoids are key modulators of inflammatory pain. Peripheral inflammation increases prostanoid levels at the site of inflammation and this contributes directly to inflammation and peripheral sensitization (prostanoids and inflammation are discussed in Ch. 33). Peripheral inflammation also increases central prostanoid levels as a result of the central induction of COX-2, to mediate widespread changes in pain sensitivity as well as fever, anorexia, altered mood and sleep patterns [19].

Basal levels of prostanoids are important for homeostatic functions in several tissues, including the kidney, gastric mucosa and platelets. Prostanoids derive from arachidonic acid that is liberated from phospholipids in the cell membrane by the action of phopholipase A2 enzymes (PLA2s). Cyclo-oxygenase (COX) is the enzyme that catalyzes the first two reactions of the prostaglandin pathway leading to the formation of PGH2, an intermediate metabolite. Tissue-specific isomerases (prostaglandin synthases) metabolize PGH2 into the prostaglandin isoforms PGE2, PGD2 and PGF2, prostacyclin (PGI2) or thromboxane (TxA2), which exert their biological actions

via GPCRs, classified as DP, EP, FP, IP and TP receptors according to their respective prostanoid ligand. Two isoforms of cyclo-oxygenase exist. COX-1 is expressed constitutively, and generally produces prostanoids in response to physiological processes requiring continuous regulation. In contrast, COX-2 is inducible and typically produces prostanoids that mediate responses to physiological stress such as injury, infection and inflammation. COX-2 is induced peripherally and in the CNS as an immediate early gene at both transcriptional and translational levels by the proinflammatory cytokines TNFα and IL1β via the NFκB transcription factor and the MAP kinase signaling pathways (see Ch. 26).

The anti-inflammatory and analgesic benefits of non-steroidal anti-inflammatory drugs (NSAIDs) derive from inhibition of the COX-2 isoform in the periphery and, it is increasingly recognized, within the CNS. NSAIDs that specifically inhibit COX-2 activity while sparing COX-1 may be beneficial through their anti-inflammation effect while having reduced risk of certain side-effects, particularly gastric erosions and bleeding. COX-2 selective drugs may, however, increase cardiovascular side-effects.

NEUROPATHIC PAIN

A broad variety of diseases may cause neuropathic pain. The majority of diseases associated with neuropathic pain involve the peripheral nervous system. These diseases include: traumatic injuries; hereditary, metabolic, inflammatory or paraneoplastic neuropathies; and infections. However, neuropathic pain can also be caused by injuries or disorders affecting the spinal cord or the brain (*central neuropathic pain*): tumors; stroke; epilepsy; and neurodegenerative disorders [20]. Genetic factors appear to contribute to inter-individual differences in the susceptibility to neuropathic pain.

Injured axons may develop spontaneous and repetitive firing known as ectopic activity. Injured primary afferents develop spontaneous action potential discharges that occur uncoupled from receptor stimulation in the periphery (Fig. 57-5). These ectopic discharges can be evoked by protons, cytokines or mechanical stimulation of the injured nerve. Another source of ectopic activity are pacemaker currents produced in the plasma membrane

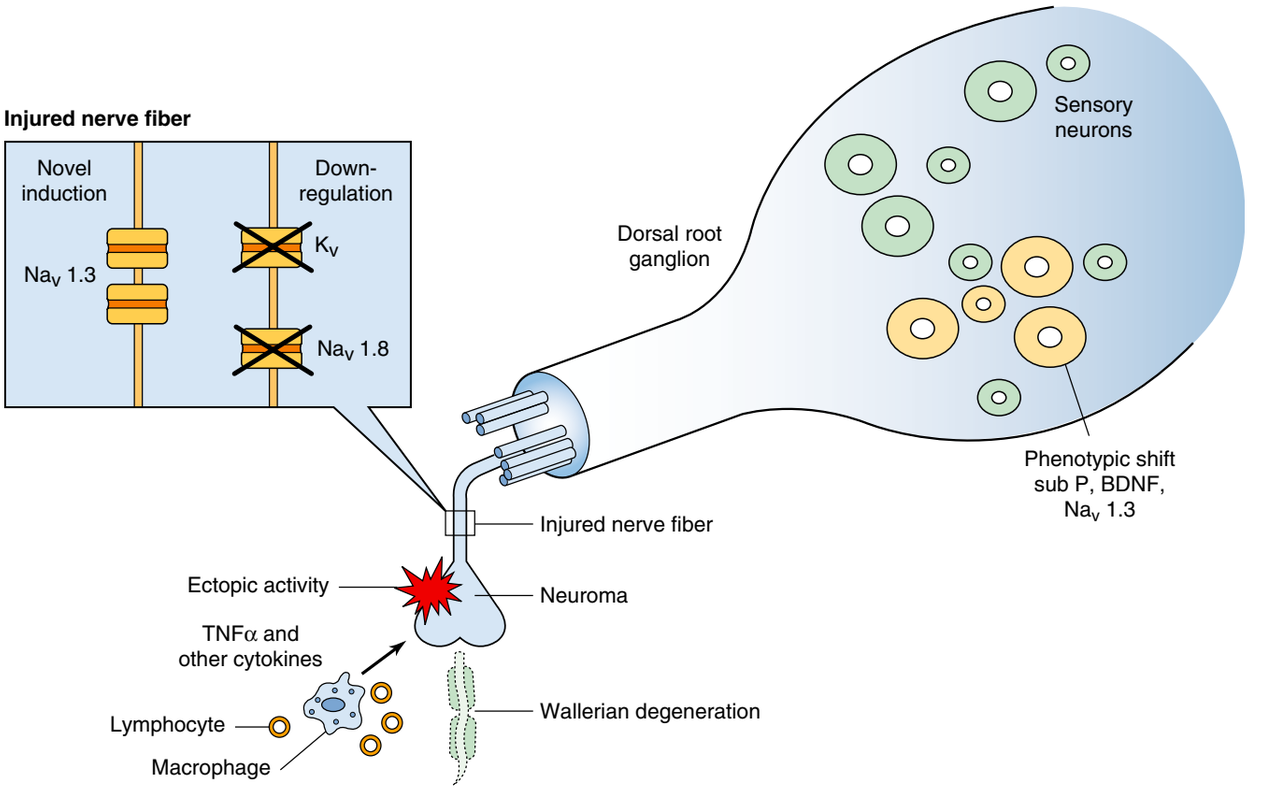

FIGURE 57-5 When severed nerve fibers fail to regenerate, a neuroma is formed. Neurotrophic factors and cytokines released at the neuroma site promote the development of ectopic activity. Changes in the composition of plasma membrane ion channels include a downregulation of $Na_V1.8$ and KV while $Na_V1.3$ is induced. In addition, injured (and neighboring uninjured) primary afferents acquire a new phenotype, producing signaling molecules such as BDNF and substance P.

as a result of changes in ion channel expression and trafficking. After nerve injury, expression of $Na_V1.8$ and $Na_V1.9$ sodium channels decreases, paralleled by a loss of TTX-resistant sodium currents. This contrasts with induction of $Na_V1.3$, a TTX -sensitive sodium channel normally only expressed in DRG neurons during development [21]. Rectifier type K_V channels regulate the pattern and frequency of action potentials by determining membrane repolarization. In large myelinated DRG neurons, K_V channels are expressed as $K_V1.1$, $K_V1.2$ and $K_V\beta2.1$, whereas $K_V4.1$ predominates in small-diameter neurons [22]. Following peripheral nerve injury the expression of K_V is reduced by more than 50%. Together with the injury-induced upregulation of $Na_V1.3$ the decrease in K_V produces a heightened responsiveness of primary sensory afferents. The $\alpha2\delta$ subunit of high-threshold voltage-gated calcium channels is upregulated many-fold by nerve injury, which explains why antiepileptic drugs that target this protein have efficacy in treating neuropathic pain.

Ectopic activity in C fibers elicits central sensitization in the dorsal horn, contributing to the generation of tactile allodynia, a prominent feature of neuropathic pain.

Incomplete nerve lesions provoke changes in the membrane excitability of afferents spared by the injury. These effects are the consequence of an altered cellular and signaling environment at the lesion site and in the DRG. Wallerian degeneration of axotomized nerve fibers involves degeneration and proliferation of Schwann cells, and an invasion of macrophages (discussed in Chs 30 and 36). Nerve injury is accompanied by a release of trophic factors at the injury site and by skin keratocytes in the innervation territory of the injured nerve. Schwann cells, invading macrophages and satellite cells in the DRG produce cytokines including TNFα, to activate uninjured primary afferents to activate them. Nerve injury alters the trafficking of sodium channels in intact neurons. A lesion of neighboring nerve fibers induces an increased integration of $Na_V1.8$ distally in the peripheral axon of intact nociceptors, leading to enhanced excitability.

Sensory neurons transform their phenotype. Microarray gene expression analysis reveals that many hundreds of transcripts change in the DRG after peripheral nerve injury [23]. Injured and neighboring uninjured sensory neurons dramatically change their phenotype following a nerve lesion, with alterations in the expression levels of many genes and *de novo* synthesis of other genes. Because of the phenotypic changes in A fibers, with novel expression of substance P and BDNF, these afferents, which normally do not produce central sensitization, begin to do so.

Spinal disinhibition allows more nociceptive signal input. Following peripheral nerve injury there is a reduction in the GABAergic component of postsynaptic inhibitory currents caused by a degeneration of GABAergic interneurons [24] (Fig. 57-6). This loss of inhibition (disinhibition) results in an overall increase in the excitability of dorsal horn neurons. The degeneration of inhibitory interneurons is due to an excitotoxic effect of primary afferent ectopic activity on dorsal horn neurons [26].

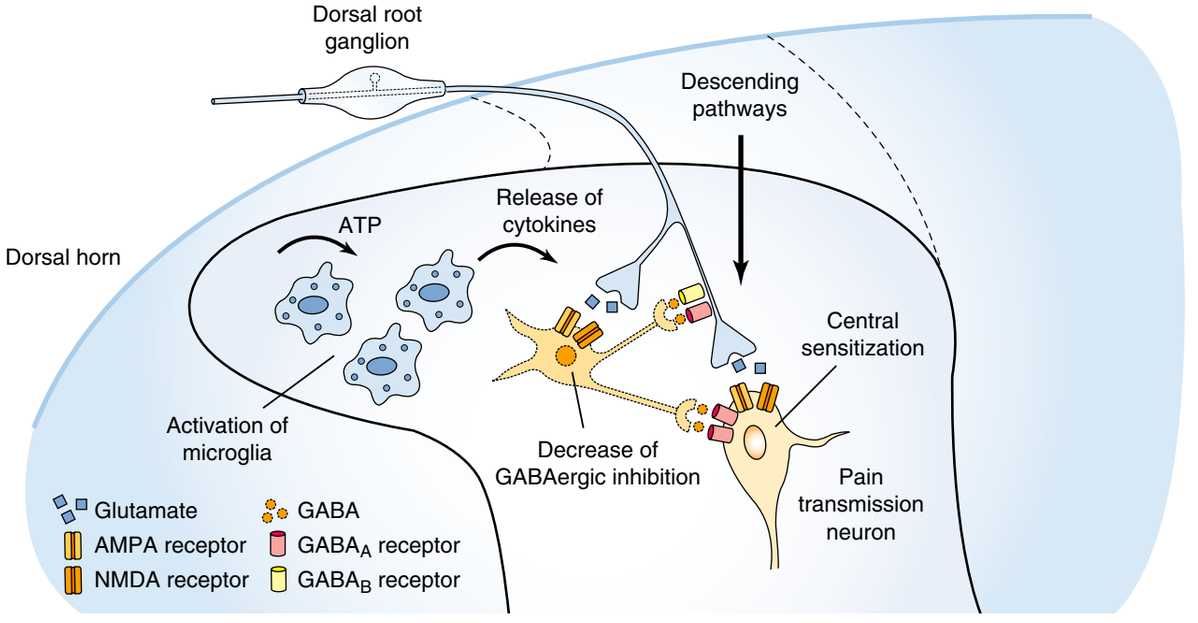

FIGURE 57-6 Central sensitization of dorsal horn neurons and a loss of inhibition after nerve injury result in altered processing of sensory input. ATP activates microglia through the P2X4 receptor. The resulting release of cytokines contributes to the development of pain through a mechanism of action that is, as yet, unknown.

Peripheral nerve injury provokes a marked neuroimmune reaction. Peripheral nerve injury also results in an activation of microglia and astrocytes in the dorsal horn of the spinal cord [25]. Activated glia and invading macrophages release cytokines including IL-1β, IL-6 and TNFα. The purinergic receptor $P2X_4$ (Ch. 17) expressed by activated microglia and activated by ATP contributes to neuropathic pain [26]. Modulation of the immune response can attenuate pain in experimental conditions; however, long-term clinical immunosuppression is hampered by its side-effects.

CONCLUSION

Pain is not a homogenous sensory state. Instead, there are several distinct types of pain: nociceptive pain, a physiological warning system mediated by activation of a specific high threshold sensory pathway; and two forms of clinical pain characterized by spontaneous pain and hypersensitivity, inflammatory and neuropathic pain. Elucidation of the molecular mechanisms in the peripheral and central nervous systems responsible for pain perception has enabled an understanding of how currently available analgesics such as morphine-like opioids and nonsteroidal anti-inflammatory drugs produce their effects, and is also revealing targets for new drugs with the potential for greater efficacy and reduced side-effects. It is increasingly clear that a feature of pain is that it reflects the modifiability or plasticity of the nervous system. A high-threshold system, switched on only by very intense stimuli can, after injury, be initiated by normally innocuous stimuli. Nociceptive pain is protective. The hypersensitivity associated with inflammatory pain can aid healing and repair by minimizing further stimulation of an injured body part, although in the case of chronic inflammatory pain, such as rheumatoid arthritis, the pain does not contribute to healing and is pathological. Neuropathic pain also lacks useful function; it represents maladaptive changes within the nervous system. The pathological changes underlying chronic inflammatory and neuropathic pain effectively represent a disease state.

MAGNETIC RESONANCE IMAGING (MRI) 940
MRI has become the preferred modality for medical and diagnostic imaging due to the superior resolution and contrast in the images 940
The real power of MRI is the ability to exploit the inherent NMR properties of different tissues and tissue pathologies 940
Volumetric and morphological brain measurements are made with MRI 940
Diffusion tensor imaging (DTI) yields information on white matter tracts 941
Signal-intensity analysis yields further insight into cellular pathology 941
Magnetization-transfer imaging (MTI) reveals pathology through signals retrieved from 'bound' protons 941
Functional magnetic resonance imaging (fMRI) maps brain function based on changes in regional blood flow 941

MAGNETIC RESONANCE SPECTROSCOPY (MRS) 942
The overall physical principles and characteristics of magnetic resonance spectroscopy (MRS) are identical to those of MRI 942
Multinuclear MRS studies have demonstrated alterations in brain of schizophrenic patients 943
MRS research is increasingly used to indicate the regions of brain affected in addiction/alcoholism 943
MRS can provide a snapshot into the metabolic processes of brain tumors 944
Phosphorus MRS studies of depressed subjects strongly indicate that this disorder arises from altered brain energy metabolism 944
Hydrogen MRS has revealed unique and consistent metabolic characteristics in the brains of patients with probable AD 944
Hydrogen and phosphorus MRS have proven to be useful tools in the characterization of several epilepsies 944

POSITRON EMISSION TOMOGRAPHY (PET) AND SINGLE PHOTON EMISSION COMPUTED TOMOGRAPHY (SPECT) 944
PET and SPECT are both functional imaging methods that use externally administered radionuclide-labeled substances to image *in vivo* physiological processes in 3-D space 944

APPLICATIONS OF PET AND SPECT FOR BRAIN FUNCTION 945
Measurements of regional cerebral blood flow by PET and of cerebral perfusion by SPECT often detect functional abnormalities before CT or MRI identifies morphological abnormalities 945
The PET method is a valuable tool for the estimation of regional glucose and oxygen metabolic rates and cerebral blood flow 946
PET and SPECT combined with principles of receptor binding permit imaging of receptors in the intact brain 946

CNS DRUG DESIGN AND PRECLINICAL/CLINICAL DRUG DEVELOPMENT 948
The site of drug action and receptor distribution are being investigated 949
The mechanism of drug action may be elucidated by studying its binding 949
Drug dosing is estimated based on proportions of receptor occupancy by the drug 949

CLINICAL APPLICATIONS OF PET AND SPECT 949
The metabolic features of brain tumors can be imaged using PET 949
Brain infarction was the first clinical application of SPECT 949
PET scans with ^{18}F-fluorodeoxyglucose (^{18}F-FDG) have an established role in the localization of epileptic foci in patients being evaluated for epilepsy surgery 949
Correlations of cognitive functions with PET or SPECT imaging are under investigation 950
PET and SPECT imaging are used to study Parkinson's and Alzheimer's diseases 950

The primary focus of this chapter is to provide an introduction to the main imaging modalities and the current biomedical research that is currently underway in the field of modern neuroimaging. Since the focus of this chapter is on neurobiology and neurochemistry, only MRI/MRS

Basic Neurochemistry: Molecular, Cellular and Medical Aspects
0-12-088397-X

and PET/SPECT are covered, since these modalities are most directly involved in neurobiological and neurochemical research. Other imaging methods, including X-ray CT, ultrasound and electroencephalography, are not covered, since their primary research use is beyond the scope of this chapter. After reading this chapter, you should have a firm grasp of the basic workings of each imaging technique and a broad, working knowledge of the applications and current research possibilities offered by each method.

MAGNETIC RESONANCE IMAGING (MRI)

MRI has become the preferred modality for medical and diagnostic imaging due to the superior resolution and contrast in the images. MRI has several advantages over X-ray CT, in that MRI does not result in any accumulated ionizing radiation dose to the subject, and it can detect spinal lesions, such as multiple sclerosis, that would otherwise go undetected in X-ray CT (see Appendix: Brief history of medical imaging, and refs [1–9]). However, MRI does pose a minimal risk to the subject in several ways.

