Basic Neurochemistry

MOLECULAR, CELLULAR AND MEDICAL ASPECTS

SEVENTH EDITION

EDITOR-IN-CHIEF

George J. Siegel, MD

Chief of Neurology Service, Edward Hines Jr. Veteran Affairs Hospital
Professor of Neurology and of Cell Biology,Neurobiology & Anatomy,
Loyola University Chicago Stritch School of Medicine
Maywood, Illinois

EDITORS

R. Wayne Albers, Ph.D.
Chief of Section on Enzymes
Laboratory of Neurochemistry
National Institute of Neurological Disorders and Stoke
National Insiitutes of Health
Bethesda, Maryland

Scott T. Brady, Ph.D.
Professor and Head
Department of Anatomy and Cell Biology
University of Illinois at Chicago
Chicago, Illinois

Donald L. Price, M.D.
Professor, Departments of Neurology and Neuroscience
Director, Division of Neuropathology,
The Johns Hopkins University School of Medicine
Baltimore, Maryland

Contents

Section Editors ix
Contributors xi
Acknowledgments and History xix
Preface xxi
Tribute to Pierre Morell xxiii

PART I

Cellular Neurochemistry and Neural Membranes 1

CHAPTER 1
Neurocellular Anatomy 3
Cedric S. Raine

CHAPTER 2
Cell Membrane Structures and Functions 21
R. Wayne Albers

CHAPTER 3
Lipids 33
Joyce A. Benjamins
Amiya K. Hajra
Bernard W. Agranoff

CHAPTER 4
Myelin Formation, Structure and Biochemistry 51
Richard H. Quarles
Wendy B. Macklin
Pierre Morell

CHAPTER 5
Membrane Transport 73
R. Wayne Albers
George J. Siegel

CHAPTER 6
Electrical Excitability and Ion Channels 95
Bertil Hille
William A. Catterall

CHAPTER 7
Cell Adhesion Molecules 111
David R. Colman
Marie T. Filbin

CHAPTER 8
The Cytoskeleton of Neurons and Glia 123
Gustavo Pigino
Laura L. Kirkpatrick
Scott T. Brady

CHAPTER 9
Intracellular Trafficking 139
Gustavo Pigino
Gerardo Morfini
Scott T. Brady

PART II

Intercellular Signaling 165

CHAPTER 10
Synaptic Transmission and Cellular Signaling: An Overview 167
Ronald W. Holz
Stephen K. Fisher

CHAPTER 11
Acetylcholine 185
Palmer Taylor
Joan Heller Brown

CHAPTER 12
Catecholamines 211
Michael J. Kuhar
Kenneth Minneman
E. Christopher Muly

CHAPTER 13
Serotonin 227
Julie G. Hensler

CHAPTER 14
Histamine 249
Lindsay B. Hough
Rob Leurs

CHAPTER 15
Glutamate 267
Bjørnar Hassel
Raymond Dingledine

CHAPTER 16
GABA and Glycine 291
Richard W. Olsen
Heinrich Betz

CHAPTER 17
Purinergic Systems 303
Joel Linden
Diane L. Rosin

CHAPTER 18
Peptides 317
Richard E. Mains
Betty A. Eipper

PART III

Intracellular Signaling 333

CHAPTER 19
G Proteins 335
Eric J. Nestler
Ronald S. Duman

CHAPTER 20
Phosphoinositides 347
Anne M. Heacock
Stephen K. Fisher

CHAPTER 21
Cyclic Nucleotides in the Nervous System 361
Ronald S. Duman
Eric J. Nestler

CHAPTER 22
Calcium 379
Gary S. Bird
James W. Putney Jr

CHAPTER 23
Serine and Threonine Phosphorylation 391
James A. Bibb
Eric J. Nestler

CHAPTER 24
Tyrosine Phosphorylation 415
Lit-Fui Lau
Richard Huganir

PART IV

Growth, Development and Differentiation 435

CHAPTER 25
Development 437
Jean de Vellis
Ellen Carpenter

CHAPTER 26
Transcription Factors in the Central Nervous System 459
James Eberwine

CHAPTER 27
Growth Factors 471
Gary E. Landreth

CHAPTER 28
Axonal Transport 485
Gerardo A. Morfini
David L. Stenoien
Scott T. Brady

CHAPTER 29
Stem Cells in the Nervous System 503
Alison K. Hall
Robert H. Miller

CHAPTER 30
Axonal Growth in the Adult Mammalian Nervous System: Regeneration and Compensatory Plasticity 517
Gwendolyn L. Kartje
Martin E. Schwab

PART V

Metabolism 529

CHAPTER 31
Energy Metabolism of the Brain 531
Mary C. McKenna
Rolf Gruetter
Ursula Sonnewald
Helle S. Waagepetersen
Arne Schousboe

CHAPTER 32
Hypoxic–Ischemic Brain Injury and Oxidative Stress 559
Laura L. Dugan
Jeong Sook Kim-Han

CHAPTER 33
Eicosanoids, Docosanoids, Platelet-Activating Factor and Inflammation 575
Nicolas G. Bazan

CHAPTER 34
Metabolic Encephalopathies 593
Roger F. Butterworth

CHAPTER 35
Apoptosis and Necrosis 603
Mark P. Mattson
Nicolas G. Bazan

PART VI

Inherited and Neurodegenerative Diseases 617

CHAPTER 36
Peripheral Neuropathy 619
David Pleasure

CHAPTER 37
The Epilepsies: Phenotype and Mechanisms 629
John W. Gibbs
James O. McNamara

CHAPTER 38
Diseases Involving Myelin 639
Richard H. Quarles
Pierre Morell
Henry F. McFarland

CHAPTER 39
Genetics of Neurodegenerative Diseases 653
Lars Bertram
Rudolph E. Tanzi

CHAPTER 40
Disorders of Amino Acid Metabolism 667
Marc Yudkoff

CHAPTER 41
Lysosomal and Peroxisomal Diseases 685
Hugo W. Moser

CHAPTER 42
Diseases of Carbohydrate, Fatty Acid and Mitochondrial Metabolism 695
Salvatore DiMauro
Darryl C. De Vivo

CHAPTER 43
Disorders of Muscle Excitability 713
Juan M. Pascual
Basil T. Darras

CHAPTER 44
Motor Neuron Diseases 731
Donald L. Price
Steven Ackerly
Lee J. Martin
Vassilis Koliatsos
Philip C. Wong

CHAPTER 45
Neurodegenerative α-Synucleinopathies and Tauopathies 745
Michel Goedert
Maria Grazia Spillantini

CHAPTER 46
Neurotransmitters and Disorders of the Basal Ganglia 761
Thomas Wichmann
Mahlon R. DeLong

CHAPTER 47
Neurobiology of Alzheimer's Disease 781
Philip C. Wong
Tong Li
Donald L. Price

CHAPTER 48
Molecular Basis of Prion Diseases 791
John Collinge
Jonathan D. F. Wadsworth

PART VII

Sensory Transduction 805

CHAPTER 49
Molecular Biology of Vision 807
Hitoshi Shichi

CHAPTER 50
Molecular Biology of Olfaction and Taste 817
Steven D. Munger

CHAPTER 51
Molecular Biology of Hearing and Balance 833
Peter G. Gillespie

PART VIII

Neural Processing and Behavior 841

CHAPTER 52
Endocrine Effects on the Brain and Their Relationship to Behavior 843
Bruce S. McEwen

CHAPTER 53
Learning and Memory 859
Joe Z. Tsien

CHAPTER 54
The Neurochemistry of Schizophrenia 875
Joseph T. Coyle

CHAPTER 55
Neurobiology of Severe Mood and Anxiety Disorders 887
J. John Mann
Dianne Currier
Jorge A. Quiroz
Husseini K. Manji

CHAPTER 56
Addiction 911
Marina E. Wolf

CHAPTER 57
Pain 927
Michael Costigan
Joachim Scholz
Tarek Samad
Clifford J. Woolf

CHAPTER 58
Neuroimaging 939
J. Eric Jensen
Perry F. Renshaw
Dean F. Wong
Weiguo Ye

Glossary 963
Amino Acids in Proteins 968
Index 969

BOXES

Box 3-1, Glycosylphosphatidylinositol-Anchored Proteins 47

Box 17-1, Inherited Diseases of Purine Metabolism 307
George J. Siegel

Box 20-1, Does the Action of Li+ on the Phosphoinositide Labeling Cycle Explain the Therapeutic Action of Li^+ in Manic Depressive Psychosis? 356

Box 32-1, Hydrogen Sulfide: Potential Neuroprotectant and Neuromodulator 573
George J. Siegel

Box 46-1, Summary of Polyglutamine Repeat Disorders 779
Sangram Sisodia

Section Editors

Part 1: Cellular Neurochemistry and Neural Membranes
Joyce A. Benjamins, Ph.D.

Part 2: Intercellular Signaling
Stephen K. Fisher, Ph.D.

Part 3 : Intracellular Signaling
R. Wayne Albers, Ph.D.

Part 4: Growth, Development and Differentiation
Jean de Vellis, Ph.D.

Part 5: Metabolism
Nicolas Bazan, M.D., Ph.D.

Part 6: Inherited and Neurodegenerative Diseases
Sangram S. Sisodia, Ph.D.

Part 7: Sensory Transduction
R. Wayne Albers, Ph.D.

Part 8: Neural Processing and Behavior
Joseph T. Coyle, M.D.

Contributors

Steven Ackerly, Ph.D.
Department of Pathology, Division of Neuropathology
The Johns Hopkins University School of Medicine
Ross 558, 720 Rutland Avenue
Baltimore, Maryland 21205

Bernard W. Agranoff, M.D.
Ralph Waldo Gerard Professor of Neurosciences in Psychiatry
Professor of Biological Chemistry, Molecular and Behavioral Neuroscience Institute
University of Michigan
205 Zina Pitcher Place
Ann Arbor, Michigan 48109-0720

R. Wayne Albers, Ph.D.
Chief of Section on Enzymes
Laboratory of Neurochemistry
National Institute of Neurological Disorders and Stroke
National Institutes of Health
Bethesda, Maryland 20892-4130

Nicolas Bazan, M.D., Ph.D.
Boyd Professor, Ernest C. and Yvette C. Villere Professor of Ophthalmology, Biochemistry and Molecular Biology and Neurology
Director, Neuroscience Center of Excellence
Louisiana State University Health Sciences Center
2020 Gravier Street
New Orleans, Louisiana 70112

Joyce A. Benjamins, Ph.D.
Professor and Associate Chair for Research
Department of Neurology
Wayne State University
4201 St. Antoine
Detroit, Michigan 48201

Lars Bertram, M.D.
Assistant Professor of Neurology, Harvard Medical School
Massachusetts General Hospital
114 16th Street
Charlestown, Massachusetts 02129

Heinrich Betz, M.D.
Director, Department of Neurochemistry
Max Planck Institute for Brain Research
Deutschordenstraße 46
D-60528 Frankfurt/Main
Germany

James Bibb, Ph.D.
Assistant Professor, Department of Psychiatry
UT Southwestern Medical Center
5323 Harry Hines Blvd
Dallas, Texas 75390-9070

Gary St. John Bird, Ph.D.
Staff Scientist, Laboratory of Signal Transduction
National Institute of Environmental Health Sciences, National Institutes of Health
111, T.W. Alexander Drive, PO Box 12233
Research Triangle Park
North Carolina 27709

Scott T. Brady, Ph.D.
Professor and Head, Department of Anatomy and Cell Biology
University of Illinois at Chicago
808 S. Wood Street, Room 578 (M/C 512)
Chicago, Illinois 60612

Roger F. Butterworth, Ph.D., D.Sc.
Director, Neuroscience Research Unit
Hôpital Saint-Luc
1058 Saint-Denis
Montreal, Quebec H2X 3J4, Canada

Ellen Carpenter, Ph.D.
Associate Professor of Psychiatry and Biobehavioral Sciences
Mental Retardation Research Center
Semel Institute for Neuroscience and Human Behavior
David Geffen School of Medicine at UCLA
University of California, Los Angeles
Los Angeles, California 90095-1759

William A. Catterall, Ph.D.
Professor and Chair, Department of Pharmacology
University of Washington School of Medicine
Mailstop 357280, Room H-409 Health Science Building
Seattle, Washington 98195-7280

David R. Colman, Ph.D.
Director, Montreal Neurological Institute and Hospital
3801 University Street
Montreal, Quebec H3A 2B4
Canada

John Collinge, C.B.E, F.R.S.
Director of MRC Prion Unit & Head of Department of Neurodegenerative Disease
Institute of Neurology, University College London
Queen Square, London WC1N 3BG
United Kingdom

Michael Costigan, Ph.D.
Instructor in Anesthesia, Harvard Medical School
Neural Plasticity Research Group, Department of Anesthesia and Critical Care
Massachusetts General Hospital
149 13th Street
Charlestown, Massachusetts 02129

Joseph T. Coyle, M.D.
Eben S. Draper Professor of Psychiatry, Harvard Medical School
McLean Hospital
115 Mill Street
Belmont, Massachusetts 02478

Dianne Currier, Ph.D.
Staff Associate, Department of Psychiatry
Columbia University
1051 Riverside Drive
New York 10032

Basil T. Darras, M.D.
Director, Neuromuscular Program, Children's Hospital Boston
Professor of Neurology (Pediatrics), Harvard Medical School
300 Longwood Ave, Fegan II
Boston, Massachusetts 02115

Mahlon R. DeLong, M.D.
Professor and Director of Neuroscience
Emory University School of Medicine
Department of Neurology, Suite 6000
101 Woodruff Circle
Atlanta, Georgia 30322

Jean de Vellis, Ph.D.
Professor of Neurobiology
Mental Retardation Research Center
Semel Institute for Neuroscience and Human Behavior
David Geffen School of Medicine at UCLA
University of California, Los Angeles
Los Angeles, California 90095-1759

Darryl C. De Vivo, M.D.
Sidney Carter Professor of Neurology
Associate Chairman for Pediatric Neurosciences and Developmental Neurobiology
Founding Director of the Colleen Giblin Research Laboratories for Pediatric Neurology
The Neurological Institute of New York at Columbia University
710 W 168 Street
New York 10032-3784

Salvatore DiMauro, M.D.
Lucy G. Moses Professor of Neurology
4-420 College of Physicians & Surgeons
630 West 168th Street
New York 10032

Raymond Dingledine, Ph.D.
Professor and Chair, Department of Pharmacology
Emory University School of Medicine
1510 Clifton Road
Atlanta, Georgia 30322

Laura L. Dugan, M.D.
Professor and Larry L. Hillblom Chair in Geriatric Medicine
Department of General Medicine, Geriatrics
University of California, San Diego – Health Sciences
9500 Gilman Drive, MC0665
La Jolla, California 92093

Ronald S. Duman, Ph.D.
Professor of Psychiatry and Pharmacology
Director of the Abraham Ribicoff Research Facilities
Yale University School of Medicine
34 Park Street, Room S308
New Haven, Connecticut 06508

James H. Eberwine, Ph.D.
Professor, Department of Pharmacology and Psychiatry
University of Pennsylvania Medical Center
36th and Hamilton Walk
Philadelphia, Pennsylvania 19104

Betty A. Eipper, Ph.D.
Professor of Neuroscience
University of Connecticut Health Center
263 Farmington Ave
Farmington, Connecticut 06030-3401

Marie T. Filbin, Ph.D.
Professor, Department of Biological Sciences
Director, Specialised Neuroscience
Research Program
Hunter College, City University of New York
3801 University Avenue, Room 636
New York 10021

Stephen K. Fisher, Ph.D.
Department of Pharmacology/Molecular
and Behavioral Neuroscience Institute
The University of Michigan Medical School
C560 MSRBII, 1150 West Medical Center Dr.
Ann Arbor, Michigan 48109-0669

John W. Gibbs III, M.D., Ph.D.
Clinical Assistant Professor of Medicine
Brody School of Medicine at East Carolina University
East Carolina Neurology, Inc.
2280 Hemby Lane
Greenville, North Carolina 27834

Peter G. Gillespie, Ph.D.
Professor of Otolaryngology and Cell Biology
Oregon Hearing Research Center &
Vollum Institute
Oregon Health & Science University
L335A, 3181 SW Sam Jackson Pk. Rd.
Portland, Oregon 97239

Michel Goedert, M.D., Ph.D.
Joint Head of Neurobiology Division
Medical Research Council Laboratory of
Molecular Biology
Hills Road
Cambridge CB2 2QH
United Kingdom

Rolf Gruetter, Ph.D.
Professor and Head, Laboratory of Functional and
Metabolic Imaging
Professor, Department of Radiology,
University of Lausanne Medical School
Professor, Department of Radiology,
University of Geneva Medical School
Ecole Polytechnique Federale de Lausanne
Institut for Complex Matter Physics
Station 3
Lausanne CH-1015
Switzerland

Amiya K. Hajra, Ph.D.
Professor of Biological Chemistry and
Senior Research Scientist
Department of Biological Chemistry
University of Michigan
1301 E. Catherine
Ann Arbor, Michigan 48109-0606

Alison K Hall, Ph.D.
Associate Professor Neurosciences and
Pharmacology
Case Western Reserve University School of
Medicine
2119 Abington Rd.
Cleveland, Ohio 44106-4975

Bjørnar Hassel, M.D., Ph.D.
Senior Scientist
Norwegian Defence Research Establishment
PO Box 25
Kjeller, N-2027
Norway

Anne Heacock, Ph.D.
Molecular and Behavioral Neuroscience
Institute
University of Michigan
C560, MSRB II, 1150 W. Medical Center Drive
Ann Arbor, Michigan 48019-0669

Joan Heller-Brown, Ph.D.
Professor and Chair, Department of
Pharmacology
University of California, San Diego
BSB Room 3024, 9500 Gilman Drive
La Jolla, California 92093-0636

Julie G. Hensler, Ph.D.
Associate Professor, Department of
Pharmacology, MC 7764
The University of Texas Health Science Center
7703 Floyd Curl Drive
San Antonio, Texas 78229-3900

Bertil Hille, Ph.D.
Professor, Department of Physiology and Biophysics
University of Washington School of Medicine
Mailstop 357290, Room H-409
Health Science Building
Seattle, Washington 98195-7290

Ronald W. Holz, M.D., Ph.D.
Professor of Pharmacology
University of Michigan Medical School
Ann Arbor, Michigan 48109-0632

Lindsay B. Hough, Ph.D.
Professor and Associate Director, Center for Neuropharmacology and Neuroscience
Albany Medical College
47 New Scotland Avenue, MC-136
Albany 12208

Richard L. Huganir, Ph.D.
Professor/Investigator, Department of Neuroscience, Howard Hughes Medical Institute
The Johns Hopkins University School of Medicine
725 North Wolfe Street, PCTB 904B
Baltimore, Maryland 21205

J. Eric Jensen, Ph.D.
Instructor in Psychiatry, Harvard Medical School
Assistant Physicist, Brain Imaging Center, McLean Hospital
115 Mill Street
Belmont, Massachusetts 02478-9106

Gwendolyn Kartje, M.D., Ph.D.
Chief, Neurology Service, Edward Hines Jr. Veterans Affairs Hospital
Vice Chair and Associate Professor of Neurology
Associate Professor of Cell Biology, Neurobiology & Anatomy
Loyola University Chicago Stritch School of Medicine
Maywood, Illinois 60141

Jeong Sook Kim-Han, Ph.D.
Research Assistant Professor, Departments of Neurology, Medicine/Geriatrics and Neurobiology
Washington University School of Medicine
660 S. Euclid Avenue, Box 8111
St. Louis, Missouri 63110

Laura L. Kirkpatrick, Ph.D.
Senior Scientific Group Leader, Molecular Genetics
Lexicon Genetics, Inc.
8800 Technology Forest Place, Building 4, Room C228
The Woodlands, Texas 77381-1160

Vassilis Koliatsos, M.D.
Associate Professor of Pathology, Departments of Pathology, Neurology, Psychiatry and Neuroscience, Division of Neuropathology
The Johns Hopkins University School of Medicine
Ross 558, 720 Rutland Avenue
Baltimore, Maryland 21205

Michael J. Kuhar, Ph.D.
Charles Howard Candler Professor of Neuropharmacology, Emory University School of Medicine
Chief, Division of Neuroscience, Yerkes National Primate Research Center of Emory University
954 Gatewood NE
Atlanta, Georgia 30329

Gary Landreth, Ph.D.
Professor of Neurosciences and Neurology, Department of Neurosciences
Alzheimer Research Laboratory
Case Western Reserve University School of Medicine
10900 Euclid Ave
Cleveland, Ohio 44106-4928

Lit-Fui Lau, Ph.D.
Senior Principal Scientist
MS 220-4013
Pfizer Global R & D
Eastern Point Road
Groton, Connecticut 06340

Rob Leurs, Ph.D.
Professor of Medicinal Chemistry
Leiden/Amsterdam Center for Drug Research
Vrije Universeteit, Faculty of Science
De Boelelaan 1083
1081 HV Amsterdam
The Netherlands

Tong Li, Ph.D.
Research Associate, Department of Pathology and Division of Neuropathology
The Johns Hopkins University School of Medicine
Ross 558, 720 Rutland Avenue
Baltimore, Maryland 21205

Joel Linden, Ph.D.
Professor of Medicine and Pharmacology
University of Virginia
MR5 Box 801394, Health Sciences Center
Charlottesville, Virginia 22908

Bruce S. McEwen, Ph.D.
Professor and Head, Laboratory of Neuroendocrinology
The Rockefeller University
1230 York Avenue
New York 10021

Henry McFarland, M.D.
Director, Clinical Neurosciences Program
Division of Intramural Research
National Institute of Neurological Disorders and Stroke
National Institutes of Health
10/5 B16
Bethesda, Maryland 20892

Mary C. McKenna, Ph.D.
Associate Professor, Department of Pediatrics
University of Maryland School of Medicine
655 W. Baltimore Street, Room 10-031
Baltimore, Maryland 21201

Wendy B. Macklin, Ph.D.
Professor, Department of Neurosciences NC30
Cleveland Clinic Foundation
9500 Euclid Avenue
Cleveland, Ohio 44195

James O. McNamara, M.D.
Carl R. Deane Professor and Chair,
Department of Neurobiology
Duke University Medical Center
401 Bryan Research Building, Research Drive
Box 3676
Durham, North Carolina 27710

Richard E. Mains, Ph.D.
Professor of Neuroscience
University of Connecticut Health Center
263 Farmington Ave
Farmington, Connecticut 06030-3401

Husseini Manji, M.D.
Director Mood & Anxiety Disorders Program
Chief, Laboratory of Molecular Pathophysiology
National Institute of Mental Health
National Institutes of Health
Building 1, Room 3B310, 1 Center Drive
Bethesda, Maryland 20892-0135

J. John Mann, M.D.
The Paul Janssen Professor of Translational Neuroscience
(in Psychiatry and Radiology)
Chief of Neuroscience, New York State Psychiatric
Institute
Columbia University
1051 Riverside Drive
New York 10032

Lee J. Martin, Ph.D.
Associate Professor of Pathology, Departments of
Pathology and Neuroscience, Division of
Neuropathology
The Johns Hopkins University School of Medicine
Ross 558, 720 Rutland Avenue
Baltimore, Maryland 21205

Mark Mattson, Ph.D.
Chief of the Laboratory of Neurosciences
National Institute on Aging Intramural
Research Program
National Institutes of Health
5600 Nathan Shock Drive
Baltimore, Maryland 21224

Robert H. Miller, Ph.D.
Professor, Department of Neurosciences
Case Western Reserve University School of
Medicine
2119 Abington Rd.
Cleveland, Ohio 44106-4975

Kenneth P. Minneman, Ph.D.
Charles Howard Candler Professor of
Pharmacology
Emory University School of Medicine
5086 Rollins Research Center
Atlanta, Georgia 30322-3090

Pierre Morell, Ph.D. (deceased)
Professor of Biochemistry and Neurobiology
University of North Carolina Neuroscience Center
Chapel Hill, North Carolina 27599

Gerardo A. Morfini, Ph.D.
Research Assistant Professor,
Department of Anatomy and Cell Biology
University of Illinois at Chicago
808 S. Wood Street, CME Room 567C,
Chicago, Illinois 60612

Hugo W. Moser, M.D.
Director, Neurogenetics Research,
Kennedy Krieger Institute
Professor of Neurology and Pediatrics,
Johns Hopkins University
707 North Broadway
Baltimore, Maryland 21205

E. Christopher Muly. M.D., Ph.D.
Assistant Professor of Psychiatry and Behavioral
Sciences, Emory University School of
Medicine
Affiliate Scientist in Residence,
Yerkes National Primate Research Center of
Emory University
954 Gatewood Road, NE
Atlanta, Georgia 30329

Steven D. Munger, Ph.D.
Assistant Professor, Department of Anatomy and
Neurobiology
University of Maryland School of Medicine
20 S. Penn Street., Room S251
Baltimore, Maryland 21201

Eric J. Nestler, M.D., Ph.D.
Lou and Ellen McGinley Distinguished
Professor and Chair, Department of Psychiatry
UT Southwestern Medical Center at Dallas
5323 Harry Hines Blvd
Dallas, Texas 75390-9070

Richard W. Olsen, Ph.D.
Professor, Department of Molecular & Medical
Pharmacology, Geffen School of Medicine
University of California – Los Angeles
Room CHS 23-120, 650 Young Drive South
Los Angeles, California 90095-1735

Juan M. Pascual, M.D., Ph.D.
Director of Molecular Biophysics,
Colleen Giblin Research Laboratories
Departments of Neurology and Pediatrics
Columbia University
710 West 168th Street
New York 10032

Gustavo Pigino, Ph.D.
Research Assistant Professor, Department of
Anatomy and Cell Biology
University of Illinois at Chicago
808 S. Wood Street, Room 578 (M/C 512)
Chicago, Illinois 60612

David E. Pleasure, M.D.
Department of Neurology, University of
California Davis
c/o Shriners Hospital for Children Northern California
2425 Stockton Boulevard
Sacramento, California 95817

Donald L. Price, M.D.
Professor, Departments of Neurology and Neuroscience
Director, Division of Neuropathology
Director, Alzheimer's Disease Research Center
The Johns Hopkins University School of Medicine
Ross 558, 720 Rutland Avenue
Baltimore, Maryland 21205

James W. Putney, Ph.D.
Chief, Calcium Regulation Section
National Institute of Environmental Health Sciences
National Institutes of Health
PO Box 12233 (MD F2-02)
Research Triangle Park, North Carolina 27709-22

Richard H. Quarles, Ph.D.
Senior Investigator, Myelin & Brain Development
Section
National Institute of Neurological Disorders and Stroke
National Institutes of Health
5625 Fishers Lane, Room 4S-30, MSC 9407
Bethesda, Maryland 20892

Jorge A. Quiroz, M.D.
Research Fellow, Laboratory of Molecular Pathophysiology
National Institute of Mental Health
National Institutes of Health
Building 1, Room 3B310, 1 Center Drive
Bethesda, Maryland 20892-0135

Cedric S. Raine, Ph.D.
Professor of Pathology, Neurology and Neuroscience
Albert Einstein College of Medicine
Yeshiva University
1300 Morris Park Ave
Bronx, New York 10461

Perry F. Renshaw, M.D., Ph.D.
Professor of Psychiatry, Harvard Medical School
Director, Brain Imaging Center, McLean Hospital
115 Mill Street
Belmont, Massachusetts 02478

Diane L. Rosin, Ph.D.
Associate Professor of Pharmacology
University of Virginia
PO Box 800735, 1300 Jefferson Park Ave
Charlottesville, Virginia 22908-0735

Tarek Samad, Ph.D.
Instructor in Anesthesia, Harvard Medical School
Neural Plasticity Research Group,
Department of Anesthesia and Critical Care
Massachusetts General Hospital
149 13th Street
Charlestown, Massachusetts 02129-2000

Joachim Scholz, M.D.
Instructor in Anesthesia, Harvard Medical School
Neural Plasticity Research Group,
Department of Anesthesia and Critical Care
Massachusetts General Hospital
149 13th Street
Charlestown, Massachusetts 02129-2000

Arne Schousboe, D.Sc.
Professor and Chair, Department of Pharmacology and
Pharmacotherapy
The Danish University of Pharmaceutical Sciences
2 Universitetsparken
DK-2100 Copenhagen
Denmark

Martin E. Schwab, Ph.D.
Professor and Chair of Neuroscience, Brain Research
Institute, University of Zurich

Acknowledgments and History

We express our debt to all the former authors and editors for their contributions that have made this book so useful over the years. We have carried forward many of these contributions into this seventh edition. In particular, we note with thanks the earlier work of former co-editors, Dr. Bernard Agranoff in the first six editions, Dr. Robert Katzman in the first three editions, Dr. Perry Molinoff in the fourth and fifth editions, and Drs. Stephen Fisher and Michael Uhler in the sixth edition. In revising this book to remain current, all chapters have been updated, some earlier chapters have been dropped and their pertinent content incorporated into other chapters, new chapters and topics amounting to about 25% of the content have been introduced and the book has been expanded as far as practical while keeping to one volume. Illustrations have been redrawn and produced in full color with an eye toward teaching and aesthetic goals. These revisions have involved rotation of authors and inclusion of many new authors. We are indebted to previous authors whose work has been continued and in many cases further developed in this revision. This is actually the way science evolves and is taught. We owe gratitude to the many investigators whose past and current research has made this new edition both necessary and possible. We regret that much important work and citations of historical significance cannot be specifically referenced in a textbook.

We are grateful to Johannes Menzel, Ph.D., of Elsevier, for his guiding the production of this edition and in keeping us all on track to ensure its timely and successful completion. We also thank Jasna Markovac, Sr. Vice President, for her long-standing encouragement and the staff of Elsevier, particularly Karen Dempsey, Kirsten Funk, and art designer Julio Esperas, for their work on this book.

Basic Neurochemistry: Molecular, Cellular and Medical Aspects had its origin in the Conference on Neurochemistry Curriculum initiated and organized by R. Wayne Albers, Robert Katzman and George J. Siegel under the sponsorship of the National Institute for Neurological Diseases and Stroke, June 19 and 20, 1969, Bronx, New York. At this conference, a group of 30 neuroscientists constructed a syllabus outline delineating the scope of a neurochemistry curriculum appropriate for medical, graduate and postgraduate neuroscience students. Out of this outline grew the first edition, edited by Wayne Albers, George Siegel, Robert Katzman and Bernard Agranoff. It was anticipated that the book would evolve with the emergence of the field and would stimulate continuing reappraisal of the scientific and educational aspects of neurochemistry. This has in fact been the case over the years of these seven editions (see Preface).

The original editors elected to assign the copyright and all royalties to the American Society for Neurochemistry (ASN), the royalties to be used for educational purposes, and as may be needed for editorial work and revisions of the book. These funds have been used to subsidize travel of graduate students and postdoctoral fellows to present their research at meetings of the ASN, to send copies of the book to libraries in underdeveloped countries and as prizes to students for their research at the ASN and International Society for Neurochemistry. In addition, these royalties have subsidized the Basic Neurochemistry Lectureships at the annual meetings of the ASN since 1979. Retrospectively, it is of historical interest that the first two Basic Neurochemistry Lectures reflected the meaning of this book in integrating molecular and functional aspects in studying the nervous system.

The first lecture given by Tomas Hokfelt, who pioneered anatomical studies based on amine fluorescence, was entitled, "Neuroanatomy for the Neurochemist" while the second lecture given by Louis Sokoloff, who invented the methodology of functional brain imaging originally based on metabolism of radionuclide labeled-2-deoxyglucose, was entitled "Neurochemistry for the Neuroanatomist". The history and further information concerning the ASN may be found at the website: www.asneurochem.org.

Preface to the Seventh Edition

This Seventh Edition of *Basic Neurochemistry: Molecular, Cellular and Medical Aspects* is appearing near to the 50th anniversary of the founding of neurochemistry as a discipline. This seems an appropriate time to examine the progress of neurochemistry and of this book. To make this brief, we will look at only two topics, which may be considered "defining" neurochemical subjects: chemical neurotransmission, and learning and memory. Fifty years ago, our understanding of the former was rudimentary and the latter could hardly be discussed in terms of credible biochemical hypotheses, although it was recognized in the preface to the first edition of *Basic Neurochemistry* (*BN1*) in 1972, that a thorough molecular understanding of learning and memory will be an ultimate achievement.

A series of "International Neurochemical Symposia" led to the organization of the International Society for Neurochemistry and subsequently the ASN. The first symposium volume (1954) was titled *Biochemistry of the Developing Nervous System* and the second volume (1956), contains an historically interesting chapter which begins:

> "It is a measure of the changed outlook among neurophysiologists that it has been thought appropriate to include ...[here] ... a discussion on the nature of synaptic transmitter substances other than acetylcholine. ... A few years ago, the whole hypothesis of the chemical mediation of impulse transmission across central synapses was meeting so much opposition that the energies of those who supported it had to be concentrated on the claims of acetylcholine."

This chapter lists tentative evidence for actions at central synapses by histamine, substance P and serotonin; but concludes that

> "pharmacological substances other than acetylcholine have been identified ... but the evidence ... is inadequate to provide solid support for the claims of any of them to be considered as [CNS] transmitter agents."

'Glutamic Acid and Glutamine' was a topic at the same symposium. This chapter's introduction stated that

> "... the high concentration of glutamic acid and glutamine in brain ... has stimulated much research. ... [their] ... metabolism seems quantitatively different in nervous system tissue although up to now no ... unique reactions have been reported."

Sixteen years later, when the first edition of *Basic Neurochemistry* appeared, Sol Snyder's chapter could classify norepinephrine, dopamine and serotonin as

> "putative neurotransmitters in certain neuronal tracts in the brain"

while Eugene Roberts and Richard Hammerschlag state in a chapter on 'Amino Acid Transmitters' that

> "Many lines of evidence ... make it seem probable that GABA is a major inhibitory transmitter in the vertebrate central nervous system".

However, they cautioned that

> "the case for an excitatory role of glutamate ... rests almost entirely on the greater concentrations of glutamate in dorsal over ventral regions of spinal cord and on the excitatory effect of glutamate when applied directly to spinal interneurons and motor neurons."

This seventh edition includes discussions of neurotransmitters ranging from acetylcholine through other amines, amino acids, purines, peptides, steroids and lipids Whereas in most cases their metabolism and receptor interactions are known, much current research involves questions of identification of effector pathways, their regulation and control.

In the *BN1* of 1972, Bernard Agranoff introduces his chapter by warning us of the undeveloped state of the "neurochemistry of learning and memory":

> "There is a common belief among biologists that the detailed mechanisms of behavioral plasticity constitute a major remaining frontier in our understanding of living systems. Certainly it is at this time the most obscure frontier and, accordingly, hypotheses run rampant."