1. The radiofrequency pulses involved in MRI cause thermal heating of the tissues, and are thus subject to FDA limits on the amount of RF power that is transmitted to a subject during a medical scan. The RF power unit is specified as the specific absorption rate (SAR) and is measured in watts per kilogram of body tissue (W/kg tissue). Powers that exceed this level put the subject at risk of tissue damage incurred as a result of the tissue's inability to remove the heat through blood flow.
2. The rapid and repetitive application of magnetic field gradients during MRI give rise to a very high rate of change of magnetic field. If this rate of change is fast enough, it can begin to cause neural stimulation of the muscles, causing involuntary twitching.
3. Very little is known about the short-term and long-term effects of exposure to high magnetic fields.

Although the power of research MRI/MRS machines for human use can be as high as 9.4 T, the FDA has imposed a limit of 3 T for routine clinical human use. Industrial manufacturers of MRI equipment are very careful to conform to all the FDA guidelines regarding magnetic field strength, gradient speed and RF power (see Appendix: Basic principles of MRI).

The real power of MRI is the ability to exploit the inherent NMR properties of different tissues and tissue pathologies. The main MR parameters are known as: longitudinal-relaxation time-constant (T1), describing the time for the magnetization to recover to its equilibrium along the main-field axis after RF perturbation; transverse-relaxation time-constant (T2), describing the transient decay of the rotating (MR signal-producing) magnetization from all nuclei in the sample after RF perturbation: and susceptibility-influenced transverse time-constant (T2*) which is identical to T2 with the additional influence of main magnetic-field inhomogeneities. Each parameter offers its own array of information-abundant measurements. In T1-weighted MR images, the ability to resolve discrete structures, tissues or pathology, is greatly enhanced by the additional contrast (ability to distinguish separate structures based solely on their differing intensity, independent of pixel size) resulting from tailoring the MR image sequence specifically to this MR parameter (Fig. 58-1). For further T1 contrast, enhancement of pathological-tissue contrast-agents can be safely delivered to the patient through injection. The contrast agent contains T1 enhancing molecules which are large enough to remain within healthy blood vessels and not to be taken up into healthy tissue, but small enough to diffuse through damaged vessels into damaged or necrotic tissues, such as infarcted, inflamed or cancerous regions. The contrast agent accumulates in these pathological tissues, and shows up as a bright region in the T1-weighted image. Similarly, T2 and T2*-weighted images can reveal unique, underlying structure or pathology that would otherwise be invisible with nonweighted images (Fig. 58-1).

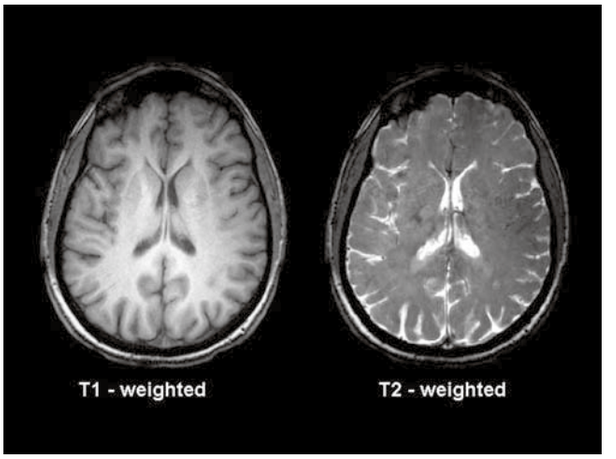

FIGURE 58-1 T1- and T2-weighted images of a normal human brain at 4 Tesla field strength. Gray and white matter is clearly differentiated in the T1-weighted scan, whereas cerebral–spinal fluid (CSF) is well differentiated from the rest of the brain in the T2-weighted image. Both image sets allow for the segmentation of gray matter, white matter and CSF for analysis.

Volumetric and morphological brain measurements are made with MRI. Modern MRI can produce detailed, high-contrast images of the entire brain in relatively short scan times with no invasive procedures or radioactivity. Thus, it is the modality of choice for detailed neuroanatomic studies in various neuropsychiatric disorders. Many groups have addressed the challenge of how to quantify subtle structural characteristics in the brain that appear to differ consistently between comparison groups. Methods such

as tissue segmentation can accurately measure the amount of gray and white matter in either a voxel, a discrete brain region or the entire brain [10]. With this analysis, investigators have uncovered neural processes that contribute to the understanding of mental illness and addiction. For example, magnetic resonance imaging reveals enlarged ventricles in the brains of schizophrenic patients [11], signifying neuronal atrophy and loss. Gray-matter volume reductions in schizophrenia have also been reported in the temporal, cerebellar and anterior-cingulate regions [12, 13]. Aside from parcellelation of tissue-types in the brain, MRI allows the detailed delineation of separate neuroanatomic structures and measurement of their dimensions in the brain. In addition, morphometric techniques are used to normalize the brain images from different subjects into a common space or coordinate system, to correct for the wide variation in brain anatomy between subjects [10]. This method can reveal subtle neuroanatomic features that are unique to neuropsychiatric patients and that may go undetected by conventional means. Consistent alterations in the neuromorphology of the anterior cingulate gyrus and the hippocampus in schizophrenia have also been shown by using high-resolution MRI morphology techniques [14–16] (see also Ch. 54).

Diffusion tensor imaging (DTI) yields information on white matter tracts. Multidimensional quantitation of various neuroanatomic structures in bulk concentrates on macroscopic brain structure and development in neuropsychiatric illness. However, these methods provide little information on the subtle organization of the tissue within these structures and interconnecting tissue. DTI, a form of MRI that exploits the Brownian motion of water molecules, can provide valuable information on the fine structure and organization of white-matter tracts that connect the various brain components. With a carefully tailored sequence of RF pulses and gradients, the fine structure of white-matter tracts can reveal quantifiable information pertaining to the degree of coherent organization (or lack of organization) in separate brain structures. Tissue that looks normal on a conventional MRI scan, may prove to be completely different with DTI, thus making this modality a promising new tool for research. Indeed, DTI has proven to be very effective in the evaluation of brain ischemia, resulting from stroke and/or traumatic brain injury [17]. White-matter abnormalities, such as in multiple sclerosis MS, can be detected and characterized with DTI. Demyelination and axonal loss in MS would likely go undetected with conventional MRI [17]. In neuropsychiatric disorders such as schizophrenia and Alzheimer's disease, as well as addictive disorders like alcoholism, DTI can reveal disconnective and disorganized fiber tracts in the interconnecting white-matter circuitry linking the various regions of the brain, caused either by abnormal brain development or neuronal-toxic damage [17–19].

Signal-intensity analysis yields further insight into cellular pathology. T1- and T2-weighted MRI imaging can differentiate pathology in brain tissues based on analyzing the signal-intensity (SI) of each pixel in the image. T1 and T2 are MR parameters that are affected by the molecular environment of the water in brain tissue. The physical basis for this is described in the Appendix in the accompanying CD-ROM. Abnormalities in the cyto-architecture of axons or in myelin structure can lead to differing image intensity in a T-weighted image. SI in the white matter of T1-weighted MRI images is decreased in multiple sclerosis, while changes in the SI of the corpus callosum in schizophrenia and obsessive-compulsive disorder (OCD) have been reported [10]. White-matter hyperintensities (WMH) detected in brain MRI scans of patients with psychiatric illness show a trend for increased prevalence of WMH in young psychiatric patients at increased risk for cardiovascular disease, rather than an increased rate of WMH in any particular psychiatric illness [20].

Magnetization-transfer imaging (MTI) reveals pathology through signals retrieved from 'bound' protons. With MTI, off-resonance pulses are used to retrieve MR signal from the population of 'bound', or not-freely-mobile protons that are found in macromolecules, fiber tracts and myelin. In conventional MRI, the signal originates from the freely mobile protons in water molecules. With a carefully designed MTI sequence, quantifiable MR signal from the 'bound' protons in various neural tissues can be acquired through transfer of some magnetization from water to produce a quantifiable image of the degree of magnetization transfer (see complete details in Appendix: Basic principles of MRI). This measurable degree of magnetization transfer can reveal underlying abnormalities in tissue pathology, thus making it a valuable research tool. The abnormal myelination that occurs in white matter in MS can be readily detected with MTI. Although not yet consistently utilized in neuropsychiatry, MTI studies in schizophrenia suggest quantifiable differences in magnetization transfer in the parieto-occipital cortex and corpus callosum [10].

Functional magnetic resonance imaging (fMRI) maps brain function based on changes in regional blood flow. The emergence of functional magnetic resonance imaging (fMRI) is proving to be a breakthrough in modern imaging research [21]. fMRI is based on susceptibility-induced signal-intensity changes in the MR image that are directly related to the iron-containing hemoglobin concentration in the tissue, and therefore it is a measure of regional blood flow. With this powerful modality, brain function can be imaged in real time, thus providing a window into the nature of neural motor, cognitive and emotional processing. Indeed, fMRI has revealed reduced response of the auditory cortex to external auditory stimuli in hallucinating schizophrenic patients, along with altered temporal cortex activation during a word presentation paradigm [21]. In other fMRI studies in schizophrenia, amygdyla activation during emotional cues was absent, compared to very predictable activation of this region in a healthy comparison group [21]. Schizophrenia patients

also exhibit either reduced or dysfunctional activation of the frontal cortical regions, compared with controls, during cognitive memory-activation tasks, lending additional support to explaining schizophrenia as an inability to adequately activate the frontal brain region when confronted with a cognitive task [22] (see detailed discussion of schizophrenia in Ch. 54).

MAGNETIC RESONANCE SPECTROSCOPY (MRS)

The overall physical principles and characteristics of magnetic resonance spectroscopy (MRS) are identical to those of MRI. In fact, magnetic resonance spectroscopy can simply be thought of as just another way of expressing the NMR signals that are recorded during an NMR experiment. However, MRS is designed to measure extremely small NMR signals of H1, C13, or P31 nuclei in specific amino acids, energy metabolites and membrane lipid components (see Appendix: Basic principles of MRS, Table 58-1). MRI measures much larger signals of water hydrogen (see details in Appendix: Basic principles of MRS, Table 58-1; Figs 58-2 to 58-4).

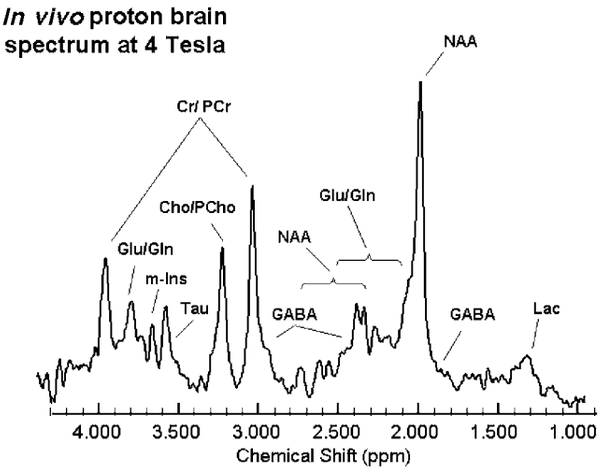

FIGURE 58-2 Hydrogen (^{1}H) spectrum from a normal human brain at 4 Tesla field strength. The spectrum is very complicated, comprised of many overlapping peaks which are difficult to resolve from each other. Spectral analysis routines make use of spectral models which are constructed from the individual spectra acquired from each biomolecule from *in vitro* solutions. This model is then fitted to the raw data and approximate concentrations for each biomolecule are extracted.

TABLE 58-1 Nuclei in MRS and common biological functions [23–25]

Nucleus	Biological function	Molecule	Abbreviation
Hydrogen(^{1}H) /Carbon (^{13}C)	Amino acids/neurotransmission/ intermediate storage/synthesis	γ-amino butyric acid	GABA
		glutamine/glutamate	Gln/Glu
		glutathione	GSH
		glycine	Gly
		acetate	Ace
		N-acetylaspartylglutamate	NAAG
		aspartate	Asp
		phenylalanine	Phe
		serine	Ser
		taurine	Tau
		threonine	Thr
		tryptophan	Trp
		tyrosine	Tyr
		valine	Val
	Energy metabolism	creatine/phosphocreatine	Cr/PCr
		adenosine-triphosphate	ATP
		glucose	Glc
		lactate	Lac
		pyruvate	
		succinate	Suc
	Membrane/lipid metabolism/ neuronal-integrity	choline/glycerophosphorylcholine/ phosphorylcholine	Cho/ PCho GPCho/
		N-acetyl aspartate	NAA
		ethanolamine/ phosphoethanolamine	Etn/PEtn
		glycerol	
		myo/scyllo-inositol	M/s-Ins
Phosphorus(^{31}P)	Energy metabolism	phosphocreatine	PCr
		adenosine triphosphate	NTP/ATP
		inorganic phosphate	Pi
	Membrane/lipid metabolism	phosphoethanolamine	PEtn
		phosphocholine	PCho
		glycerophosphoethanolamine	GPEtn
		glycerophosphocholine	GPCho
		membrane phospholipid	MP
Lithium(^{7}Li)	Lithium drug metabolism	lithium-containing pharmaceuticals	Li
Fluorine(^{19}F)	Fluorine drug metabolism	fluorine-containing pharmaceuticals	F
Sodium(^{23}Na)	Sodium distribution	inter/intra-cellular sodium	Na

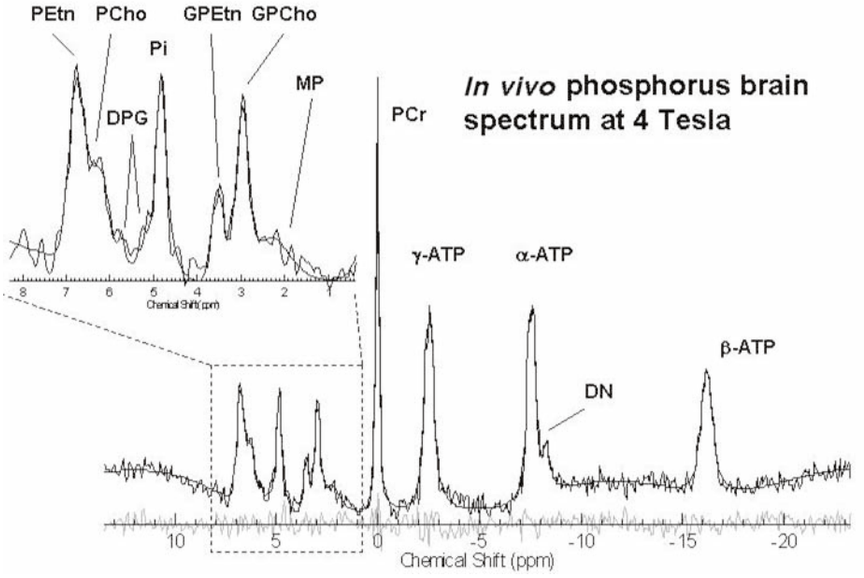

FIGURE 58-3 Phosphorus (^{31}P) spectrum from a normal human brain at 4 Tesla field strength. Unlike the hydrogen (^{1}H) spectrum, The phosphorus spectrum is not as complicated, comprised of much fewer overlapping peaks. Like hydrogen spectrum analysis, phosphorus spectral analysis routines makes use of spectral models. The inset depicts a close-up of the spectral region where membrane phospholipid metabolites are found. Energetics can be measured from extracting relative peak area ratios of ATP to PCr. Tissue pH, a measure of the acidity or alkalinity, can be derived from the relative spectral separation of Pi and PCr.

Multinuclear MRS studies have demonstrated alterations in brains of schizophrenic patients. Phosphorus MRS studies, looking at both first-onset-unmedicated and chronic-medicated schizophrenia, consistently report alterations in the phospholipid profile in the frontal and temporal cortex [26–30]. Typically, phosphomonoester (PME) levels are lower than in controls, and phosphodiesters (PDE) levels are higher in schizophrenia, but opposite directionality in the levels of these membrane metabolite compounds also have been reported [25, 30]. It is thought that membranes in schizophrenia are broken down or metabolized at a higher rate than can be produced, leading to eventual neurodegeneration and progression of symptoms over time. These phosphorus findings are complemented by the findings of altered glutamate, glutamine and NAA levels in schizophrenia, revealed with high-resolution hydrogen [31] or proton MRS studies of the anterior cingulate gyrus and thalamus [32, 33]. Overall, the hydrogen and phosphorus MRS studies in schizophrenia potentially point to a neurodegenerative process involving focal regions of the brain, emphasizing involvement of the frontal and temporal cortex, as well as the anterior cingulate gyrus, thalamus and cerebellum [34] (see Ch. 54).

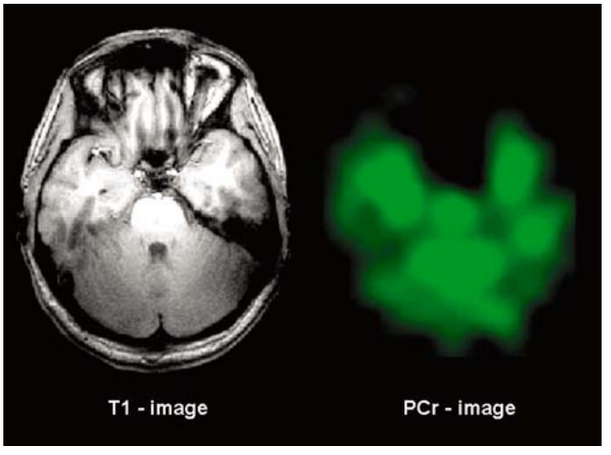

FIGURE 58-4 Chemical-shift image of PCr (right) in a normal human brain at 4 Tesla field strength. Shown on the left is the corresponding T1-weighted image from the same subject. Chemical-shift images can be expressed differently. Here, the peak area of PCr is expressed in terms of image intensity. However, for each voxel in the image, an entire phosphorus spectrum can be extracted, and all metabolites measured.

MRS research is increasingly used to indicate the regions of brain affected in addiction/alcoholism. The increasing use and availability of illicit narcotics, such as heroin and cocaine, as well as alcohol, in modern society, hardly needs mention. MRS research in addiction provides a major avenue for identifying the anatomic regions of brain involved, and the molecular pathology, with the hope of eventually developing more effective strategies in drug treatment programs [35]. Studies with phosphorus MRS have revealed transient alterations in phospholipid metabolism and phosphoenergetics in the brains of opiate-dependent patients undergoing methadone-maintenance therapy. These data show a consistent pattern of increasing

levels of PCr and decreasing levels of phosphodiesters and phosphodiesters in the brain during acute and long-term methadone-maintenance therapy, compared to initial therapy and withdrawal from heroin use [36–38]. Interestingly, phosphorus MRSI indicates that the changes are focused in the frontal lobes, a finding consistent with MRS research in other neurospsychiatric disorders (see the detailed discussion of addiction in Chapter 56).

MRS can provide a snapshot into the metabolic processes of brain tumors. Imaging research has investigated the biochemical functioning of brain tumors. Tumor biopsies can provide valuable cellular structural, histological and genetic information about the nature of malignant tissue, but MRS methodology allows analysis of the metabolic processes within tumor tissue, as well as measurement of the effects of treatment with chemotherapy and radiation. Hydrogen MRS of brain tumors *in vivo* have revealed marked differences in the ratios of NAA, Cho and Cr, compared to healthy tissue [39–42]. Elevated mobile lipid levels detected with hydrogen spectroscopy suggest tumor necrosis, and thereby provides a useful prognostic tool.

Phosphorus MRS studies of depressed subjects strongly indicate that this disorder arises from altered brain energy metabolism. Like any other debilitating mental illness, depression and bipolar disorders cost millions of dollars annually in treatment and loss of productivity (see discussion in Ch. 55). Two phosphorus MRS studies show very consistent and similar results, with reduced levels of nucleoside triphosphates (NTP), the main source of energy in living tissue [43, 44]. What is interesting is that this finding seems to contradict the expectation that NTP levels in living tissue remain absolutely constant, regardless of the metabolic demand placed on the tissue, with PCr providing the buffer to maintain steady NTP levels. This research has prompted more in-depth questions, and given rise to interesting theories concerning mitochondrial dysfunction as the possible underlying cause in depression, as well as other neuropsychiatric disorders (see discussions in Ch. 55).

Hydrogen MRS has revealed unique and consistent metabolic characteristics in the brains of patients with probable AD. Although Alzheimer's disease (AD) is not formally diagnosed until postmortem brain examination, it can be tentatively diagnosed during life as being 'clinically probable AD' (see Ch. 47). Alzheimer's shares common symptoms with other dementias, and is often difficult to diagnose based only on symptoms. Two recent studies have shown that ratios of *N*-acetyl-aspartate to creatine (NAA/Cr) are reduced in probable AD, indicative of either neuronal loss or neuronal atrophy [45–47]. The other consistent finding in these studies is increased ratios of myoinositol to creatine (MI/Cr), suggesting enhanced neuronal gliosis and/or altered myoinositol metabolism in probable AD.

Hydrogen and phosphorus MRS have proven to be useful tools in the characterization of several epilepsies. Epilepsy is a neurological condition in which sudden, uncontrollable firing of neurons in the brain causes seizures. The debilitating aspect of this disorder is the unpredictability and possible injury or death resulting from these seizures. Epilepsy is divided into several subtypes, each with their own set of symptoms and characteristics (see Ch. 37). In patients with juvenile myoclonic epilepsy (JME), for example, reduced ratios of NAA/Cr have been found in bilateral thalami, whereas hydrogen MRS of idiopathic generalized epilepsy (IGE), has shown increased glutamine and glutamate (Glx) levels and decreased NAA levels in the frontal lobes of patients compared with healthy volunteers, suggesting increased neuronal excitability (increased Glx) and neuronal loss or dysfunction (reduced NAA) in IGE [48–52].

POSITRON EMISSION TOMOGRAPHY (PET) AND SINGLE PHOTON EMISSION COMPUTED TOMOGRAPHY (SPECT)

PET and SPECT are both functional imaging methods that use externally administered radionuclide-labeled substances to image *in vivo* physiological processes in 3-D space. These substances may be radionuclide-labeled ligands, metabolites, drugs, nondiffusible tracers, CO_2, H_2O and O_2. Both methods involve the measurement of gamma radiation, emitted from radioactive atoms or processes resulting from the decay of these atoms, with energies of 511 kilo electron volts (keV) in the case of PET or in the order of hundreds of keV in the case of SPECT. Both methods have the unique characteristic of employing the tracer principle, which permits high sensitivity for functional measurements, usually much greater than that achieved by the MR magnetic resonance imaging technique, because with PET and SPECT individual molecules, selected for their specificity, are being imaged as they exhibit their specific functional action. These physiological measurements are used not only to measure normal biochemical processes, but those in disease and those related to therapy. Such measurements include: regional blood flow/perfusion; blood volume; glucose and oxygen metabolism; pre-, post- and intrasynaptic neuroreceptor-transmitter activity; receptor density and affinity; neurotransmitter transporter density; neuronal enzyme activity; and the delivery of drugs across the blood–brain barrier into areas of interest and which bind to molecules of interest, such as receptors or transporters. In addition, these methods can be used to image gene expression and effects of gene therapy. (For detailed technical comparisons, see Appendix: PET versus SPECT: similarities and contrasts, Table 58-2.)

SPECT is routinely available in most nuclear medicine clinics throughout the world, whereas PET is more specialized, but is increasingly available in countries with high levels of medical technology especially with the advent

TABLE 58-2 Typical radionuclides employed in PET/SPECT and physical properties

Isotope	PET/SPECT	Decay mode (%)	Half-life (min)	Energy (Mev) (max/most abundant)	Range in H_2O mm (half-value thickness)	Production: cyclotron (C), reactor (R), generator (G)
^{11}C	PET	β^+ 100	20.1	0.97	4	C
^{18}F	PET	β^+ 97 EC 3	109.8	0.64	2	C and R
^{15}O	PET	β^+ 100	2.04	1.74	8	C
^{13}N	PET	β^+ 100	9.996	1.20	5	C

of clinical uses. In either case, the principle consists of chemically linking a radioactive atom with water, a gas, or any ligand or pharmaceutical used in tracer quantities, which is then inhaled by the subject or injected intravenously. Virtually all areas of the human body can be visualized, but for purposes of this chapter we will emphasize the CNS.

APPLICATIONS OF PET AND SPECT FOR BRAIN FUNCTION

Knowledge about brain function has been revolutionized by PET and SPECT radiopharmaceuticals that measure specific biochemical processes or proteins in living animal or human brain. The challenge is to develop these radiotracers so that they can cross the blood–brain barrier (BBB) and still maintain sensitivity and specificity in binding to the target. (For technical details with respect to the different functions measured, pharmaceuticals, resolution, limitations, imaging equipment and relative risks, see Appendix: Advantages and disadvantages of PET and SPECT, Table 58-3 [54, 55]; for basic radiochemistry for PET, SPECT [56–59] and for validation of radiotracers [60–62] see Appendix: Fundamentals of radiotracer methodology and Fig. 58-5).

Measurements of regional cerebral blood flow by PET and of cerebral perfusion by SPECT often detect functional abnormalities before CT or MRI identifies morphological abnormalities. The function of the cerebral tissue depends critically on the regional cerebral blood flow (rCBF) and rate of metabolism (see Ch. 31). Impairment of blood flow or the rate of consumption of O_2 or glucose constitutes a pathological condition which can be

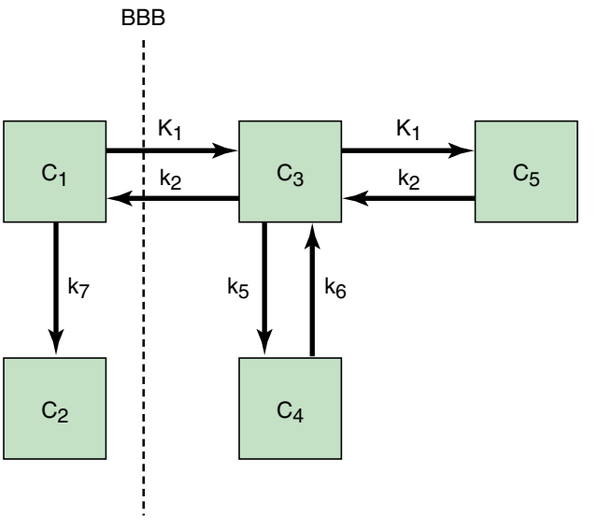

FIGURE 58-5 This is a typical co-compartmental model used in PET or SPECT dynamic image. Compartments such as C_1 and C_2 could be native plasma activity and metabolites respectively. After the radiotracer crosses the blood–brain barrier and enters compartment C_3 this could be the free or precursor pool, C_5 could be the product of either receptor binding or the final step for the measurement of same metabolism, e.g. glucose-6-phosphate, and product of C_4 could be a secondary binding site. For example, the rate constants such as K_1 are (typically) blood flow and tracer extraction. k_2 is typically the dissociation from the blood supply, k_7 same metabolism, k_3 and k_4 the association and dissociation to the receptor or to the final product enzyme step. For example in k_5, k_6 reversibly steps to another receptor. This compartment model could be easily used for FDG glucose metabolism, enzyme activity (dopadecarboxylase) or receptor binding say to D_2 (C_5) or serotonin (C_4) sites. It could even be used for blood flow, except that C_3, C_5, and C_4 would be collapsed to one compartment, and C_1 and C_2 would collapse to a second compartment. Models such as these with the blood–brain barrier of plasma on the one side and the brain compartments on the other are typically used in PET and SPECT quantitation. The ultimate goal is to simplify these methods but initially this is what is necessary for the appropriate quantification of any physiological process using these PET/SPECT imaging methods.

detected on a regional basis in three dimensions by these methods [63].

Radiolabeled agents used to assess brain perfusion by SPECT. Examples include Technetium-99m-hexamethyl propylamine oxime (^{99m}Tc-HMPAO), which is a lipid-soluble macrocyclic amine, permitting rapid diffusion across the blood–brain barrier (BBB). Once it crosses the BBB, ^{99m}Tc-HMPAO is converted into a hydrophilic compound in the presence of intracellular glutathione, which is incapable of rapid back-diffusion. Technetium-99m-bicisate (bicisate ethyl cysteinate dimer, ^{99m}Tc-ECD) is another lipophilic agent that can enter the brain by rapid diffusion. It is converted in the brain by an esterase to a negatively charged complex that cannot diffuse back across the BBB. Brain uptake of both ^{99m}Tc-HMPAO and ^{99m}Tc-ECD are rapid, and reach their maxima within 5–10 minutes of injection.Their regional distributions are proportional to rCBF but do not represent parametric units of rate of blood flow.

The PET method is a valuable tool for the estimation of regional glucose and oxygen metabolic rates and cerebral blood flow. The measurement of glucose metabolic rate is based on the principle that the phosphorylation of glucose to glucose 6-phosphate catalyzed by hexokinase is rate-limiting. The antimetabolite analog 2-deoxyglucose competes with glucose for entry into the cells and phosphorylation by hexokinase, but 2-deoxyglucose 6-phosphate is not metabolized further in the glycolytic sequence. ^{18}F-2-deoxyglucose (^{18}F-DG) is used in tracer quantities and enters brain along with glucose. ^{18}F-labeled 2-deoxyglucose 6-phosphate accumulates in the cells where formed, and the amount accumulated is a measure of the rate of glucose metabolism (see Ch. 31). An example of an FDG image is given in PET (Fig. 58-6). Examples of FDG use for epilepsy, cognitive function and brain tumor are given below. In addition, the short half-life of oxygen-15 ($t^1/_2$=2.1 min) allows for rapid sequential studies of cerebral blood flow using $H_2{}^{15}O$.

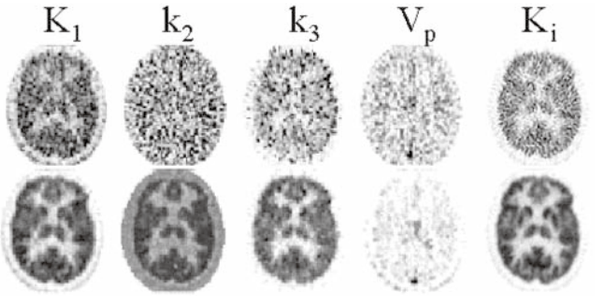

FIGURE 58-6 FDG. The parametric images of K_1, k_2, k_3, V_p. K_1 (ml/min/g) is the forward transport rate constant of FDG from plasma across the blood–brain barrier (BBB) to brain tissue, k_2 (1/min) is the reversed transport across the BBB, k_3 (1/min) is the phosphorylation rate constant, and V_p (ml/g) is the fractional plasma volume in tissue. The images were generated by conventional weighted nonlinear regression (top row) and nonlinear ridge regression with spatial constraint (bottom row). The K_i (K_1 $k_3/(k_2+ k_3)$) was calculated after pixel-wise model fitting. (Yun Zhou *et al.* Improved parametric image generation using spatial–temporal analysis of dynamic PET studies. *Neuroimage*, 15: 697–707, 2002.)

PET and SPECT combined with principles of receptor binding permit imaging of receptors in the intact brain. Over 20 years ago, in a number of almost simultaneous studies involving PET and SPECT, researchers developed the technique of radiolabeling receptor ligands that had a high affinity for CNS receptors. Although this initially began with an antagonist to the D_2 dopamine system, radiolabeled agonists for the muscarinic cholinergic system are now also employed. Many of these radiotracers are successfully used because of the ability to replace a stable carbon (^{12}C) with a radioactive positron emitter (^{11}C) or a fluorine (^{18}F). Alternatively, derivatizing the substance, for example by adding an ^{11}C, ^{18}F or ^{123}I where the atom did not exist, causes a minor modification to the pharmacologic affinity of these ligands. By radiolabeling ligands with PET or SPECT isotopes, however, the labeled ligands allow external imaging and, most importantly, reflect directly much of the drug action that is associated with neuroreceptor binding and neurotransmission. (For a detailed discussion, see Appendix: Fundamentals of radiotracer methodology.)

As shown in Figure 58-7, the *in vivo* efficacy of receptors on the absiccal axis correlates with the *in vitro* binding values (IC50) obtained by measures of binding to tissue homogenates. Since radioligands with a higher affinity as well as higher selectivity tend to underlie the principles of receptor labeling it has an important role in potential drug efficacy (see the section on drug development below).

Quantification of neuroreceptors with PET/SPECT. The typical process consists of identifying an appropriate ligand that is known already to bind *in vitro* or *ex vivo* animal models. Then the radiosynthetic process for providing a positron- or SPECT-emitting radiotracer is obtained. The latter is often a difficult task, and only a very small fraction of such ligands can be labeled in this fashion. Once this is obtained, the radiotracer must then be studied first in small animals and then in nonhuman primates to examine its usability. At any stage, species differences can result in lack of penetration into the brain or rapid metabolism [64]. The validation studies in small animals and baboons typically consist of *in vitro* studies, including saturability and competition with other chemically different but pharmacologically related drugs. Once receptor criteria have been established, the radiotracer is considered appropriate for quantification either in nonhuman primates or in human beings. Of course, the appropriate safety profiles including toxicology and radiation dosimetry must be carried out [64]. One of the newest advances in PET instrumentation is the development of dedicated cameras for imaging rats and mice and nonhuman primates.

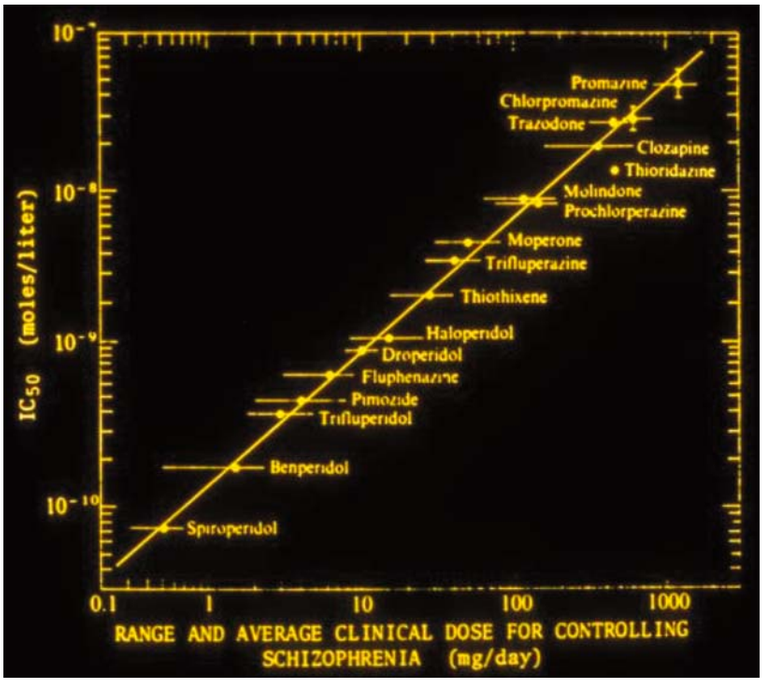

FIGURE 58-7 The IC_{50} values (ordinate) are the concentrations of the antipsychotic drugs that reduce the stereospecific component of ^{3}H-haloperidol binding by 50%. The abscissa indicates the average values (and ranges) of doses used for schizophrenia. (From Seeman, P. *et al.* Antipsychotic drug doses and neuroleptic/dopamine receptors. *Nature* 261: 717–719, 1976)

This methodology provides resolution of approximately 1 mm. Thus, not only *in vitro* but *in vivo* data from genetic knockouts and other animal models can be obtained with PET and more recently SPECT imaging [65].