In contrast, Agranoff's chapter in the *BN6* of 1999 is illuminated by studies of genetically engineered "dunce flies" and by fMRI maps of spatial localization made possible by advances in our understanding of the underlying neurochemistry. Most notably, these maps show verbal memory is localized just where Paul Broca claimed it to be in 1865! An important current trend in neurochemistry is the increasing appreciation of functional integration at multiple levels: control of receptor types and subtypes in the plasmalemma, transmission of signals into the cell via networks of molecular interactions that are regulated at both transcriptional and translational levels. The nervous system uniquely employs neurotransmitters and synapses to extend these networks to mediating both efferent and afferent functions. Neuroscientists must increasingly address how systemic brain functions arise from these intricate intracellular and intercellular molecular networks. The 'learning and memory' chapter has progressed from 'dunce flies' to 'smart mice' as Joe Tsien, in *BN7*, outlines experiments that affirm some long held physiologic concepts such as Hebb's rule; and asks further questions about mechanisms of 'remote memory' storage and the possible relation of hippocampal neurogenesis to memory clearance.

These advances reinforce the "unifying objective" of neurochemistry stated in the 1972 preface of *BN1*:

> "Its central, unifying objective is the elucidation of biochemical phenomena that subserve the characteristic activity of the nervous system or are associated with neurological diseases. This objective generates certain subsidiary ... goals ... (1) isolation and identification of components; (2) analysis of their organization ... and (3) a description of the temporal and spatial relations of these components and [of] their interactions to [produce] the activity of the intact organ. A comprehensive description ... should be continuous from the molecular level to the most complex level of integration."

It appears that neurochemistry is now heading more energetically and successfully than ever into the third subsidiary goal.

George J. Siegel
R. Wayne Albers

For the Editors

Pierre Morell, Ph.D. 1941–2003

Pierre with wife, Bonnie

Pierre Morell was an author for at least one of the myelin chapters in all six previous editions of *Basic Neurochemistry*. For editions 4, 5 and 6, I had the privilege and honor of being a co-author with him for both the basic and clinical chapters. He was enthusiastically participating in the early planning for this seventh edition until his untimely death in 2003. The current chapters on the structure and diseases of myelin are still based largely on the strong foundation that he and his co-authors developed in the earlier editions. Pierre's authorship of these chapters over the years is just one example of his numerous contributions to myelin research and neurochemistry in general. Particularly significant were two editions of the book entitled *Myelin*, published in 1977 and 1984 for which he was the sole editor. The latter still serves as a comprehensive reference for basic information and early research on myelin. Pierre was a leader in myelin research throughout his career, with an emphasis on the metabolism and function of myelin lipids and proteins. He frequently investigated abnormalities of myelin caused by malnutrition, toxins and genetic factors to gain important insights into the formation, maintenance and breakdown of myelin sheaths. This prolific research was funded largely by 33 years of continuous support from the National Institutes of Health.

Pierre attended the Bronx High School of Science, Columbia University and The Albert Einstein College of Medicine (AECOM) of Yeshiva University, followed by postdoctoral training at the University of Michigan. He joined the faculty at AECOM in the late 1960s and moved to the University of North Carolina (UNC) at Chapel Hill in 1973, where he was Professor of Biochemistry and Biophysics at the time of his premature death. He was a dedicated and wise mentor to numerous students,

postdoctoral fellows and junior faculty members, many of whom are noteworthy investigators in the myelin field and other areas today. His tireless support of neurochemistry included service in many capacities within the American Society for Neurochemistry, of which he was a founding member, and International Society for Neurochemistry, as well as numerous other professional activities.

In addition to his intellectual and creative talents as a neuroscientist, Pierre was a caring person known for his witty remarks and enthusiastic demeanor in all aspects of life. In recent years, he became an avid scuba diver and teacher of this sport at UNC. His wife Bonnie and two children, David and Sharon, were paramount in his life. Although we in the neurochemistry community will greatly miss this remarkable scientist, colleague and friend, we can celebrate his life and outstanding career.

UNDERSTANDING NEUROANATOMY IS NECESSARY TO STUDY NEUROCHEMISTRY 3
Diverse cell types are organized into assemblies and patterns such that specialized components are integrated into a physiology of the whole organ 3

CHARACTERISTICS OF THE NEURON 4
General structural features of neurons are the perikarya, dendrites and axons 5
Neurons contain the same intracellular components as do other cells 6
Molecular motors move organelles and particles along axonal microtubules 9
Molecular markers can be used to identify neurons 11

CHARACTERISTICS OF NEUROGLIA 11
Virtually nothing can enter or leave the central nervous system parenchyma without passing through an astrocytic interphase 11
Oligodendrocytes are myelin-producing cells in the central nervous system 13
The microglial cell plays a role in phagocytosis and inflammatory responses 14
Ependymal cells line the brain ventricles and the spinal cord central canal 15
The Schwann cell is the myelin-producing cell of the peripheral nervous system 16
The extracellular space between peripheral nerve fibers is occupied by bundles of collagen fibrils, blood vessels and endoneurial cells 18

UNDERSTANDING NEUROANATOMY IS NECESSARY TO STUDY NEUROCHEMISTRY

Despite the advent of molecular genetics in neurobiology, our understanding of the functional relationships of the components of the CNS remains in its infancy, particularly in the areas of cellular interaction and synaptic modulation. Nevertheless, the fine structural relationships of most elements of nervous system tissue have been described well [1–5]. The excellent neuroanatomical atlases of Peters *et al.* [3] and Palay and Chan-Palay [1] should be consulted for detailed ultrastructural analyses of specific cell types, particularly of neurons with their diverse forms and connections. This chapter provides a concise description of the major cytoarchitectural features of the nervous system, an introduction to the historical literature and a structural roadmap for the neurochemist. Although the fine structure of the organelles of the CNS and PNS is not peculiar to these tissues, the interactions between cell types, such as synaptic contacts between neurons and myelin sheaths around axons, are unique. These specializations and those that allow for the sequestration of the CNS from the outside world, namely, the blood–brain barrier (BBB) and the absence of lymphatics, become major issues in considerations of normal and disease processes in the nervous system. For the sake of simplicity, the present section is subdivided into a section on general organization and a section regarding major cell types.

Diverse cell types are organized into assemblies and patterns such that specialized components are integrated into a physiology of the whole organ. The CNS parenchyma is made up of nerve cells and their afferent and efferent extensions, dendrites and axons, all closely enveloped by glial cells. Coronal section of the cerebral hemispheres of the brain reveals an outer convoluted rim of gray matter overlying the white matter (Fig. 1-1). Gray matter, which also exists as islands within the white matter, contains mainly nerve cell bodies and glia and lacks significant amounts of myelin, the lipid component responsible for the whiteness of white matter. More distally along the neuraxis in the spinal cord, the cerebral situation is reversed: white matter surrounds gray matter, which is arranged in a characteristic H formation (Fig. 1-2).

A highly diagrammatic representation of the major CNS elements is shown in Figure 1-3. The entire CNS is bathed both internally and externally by cerebrospinal fluid (CSF), which circulates throughout the ventricular and leptomeningeal spaces. This fluid, a type of plasma

Basic Neurochemistry: Molecular, Cellular and Medical Aspects
0-12-088397-X

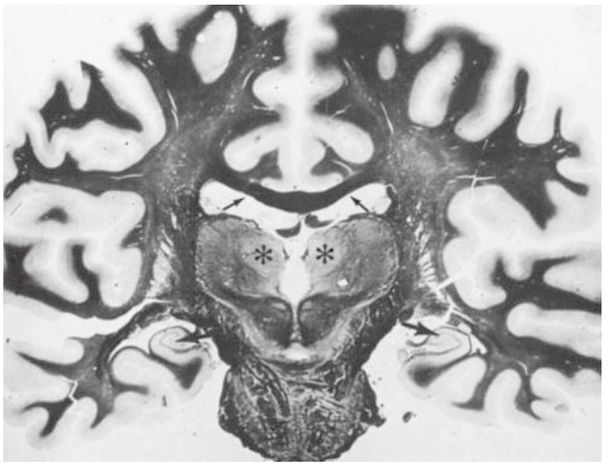

FIGURE 1-1 Coronal section of the human brain at the thalamic level stained by the Heidenhain technique for myelin. Gray matter stains faintly; all myelinated regions are black. The thalamus (*) lies beneath the lateral ventricles and is separated at this level by the beginning of the third ventricle. The roof of the lateral ventricles is formed by the corpus callosum (*small arrows*). Ammon's horns are shown by the *large arrows*. Note the outline of gyri and sulci at the surface of the cerebral hemispheres, sectioned here near the junction of the frontal and parietal cortices.

ultrafiltrate, plays a significant role in protecting the CNS from mechanical trauma, balancing electrolytes and protein and maintaining ventricular pressure (see Ch. 32). The outer surface of the CNS is invested by the triple-membrane system of the meninges. The outermost is the dura mater, derived from the mesoderm, which is tightly adherent to the inner surfaces of the calvaria. The arachnoid membrane is closely applied to the inner surface of the dura mater. The innermost of the meninges, the pia mater, loosely covers the CNS surface. The pia and arachnoid together, derived from the ectoderm, are called the leptomeninges. CSF occupies the subarachnoid space, between the arachnoid and the pia, and the ventricles. The CNS parenchyma is overlaid by a layer of subpial astrocytes, which in turn is covered on its leptomeningeal aspect by a basal lamina (Fig. 1-3). On the inner, or ventricular, surface, the CNS parenchyma is separated from the CSF by a layer of ciliated ependymal cells, which are thought to facilitate the movement of CSF. The production and circulation of CSF are maintained by the choroid plexus, grape-like collections of specialized vascular elements and cells that protrude into the ventricles. Resorption of CSF is effected by vascular structures known as arachnoid villi, located within the leptomeninges over the surface of the brain (see Ch. 32).

Ependymal cells abut layers of astrocytes, which in turn envelop neurons, neurites and vascular components. In addition to neurons and glial cells, such as astrocytes and oligodendrocytes, the normal CNS parenchyma contains blood vessels and microglial cells, the resident macrophages of the CNS.

The PNS and the autonomic nervous system consist of bundles of myelinated and nonmyelinated axons, extending to and from the CNS, which are intimately enveloped by Schwann cells, the PNS counterpart of oligodendrocytes. Nerve bundles are enclosed by the perineurium and the epineurium, which are tough, fibrous, elastic sheaths. Between individual nerve fibers are isolated connective tissue, or endoneurial cells, and blood vessels. The ganglia, such as dorsal root and sympathetic ganglia, are located peripherally to the CNS and are made up of large neurons, usually unipolar or bipolar, surrounded by satellite cells, which are specialized Schwann cells. A dendrite and an axon, both of which can be up to several feet in length, arise from each neuron. Occasionally, within both the CNS and PNS, mast cells can be seen in the perivascular space.

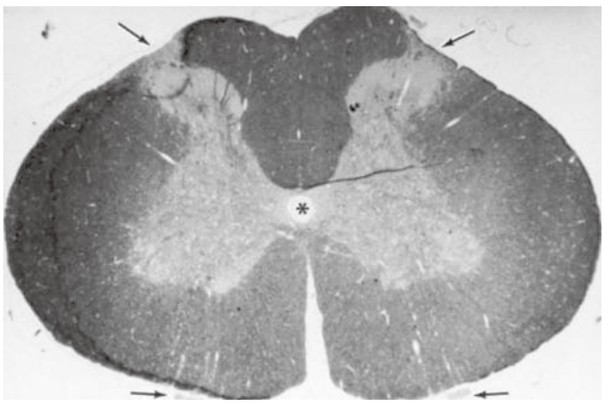

FIGURE 1-2 Transverse section of a rabbit lumbar spinal cord at L-1. Gray matter is seen as a paler-staining area in an H configuration formed by the dorsal and ventral horns with the central canal in the center (*). The dorsal horns would meet the incoming dorsal spine nerve roots at the *upper arrows*. The anterior roots can be seen below (*lower arrows*), opposite the ventral horns, from which they received their fibers. The white matter occupies a major part of the spinal cord and stains darker. Epon section, 1 µm, stained with toluidine blue.

CHARACTERISTICS OF THE NEURON

From a historical standpoint, no other cell type has attracted as much attention or caused as much controversy as the nerve cell. It is impossible in a single chapter to delineate comprehensively the extensive structural, topographical and functional variation achieved by this cell type. Consequently, despite an enormous literature, the neuron still defies precise definition, particularly with regard to function. It is known that the neuronal population usually is established shortly after birth, that mature neurons do not divide and that in humans there is a daily dropout of neurons amounting to approximately 20,000 cells. These facts alone make the neuron unique.

Neurons can be excitatory, inhibitory or modulatory in their effect and motor, sensory or secretory in their function [6]. They can be influenced by a large repertoire of neurotransmitters and hormones (see Ch. 10). This enormous repertoire of functions, associated with different

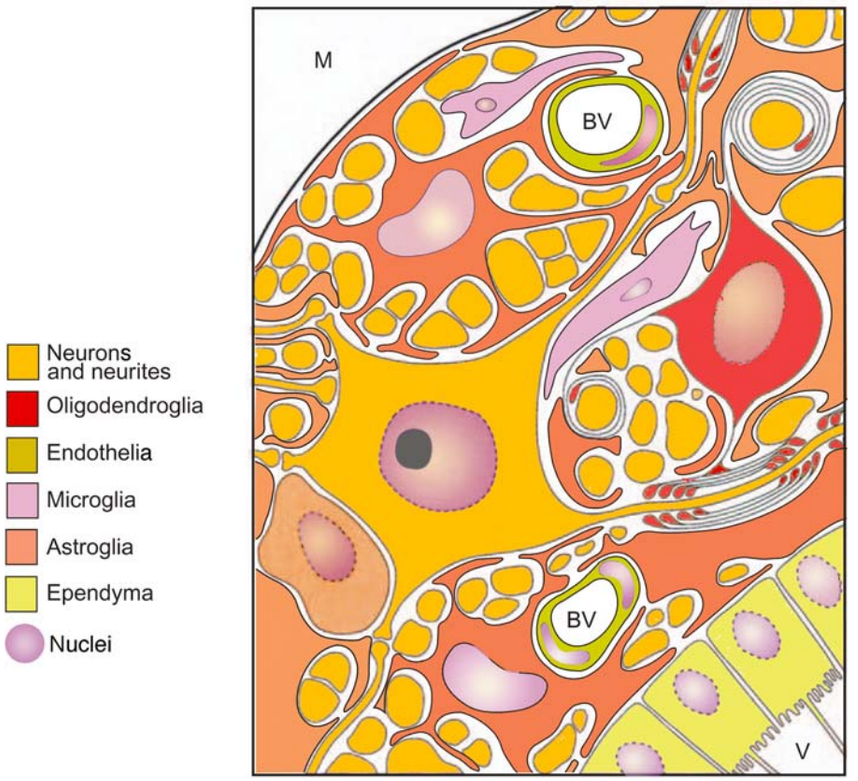

FIGURE 1-3 The major components of the CNS and their interrelationships. Microglia are depicted in light purple. In this simplified schema, the CNS extends from its meningeal surface (*M*) through the basal lamina (*solid black line*) overlying the subpial astrocyte layer of the CNS parenchyma and across the CNS parenchyma proper (containing neurons and glia) and subependymal astrocytes, to ciliated ependymal cells lining the ventricular space (*V*). Note how the astrocyte also invests blood vessels (*BV*), neurons and cell processes. The pia-astroglia (glia limitans) provides the barrier between the exterior (dura and blood vessels) and the CNS parenchyma. One neuron is seen (**center**), with synaptic contacts on its soma and dendrites. Its axon emerges to the right and is myelinated by an oligodendrocyte (**above**). Other axons are shown in transverse section, some of which are myelinated. The oligodendrocyte to the lower left of the neuron is of the nonmyelinating satellite type. The ventricles (*V*) and the subarachnoid space of the meninges (*M*) contain cerebrospinal fluid.

developmental influences on different neurons, is largely reflected in the variation of dendritic and axonal outgrowth. Specialization also occurs at axonal terminals, where a variety of junctional complexes, known as synapses, exist. The subtle synaptic modifications are best visualized ultrastructurally, although immunohistochemical staining also permits distinction among synapses on the basis of transmitter type.

General structural features of neurons are the perikarya, dendrites and axons. The stereotypical image of a neuron is that of a stellate cell body, the perikaryon or soma, with broad dendrites emerging from one pole and a fine axon emerging from the opposite pole. This impression stems from the older work of Purkinje, who first described the nerve cell in 1839, and of Deiters, Ramón y Cajal and Golgi (see [3]) at the end of the 19th century and the early 20th century. However, this picture does not hold true for many neurons. The neuron is the most polymorphic cell in the body and defies formal classification on the basis of shape, location, function, fine structure or transmitter substance. Although early workers described the neuron as a globular mass suspended between nerve fibers, the teased preparations of Deiters and his contemporaries soon proved this not to be the case. Later work, using impregnation staining and culture techniques, elaborated on Deiters's findings. Before the work of Deiters and Ramón y Cajal, both neurons and neuroglia were believed to form syncytia, with no intervening membranes. Today, of course, we are familiar with the specialized membranes and the enormous variety of nerve cell shapes and sizes. They range from the small, globular cerebellar granule cells, with a perikaryal diameter of approximately 6–8 µm, to the pear-shaped Purkinje cells and star-shaped anterior horn cells, both of which may reach diameters of 60–80 µm in humans. Perikaryal size is generally a poor index of total cell volume, however, and it is a general rule in neuroanatomy that neurites occupy a greater percentage of the cell surface area than does the soma. For example, the pyramidal cell of the somatosensory cortex has a cell body that accounts for only 4% of the total surface area, whereas from its dendritic tree the dendritic spines alone claim 43% (Mungai, quoted by Peters *et al.* [3]). Hyden [2] quotes Scholl (1956), who calculated that the

perikaryon of a 'cortical cell' represents 10% of the neuronal surface area. In the feline reticular formation, some giant cells possess ratios between soma and dendrites of about 1:5. A single axon is the usual rule, but some cells, like the Golgi cells of the cerebellum, are endowed with several axons, some of which may show branching.

The extent of the branching displayed by the dendrites is a useful index of their functional importance. Dendritic trees represent the expression of the receptive fields, and large fields can receive inputs from multiple origins. A cell with a less developed dendritic ramification, such as the cerebellar granule cell, has synapses with a more homogeneous population of afferent sources.

The axon emerges from a neuron as a slender thread and frequently does not branch until it nears its target. In contrast to the dendrite and the soma, the axon is myelinated frequently, thus increasing its efficiency as a conducting unit. Myelin, a spirally wrapped membrane (see Ch. 4), is laid down in segments, or internodes, by oligodendrocytes in the CNS and by Schwann cells in the PNS. The naked regions of axon between adjacent myelin internodes are known as nodes of Ranvier (see below).

Neurons contain the same intracellular components as do other cells. No unique cytoplasmic inclusions of the neuron distinguish it from any other cell. Neurons have all the morphological counterparts of other cell types, the structures are similarly distributed and some of the most common, the Golgi apparatus and mitochondria, for example, were described first in neurons (Fig. 1-4).

The nucleus is large and usually spherical, containing a prominent nucleolus. The nucleochromatin is invariably pale, with little dense heterochromatin. In some neurons, such as the cerebellar granule cells, the nucleoplasm may show more differentiation and dense heterochromatin. The nucleolus is vesiculated and clearly delineated from the rest of the nucleoplasm. It usually contains two textures: the pars fibrosa, which are fine bundles of filaments, and the pars granulosa, in which dense granules predominate. An additional juxtaposed structure, found in neurons of the female of some species, is the nucleolar satellite, or sex chromatin, which consists of dense but loosely packed, coiled filaments. The nucleus is enclosed by the nuclear envelope, made up on the cytoplasmic side by the perikaryon inner membrane, which sometimes is seen in continuity with the endoplasmic reticulum (Fig. 1-5), and a more regular membrane on the inner, or nuclear, aspect of the envelope. Between the two is a clear channel of between 20 and 40 nm. Periodically, the inner and outer membranes of the envelope come together to form a single diaphragm, a nuclear pore (Fig. 1-5). In tangential section, nuclear pores are seen as empty vesicular structures, approximately 70 nm in diameter. In some neurons, as in Purkinje cells, that segment of the nuclear envelope which faces the dendritic pole is deeply invaginated.

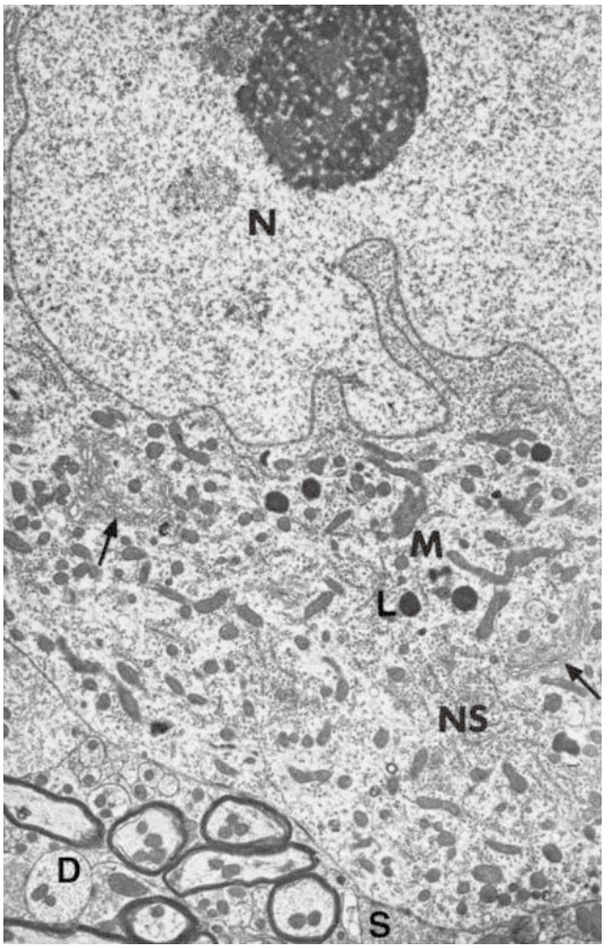

FIGURE 1-4 A motor neuron from the spinal cord of an adult rat shows a nucleus (*N*) containing a nucleolus, clearly divisible into a pars fibrosa and a pars granulosa, and a perikaryon filled with organelles. Among these, Golgi apparatus (*arrows*), Nissl substance (*NS*), mitochondria (*M*) and lysosomes (*L*) can be seen. An axosomatic synapse (*S*) occurs below, and two axodendritic synapses abut a dendrite (*D*). ×8,000.

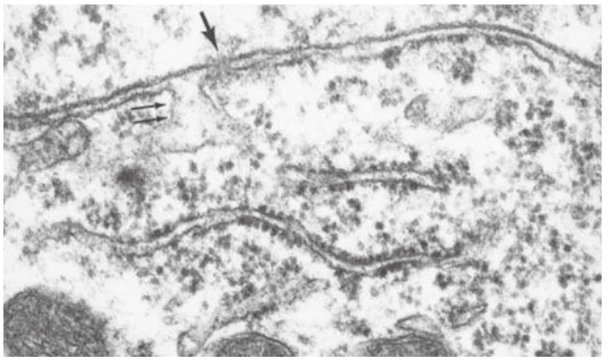

FIGURE 1-5 Detail of the nuclear envelope showing a nuclear pore (*single arrow*) and the outer leaflet connected to the smooth endoplasmic reticulum (ER) (*double arrows*). Two cisternae of the rough ER with associated ribosomes are also present. ×80,000.

The perikaryon, or body of the neuron, is rich in organelles (Fig. 1-4). It often stands out poorly from a homogeneous background neuropil, most of which is composed of nonmyelinated axons and dendrites, synaptic complexes and glial cell processes. Closer inspection shows that, like all cells, the neuron is delineated by a typical triple-layered unit membrane approximately 7.5 nm wide. Among the most prominent features of the perikaryal cytoplasm is a system of membranous cisternae, divisible into rough or granular endoplasmic reticulum (ER), which forms part of the Nissl substance; smooth or agranular ER; subsurface cisternae; and the Golgi apparatus. Although these various components are interconnected structurally, each possesses distinct enzymological properties. Also present within the cytoplasm are abundant lysosomes; lipofuscin granules, which also are termed *aging pigment*; mitochondria; multivesicular bodies; neurotubules; neurofilaments; and ribosomes.

Nissl substance consists of the intracytoplasmic basophilic masses that ramify loosely throughout the cytoplasm and is typical of most neurons (Figs 1-4, 1-5). The distribution of Nissl substance in certain neurons is characteristic and can be used as a criterion for identification. By electron microscopy (EM), this substance is seen to comprise regular arrays or scattered portions of flattened cisternae of the rough ER surrounded by clouds of free polyribosomes. The membranes of the rough ER are studded with rows of ribosomes, which produce the granular appearance of the rough ER. A space of 20–40 nm is maintained within cisternae. Sometimes, cisternal walls meet at fenestrations. Unlike the rough ER of glandular cells or other protein-secreting cells, such as plasma cells, the rough ER of neurons probably produces most of its proteins for use within that neuron, a feature imposed by the extraordinary functional demands placed on the cell. Nissl substance does not penetrate axons but does extend along dendrites.

Smooth endoplasmic reticulum is present in most neurons, although it is sometimes difficult to differentiate it from the rough ER owing to the disorderly arrangement of ribosomes. Ribosomes are not associated with these membranes, and the cisternae usually assume a meandering, branching course throughout the cytoplasm. In some neurons, the smooth ER is quite prominent, for example, in Purkinje cells. Individual cisternae of the smooth ER extend along axons and dendrites (see Chs 8 and 9).

Subsurface cisternae are a system of smooth, membrane-bound, flattened cisternae that can be found in many neurons. These structures, referred to as hypolemmal cisternae by Palay and Chan-Palay [1], abut the plasmalemma of the neuron and constitute a secondary membranous boundary within the cell. The distance between these cisternae and the plasmalemma is usually 10–12 nm and, in some neurons, such as the Purkinje cells, a mitochondrion may be found in close association with the innermost leaflet. Similar cisternae have been described beneath synaptic complexes, but their functional significance is not known. Some authors have suggested that such a system may play a role in the uptake of metabolites. Membrane structures are described in Chapter 2.

The *Golgi apparatus* is a highly specialized form of agranular reticulum and is visualized best using the metal impregnation techniques of Golgi. Ultrastructurally, the Golgi apparatus consists of aggregates of smooth-walled cisternae and a variety of vesicles. It is surrounded by a heterogeneous assemblage of organelles, including mitochondria, lysosomes and multivesicular bodies. In most neurons, the Golgi apparatus encompasses the nucleus and extends into dendrites but is absent from axons. A three-dimensional analysis of the system reveals that the stacks of cisternae are pierced periodically by fenestrations. Tangential sections of these fenestrations show them to be circular profiles. A multitude of vesicles is associated with each segment of the Golgi apparatus, particularly 'coated' vesicles, which proliferate from the lateral margins of flattened cisternae (Fig. 1-6) (see Ch. 9). Such structures have been variously named, but the term alveolate vesicle seems to be generally accepted. Histochemical staining reveals that these bodies are rich in acid hydrolases, and they are believed to represent primary lysosomes [7]. Acid phosphatase is also found elsewhere in the cisternae but in lesser amounts than in alveolate vesicles.

The *lysosome* is the principal organelle responsible for the degradation of cellular waste. It is a common constituent of all cell types of the nervous system and is particularly prominent in neurons, where it can be seen at various stages of development (Fig. 1-4). It ranges in size from 0.1 to 2 μm in diameter. The primary lysosome is elaborated from Golgi saccules as a small, vesicular structure (Fig. 1-6). Its function is to fuse with the membrane of waste-containing vacuoles, termed *phagosomes*, into which

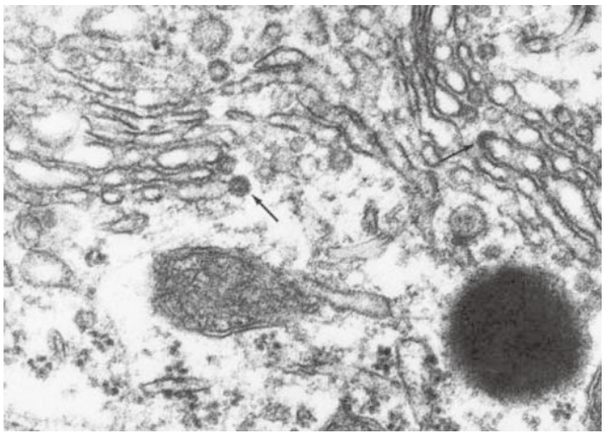

FIGURE 1-6 A portion of a Golgi apparatus. The smooth-membraned cisternae appear beaded. The many circular profiles represent tangentially sectioned fenestrations and alveolate vesicles (primary lysosomes). Two of the latter can be seen budding from Golgi saccules (*arrows*). Mitochondria and a dense body (secondary lysosomes) are also present. ×60,000.

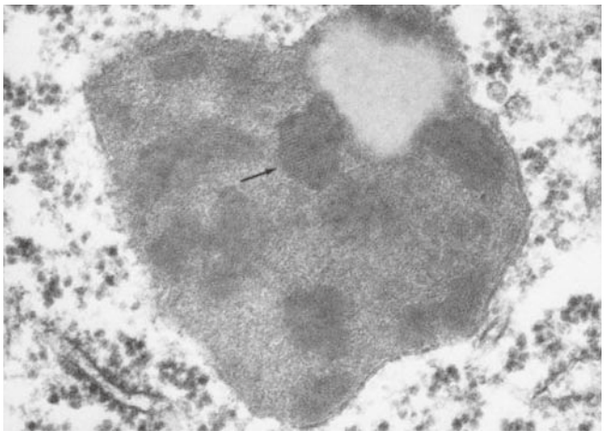

FIGURE 1-7 A lipofuscin granule from a cortical neuron shows membrane-bound lipid (dense) and a soluble component (gray). The denser component is lamellated. The lamellae appear as paracrystalline arrays of tubular profiles when sectioned transversely (*arrow*). The granule is surrounded by a single-unit membrane. Free ribosomes also can be seen. ×96,000.

it releases hydrolytic enzymes (see Ch. 41). The sequestered material is then degraded within the vacuole, and the organelle becomes a secondary lysosome; it is usually electron-dense and large. The matrix of this organelle will give a positive reaction when tested histochemically for acid phosphatase. Residual bodies containing nondegradable material are considered to be tertiary lysosomes, and in the neuron some are represented by lipofuscin granules (Fig. 1-7). These granules contain brown pigment and lamellar stacks of membrane material and are more common in the aged brain [7].

Multivesicular bodies are usually found in association with the Golgi apparatus and are visualized by EM as small, single membrane-bound sacs approximately 0.5 μm in diameter. They contain several minute, spherical profiles, sometimes arranged about the periphery. They are believed to belong to the lysosome series prior to secondary lysosomes because they contain acid hydrolases and apparently are derived from primary lysosomes.

Neurotubules, (neuronal microtubules), have been the subject of intense research [8]. They usually are arranged haphazardly throughout the perikaryon of neurons but are aligned longitudinally in axons and dendrites. Each neurotubule consists of a dense-walled structure enclosing a clear lumen, in the middle of which may be found an electron-dense dot. High-resolution studies indicate that each microtubule wall consists of 13 filamentous subunits arranged helically around a lumen (see also Chs 8 and 28). The diameter of neurotubules varies between 22 and 24 nm. Axonal microtubules display 5 nm filamentous side-arms known to be involved in axoplasmic transport in association with the molecular motor proteins, kinesin and dynein (see below).

Neurofilaments belong to the family of intermediate filaments and usually are found in association with neurotubules. The function of these two organelles has been debated for some time [8,9], and current views of their roles in the maintenance of form and in axoplasmic transport are discussed in Chapters 8 and 28. Neurofilaments have a diameter of approximately 10 nm, are of indeterminate length and frequently occur in bundles. They are constant components of axons but are rarer in dendrites. In the axon, individual filaments possess a minute lumen and interconnect by proteinaceous side-arms, thereby forming a meshwork. Because of these cross-bridges, they do not form tightly-packed bundles in the normal axon, in contrast to filaments within astrocytic processes (see Fig. 1-14), which lack cross-bridges. Neurofilaments within neuronal somata usually do not display cross-bridges and can be found in tight bundles. A form of filamentous structure finer than neurofilaments is seen at the tips of growing neurites, particularly in the growth cones of developing axons. These structures, known as microfilaments, are 5 nm in size and are composed of actin, belonging to a family of molecules (myosins), involved in mechanical stress and organelle transport via nanotubular highways known as 'tunneling nanotubes' [10]. Actin microfilaments facilitate movement and growth since it has been shown that axonal extension can be arrested pharmacologically by treatment with compounds that depolymerize these structures. The biochemistry of neurotubules and neurofilaments is dealt with in more detail in Chapter 8 and in Soifer [8] and Wang *et al.* [9].

Mitochondria are the centers for oxidative phosphorylation and the respiratory centers of all cells. While usually aerobic, some mitochondria (e.g. in some bacteria), are known that function anaerobically. These organelles occur ubiquitously in the neuron and its processes (Figs 1-4, 1-6). Their overall shape may change from one type of neuron to another but their basic morphology is identical to that in other cell types. Mitochondria consist morphologically of double-membraned sacs surrounded by protuberances, or cristae, extending from the inner membrane into the matrix space [7].

The axon becomes physiologically and structurally divisible into the following distinct regions as it egresses: the axon hillock, the initial segment, the axon proper and the axonal termination [3]. The segments differ ultrastructurally in membrane morphology and the content of the rough and smooth ER. The axon hillock may contain fragments of Nissl substance, including abundant ribosomes, which diminish as the hillock continues into the initial segment. Here, the various axoplasmic components begin to align longitudinally. A few ribosomes and the smooth ER persist, and some axoaxonic synapses occur. More interesting, however, is the axolemma of the initial segment, the region for the generation of the action potential, which is underlaid by a dense granular layer similar to that seen at the nodes of Ranvier. Also present in this region are neurotubules, neurofilaments and mitochondria. The arrangement of the neurotubules in the initial segment, unlike their scattered pattern in the distal axon,

is in fascicles; they are interconnected by side-arms [3,10]. Beyond the initial segment, the axon maintains a relatively uniform morphology. It contains the axolemma without any structural modification, except at nodes and the termination, where submembranous densities are seen; microtubules, sometimes cross-linked; neurofilaments, connected by side-arms; mitochondria; and tubulovesicular profiles, probably derived from the smooth ER. Myelinated axons show granular densifications beneath the axolemma at the nodes of Ranvier [6,11], and synaptic complexes may occur in the same regions. In myelinated fibers, there is a concentration of sodium channels at the nodal axon, a feature underlying the rapid, saltatory conduction of such fibers [12] (see Chs 6 and 12). The terminal portion of the axon arborizes and enlarges at its synaptic regions, where it might contain synaptic vesicles beneath the specialized presynaptic junction.

Molecular motors move organelles and particles along axonal microtubules. Molecular motors exist along axonal microtubules and are visualized structurally as 10–15 nm side arms. These structures are known to comprise kinesin and dynein. The kinesins, a large family of >140 proteins, are involved in the transport of a variety of cargo membranous organelles, mRNA, intermediate filaments and signaling molecules. The dyneins form an equally large family and are involved in microtubule bending and flagellar (ciliary) beating. Both kinesin and dynein motors are ATP-dependent and display directionality. Conventional kinesin, a processive dimeric motor, moves material along microtubules in a plus-end direction (anterograde; away from the centrosome), in eight 3 nm center-of-mass steps for each ATP hydrolyzed. The globular heads of kinesin move in a hand-over-hand mechanism, not an inchworm mechanism, as believed previously [13]. Several nonconventional kinesins are known to exist that move materials towards the minus-end of the microtubule, towards the cell body (retrograde). Dyneins generally move cargo retrogradely, towards the minus-end only (see Ch. 28).

The dendrites are the afferent components of neurons and frequently are arranged around the neuronal soma in stellate fashion. In some neurons, they may arise from a single trunk, from which they branch into a dendritic tree. Unlike axons, they generally lack neurofilaments, although they may contain fragments of Nissl substance; however, large branches of dendrites in close proximity to neurons may contain small bundles of neurofilaments. Some difficulty may be encountered in distinguishing small unmyelinated axons or terminal segments of axons from small dendrites. In the absence of synaptic data, they can often be assessed by the content of neurofilaments. The synaptic regions of dendrites occur either along the main stems (Fig. 1-8) or at small protuberances known as dendritic spines or thorns. Axon terminals abut these structures.

The synapse is a specialized junctional complex by which axons and dendrites emerging from different

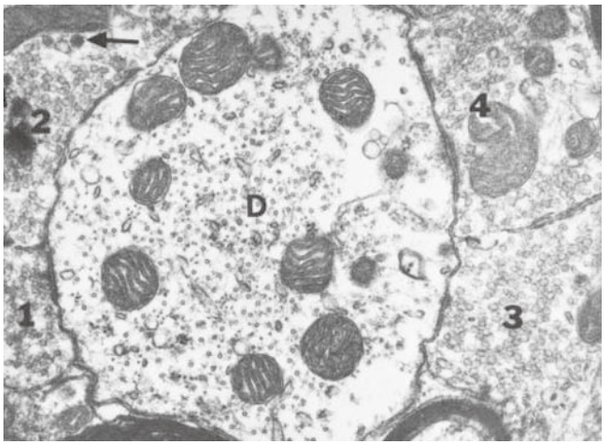

FIGURE 1-8 A dendrite (*D*) emerging from a motor neuron in the anterior horn of a rat spinal cord is contacted by four axonal terminals: terminal *1* contains clear, spherical synaptic vesicles; terminals *2* and *3* contain both clear, spherical and dense-core vesicles (*arrow*); and terminal *4* contains many clear, flattened (inhibitory) synaptic vesicles. Note also the synaptic thickenings and, within the dendrite, the mitochondria, neurofilaments and neurotubules. ×33,000.

neurons intercommunicate [14]. This was proposed first by Sherrington in 1897, who also proposed the term 'synapse'. The existence of synapses was immediately demonstrable by EM and can be recognized today in a dynamic fashion by Nomarski optics (differential interference microscopy), confocal optics, light microscopy and scanning EM. With the development of neurochemical approaches to neurobiology, an understanding of synaptic form and function becomes of fundamental importance. As was noted in the first ultrastructural study on synapses (Palade and Palay in 1954, quoted in [4]), synapses display interface specialization and frequently are polarized or asymmetrical. The asymmetry is due to the unequal distribution of electron-dense material, or thickening, applied to the apposing membranes of the junctional complex and the heavier accumulation of organelles within the presynaptic component. The closely applied membranes constituting the synaptic site are overlaid on the presynaptic and postsynaptic aspects by an electron-dense material similar to that seen in desmosomes and separated by a gap or cleft of 15–20 nm. The presynaptic component usually contains a collection of clear, 40–50 nm synaptic vesicles. These synaptic vesicles are important in packaging, transport and release of neurotransmitters and after their discharge into the synaptic cleft, they are recycled with the axon terminal [6,15]. Also present are small mitochondria approximately 0.2–0.5 μm in diameter (Figs 1-8–1-10). Occasionally, 24 nm microtubules, coated vesicles and cisternae of the smooth ER are found in this region. On the postsynaptic side is a density referred to as the subsynaptic web but, apart from an infrequent, closely applied packet of smooth ER or subsurface cisternae belonging to the hypolemmal system, there are no aggregations of organelles in the dendrite.

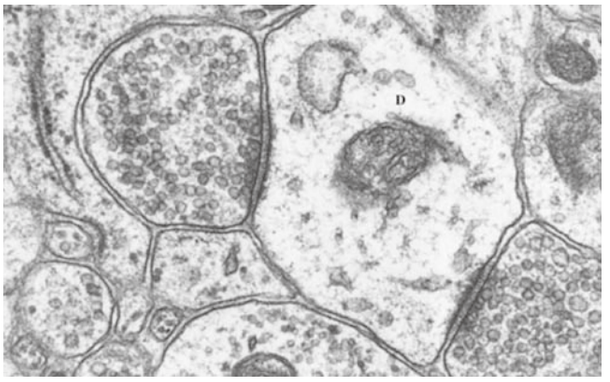

FIGURE 1-9 A dendrite (*D*) is flanked by two axon terminals packed with clear, spherical synaptic vesicles. Details of the synaptic region are clearly shown. ×75,000.

At the neuromuscular junction, the morphological organization is somewhat different. Here, the axon terminal is greatly enlarged and ensheathed by Schwann cells; the postsynaptic or sarcolemmal membrane displays less density and is infolded extensively.

Before elaborating further on synaptic diversity, it might be helpful to outline briefly other ways in which synapses have been classified in the past. Using the light microscope, Ramón y Cajal was able to identify 11 distinct groups of synapses [16]. Today, most neuroanatomists apply a more fundamental classification schema to synapses, depending on the profiles between which the synapse is formed, such as axodendritic, axosomatic, axoaxonic, dendrodendritic, somatosomatic and somatodendritic synapses. Unfortunately, such a list disregards whether the transmission is chemical or electrical and, in the case of chemical synapses, this classification does not address the neurotransmitter involved.

FIGURE 1-10 An axonal terminal at the surface of a neuron from the dorsal horn of a rabbit spinal cord contains both dense-core and clear, spherical synaptic vesicles lying above the membrane thickenings. A subsurface cisterna (*arrow*) is also seen. ×68,000.

In terms of physiological typing, three groups of synapses are recognized: excitatory, inhibitory and modulatory. Some neuroanatomical studies [14] have claimed that excitatory synapses possess spherical synaptic vesicles, whereas inhibitory synapses contain a predominance of flattened vesicles (Fig. 1-8). Other studies [17] have correlated this synaptic vesicular diversity with physiological data. In his study on the cerebellum, Gray [17] showed that neurons with a known predominance of excitatory input on dendrites and an inhibitory input on the cell body possessed two corresponding types of synapse; however, although this interpretation fits well in some loci of the CNS, it does not hold true for all regions. Furthermore, some workers consider that the differences between flat and spherical vesicles may reflect an artifact of aldehyde fixation or a difference in physiological state at the time of sampling. In light of these criticisms, it is clear that confirmation of the correlation between flattened vesicles and inhibitory synapses is required.

Another criterion for the classification of synapses by EM was introduced in 1959 by Gray [17]. Briefly, certain synapses in the cerebral cortex can be grouped into two types, depending on the length of the contact area between synaptic membranes and the amount of postsynaptic thickening. Relationships have been found between type 1 synapses, which have closely apposed membranes over long distances and a large amount of associated postsynaptic thickening, and excitatory axodendritic synapses. Type 2 synapses, which show less close apposition and thickening at the junction, are mainly axosomatic and are believed to be inhibitory. This broad grouping has been confirmed in the cerebral cortex by a number of workers but it does not hold true for all regions of the CNS.

Most of the data from studies on synapses *in situ* or on synaptosomes have been on cholinergic transmission. There is a vast family of chemical synapses that utilize biogenic amines (see Ch. 12) as neurotransmitter substances. Morphologically, catecholaminergic synapses are similar but possess, in addition to clear vesicles, slightly larger dense-core or granular vesicles of variable dimension (Figs 1-8, 1-10). These vesicles were identified first as synaptic vesicles by Grillo and Palay (see Bloom [18]), who segregated classes of granular vesicles based on vesicle and core size, but no relationship was made between granular vesicles and transmitter substances. About the same time, EM autoradiographic techniques were being employed and, using tritiated norepinephrine, Wolfe *et al.* [19] labeled granular vesicles within axonal terminals. Catecholaminergic vesicles generally are classified on a size basis, and not all have dense cores. Another, still unclassified, category of synapses may be the so-called silent synapses observed in CNS tissue both *in vitro* and *in vivo*. These synapses are morphologically identical to functional synapses but are physiologically dormant.

Finally, with regard to synaptic type, there is the well-characterized electrical synapse [20], where current can pass from cell to cell across regions of membrane

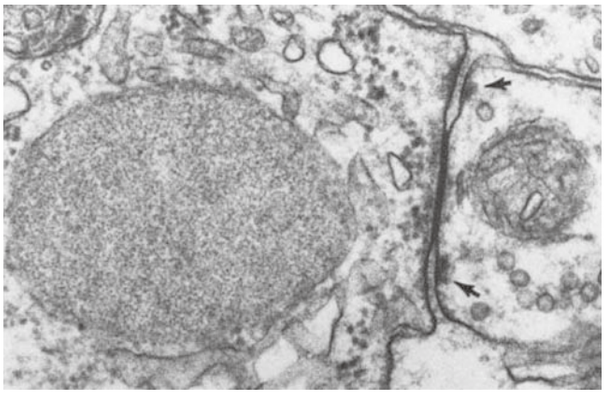

FIGURE 1-11 An electrotonic synapse is seen at the surface of a motor neuron from the spinal cord of a toadfish. Between the neuronal soma (**left**) and the axonal termination (**right**), a gap junction flanked by desmosomes (*arrows*) is visible. (Photograph courtesy of Drs G. D. Pappas and J. S. Keeter.) ×80,000.

apposition that essentially lack the associated collections of organelles present at the chemical synapse. In the electrical synapse (Fig. 1-11), the unit membranes are closely apposed, and indeed, the outer leaflets sometimes fuse to form a pentalaminar structure; however, in most places, a gap of approximately 20 nm exists, producing a so-called gap junction. Not infrequently, such gap junctions are separated by desmosome-like regions [3]. Sometimes, electrical synapses exist at terminals that also display typical chemical synapses; in such cases, the structure is referred to as a mixed synapse. The comparative morphology of electrical and chemical synapses has been reviewed by Pappas and Waxman [20].

Molecular markers can be used to identify neurons. Characterization of the vast array of neuron-specific cytoskeletal elements, such as intermediate filaments, microtubules and their associated proteins [21,22], and the neurotransmitters and their receptors [6,21], has led to the development of correspondingly large numbers of molecular and immunological probes, which now are applied routinely in neuroanatomical analyses. Under normal conditions, the neuron is incapable of participating in T-cell interactions via the expression of major histocompatibility complex (MHC) antigens or the production of soluble mediators, such as cytokines. However, neurons do possess unique proteins, some of which are antigenic, that normally are sequestered by the BBB from the circulating immune system. This theoretically renders the CNS vulnerable to immune-mediated damage should the BBB be breached.

CHARACTERISTICS OF NEUROGLIA

In 1846, Virchow first recognized the existence in the CNS of a fragile, non-nervous, interstitial component made up of stellate or spindle-shaped cells, morphologically distinct from neurons, which he named neuroglia, or 'nerve glue' [3]. It was not until the early part of the 20th century that this interstitial element was classified as consisting of distinct cell types [3,4]. Today, we recognize three broad groups of glial cells: (a) true glial cells or macroglia, such as astrocytes and oligodendrocytes, of ectodermal origin, the stem cell of which is the spongioblast; (b) microglia, of mesodermal origin; and (c) ependymal cells, also of ectodermal origin and sharing the same stem cell as true glia. Microglia invade the CNS at the time of vascularization via the pia mater, the walls of blood vessels and the tela choroidea. Glial cells differ from neurons in that they possess no conventional synaptic contacts and retain the ability to divide throughout life, particularly in response to injury. The rough schema represented in Figure 1-3 demonstrates the interrelationships between glia and other CNS components.

Virtually nothing can enter or leave the central nervous system parenchyma without passing through an astrocytic interphase. The complex packing achieved by the processes and cell bodies of astrocytes underscores their involvement in brain metabolism. Although astrocytes traditionally have been subdivided into protoplasmic and fibrous astrocytes [4], these two forms probably represent the opposite ends of a spectrum of the same cell type. However, Raff *et al.* [23] have suggested that the two groups might derive from different progenitors and that the progenitor of the fibrous astrocyte is the same as that of the oligodendrocyte, although recent evidence supports a lineage for myelinating oligodendrocytes involving motor neurons [24]. The structural components of fibrous and protoplasmic astrocytes are identical; the differences are quantitative. In the early days of EM, differences between the two variants were more apparent owing to imprecise techniques, but, with the development of better procedures, the differences became less apparent.

Protoplasmic astrocytes range in size from 10–40 μm, frequently are located in gray matter in relation to capillaries and have a clearer cytoplasm than do fibrous astrocytes (Fig. 1-12). Within the perikaryon of both types of astrocyte are scattered 9 nm filaments and 24 nm microtubules (Fig. 1-13); glycogen granules; lysosomes and lipofuscin-like bodies; isolated cisternae of the rough ER; a small Golgi apparatus opposite one pole of the nucleus; and small, elongated mitochondria, often extending together with loose bundles of filaments along cell processes. A centriole is not uncommon. Characteristically, the nucleus is ovoid and the nucleochromatin homogeneous, except for a narrow, continuous rim of dense chromatin and one or two poorly defined nucleoli. The fibrous astrocyte occurs in white matter (Fig. 1-13). Its processes are twig-like, being composed of large numbers of 9 nm glial filaments arranged in tight bundles. The filaments within these cell processes can be distinguished from neurofilaments by their close packing and the absence of side-arms (Figs 1-13, 1-14). Desmosomes (mediated by cadherins) and gap junctions (mediated by connexins)

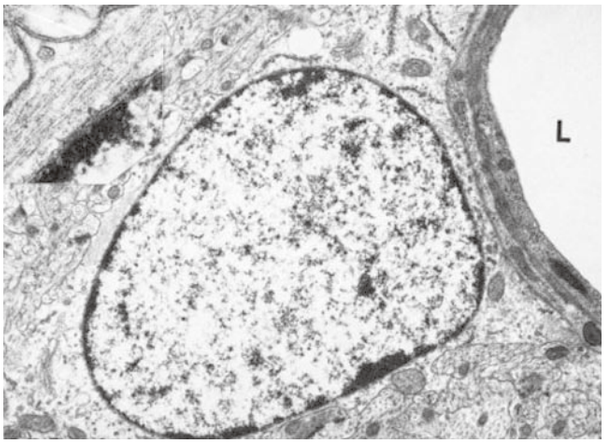

FIGURE 1-12 A protoplasmic astrocyte abuts a blood vessel (lumen at *L*) in rat cerebral cortex. Note the denser oligodendrocytic cytoplasm and the prominent filaments within the astrocyte. ×15,000. **Inset a:** Detail of the oligodendrocyte, showing microtubules (*arrows*) and absence of filaments. ×45,000. **Inset b:** Detail of astrocytic cytoplasm showing filaments, glycogen, rough endoplasmic reticulum and Golgi apparatus. ×45,000.

FIGURE 1-14 Transverse sections of a myelinated axon (**left**) and the process of a fibrous astrocyte (**right**) in dog spinal cord. The axon contains scattered neurotubules and loosely packed neurofilaments interconnected by side-arm material. The astrocytic process contains a bundle of closely packed filaments with no cross-bridges, flanked by several microtubules. Sometimes, a lumen can be seen within a filament. ×60,000.

occur between adjacent astrocytic processes. The latter also occur between astrocyte processes and myelin.

In addition to protoplasmic and fibrous forms, regional specialization occurs among astrocytes. The outer membranes of astrocytes located in subpial zones and those facing blood vessels (which are in most cases formed from invaginations of the pial surface as blood vessels penetrated into the CNS from the meningeal surface during development), possess a specialized thickening, sometimes called 'hemidesmosomes'. Desmosomes and gap junctions are very common in these regions between astrocytic processes. In the cerebellar cortex, protoplasmic astrocytes can be segregated into three classes, each ultrastructurally distinct: the Golgi epithelial cell, the lamellar or velate astrocyte and the smooth astrocyte [1].

Astrocyte functions have long been debated. Their major role is related to a connective tissue or skeletal function since they invest, possibly sustain and provide a packing for other CNS components. In the case of astrocytic ensheathment around synaptic complexes and the bodies of some neurons, such as Purkinje cells, it has been speculated that the astrocyte isolates these structures and their neurotransmitters, which may be released into the extracellular space, since some neurotransmitters are capable of precipitating cell damage if extracellular accumulations are not rapidly cleared. In the case of glutamate, an excitatory neurotransmitter, this can lead to glutamate excitotoxicity due to overactivation of ion channels on nerve cells and the excessive entry of calcium, which can trigger apoptosis. Under normal circumstances, the astrocyte is involved in glutamate uptake, whereby it enzymatically detoxifies this transmitter substance, converting it to glutamine, which is then recycled to the neuron (see Chs 5 and 15).

One well-known function of the astrocyte is concerned with repair. Subsequent to trauma, astrocytes invariably proliferate, swell, accumulate glycogen and undergo fibrosis by the accumulation of filaments, expressed neurochemically as an increase in glial fibrillary acidic protein (GFAP). This state of gliosis may be total, in which case all other elements are lost, leaving a glial scar, or it may be a generalized response occurring against a background of regenerated or normal CNS parenchyma. Fibrous astrocytosis can occur in both the gray and white matter, thereby indicating common links between protoplasmic and fibrous astrocytes. With age, both fibrous and protoplasmic astrocytes accumulate filaments. In some diseases, astrocytes become macrophages. It is interesting to note that the astrocyte is probably the most disease-resistant component in the CNS because very few diseases, other than alcoholism, cause depletion of astrocytes.

Another putative role of the astrocyte is its involvement in transport mechanisms (see Ch. 5) and in the BBB system (see Ch. 32). Astrocytes interact with neurons in various metabolic and transport processes. It was believed for some time that transport of water and electrolytes was effected by the astrocyte, a fact never definitively demonstrated and largely inferred from pathological or experimental evidence. It is known, for example, that damage to the brain vasculature, local injury due to heat or cold and inflammatory changes produce focal swelling of astrocytes, presumably owing to disturbances in fluid transport. The astrocytic investment of blood vessels suggests a role in the BBB system, but the studies of Reese and Karnovsky [25] and Brightman [26] indicate that the astrocytic end-feet provide little resistance to the movement of molecules and that blockage of the passage of material into the brain occurs at the endothelial-cell-lining blood vessels (see Ch. 32). CNS endothelial cells display selective transport by transcytosis and the surface of the astrocyte also frequently displays evidence of endocytosis by the presence of clathrin-coated pits, structures known to be involved in a number of secretory and recycling mechanisms. During inflammation, these mechanisms are disrupted and there are alterations in permeability of endothelial tight junctions and formation of edema within and around neighboring astrocytes. Finally, it is believed that astrocytes are responsible for the regulation of local pH levels and local ionic balances.

Molecular markers of astrocytes. Although antigenically distinct from other cell types by virtue of its expressing GFAP [27], there is no documented evidence of astrocytic disease related to an immunological response to GFAP on any astroglial molecule. GFAP remains singularly the most used cytoplasmic marker of astrocytes. Another protein with phenotypic specificity for astrocytes is S100β, a marker that develops earlier than GFAP in astrocytes and can therefore be used to identify less mature cells. A reliable marker for astrocytic membranes remains to be described. Interestingly, there is increasing evidence demonstrating the ability of astrocytes to serve as accessory cells of the immune system in a number of immune-mediated conditions [27,28]. In this regard, astrocytes have been shown *in vitro* to express class II MHC antigens, which are molecules essential for the presentation of antigen to helper/inducer $CD4^+$ T cells, as well as their ability to synthesize a number of cytokines, such as interleukin-1, tumor necrosis factor, interferon γ and several chemokines, e.g. Groα. (see Chs 35 and 39). It appears, therefore, that in circumstances in which the BBB is interrupted, the astrocyte is a facultative phagocyte with the potential to interact with lymphocytes.

Oligodendrocytes are myelin-producing cells in the central nervous system. The ultrastructural studies of Schultz *et al.* (1957) and Farquhar and Hartman (1957) (discussed in [4]) were among the first to contrast the EM features of oligodendrocytes with astrocytes (Fig. 1-12). The study of Mugnaini and Walberg [4] more explicitly laid down the morphological criteria for identifying these cells and, apart from subsequent technical improvements, our EM understanding of these cells has changed little since that time [5,29].

As with astrocytes, oligodendrocytes are highly variable, differing in location, morphology and function, but definable by some morphological criteria. The cell soma ranges from 10 to 20 μm and is roughly globular and more dense than that of an astrocyte. The margin of the cell is irregular compressed against the adjacent neuropil, and may show the presence of coated pits. Few cell processes are seen, in contrast to the astrocyte. Within the cytoplasm, many organelles are found. Parallel cisternae of rough ER and a widely-dispersed Golgi apparatus are common. Free ribosomes occur, scattered amid occasional multivesicular bodies, mitochondria and coated vesicles. Distinguishing the oligodendrocyte from the astrocyte are the apparent absence of glial filaments and the constant presence of 24 nm microtubules (Fig. 1-13). Microtubules are most common at the margins of the cell, in the occasional cell process and in the cytoplasmic loops around myelin sheaths. Lamellar dense bodies, typical of oligodendrocytes, are also present [5]. The nucleus is usually ovoid, but slight lobation is not uncommon. The nucleochromatin stains heavily and contains clumps of denser heterochromatin; the whole structure is sometimes difficult to discern from the background cytoplasm. Desmosomes and gap junctions occur between interfascicular oligodendrocytes [5].

Ultrastructural and labeling studies on the developing nervous system (see Ch. 27) have demonstrated variability in oligodendrocyte morphology and activity. Mori and Leblond (see [5]) separated oligodendrocytes into three groups based on location, stainability and DNA turnover. Their three classes correspond to satellite, intermediate and interfascicular, or myelinating, oligodendrocytes. Satellite oligodendrocytes are small (≈10 μm), restricted to gray matter and closely applied to the surface of neurons.

They are assumed to play a role in the maintenance of the neuron and are potential myelinating cells. Interfascicular oligodendrocytes are large (≈20 μm) during myelination but, in the adult, range from 10 to 15 μm, with the nucleus occupying a large percentage of the cell volume. Intermediate oligodendrocytes are regarded as satellite or potential myelinating forms. The nucleus of these cells is small, the cytoplasm occupying the greater area of the soma.

Myelinating oligodendrocytes have been studied extensively [5,30] (see Ch. 4). Examination of the CNS during myelinogenesis (Fig. 1-15) reveals connections between the cell body and the myelin sheath [31]; however, connections between these elements have never been demonstrated in a normal adult animal, unlike the PNS counterpart, the Schwann cell. In contrast to the Schwann cell (see below), the oligodendrocyte is capable of producing many internodes of myelin simultaneously. It has been estimated that oligodendrocytes in the optic nerve produce between 30 and 50 internodes of myelin [5]. In addition to this heavy structural commitment, the oligodendrocyte possesses a slow mitotic rate and a poor regenerative capacity. Damage to only a few oligodendrocytes, therefore, can be expected to produce an appreciable area of primary demyelination. In most CNS diseases in which myelin is a target, oligodendrocytes are among the most vulnerable elements and the first to degenerate (see Ch. 39).

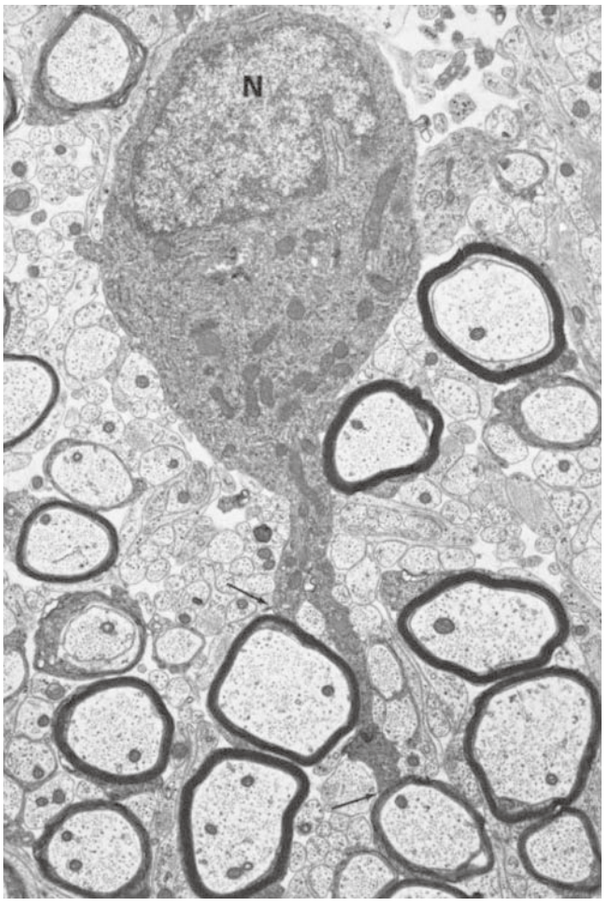

FIGURE 1-15 A myelinating oligodendrocyte, nucleus (*N*), from the spinal cord of a 2-day-old kitten extends cytoplasmic connections to at least two myelin sheaths (*arrows*). Other myelinated and unmyelinated fibers at various stages of development, as well as glial processes, are seen in the surrounding neuropil. ×12,750.

Somewhat analogous to the neuron, the relatively small oligodendrocyte soma produces and supports many more times its own volume of membrane and cytoplasm. For example, consider an average 12 μm oligodendrocyte producing 20 internodes of myelin [5]. Each axon has a diameter of 3 μm and is covered by at least six lamellae of myelin, each lamella representing two fused layers of unit membrane. By statistical analysis, taking into account the length of the myelin internode, which is possibly 500 μm, and the length of the membranes of the cell processes connecting the sheaths to the cell body (≈12 μm), the ratio between the surface area of the cell soma and the myelin it sustains is approximately 1:620. In most cases, however, this ratio is probably in the region of 1:3,000. In rare instances, oligodendrocytes elaborate myelin around structures other than axons in that myelin has been documented around neuronal somata and nonaxonal profiles.

Molecular markers of oligodendrocytes. The oligodendrocyte is potentially highly vulnerable to immune-mediated damage since it shares with the myelin sheath many molecules with known affinities to elicit specific T- and B-cell responses, which lead to its destruction. Chapter 39 describes the immune process in demyelination. Many of these molecules, such as myelin basic protein, proteolipid protein, myelin-associated glycoprotein, myelin/oligodendrocyte protein, galactocerebroside, myelin oligodendrocyte glycoprotein (MOG) and others, have been used to generate specific antibodies, which are routinely applied to anatomical analyses of oligodendrocytes *in vivo* and *in vitro*. However, while the oligodendrocyte expresses no class I or II MHC molecules [32], it has recently been found to demonstrate a wide array of cytokine receptors, both pro-inflammatory and regulatory [33], suggestive of innate and adaptive abilities to participate in immune responses.

The microglial cell plays a role in phagocytosis and inflammatory responses. Of the few remaining types of CNS cell, the most interesting, and probably the most enigmatic, is the microglial cell, a cell of mesodermal origin, located in the normal brain in a resting state (Fig. 1-3) and purported to become a very mobile, active macrophage during disease (see Ch. 35) and the major effector cell in immune-mediated damage in the CNS. Microglia can be stained selectively and demonstrated by light microscopy using Hortega's silver carbonate method, but no comparable technique exists for their

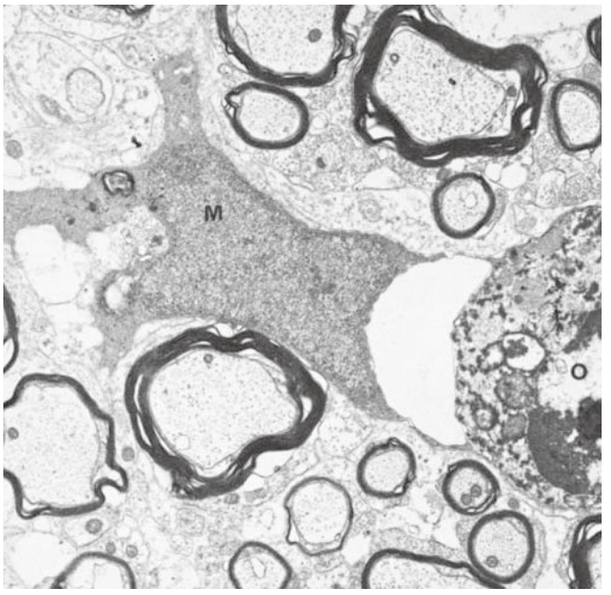

FIGURE 1-16 A microglial cell (*M*) has elaborated two cytoplasmic arms to encompass a degenerating apoptotic oligodendrocyte (*O*) in the spinal cord of a 3-day-old kitten. The microglial cell nucleus is difficult to distinguish from the narrow rim of densely staining cytoplasm, which also contains some membranous debris. ×10,000.

ultrastructural demonstration. A wide array of immunocytochemical markers are available for microglia, including anti-MHC II and anti-CD45 (LCA).The cells have spindle-shaped bodies and a thin rim of densely-staining cytoplasm difficult to distinguish from the nucleus. The nucleochromatin is homogeneously dense and the cytoplasm does not contain an abundance of organelles, although representatives of the usual components can be found. During normal wear and tear, some CNS elements degenerate and microglia phagocytose the debris (Fig. 1-16). Their identification and numbers, as determined by light microscopy, differ from species to species. The CNS of rabbit is richly endowed. In a number of disease instances, such as trauma, microglia are stimulated and migrate to the area of injury, where they phagocytose debris. The relatively brief mention of this cell type in the major EM textbooks [3] and the reported conflicting EM descriptions [34] were indicative of the uncertainty attached to their identification at those timepoints. Pericytes are believed by some to be a resting form of microglial cell. Perivascular macrophages, which are of bone marrow origin and are distinct from parenchymal microglia, have also been described and these cells are known to traffic between the CNS and the lymphoid system.

Molecular markers of microglial cells. In the past 10–15 years there has been a veritable explosion of activity in the field of microglial cell biology with the realization that this cell type is capable of functioning as a highly efficient accessory and effector cell of the immune system. While no particularly microglia-specific molecule has been identified, a number of antibodies raised against monocytic markers and complement receptor molecules stain microglial cells *in situ* and *in vitro*. Microglia express class II MHC upon activation [35–38], frequently in the absence of a T-cell response. This suggests that class II MHC expression may represent a marker of activation or in some way elevate the cells to a state of immunological awareness or competence. Microglia are major producers of a large number of proinflammatory cytokines with known effects upon T cells [33]. Taken in concert, an abundance of evidence for an immunological role for microglia in a wide spectrum of CNS conditions supports the putative monocytic origin of this cell type and bestows upon it the role of the major effector of immune mediated damage in the CNS.

Ependymal cells line the brain ventricles and the spinal cord central canal. Ependymal cells are arranged in single palisade arrays and line the ventricles of the brain and central canal of the spinal cord. They are usually ciliated, their cilia extending into the ventricular cavity. Their fine structure has been elucidated by Brightman and Palay [39]. They possess several features that clearly differentiate them from any other CNS cell. The cilia emerge from the apical pole of the cell, where they are attached to a blepharoplast, the basal body (Fig. 1-17), which is anchored in the cytoplasm by means of ciliary rootlets and a basal foot. The basal foot is the contractile component that determines the direction of the ciliary beat. Like all flagellar structures, the cilium contains the common microtubule arrangement of nine peripheral pairs around a central doublet (Fig. 1-17). In the vicinity of the basal body, the arrangement is one of nine triplets; at the tip of each cilium, the pattern is one of haphazardly organized

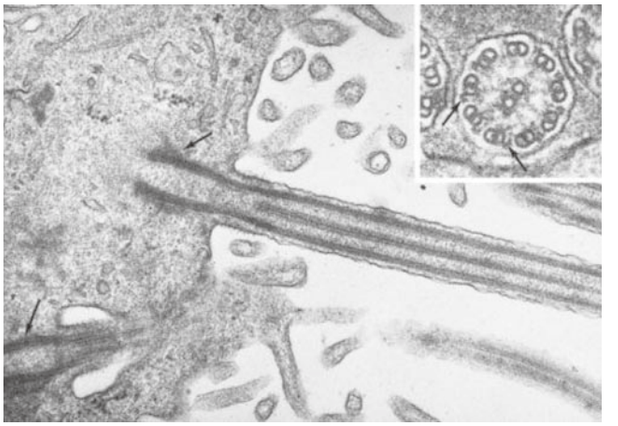

FIGURE 1-17 The surface of an ependymal cell contains basal bodies (*arrows*) connected to the microtubules of cilia, seen here in longitudinal section. Several microvilli are also present. ×37,000. **Inset:** Ependymal cilia in transverse section possess a central doublet of microtubules surrounded by nine pairs, one of each pair having a characteristic hook-like appendage (*arrows*). ×100,000.