Neuroreceptor ligands for PET. As a direct result of work in the 1960s and 1970s predominantly in the dopamine system (Fig. 58-8), a number of high-affinity and clinically potent ligands such as spiroperidol (spiperone) were employed for the first PET human imaging studies in 1983 with [^{11}C]3-*N* methylspiperone. Interestingly in that same year, the first SPECT radioligand ^{123}I-QNB and the first measurement of presynaptic dopamine ^{18}F-fluorodopa were developed as well. Since then, a myriad of radioligands has been developed for multiple dopamine and serotonin subtypes and other neuroreceptor transmitter systems. It is this rich number of radioligands that has allowed many of the clinical applications which are described later in this chapter.

Neuroreceptor ligands for SPECT. Neuroreceptor ligands make neuroreceptor imaging available, due to their properties of selectivity, affinity and reversibility of receptor binding. Therefore, the receptor density and dynamic measurement of neurotransmission can be obtained non-invasively, which helps us to understand neuropsychiatric conditions. Currently, the commonly used neuroreceptor ligands for SPECT are *Iodine-123-QNB, Iodine-123-IBZM, Iodine-123-epidepride.*

Iodine-123-QNB (quinuclidinyl benzilate) is a ligand for the cerebral postsynaptic acetylcholine muscarinic receptor, and has been used to image these receptors in the brains of normal subjects and patients with Alzheimer's disease [66–68]. Both *Iodine-123-IBZM* and *Iodine-123-epidepride* have been developed for dopamine D_2 receptor imaging and studies showed that I-123-epedepride is superior to I-123-IBZM [69, 70], and may prove useful in studies of Parkinson's disease and other movement disorders as well as in schizophrenia. Iodine-123 labeled ligands have been used for imaging the serotonin receptors, such as *I-123-5-I-R91150* [71, 72] for 5-HT_2A receptor and *I-123-beta-CIT* [73] for serotonin transporter. These research radiotracers, however, have not yet reached the stage of routine clinical practice.

^{99m}Tc- labeled imaging agents: ^{99m}Tc has a suitable energy and half-life, is readily available and is suitable for large-scale clinical use. *^{99m}Tc-TRODAT-1* is a recently developed radiotracer that selectively binds to the dopamine transporters (DAT) [74, 75], and has been used for studies of Parkinson's disease and attention deficit syndrome [76, 77]. A study has shown that it is possible to synthesize a ^{99m}Tc-based ligand for the 5-HT_{2A} receptor [78]. More recently, SPECT radioligands for the nicotinic cholinergic system have been developed (Fig. 58-8).

L. *et al.* [^{123}I]5-A-85380 dynamic SPECT studies in normals: kinetic analysis and parametric imaging. *Nuclear Science Symposium Conference Record*, Institute of Electrical and Electronics Engineers (IEEE), Inc. 2001; 3, pp. 1335–1340.)

CNS DRUG DESIGN AND PRECLINICAL/CLINICAL DRUG DEVELOPMENT

It is now possible to image not only postsynaptic, but presynaptic and intrasynaptic neurotransmission (Fig. 58-5). Presynaptic sites, such as the dopamine transporter and the serotonin transporter; the presynaptic dopamine vesicular transporter (VMAT-2) and the acetylcholine transporter; extrasynaptic sites such as the enzymes which break down neurotransmitters, e.g. MAO A and MAO B; with radioligands that bind to post or pre-synaptic sites, i.e. dopamine competing with radioligands such as ^{11}C raclopride (see Fig. 58-9) (PET (Fig. 58-10) can be measured under basal conditions or following drugs which either decrease (e.g. AMPT) or increase (e.g. intravenous amphetamine) intrasynaptic dopamine.

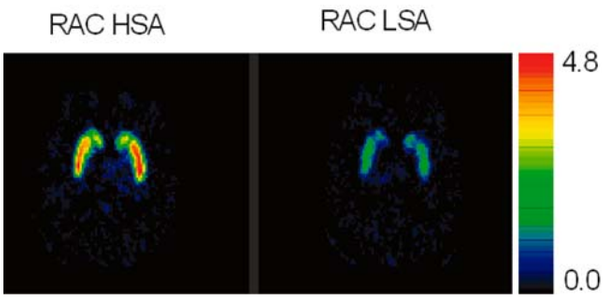

FIGURE 58-9 These images are generated from a healthy normal control subject using high-specificity activity (HSA) ^{11}C-raclopride (left) and low-specificity activity (LSA) ^{11}C-raclopride (right) by linear regression with spatial constraint method to estimate binding potential, as per the method of Zhou Y. *et al.* Linear regression with spatial constraint to generate parametric images of ligand-receptor dynamic PET studies with a simplified reference tissue model. *Neuroimage* 18: 975–989, 2003.

The myriad number of sites that can now be imaged has led to applications in multiple disorders, with the ability to study multiple components of these disorders. Some of the most important applications have included looking at the pathophysiology of disorders by examining abnormalities compared to healthy controls, and monitoring disease progression without or with medication. The most striking examples of this have included schizophrenia or abnormalities of multiple sites [79]; substance abuse [80] including cocaine and methamphetamine abuse; and Parkinson's disease [81, 82]. Thus, for example, in the case of schizophrenia, evidence that may be integrated with both chronic and phasic dopamine changes originally described by electrophysiologically processes might in fact explain finding elevated D_2 receptors and increased dopa decarboxylase measurements with ^{18}F-fluorodopa, and elevation of intrasynaptic dopamine challenge following psychostimulants such as amphetamine. Conversely, a number of studies in chronic cocaine users have shown decreases in intrasynaptic dopamine as well as D_2 receptor binding and density. Remarkable changes have been observed by measuring the dopamine transporter in Parkinson's disease, which may precede severe clinical symptoms, and this is now being

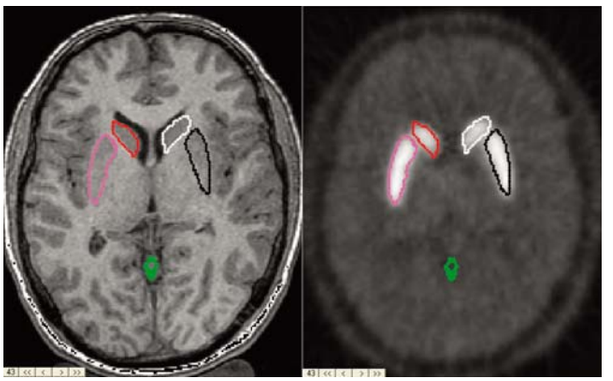

FIGURE 58-10 This image shows the volume of interest (VOI) drawn on MRI (left) matches the VOI on the PET scan (right) with ^{11}C-rclopride using MatLab program.

actively used to monitor other major neuropsychiatric disorders such as depression [83] and dementia.

The site of drug action and receptor distribution are being investigated. An additional application in studying neurochemical changes and their relationship to treatment include the use of neuroreceptor imaging for drug design and preclinical drug development. Therefore, such applications for use in CNS drug design include:

1. Radiolabeling of a candidate drug to observe its distribution within brain;
2. Determining the underlying rationale for studying a neuroreceptor system, e.g. the dopamine hypothesis for cocaine abuse and schizophrenia;
3. Understanding the mechanism of action of various drugs, especially those that act on neuroreceptors systems;
4. Guidance for therapeutic drug dosing in patient studies by estimating receptor occupancy preclinically or in normal volunteers [94].

We will briefly elaborate on the last two of these applications in our evolving understanding of actions of drugs and rational drug dosing.

The mechanism of drug action may be elucidated by studying its binding. An example of mechanism of action is the study of the dopamine transporter inhibitor GBR12909 as a possible drug for substance abuse and psychostimulant abuse. It was suggested by results from microdialysis studies in animals that this drug would increase basal dopamine but inhibit psychostimulant dopamine release. The drug was subsequently studied in a nonhuman primate PET study by Villemagne *et al.* [95]. Here the reduction in binding of the radiotracer [^{11}C] raclopride was diminished following administration of the drug GBR12909, while the basal levels of dopamine increased. Therefore, this drug could potentially be used to treat psychostimulant abuse, but reduce cocaine craving or amphetamine craving.

Drug dosing is estimated based on proportions of receptor occupancy by the drug. PET and SPECT neuroreceptor imaging now has a major role in helping determine what is the most likely therapeutic dose, and what dose should be used in clinical trials of drugs whose action is receptor-mediated. Examples of such drugs include anxiolytics, antipsychotics, some antidepressants acting through the serotonin transporters, and anxiolytics acting through various receptor systems, such as NK1 and GABA. It has been shown for antipsychotics as well as for a number of antidepressants, that 60–80% receptor antagonism of the dopamine receptors or of the serotonin transporters is associated with therapeutic plasma levels of the particular drug [96]. Hence the receptor occupancy plotted against plasma levels of parent drug showing the 'window of therapy zone' can be derived in nonhuman primate studies and normal volunteers to guide dosing in patient populations and early Phase 1 studies with normal volunteers for alternate FDA approval. Such studies not only are of great economic value, by leading to cost saving, but are of great clinical importance in saving needless overdosing or underdosing of human subjects when developing clinical trials. This principle of using imaging as a biomarker or surrogate marker has the most important role in imaging of receptors.

CLINICAL APPLICATIONS OF PET AND SPECT

The metabolic features of brain tumors can be imaged using PET. These measurable features include glucose metabolism, blood flow and oxygen consumption. FDG-PET can be used to monitor the rate of glucose uptake and level of hexokinase gene expression throughout the body, and has been widely used as a surrogate marker [31]. FDG is extensively utilized in PET neuroimaging. FDG PET imaging helps to identify malignant brain tumors as the increased glucose metabolism of the malignancy is reflected in the PET image. The co-registration of the PET imaging with the MRI (or CT) helps to give information on the prognosis. PET images co-registered with MRI (or, more recently, using combined PET and CT, i.e. PET/CT scanners [97] are also used to test for the presence of residual and recurrent tumors afters surgery and to monitor patients for degeneration of slowly growing, low grade tumors into rapidly growing, high grade malignancies. [97a, 98].

Brain infarction was the first clinical application of SPECT. Decreases in relative cerebral perfusion were imaged by SPECT for diagnosis. Decreased rCBF is visualized in the form of decreased signal on SPECT and PET. The sensitivity and specificity of brain SPECT for infarct localization are 85.5% and 97.6%, respectively [99]. Blood-flow imaging is useful in the evaluation of response to therapy in patients with cerebrovascular diseases [100].

PET scans with ^{18}F-fluorodeoxyglucose (^{18}F-FDG) have an established role in the localization of epileptic foci in patients being evaluated for epilepsy surgery. Epilepsy is one of the most common neurological disorders, which is a clinical condition of recurrent seizures, resulting from excessive, uncontrolled electrical activity in the brain [101, 102] (see Ch. 37). With recent advances in neuroimaging, management of the drug-resistant focal epilepsy now increasingly relies on neurosurgery to resect the 'epileptic focus'. FDG-PET scans between seizures (interictal) is the more common approach. The region of hypometabolism was also the location of the recorded electronic seizure onset [103]. The decision regarding seizure surgery depends on a concordance of data from

multiple investigations, including video EEG, neuropsychological tests, MRI, ictal and interictal SPECT and PET. FDG-PET may also be useful in directing placement of intracranial electrodes for presurgical evaluation of refractory seizures.

Correlations of cognitive functions with PET or SPECT imaging are under investigation. Regional brain function is tightly coupled to regional energy metabolism and regional cerebral blood-flow (rCBF), and brain energy is normally produced by glucose metabolism [104, 105] (see Ch. 31). PET and SPECT have the ability to noninvasively image regional cerebral energy metabolism and/or blood flow, to allow localization of cerebral function in humans by using different radiotracers. For example, ^{18}F-FDG PET allows the determination of regional cerebral glucose ($rCMR_{glu}$) metabolism and function in human brain [106, 107], and ^{15}O-H_2O PET and ^{99m}Tc-HMPAO SPECT can determine rCBF [111].

Close relationships between the mean CBF and cognitive function have been observed [108]. For example, in patients with Parkinson's disease and Alzheimer's disease, their cognitive function impairment is significantly negatively correlated with rCBF [109–111].

PET and SPECT imaging are used to study Parkinson's and Alzheimer's diseases.

Parkinson's disease (PD) is a progressive disorder consisting of a variable combination of symptoms of tremor, rigidity, postural imbalance and bradykinesia[112, 113]. It causes disability in most individuals that cannot be completely controlled with available medications (see Ch. 46). Current pharmacologic treatments for PD are all symptomatic, and aimed at either restoring dopaminergic tone or blocking excessive glutamatergic or cholinergic activity. Neuroimaging techniques developed in the past decades have greatly aided in the diagnosis of PD by measuring residual presynaptic dopamine cell markers [114]. More importantly, today's neuroimaging can provide insights into the natural history of PD.

SPECT and PET are both established modalities for monitoring disease progression and providing the rationale for testing new drugs as putative neuroprotective or neurorestorative agents. The radioligands which target dopaminergic system for both SPECT and PET have been widely used to evaluate patients with PD, including Iodine-123-epidepride, ^{18}F-dopa, ^{11}C-VMAT2, and dopamine transporter ligands [115–120]. Studies with Iodine-123-β CIT SPECT and ^{18}F-DOPA PET demonstrated that at the time of emergence of PD symptoms there is approximately 40–60% reduction of radiotracer uptake in the striatum and putamen [121–123].

Alzheimer's Disease (AD) is the most important and most common terminal disease in ageing populations [124, 125] (see Ch. 47). Its prevalence is continuing to increase with increased human life expectancy. Mental degeneration is insidious, and progressive memory loss is the most important symptom. The current treatment options remain limited, so early diagnosis is now a key problem with this disease, since new therapeutic agents are likely to be more effective when given early in the course of the disease [126].

Brain SPECT of AD patients typically shows bilateral posterior temporal and parietal hypoperfusion. The areas of reduced perfusion are secondary to the reduced brain metabolism in areas of neuronal depletion. This scintigraphic pattern of bilateral decreased posterior parietal–temporal perfusion has a predictive value of greater than 80% for AD [63]. The sensitivity and specificity of brain SPECT for the diagnosis of AD are 86% and 96%, respectively [127].

AD also produces a typical pattern of glucose metabolic derangement on FDG PET scans, which consists of selective hypometabolism in the posterior–parietal and temporal lobes [128]. The sensitivity and specificity of the visual assessment of PET has recently been evaluated in 284 patients with dementia, 146 of whom had a 2-year follow-up, and 138 had pathological confirmation [129]. A most promising approach is radiolabeled dyes that bind to amyloid plaques, one of the pathological signs of AD. If developed fully it promises potentially earlier detection and monitoring of AD [130].

APPENDIX

Brief history of medical imaging. From the first discovery of X-rays by Wilhelm Roentgen in 1895, medical neuroimaging has progressed rapidly over the last century as an invaluable tool for the detection, characterization and treatment of countless neuropathological and neuropsychiatric disorders. Medical research has also embraced the fascinating science of medical neuroimaging as a powerful tool to probe the inner workings of the brain on a biological, biochemical and biophysical level. Indeed, the X-ray soon produced the first image, leading to the eventual development of modern X-ray computed tomography (X-ray CT) [1, 2] Computer-assisted tomographic image reconstruction, in which a two-dimensional image 'slice' through the object is created from a series of multi-angle one-dimensional image 'projections', was originally utilized in other well-known imaging modalities, which came to be know as Positron Emission Tomography (PET) and Single-Photon Computer-Assisted Tomography (SPECT) [3]. Unlike X-ray CT, in which a beam of X-rays from an external source are passed through the object and attenuation data recorded, PET and SPECT record the emission of photons originating from within the object, introduced via a decaying radioisotope, from multiple angles around the object. Whereas X-ray CT is very useful in providing static attenuation information about internal structures, and is the standard in any well-equipped hospital, PET

and SPECT provide information pertaining to the internal distribution of the radioactive label, therefore giving these imaging modalities the ability to trace and record the uptake and metabolism of the radiolabeled biochemicals *in vivo*. This functional aspect of PET and SPECT makes them an invaluable probe for investigating the workings of many biological and biochemical systems *in vivo*.

In the 1930s, two physicists working independently reported that certain nuclei placed in a magnetic field absorbed energy transmitted at their specific precessional frequency in the field, and emitted energy when they were allowed to return to their original energy state. In 1952 Felix Bloch and Edward Purcell were awarded the Nobel Prize in Physics for their discovery, giving birth to magnetic resonance spectroscopy [4, 5]. Soon, it was discovered that several species of nuclei in magnetic fields were sensitive to perturbation by radiofrequency (NMR-visible), and that the signal they emitted in return contained detailed information on the structure and composition of the molecules in which the nuclei were contained. Compounds, organic and inorganic alike, had a unique spectral signature, and the signals from hydrogen, phosphorus carbon and other biologically prevalent nuclei in these compounds each had distinct properties and characteristics. With this powerful tool, known commonly as nuclear magnetic resonance spectroscopy (NMRS), scientists could begin to investigate the *in vivo* biochemical workings of live specimens. In the 1970s, a physician from Brooklyn proposed to use NMR as a tool for characterizing and distinguishing different tissue pathologies in medical diagnosis [6]. At approximately the same time, a professor of chemistry in New York published the first water-proton magnetic resonance image of two water-filled tubes, work that would eventually earn Paul Lauterbur the Nobel Prize in physics [7]. This new medical imaging modality would come to be known as magnetic resonance imaging (MRI), and would prove to become one of the most powerful medical and research tools of the modern age. With Damadian's proposal of pathological characterization of tissue types based on their NMR properties, combined with modern image acquisition/reconstruction technology, MRI remains at the forefront of modern medical imaging.

Technical developments in MRI have since spawned numerous other breakthroughs in the field of NMR. In the early 1980s, it was demonstrated that a spatial image of the complete spectrum of a sample could be created, by slightly altering the acquisition and reconstruction parameters of the established MRI experiment [8]. Unlike conventional MRI, which relies on the magnitude of the water resonance signal to create an image, magnetic resonance spectroscopic imaging (MRSI) combines spectroscopy with imaging, and has since become a staple of modern MRS research. Magnetic resonance imaging finally entered the functional realm in the late 1980s, when it was discovered that the iron content of hemoglobin in blood caused enough of a distortion of the local magnetic field, that the resultant signal fluctuation could be detected in an MR image [9]. This effect, known as the BOLD (blood-oxygenation-level dependent) effect is most apparent when the oxygenated hemoglobin content of the blood in a given region changes over time, causing a proportional change in image intensity. With the advent of rapid imaging techniques, functional magnetic resonance imaging (fMRI) can record the transient activation and inactivation of brain regions that occur during the execution of a given task, be it motor, cognitive or emotional.