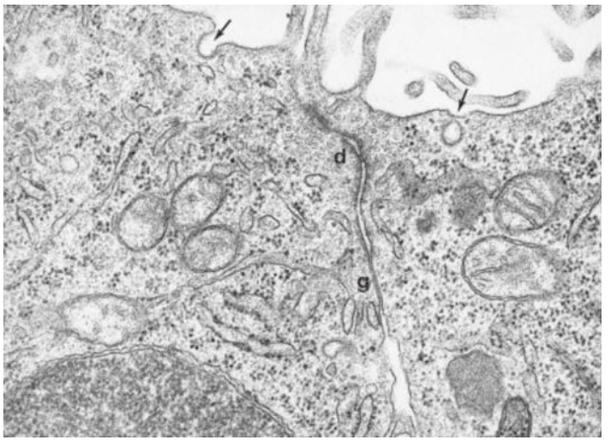

FIGURE 1-18 A typical desmosome (*d*) and gap junction (*g*) between two ependymal cells. Microvilli and coated pits (*arrows*) are seen along the cell surface. ×35,000.

single tubules. Also, extending from the free surface of the cell are numerous microvilli containing actin microfilaments (Fig. 1-17). The cytoplasm stains intensely, having an electron density about equal to that of the oligodendrocyte, whereas the nucleus has a similar density to that of the astrocyte. Microtubules, large whorls of filaments, coated vesicles, rough ER, Golgi-apparatus, lysosomes and abundant small, dense mitochondria are also present in ependymal cells. The base of the cell is composed of involuted processes that interdigitate with the underlying neuropil. The lateral margins of each cell characteristically display long, compound, junctional complexes (Fig. 1-18) made up of desmosomes, termed *zonula adherentes*, and gap junctions [3]. Overlying specialized secretory zones around the ventricles (the subventricular organs) and choroid plexus, the ependymal lining is different and the cells are connected at their apical poles by tight junctions called *zonula occludentes*, the latter expressing the junctional protein occludin. Desmosomes (cadherins) and gap junctions (connexins) are also present at the lateral aspects of the cells [40].

The biochemical properties of these structures are known. Desmosomes display protease sensitivity, divalent cation dependency and osmotic insensitivity; and their membranes are mainly of the smooth type. In direct contrast to desmosomes, the tight junctions as well as gap junctions and synapses display no protease sensitivity, divalent cation dependency or osmotic sensitivity, while their membranes are complex. These facts have been used in the development of techniques to isolate purified preparations of junctional complexes.

The Schwann cell is the myelin-producing cell of the peripheral nervous system. When axons leave the CNS, they lose their neuroglial interrelationships and traverse a short transitional zone where they are invested by an astroglial sheath enclosed in the basal lamina of the glia limitans. The basal lamina then becomes continuous with that of axon-investing Schwann cells, at which point the astroglial covering terminates. Schwann cells, therefore, are the axon-ensheathing cells of the PNS, equivalent functionally to the oligodendrocyte of the CNS (see Ch. 4). Along the myelinated fibers of the PNS, each internode of myelin is elaborated by one Schwann cell and each Schwann cell elaborates one internode [30]. This ratio of one internode of myelin to one Schwann cell is a fundamental distinction between this cell type and its CNS analog, the oligodendrocyte, which is able to proliferate internodes in the ratio of 1:30 or greater. Another distinction is that the Schwann cell body always remains in intimate contact with its myelin internode (Fig. 1-19), whereas the oligodendrocyte extends long, attenuated processes toward its internodes. Periodically, myelin lamellae open up into ridges of Schwann cell cytoplasm, producing bands of cytoplasm around the fiber, Schmidt–Lanterman incisures, reputed to be the stretch points along PNS fibers. These incisures usually are not present in the CNS. The PNS myelin period is 11.9 nm in preserved specimens, which is some 30% less than in the fresh state, in contrast to the 10.6 nm of central myelin. In addition to these structural differences, PNS myelin

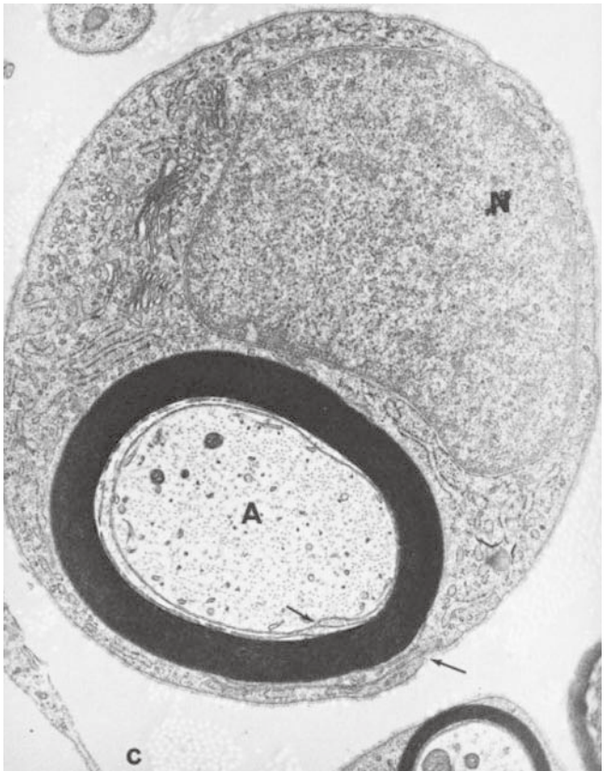

FIGURE 1-19 A myelinated PNS axon (*A*) is surrounded by a Schwann cell nucleus (*N*). Note the fuzzy basal lamina around the cell, the rich cytoplasm, the inner and outer mesaxons (*arrows*), the close proximity of the cell to its myelin sheath and the 1:1 (cell:myelin internode) relationship. A process of an endoneurial cell is seen (**lower left**), and unstained collagen (*c*) lies in the endoneurial space (*white dots*). ×20,000.

differs biochemically and antigenically from that of the CNS (see Ch. 4). Not all PNS fibers are myelinated but, in contrast to nonmyelinated fibers in the CNS, nonmyelinated fibers in the PNS are suspended in groups within the Schwann cell cytoplasm, each axon connected to the extracellular space by a short channel, the mesaxon, formed by the invaginated Schwann cell plasmalemma.

Ultrastructurally, the Schwann cell is unique and distinct from the oligodendrocyte. Each Schwann cell is surrounded by a basal lamina made up of a mucopolysaccharide approximately 20–30 nm thick that does not extend into the mesaxon (Fig. 1-19). The basal laminae of adjacent myelinating Schwann cells at the nodes of Ranvier are continuous, and Schwann cell processes interdigitate so that the PNS myelinated axon is never in direct contact with the extracellular space. These nodal Schwann cell fingers display intimate relationships with the axolemma (Figs 1-20, 1-21), suggesting that the entire nodal complex might serve as an electrogenic pump for the recycling of ions [10]. A similar arrangement between the nodal axon and the fingers of astroglial cells is seen in the CNS. The Schwann cells of nonmyelinated PNS fibers overlap, and there are no nodes of Ranvier.

The cytoplasm of the Schwann cell is rich in organelles. A Golgi apparatus is located near the nucleus, and cisternae of the rough ER occur throughout the cell. Lysosomes, multivesicular bodies, glycogen granules and lipid granules, also termed pi granules, also can be seen. The cell is rich in microtubules and filaments, in contrast to the oligodendrocyte. The plasmalemma frequently shows pinocytic vesicles. Small, round mitochondria are scattered throughout the soma. The nucleus, which stains intensely, is flattened and oriented longitudinally along the nerve fiber. Aggregates of dense heterochromatin are arranged peripherally [3].

FIGURE 1-21 A transverse section of the node of Ranvier (7–8 μm across) of a large fiber shows a prominent complex of Schwann cell fingers around an axon highlighted by its subaxolemmal densification and closely packed organelles. The Schwann cell fingers arise from an outer collar of flattened cytoplasm and abut the axon at regular intervals of approximately 80 nm. The basal lamina of the nerve fiber encircles the entire complex. The nodal gap substance is granular and sometimes linear. Within the axoplasm, note the transversely sectioned sacs of beaded smooth endoplasmic reticulum (ER); mitochondria; dense lamellar bodies, which appear to maintain a peripheral location; flattened smooth ER sacs; dense-core vesicles; cross-bridged neurofilaments; and microtubules, which in places run parallel to the circumference of the axon (**above left** and **lower right**), perhaps in a spiral fashion. ×16,000.

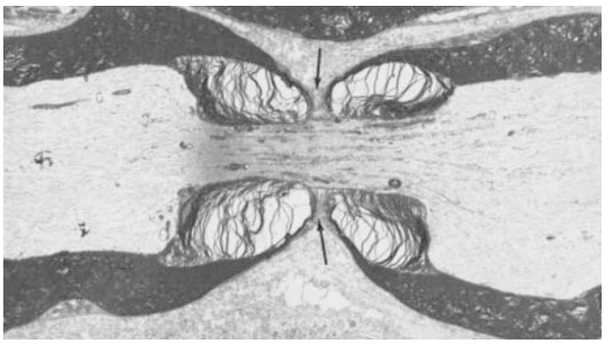

FIGURE 1-20 Low-power electron micrograph of a node of Ranvier in longitudinal section. Note the abrupt decrease in axon diameter and the attendant condensation of axoplasmic constituents in the paranodal and nodal regions of the axon. Paranodal myelin is distorted artifactually, a common phenomenon in large-diameter fibers. The nodal gap substance (*arrows*) contains Schwann cell fingers, the nodal axon is bulbous and lysosomes lie beneath the axolemma within the bulge. Beaded smooth endoplasmic reticulum sacs are also seen. ×5,000.

In sharp contrast to the oligodendrocyte, the Schwann cell responds vigorously to most forms of injury (see Ch. 39). An active phase of mitosis occurs following traumatic insult, and the cells are capable of local migration. Studies on their behavior after primary demyelination have shown that they are able to phagocytose damaged myelin. They possess remarkable reparatory properties and begin to lay down new myelin approximately 1 week after a fiber loses its myelin sheath. Studies on PNS and CNS remyelination [41] have shown that, by 3 months after primary demyelination, PNS fibers are well remyelinated, whereas similarly affected areas in the CNS show relatively little proliferation of new myelin (see Ch. 29). Under circumstances of severe injury, such as transection, axons degenerate and the Schwann cells form tubes, termed *Büngner bands*, containing cell bodies and processes surrounded by a single basal lamina. These structures provide channels along which regenerating axons

might later grow. The presence and integrity of the Schwann cell basal lamina is essential for reinnervation.

The extracellular space between peripheral nerve fibers is occupied by bundles of collagen fibrils, blood vessels and endoneurial cells. Endoneurial cells are elongated, spindle-shaped cells with tenuous processes relatively poor in organelles except for large cisternae of the rough ER. There is some evidence that these cells proliferate collagen fibrils. Sometimes mast cells, the histamine producers of connective tissue, can be seen. Bundles of nerve fibers are arranged in fascicles emarginated by flattened connective tissue cells forming the perineurium, an essential component in the blood–nerve barrier system. Fascicles of nerve fibers are aggregated into nerves and invested by a tough elastic sheath of cells known as the epineurium [42].

Cell Membrane Structures and Functions

R. Wayne Albers

PHOSPHOLIPID BILAYERS 21
Cells are bounded by proteins arrayed in lipid bilayers 21
Amphipathic molecules can form bilayered lamellar structures spontaneously if they have an appropriate geometry 22

MEMBRANE PROTEINS 24
Membrane integral proteins have transmembrane domains that insert directly into lipid bilayers 24
Many transmembrane proteins that mediate intracellular signaling form complexes with both intra- and extracellular proteins 25
Membrane associations can occur by selective protein binding to lipid head groups 25

BIOLOGICAL MEMBRANES 25
The fluidity of lipid bilayers permits dynamic interactions among membrane proteins 25
The lipid compositions of plasma membranes, endoplasmic reticulum and Golgi membranes are distinct 26
Cholesterol transport and regulation in the central nervous system is distinct from that of peripheral tissues 26
In adult brain most cholesterol synthesis occurs in astrocytes 26
The astrocytic cholesterol supply to neurons is important for neuronal development and remodeling 27
The structure and roles of membrane microdomains (rafts) in cell membranes are under intensive study but many aspects are still unresolved 28
Mechanical functions of cells require interactions between integral membrane proteins and the cytoskeleton 29
The spectrin–ankyrin network comprises a general form of membrane-organizing cytoskeleton within which a variety of membrane–cytoskeletal specializations are interspersed 29
Interaction of rafts with cytoskeleton is suggested by the results of video microscopy 29

Neurons are specialized to integrate selected extracellular signals, both spatially and temporally. In addition to generating action potentials and, through synaptic activity, signaling other cells, structural modifications are initiated within neurons that may be as transient as ion channel gating or as long lasting as memory. Nearly all of this activity involves cell membranes and many of these membrane functions are discussed in subsequent chapters. This chapter begins with brief discussions of the physical chemistry underlying the lipid and protein components of cell membranes (Figs 2-1–2-4), proceeds to examine some aspects of membrane biochemistry relevant to neurons and their supporting cells, and concludes with discussion of some issues of cell membrane functions that are subjects of current investigations.

To perform its unique functional role each neuron must regulate a host of intracellular activities. that occur in axons and dendrites distant from the cell nucleus. For example, axonal guidance during development, or remodeling of dendritic spines in response to local input, each involves many different complex control systems that are highly localized and largely autonomous. [1].

PHOSPHOLIPID BILAYERS

Cells are bounded by proteins arrayed in lipid bilayers.

The importance of lipids in membrane structure was established early in the 20th century when pioneering biophysicists established positive correlations between cell membrane permeabilities to small non-electrolytes and the oil/water partition coefficients of these molecules. Contemporary measurements of the electrical impedance of cell suspensions suggested that cells are surrounded by a hydrocarbon barrier, which was first estimated to be about 3.3 nm thick. This was originally thought to be a lipid monolayer. Among the pioneering biophysical experiments were those that established that the ratio of the area of a monolayer formed from erythrocyte

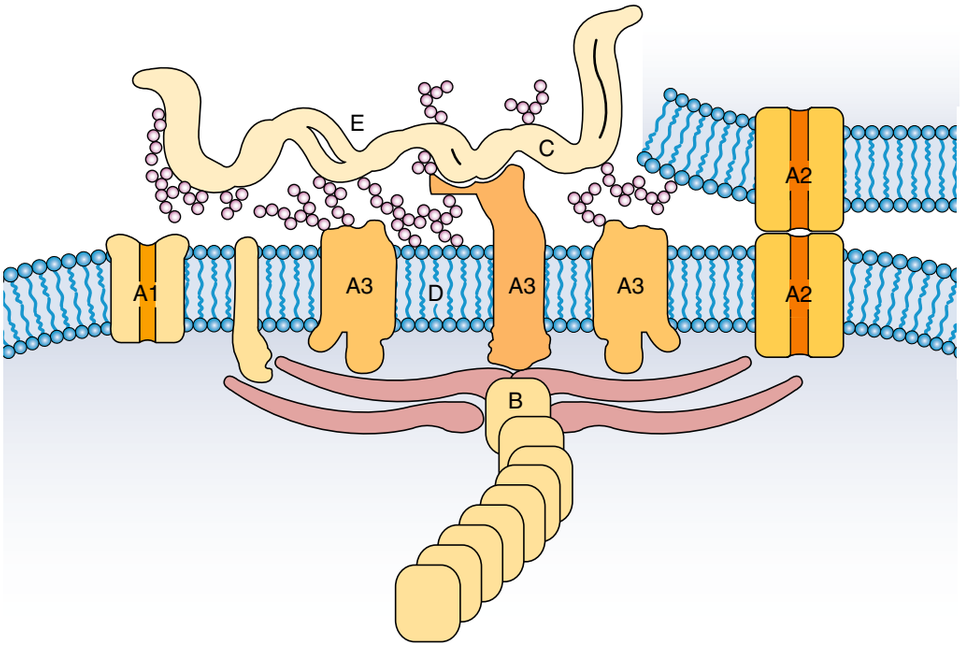

FIGURE 2-1 Overview of plasma membrane structure. Plasma membranes are distinguishable from other cellular membranes by the presence of both glycolipids and glycoproteins on their outer surfaces and the attachment of cytoskeletal proteins to their cytoplasmic surfaces. Interrelations among typical membrane components are depicted. Proteins that are inserted through the lipid bilayer (*A1–A3*), termed 'integral' membrane proteins, are often glycosylated (*lavender circles*), as are some bilayer lipids (*D*) and many components of the extracellular matrix (*E*). Many interactions at the extracellular surface are stabilized by hydrogen bonding among these glycosyl residues. Certain integral membrane proteins can interact by virtue of specific receptor sites with intracellular proteins (*B*), with extracellular components (*C*) and to form specific junctions with other cells (*A2*). A host of integral membrane proteins mediates different signal-transduction and active-transport pathways.

membrane lipids to the surface area of these cells is nearly 2. These and other studies of the physical chemistry of lipids led to the concept of a continuous lipid bilayer as a major component of cell membranes. This concept received support from other approaches, including measurements of X-ray diffraction patterns of intact cell membranes.

Forces acting between lipids and between lipids and proteins are primarily noncovalent, consisting of electrostatic, hydrogen-bonding and van der Waals interactions. These are weak interactions relative to covalent bond formation, but they sum to produce very stable associations. Ionic and polar parts of molecules exposed to water will become hydrated. Substances dissolve in a solvent only if their molecules interact with the solvent more strongly than with each other. In aqueous solution large molecules having two or more domain surfaces of differing polarity will form an internal hydrophobic phase and hydrate the more polar surfaces. Such molecules are termed amphipathic and include most biological lipids and proteins.

Amphipathic molecules can form bilayered lamellar structures spontaneously if they have an appropriate geometry. Most of the major cell membrane lipids have a polar head, most commonly a glycerophosphorylester moiety, and a hydrocarbon tail, usually consisting of two esterified fatty acids. Both domains have similar cross-sectional areas. Consequently, as the head groups interact with each other and with water, and the nonpolar tails aggregate with each other to form an internal phase, the similar cross-sections of the two phases can produce planar bilayers.

Three principal phases with different structures are formed by phospholipids in the presence of water [2] (Fig. 2-2). Although the lamellar, or bilayer, structure is generally found in cell membranes, the hexagonal phases may occur transiently during membrane shape transformations. The importance of molecular geometry for bilayer stability is illustrated by the effects of phospholipase A_2, a component of many venoms, on erythrocytes: this enzyme removes the C-2 fatty acid from phospholipids to produce lysophosphatides. Because of the 'conical' geometry of lysophosphatides, this process ultimately destabilizes bilayers relative to the hexagonal phase structures; this disrupts cell membranes and lyses the cells. Detergents are amphipathic molecules with abilities to transform lipid bilayers into water-soluble micelles. In contrast to the destabilizing effects of lysophosphatides and other detergents, cholesterol stabilizes bilayers by intercalating at the interface between head and tail regions of phospholipid so as to satisfy the bulk requirements for a planar geometry.

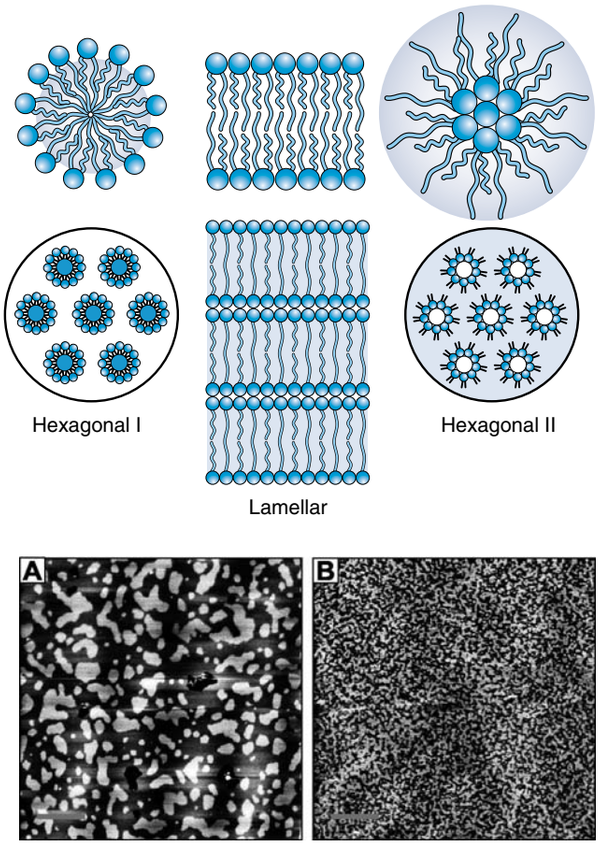

FIGURE 2-2 **Top row:** Complex lipids interact with water and with each other to form different states of aggregation, or 'phases', shown here schematically. *Open circles* or *ellipses* represent the more polar head groups, and *dark lines* and *areas* represent nonpolar hydrocarbon chains. The phase structures are generally classified as illustrated in the **middle row** of the figure. The hexagonal I and lamellar phases can be dispersed in aqueous media to form the micellar structures shown in the **top row.** Hexagonal II phase lipids will form 'reverse micelles' in nonpolar solvents. The stability of lamellar structures relative to hexagonal structures depends upon fatty acid chain length, presence of double bonds, relative sizes of polar head and hydrocarbon tail groups and temperature. **Bottom row:** Atomic Force Microscopic images (6×6 mm, scale bar 1 mm, z-scale of 5 nm) showing (left) domains in bilayers of 1:1 sphingomyelin:dioleylphosphatidylcholine combined with 30% cholesterol and (right) domains of 1:1 dipalmitylphosphatidylcholine:dioleylphosphatidylcholine combined with 30% cholesterol. Lighter areas are higher than darker areas. From [31] with permission.

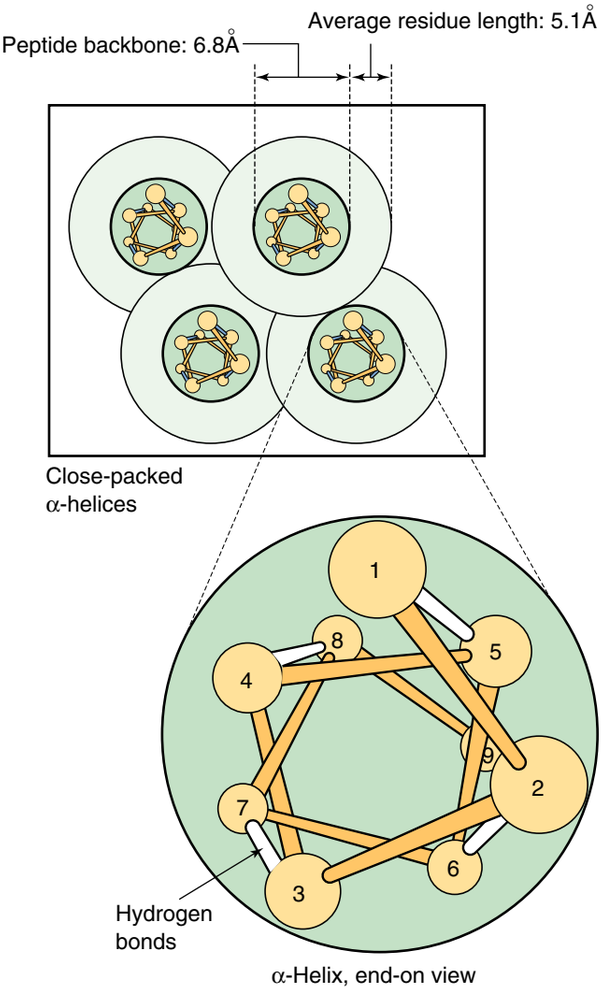

FIGURE 2-3 The transmembrane domains of integral membrane proteins are predominantly α-helices. This structure causes the amino acid side chains to project radially. When several parallel α-helices are closely packed, their side chains may intermesh as shown, or steric constraints may cause the formation of interchain channels. The outwardly directed residues must be predominantly hydrophobic to interact with the fatty acid chains of lipid bilayers. The bilayer is about 3 nm thick. Each peptide residue extends a helix by 1.5 Å. Thus, although local modifications of the bilayer or interactions with other membrane polypeptides may alter this requirement, transmembrane segments usually require about 20 residues to span the bilayer. Integral membrane proteins are characterized by the presence of hydrophobic segments approximating this length.

The multilamellar bilayer structures that form spontaneously on adding water to solid- or liquid-phase phospholipids can be dispersed to form vesicular structures called liposomes. These are often employed in studies of bilayer properties and may be combined with membrane proteins to reconstitute functional membrane systems. A valuable technique for studying the properties of proteins inserted into bilayers employs a single bilayer lamella, also termed a black lipid membrane, formed across a small aperture in a thin partition between two aqueous compartments. Because pristine lipid bilayers have very low ion conductivities, the modifications of ion-conducting properties produced by membrane proteins can be measured with great sensitivity (Ch. 6).

In aqueous systems, membrane lipids may exist in a gel-like solid state or as a two-dimensional liquid. In the case of pure phospholipids, these states interconvert at a well-defined transition temperature, T_c, that increases with alkyl chain length and decreases with introduction of alkyl chain unsaturation. In cell membranes, which have marked heterogeneity in both the polar and nonpolar domains of the bilayer, this state is described as 'liquid disordered'. The presence of sufficient sphingolipids, with

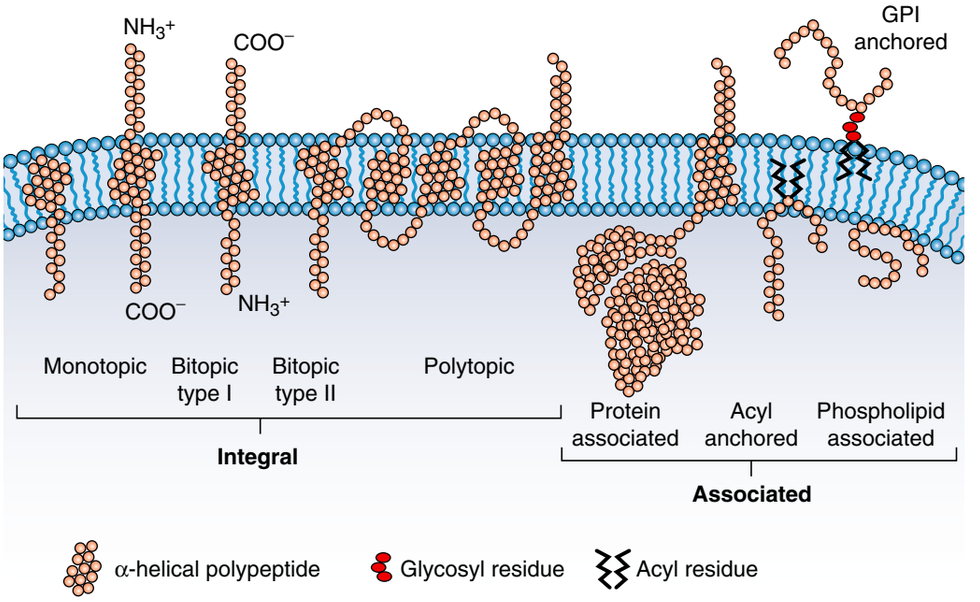

FIGURE 2-4 **Left:** Integral membrane proteins can be classified with respect to the orientation and complexity of their transmembrane segments. **Right:** Proteins may associate with membranes through several types of interactions with the bilayer lipids and by interacting with integral membrane proteins. They can also be 'anchored' by integration into the bilayer of covalently bound lipids. GPI = glycosylphosphatidylinositol.

saturated alkyl chains, and of cholesterol, which has a rigid planar structure, can cause a 'liquid ordered' structure to separate laterally into microdomains that are in phase equilibrium with 'liquid disordered' structures (Fig. 2-2, bottom row). Such microdomains consisting of 'lipid rafts' enriched in cholesterol and sphingomyelin may function, in biomembranes, to concentrate or localize certain membrane proteins, as discussed below.

Alkyl chain heterogeneities cause cell membrane bilayers to remain in the fluid state over a broad temperature range. This permits rapid lateral diffusion of membrane lipids and proteins within the plane of the bilayer. The lateral diffusion rate for an unconstrained phospholipid in a bilayer is of the order of $1\,mm^2\,s^{-1}$; an integral membrane protein such as rhodopsin would diffuse $\approx 40\,nm^2\,s^{-1}$.

MEMBRANE PROTEINS

Membrane integral proteins have transmembrane domains that insert directly into lipid bilayers. Transmembrane domains (TMDs) consist predominantly of nonpolar amino acid residues and may traverse the bilayer once or several times. High-resolution structural information is available for only a few integral membrane proteins, primarily because it is difficult to obtain membrane protein crystals that are adequate for X-ray diffraction measurements.

TMDs usually consist of a helix. The peptide bond is intrinsically polar and can form internal hydrogen bonds between carbonyl oxygens and amide nitrogens, or either of these may be hydrated. Within the lipid bilayer, where water is essentially excluded, peptides usually adopt the α helical configuration that maximizes their internal hydrogen bonding. A length of a helix of 18–21 amino acid residues is sufficient to span the usual width of a lipid bilayer (Fig. 2-3). Because the surface properties of a helix are determined by its side chains, a single helical segment that can insert into or through a bilayer will consist largely of hydrophobic residues.

Integral membrane proteins with one transmembrane domain may have 'soluble' domains at either or both surfaces. An example of a monotopic protein, cytochrome b5 has a single hydrophobic segment that forms a hairpin loop, acting as an anchor to the cytoplasmic surface but probably not totally penetrating the bilayer.

Bitopic proteins with a single transmembrane helix are more common. If oriented with the N-terminus extracytoplasmic, they are classified as type I or, if cytoplasmic, type II (Fig. 2-4). Bitopic membrane proteins are often involved in signal transduction, as exemplified by receptor-activated tyrosine kinases (Ch. 24): agonist occupation of an extracytoplasmic receptor domain can transmit structural changes via a single transmembrane helix to activate the latent kinase activity in a cytoplasmic domain.

Ion channels, transporters and many receptors are polytopic. Polar and helix-destabilizing residues are likely to occur within their transmembrane segments to form the requisite gates, channels or binding domains. Transmembrane helices in polytopic proteins are usually

closely packed. Examples of this are G-protein-coupled receptors (GPCRs; Ch. 19), and the sarcoplasmic Ca^{2+} pump (Ch. 5). Each peptide bond has a significant dipole moment, which is transmitted to the ends of a helix. This circumstance favors close packing of antiparallel helices and is the observed disposition of helices in bacteriorhodopsin [3]. In oligomeric transmembrane proteins, intersubunit packing can encompass extramembranous protein domains and bilayer lipids.

Many transmembrane proteins that mediate intracellular signaling form complexes with both intra- and extracellular proteins. For example, neural cell adhesion molecules (NCAMs) are cell-surface glycoproteins (Ch. 7). The extracellular domains of NCAMs can activate fibroblast growth factor receptors when clustered by reaction with NCAM antibodies [4] or by homotypic binding to domains of adjacent cells (see Fig. 7-2). Activation was found to sequester a complex of NCAM, βI spectrin and $PKC\beta_2$ into rafts, as defined by the operational criteria discussed on p. 28.

Membrane associations can occur by selective protein binding to lipid head groups. One example is spectrin, which binds to phosphatidylinositol-4,5-bisphosphate by means of a pleckstrin-homology (PH) domain [5] (Fig. 2-5). and also to phosphatidyl serine [6] (Fig. 2-6).

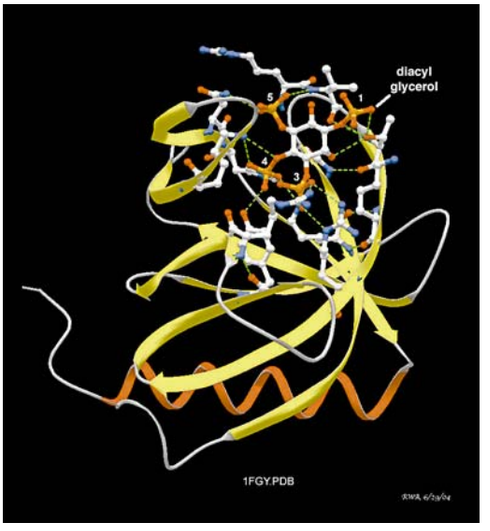

FIGURE 2-5 The pleckstrin homology (PH) domain of GrP1, a GDP–GTP (guanosine 5′ triphosphate) exchange factor for Arf GTPases. Activation of GrP1 occurs when this domain binds to PI(3,4)P2 or PI(3,4,5)P3 produced in the inner leaflet of plasma membranes by a PI3-kinase (Ch. 20). This structure is shown complexed with inositol 1,3,4,5-tetraphosphate as it was crystallized for X-ray diffraction, whereas diacyl glycerol would be esterified to the inositol 1-phosphate in the membrane-bound form. The amino-acid residues (ball and stick models) shown are those that approach the inositol tetraphosphate near enough to form hydrogen bonds (green dashes). Model constructed from Protein Data Base coordinates 1fgy [32] using DeepView 3.7 [33].

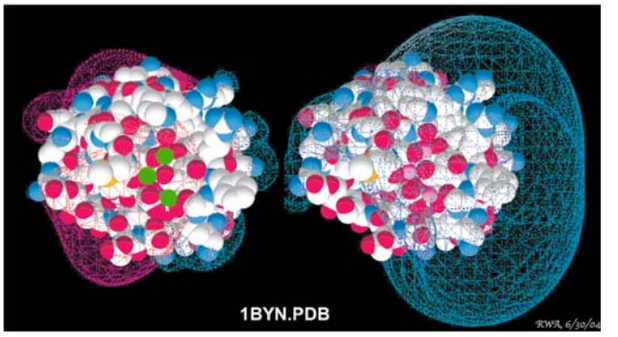

FIGURE 2-6 The C2 Ca^{2+}-dependent lipid-binding domain of synaptotagmin. Although binding calcium to this domain has little effect on its conformation, it produces a markedly increased affinity for negatively charged phospholipids such as phosphatidyl serine. The red and blue grids are isopotential lines over the molecular surface: red = negative, blue = positive potentials. On the left are the isopotential grids for the domain in the absence of calcium (the green circles mark the empty Ca^{2+} binding sites). On the right are isopotential grids after calcium binding (Ca^{2+} atoms = magenta spheres) which intensifies the positive field on the right, which presumably increases its affinity for the negatively charged phospholipids. More sophisticated evaluations of C2 domains from different proteins show that in some cases Ca^{2+} binding drives the binding surface to neutral potential, possibly favoring binding to zwitterionic phospholipids [34]. These models were constructed from Protein Data Base coordinates 1byn [35] using DeepView 3.7 [33].

Ca^{2+} influx initiates protein and membrane associations by several different mechanisms. Allosteric regulation of the hydrophobicity of protein-binding surfaces frequently occurs. One of the best studied examples is the Ca^{2+}-dependent binding of calmodulin to other proteins (Ch. 22). Annexins are a family of proteins that exhibit Ca^{2+}-dependent associations with cell membranes through direct interaction with phospholipids, and conversely, interactions with phospholipids increase their affinities for Ca^{2+} [7].

BIOLOGICAL MEMBRANES

The fluidity of lipid bilayers permits dynamic interactions among membrane proteins. For example, the interactions of a neurotransmitter or hormone with its receptor can dissociate a 'transducer' protein, which in turn will diffuse to interact with other effector proteins (Ch. 19). A given effector protein, such as adenylyl cyclase, may respond differently to different receptors because of mediation by different transducers. These dynamic interactions require rapid protein diffusion within the plane of the membrane bilayer. Receptor occupation can initiate extensive redistribution of membrane proteins, as exemplified by the clustering of membrane antigens consequent to binding bivalent antibodies [8]. In contrast to these examples of lateral mobility, the surface distribution of integral membrane proteins can be fixed by interactions with other proteins. Membranes may also be partitioned into local spatial domains consisting of networks

of cytoskeletal and scaffolding proteins or lipid rafts. This partitioning may restrict the translational motion of enmeshed proteins and yet allow rapid rotational diffusion. Examples of such spatial localization include restriction of Na,K-pumps to the basolateral domains of most epithelial cells, Na^+ channels to nodes of Ranvier and nicotinic acetylcholine receptors to the postsynaptic membranes of neuromuscular junctions.

Because membranes components participate in nearly every cell activity their structures are also dynamic and far from the equilibrium states that are most readily understood in biophysical terms. Newly synthesized bilayer lipids are initially associated with endoplasmic reticulum (Ch.3) whereas phospholipids initially insert into the cytoplasmic leaflet while cholesterol and sphingolipids insert into the luminal endoplasmic reticulum (ER) leaflet. Glycosylation of ceramides occurs as they transit the Golgi compartments, forming cerebrosides and gangliosides in the luminal leaflet. Thus, unlike model systems, the leaflets of ER membranes are asymmetric by virtue of their mode of biosynthesis.

The lipid compositions of plasma membranes, endoplasmic reticulum and Golgi membranes are distinct. All have asymmetric distributions of lipids between cytoplasmic and exocytoplasmic leaflets. Little is known of the intrinsic mechanisms that maintain the distinctions among these interacting membrane classes. As Golgi vesicles fuse into the plasma membrane their luminal surface becomes extracellular at the plasma membrane surface. The aminophospholipids PS and PE remain cytoplasmic but most PC is transported to the exo-leaflet, perhaps by the ATP-dependent ABCA1 transporters that occur in both neurons and glia. Conditions that elevate cell Ca^{2+}, such as anoxia, can activate a Ca^{2+}-dependent 'scramblase' that catalyzes transverse phosphatidylserine movements. Exposure of phosphatidyl-serine extracellularly constitutes a phagocytotic signal to microglia and other phagocytes that express surface receptors for phosphatidylserine [9]. An ATP-dependent aminophospholipid translocase activity in plasma membranes prevents this occurrence in healthy cells.

Cholesterol transport and regulation in the central nervous system is distinct from that of peripheral tissues. Blood-borne cholesterol is excluded from the CNS by the blood–brain barrier. Neurons express a form of cytochrome P-450, 46A, that oxidizes cholesterol to 24(S)-hydroxycholesterol [11] and may oxidize it further to 24,25 and 24,27-dihydroxy products [12]. In other tissues hydroxylation of the alkyl side chain of cholesterol at C22 or C27 is known to produce products that diffuse out of cells into the plasma circulation. Although the rate of cholesterol turnover in mature brain is relatively low, 24-hydroxylation may be a principal efflux path to the liver because it is not further oxidized in the CNS [10].

During brain development *de novo* cholesterol synthesis occurs at high rates at various stages in all brain cell types. In human adults, brain cholesterol constitutes 23% of total body cholesterol, about ten times higher than the average of all tissues. Much of this cholesterol derives from the oligodendrocyte plasma membrane component of myelin; about 80% is associated with myelin in mouse brain and a somewhat larger fraction in human. In contrast to its high content, the metabolic turnover of adult brain cholesterol is relatively low: for humans the turnover rate is estimated to be 0.03% per day for brain compared to 0.7% per day for whole body cholesterol [10].

In adult brain most cholesterol synthesis occurs in astrocytes. Apoprotein E (apoE) is the major apolipoprotein of the CNS and it is secreted by astrocytes. In astrocyte cultures apoE appears in the media as cholesterol-rich particles of a size similar to peripheral HDL (5–12 nm) (Fig. 2-7). The ATP-dependent transporter ABCA1, expressed by both astrocytes and neurons, promotes the formation of the apoE-stabilized high-density lipoprotein (HDL)-sized particles from astrocytic cholesterol.

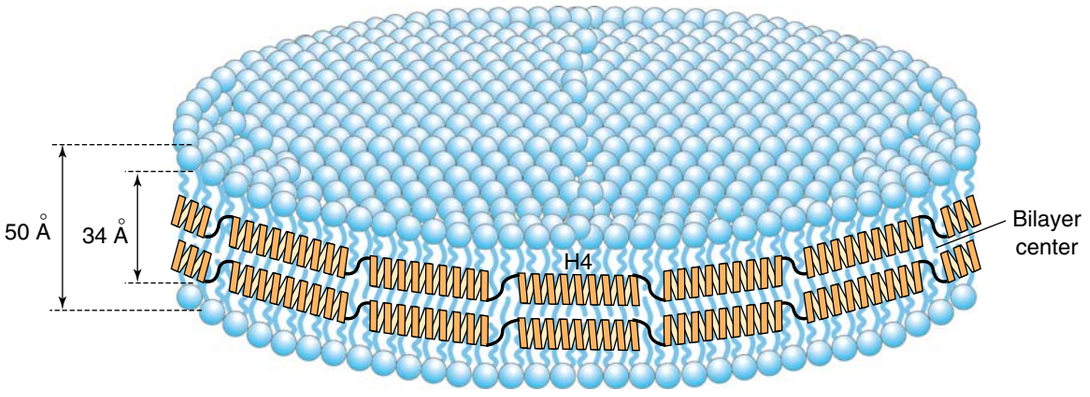

FIGURE 2-7 Putative model of apoE in rHDL. Two molecules of apoE of a total of about four molecules per discoidal particle are depicted to circumscribe the periphery of a bilayer of phospholipids. The helical axes are orientated perpendicular to the phospholipid fatty acyl chains. Adapted from [36] with permission.

Although the extracellular release of cholesterol is sometimes described as a passive 'shedding' process, in astrocytes it seems clear that cholesterol and phospholipid are mobilized from plasma membranes and that their transfer to extracellular apoE to form lipoprotein particles is facilitated by ABCA1 transporters. The mechanism for cholesterol transfer into neurons is less certain. There are seven members of the 'low-density lipoprotein receptor' (LDLR) family and they all are expressed either in developing or adult brain. They are all type I bitopic membrane receptors that uniformly incorporate a characteristic array of domains: they exhibit, extracellularly, a ligand-binding domain and between one and eight epidermal growth factor domains and, intracellularly, one or two NPxY motifs that act both as phosphotyrosine-binding domains and endocytotic signals. Two LDLRs, apoER2 and very-low-density lipoprotein receptor (VLDLR), are apoE receptors expressed on neuron plasma membranes and probably mediate HDL-lipid uptake into neurons. These same receptors interact with signaling ligands and adaptor proteins that mediate neuronal migration during brain development [13]. These signaling pathways are thought to have a role in adult brain, perhaps involving axoplasmic transport of essential components for synaptic remodeling (Chs 9, 53) and subject to damage in Alzheimer's disease (Ch. 47).

Although apoE HDL particles are formed by astrocytes *in vitro,* the brain contents of apoE knockout (–/–) were not found to differ in lipid content in comparison to those obtained from normal animals [14]. A probable explanation is that newly synthesized cholesterol can be transported from astrocyte ER to plasma membrane via an alternative route that employs caveolae to form apoA1-HDL [15].

The astrocytic cholesterol supply to neurons is important for neuronal development and remodeling. This is supported by neuronal cell culture observations [16]. Pure cultures of rat retinal ganglion cells from 8-day-old rats, in the absence of glia or serum, will extend axons and form synapses (autapses) that display low frequency postsynaptic currents. Co-culturing these neurons with glia from 2-day-old rats was observed to stimulate the formation of twice as many synapses and these exhibited about 12 times higher frequencies of postsynaptic activity. Astrocytes and oligodendrocytes, but not microglia, produced similar effects, as did replacement of the glia with glial-conditioned culture medium. ApoE was secreted by glia into their culture medium, but adding recombinant apoE to the retinal ganglion cell cultures did not stimulate the formation of synapses nor did it increase their efficacy. However both of these effects were replicated simply by adding cholesterol to the retinal ganglion cell cultures (Fig. 2-8).

Other investigators have grown similar purified preparations of retinal ganglion cells on channel-inscribed plates that cause the axons to extend linearly to permit measurement of axon elongation rates [17]. These axons will grow across siliconized barriers into side channels, which effectively isolates, externally, the axon membranes from the soma. Glial-conditioned medium was found to stimulate the axon elongation rates about 50% for several days when added to the side channels, but it had no effect if present only in the central compartments containing the neuronal soma. HDL lipoproteins, purified from glial-conditioned medium, stimulated equally well but, unlike the effects on synapses in the previous study, neither pure apoE nor cholesterol could replace the lipoprotein in stimulating axon elongation. The problem of why cholesterol is sufficient to support synapse formation but not axon elongation remains unresolved.

The stimulations of synaptic activity and of axon elongation observed in these experiments were both inhibited by RAP, an inhibitor protein selective for members of the LDLR family. These inhibitions are most readily explained as resulting from blockade of apoE-lipoprotein uptake via neuronal LDL receptors. Developing neurons can synthesize cholesterol but this capacity decreases as neurons mature. Under conditions of rapid extension of neurites, glial support may be necessary to meet the large energy demands of neuronal membrane biosynthesis (Ch. 31) and also to circumvent the limitations of endocytotic vesicle trafficking from neuronal soma to distal axons and dendrites (Ch. 9). Even in adult brain continuous cholesterol synthesis is necessary for the remodeling of synapses that is now recognized to be part of information processing (Ch. 50).

Cholesterol and sphingolipids are synthesized and transported through the ER and Golgi systems [18]. However they are present at much higher levels in the outer leaflet of plasma membranes. Adding cholesterol and sphingomyelin to synthetic lipid bilayer can produce thicker 'liquid ordered' membranes. This has led to proposals that bilayer thickness may be a factor in sorting integral membrane proteins between ER and Golgi. Liquid ordered bilayers have an 'elastic' ability to adjust their thickness as they interact with TMDs. Alkyl chain associations with hydrophobic protein residues are energetically favorable relative to interactions with more polar surfaces. This adjustment has an energetic cost that depends on the extent of bilayer deformation [19]. Because many plasma membrane integral proteins (PMIPs) are polytopic, with TMDs of varying length, the alkyl chain heterogeneity in length and unsaturation of lipid bilayers may be factors in sorting proteins into different membranes.

Mechanisms of selection of integral membrane proteins for transit through or retention by the Golgi system are largely unknown. Shortening the TMD of a plasma membrane protein was found to result in Golgi retention [20] and the converse effect occurs on lengthening the TMD of a normally retained Golgi protein [21]. The lengths of transmembrane domains for Golgi-retained proteins are usually less than for those directed to the plasma membrane.

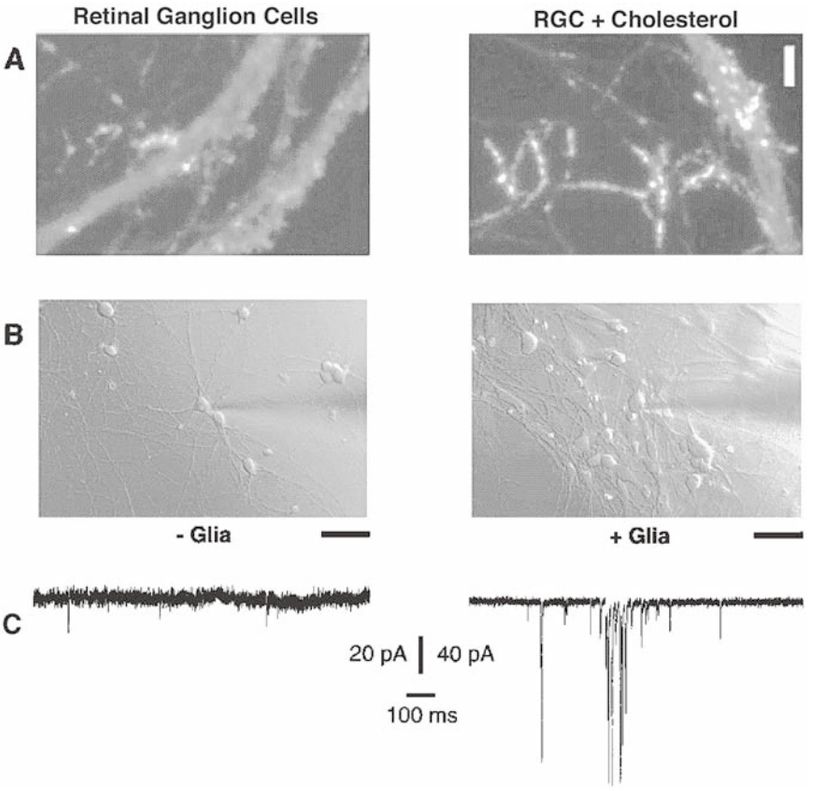

FIGURE 2-8 Cholesterol increases the number and release efficacy of synapses in single retinal ganglion cells. (**A**) Fluorescence micrographs of retinal ganglion cell synapses labeled by a synapsin I–specific antibody. The cells were cultured in the absence (left) or presence (right) of cholesterol. Scale bar = 5 µm. (Reproduced from [37] with permission.) (**B**) Hoffmann-modulation contrast micrographs of retinal ganglion cells cultured for 5 days in defined, serum-free medium in the absence (left) or presence (right) of collicular glia. Scale bar = 50 µm. The density of neurons was similar in both cultures. (**C**) Spontaneous synaptic activity in these cells: whole-cell patch-clamp recordings of spontaneous excitatory postsynaptic currents (EPSCs) at a holding potential of −70 mV. (Reproduced from [38], with permission.)

The structure and roles of membrane microdomains (rafts) in cell membranes are under intensive study but many aspects are still unresolved. Unlike in synthetic bilayers (Fig. 2-2), no way has been found to directly visualize rafts in biomembranes [22]. Many investigators operationally define raft components as those membrane lipids and proteins (a) that remain insoluble after extraction with cold 1% Triton X-100 detergent, (b) that are recovered as a low density band that can be isolated by flotation centrifugation and (c) whose presence in this fraction should be reduced by cholesterol depletion.

Much of the plasma membrane cholesterol is removed by incubating cells with β-methylcyclodextrin for several hours. Cells remain viable after this treatment but the raft fraction is reduced and it is inferred that the depleted proteins are normally associated with cholesterol-dependent lipid rafts. Some, but not all, glycosylphosphatidylinositol (GPI)-anchored proteins are recovered in the fractions defined by this procedure.

A proteomic study of the HeLa cell proteins in raft fractions, identified by these criteria and estimated by quantitative mass spectrometry, has identified 241 'authentic raft proteins' [23]. This analysis found that the 'raft proteins' most enriched relative to total membrane proteins belong to several classes of signaling protein: kinases and phosphatases, heterotrimeric G proteins and small G proteins. Notice that most of the raft proteins identified in this way are not PMIPs but rather they are proteins that associate with the cytoplasmic lipid leaflet or with cytoplasmic domains of PMIPs.

The inability to visualize rafts in biological membranes by direct optical methods suggests that they are very small and/or very transient. This has been investigated by methods such as fluorescence recovery after photolysis (FRAP), which provides information about lateral diffusion, and fluorescence resonant energy transfer (FRET), which can detect 'molecular crowding' when separation distances are less than ≈1 nm. These experiments have generally supported the existence of very small domains of restricted lateral diffusion and of protein clustering in living cell plasma membranes.

GPI-anchored proteins (GP-APs) are synthesized in the cytoplasm and their transport into the ER occurs during the process of acquiring a GPI anchor, which is ultimately sorted into the outer leaflet of plasma membranes [24]. A FRET study of fluorophore-labeled GPI-APs in cultured

cells [25] concluded that most of the GPI-APs existed as monomers in these cells but a significant fraction, 20–40%, exist as very small, dense clusters that may be a signal for endocytosis. They also suggest that the size of these GPI-AP clusters may be controlled by processes that regulate plasma membrane cholesterol.

The membrane-associated small G proteins H-Ras and K-Ras have been studied with respect to their association with cytoplasmic leaflets. These two proteins have nearly identical structures and functions but different membrane anchors, membrane distributions and effector responses. Application of the FRAP method to fluorescent constructs of H-Ras and K-Ras revealed that only H-Ras in its guanosine 5′ diphosphate (GDP)-bound form associates with cholesterol-dependent rafts [26].

In addition to fluorescence methods, another study [27] developed a method to permit electron microscopic localization of Ras anchor domains on cytoplasmic membrane surfaces by immunogold labeling. The particle neighbor distances can be analyzed to obtain information about possible domain structure. Expressing H-Ras and K-Ras in baby hamster kidney cells, a nonrandom particle distribution was obtained from which the estimated mean raft size was 7.5–22 nm and about 35% of the membrane area consists of rafts. The same technique applied to cells that had been incubated with β-cyclodextrin to reduce cholesterol produced completely random distributions of H-Ras. This cholesterol dependence suggests some type of coupling of rafts across the inner and outer membrane leaflets.

Mechanical functions of cells require interactions between integral membrane proteins and the cytoskeleton. These functions include organization of signaling cascades, formation of cell junctions and regulation of cell shape, motility, endo- and exocytosis. Several different families of membrane-associated proteins mediate specific interactions among integral membrane proteins, cytoskeletal proteins and contractile proteins. Many of these linker proteins consist largely of various combinations of conserved protein-association domains, which often occur in multiple variant copies.

In erythrocytes and most other cells, the major structural link of plasma membranes to the cytoskeleton is mediated by interactions between ankyrin and various integral membrane proteins, including Cl^-/HCO_3^- antiporters, sodium ion pumps and voltage-dependent sodium ion channels. Ankyrin also binds to the ≈100 nm, rod-shaped, antiparallel αβ heterodimers of spectrin and thus secures the cytoskeleton to the plasma membrane. Spectrin dimers self-associate to form tetramers and further to form a polygonal network parallel to the plasma membrane (Fig. 2-9D). Neurons contain both spectrin I, also termed erythroid spectrin, and spectrin II, also termed fodrin. Spectrin II is found throughout neurons, including axons, and binds to microtubules, whereas spectrin I occurs only in the soma and dendrites. This spectrin network further binds to actin microfilaments and to numerous other ligands. These associations are probably dynamic. For example, phosphorylation of ankyrin can alter its affinity for spectrin. The functions of the multiple protein-interaction domains of both spectrin and ankyrin have been as yet only partially defined (see Ch. 8).

The spectrin–ankyrin network comprises a general form of membrane-organizing cytoskeleton within which a variety of membrane–cytoskeletal specializations are interspersed. Many of these are concerned with cell-cell or cell-matrix interactions (Ch. 7). The several morphological types of cell–cell junctions are associated with junction-specific structural and linking proteins. For example, tight junctions, also termed zona occludens, are constructed of the integral membrane protein occludin, which binds the linking proteins ZO-1 and ZO-2 [15]. These linking proteins are members of a large family, termed membrane-associated guanylyl kinase homologs (MAGUKs). The general structure of this family has, distributed from the N-terminus to the C-terminus, one or more PDZ-binding domains, a src-homology-3 (SH3) domain (see Ch. 25) and a guanylyl kinase homolog domain. Other members of the PDZ family are expressed in neurons at postsynaptic densities. One of these, PSD-95, contains two N-terminal PDZ domains that can bind to a motif, –E–S/T–D–V–, that occurs in *N*-methyl-D-aspartate (NMDA) receptors. Multimeric clusters of these receptors or channels can be formed through disulfide cross-linking between cysteines of the N-terminal domains of PSD-95 molecules [28]. Different PDZ domains within a single linker protein can display different peptide motif selectivities. Accordingly, it has been suggested that a given linker protein may simultaneously bind to multiple different channels and receptors to produce complex clusters at various postsynaptic sites.

Interaction of rafts with cytoskeleton is suggested by the results of video microscopy. Brightfield video microscopy can record movements of single 40 nm gold particles on the outer surface of cells in culture. Such particles, if coated with an appropriate binding protein can bind to a component of the cell surfaces. In the experiments to be described, gold particles with fluorescein antibody were attached to fluorescein-derivatized dioleyl phosphatidyl ethanolamine under conditions designed to produce beads with predominantly single molecules attached. These were introduced into cells on coverslip cultures, and the movements of these particles were recorded with digital video and analyzed (Fig. 2-10) [29]. Fig. 2-10A shows the video trace of a single particle's movement over 10 seconds, which appears random and unstructured when recorded at 33 ms intervals. The same particle movements, when recorded at 110 μs intervals (300 times faster), reveals a path consisting of random hops from one 'confinement compartment' to another,

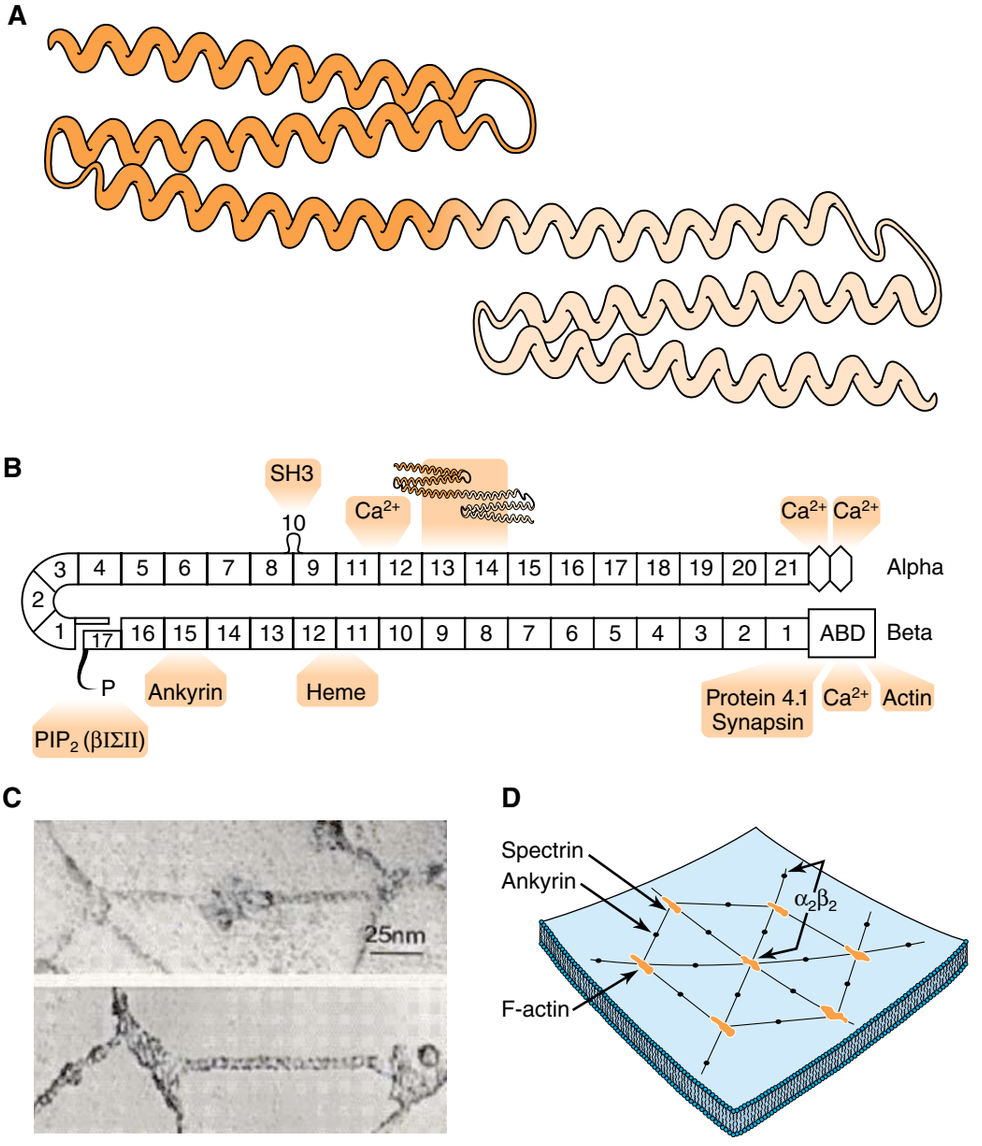

FIGURE 2-9 The ankyrin–spectrin lattice. (**A**) Structural model of a spectrin repeat unit based on the crystal structure of a dimer of the 14th repeat unit of *Drosophila* spectrin. (Adapted from [39], with permission.) (**B**) Cartoon of the domain structure of a spectrin dimer. Many of the repeat units of spectrin constitute binding domains with different specificities. Some of these have been identified and are labeled here. ABD = actin-binding domain; PIP2 = phosphatidylinositol-4,5-bisphosphate domain – occurs only on the βIΣII isoform; SH3 = src homology 3 domain. (Adapted from [40] with permission). (**C**) Electron micrographs of rotary shadowed spectrin tetramers. Note the periodic substructure of spectrin filaments and the putative site of a complex with an ankyrin molecule (top, center). (Redrawn from [41], with permission.)

usually at less than 33 ms intervals and thus only detectable at the higher speeds. Additional experiments were designed to examine the generality of this phenomenon in different cell types and to establish the structure of the confinement compartments. Compartmentation was detected in all of eight mammalian cell types examined with sizes ≈32–230 nm diameter. Prior treatment of the cells with the actin depolymerizing agent cytochalasin on average increased the compartment size approximately twofold. Treatment with an actin stabilizing agent had little effect on the compartment size but increased the median residency time approximately sevenfold. Both the size and the actin dependence suggest that the actin–spectrin network may be the source of the compartments.

Another research group has applied gold particle tracking to measure movements of the μ-opioid GPCR on the surface of GPCR-transfected fibroblasts [30]. They describe the pattern observed in Fig. 2-11 as a 'walking defined diffusion mode'. More than 90% of the observed particles displayed this pattern, which consists of rapid

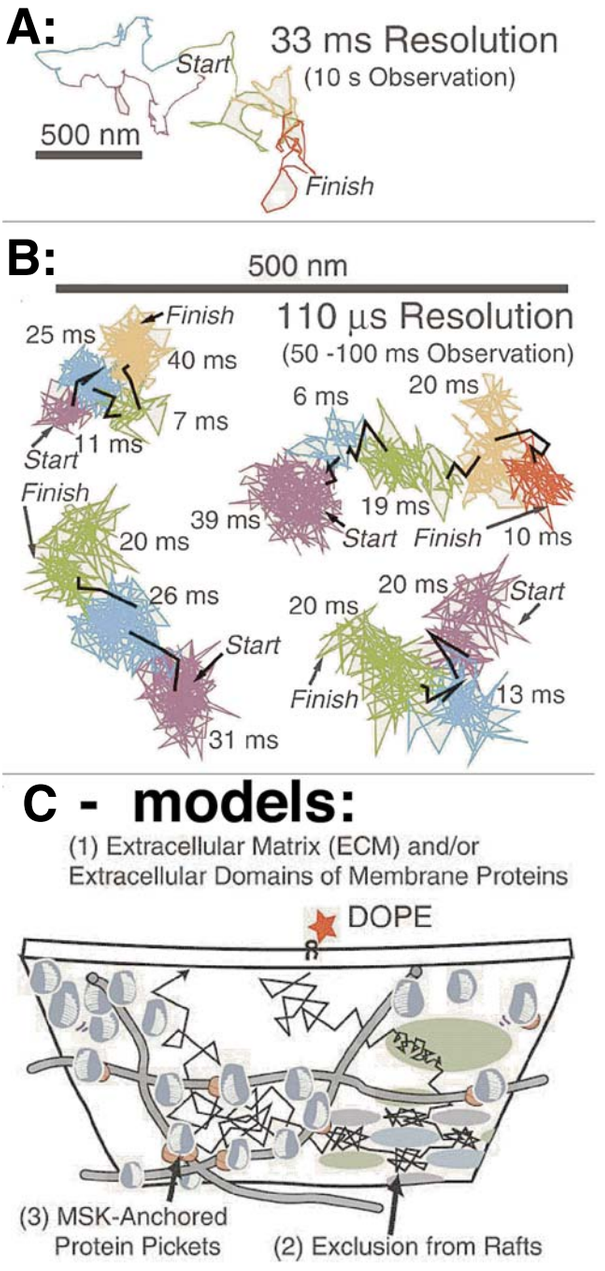

FIGURE 2-10 Tracking a gold particle attached to a single molecule of phosphatidyl ethanolamine. What appears to be simple Brownian diffusion at a time resolution of 33 ms per video frame (**A**) is revealed to actually consist of fast 'hop diffusion' by recording 300 times faster (**B**) at 110 µs per video frame. In (**A**) each color represents 60 frames = 2 seconds. In (**B**) each color indicates an apparent period of confinement within a compartment and black indicates intercompartmental hops. The residency time for each compartment is indicated. The hypothetical explanations are illustrated in part (**C**) and discussed in the text. Adapted from [29].

diffusion within a 'domain area' (with a mean size of about 150 nm) combined with a much slower (≈10-fold) drift of the whole domain.

These authors interpret their data as the natural result of restrictions imposed on the free diffusion of the labeled receptor by encounters with other transmembrane proteins in the bilayer. However they consider that their data are incompatible with the hop and skip model based on spectrin mesh confinement.

PROPERTIES OF BRAIN LIPIDS 33
Lipids have multiple functions in brain 33
Membrane lipids are amphiphilic molecules 34
The hydrophobic components of many lipids consist of either isoprenoids or fatty acids and their derivatives 34
Isoprenoids have the unit structure of a five-carbon branched chain 34
Brain fatty acids are long-chain carboxylic acids that may contain one or more double bonds 34

COMPLEX LIPIDS 34
Glycerolipids are derivatives of glycerol and fatty acids 34
In sphingolipids, the long-chain aminodiol sphingosine serves as the lipid backbone 37

ANALYSIS OF BRAIN LIPIDS 38
Chromatographic methods are employed to analyze and classify brain lipids 38

BRAIN LIPID BIOSYNTHESIS 39
Acetyl coenzyme A is the precursor of both cholesterol and fatty acids 39
Phosphatidic acid is the precursor of all glycerolipids 42
Sphingolipids are biosynthesized by adding head groups to the ceramide moiety 44

GENES FOR LIPID-SYNTHESIZING ENZYMES 44

LIPIDS IN THE CELLULAR MILIEU 46
Lipids are transported between membranes 46
Membrane lipids may be asymmetrically oriented 46
Some proteins are bound to membranes by covalently linked lipids 46
Lipids have multiple roles in cells 46

Lipids have critical roles in nervous system structure and function. Synaptic complexes and myelin are characterized by unique lipid compositions that contribute to the specialized properties of these nervous system structures. Multiple signaling pathways involving lipid intermediates regulate cell differentiation and synaptic transmission. Lipid modification of proteins is a key mechanism for modulating the activity of trophic factors and receptors. Since lipids constitute about one-half of brain tissue dry weight, it is not surprising that lipid biochemistry and neurochemistry have evolved together. Like other tissues, the brain contains phospholipids, sterols and sphingolipids. Many complex lipids, including gangliosides, cerebrosides, sulfatides and phosphoinositides, were first discovered in brain, where they are highly enriched compared to other tissues. Phospholipids account for the high total phosphorus content of brain, which led to an alchemical mystique in the 19th century that associated phosphorescence with thought and to the apocryphal claim that fish are good 'brain food' since fish, too, are rich in phosphorus.

PROPERTIES OF BRAIN LIPIDS

Lipids have multiple functions in brain. They have two principal functions in the body: as repositories of chemical energy in storage fat, primarily triglycerides, and as structural components of cell membranes. The brain contains virtually no triglyceride, so it is in their role as membrane components that brain lipids initially commanded the attention of neurochemists. Later, some biomessenger functions of nonmembrane lipids, such as steroid hormones and eicosanoids, became evident. Some membrane lipids, such as inositides and phosphatidylcholine, which were previously believed to have only a structural role, also have important functions in signal transduction across biological membranes. Cholesterol and sphingolipids play a central role in formation of lipid rafts, which function in protein trafficking and signaling at the cell

Basic Neurochemistry: Molecular, Cellular and Medical Aspects

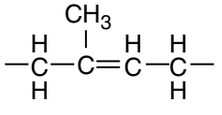
surface (see Ch. 2). In addition, lipids covalently coupled to proteins play a major role in anchoring marker proteins within biomembranes (see below). These discoveries established that lipids participate in both the function and the structure of neural membranes.

Membrane lipids are amphiphilic molecules. All membrane lipids have a small polar, or hydrophilic, and a large nonpolar, or hydrophobic, component. The hydrophilic regions of lipid molecules associate with water and water-soluble ionic compounds by hydrogen and electrostatic bonding. The hydrophobic regions cannot form such bonds and therefore associate with each other outside the aqueous phase. Depending on the relative dominance of the hydrophobic and hydrophilic regions of a given lipid molecule, these amphiphiles will form either aggregates, also termed micelles, or bilayers. Lipid molecules containing comparatively large polar groups, such as lysolipids, gangliosides and natural or synthetic detergents, which are fairly soluble in water, tend to form micelles once the solubility limit, or critical micellar concentration, is reached. Most membrane lipids tend to associate in a hydrophobic 'tail-to-tail' fashion to form bilayers (see Ch. 2).

The hydrophobic components of many lipids consist of either isoprenoids or fatty acids and their derivatives. Lipids were originally defined operationally, on the basis of their extractability from tissues with organic solvents such as a chloroform/methanol mixture, but this is no longer the sole criterion. For example, the protein component of myelin proteolipid is extractable into lipid solvents but, nevertheless, is not considered to be a lipid since its structure is that of a highly hydrophobic polypeptide. In fact, many integral membrane proteins contain 'hydrophobic' membrane-spanning regions (see Ch. 2). Conversely, gangliosides are considered to be lipids on the basis of their structure, even though they are water-soluble. It is apparent, then, that lipids are defined not only by their physical properties but also on the basis of their chemical structure. Chemically, lipids can be defined as compounds containing long-chain fatty acids and their derivatives or linked isoprenoid units. Fatty acids in lipids are either esterified to the trihydroxy alcohol glycerol or are present as amides of sphingosine, a long-chain dihydroxyamine. The isoprenoids are made up of branched-chain units and include sterols, primarily cholesterol.