Basic principles of MRI. The NMR signal in magnetic resonance imaging originates from the rapidly precessing hydrogen nuclei in the sample when they are placed in the main, static magnetic field (B_0). Each nucleus can be thought of as a tiny bar magnet with two magnetic poles, therefore each having a magnetic moment or vector. Any nucleus within the sample can exist in two distinct energy states, corresponding to the direction of its magnetic moment (low-energy), or opposite to the direction of the main magnetic field vector (high-energy). In a sample with many nuclei, there will always be a population of nuclei in the high-energy state, and another population in the low-energy state. In the presence of the main magnetic field, there will be an excess of nuclei forced into the high-energy state, thus giving rise to a net magnetic moment to some of all nuclei in the entire sample. It is this excess of high-energy nuclei (approximately one nucleus in a million) that gives rise to the observed NMR signal. Each hydrogen nucleus precesses (similar to a top) about the main magnetic field vector at a specific frequency, determined by the strength of the main field (measured in Tesla) and an inherent property of the nucleus called the gyromagnetic constant (γ). For hydrogen, γ is 42.577 megahertz per Tesla (MHz/T) and the nucleus would therefore precess at 4T field strength, for example, at 170.3 MHz (170,300,000 precessions per second). The precessional frequency, of a nucleus as it relates to main field strength and gyromagnetic constant is known as the Larmor frequency, as described by the equation, ω - γB_0, where ω is the Larmor frequency [5]. In order to extract a measurable signal from the sample, energy must be transmitted into the sample by way of a radiofrequency (RF) pulse delivered at the Larmor, or resonant, frequency of the hydrogen nucleus. Once the RF pulse is terminated, the system of nuclei returns back to its lower-energy state, emitting a small but detectable RF signal that can be recorded. It is in this signal that detailed spatial and spectral information is contained that can be extracted to form a MRI image. In MRI, spatial information about the sample is introduced into the NMR signal with the application of magnetic field gradients in three dimensions. The gradients, which vary linearly in space in three dimensions, cause a known and momentary linear grade of the main magnetic field.

In one spatial dimension (usually denoted as the 'slice-select' direction), a selective RF pulse with a certain

resonant frequency and bandwidth perturbs only those nuclei precessing within the specified frequency range of the pulse. By varying the center frequency of the RF pulse and either the bandwidth of the RF pulse, or the magnitude of the applied gradient, one can adjust the spatial position and thickness of the planar image 'slice', containing the perturbed nuclei. In addition to the slice-selective gradient, another gradient is applied in one of the planar dimensions, usually denoted as the 'phase-encode' gradient, and is stepped incrementally in magnitude with a predetermined step-size, range and number which determine the spatial field-of-view (FOV) that will be sampled in the MR image, as well as the degree of spatial resolution (the ability to delineate separate structures from each other) that will be obtained in the final MR image.

The application of this series of phase-encode gradients links the resultant phase of each nucleus with its position in space. While the NMR signal after each gradient step is digitally recorded, a third gradient is simultaneously applied in the perpendicular planar dimension ('readout-gradient') with a pre-determined and fixed time of duration and strength, again, dictating the FOV and spatial resolution of the MRI image sampled in that dimension. Although applied in different manners, the readout and phase-encode gradients achieve identical end-results. Throughout this entire (and repetitive) procedure, the recorded digital NMR signals are entered into a data matrix known as 'k-space'. This recorded data set contains all of the spectral and spatial phase information needed to construct the final MR image. The sample has, in essence, been discretely sampled into its individual spatial frequency components.

Structures at given locations within the sample are now each described as an oscillating signal with a unique amplitude, phase and frequency in k-space. A mathematical operation called a fast Fourier transform, performed on the k-space matrix, extracts the original amplitude and location of each structure within the sample, representing the original structure as a rectilinear, two-dimensional matrix of discrete elements, or pixels (picture–elements), each varying in gray-scale intensity depending on the amount of signal at that spatial location. Standard clinical and research MR images are usually described as 128 or 256 pixels per dimension, and achieve submillimeter pixel resolution. At this resolution, fine structures such as cerebellar striations or small vessels can be resolved in the brain.

Basic principles of MRS. The overall physical principles and characteristics of magnetic resonance spectroscopy (MRS) are identical to those described previously in the MRI section. In fact, magnetic resonance spectroscopy can simply be thought of as just another way of expressing the NMR signals that are recorded during an NMR experiment. Whether it is an MRI or and MRS experiment, virtually all of the same equipment is used and all of the basic NMR principles still apply. The prime difference that separates basic MRS from modern-day MRI is that in MRS, the entire NMR signal is recorded in the absence of a readout gradient (although in more-recent rapid MRSI experiments, spectral/spatial encoding gradients are applied during NMR signal readout). However, in MRS (unlike MRI), some aspects of the NMR signal are much more emphasized and are of extreme importance in acquiring clinically or experimentally relevant MRS data.

In MRS, the NMR signals of interest are typically very small, and in some cases are difficult to differentiate from the ambient noise in the recorded NMR signal. For example, the metabolites that are measured with hydrogen spectroscopy are approximately 1/10,000 the strength, or amplitude, of the hydrogen water signal that is recorded in standard MRI (see **Fig. 58-2**). The NMR signals in MRS of other nuclei (i.e. phosphorus) are even less sensitive and more susceptible to corruption by ambient NMR noise. Signal-to-noise ratio (S/N), the ratio of measurable NMR signal over the baseline NMR noise, is therefore a fundamental and limiting parameter of the quality and measurability of the signal in MRS. Modern-day MR systems are usually equipped with specialized hardware that is extremely sensitive to the weak signals recorded in MRS, for maximum S/N. Aside from very low *in vivo* concentrations and inherent nuclear properties, other prime factors that greatly influence the S/N in MRS are the T1, T2 and T2* parameters described previously. Magnetic resonance spectroscopy protocols must therefore be very fine-tuned to the specific nucleus and metabolites under study, as well as the target-organ and pathology. **(Table 58-1.)**

In MRI an image is produced that allows clear visual examination of the structures and/or pathology of interest, thus making it an invaluable tool in radiology. However, in diagnostic imaging, a thorough visual examination by a trained radiologist usually suffices, with little or no attempt at actually quantifying the data. In MRS, quantifying the data and obtaining a hard measurement of metabolite concentrations is the ultimate goal. When the recorded NMR signal is Fourier transformed in MRS, a spectrum results, representing a series of resonant lines, or 'peaks' across a spectral bandwidth (expressed in Hz or ppm) where these spectral lines represent different biomolecules in the sample. Magnetic resonance spectroscopy is based on a phenomenon known as 'chemical-shift', in which the surrounding electronic environment about a nucleus within a molecule acts to partially shield the nucleus from the main magnetic field. This shielding effect results in a very slight change in the local magnetic field that the nucleus experiences, thus causing it to precess at a slightly different frequency. Nuclei contained in different molecules will each have precessional frequencies that are slightly different from one another, manifested as separate spectral lines. A single molecule can have multiple resonant lines, depending on its composition, structure and another phenomenon called *J-coupling*, which refers to the influence that exists between neighboring nuclei, affecting their resonant line patterns. When many biomolecules exist in the sample, as is the case *in vivo*, a very complicated

spectrum of overlapping resonant lines results, making it very difficult to assign any given peak to its corresponding biomolecule, as well as quantifying the area under each overlapping peak. It is for this reason that scientists have strived to work at higher magnetic field strengths, since both S/N and spectral resolution (the ability to resolve overlapping resonant lines) are increased at high field. By deriving the area under each spectral line and correcting for the many factors affecting this area, the concentrations of the corresponding biomolecules in the sample can be calculated (Figs 58-2, 58-3). Spectral quantitation is an active area of research and many complex strategies and algorithms have been developed to perform this difficult task. However, they will not be discussed here.

The ability to spatially localize the NMR signal to a specific structure within a sample is of utmost importance in MRS. Spatial localization in MRS can be separated into two categories, single-voxel MRS and multivoxel MRS, each having its own set of advantages and disadvantages. In single-voxel MRS, a voxel (volume–element) of chosen dimensions is placed over the region of interest, guided by MR images. The MRS sequence parameters are then optimized for this specific location and the NMR signal recorded. Like the slice-selective gradient and RF pulse previously described, the single MRS voxel is defined in three dimensions, using a combination of orthogonal and intersecting slice-selective gradients and RF pulses. The advantages of this technique (there are many methods to achieve a single voxel) are the ability to optimize all of the MRS sequence parameters for this location, resulting in maximum spectra quality. The disadvantage is clear, being limited only to one or two fixed locations per scan session. In multivoxel MRS, the advantage is more information collected per scan session (Fig. 58-4). In spectroscopic imaging (MRSI), another main advantage is the ability to reposition voxels indefinitely after data collection. Spectroscopic imaging, which can be done in one, two or three dimensions, uses a combination of slice-selective and phase-encoding gradients to collect k-space and Fourier transform to localize the matrix of voxels. The disadvantage is the relative inability to optimize the MRS sequence parameters over the entire area of interest, a problem mainly due to imperfect RF coil and magnetic field homogeneity, and the rather poor voxel definition resulting from the discrete nature of the digital sampling and Fourier transform method of localization.

PET versus SPECT: similarities and contrasts. In research, PET and SPECT have very complementary roles at times. SPECT, the commonly used tool in all of nuclear medicine, primarily uses external imaged isotopes ^{123}I or ^{99m}Tc (energies of 159 and 140 (keV); half lives of 13 h and 6 h, respectively), and to a lesser extent ^{131}I (89% 191 keV and electrons of multiple energies; and half life of 8 days) as well as ^{111}In) (Table 58-2). For research purposes primarily ^{123}I and ^{99m}Tc are used. Each emits a single gamma ray, which is externally imaged using light-emitting crystals which are then detected and passed on as the radioactive signal. By rotating these crystals relative to the emissions, three-dimensional pictures can be obtained. Both ^{123}I and ^{99m}Tc are available commercially throughout the world, although the latter is more routinely available since it is available as a generator, whereas the former is typically cyclotron-produced and distributed from one or two sites per country or numbers of countries as a unit dose.

Positron emission tomography, in contrast, uses radioisotope specifically ^{11}C, ^{18}F, ^{18}O or ^{13}N. All of these have much shorter half-lives typically from two minutes up to 110 minutes. Because of the short half-life and the nature of the radioisotopic production, they must be made by cyclotron, which is either onsite or within a few miles of the location of the imaging camera (i.e. the PET camera). The production of three-dimensional images is somewhat different with PET compared to SPECT. For all of these positron emitting isotopes, the positron travels only a few millimeters (depending on each isotope) when it encounters negative electrons (the electrons that populate all living tissue), whereupon the two particles annihilate. This results in two gamma-rays, each 511 keV in energy (because of conservation of energy), and at almost 180° to each other (based on conservation of momentum). The angle of the degree to which it is not 180° relates to whether the electron or positron has some finite kinetic energy, i.e. whether they are moving very slowly or quickly relative to one another at the time of self-annihilation, in order to satisfy the conservation of momentum. These two gamma-rays, both traveling at the speed of light, as all electromagnetic radiation does, interact with detectors at approximately 180° to each other. Detectors, which measure millions of these operations at two opposing sides within a certain time window, detects each event as coming from a location within the center, e.g. the brain. After many of these processes are obtained and processed, three-dimensional images can be obtained.

At present, most PET scanners can acquire in both a two-dimensional as well as a three-dimensional mode, whereas SPECT cameras measure in a three-dimensional mode. The physical property of the dual-positron gamma-rays emission lends itself to mathematical reconstruction algorithms to produce three-dimensional images in which the calculations are much closer to exact theoretical ones than those of SPECT. This is, in part, due to the two-photon as opposed to single-photon approach. PET can now achieve resolutions, for example in animal-dedicated scanners, in the order of 1 or 2 mm. The resolution is inherently limited theoretically only by the mean free path or distance in which the positron travels before it annihilates with an electron, e.g. those in biological water 2–8 mm. SPECT, although achieving millimeter resolution with the appropriate instrumentation, cannot quite achieve these levels.

Advantages and disadvantages of PET and SPECT.
Positron emission tomography. The half-life of the isotopes also makes a difference to their application.

For example, the short half-lives of ^{15}O and ^{11}C allow multiple repeat studies within a few minutes to hours. This allows measurement of behavioral or cognitive changes (this was the original approach prior to the fMRI) as well as effects of drugs on neurotransmitter levels and occupancy, all within the same few hours or days. Even ^{18}F allows repeat studies within a few hours, whereas with SPECT imaging, at least one or two or more days are required if a drug perturbation, etc. is employed, compared to baseline, because of the interference of the prior study's radioactivity. The longer half-life of SPECT compounds, however, has several advantages. As described in the kinetic modeling section below, this allows the quantification to be simplified if the radiotracer reaches or approaches a quasi steady-state (i.e. the radioactivity in brain areas of interest compared to other brain areas or plasma is not changing). Hence, SPECT radiotracers often precede or may be preferred for kinetic reasons.

Radiopharmaceutical production: PET versus SPECT. Perhaps the biggest difference between PET and SPECT, however, exists in the variety of radiochemical processes and radiopharmaceuticals that can be developed. PET has much greater versatility, because the radioactive atoms are already smaller and much more common in biological molecules. In particular ^{11}C is often successfully employed to isotopically replace (replacing a stable ^{12}C for radioactive ^{11}C) without any modification of the chemical or pharmacological properties of the drug. Hence, it is possible to then image a radiopharmaceutical of a drug (e.g. ^{11}C cocaine for dopamine transporters or ^{11}C methylphenidate for dopamine transporter or ^{11}C MDL100907 for $5HT_{2A}$ receptors) as if one is actually imaging the native drug itself that is nonradioactive. This has tremendous power in fully understanding the pharmacokinetics and dynamics of the radiopharmaceutical, and extrapolating immediately to its unlabeled counterpart, even at therapeutic levels. Other substitutions, such as ^{11}C methylations or propylations or other alkylations, may make only moderate modifications to the pharmacology, such as changing the lipophilicity, etc. Similar to ^{18}F as an addition to a biological molecule of interest (typically around 400 molecular weight) may not cause major changes, because again its molecular weight is relatively small. So both ^{11}C and ^{18}F (the latter used in the radiolabeling of deoxyglucose, a precursor to the hexokinase step to measure regional cerebral glucose metabolism) or ^{18}F fluorodopa to measure dopa decarboxylase activity have been very successful in CNS research, and more recently in clinical applications (see below). Hence, many biological molecules, especially new CNS drugs such as antipsychotics (e.g. D_2/D_3 radioligand ^{11}C raclopride) or derivatives of neuroleptics (^{11}C-*N*-methylspiperone, a methylated derivative of spiperone, an early antipsychotic) or ^{11}C-chlorpromazine or ^{18}F-haloperidol are all examples of isotopic substitutions of drugs that bind to D_2 receptors, and have been used in the treatment of schizophrenia and other psychoses.

For SPECT, the radiolabeling with ^{123}I, ^{131}I, and ^{99m}Tc is more complex, especially for the latter where special chelates are needed to shield the charged portions of the radiopharmaceutical, which would prohibit passage across the blood–brain barrier. For example, there are no SPECT ligands for oxygen or glucose metabolism. Since both ^{123}I, ^{131}I and ^{99m}Tc are all relatively large atoms compared to PET isotopes, ^{11}C, ^{18}F, ^{13}N and ^{15}O preservation of pharmacologic properties is also difficult, but has been achieved. Indeed, measurements of the dopamine transporter, D_2/D_3, serotonin receptor (e.g. $^{123,125}I$-IodoLSD) and other radioligands have been employed for dopamine, serotonin and ^{123}I-QNB for the muscarinic cholinergic system have been successfully employed in animal and human imaging. Their long-lived properties also help to improve image quality and imaging counting statistics, since radioactivity is a statistical event requiring sufficient time to create an image.

Furthermore, some of these PET and SPECT ligands have been translated back to autoradiograms, such as ^{125}I ligands of SPECT compounds, where the β decay is detected in the film emulsions. It is of interest that, historically, *in vivo* autoradiography led to much of the imaging work, in particular both FDG and receptor imaging, so that in some ways, *in vivo* autoradiography has been extended to PET and SPECT external imaging, but to the latter with much more flexibility. In the case of autoradiography, even if the animals are injected *in vivo*, they are eventually sacrificed and slices are then incubated with photographic film to visualize the brain structures. With PET and SPECT, nonhuman primates, humans and even rodents are imaged over and over again to allow the measurement of disease progression, treatment effect and drug perturbations; hence, it is a powerful tool for these procedures.

Strengths and limitations of PET/SPECT imaging for neurochemical applications. Because so much of neurochemistry involved tracing biochemical processes, the tracer principle, which embodies these methods, starting with the first studies of fluorodeoxyglucose and glucose metabolism and continuing with receptor and second messenger imaging, is indeed the strength of these techniques. Some inherent weaknesses, however, are described below.

Finite resolution and partial volume effects. Although this can occur in other areas of imaging such as MRS, it is particularly an issue for SPECT and PET because of the finite resolution of the imaging instruments. Resolution is typically imaged as the response of the detector crystal and associated electron to the point or line source. These peak in the center and fall off from a point source, for example, in shapes that simulate Gaussian curves. These are measures of the ability to resolve two points, e.g. two structures in a brain. Because brain structures, in particular, are often smaller than the FWHM for PET or SPECT, the radioactivity measured in these areas is underestimated both by its small size (known as the partial volume effect), but also spillover from adjacent radioactivity

from other regions which cannot be resolved from the region of interest. Hence, very small structures of the brain, such as the head of the caudate, or even smaller, such as the choroid plexus, suffer from this. However, new methodology is being developed to make these corrections. So far, many neuroscience advances have been made without these corrections, because the changes are relative between control states and treatment states.

Relative risk of ionizing radiation. Another inherent difference between PET/SPECT and MRI/MRS is that the former is referred to as ionizing radiation. Indeed, there is a greater risk associated with potential DNA, chromosome or tissue damage, but the radioactivity levels which are employed, especially for human studies, are below those that even occupationally-exposed workers are allowed to receive, and are generally considered to be of only moderate risk. Indeed, we still are not totally certain of the effects of other radiological procedures such as high field MRI (which can still potentially cause molecular excitations and changes with unknown long-term effects) or ultrasound (which can cause heating). In general all of these radiological procedures, when carefully weighed against the potential scientific benefits, are considered relatively low risk, which is why these methods have become so widely used.

Imaging equipment. Either PET or SPECT consists of rings of crystals, such as sodium iodide or other crystals (see Table 58-2) in which the gamma-radiation interacts, and the subsequent reaction results in light being emitted, which is then captured by photoelectric tubes. These transmit electrical impulses, which are detected either singly as in SPECT, or in coincidence as in PET. Additional factors that have to be considered in the quantification of these procedures include: *scatter*, which occurs with both PET and SPECT; *random* coincidences, which means two detectors going off at 180° to one another that do not originate from the same positron–electron interaction, and therefore should not be counted; and degradations in resolution due to small angular differences; and even differences in the time of travel (for example, in PET, for one of the two annihilation photons arriving at the detectors at different times). Some (such as randoms), can be corrected computationally, but others (such as scatter) are more complex, depending on the organ imaged. In fact, some instruments, although not altogether successful, have attempted to track the time of flight for one photon compared to another, both traveling at the speed of light. Another potential error is the depth of interaction — that is, precisely where the photon interacts within the crystal, so corrections for this are also being made at higher, more technical scanners.

Finally, newer scanners are being developed with both PET and another modality, such as computed tomography (X-ray CT), where a subject would be scanned first with X-ray CT for anatomy and for attenuation correction, and then imaged for their PET or SPECT measurements. Attenuation correction is necessary, because the photons, either from PET or SPECT which emerge from the body, are deflected or undergo interaction or reductions in energy as they emit from the center of the body. Hence, even a cylinder filled uniformly with radioactivity would exhibit the appearance of less activity in the center of the cylinder than at the edges, because of this attenuation effect. Corrections can be made in a number of ways including correcting using the known attenuation coefficients for water (known as calculated attenuation) or using a radioactive source which rotates around the source (typically used in PET with the germanium source) or with x-ray CT for attenuation values. All of these boost the signals, which are deeper in a human structure such as the center of the brain, to correct for this attenuation; this is largely successful and allows for an essentially uniform image when radioactivity is uniform.

New PET scanners are being developed with increasingly efficient electronics, but especially new crystals for detecting the gamma rays. These detector materials may have higher sensitivity or quantification depending on a number of factors, including their density, their effective atomic number and the delay time from the interaction to the light emission which is ultimately measured in the electronic detectors. The original sodium iodide crystals are now being replaced by those with higher density (effective Z), and a much shorter delay time, such as bismuth germinate oxide (BGO), barium fluoride (Ba F_2), and, most recently, leutetium oxyortho silicate (LSO).

The resolution and sensitivity of an imaging device depend on a number of variables, ; for example, spatial resolution in SPECT is limited primarily by collimator resolution. Typical gamma camera SPECT systems have in-plane spatial resolution in the final reconstructed image of about 12 mm for high-resolution imaging. Resolution and sensitivity in PET is given in Table 58-3.

Fundamentals of radiotracer methodology.

Basic radiochemistry for PET, SPECT — Principles of labeling with radioisotopes and typical 'successful ligands'. *Typical validation for radiochemical and radiopharmaceutical purity.* Quality control is very important to ensure the safety and efficacy of radiopharmaceuticals. One important quality parameter is the radiochemical purity of the radiolabeled product. This is defined as the fraction of the total radioactivity in the desired chemical form in the radiopharmaceutical [56]. Radiochemical impurities come from incomplete labeling, shift of equilibrium, radiolysis (β decay), temperature or pH change, exposure to light,

TABLE 58-3 Performance characteristics for the current commercial clinical PET scanners

		2D	3D
Resolution FWHM (mm)			
	Axial	4.0–5.0	3.5–6.2
	Transaxial	4.8–6.2	4.8–6.3
System sensitivity (net trues) (cps/Bq/ml)		4.9– 5.4	21.1–31.0

and air oxidation. Examples of radiochemical impurity are free $^{99m}TcO_4^-$ and $^{99m}TcO_2$ in many ^{99m}Tc-labeled compounds. Radiochemical impurities in a given radiopharmaceutical can be tested using precipitation, thin-layer chromatography (TLC), paper and gel electrophoresis, ion exchange, mini columns or HPLC and distillation [57–59].

Validation of radiotracers. In vitro *versus* in vivo *rodent study.* Depending on the function being measured, the radiotracers must be further validated pharmacologically. For example, for neuroreceptor binding ligands, it must satisfy characteristics such as saturability, i.e. carrier added (unlabeled ligand) can compete with the radiotracer; stereo specificity (i.e. known unlabelled isomers with higher or lower affinity to the receptor of interest will block the radiotracer's uptake or block it less, respectively); pharmacologic specificity (i.e. unlabeled drugs will inhibit the radiotracer proportional to their binding affinity) and manipulation of receptor site (i.e. up- or down-regulation can be demonstrated by the radiotracer). These validation studies are typically carried out i*n vivo* in rodent and small animal studies first. Together with these validation studies, especially in the case of receptor tracers, metabolism of the radiopharmaceutical is needed. This is because if they cross the blood–brain barrier the radiolabeled metabolites of these radiotracers can obscure the imaging pattern quantified and hence degrade the quantification of the function being measured. Thus, not only the metabolites in whole blood or plasma are measured, but the absence of these metabolites (in labeled or unlabeled form) crossing the blood–brain barrier is an essential part of the validation studies.

Role of mathematical modeling for quantification — differences between simple tissue time–activity curve and model parameters with examples, e.g. FDG, glucose metabolism, blood flow and receptors, measures of binding potential and receptor density. Since PET or SPECT radiopharmaceuticals ideally depict physiological processes, like many biochemical processes, the underlying kinetics must be fully understood to interpret the imaging results. This, especially during the validation phase, begins with dynamic images to obtain the entire time course of the radiotracer. This is in addition to simply quantifying the varied regions of the brain images obtained, such as in an autoradiogram and in SPECT studies. Here is an important distinction between autoradiograms in *in vitro* studies and in *in vivo* imaging. In the former, conditions are typically obtained to place the radiotracer into conditions of equilibrium by such methods as temperature, mixing, etc. In an *in vivo* study, it is not possible to manipulate these factors, of course, so either radiotracers that reach a quasi-equilibrium are employed or those that do not are analyzed using mathematical modeling or kinetic modeling techniques. These latter procedures require, not only dynamic images of the radiotracer in brain over time, but also plasma samples of radioactivity to indicate the so-called 'input function' of the radiotracer prior to entering into brain. One of the most successful and earliest models were those for two-compartment modeling involving blood flow (Kety–Schmidt model) and the for glucose metabolism (Sokoloff–Phelps–Huang method). Indeed, the Sokoloff method originally employed ^{14}C-deoxyglucose measurements and autoradiograms in rodents, but also with arterial sampling to measure the radiotracer input function. This was later translated into PET imaging using ^{18}F-FDG and modeling, using first dynamic scanning and arterial inputs, and later simplified to single-scan 'parametric images' once some of the human rate constants were established.

To calculate these measures in PET/SPECT, typically two- or three-compartment models are employed. Such models have been the basis for extension into neuroreceptor imaging of the methods described below.

In all of these models, first dynamic measurements are entered into a series of mathematical equations where rate constants, just like those in biochemical equations, are derived. These rate constants are assigned biological meaning, such as hexokinase activity in the case of glucose metabolism or dopa-decarboxylase in the case of ^{18}F-fluorodopa measurements or binding to a receptor from a tissue pool to a tissue receptor area as in the case of D_2 dopamine receptor imaging. This type of compartmental modeling has many variations, and even has procedures (such as those involving not only bolus injections of the radiotracer, but also bolus plus constant infusion) to attempt to force the radiotracer into a equilibrium state to simplify the modeling. As in the example of receptor system, if such quasi-equilibrium conditions can exist, then simpler approaches to measuring receptor density and affinity, such as those in a Scatchard analysis can apply. In other cases where there is nonequilibrium, more sophisticated dynamic kinetic modeling is needed.

The ultimate goal of these models, of course, is to estimate parameters of interest, whether it is oxygen or glucose metabolism, receptor density, enzyme activity, etc. In some cases the imaging can be ultimately simplified into single maps, such as parameter maps of glucose metabolism or receptor density. In other cases these parameters can only be obtained from deriving them from the mathematical models. In any event, this represents a relatively unique aspect of neuroimaging, which is not typically required in all aspects of MRI or MRS, and only required in specialized areas (such as where tracers are used in MRI). This is a routine procedure, however, that is needed in PET and SPECT. Despite the apparent complexity, this is also one of the greatest strengths of these imaging techniques, in that they allow the measurement of so many different types of biochemical functions.

Mathematical modeling of radiotracers of the radiotracer uptake to obtain the biological parameters of interest (receptor density, affinity, glucose metabolism, etc.) plays an extremely important role in PET and SPECT imaging, much more so than in many other areas of imaging.

This is because the processes being followed are physiological and biochemical in nature, and therefore cannot be determined typically by a single snapshot in time, such as a structural image; a time series needs to be obtained, and this time series needs to be interpreted to derive the parameters of interest. Many of the measurements have previously been initiated and often validated in animals and animal models or in *in vitro* conditions. However, there are restrictions that mean that, despite the great benefits of *in vivo* imaging (repeatability, relevance, etc.) specific conditions cannot be obtained for practical reasons. For example, in an *in vitro* assay, saturation conditions and incubations cannot be done as in the typical *in vivo* model, nor can tissues be washed clean of nonspecific binding. Thus, mathematical models are needed to infer from the observables, that is brain images over time and radioactivity in plasma over time, in order to obtain the biological parameters. Several references discussing mathematical modeling exist [60, 61]. Typical models for brain imaging, in theory, could be multiple compartments, but are for practical reasons (due to limitations of data, time points and instrumentation) typically a plasma, together with one, two or three tissue compartments. A minimum is that the one tissue compartment include the area of interest. For example, for glucose metabolism, it would be the hexokinase step. For receptor binding, it would be the receptor itself. For enzyme kinetics it would be the product of the reaction. However, for some models additional compartments might be required, such as that including nonspecific binding (e.g. in receptor binding) or the precursor pool (e.g. for glucose metabolism and FDG) or an intermediary step (e.g. as in enzyme kinetics), and hence multiple compartments might be proposed. All of these result in the need to analyze and extract the rate constants of interest, which join the various compartments, just as in the case of, say, a biochemical or organic chemistry synthetic route. These parameters are often estimated through various mathematical methods such as nonlinear regression and the solutions of differential equations, which would be beyond the scope of this chapter. Nevertheless, there are many advances, including those that describe these parameter estimates, not only to a single dynamic time–activity curve in a region of interest (e.g. over the basal ganglia), but more recently throughout the entire image on a pixel by pixel basis (e.g. typically over 256×256). Although the latter is more computationally difficult, it has a number of advantages in terms of reproducibility, test–retest and is being increasingly used.

A typical compartmental model, with multiple compartments, is given in PET, Fig. 54-5.

Another issue for quantification is the effect of the finite resolution of PET/SPECT relative to small structures being imaged. This can result in the so called 'Partial Volume Effect' which is characterized by an underestimation of the true radioactivity. This is an area of increasing research, but is not a major limitation when there is not a large difference between patients and controls in the volume of structures, or when subjects are being used as their own controls [62].

Glossary

AA	arachidonic acid
AADC	aromatic L-amino acid decarboxylase
AANAT	aryl alkylamine *N*-acetyltransferase
ABC	ATP-binding cassette
AC	adenylyl cyclase
ACh	acetylcholine
AChBP	acetylcholine binding protein
AChE	acetylcholinesterase
AChR	acetycholine receptor
ACTH	adrenocorticotrophic hormone
AD	Alzheimer's disease
ADP	adenosine 5′-diphosphate
AIDS	acquired immunodeficiency syndrome
AIF	apoptosis-inducing factor
AKAP	protein kinase A anchoring protein
AL	argininosuccinate lyase
ALD	adrenoleukodystrophy
ALS	amyotrophic lateral sclerosis
AMAN	acute motor axonal neuropathy
AMD	(i) acid maltase deficiency; (ii) age-related macular degeneration
AMN	adrenomyeloneuropathy
AMOG	adhesion molecule on glia
AMP	adenosine 5′-monophosphate
AMPA	α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid
AMP-PNP	adenylylimidodiphosphate
AMPT	α-methyl-*p*-tyrosine
ANP	atrial natriuretic peptide
AP	adaptin
APBD	adult polyglucosan body disease
APDC	2R,4R-4-aminopyrrolidine-2,4-dicarboxylate
ApoE	apolipoprotein E
APP	amyloid precursor protein
APPL	β-amyloid precursor-like protein
APRT	adenine phosphoribosyltransferase
AQP	aquaporin
ARAS	ascending reticular activating system
ARF	ADP-ribosylation factor
ARIA	ACh receptor-inducing activity
βARK	β-adrenergic receptor kinase
ARTN	artemin
AS	argininosuccinate synthetase
ASA	arylsulfatase A
AS-C	achaete–scute gene complex for sense organs
ASIC	acid-sensing ion channels
ASL	adenylsuccinate lyase
ATF	activating transcription factor
ATP	adenosine 5′-triphosphate
AZM	active zone material
BBB	blood–brain barrier
BCAA	branched chain amino acids
BDNF	brain-derived neurotrophic factor
BDZ	benzodiazepine
BH4	tetrahydrobiopterin
BMAA	β-*N*-methylamino-L-alanine
BMP	bone morphogenetic proteins
BNP	brain natriuretic peptide
BOAA	β-*N*-oxylylamino-1-alanine
BOLD	blood oxygenation level dependent
BSE	bovine spongiform encephalopathy
BTX	batrachotoxin
BuChE	butyryl cholinesterases
CA	(i) catecholamine; (ii) cornu ammonis
CACH	childhood ataxia with central nervous system hypomyelination
CAE	childhood absence epilepsy
CAM	cell adhesion molecule
CaMK	Ca^{2+}-calmodulin-dependent protein kinase
cAMP	cyclic adenosine 3′,5′-monophosphate
CART	cocaine- and amphetamine-regulated transcript
CAT	computer assisted tomography
CBD	cortical basal degeneration
CBF	cerebral blood flow
CBP	CREB-binding protein
CBV	cerebral blood volume
CCK	cholecystokinin
CDF	cholinergic differentiation factor
CDK	cyclin-dependent kinase
cDNA	complementary DNA
CDP	cytidine diphosphate
CDP-DAG	cytidine diphosphate diacylglycerol
Cer-Glc	glucocerebroside
CF	climbing fiber
cGMP	cyclic guanosine 3′,5′-cyclic monophosphate
CGN	*cis*-Golgi network
CGRP	calcitonin gene-related peptide
ChAT	choline acyltransferase
CHE	cholinesterase
CHT	choline transporter
CICR	Ca^{2+}-induced Ca^{2+} release
CIDP	chronic inflammatory demyelinating polyneuropathy
CJD	Creutzfeldt–Jakob disease
CK	creatine kinase
CLIP	cytoplasmic-linker protein
CLN	neuronal ceroid lipofuscinoses
CME	clathrin-mediated endocytosis
CMP	cytidine monophosphate
CMR	cerebral metabolic rate
CMR_{glc}	cerebral metabolic rate for glucose
CMRA	cerebral metabolic rate for ammonia
$CMRO_2$	cerebral metabolic rate for oxygen
CMT	Charcot–Marie–Tooth disease