Isoprenoids have the unit structure of a five-carbon branched chain. Isoprenoid units have the formula C_5H_8 and the structure:



The most abundant of these in brain is cholesterol. Unlike other tissues, normal adult brain contains virtually no cholesterol esters. Desmosterol, the immediate biosynthetic precursor of cholesterol, is found in developing brain and in some brain tumors but not in normal adult brain. Other isoprenoid substances present in brain are the dolichols, very long (up to C_{100}) branched-chain alcohols that are cofactors for glycoprotein biosynthesis; squalene, which is the linear C_{30} precursor of all steroids; and the carotenoids, including retinal and retinoic acid. Some isoprene units, such as farnesyl (C_{15}) and geranylgeranyl (C_{20}), have been shown to be covalently linked via thioether bonds to membrane proteins (see below for structures of some of these compounds and for the numbering system for cholesterol).

Brain fatty acids are long-chain carboxylic acids that may contain one or more double bonds. The brain contains a variety of straight-chain monocarboxylic acids, usually with an even number of carbon atoms ranging from C_{12} to C_{26}. The hydrocarbon chain may be saturated or may contain one or more double bonds, all in *cis* (Z) configuration. When multiple double bonds are present, they are nonconjugated and almost always three carbons apart. The unsaturated fatty acids are classified by the location of the double bond most distal from the carboxyl end. The most prevalent series, n being the number of carbon atoms in the fatty acid, are n-3 (n minus 3), n-6 and n-9. Thus, linoleic acid, which has 18 carbons (Fig. 3-1), is a member of the n-6 family because the double bond most distal from the carboxyl end is at 18-6, or the C-12 position. Since the next double bond is separated by three carbon atoms, it is between C_9 and C_{10}. A similar, widely used but nonstandard nomenclature employs the omega (ω) designation, indicating the position of the first double bond counting from the methyl (ω-carbon) end. These nomenclature conventions are convenient from both the biochemical and the nutritional points of view since fatty acids are elongated or degraded *in vivo* by two carbon units from the carboxyl end and animals need certain polyunsaturated fatty acids, termed essential fatty acids, in their diet, as discussed below and in Chapter 33. The complete shorthand notation for fatty acids consists of the number of carbon atoms followed by the number of double bonds and the position of the first double bond. Linoleic acid is thus 18:2 (n-6) or, alternatively, 18:2ω6. The brain contains some unusual fatty acids, such as very long (20–26 carbons), odd-numbered and 2-hydroxy fatty acids, prevalent in the cerebrosides. A list of major brain fatty acids with their common names and structures is given in Figure 3-1.

COMPLEX LIPIDS

Glycerolipids are derivatives of glycerol and fatty acids. Most brain glycerolipids are derivatives of phosphatidic acid (PtdOH), which is diacylated *sn*-glycerol-3-phosphate. The notation *sn* refers to stereochemical

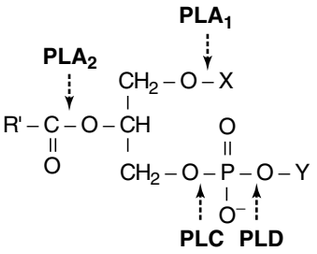
Structure	Chemical name	Trivial name	Abv.
	Dodecanoic acid	Lauric acid	12:0
	Tetradecanoic acid	Myristic acid	14:0
	Hexadecanoic acid	Palmitic acid	16:0
	Octadecanoic acid	Stearic acid	18:0
	9-Octadeceanoic acid	Oleic acid	18:1(n-9)
	9,12-Octadecadienoic acid	Linoleic acid	18:2(n-6)
	9,12,15-Octadecatrienoic acid	Linolenic acid	18:3(n-3)
	5,8,11,14-Eicosatetraenoic acid	Arachidonic acid	20:4(n-6)
	5,8,11,14,17-Eicosapentenoic acid	EPA	20:5(n-3)
	4,7,10,13,16,19-Docosahexenoic acid		22:6(n-3)
	Tetracosanoic acid	Lignoceric acid	24:0
	15-Tetracoseanoic acid	Nervonic acid	24:1(n-9)
	2-Hydroxytetracosanoic acid	Cerebronic acid	24h:0
	3,7,11,15-Tetramethylhexadecanoic acid	Phytanic acid	

FIGURE 3-1 Structures of some fatty acids of neurochemical interest (see also Fig. 3-7 and text). The 'n minus' nomenclature for the position of the double bond(s) is given here. Note that the position of the double bond from the carboxyl end can be indicated by the symbol Δ, so that linoleic acid may be also be designated as $18{:}2^{\Delta 9,12}$. The linolenic acid shown is the α isomer.

numbering, with the secondary hydroxyl group of glycerol at C-2 shown on the left, that is, the l-configuration of Fischer's projection, and the phosphate at C-3. This special nomenclature is employed because, unlike the trioses or other carbohydrates, glycerol does not have a reporter carbonyl group to assign an absolute D- or L-configuration. As shown in Figure 3-2, the hydroxyl groups on C-1 and C-2 of glycerolipids are esterified with fatty acids. The substituent at *sn*-1 is usually saturated, whereas that at *sn*-2 is unsaturated. In addition, there are lipid species in which *sn*-1 is ether-linked either to an aliphatic alcohol, termed an alkyl, or to an α,β-unsaturated alcohol, alk-1-enyl. The latter lipids are referred to as plasmalogens (Fig. 3-2). While diacylglycerophospholipids are saponifiable, that is, they contain alkali-labile ester bonds, and are acid-stable, the alkenyl ethers are alkali-stable and acid-labile. Alkyl ethers are stable to both acids and bases. A useful general term that includes all of these various aliphatic substituents, acyl, alkenyl and alkyl, is 'radyl,' for example, 1,2-diradyl-*sn*-glycerol-3-phosphorylethanolamine is a term that includes phosphatidylethanolamine (PtdEtn) as well as its plasmalogen analogs.

If positions 1 and 2 are acylated and the *sn*-3 hydroxyl group is free, the lipid is 1,2-diacyl-*sn*-glycerol (DAG). The DAGs play both a biosynthetic (see later) and a cellular regulating role in that they activate protein kinase C (PKC) (see Chs 20 and 23). In addition, DAGs can be fusogenic and have been proposed to play a role in altering cell morphology, for example, in fusion of synaptic vesicles (see Ch. 9). Other non-phosphorus-containing glycerides of interest are DAG-galactoside and its sulfate. These minor glycolipids are found primarily in white matter and appear to be analogous to their sphingosine-containing counterparts, the cerebrosides, described below.

Glycerophospholipid classes are defined on the basis of the substituent base at *sn*-3 of the diacylglycerophosphoryl (phosphatidyl) function (Fig. 3-2). The bases are short-chain, polar alcohols phosphodiester-linked to PtdOH. The amount and distribution of these lipids vary with brain regions and with age [1, 2]. In quantitatively decreasing order in adult human brain, they are PtdEtn, including plasmalogens; phosphatidylcholine (PtdCho, 'lecithin'); and phosphatidylserine (PtdSer). The phosphoinositides include phosphatidylinositol (PtdIns), phosphatidylinositol-4-phosphate (PtdIns-4-P) and phosphatidylinositol 4,5-bisphosphate (PtdIns(4,5)P_2); they are quantitatively minor phospholipids but play an important role in signal transduction. They are also abbreviated as PI, PIP and PIP_2 respectively, and are discussed in more detail, as are the phosphatidylinositide-3-phosphate (PI3P) family of inositides, in Chapter 20. The phosphatidylglycerols in brain, as in other tissues, are present in mitochondrial membranes. Of these, cardiolipin (bisphosphatidylglycerol) is the most prevalent.



Y	Lipid	Abv.
H	Phosphatidate	PtdOH
$CH_2-CH_2-\overset{+}{N}H_3$	Phosphatidylethanolamine	PtdEtn
$CH_2-CH_2-\overset{+}{N}(CH_3)_3$	Phosphatidylcholine	PtdCho
$CH_2(NH_3^+)-CH(COO^-)-H$	Phosphatidylserine	PtdSer
	Phosphatidylinositol	PtdIns
$CH_2-CH(OH)-CH_2HO$	Phosphatidylglycerol	PtdGro
Phosphatidylglycerol	Cardiolipin	PtdGroPtd

FIGURE 3-2 The structure of phosphoglycerides. In most lipids, X is acyl, that is, R–(C=O). In alkyl ethers, present mainly in brain ethanolamine phosphoglycerides (2–3%), X is a long-chain hydrocarbon (C_{16}, C_{18}). For plasmalogens, which constitute about 60% of adult human brain PtdEtn, X is 1-alk-1′enyl (i.e. –CH=CH–R). *Arrows* indicate sites of enzymatic hydrolysis of the phosphoglycerides. *PLA_1*, phospholipase A_1; *PLA_2*, phospholipase A_2; *PLC*, phospholipase C; *PLD*, phospholipase D. Note that *myo*-inositol is written in the D-configuration, where the 1′ position is linked to the PtdOH moiety. For polyphosphoinositides, additional phosphate groups are present in the 3, 4 or 5 positions. See Chapter 21 for further detail regarding the stereochemistry of inositol and the use of the turtle representation.

Each phospholipid class in a given tissue has a characteristic fatty acid composition. Though the same fatty acid may be present in a number of lipids, the quantitative fatty acid composition is different for each class of lipids and remains fairly constant during the growth and development of the brain. A typical distribution profile of the major fatty acids in rat brain phospholipids is given in Table 3.1. Not only do the phosphoglycerides differ in the structure of the polar head groups, or phospholipid classes, but within each class there are a variety of combinations of pairs of fatty acids, giving rise to molecular species that differ in the nature and positional distribution of fatty acids esterified to the glycerol backbone. For example, the 1-stearoyl, 2-arachidonyl (18:0-20:4) species is predominant in inositides, while 22:6 acids are enriched in PtdEtn and PtdSer [3]. The fatty acid substituents for a given phospholipid class isolated from white and gray matter may differ dramatically. Thus, white matter PtdEtn

TABLE 3-1 Distribution profile of the major individual molecular species in the diacylglycerol moieties of rat brain phosphoglycerides*

Fatty acid						
C-1	**C-2**	**PtdIns (mol %)**	**PtdIns4,5P_2 (mol %)**	**PtdCho (mol %)**	**PtdEtn (mol %)**	**PtdSer (mol %)**
16:0	22:6	1.4	0.1	3.3	4.8	0.8

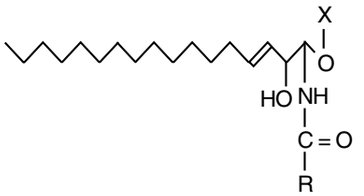
*Adapted from [3]. PtdIns, phosphatidylinositol; PtdIns(4,5)P_2, phosphatidylinositol-4,5-*bis*phosphate; PtdCho, phosphatidylcholine; PtdEtn, phosphatidylethanolamine; PtdSer, phosphatidylserine.

contains 42% 18:1 and 3% 22:6, while gray matter PtdEtn contains only 12% 18:1 and 24% 22:6 [4]. As noted below, brain lipids contain some unusually long and polyunsaturated fatty acids from both the ω3 and ω6 families of essential fatty acids, which cannot be biosynthesized in the animal body *de novo* (see also Ch. 33). This implies the existence of a mechanism for transporting essential fatty acids across the blood–brain barrier. There is considerable interest in the role of the polyunsaturated fatty acids and their metabolites in brain after breakdown of their parent phospholipids in conditions such as ischemia and anoxia (see Chs 31 and 32).

In sphingolipids, the long-chain aminodiol sphingosine serves as the lipid backbone. Sphingosine resembles a monoradyl glycerol but has asymmetric carbons at both C-2 and C-3. The chiral configuration is like that of the tetrose D-erythrose. That is, the amino group at C-2 and hydroxyl group at C-3 are in *cis* configuration (2S, 3R). Unlike unsaturated fatty acids, the double bond between C-4 and C-5 in sphingosine is in the *trans* (E) configuration. In the IUPAC-IUB nomenclature, the saturated analog of sphingosine, dihydrosphingosine or D-erythro-2-amino-1,3-octadecanediol, is termed sphinganine and sphingosine is (E-4) sphingenine. While in most sphingolipids the sphingosine is 18 carbons long, in brain gangliosides there is a significant representation of the C_{20} homolog.

The amino group of sphingosine is acylated with long-chain fatty acids and the *N*-acylated product is termed a ceramide (Fig. 3-3). C-1 of ceramide is linked to different head groups to form various membrane lipids. For example, sphingomyelin is the phosphodiester of ceramide and choline. The fatty acids in sphingomyelin have a bimodal distribution: in white matter they are mostly 24 carbons long (lignoceric and nervonic) while in gray matter stearic acid (18:0) predominates (see Table 3.1). Most of the glycolipids in brain consist of ceramide glycosidically linked at C-1 with different mono- or polysaccharides. The major glycolipid of mammalian brain is galactocerebroside, in which galactose is β-glycosidically linked to ceramide; it constitutes about 16% of total adult human brain lipid. Sulfatide is galactocerebroside esterified to sulfate at the 3 position of galactose and constitutes about 6% of brain lipid. Cerebrosides are present mainly in brain white matter, especially in myelin, and generally contain very-long-chain normal (lignoceric and nervonic), α-hydroxy (cerebronic) and odd-numbered fatty acids, such as 23:0 and 23h:0. Myelin is a specialized plasma membrane that surrounds nerve processes and is elaborated by oligodendroglial cells in the CNS and by Schwann cells in the peripheral nervous system (see Chs 1 and 4). A number of neurological disorders appear to involve selectively myelin (Ch. 38). Brain also contains many other glycolipids that are polysaccharide derivatives of glucocerebroside (Cer-Glc). Many monosaccharides, such as galactose (Gal), glucose (Glc), *N*-acetylglucosamine (GlcNAc), *N*-acetylgalactosamine (GalNAc), fucose and others, are present in various linkages in these carbohydrate head groups. One important carbohydrate is sialic acid, or *N*-acetyl (or *N*-glycolyl)-neuraminic acid (NANA), an *N*-acylated, nine-carbon amino sugar (Fig. 3-4B)



X	Lipid	Abv.
H	Ceramide	Cer
O^- $P-O-CH_2CH_2\overset{+}{N}(CH_3)_3$ O	Sphingomyelin	CerPCho
CH_2OH HO O OH OH	Galactocerebroside	CerGal
CH_2OH O OH OH OH	Glucocerebroside	CerGlc
Lactose (Glc-Gal)	Lactosylceramide	CerLac

FIGURE 3-3 Structure of some simple sphingolipids. X may be a complex polysaccharide either containing sialic acid (gangliosides) or not (globosides). See also Figures 3-4 and 3-9 for the nomenclature and structure of some of the complex brain sphingolipids.

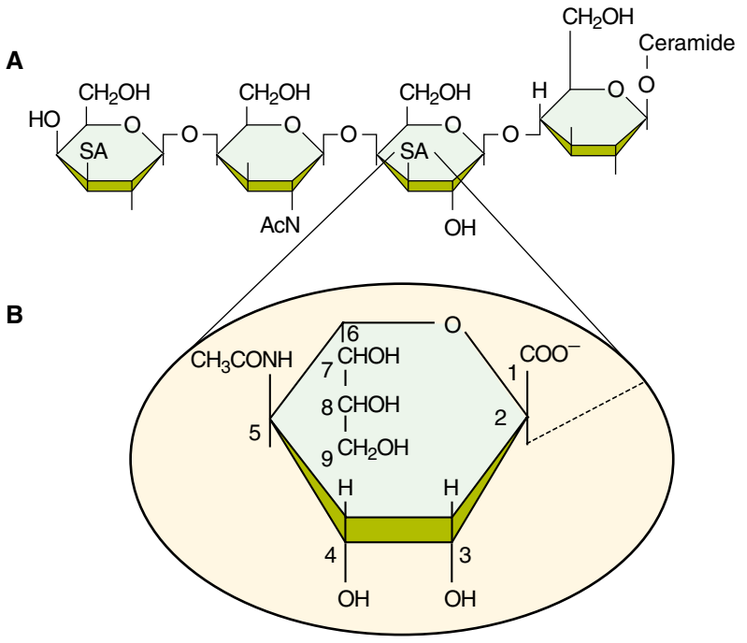


FIGURE 3-4 (**A**) The structure of a major brain ganglioside, which is termed GD1a according to the nomenclature of Svennerholm. G denotes ganglioside, D indicates disialo, 1 refers to the tetrasaccharide (Gal-GalNac-GalGlc-) backbone and a distinguishes positional isomers in terms of the location of the sialic acid residues (see also Fig. 3-9). In IUPAC-IUB nomenclature, this ganglioside is termed IV^{3}NeuAc,II^{3}NeuAc-Gg$_4$Cer, where the roman numerals indicate the sugar moiety (from ceramide) to which the sialic acids (NeuAC) are attached and the arabic numeral superscript denotes the position in the sugar moiety where NeuAC are attached; Gg refers to the ganglio (Gal-GalNAc-Gal-Glc) series and the subscript 4 to the four-carbohydrate backbone for the 'ganglio' series. (**B**) The structure of sialic acid, also called *N*-acetyl neuraminic acid (NeuAc or NANA). Human brain gangliosides are all *N*-acetyl derivatives; however, some other mammalian, such as bovine, brain may contain the *N*-glycolyl derivatives. The metabolic biosynthetic precursor for sialylation of glycoconjugates is CMP-sialic acid, forming the phosphodiester of the 5′OH of cytidine and the 2-position of neuraminic acid.

containing a free carboxyl group. NANA is enzymatically formed by condensation of *N*-acetyl (or *N*-glycolyl)-mannosamine with phosphoenolpyruvate. The sialic acid-containing glycolipids contain a free carboxylic group and are termed gangliosides. Many gangliosides have been identified in neural and other tissues, and their classification and nomenclature are somewhat complex. Svennerholm classified the gangliosides according to the number of sialic acid residues present in the molecule and its relative migration rate on thin-layer chromatograms (Fig. 3-5). IUPAC-IUB has proposed a different systematic nomenclature for both gangliosides and neutral glycolipids, or globosides. The structure and nomenclature of a major brain ganglioside are given in Figure 3-4A (see below for other gangliosides).

ANALYSIS OF BRAIN LIPIDS

Chromatographic methods are employed to analyze and classify brain lipids. The lipids from brain are generally extracted with a mixture of chloroform and methanol using variations of a method originally described by Folch *et al.* In most procedures, the tissue or homogenate is treated with 19 volumes of a 2:1 (v/v) mixture of chloroform methanol. A single liquid phase is formed, leaving behind a residue of macromolecular material, primarily protein, with lesser amounts of DNA, RNA and polysaccharides. The subsequent addition of a small amount of water to the $CHCl_3$-methanol extract leads to separation into chloroform-rich and aqueous methanol phases; the lower chloroform phase contains the lipids, whereas low-molecular-weight metabolites and polar lipids, such as gangliosides, are in the upper phase. If the lower phase is evaporated to dryness and taken back up in a lipid solvent such as chloroform, proteolipid protein remains undissolved and can be removed at this point. Gangliosides can be extracted from the aqueous phase by repartitioning into an apolar solvent. Acidic phospholipids such as the polyphosphoinositides are poorly extracted at neutral pH, so it is necessary to acidify the initial chloroform methanol mixture for their recovery [6]. Unfortunately, the acidity leads to cleavage of plasmalogens, primarily alkenyl-acyl PtdEtn. There is thus no single procedure that results in quantitative recovery of all brain lipids. Lipid classes are separated from a lipid extract by thin-layer chromatography (TLC), ion-exchange chromatography or high-performance liquid chromatography (HPLC) using silicic acid as the stationary phase. For analysis of individual fatty acids in a given lipid class,

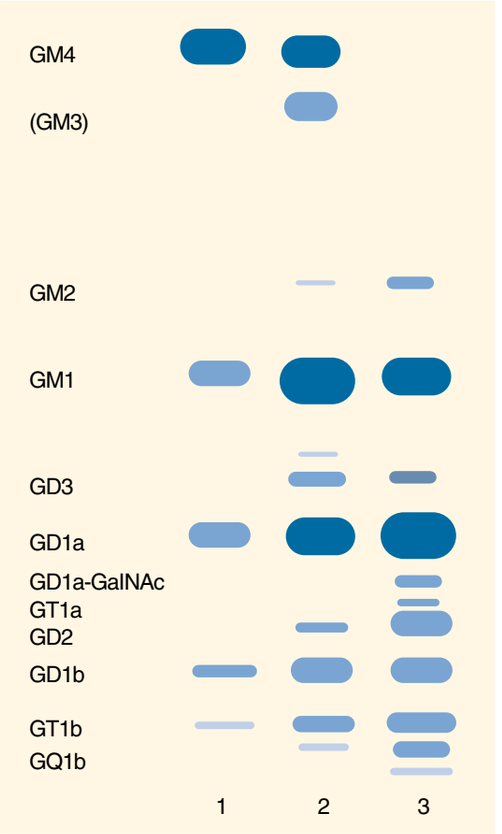

FIGURE 3-5 Diagrammatic representation of thin-layer chromatograms of gangliosides from normal human white matter (*lane 2*) and gray matter (*lane 3*). *Lane 1* contains a mixture of isolated standards. Each lane contains about 7 µg sialic acid. Merck precoated HPTLC plates (silica gel 60, 200 µm thick) were used. The plate was developed with chloroform–methanol–water, 60:40:9 (containing 0.02% $CaCl_2 \cdot 2H_2O$). The bands were visualized with resorcinol–hydrochloric acid reagent. See legend to Figures 3-4 and 3-9 for nomenclature. (Courtesy of R. K. Yu, see also Yu and Ando [5].)

methyl esters can be prepared directly by alkaline methanolysis of extracted lipid bands scraped from TLC plates following visualization, usually with a fluorescent spray. The amide-bound fatty acids of the sphingolipids require more vigorous conditions of methanolysis, such as treatment with hot HCl methanol. The methyl esters are then separated by gas–liquid chromatography (GLC). The molecular species can also be separated by reverse-phase HPLC. For this purpose, a reporter group, such as the ultraviolet-absorbing benzoyl group, can be attached either directly to the lipids in the carbohydrate portion of glycolipids or to the DAG backbone of lipid after hydrolysis of the polar head group [3]. In this method, separation of the derivatized DAGs is achieved on the basis of their differences in hydrophobicity. Gangliosides are separated from each other by HPTLC, as shown in Figure 3-5.

The lipid composition of mammalian brain analyzed by these methods is found to change with age and is different from one region to another [1]. A typical lipid composition of gray and white matter in adult human brain is given in Table 3-2.

Recently, a quantitative electrospray ionization/mass spectrometry method (ESI/MS) has been developed to analyze the molecular profile, or 'lipidome' of different lipid classes in very small samples. In this method, total lipid extracts from tissues or cultured cells can be directly analyzed. By manipulating the ionization method, the mass spectrographs of polar or even non-polar lipids can be obtained [8]. This method and the use of lipid arrays allow precise and quantitative identification of the lipid profile of a given tissue, and map functional changes that occur.

BRAIN LIPID BIOSYNTHESIS

Acetyl coenzyme A is the precursor of both cholesterol and fatty acids. The hydrophobic chains of lipids, that is, fatty acids and isoprenoids, are biosynthesized from the same two-carbon donor, acetyl coenzyme-A (acetyl-CoA), with differences in condensation leading to different products. In cholesterol biosynthesis, two acetyl-CoAs are condensed to form acetoacetyl-CoA, which can be further condensed with a third acetyl-CoA to form a C_6 branched-chain dicarboxylic acyl-CoA, termed β-hydroxy-β-methyl-glutaryl (HMG)-CoA. HMGCoA is reduced by $2NADPH^+$ to form mevalonic acid, and this reduction is catalyzed by the enzyme HMGCoA reductase, the principal regulatory enzyme for the biosynthesis of isoprenoids [9]. Mevalonic acid undergoes pyrophosphorylation by two consecutive reactions with ATP, and the product is decarboxylated to form isopentenyl pyrophosphate. This C_5H_8 isoprene unit is the building block of all isoprenoids. Two isoprene units, isopentenyl pyrophosphate and dimethyl allyl pyrophosphate, condense to form geranyl pyrophosphate (C_{10}), which then condenses with another C_5 unit to form farnesyl pyrophosphate (C_{15}), the precursor of many different isoprenoids, such as dolichol, a very-long-chain (up to C_{100}) alcohol; a redox coenzyme, ubiquinone; and cholesterol. Polyisoprenyl pyrophosphates also alkylate some proteins via a thioether bond, which bonds them to biomembranes (see below). During cholesterol biosynthesis, two farnesyl pyrophosphate molecules reductively condense in a head-to-head manner to form squalene, a C_{30} hydrocarbon. Squalene is oxidatively cyclized to form lanosterol, a C_{30} hydroxysteroid. After three demethylations, lanosterol is converted to cholesterol (C_{27}). An outline of the pathway of biosynthesis of cholesterol is shown in Figure 3-6. Once formed, brain cholesterol turns over very slowly, and there is both metabolic and analytic evidence to indicate an accretion of brain cholesterol with age.

Fatty acids are biosynthesized via elongation of C_2 units. Here, acetyl-CoA is carboxylated by bicarbonate to form

TABLE 3-2 Lipid composition of normal adult human brain*

*Modified from Suzuki [7].

†Phospholipid fractions include plasmalogen, assuming that all plasmalogen is present as PtdEtn. Ratios of PtdEtn to PtdCho are 4:1 in white matter and 1:1 in gray matter. In intact brain (based on analysis of rapidly microwaved rat brain), phosphoinositides are present in both white and gray matter in the ratio of 5:0.3:1 for phosphatidylinositol (PtdIns) phosphatidylinositol-4-phosphate (PtdIns4P_2), phosphatidylinositol-4,5-bisphosphate (PtdIns4,5P_2). Gangliosides are calculated on the basis of total sialic acid, assuming that sialic acid constitutes 30% of the weight of a typical ganglioside; GD_{1a} is the major ganglioside of both gray and white matter. PtdEtn, phosphatidylethanolamine; PtdCho, phosphatidylcholine; PtdSer, phosphatidylserine.

malonyl-CoA, which then condenses with an acyl-CoA to form a β-ketoacyl-CoA and CO_2. This release of CO_2 (HCO_3^-) drives the reaction forward and elongates the chain by acetyl units. The ketone group is then enzymatically reduced, dehydrated and hydrogenated, resulting in an acyl-CoA that is two carbons longer than the parent acyl-CoA. NADPH acts as the reducing agent for the reduction of both the ketone group and the double bond. All four reactions, condensation, reduction, dehydration and hydrogenation, are carried out by fatty acid synthase, a large, multifunctional, dimeric enzyme. This cycle is repeated until the proper chain length (>C_{12}) is attained, after which the fatty acid is hydrolyzed from its thioester link with the enzyme. Preformed or exogenous fatty acids are extended by a similar mechanism and catalyzed by enzyme(s) present in the endoplasmic reticulum [10]. There is also a minor mitochondrial chain-elongation system in which acetyl-CoA rather than malonyl-CoA is utilized to lengthen the fatty acid chain. Fatty acids are converted to unsaturated fatty acids mainly in the endoplasmic reticulum. Fatty acyl-CoA desaturases, of which Δ^9-desaturases are most active, remove two hydrogens from the CH_2 CH_2 groups of long-chain intermediates, such as octadecanoyl-CoA, by oxidizing them with molecular oxygen. In brain, this enzyme is responsible for the conversion of stearic acid (18:0) to oleic acid (18:1ω9) and palmitic acid (16:0) to palmitoleic acid (16:1ω7) (see Fig. 3-1). The electrons are transferred via cytochrome b_5 which in turn is reduced to NADH via cytochrome b_5 reductase. In brain, polyunsaturated fatty acids, such as arachidonic (20:4ω6) and docosahexenoic acids (22:6ω3), are major phospholipid components. They are formed by chain elongation and desaturation of shorter-chain fatty acids (Fig. 3-7). In animals, additional double bonds can be introduced only between an existing double bond and the fatty acid carboxyl group. For example, stearic acid (18:0) is converted to oleic acid (18:1ω9) in brain but cannot be further converted to linoleic acid (18:2ω6). This means that the fatty acids of the ω3 and ω6 series can be obtained only via dietary sources, mainly from plants. They are termed 'essential fatty acids' and have important physiological roles. If the ω3 and ω6 precursors are not available in the diet, then ω9 fatty acids are further chain-elongated and desaturated to form abnormal fatty acids, as a compensatory response of the brain. One of these is 20:3ω9 (Fig. 3-7), termed 'Mead acid' after its discovery by James Mead in the tissues of animals fed a fat-free diet over extended periods. Mead acid substitutes for arachidonic acid and, like arachidonic acid in normal animals, is enriched in the inositides of essential fatty acid-deficient animals.

Fatty acids are degraded by two-carbon units in a reverse manner analogous to their biosynthesis. The acyl-CoAs are first dehydrogenated to α,β-unsaturated acyl-CoA, and then hydrated to β-hydroxyacyl-CoA, followed by oxidation to β-ketoacyl-CoA. The C–C bond between C-2 and C-3 of the latter compound is broken by a free CoA molecule via thiolysis to form an acyl-CoA that is two carbons shorter and acetyl-CoA. Unlike fatty acid biosynthesis, each step of the β oxidation of fatty acids is

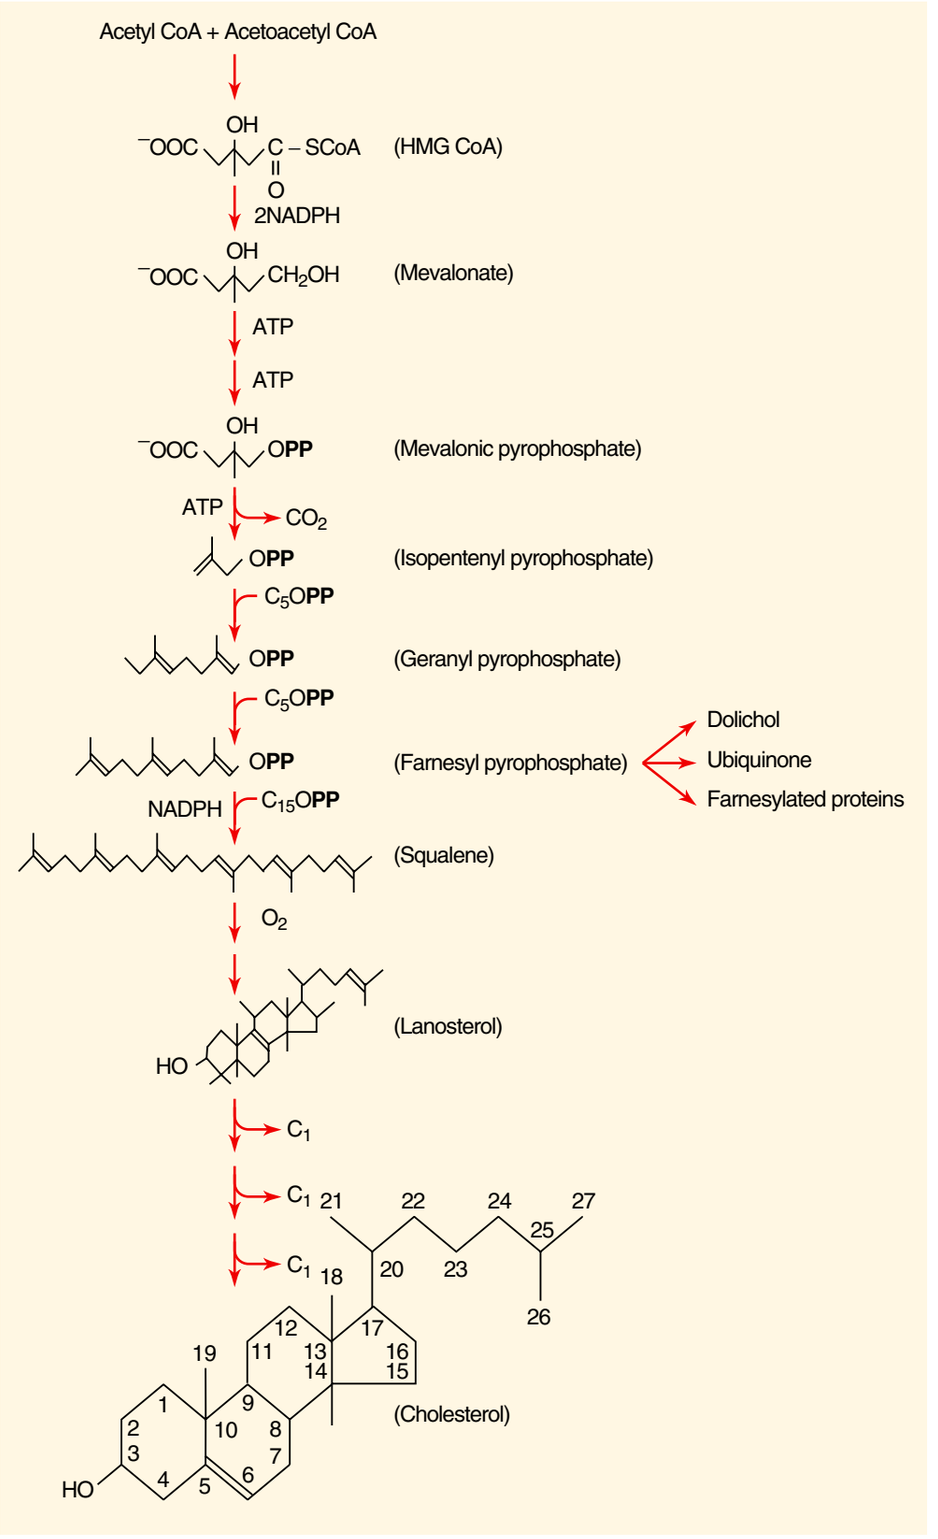

FIGURE 3-6 Pathways of biosynthesis of isoprenoids.