CNG	cyclic nucleotide-gated channel
CNP	(i) 2′,3′-cyclic nucleotide 3′-phosphodiesterase; (ii) C-type natriuretic peptide
CNPase	2′,3′-cyclic nucleotide 3′-phosphodiesterase
CNS	central nervous system
rCNT	nucleoside cotransporter
CNTF	ciliary neurotrophic factor
CoA	coenzyme A
COMT	catechol-*O*-methyltransferase
COPI	coat protein
CORT	corticosterone
COX	(i) cyclooxygenase; (ii) cytochrome oxidase
CPE	carboxypeptidase E
CPEB	cytoplasmic polyadenylation element binding protein
CPK	creatine phosphokinase
CPM	central pontine myelinolysis
CPS	carbamyl phosphate synthetase
CPT	carnitine palmitoyltransferase
CRE	cAMP responsive element
CREB	CRE-binding protein
CREM	CRE-modulatory protein
CRF	corticotropin-releasing factor
CRH	corticotrophin-releasing hormone
CRP	creatine phosphate
CSF	cerebrospinal fluid
CSPG	chondroitin sulfate proteoglycans
CT	computed tomography
CT-1	cardiotrophin 1
CTP	cytidine 5′-triphosphate
DA	dopamine
DAAO	D-amino acid oxidase
DAG	diacylglycerol
DAO	diamine oxidase
DARPP-32	dopamine- and cAMP-related phosphoprotein (32 kDa)
DAT	dopamine transporter
DBH	dopamine β-hydroxylase
DBM	dopamine β-monooxygenase
DBS	deep brain stimulation
DDC	dopa decarboxylase
DHA	docosahexaenoic acid
DHAP	dihydroxyacetone phosphate
DHAP-AT	dihydroxyacetone phosphate acyl transferase
DHPG	3,5-dihydroxyphenylglycine
DHPR	dihydropteridine reductase
DHT	5α-dihydroxytestosterone
DIC	Differential Interference Contrast
DIPP	diphosphoinositol polyphosphate phosphatase
L-DOPA	3,4-dihydroxyphenylalanine
DRG	dorsal root ganglia
DTI	diffusion tensor imaging
EAAT	excitatory amino acid transporter
EAE	experimental allergic encephalomyelitis
EAN	experimental allergic neuritis
ECM	extracellular matrix
EDRF	endothelium-derived relaxing factor
EE	early endosomes
EEG	electroencephalogram
EFTU	eukaryotic elongation factor
EGF	epidermal growth factor
EGFR	epidermal growth factor receptor
EGTA	ethyleneglycotetraacetic acid
ELH	egg laying hormone
ELISA	enzyme-linked immunoabsorbant assay
EM	electron microscopy
EMG	electromyogram
EMP	epthelial membrane proteins
EOFAD	early-onset familial Alzheimer's disease
EPA	eicosapentaenoic acid
EphR	erythropoietin-producing hepatocellular receptor
EPP	evoked end-plate potential
EPSP	excitatory postsynaptic potential
ER	endoplasmic reticulum
ERG	early-response genes
ERGIC	ER–Golgi intermediate compartment
ERK	extracellularly regulated kinase
ERP	event-related potentials
ES	embryonic stem cell
ESI/MS	electrospray ionization/mass spectrometry
ETF	electron-transferring flavoprotein
FABP	fatty acid binding proteins
FAD	flavin adenine dinucleotide
FALS	familial amyotrophic lateral sclerosis
fCJD	familial Creutzfeldt–Jakob disease
FDC	follicular dendritic cell
FFA	free fatty acid
FFI	fatal familial insomnia
FGF	fibroblast growth factor
FGFR	fibroblast growth factor receptor
FMRF-NH_2	Phe–Met–Arg–Phe-amide
fMRI	functional magnetic resonance imaging
FRAP	fluorescence recovery after photolysis
FRET	fluorescence resonant energy transfer
FSH	follicle-stimulating hormone
FTD	frontotemporal dementia
GABA	γ-aminobutyric acid
GABA-T	GABA transaminase
GAD	glutamic acid decarboxylase
GAG	glycosaminoglycans
Gal	galactose
galC	galactocerebroside
GalNAc	*N*-acetylgalactosamine
GAP	GTPase-activating protein
GAP-43	growth-associated protein (43 kDa)
GAT	GABA transporter
GBS	Guillain–Barré syndrome
GC	(i) glucocorticoid; (ii) Golgi complex; (iii) guanylyl cyclase
GDF	GDI-displacement factor
GDH	glutamate dehydrogenase
GDI	varying nucleotide dissociation inhibitor
GDNF	glial-derived neurotrophic factor
GDP	guanosine 5′-diphosphate
GDPH	glycerol phosphate dehydrogenase
GEF	guanine nucleotide exchange factor
GEMSA	guanidinoethylmercaptosuccinic acid
GFAP	glial fibrillary acidic protein
GFP	green fluorescent protein
GGF	glial growth factor
GIP	GTPase inhibitory protein
GIRK	G-protein-coupled inwardly rectifying K^+ channel
GLAST	glutamate–aspartate transporter
GLC	gas–liquid chromatography
Glc	glucose
Glc-6-P	glucose-6-phosphate
GlcNAc	*N*-acetylglucosamine
GLT	glutamate transporter
GLUT	glucose transporter
GMP	guanosine 5′-monophosphate
GnRH	gonadotropin-releasing hormone
GPCR	G-protein-coupled receptor
GPDH	glycerol phosphate dehydrogenase
GPI	glycosylphosphatidylinositol
GRE	glucocorticoid response element
GRK	G protein receptor kinase
GS	glycogen synthetase
GSH	glutathione
GSS	Gerstmann–Straussler–Scheinker syndrome
GTP	guanosine 5′-triphosphate
GTRAP	glutamate transporter-associated protein
HCSMA	hereditary canine spinal muscular atrophy
HD	Huntington's disease
HDC	L-histidine decarboxylase
HDL	high-density lipoprotein
HGF	hepatocyte growth factor
HGPRT	hypoxanthine–guanine phosphoribosyltransferase
5-HIAA	5-hydroxyindoleacetic acid
HIF	hypoxia-inducible factor
HIOMT	5-hydroxyindole-*O*-methyltransferase
HIV	human immunodeficiency virus
HLH	helix–loop–helix transcriptional regulator
HMG	β-hydroxy-β-methylglutaryl
HMIT	H^+-myo-inositol cotransporter

HMT	histamine *N*-methyltransferase
HNPP	hereditary neuropathy with predisposition to pressure palsies
HPLC	high-performance liquid chromatography
HPPD	hallucinogen persisting perception disorder
HPRT	hypoxanthine phosphoribosyltransferase
HPTLC	high-performance thin layer chromatography
HSF	heat shock factor protein
HSP	heat shock protein
5-HT	5-hydroxytryptamine (serotonin)
5-HTP	5-hydroxytryptophan
HVA	homovanillic acid
IAA	imidazoleacetic acid
IBMX	isobutylmethylxanthine
ICAM	intercellular adhesion molecule
IDPN	β,β′-iminodipropionitrile
IF	intermediate filaments
Ig	immunoglobulin
IGE	idiopathic generalized epilepsy
IGF	insulin-like growth factor
IKK	Iκ-kinase
IL	interleukin
IMP	inosine monophosphate
INSR	insulin receptor
IP	inositol phosphate
IPSP	inhibitory postsynaptic potential
IRD	infantile Refsum disease
IRS	insulin receptor substrate
JME	juvenile myoclonic epilepsy
JNK	c-Jun N-terminal kinase
JP	joining peptide
KA	kainic acid
αKGDH	α-ketoglutarate dehydrogenase
KRP	kinesin related protein
LBD	Lewy body dementia
LC	locus ceruleus
LCAD	long chain acyl-CoA dehydrogenase
LCHAD	long chain 3-hydroxyacyl-CoA dehydrogenase
LDCV	large dense core vesicle
LDH	lactate dehydrogenase
LDL	low density lipoprotein
LDLR	low density lipoprotein receptor
LE	late endosomes
LEMS	Lambert–Eaton myasthenic syndrome
LH	lutenizing hormone
LHRH	luteinizing hormone-releasing hormone
LIF	leukemia inhibitory factor
LNS	Lesch–Nyhan syndrome
LOAD	late onset Alzheimer's disease
βLPH	β-lipotropin
LPS	lipopolysaccharide
LRR	leucine-rich repeat
LSD	lysergic acid diethylamide
LTD	long-term depression
LTP	long-term potentiation
LTX	latrotoxins
M6P	mannose 6-phosphate
mAChR	muscarinic acetylcholine receptor
MADA	myoadenylate deaminase
MAG	myelin-associated glycoprotein
MAGUK	membrane-associated guanylyl kinase homolog
MAL	myelin and lymphocyte tetraspan protein
MAO	monoamine oxidase
MAOI	monoamine oxidase inhibitor
MAP	microtubule-associated protein
MAPK	mitogen-activated protein kinase
MAPKAP	MAP-kinase-activated protein kinase
MAPT	microtubule-associated protein tau
MARCKS	myristolated alanine-rich protein kinase C substrate
MAS	malate–aspartate shuttle
MASC	myotube-associated specificity component
MBO	membrane-bounded organelle
MBP	myelin basic protein
MCI	mild cognitive impairment
MDCK	Madin–Darby canine kidney
MDH_m	mitochondrial malate dehydrogenase
MDMA	3,4-methylenedioxymethamphetamine
MDR	multidrug resistance protein
MEK	MAPK/ERK activating kinase
MEKK	MEK kinase
MELAS	mitochondrial myopathy, encephalopathy, lactic acidosis, and stroke-like episodes
MEPP	miniature end-plate potential
MERRF	myoclonus epilepsy with ragged red fibers
MF	microfilament
MG	myasthenia gravis
MH	malignant hyperthermia
t-MH	*tele*-methylhistamine
MHC	major histocompatibility complex
MHPG	3-methoxy-4-hydroxyphenylglycol
t-MIAA	*tele*-methylimidazole acetic acid
MIPP	multiple inositol polyphosphate phosphatase
MKP	MAP-kinase phosphatase
ML	mucolipidosis
MLD	metachromatic leukodystrophy
MMA	methylmalonic acid
MMN	multifocal motor neuropathy
MMP	matrix metalloproteinases
MND	motor neuron disease
MOG	myelin–oligodendrocyte glycoprotein
MPP^+	1-methyl-4-phenylpyridinium
MPS	mucopolysaccharidoses
MPTP	1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine
MRI	magnetic resonance imaging
mRNA	messenger RNA
MRP	multidrug resistant protein
MRS	magnetic resonance spectroscopy
MS	multiple sclerosis
MSD	multiple sulfatase deficiency
αMSH	α-melanocyte-stimulating hormone
MSP	macrophage stimulating protein
MSUD	maple syrup urine disease
MT	microtubule
mtDNA	mitochondrial DNA
MTI	magnetization-transfer imaging
MTOC	mictotubule-organizing center
MuSK	muscle-specific kinase
MVB	multivesicular body
NAA	*N*-acetyl aspartate
NAADP	nicotinic acid–adenine dinucleotide phosphate
NAAG	*N*-acetylaspartyl glutamate
NADH	nicotinamide adenine dinucleotide, reduced form
NADPH	nicotinamide adenine dinucleotide phosphate, reduced form
NAG	*N*-acetylglutamate
NALD	neonatal adrenoleukodystrophy
NANA	*N*-acetylneuraminic acid
NARP/MILS	neuropathy, ataxia, retinitis pigmentosa/maternally inherited Leigh's syndrome
NBD	nucleotide-binding domain
NC	neural crest
NCAM	neural cell adhesion molecule
NCX	Na^+/Ca^{2+} exchanger
NDF	neu differentiation factor
nDNA	nuclear DNA
NE	norepinephrine
NET	norepinephrine transporter
NF	(i) neurofilament; (ii) neurofibromatosis
NFT	neurofibrillary tangle
NGF	nerve growth factor
NGFR	nerve growth factor receptor
NgR	Nogo receptor
NHE	Na^+/H^+ antiporter
NIPP	nuclear inhibitor of protein phosphatase
NMDA	*N*-methyl-D-aspartate
NMJ	neuromuscular junction
NMR	nuclear magnetic resonance
NO	nitric oxide
NOS	nitric oxide synthase
NPC	Niemann–Pick disease type C
NPD1	neuroprotectin D1
NPY	neuropeptide Y

NRPE *N*-retinylidene phosphatidylethanolamine
NRPTK nonreceptor protein tyrosine kinase
NRTN neurturin
NS Nissl substance
NSAID nonsteroidal anti-inflammatory drug
NSE neuronal enolase
NSF *N*-ethylmaleimide-sensitive factor
NT neurotrophin
NTP nucleoside triphosphate
NTS nucleus tractus solitarius
OCD obsessive–compulsive disorder
OCRL oculocerebrorenal syndrome
6-OHDA 6-hydroxydopamine
OL oligodendrocyte
OLP oligodendrocyte progenitor
OLS ouabain-like substance
3-OMD 3-*O*-methyldopa
OMgp oligodendrocyte-myelin glycoprotein
OR odorant receptor
OSN olfactory sensory neuron
OTC ornithine transcarbamylase
PA phosphatidic acid
PACAP pituitary adenylyl cyclase-activating peptide
PAF platelet-activating factor
PAG periaqueductal gray
PAH phenylalanine hydroxylase
PAK p21-activated kinase
PAL peptidyl-α-hydroxyglycine α-amidating lyase
PAM peptidylglycine α-amidating monooxygenase
PARP polyADP–ribose polymerase
PAS periodic acid Schiff base
PBD peroxisome biogenesis disorders
PC (i) phosphatidylcholine; (ii) prohormone convertase
PCA *para*chloroamphetamine
PCD programmed cell death
PCP phencyclidine
PCPA *para*chlorophenylalanine
PCr phosphocreatine
PCR polymerase chain reaction
PD Parkinson's disease
PDE (i) phosphodiester; (ii) phosphodiesterase
PDGF platelet-derived growth factor
PDGFR platelet-derived growth factor receptor
PDHC pyruvate dehydrogenase complex
PDK phosphoinositide-dependent kinase
PEO progressive external ophthalmoplegia
PEP priming of exocytosis protein
PEPCK phosphoenolpyruvate carboxykinase
PET positron emission tomography
PEX peroxin
PFK phosphofructokinase
PG prostaglandin
PGK phosphoglycerate kinase
PGM phosphoglycerate mutase
PH pleckstrin-homology
PHDC pyruvate dehydrogenase
PHF paired, helically wound filament
PHM peptidylglycine α-hydroxylating monooxygenase
PI (i) phosphatidylinositol; (ii) phosphoinositide
PI3K phosphatidylinositol 3-kinase
PIP phosphatidylinositol 4-phosphate
PIP_2 phosphatidylinositol 4,5-*bis*phosphate
PI-PLC phosphoinositide-specific phospholipase C
PKA protein kinase A
PKC protein kinase C
PKG protein kinase G
PKU phenylketonuria
PLA phospholipase A
PLC phospholipase C
PLD phospholipase D
PLP proteolipid protein
PMCA plasma-membrane Ca^{2+} pump
PMD Pelizaeus–Merzbacher disease
PME phosphomonoester
PMIPs plasma membrane intergral proteins
PML progressive multifocal leukoencephalopathy
PMN progressive motor neuropathy
PMP (i) peripheral myelin protein; (ii) peroxisomal membrane proteins
PNMT phenylethanolamine *N*-methyltransferase
PNS peripheral nervous system
PNUTS phosphatase 1 nuclear targeting subunit
POMC proopiomelanocortin
PP protein phosphatase
PPN pedunculopontine nucleus
PPS pentose phosphate shunt
PRL prolactin
PrP prion protein
PrP^{Sc} scrapie prion protein
PS (i) pregnenolone sulfate; (ii) presenilin
PSA polysialic acid
PSD postsynaptic density
PSEN presenilin
PSEP postsynaptic excitatory potential
PSP progressive supranuclear palsy
PSPN persephin
PSR phosphatidylserine receptor
PTB phosphotyrosine binding domain
PTBR peripheral-type benzodiazepine receptor
PtdCho phosphatidylcholine
PtdEtn phosphatidylethanolamine
PtdIns phosphatidylinositol
PtdIns 4P phosphatidylinositol 4-phosphate
PtdIns $4,5P_2$ phosphatidylinositol 4,5-*bis*phosphate
PtdOH phosphatidic acid
PtdSer phosphatidylserine
PTEN phosphatase and tensin homolog
PTH parathyroid hormone
PTK protein tyrosine kinase
PTP protein tyrosine phosphatase
PTS peroxisomal targeting signal
PTSD post-traumatic stress disorder
PUFA polyunsaturated fatty acids
PVN paraventricular nucleus
PYK proline-rich tyrosine kinase
PZ pirenzepine
RACK receptors for activated protein kinase C
RAGS repulsive axon guidance signal
RCDP rhizomelic chondrodysplasia punctata
REM rapid eye movement
RER rough endoplasmic reticulum
RFLP restriction fragment length polymorphism
RGS regulators of G protein signaling
RME receptor-mediated endocytosis
ROCK Rho-A/Rho kinase pathway
ROS reactive oxygen species
RP retinitis pigmentosa
RPE retinal pigment epithelium
RPTK receptor protein tyrosine kinase
RRP readily reuseable pool
RTK receptor tyrosine kinase
RTN reticulons
RVM rostral ventromedial medulla
SAD seasonal affective disorder
SAG Schwann cell membrane-associated glycoprotein
SAH *S*-adenosylhomocysteine
SAICAR succinylaminoimidazole carboxamide ribotide
SAM *S*-adenosylmethionine
SAPK stress-activated protein kinase
SAR specific absorption rate
SBP serotonin-binding protein
SCa slow component a
SCAD short chain acyl-CoA dehydrogenase
SCb slow component b
SCF stem cell factor
SCHAD short chain 3-hydroxyacyl-CoA dehydrogenase
SCIP suppressed cyclic AMP-inducible POU domain protein
SCN suprachiasmatic nuclei
ScTX scorpion toxin
SDS sodium dodecylsulfate