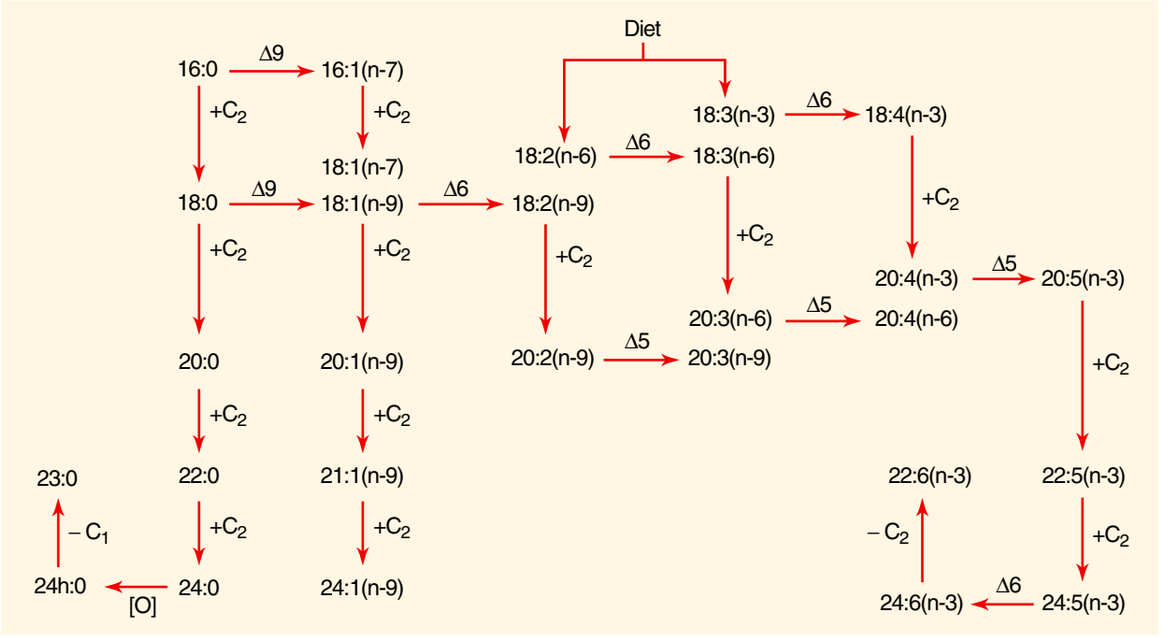

FIGURE 3-7 Pathways for the interconversion of brain fatty acids. Palmitic acid (16:0) is the main end product of brain fatty acid synthesis. It may then be elongated, desaturated, and/or β-oxidized to form different long chain fatty acids. The monoenes (18:1 Δ^7, 18:1 Δ^9, 24:1 Δ^{15}) are the main unsaturated fatty acids formed de novo by Δ^9 desaturation and chain elongation. As shown, the very long chain fatty acids are α-oxidized to form α-hydroxy and odd numbered fatty acids. The polyunsaturated fatty acids are formed mainly from exogenous dietary fatty acids, such as linoleic (18:2, n–6) and α-linoleic (18:2, n–3) acids by chain elongation and desaturation at Δ^5 and Δ^6, as shown. A Δ^4 desaturase has also been proposed, but its existence has been questioned. Instead, it has been shown that unsaturation at the Δ^4 position is effected by 'retroconversion' i.e. Δ^6 unsaturation in the endoplasmic reticulum, followed by one cycle of β-oxidation (–C2) in peroxisomes [11]. This is illustrated in the biosynthesis of DHA (22:6, n–3) above. In severe essential fatty acid deficiency, the abnormal polyenes, such as 20:3, n–9 are also synthesized *de novo* to substitute for the normal polyunsaturated acids.

catalyzed by a distinct enzyme. These are present both in mitochondria and in peroxisomes. Though the biochemical steps are similar in the two cellular compartments, there are some differences between peroxisomal and mitochondrial β-oxidation pathways. In mitochondria, the first dehydrogenation is carried out by an FAD-containing enzyme, which is coupled to oxidative phosphorylation, thus generating ATP. In peroxisomes, however, this dehydrogenation is carried out by a flavin-containing oxidase, which reacts directly with molecular oxygen to form H_2O_2, which is further decomposed by peroxisomal catalase to H_2O and O_2, thus wasting the chemical energy. Two separate mitochondrial enzymes, enoyl-CoA hydratase and β-hydroxy acyl-CoA dehydrogenase, catalyze the next two reaction steps, while in peroxisomes both the reactions are catalyzed by a single multifunctional enzyme protein. The peroxisomal β-oxidation pathway is probably responsible for the oxidation of very-long-chain fatty acids (>C_{22}), which are enriched in brain. Evidence for this is provided by a number of genetic diseases involving peroxisomal disorders, such as Zellweger's cerebrohepatorenal syndrome and adrenoleukodystrophy, in which there is an accumulation of such very-long-chain fatty acids [12], especially in neural tissues (see Ch. 41).

In addition to the classical β oxidation of fatty acids, known to occur in all tissues, significant α oxidation, especially of the fatty acids of galactocerebroside, occurs in brain. In this reaction, carbon 2, termed the α carbon, of a long-chain fatty acid is hydroxylated, then oxidized and decarboxylated to form a fatty acid one carbon shorter than the parent fatty acid. This quantitatively minor α-hydroxylation pathway may explain the origins of both the comparatively large amounts of odd carbon fatty acids and of 2-hydroxy fatty acids in brain galactocerebrosides. Another α-oxidation pathway normally present in liver and other tissues is defective in the genetic disorder Refsum's disease. This results in the failure to metabolize the dietary branched-chain fatty acid phytanic acid (see Fig. 3-1), which can be initially metabolized only by ω oxidation in these patients [13]. In Refsum's disease, this branched-chain fatty acid accumulates in nervous tissues, resulting in severe neuropathy (see Ch. 41)

Phosphatidic acid is the precursor of all glycerolipids. *sn*-Glycerol-3-phosphate (G-3-P), formed from the reduction of dihydroxyacetone phosphate (DHAP) by NADH catalyzed by glycerophosphate dehydrogenase, is consecutively acylated with two acyl-CoAs to form PtdOH. Alternatively, DHAP may be first acylated then reduced by NADPH to lysophosphatidate, or 1-acyl-GP, which is further acylated to form PtdOH. Acyl DHAP is also the precursor of ether lipids. The ether bond is formed in a

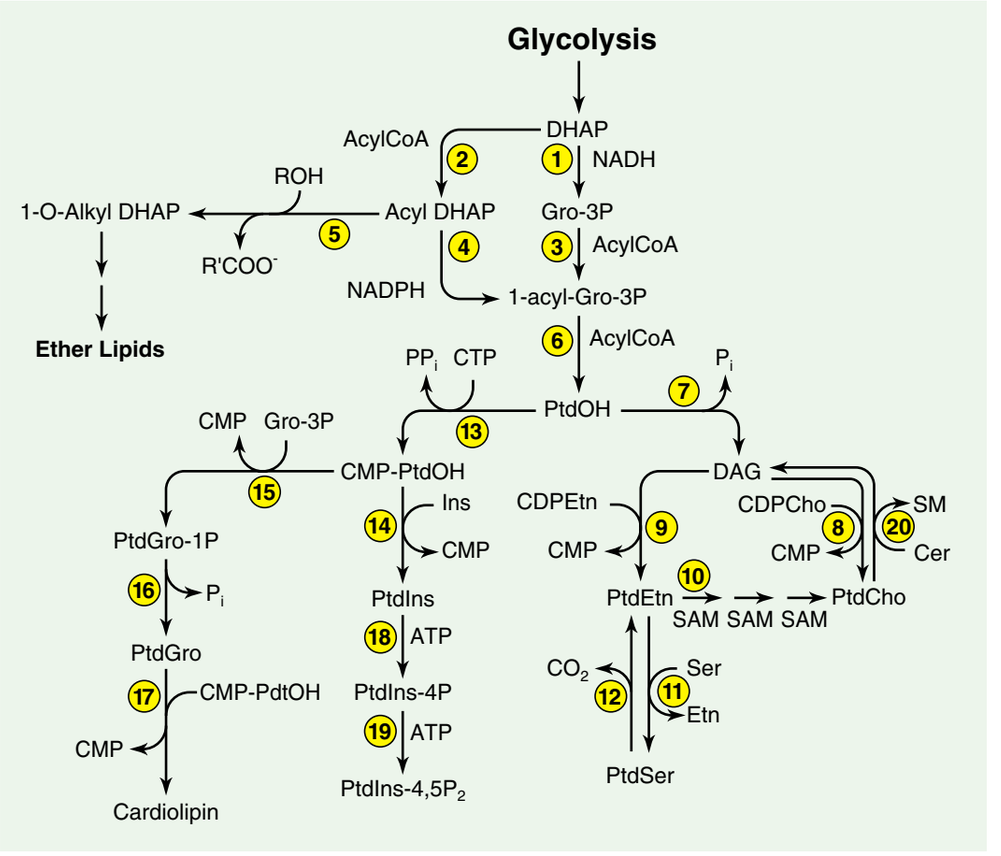

FIGURE 3-8 Schematic representation of glycerophospholipid biosynthesis. Note that dihydroxyacetone phosphate (*DHAP*) may be reduced to glycerophosphate or may be first acylated and then serve as a precursor of ether lipid. The alkyl analog of phosphatidic acid (i.e. 1-*O*-alkyl,2-acyl-*sn*-glycerol-3-P) is converted to the alkyl analog of phosphatidylethanolamine (*PtdEtn*) by the same diacylglycerol (*DAG*) pathway as shown for the diacyl lipids, and the alkyl analog of PtdEtn is dehydrogenated to form the 1-alk-1′enyl analog of PtdEtn, plasmalogen (not shown). As mentioned in the text, phosphatidic acid (*PtdOH*) is converted to DAG, which is converted to the major brain lipids phosphatidylcholine (*PtdCho*) and PtdEtn. The acidic lipids are formed via the conversion of PtdOH to CDP-DAG (CMP-PtdOH). PtdCho and PtdEtn are interconverted either via methylation or via base-exchange reactions to phosphatidylserine (*PtdSer*). Not only PtdEtn (as shown) but also PtdCho is converted to PtdSer by base-exchange reaction. Exchange of the head group of PtdCho with ceramide to form sphingomyelin is also shown. The enzymes catalyzing lipid biosynthesis are as follows: *1*, glycerophosphate dehydrogenase; *2*, dihydroxyacetone phosphate acyltransferase; *3*, *sn*-glycerol-3-phosphate acyltransferase; *4*, acyl/alkyl dihydroxyacetone phosphate reductase; *5*, alkyl dihydroxyacetone phosphate synthase; *6*, 1-acyl glycerol-3-phosphate acyltransferase; *7*, phosphatidate phosphohydrolase; *8*, diacylglycerol cholinephosphotransferase; *9*, diacylglycerol ethanolaminephosphotransferase; *10*, phosphatidylethanolamine *N*-methyl transferase and phosphatidyl-*N*-methylethanolamine *N*-methyl transferase; *11*, phosphatidylethanolamine:serine transferase; *12*, phosphatidylserine decarboxylase; *13*, phosphatidate cytidyltransferase; *14*, phosphatidylinositol synthase; *15*, CDP-DAG:glycerol-3-phosphate phosphatidyltransferase; *16*, phosphatidylglycerol phosphatase; *17*, cardiolipin synthase; *18*, phosphatidylinositol-4-kinase; *19*, phosphatidylinositol-4-phosphate 5-kinase; *20*, phosphatidylcholine:ceramide cholinephosphotransferase.

reaction where the acyl group of acyl DHAP is substituted by a long-chain alcohol to form 1-*O*-alkyl DHAP, which is then reduced and converted to 1-alkyl,2-acyl-*sn*-G-3-P, and which is in turn converted to the alkyl ether analog of PtdEtn, the precursor of Ptd-Etn plasmalogen (Fig. 3-8).

Phosphatidate may be hydrolyzed to 1,2-diacyl-*sn*-glycerol (DAG), which is the precursor of the zwitterionic membrane lipids PtdCh, PtdEtn and PtdSer. PtdCho is formed by the transfer of the phosphocholine group from CDP-choline to DAG, and PtdEtn is formed by a corresponding transfer of the head group from CDP-ethanolamine. The enzymes catalyzing the synthesis of CDP-choline and CDP-ethanolamine regulate the overall biosynthesis of PtdCho and PtdEtn. In a minor alternative pathway, Ptd-Etn is converted to PtdCho by sequential methylations, the methyl donor being *S*-adenosylmethionine. In animals, there is no direct pathway for the formation of PtdSer. PtdSer is formed in brain by a base-exchange reaction between Ptd-Etn, or PtdCho, and serine. PtdSer is in turn decarboxylated in mitochondria to form PtdEtn [14].

The acidic phospholipids are synthesized by a completely different pathway, in which the phosphate group in PtdOH is retained in the product. In this scheme, PtdOH is converted to the liponucleotide CMP-PtdOH (CDP-DAG) (Fig. 3-8). CDP-DAG reacts with inositol to form PI

or with *sn*-glycerol-3-phosphate (Gro3-P) to form phosphatidyl glycerophosphate, which is then converted to cardiolipin (bisphosphatidylglycerol), a mitochondria-specific phospholipid. PI is phosphorylated in the inositol moiety to form PIP, which is an intermediate in a pathway that mediates signal transduction across membranes (see Ch. 20). The pathways from brain phospholipid biosynthesis, including the enzymes that catalyze each step, are summarized in Figure 3-8.

The newly biosynthesized phosphoglycerides undergo deacylation to the corresponding lysolipids, which can be further degraded or reconverted to the parent lipids by reacylation, often with a different fatty acyl substitute. The reacylation of lysolipids occurs by transferring acyl groups from acyl-CoAs or from other phospholipids either by CoA-dependent or CoA-independent acyltransferase. The acyltransferase(s) catalyzing the reacylation reactions is very specific toward the acyl donor and lysolipid substrates. It is thought that the specific distribution of fatty acids in each individual class of membrane phosphoglycerides is regulated by these 'deacylation–reacylation' mechanisms. Thus, the initial fatty acid composition of a biosynthesized lipid may not reflect its ultimate composition.

Most of the enzymes catalyzing the biosynthesis of glycerolipids are bound to endoplasmic reticular membranes, although those catalyzing the biosynthesis of cardiolipin are mitochondrial. The acyl-DHAP pathway enzymes, obligatory for the synthesis of ether lipids, are in peroxisomes [15], a finding that explains the deficiency of ether lipids in patients suffering from genetic peroxisomal disorders, as noted above.

The phosphoglycerides are hydrolyzed by specific phospholipases, as indicated in Figure 3-2. The acyl groups at C-1 and C-2 are hydrolyzed by phospholipases A_1 and A_2 (PLA_1, PLA_2), respectively. The presence of PLA_1 in brain is inferential. The head groups are hydrolyzed by class-specific phospholipases. Thus, PtdCho and PI are cleaved by different phospholipases. The bond between DAG and phosphate is hydrolyzed by PLC, whereas that between the phosphate and the polar alcohol is hydrolyzed by phospholipase D. These enzymes can be important not only for the catabolism of these lipids but also for the generation of biological signal-transduction-messenger lipid products, such as DAG or arachidonic acid (see Ch. 20). Many of these enzymes are regulated, indirectly or directly, by cell-surface receptors. The brain also contains specific hydrolases, plasmalogenase and lysoplasmalogenase, which catalyze the hydrolysis of the alkenyl ether bond to form long-chain aldehydes and lysolipids or glycerophosphorylethanolamine, respectively.

Sphingolipids are biosynthesized by adding head groups to the ceramide moiety. Sphinganine, also termed dihydrosphingosine, is biosynthesized by a decarboxylating condensation of serine with palmitoyl-CoA to form a keto intermediate, which is then reduced by NADPH (Fig. 3-9). Sphinganine is acylated, then dehydrogenated to form ceramide. Free sphingosine, also termed sphingenine, 'salvaged' from sphingolipid breakdown can be enzymatically acylated with acyl-CoA to form ceramide.

Ceramide is the precursor of all sphingolipids; sphingomyelin is formed by a reaction that transfers the head group of PtdCho to ceramide to form sphingomyelin and DAG (Figs 3-8, 3-9), while sphingosine-containing glycolipids are formed from consecutive glycosylation of ceramide by various nucleotide carbohydrate derivatives. For example, galactocerebroside is formed by glycosylation of ceramide with UDPGal, whereas glucocerebroside is formed by glycosylation of ceramide with UDPGlc [16]. The latter, Cer-Glc, is the precursor of neutral glycolipids, also termed globosides, and acidic glycolipids, also termed gangliosides. The CMP derivative of the *N*-acetyl (or *N*-glycolyl) neuraminic acid NANA, or NeuAc, is the donor of this moiety to form gangliosides. Some of the reactions forming these complex glycolipids are shown in Figure 3-9. The specificity of these membrane-bound glycosyl transferases toward the lipid substrate and to the water-soluble nucleotide derivatives determine the structures of the products.

These same glycolipids are broken down by specific hydrolases present in lysosomes and stimulated by non-catalytic lysosomal proteins. A congenital deficiency of either one of the hydrolases or in the helper proteins results in the accumulation of lipid intermediates in lysosomes, leading to a lysosomal storage disease. For example, in Gaucher's disease, Cer-Glc accumulates because of a defect in its hydrolysis, whereas in Tay–Sachs disease, the GM2-ganglioside concentration is increased because of a deficiency in the hydrolase releasing *N*-acetylgalactosamine (see Ch. 41).

GENES FOR LIPID-SYNTHESIZING ENZYMES

Because of interest in these genetic diseases, genes coding for a number of these hydrolytic enzymes have been identified and cloned. Progress has also been made in the elucidation of genes coding for biosynthetic enzymes, including several transferases in the pathway for ganglioside formation and the UDP-galactosyltransferase that leads to cerebroside formation (see Ch. 4). In recent years, dozens of genes coding for enzymes catalyzing synthesis of cholesterol, phospholipids, galactolipids and gangliosides have been cloned. In pathways for phospholipid synthesis, the DNA coding for the key enzyme CDP-DAG synthase has been cloned from a human cell line [17].

Mutant or knockout mice defective in specific enzymes involved in lipid synthesis have provided powerful tools for genetic analysis of lipid function in the nervous system. For example, disruption of the genes for ceramide galactosyl transferase or galactosyl ceramide sulfotransferase,

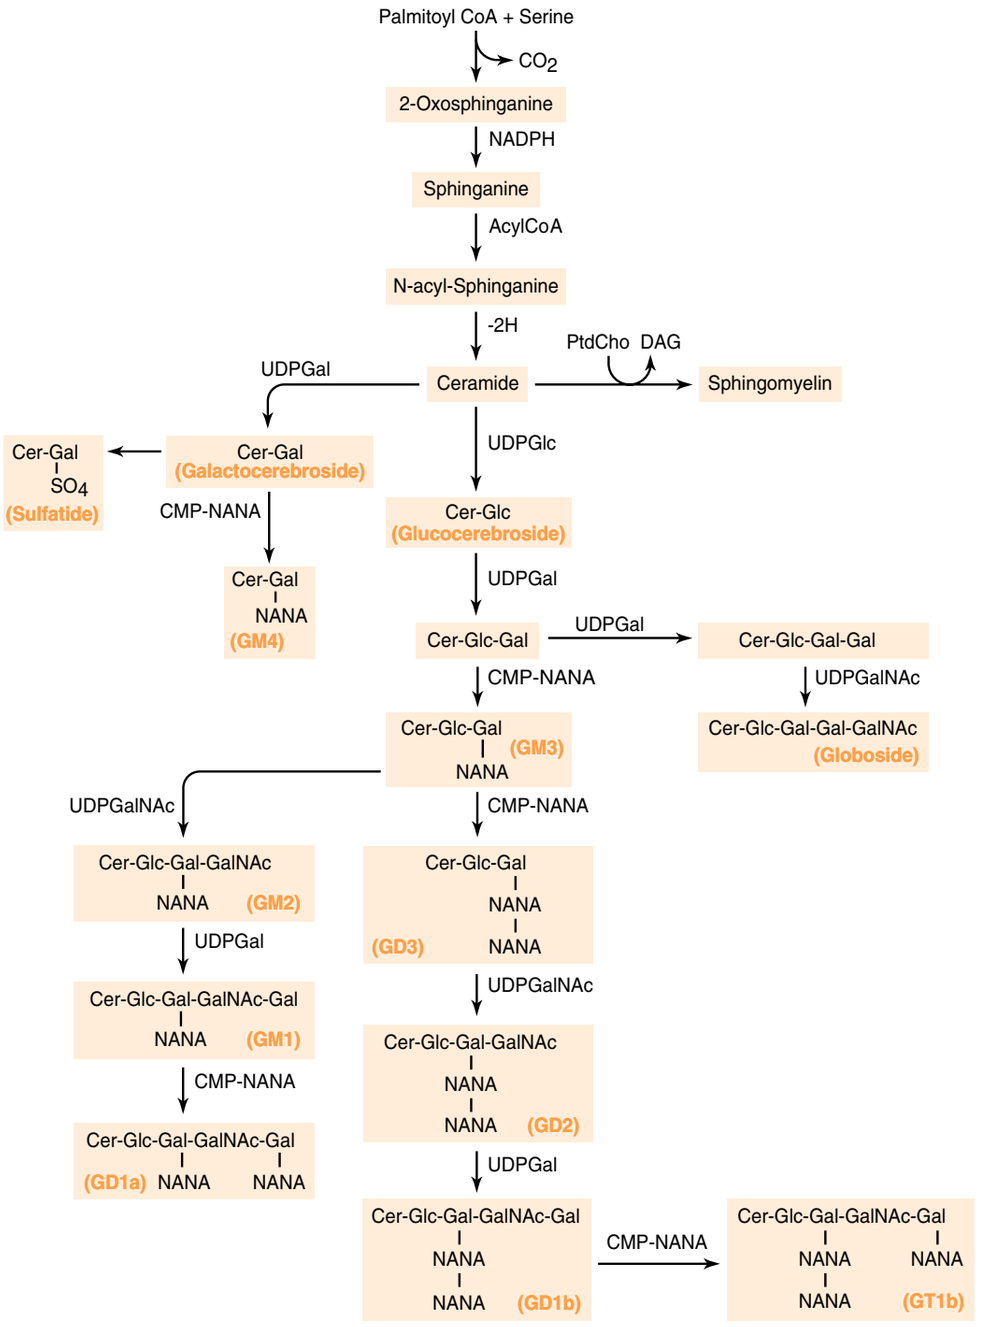

FIGURE 3-9 Pathways for biosynthesis of sphingolipids. Ceramide (*Cer*) is the precursor of all sphingolipids. Ceramide is converted to cerebroside (*Cer-Gal*), the main brain glycolipid, which is further converted to cerebroside sulfate (sulfatide) as shown. Cer-Gal is also converted to ganglioside (*GM4*), which is present in brain myelin. Most other gangliosides originate from Cer-Glc, and the main pathways for formation of these lipids are shown. The abbreviations using Svennerholms's nomenclature are shown in parentheses. (See Figs 3-4, 3-5.) The first letter, G, is for ganglioside. The second letter, M, D, T or Q, represents the number of sialic acid residues. Isomeric configurations of NANAs are distinguished by a and b. The main gangliosides of adult human brain are GM1, GD1a, GD1b and GT1b.

enzymes synthesizing galactocerebroside and sulfatide, both major sphingolipid components of myelin, gave unexpected results. While myelination and compaction of myelin was not affected initially, the mice displayed abnormal paranodal junctions and later disruption of myelin stability. Comparison of the two kinds of knockout showed that sulfatide plays a critical role in the proper localization and maintenance of Na^+ channels at the paranode [18] (see Chapter 4). Negative phenotypes can be informative as well. The hypothesis that complex gangliosides play a role in synaptic transmission was examined by deleting GM2/GD2 synthase, an enzyme

that catalyzes an early step in ganglioside biosynthesis, then testing neurotransmitter release at the neuromuscular junction [19]. Transmitter release was not altered under normal conditions, indicating a redundancy in complex ganglioside function at the synapse.

LIPIDS IN THE CELLULAR MILIEU

Lipids are transported between membranes. As indicated above, lipids are often biosynthesized in one intracellular membrane and must be transported to other intracellular compartments for membrane biogenesis. Because lipids are insoluble in water, special mechanisms must exist for the inter- and intracellular transport of membrane lipids. Vesicular trafficking, cytoplasmic transfer-exchange proteins and direct transfer across membrane contacts can transport lipids from one membrane to another. The best understood of such mechanisms is vesicular transport, wherein the lipid molecules are sorted into membrane vesicles that bud out from the donor membrane and travel to and then fuse with the recipient membrane. The well characterized transport of plasma cholesterol into cells via receptor-mediated endocytosis is a useful model of this type of lipid transport. [9, 20]. A brain specific transporter for cholesterol has been identified (see Chapter 5). It is believed that transport of cholesterol from the endoplasmic reticulum to other membranes and of glycolipids from the Golgi bodies to the plasma membrane is mediated by similar mechanisms. The transport of phosphoglycerides is less clearly understood. Recent evidence suggests that net phospholipid movement between subcellular membranes may occur via specialized zones of apposition, as characterized for transfer of PtdSer between mitochondria and the endoplasmic reticulum [21].

Membrane lipids may be asymmetrically oriented. In the 'fluid-mosaic' model of biomembranes, the lipids form a bimolecular leaflet in which proteins are embedded (see Ch. 2). This model, with some modifications, is useful in explaining a number of membrane phenomena, but it does not take into account the complex arrangement and function of various polar head groups and different fatty acids present in biomembrane lipids. In some biomembranes, such as those of red blood cells, the choline-containing phospholipids PtdCho and sphingomyelin are known to be enriched in the outer leaflet, while the amino lipids PtdEtn and PtdSer are concentrated in the inner leaflet of the plasma membrane. This arrangement probably also exists in the plasma membrane of most other cells. Studies with the serine-binding protein annexin V indicate that PtdSer appears in the plasma membrane outer leaflet in apoptosis [22]. The glycolipids, especially the gangliosides, are enriched in the extracellular side of the plasma membrane, where they may function in intercellular communication and act as receptors for certain ligands; for example, GM1 acts as a receptor for cholera toxin and GD1b for tetanus toxin. It is not clear how this asymmetric distribution of lipids in biomembranes originates. Lipids can move freely within the same plane of the bilayer but their movement from one leaflet of the bilayer to another is thermodynamically restricted. It is postulated that membranes contain proteins that catalyze a 'flip-flop' transbilayer movement of lipids. Specificity of such 'flippase', 'floppase' and 'scramblase' activities may be responsible for the asymmetric distribution of lipids between the inner and outer leaflets of the membrane bilayer. In support of this hypothesis, it has been shown that plasma membrane contains an ATP-dependent phospholipid translocase that selectively catalyzes the transport of the aminophospholipids PtdSer and PtdEtn but not of PtdCho from the outer to the inner lipid layer of the membrane [23]. A glucosyl ceramide translocase, required for transport of glucosyl ceramide from the cytoplasmic surface to the luminal surface of the Golgi membrane for synthesis of neutral glycosphingolipids, has been identified as multiple drug resistance protein 1 [24] (see Chs 2 and 5).

Some proteins are bound to membranes by covalently linked lipids. In recent years, a number of membrane-bound proteins have been shown to be covalently linked with various lipids, which anchor the protein to the lipid bilayer. PI-anchored proteins constitute a major family of membrane-tethered proteins (Box 3-1). In myelin proteolipid protein, fatty acids (16:0, 18:0, 18:1) are attached to the cysteine moieties in the protein as thioesters. A number of cellular proteins are also acylated with myristic acid (14:0) to the free amino group of *N*-terminal amino acids. A class of proteins, including Ras, a proto-oncogene product, has been shown to form covalent links with farnesyl (C_{15}) or C_{20} isoprenes via a thioether linkage to cysteine [25]. The lipid anchor in Ras, which occupies a central position in intracellular signal transduction, is required for its activity. The Hedgehog family of proteins contains palmitic acid linked to the amino terminal domain and cholesterol covalently linked to the carboxy terminal signaling domain [26], making them the only sterolated proteins identified to date. These proteins are of critical importance in patterning during development and in tumorigenesis (see Chapter 29). Lipidated Hedgehog proteins are secreted from cells via the membrane transporter Dispatched, and then transduce signals through two membrane bound receptors, Patched and Smoothened.

Lipids have multiple roles in cells. Recent discoveries show that the same lipid may have both structural and regulatory roles in the cell. For example, while arachidonic acid (20:4ω6) is a major constituent of brain inositides and PtdEtn, the free acid is also a precursor of a number of important biomessengers, the eicosanoids, such as prostaglandins, prostacyclins, leukotrienes and thromboxanes

BOX 3-1
Glycosylphosphatidylinositol-Anchored Proteins

A bacterial phosphatidylinositol specific phospholipase C (PI-PLC) had been available for many years before it was demonstrated to strip a number of membrane-bound proteins from eukaryotic cell surfaces [1]. Such proteins are anchored by a PI moiety in which the 6 position of inositol is glycosidically linked to glucosamine, which in turn is bonded to a polymannan backbone (Fig. 3-10). The polysaccharide chain is joined to the carboxyl terminal of the anchored protein via amide linkage to ethanolamine phosphate. The presence of a free NH_2 group in the glucosamine residue makes the structure labile to nitrous acid. Bacterial PI-PLC hydrolyzes the bond between DAG and phosphatidylinositols, releasing the water-soluble protein polysaccharide-inositol phosphate moiety. These proteins are tethered by glycosylphosphatidylinositol (GPI) anchors. They occur widely in nature, from trypanosome cell-surface antigens to placental alkaline phosphatase. In yeast and protozoa, cell-surface proteins appear to be ceramide- or GPI-anchored. The concept of a hydrophilic cell-surface protein tethered by a membrane lipid may be misleading since some GPI-anchored proteins appear to fulfill roles generally served by membrane-spanning proteins in higher animal cells, such as signal-transducing receptor proteins, ion channels and transporters. GPI-anchored proteins of neurobiological interest include rat Thy-1 antigen, neural cell adhesion molecules (NCAMs), Nogo receptor and prion protein [2] (see Chs 30 and 48). The prion GPI-anchor contains sialic acid and is found in lipid rafts. If normal prion protein is modified so that it cannot form a GPI anchor on the cell membrane, the abnormal

Glycosylphosphatidylinositol-Anchored Proteins

misfolded prion protein can no longer induce the disease scrapie [3]. Interest in GPI-anchored protein complexes also stems from indications that they can act as signals for protein sorting and localization [4], and may be linked to trophic proteins that mediate chemical affinity gradients during development. The inositol glycan complex of GPI may also have messenger-like properties in growth factor actions. A defect in GPI-anchor formation gives rise to the blood disorder paroxysmal nocturnal hemoglobinuria. For some GPI anchors, the PI moiety may contain alkyl ethers at C-1 of the glycerol, generally not found in free PI, and the 2-position of inositol can be esterified with a fatty acid, which renders the molecule resistant to PLC action. The lipid polysaccharide backbone is biosynthesized by sequential addition of the carbohydrate moiety to PtdIns, which initially reacts with UDPGlcNAc to form PI-6–1Glc NAc, and is then deacetylated. D-mannose moieties are next transferred from dolichol-P-mannose to make the polysaccharide backbone, which then undergoes phosphodiesteratic linkage with phosphoethanolamine derived from phosphatidylethanolamine [5, 6]. The GPI is anchored via amide linkage of the ethanolamine amino group and the C-terminal amino acid of a protein, and the complex is then transported to the outer surface of the plasma membrane. While the sequence of carboxy-terminal amino acids that signal GPI linkage is complex, it has been possible to splice nucleotide sequences coding for such sequences to mRNAs and to transfect cells which then produce novel cell-surface proteins. Proteins released by phospholipase have been shown to be reincorporated and GPI-anchored, even into other cell types. This has led to the concept of 'painting' cell surfaces for potential therapeutic uses, such as prevention of transplant rejection [7].

(see Ch. 33). Arachidonic acid itself acts as a biomessenger by activating certain isoforms of PKC. It may also be found in a derivatized form. It has been identified in amide linkage with ethanolamine as anandamide or esterified to the 2-position of glycerol, and both have been proposed as possible endogenous ligands for brain cannabinoid receptors [27]. Oleic acid amide has been reported to be an endogenous sleep-promoting factor [28], as has the prostanoid prostaglandin D_2 [29].

DAG is an important precursor for lipid biosynthesis in the endoplasmic reticulum, but in the plasma membrane it acts as a second messenger, activating PKC. Major structural lipids, such as PI and PtdCho, are also intimately involved in the signal-transduction process (see Ch. 23). The ether lipid 1-*O*-hexadecyl-2-acetyl-*sn*-glycero-3-phosphocholine, termed platelet activating factor and commonly referred to as PAF, has potent biomessenger activity in aggregating platelets, releasing eicosanoids and modulating glutamate release and plasticity at the synapse [30] (see Ch. 33). Lysophosphatidic acids have been identified as extracellular ligands acting via several G-protien-coupled receptors. Sphingolipids, including ceramide, sphingosine and sphingosine-1-phosphate, have been implicated in cell regulatory processes, such as cell-cycle arrest, apoptosis and stress-activated protein kinase actions [31, 32]. For example, tumor necrosis factor, the cytokine interleukin-1β and nerve growth factor act through their receptors to induce sphingomyelin hydrolysis to ceramide, which then activates a number of downstream activities, including protein kinases and phosphatases, triggering cell-cycle arrest, proliferation, differentiation or cell death (see also Chs 33 and 35).

THE MYELIN SHEATH 51
Myelin facilitates conduction 51
Myelin has a characteristic ultrastructure 52
Myelin is an extension of a glial plasma membrane 55
Myelin affects axonal structure 56

CHARACTERISTIC COMPOSITION OF MYELIN 56
The composition of myelin is well characterized because it can be isolated in high yield and purity by subcellular fractionation 56
Central nervous system myelin is enriched in certain lipids 56
Peripheral and central nervous system myelin lipids are qualitatively similar 58
Central nervous system myelin contains some unique proteins 58
Peripheral nervous system myelin also contains unique proteins 63
Some classically defined myelin proteins are common to both peripheral and central myelin 64
Myelin sheaths contain other proteins, some of which have only recently been established as myelin-related 65

DEVELOPMENTAL AND METABOLIC ASPECTS OF MYELIN 67
The developmental progress of myelination varies between regions and species 67
Synthesis of myelin components is very rapid during deposition of myelin 67
Sorting and transport of lipids and proteins takes place during myelin assembly 68
The composition of myelin changes during development 68
Spontaneous mutations in experimental animals provide insights about the structure and assembly of myelin 68
Myelin components exhibit great heterogeneity of metabolic turnover 69

The morphological distinction between white matter and gray matter is one that is useful for the neurochemist. White matter, so called for its glistening white appearance, is composed of myelinated axons, glial cells and blood vessels. Gray matter contains, in addition, the nerve cell bodies with their extensive dendritic arborizations. The predominant element of white matter is the myelin sheath, which comprises about 50% of the total dry weight and is responsible for the gross chemical differences between white and gray matter.

THE MYELIN SHEATH

The myelin sheath is a greatly extended and modified plasma membrane, which is wrapped around the nerve axon in a spiral fashion. A comprehensive review of the older literature on the structure, biochemistry and other aspects of myelin is available in a book published 20 years ago [1], whereas newer developments in the myelin field are covered in detail in a recent two-volume set [2]. The myelin membranes originate from, and are part of, Schwann cells in the PNS and oligodendrocytes in the CNS (see Ch. 1). Each myelin-generating cell furnishes myelin for only one segment of any given axon. The periodic interruptions where short portions of the axon are left uncovered by myelin are the *nodes of Ranvier*, and they are critical to the functioning of the axon and the myelin. The segments of myelinated axons between nodes are called internodes.