SE	status epilepticus
SEK	SAPK kinase
SER	smooth endoplasmic reticulum
SERCA	smooth endoplasmic reticulum Ca^{2+} transporter
SERT	serotonin transporter
SES	socioeconomic status
SGLT	sodium-dependent glucose transporter
SGPG	sulfate-3-glucuronyl paragloboside
SHIP	src homology inositol phosphatase
SHMT	serine hydroxymethyltransferase
SHP	SH2 domain containing protein tyrosine phosphatase
SIF	small, intensely fluorescent cells
SLC	solute carrier
SMA	spinal muscular atrophy
SMDF	sensory and motor neuron-derived growth factor
SMN	survival motor neuron
SMP	Schwann cell myelin protein
SNAP	soluble NSF attachment protein
SNARE	soluble (*N*-ethylmaleimide-sensitive fusion protein) attachment protein receptor
SNCA	gene coding for α-synuclein
SNP	single nucleotide polymorphism
SNS	sympathetic nervous system
SOD	superoxide dismutase
SOS	son of sevenless
SPECT	single photon emission computerized tomography
SR	sarcoplasmic reticulum
SRF	serum responsive factor
SRP	signal recognition particle
SRR	synaptic re-entry reinforcement
SSRI	selective serotonin reuptake inhibitor
SSV	small secretory vesicle
ST/AR	1-stearoyl, 2-arachidonyl
STN	subthalmic nucleus
STT	spinothalamic tracts
SUR	sulfonylurea receptor
SVZ	subventricular zones
TCA	(i) tricarboxylic acid; (ii) tricyclic antidepressant
TCR	T-cell receptor
TDP	thiamine diphosphate
TGFβ	transforming growth factor β
TGN	*trans*-Golgi network
TH	tyrosine hydroxylase
THC	tetrahydrocannabinol
THIP	4,5,6,7-tetrahydroisoxolo-[5,4-*c*]-pyridine-3-ol
TLC	thin-layer chromatography
TLE	temporal lobe epilepsy
TM; TMD	transmembrane spanning domain
TNF	tumor necrosis factor
TOR	target of rapamycin
TP	trifunctional protein
TPA	(i) tissue plasminogen activator; (ii) 12-D-tetradecanoyl phorbol-13-acetate
TPH	tryptophan hydroxylase
TRC	taste receptor cell
TRE	12-D-tetradecanoyl phorbol-13-acetate response element
TRH	thyrotropin-releasing hormone
TRP	transient receptor potential
TSH	thyroid stimulating hormone
TTP	thiamine triphosphate
TTX	tetrodotoxin
UCB	unconjugated billirubin
UDP	uridine 5′-diphosphate
UTP	uridine 5′-triphosphate
VAChT	vesicular acetylcholine transporter
VAMP	vesicle-associated membrane protein
VASE	variable alternative spliced exon
VDAC	voltage-dependent anion channel
VEGF	vascular endothelial growth factor
VGLUT	vesicular glutamate transporter
VGSC	voltage-gated sodium-ion channels
VIP	vasoactive intestinal peptide
VLCAD	very long chain acyl-CoA dehydrogenase
VLCFA	very long chain fatty acids
VLDLR	very-low-density lipoprotein receptor
VMAT	vesicular membrane amine transporters
VMH	ventromedial hypothalamus
VN	veromonasal neuron
VNO	vomeronasal organ
VPA	valproate
VTA	ventral tegmental area
VWMD	vanishing white matter disease
WM	white matter
X-ALD	X-linked adrenoleukodystrophy

Amino Acids in Proteins

Symbol			Codons					
One letter	**Three letter**	**Name**						
A	Ala	Alanine	GCA	GCC	GCG	GCU		
C	Cys	Cysteine	UGC	UGU				
D	Asp	Aspartate	GAC	GAU				
E	Glu	Glutamate	GAA	GAG				
F	Phe	Phenylalanine	UUC	UUU				
G	Gly	Glycine	GGA	GGC	GGG	GGU		
H	His	Histidine	CAC	CAU				
I	Ile	Isoleucine	AUA	AUC	AUU			
K	Lys	Lysine	AAA	AAG				
L	Leu	Leucine	UUA	UUG	CUA	CUC	CUG	CUU
M	Met	Methionine	AUG					
N	Asn	Asparagine	AAC	AAU				
P	Pro	Proline	CCA	CCC	CCG	CCU		
Q	Gln	Glutamine	CAA	CAG				
R	Arg	Arginine	AGA	AGG	CGA	CGC	CGG	CGU
S	Ser	Serine	AGC	AGU	UCA	UCC	UCG	UCU
T	Thr	Threonine	ACA	ACC	ACG	ACU		
V	Val	Valine	GUA	GUC	GUG	GUU		
W	Trp	Tryptophan	UGG					
Y	Tyr	Tyrosine	UAC	UAU				

Index

Note: Page numbers in *italics* indicate figures; page numbers followed by t are tables.

ABC transporters, 74
Absence seizures, 635
Acetyl coenzyme A
  acetylcholine synthesis, 192
  precursor of cholesterol and fatty acids, 39–42, *41*, 42
Acetylcholine, 185–208
  See also Acetylcholinesterase.
  chemistry, 185–186, *186*
  cholinergic nervous system, 186–189
    functional aspects, 189–191
      autonomic ganglia, 190, 190t
      blocking agents in paralysis, 191
      brain and spinal cord, 189–190
      parasympathetic effector sites, 190, 190t
      skeletal muscle, 191
    receptor subtypes, 186–189, *187*
  hydrolysis, 197
  neuromuscular junction, 170–172, *172*, 174–175
  quantal release, 194
  receptors, 430–431
    cell-surface, 178
    ion channels, 108
    muscarinic, 203–208
      adenylyl cyclase inhibition, 203
      ion channel regulation, 203
      phospholipase C stimulation, 203
      radioligand-binding studies, 205
      transgenic mice, 207–208
    nicotinic, 197–203
      desensitization, 201–202
      during differentiation and synapse formation, 202–203
      ligand binding and activation, 201
      ligand-gated channels, 202
Acetylcholine *(Continued)*
      pseudoaxis of symmetry, 198–201, *200*
      structure, 197–198
  release at cholinergic synapses, 193–194
  storage in cholinergic neuron, 194–195
  striatal neurons, 764
  synaptic transmission, 167
  synthesis, 192, *192*
    choline uptake into nerve ending, 192–193, *192*
  transport into synaptic vesicle, 192–193
Acetylcholine receptor-inducing activity (ARIA), 481
Acetylcholinesterase
  deficiency, 720
  distribution, 195
  gene structure, *196*
  inhibition mechanisms, 197
  molecular forms, 195, *195*
  neurotransmitter release, 172
  structure, 195–197
N-Acetylglutamate synthetase, 679
Acid maltase deficiency, 699–700, 703
Aconitine, and sodium channels, 101
Acquired immunodeficiency syndrome (AIDS), myelin disorder, 647
Acromegaly, G proteins, 344
Actin microfilaments, 129–131, 130t
Actin-related protein, 497
Action potentials, 98–99
  depolarization, 99
  permeability changes, 98
Activator protein deficiency, 687
Active transport. *See* Membrane transport.
Acyl CoA dehydrogenase, very-long-chain, 699
Addiction and drug abuse, 911–924
  general principles, 911–912
    characterization of addiction, 911–912
    compulsion, 912
  major drug classes, *913*
    cannabinoids (marijuana), 919–921
      derivatives of *Cannabis sativa* plant, 919
      endocannabinoids as endogenous ligands, 919–920, *920*
      endocannabinoids as retrograde messengers, 920–921
      receptors, 919
      similarities between endogenous opioid and cannabinoid systems, 921
    ethanol, sedatives and anxiolytics, 922–923
    hallucinogens and dissociative drugs, 923
    nicotine, 921–922
      addictive properties of tobacco, 921
      agonist of nicotinic acetylcholine receptor, 921
      ventral tegmental area (VTA), 921–922
    opiates, 914–916
      adaptations in receptor signaling during chronic treatment, 915–916
      endogenous systems and reward circuitry, 916
      morphine and heroin, 914

Addiction and drug abuse *(Continued)*
three classical receptor types, 914–915
upregulation of cAMP second-messenger pathway, 916
psychomotor stimulants, 916–919
cocaine and amphetamines, 916
dopamine receptor signaling through PKA pathway, 918–919, *918*
elevated monoamine levels, 917–918
targeting of dopamine (DAT), serotonin (SERT) and norepinephrine (NET) transporters, 916–917
neuronal circuitry of addiction, 912–914
peventing relapse, 912–914
reinforcers, 912
neuronal plasticity, 923–924
Adenine phosphoribosyltransferase (APRT), in Lesch–Nyhan syndrome, 307
Adenosine
See also Purinergic systems.
binding to adenylyl cyclase, 308–312
metabolites, *308*
neuromodulation, 304–305
receptors
A_1-, 313–314, *313*
A_2-, 314
agonists and antagonists, *311*
amino acid sequence, *309*
dendrogram, *310*
P2 classification, 312t
subtypes, 308–312, *309*, 310t
Adenylyl cyclase
See also Cyclic nucleotides.
adenosine binding, 308–312
G protein regulation, 338
Adhesion molecules. *See* Cell adhesion molecules.
ADP-ribosylation of G proteins, 344
Adrenal gland
adenylyl cyclase forms, 362
hormones and behavior effects, 845
β-Adrenergic receptors, protein phosphorylation, 404–405, *406*
Adrenocorticotrophic hormone (ACTH)
histamine effects, 261
Adrenoleukodystrophy
fatty acids, β-oxidation of, 42
neonatal, 691
PNS and CNS neuropathy, 647–648
X-linked, 691–692

Sulfatide, 45
Sulfur amino acids, 674–678
Superoxide dismutase 1 (SOD1), 570, 733
Sweating, muscarinic receptors, 189–190
Sweet taste, 827–829
Symporters, *74*
neurotransmitter, 84–86
Synapse, *863*
acetylcholinesterase inhibition, 197
anatomy, 10–11, *10–11*
cellular signaling, 177–182
cell-surface receptors, 177–182, *178*
cross-talk, 179–181, *180*
gene transcription, 181
nitric oxide, 181–182
plasticity
neurotrophin effects, 477
proteins, 159t
transmission, 167–182
neurotransmitter release, 168–169, *168*
exocytosis analysis, 169–170, *170*
presynaptic events, 175–177, *175*
protein release, 177
Synapsins
protein delivery to membranes, 492
protein phosphorylation, 405–406
Synaptic re-entry reinforcement (SRR), 869–870
sleep, 870–871
Synaptic vesicles
acetylcholine transport, 192–193
anterograde transport, 491–492
life cycle, *160*
serotonin storage, 233–234
trafficking, 158–162
exocytosis, 158–160
organization of presynaptic terminal, 158
recycling, 160–162, *161*
Synaptogenesis. *See* Axons, sprouting and regeneration.
Synaptojanins, 350
Synaptosomes, 169–170
α-Synucleinopathies, 745–746, 746t
animal models, 750–751
flies, worms and yeasts, 751
rodents and primates, 750
multiple system atrophy, 749, *749*
outlook, 751
Parkinson's disease and other Lewy body diseases, 747–748, *747*
Lewy body filaments, 747–748
α-synuclein mutations, 747
synthetic filaments, 750, *750*
synuclein family, 746–747, *747*

T cells
autoimmune demyelination, 640–641
multiple sclerosis, 643
Transmembrane domains
histamine receptors, 256
serotonin transporter, *235*
Tardive dyskinesia
dopamine receptors, 222
GABAergic function, 291
Tarui's disease, 697

Taste, 825–829
gustducin, 828–829, *829*
information coding, 826
ion channels, 826–827
primary stimuli, 825
salt and acid transduction, 826–827
second messengers, 827
sweet, bitter and umami, 827–829
taste buds, 825–826, *825*
innervation, 826
TATA box, in transcription, 460
Tau protein
cytoskeletal, 127, 132
Tauopathies, 745–746, 746t
Alzheimer's disease, 752–753
animal models, 756–757, *756*, *757*
flies and worms, 757
rodents, 756–757
mutations, 754–755, *754*
outlook, 757–758
sporadic tauopathies, 753–754
FTDP-17 syndromes, 755
Pick's disease, 753–754
synthetic filaments, 755
tau isoforms and interactions with microtubules, 751–752, *752*
phosphoprotein, 752
six isoforms in adult human brain, 751
Tautomerism, of histamine, 250
Tay–Sachs disease, 687
demyelination, 649–650
sphingolipid synthesis, 44, 687
Tellurium, 649
Temporal lobe, 860, *860*
Temporal lobe epilepsy (TLE), 632
Terfenadine, sedative properties, 262
Testosterone
aromatization, 848–849
behavior effects, 845
Tetrahydrocannabinoids, 919
Tetraspan proteins, 65–66
Tetrodotoxin
blockade of adenosine, 312
sodium channels, 101–105
Theiler's virus, 641
Thiamine
Wernick's encephalopathy, 599–600, *600*, *601*
Thioridazine, 877
Threonine. *See* Serine and threonine phosphorylation.
Thrombolytic drugs, 571
Thymosins, 131
Thyroid hormones
brain receptors, 853–854, *853*
Thyrotropin releasing hormone (TRH), 252
neurotransmission, 169
Tight junctions
ependymal cells, 14
Tomaculous neuropathy, 624
Toxins
G proteins, 344
ion channels, 101
myelin disorders, 649
Transcription factors, 459–469
cAMP, 466–469
CREB protein, 467, *468*
phosphorylation, 466–467
transgenic models, 467–469
development, 442–444, *442*, 448
drug development, 469
glucocorticoid and mineralocorticoid receptors, 463–466
protein phosphorylation, 410
second messengers, 181
transcriptional process, 459–461, *460*
regulation, 461–463
Transducer proteins, 25
Transducin, 338
Transferrin, 454, *454*
Transforming growth factors, 479–480
bone morphogenetic proteins, 480
glial-derived neurotrophic factor, 480
Transgenic models
muscarinic receptor subtypes, 207–208
serotonin catabolism, 238
transcription factors, 467–469
Trans-Golgi network (TGN), 148–151, *152*
Transmembrane binding domains (TMDs), 82, 83
Transmembrane domains
neuropeptide receptors, 326–328
protein tyrosine kinases, 419–422
protein tyrosine phosphatases, 426
proteins, 24–25
cellular signaling, 179
Transport systems
See also Membrane transport.
acetylcholine in synaptic vesicle, 192–193
astrocytes, 13
blood–brain–CSF barriers. *See* Blood–brain barrier.
lipids, 46–48
membrane dynamics. *See* Cell membranes.
membrane potentials, 98
myelin assembly, 68
Transporters
adenosine and inosine, 306
catecholamine storage, 213–214, 216–217
serotonin (SERT), 231, 234–236, *235*
Transthyretin, 624
Tricarboxylic acid cycle, 543–544
See Krebs cycle.
acetyl coenzyme A, 543–544
pyruvate carboxylation, 544
pyruvate dehydrogenase complex, 543
Tricyclic antidepressants (TCAs), 236
Trk receptors
growth factors, 474–475, *474*
IgCAMs, 112–113
Tropomyosin, 717, *718*
TRP channels, 108
Tryptophan
cadherins, 115
serotonin precursor, 231–232, *232*
Tryptophan hydroxylase, 231–232, 233
Tubocurarine, 187, 191
Tubulin
CNS myelin, 63–64
neuronal microtubules, 124–127, *125*, 126t
slow axonal transport, 493–495
Tumor necrosis factor
autoimmune demyelination, 641
Tyramine, MAO inhibitors, 214
Tyrosine
phosphorylation, 415–433
nervous system, 415–416, *415*
acetylcholine receptors, 430–431
axon guidance, 428
CNS synapse, 429–430
GABA receptors, 432
lifetime of neuron, *428*
neuromuscular synapse, 428–429
neuronal survival and differentiation, 426–428
NMDA receptors, 431–432
synapse transmission and plasticity, 430
voltage-gated ion channels, 432–433
nonreceptor protein kinases, *416*
intracellular second messengers, 418
regulatory domain, 418
SH1 domain, 416, 418
SH2 domain, 416
SH3 domain, 417–419
protein tyrosine phosphatases, 423–426, *424*
structure, 424
receptor protein kinases, 419–422
activation of, 422, *422*
cytoplasmic domain, 422
extracellular region, 419–422
inactivation of, 422
transmembrane domain, 422
tyrosine phosphorylation, 423, *423*
Tyrosine hydroxylase
catecholamine synthesis, 212, 214
protein phosphorylation, 403–404, 410
Tyrosine kinase, 179

Umami taste, 825, 827–829
Urea cycle, 678–681, *678*
Uremic encephalopathy, 598–599
Uridine triphosphate (UTP). *See* Purinergic systems.

van der Walls' forces, 22
Vascular endothelial growth factor (VEGF), 733
Vasoactive intestinal polypeptide (VIP)
  neurotransmission, 169
  protein phosphorylation, 410
Vasopressin
  See also Neuropeptides.
  adaptive response, 320–321
  diabetes insipidus, 330
  histamine effects, 261
  neurotransmission, 169
Venom toxins, 727–729
  sodium channels, 101
Ventral tegmental area (VTA), 921–922
Ventricles, brain, 16
Veratridine, 101, 103
Vesicle monamine transporters (VMAT), 917
Vesicles
  coated. *See* Coated vesicles.
  Golgi apparatus, 7
  membrane transporters
    catecholamine storage, 213–214
    serotonin, 233
  serotonin storage, 233–234
  synaptic. *See* Synaptic vesicles.
Vesicular glutamate transporters (VGLUTs), 271
Video microscopy, axonal transport, 485–486, *486*, 488, 492
Vimentin, 128
Viruses
  infections, 641
Vision, 807–815
  age-related macular degeneration, 815
  color blindness, 814
  cone cell pigments, 812
  photoreceptor membranes, 809–812
  phototransduction, 812–814
    G protein/cGMP system, 812–813, *813*
    sodium channels, 812–813
  physiology, 807–809, *808*
    photoreceptor cells, 807
    rod and cone cells, 807
  retinosa pigmentosa, 814–815
  rhodopsin, 587
    opsin and retinal formation, 809, *811*
    regeneration, 809–812
    rod membranes, 809–812
Visna diseases, 641
Vitamin B_{12} (cobalamin), 677–678
Vitamin D
  brain receptors, 852
  metabolism, 849
Vitamins, deficiency, 649
Voltage-gated ion channels. *See* Calcium; Gating mechanisms; Ion channels.
Voltage-gating, 103, *104*
  functional properties, 100–101
  molecular components, 101–103, *102*
Volume transmission, 238
Vomeronasal organ, 824
Von Gierke's disease, 704
von Recklinghausen's disease, 625
Wallerian degeneration, 518–519, *519*, 519t, 621, 649–650
Water
  permeability in lipid bilayers, 24
Wernicke's encephalopathy, 251, 262, 599–600, *600*, *601*
White matter
  anatomy, 3–4, *4*, 51, 58
  astrocytes, 12
  inherited disorders, 647–648
  lipid composition, 40t
  lipid structure, 37
Whitten effect, 845
Wilson's disease, 773–774, *774*
  animal models, 774
  copper transport, 82
  molecular, pathophysiologic and genetic aspects, 774
  treatment, 774–775
Wortmannin, 348

X chromosome, in color blindness, 814
Xanthine oxidase, 570
X-ray diffraction, myelin structure, 52

Zellweger's cerebrohepatorenal syndrome
  β-oxidation of factty acids, 42
Zinc
  finger proteins
    corticosteroid regulation of transcription, 464