Myelin facilitates conduction. Myelin is an electrical insulator, although its function of facilitating conduction in axons has no exact analogy in electrical circuitry [3]. In unmyelinated fibers, impulse conduction is propagated by local circuits of ion current that flow into the active region of the axonal membrane, through the axon, and

†Pierre Morell tragically passed away early in the preparation of this chapter. A remembrance of his life and work appears on p. xxiii

Basic Neurochemistry: Molecular, Cellular and Medical Aspects

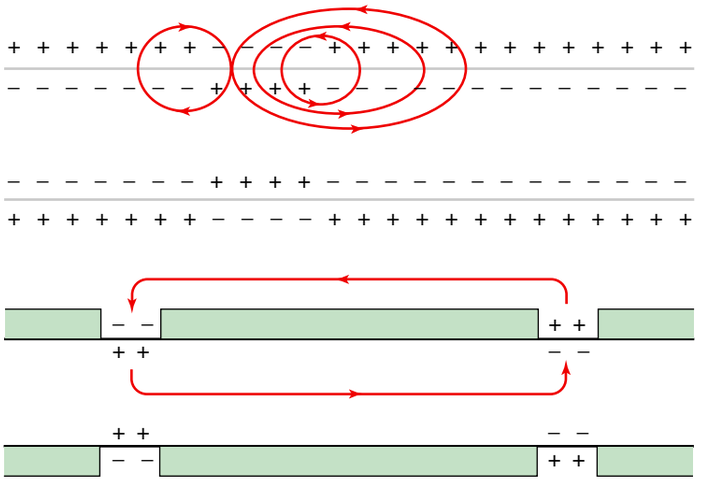

FIGURE 4-1 Impulse conduction in unmyelinated (*top*) and myelinated (*bottom*) fibers. The arrows show the flow of action currents in local circuits into the active region of the membrane. In unmyelinated fibers the circuits flow through the adjacent piece of membrane but in myelinated fibers the circuit flow jumps to the next node.

out through adjacent sections of the membrane (Fig. 4-1). These local circuits depolarize the adjacent piece of membrane in a continuous sequential fashion. In myelinated axons, the excitable axonal membrane is exposed to the extracellular space only at the nodes of Ranvier; this is the location of sodium channels. When the membrane at the node is excited, the local circuit generated cannot flow through the high-resistance sheath and therefore flows out through and depolarizes the membrane at the next node, which might be 1 mm or farther away (Fig. 4-1). The low capacitance of the sheath means that little energy is required to depolarize the remaining membrane between the nodes, which results in an increased speed of local circuit spreading. Active excitation of the axonal membrane jumps from node to node; this form of impulse propagation is called *saltatory conduction* (Latin *saltare*, 'to jump'). Such movement of the wave of depolarization is much more rapid than is the case in unmyelinated fibers. Furthermore, because only the nodes of Ranvier are excited during conduction in myelinated fibers, sodium flux into the nerve is much less than in unmyelinated fibers, where the entire membrane is involved.

Comparison of two different nerve fibers which both conduct at 25 m/s at 20°C demonstrates the advantage of myelination. The 500 µm diameter unmyelinated giant axon of the squid requires 5,000 times as much energy and occupies about 1,500 times as much space as a 12 µm diameter myelinated nerve in a frog. Conduction velocity in myelinated fibers is proportional to the diameter, while in unmyelinated fibers it is proportional to the square root of the diameter. Thus, differences in energy and space requirements between the two types of fiber are exaggerated at higher conduction velocities. If nerves were not myelinated and equivalent conduction velocities were maintained, the human spinal cord would need to be as large as a good-sized tree trunk. Myelin, then, facilitates conduction while conserving space and energy [3].

Myelin has a characteristic ultrastructure. Myelin, as well as many of its morphological features, such as nodes of Ranvier and Schmidt–Lantermann clefts, can be seen readily in the light microscope (Fig. 4-2). Further insight comes from biophysical studies of structures with parallel axons, sciatic nerve as representative of the PNS and optic nerve or tract as representative of the CNS. Myelin, when examined by polarized light, exhibits both a lipid-dependent and a protein-dependent birefringence. Low-angle X-ray diffraction studies of myelin provide electron density plots of the repeating unit that show three peaks (each corresponding to protein plus lipid polar groups) and two troughs (lipid hydrocarbon chains). The repeat distance varies somewhat depending on the species and whether the sample is from CNS or PNS. Thus, the results from these two techniques are consistent with a protein–lipid–protein–lipid–protein structure, in which

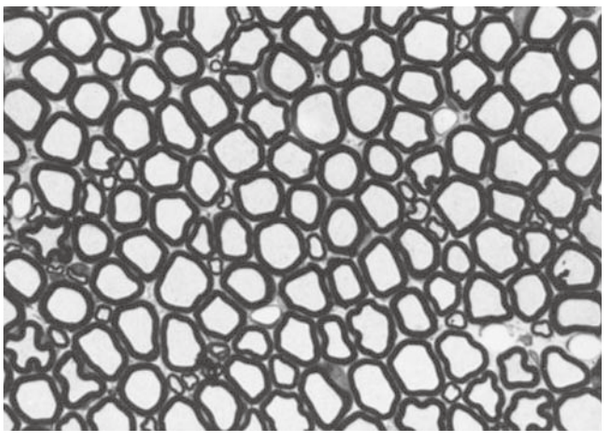

FIGURE 4-2 Light micrograph of a 1 µm Epon section of rabbit peripheral nerve (anterior root), stained with toluidine blue. The myelin sheath appears as a thick black ring around the pale axon. (Courtesy of Dr Cedric Raine.)

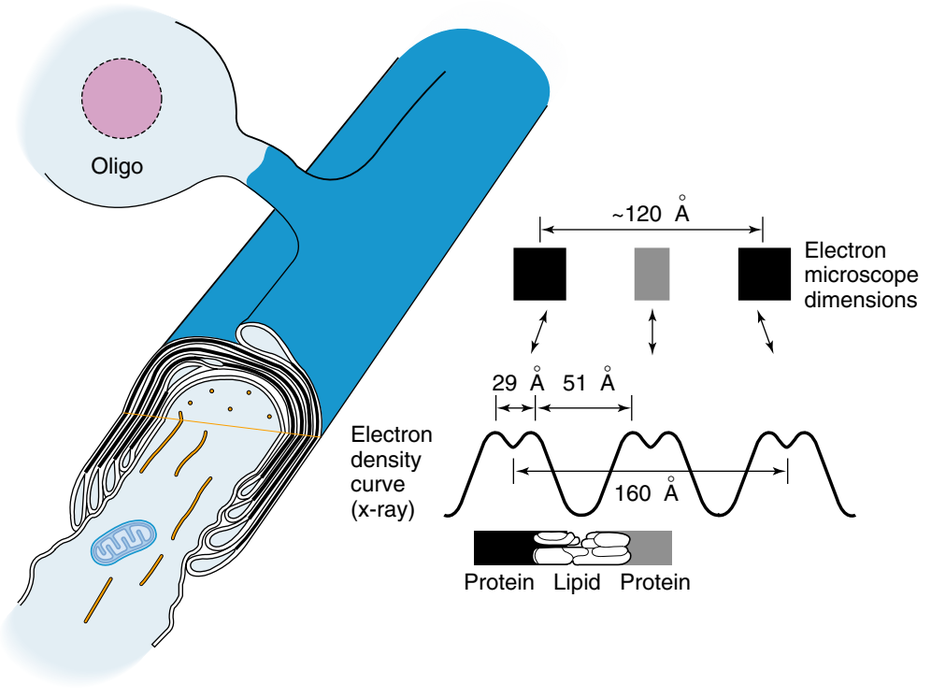

FIGURE 4-3 A composite diagram summarizing some of the ultrastructural data on CNS myelin. At the top an oligodendroglial cell is shown connected to the sheath by a process. The cutaway view of the myelin and axon illustrates the relationship of these two structures at the nodal and paranodal regions. (Only a few myelin layers have been drawn for the sake of clarity.) At the internodal region, the cross-section reveals the inner and outer mesaxons and their relationship to the inner cytoplasmic wedges and the outer loop of cytoplasm. Note that, in contrast to PNS myelin, there is no full ring of cytoplasm surrounding the outside of the sheath. The lower part of the figure shows roughly the dimensions and appearance of one myelin repeating unit as seen with fixed and embedded preparations in the electron microscope. This is contrasted with the dimensions of the electron density curve of CNS myelin obtained by X-ray diffraction studies in fresh nerve. The components responsible for the peaks and troughs of the curve are sketched below. (Adapted with permission from Norton, W. T. The myelin sheath. In E. S. Goldensohn and S. H. Appel (eds), *Scientific Approaches to Clinical Neurology*. Philadelphia: Lea & Febiger, 1977, pp. 259–298.)

the lipid portion is a bimolecular leaflet and adjacent protein layers are different in some way. Figure 4-3 shows data for mammalian optic nerve with a repeat distance of 80 Å. This spacing can accommodate one bimolecular layer of lipid (about 50 Å) and two protein layers (about 15 Å each). The main repeating unit of two such fused unit membranes is twice this, or 160 Å. (See Kirschner and Blaurock [4] for discussion and references.) Although it is useful to think of myelin in terms of alternating protein and lipid layers, this concept has been modified to be compatible with the 'fluid mosaic' model of membrane structure that includes intrinsic transmembrane proteins as well as extrinsic proteins.

Information concerning myelin structure is also available from electron microscope studies, which visualize myelin as a series of alternating dark and less dark lines (protein layers) separated by unstained zones (the lipid hydrocarbon chains) (Figs 4-4 to 4-7). There is asymmetry in the staining of the protein layers. The less dark, or intraperiod, line represents the closely apposed outer protein

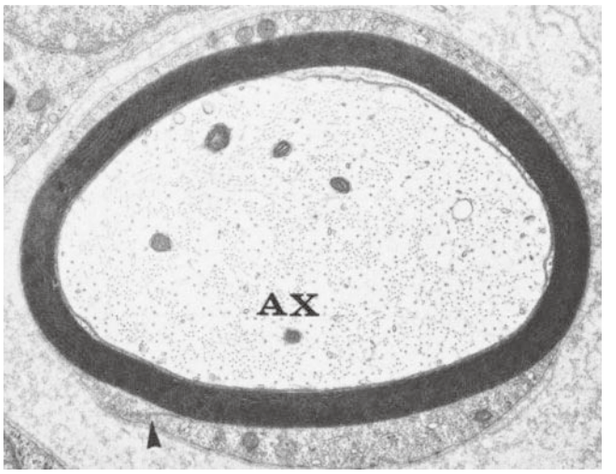

FIGURE 4-4 Electron micrograph of a single peripheral nerve fiber from rabbit. Note that the myelin sheath has a lamellated structure and is surrounded by Schwann cell cytoplasm. The outer mesaxon (*arrowhead*) can be seen in lower left. AX, axon. (Courtesy of Dr Cedric Raine.)

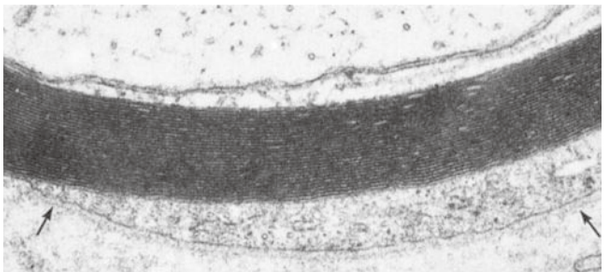

FIGURE 4-5 Higher magnification of Figure 4-4 to show the Schwann cell cytoplasm covered by basal lamina (*arrows*).

layers of the original cell membrane; the membranes are not actually fused, as they can be resolved as a double line at high resolution (Figs 4-6, 4-7). The dark, or major period, line is the fused, inner protein layers of the cell membrane. The repeat distances observed by electron microscopy are less than those calculated from the low-angle X-ray diffraction data, a consequence of the considerable shrinkage that takes place after fixation and dehydration. However, the difference in periodicity between the PNS myelin and CNS myelin is maintained; peripheral myelin has an average repeat distance of 119 Å and the central myelin of 107 Å.

Nodes of Ranvier. Two adjacent segments of myelin on one axon are separated by a node of Ranvier. In this region the axon is not covered by myelin. At the paranodal region and the Schmidt–Lantermann clefts (see below), the cytoplasmic surfaces of myelin are not compacted and Schwann or glial cell cytoplasm is included within the sheath. To visualize these structures, one may refer to Figures 4-8 and 4-9, which show that if myelin were unrolled from the axon it would be a flat, spade-shaped sheet surrounded by a tube of cytoplasm. Thus, as shown in electron micrographs of longitudinal sections of axon paranodal regions, the major dense line formed by apposition of the cytoplasmic faces opens up at the edges of the sheet, enclosing cytoplasm within a loop (Figs 4-3, 4-9).

FIGURE 4-6 Magnification of the myelin sheath of Figure 4-4. Note that the intraperiod line (*arrows*) at this high resolution is a double structure. (Courtesy of Dr Cedric Raine.)

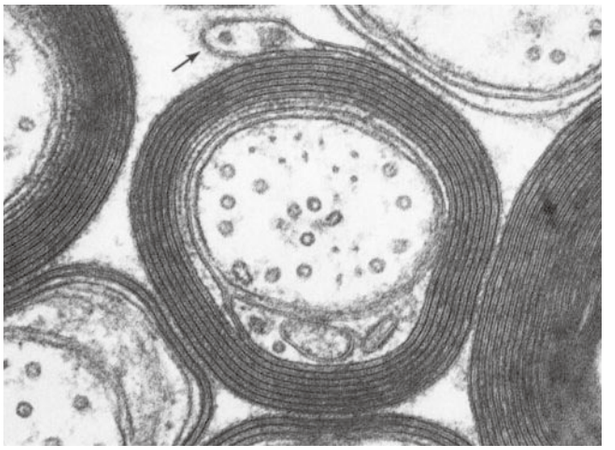

FIGURE 4-7 A typical CNS myelinated fiber from the spinal cord of an adult dog. Contrast this figure with the PNS fiber in Figure 4-4. The course of the flattened oligodendrocytic process, beginning at the outer tongue (*arrow*), can be traced. Note that the fiber lacks investing cell cytoplasm and a basal lamina–as is the case in the PNS. The major dense line and the paler, double intraperiod line of the myelin sheath can be discerned. The axon contains microtubules and neurofilaments.

These loop-shaped terminations of the sheath at the node are called *lateral loops*. The loops form membrane complexes with the axolemma called *transverse bands*, whereas myelin in the internodal region is separated from the axon by an extracellular gap of *periaxonal space*. The transverse bands are helical structures that seal the myelin to the axolemma but provide, by spaces between them, a tortuous path from the extracellular space to the periaxonal space.

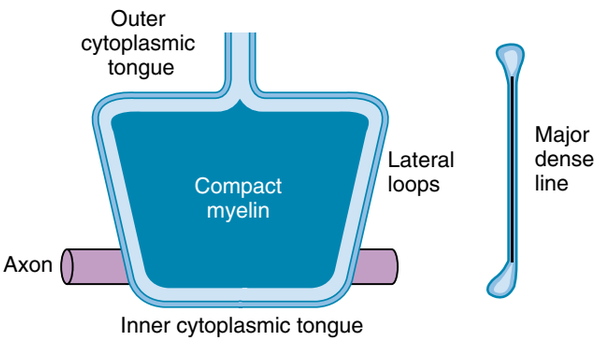

FIGURE 4-8 A diagram showing the appearance of CNS myelin if it were unrolled from the axon. One can visualize this structure arising from Figure 4-3 if the glial cell process were pulled straight up and the myelin layers separated at the intermediate period line. The whole myelin internode forms a spade-shaped sheet surrounded by a continuous tube of oligodendroglial cell cytoplasm. This diagram shows that the lateral loops and inner and outer cytoplasmic tongues are parts of the same cytoplasmic tube. The drawing on the right shows the appearance of this sheet if it were sectioned along the vertical line, indicating that the compact myelin region is formed of two unit membranes fused at the cytoplasmic surfaces. The drawing is not necessarily to scale. (Adapted from Hirano, A. and Dembitzer, H. M. A structural analysis of the myelin sheath in the central nervous system. *J. Cell Biol.* 34: 555–567, 1967.)

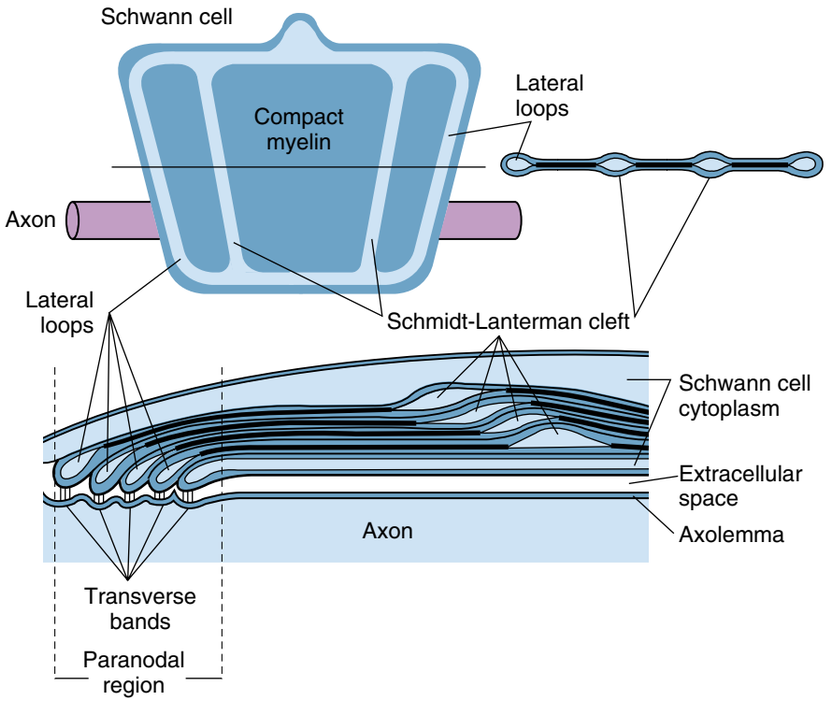

FIGURE 4-9 A diagram similar to Figure 4-8 but showing one Schwann cell and its myelin sheath unrolled from a peripheral axon (**top left**). The sheet of PNS myelin is, like CNS myelin, surrounded by a tube of cytoplasm and has additional tubes of cytoplasm, which make up the Schmidt–Lantermann clefts, running through the internodal regions. The horizontal section (top right) shows that these additional tubes of cytoplasm arise from regions where the cytoplasmic membrane surfaces have not fused. The diagram at the bottom is an enlarged view of a portion of the top left diagram, with the Schwann cell and its membrane wrapped around the axon. The tube forming the lateral loops seals to the axolemma at the paranodal region, and the cytoplasmic tubes in the internodal region form the Schmidt–Lantermann clefts. These drawings are not to scale. (Adapted from Hirano, A. and Dembitzer, H. M. A structural analysis of the myelin sheath in the central nervous system. *J. Cell Biol.* 34: 555–567, 1967.)

Schmidt–Lantermann clefts are structures where the cytoplasmic surfaces of the myelin sheath have not compacted to form the major dense line and therefore contain Schwann or glial cell cytoplasm (Fig. 4-9). They are common in peripheral myelin but rare in the CNS. These inclusions of cytoplasm are present in each layer of myelin. The clefts can be visualized in the unrolled myelin sheet as tubes of cytoplasm similar to the tubes making up the lateral loops but in the middle regions of the sheet, rather than at the edges (Fig. 4-9).

Myelin is an extension of a glial plasma membrane. Myelination in the PNS is preceded by invasion of the nerve bundle by Schwann cells, rapid multiplication of these cells and segregation of the individual axons by Schwann cell processes. Smaller axons (≤1 μm), which will remain unmyelinated, are segregated; several may be surrounded by one Schwann cell, each within its own pocket, similarly to the single axon shown in Figure 4-10A. Large axons (≥1 μm) destined for myelination are enclosed singly, one cell per axon per internode. These cells line up along the axons with intervals between them; the intervals become the nodes of Ranvier.

Before myelination the axon lies in an invagination of the Schwann cell (Fig. 4-10A). The plasmalemma of the cell then surrounds the axon and joins to form a double membrane structure that communicates with the cell surface. This structure, called the *mesaxon*, then elongates around the axon in a spiral fashion (Fig. 4-10). Thus, formation of myelin topologically resembles rolling up a sleeping bag: the mesaxon winds about the axon, and the cytoplasmic surfaces condense into a compact myelin sheath and form the major dense line. The two external surfaces form the myelin intraperiod line.

In the CNS, myelin is formed by oligodendrocytes. This has many similarities but also points of difference with respect to myelination in the PNS. CNS nerve fibers are not separated by connective tissue nor are they surrounded by cell cytoplasm, and specific glial nuclei are not obviously associated with particular myelinated fibers. CNS myelin is a spiral structure similar to PNS myelin: it has an inner mesaxon and an outer mesaxon that ends in a loop, or tongue, of glial cytoplasm (Fig. 4-3). Unlike peripheral nerve, where the sheath is surrounded by Schwann cell cytoplasm on the inside and outside (Fig. 4-10), the cytoplasmic tongue in the CNS is restricted to a small

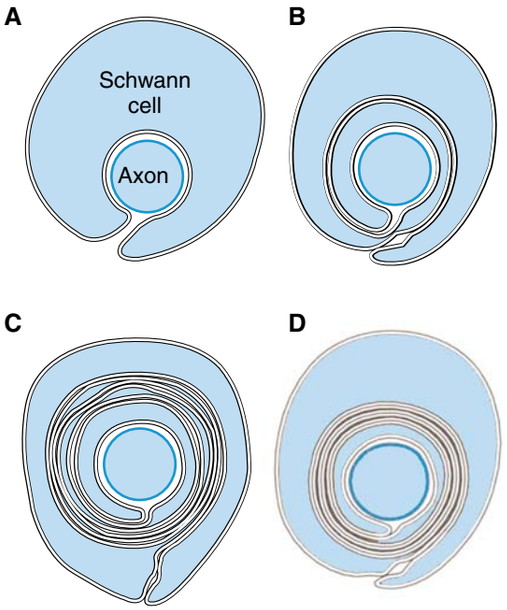

FIGURE 4-10 Myelin formation in the peripheral nervous system. (**A**) The Schwann cell has surrounded the axon but the external surfaces of the plasma membrane have not yet fused in the mesaxon. (**B**) The mesaxon has fused into a five-layered structure and spiraled once around the axon. (**C**) A few layers of myelin have formed but are not completely compacted. Note the cytoplasm trapped in zones where the cytoplasmic membrane surfaces have not yet fused. (**D**) Compact myelin showing only a few layers for the sake of clarity. Note that Schwann cell cytoplasm forms a ring both inside and outside of the sheath. (Adapted with permission from Norton, W. T. The myelin sheath. In E. S. Goldensohn and S. H. Appel (eds), *Scientific Approaches to Clinical Neurology*. Philadelphia: Lea & Febiger, 1977, pp. 259–298.)

portion of the sheath (Figs 4-3, 4-8). This glial tongue is continuous with the plasma membrane of the oligodendroglial cell through slender processes. One oligodendrocyte can myelinate as many as 40 or more separate axons.

Myelin deposition in the PNS may result in a single axon having up to 100 myelin layers, and it does not appear that myelin is laid down by a simple rotation of the Schwann cell around the axon. In the CNS, such rotation is precluded by the fact that one glial cell can myelinate several axons. During myelination, there are increases in the length of the internode, the diameter of the axon and the number of myelin layers. Myelin is therefore expanding in all planes at once. Any mechanism to account for this growth must assume that the membrane system is able to expand and contract, and that layers slip over each other.

Myelin affects axonal structure. The presence of a myelin sheath affects the structure of the axon that it surrounds [5], presumably optimizing its properties for transmission of action potentials by saltatory conduction. Generally, one of the effects of myelin is to increase axonal diameter by inducing biochemical changes in components of the axonal cytoskeleton such as neurofilaments (see Ch. 8). The effects of myelin on axonal structure imply that there are signaling mechanisms from myelin or myelin-forming glia to axons. A common theme, emerging from recent research on transgenic mice deficient for some of the myelin proteins described later in this chapter, is that, in addition to their roles in the structure of the myelin sheaths, several of them are necessary for the normal formation, maintenance and survival of the axons that are ensheathed.

CHARACTERISTIC COMPOSITION OF MYELIN

The composition of myelin is well characterized because it can be isolated in high yield and purity by subcellular fractionation. If CNS tissue is homogenized in media of low ionic stren gth, myelin peels off the axons and reforms in vesicles of the size range of nuclei and mitochondria. Because of their high lipid content, these myelin vesicles have the lowest intrinsic density of any membrane fraction of the nervous system. Procedures for isolation of myelin take advantage of both of these properties – large vesicle size and low density [1]. Peripheral nerve myelin can be isolated by similar techniques, but especially vigorous homogenization conditions are required because of the large amounts of connective tissue and, sometimes, adipose tissue present in the nerve. The slightly lower density of PNS myelin requires some adjustment of gradient composition to prevent loss of myelin.

Myelin *in situ* has a water content of about 40%. The dry mass of both CNS and PNS myelin is characterized by a high proportion of lipid (70–85%) and, consequently, a low proportion of protein (15–30%). By comparison, most biological membranes have a higher ratio of proteins to lipids. The currently accepted view of membrane structure is that of a lipid bilayer with integral membrane proteins embedded in the bilayer and other extrinsic proteins attached to one surface or the other by weaker linkages. Proteins and lipids are asymmetrically distributed in this bilayer, with only partial asymmetry of the lipids. The proposed molecular architecture of the layered membranes of compact myelin fits such a concept (Fig. 4-11). Models of compact myelin are based on data from electron microscopy, immunostaining, X-ray diffraction, surface probes studies, structural abnormalities in mutant mice, correlations between structure and composition in various species, and predictions of protein structure from sequencing information [4].

Central nervous system myelin is enriched in certain lipids. Table 4-1 lists the composition of bovine, rat, and human myelin compared to bovine and human white matter, human gray matter, and rat whole brain [1] (see Ch. 3). While there are no absolutely 'myelin-specific' lipids, cerebroside (galactosyl ceramide) is the most typical of myelin. With the exception of early development,

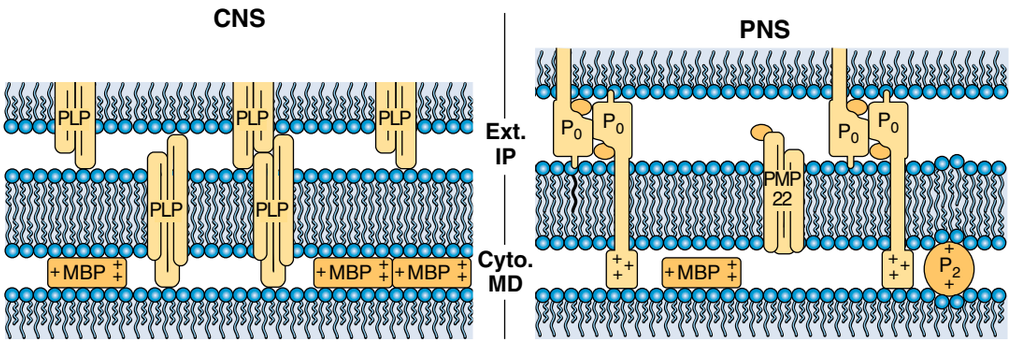

FIGURE 4-11 Diagrammatic representation of current concepts of the molecular organization of compact CNS and PNS myelin. The apposition of the extracellular (*Ext.*) surfaces of the oligodendrocyte or Schwann cell membranes to form the intraperiod (*IP*) line are shown in the upper part of the figure. The apposition of the cytoplasmic (*Cyto.*) surfaces of the membranes of the myelin-forming cells to form the major dense (*MD*) line are shown in the lower part of the figure. The width of the lipid bilayers and the spacing of the intraperiod and major dense lines in this figure are proportional to those determined by X-ray diffraction [4]. See the text for a detailed description of this model. The dark orange structures on P_0 and PMP represent the single oligosaccharide moieties on each protein. The blip at the apex of P_0 represents the tryptophan residue, which X-ray analysis suggests may interact with the apposing bilayer, but the expected tetramerization of P_0 is not shown for diagrammatic simplification. Although PLP molecules may exhibit homophilic interactions as suggested at one position in the figure, there is no strong experimental evidence to support this as in the case of P_0. These diagrams do not include CNP, MAG and other quantitatively minor proteins of isolated myelin, because they probably do not play a major structural role in most of the compact myelin. In fact, many of them are localized selectively in regions of myelin sheaths distinct from the compact myelin.

the concentration of cerebroside in brain is directly proportional to the amount of myelin present. As much as one-fifth of the total galactolipid in myelin is sulfatide, in which the 3-hydroxyl moiety on the galactose of cerebroside is sulfated. Presumably, the glycolipids in myelin, as in other membranes, are preferentially localized on the extracellular membrane face at the intraperiod line. Because of the specificity and quantitative significance of galactocerebroside in oligodendrocytes and myelin, it had long been thought that it would be essential for the formation and maintenance of myelin, but in fact it is not. A UDP-galactose:ceramide galactosyltransferase-null mouse was generated, which eliminates the obligate terminal step in cerebroside biosynthesis and thereby additionally sulfatide formation [6]. Thus, these mice synthesize no cerebroside or sulfatide. Surprisingly, the myelin formed by these mice is relatively normal, although there are subtle structural alterations in the myelin sheaths and neurological abnormalities, both of which become progressively more severe with age. Particularly severe defects occur in

TABLE 4-1 Composition of central nervous system myelin and brain

	Myelin			*White matter*			
Substance*	**Human**	**Bovine**	**Rat**	**Human**	**Bovine**	**Gray matter (human)**	**Whole brain (rat)**

†Plasmalogens are primarily ethanolamine phosphatides.

the CNS paranodal loops, where glia–axon tight junctions are located. Abnormalities in the PNS of these knockout mice are much less severe. Mice lacking the sulfotransferase that converts cerebroside to sulfatide exhibited similar paranodal disorganization in the CNS, indicating that sulfatide is important for establishing the normal oligodendroglial–axon interactions in the paranodal region [6, 7]. The lack of sulfatide also results in abnormal distribution of Na^+ and K^+ channels in the paranodal and nodal regions of myelinated axons. In addition to their role in myelin itself, experiments with cultured oligodendrocytes have demonstrated that both galactocerebroside and sulfatide also have important functions in the differentiation of oligodendrocytes, with sulfatide being particularly important [7].

In addition to cerebroside/sulfatide, the major lipids of myelin are cholesterol and phospholipids [1]. On a molar basis, CNS myelin preparations contain cholesterol, phospholipid and galactolipid in a ratio varying between 4:3:2 and 4:2:2. Thus, myelin contains substantially more molecules of cholesterol than any other single lipid, although on the basis of weight the content of galactolipids is comparable and total phospholipids are most abundant (Table 4-1). A characteristic phospholipid, and the single most prominent one, is ethanolamine-containing plasmalogen (glycerophospholipid containing an alkenyl ether bond– see Ch. 3). Lecithin is also a major myelin constituent, and sphingomyelin is a relatively minor one. Cholesterol is enriched on the extracellular face of the myelin membrane, whereas ethanolamine plasmalogen is asymmetrically localized to the cytoplasmic half of the bilayer. Not only is the lipid class composition of myelin highly characteristic of this membrane, the fatty acid composition of many of the individual lipids is distinctive.

The data in Table 4-1 indicate that myelin accounts for much of the total lipid of white matter, and that the lipid composition of gray matter is quite different from that of myelin. The composition of brain myelin from all mammalian species studied is very much the same. There are, however, some species differences; for example, myelin of rat has less sphingomyelin than does that of bovine or human (Table 4-1). Although not shown in the table, there are also regional variations; for example, myelin isolated from the spinal cord has a higher lipid-to-protein ratio than brain myelin from the same species.

In addition to the lipids of CNS myelin listed in Table 4-1, there are some other minor lipids, including polyphosphoinositides (see Ch. 3),which account for between 5% and 8% of the total myelin phosphorus; some fatty acid esters of galactocerebroside; and two galactosyldiglycerides [1]. Myelin from mammals also contains 0.1–0.3% ganglioside (complex sialic acid-containing glycosphingolipids). The major ganglioside in CNS myelin is a monosialoganglioside (GM1) and there are very low amounts of the polysialogangliosides characteristic of neuronal membranes. Myelin from certain species (including human) contains an additional novel ganglioside as a major component: sialosylgalactosylceramide (GM4).

Peripheral and central nervous system myelin lipids are qualitatively similar. However, there are quantitative differences. PNS myelin has less cerebroside and sulfatide and considerably more sphingomyelin than CNS myelin. Of interest is the presence of the LM1 ganglioside, sialosyl-lactoneotetraosylceramide, as a characteristic component of myelin in the PNS of some species. These differences in lipid composition between CNS and PNS myelin are not, however, as dramatic as the differences in protein composition discussed below.

Central nervous system myelin contains some unique proteins. The protein composition of CNS myelin is simpler than that of other brain membranes, with the myelin basic protein (MBP) and proteolipid protein (PLP) making up 60–80% of the total in most species. Many other proteins and glycoproteins are present to a lesser extent. With the exception of MBP, myelin proteins are neither easily extractable nor soluble in aqueous media. However, like other membrane proteins, they may be solubilized in sodium dodecylsulfate solutions and, in this condition, can be separated readily by electrophoresis in polyacrylamide gels. This technique separates proteins primarily according to their molecular weight (a common notation is M_r for relative molecular mass, and another is to state molecular weight in kilodaltons, kDa). The presence of bound carbohydrates or unusual structural features distort somewhat the relationship between electrophoretic migration and molecular weight, so that terminology for location of a protein in such a gel is taken to mean 'apparent' molecular weight. The protein composition of human and rat brain myelin are illustrated in Figure 4-12, B and D, respectively. The quantitative predominance of two proteins in human CNS myelin is clear, i.e. MBP and PLP. These two proteins are major constituents of all mammalian CNS myelin membranes and similar proteins are present in myelin membranes of many lower species. The overall orientation of these two proteins in compact CNS myelin is depicted in Fig. 4-11.

Proteolipid protein. Myelin PLP, also known as the Folch–Lees protein [8, 9], has the unusual physical property of solubility in organic solvents. The molecular mass of PLP is about 30,000, although it migrates anomalously on sodium dodecyl sulfate (SDS) gels and gives a lower apparent molecular mass. The amino acid sequence, strongly conserved during evolution, contains four membrane spanning domains, and PLP is described as one of the tetraspan proteins. Both the N- and C-termini are on the cytoplasmic side, as shown in Fig. 4-11. An important role for PLP in stabilizing the intraperiod line of CNS myelin has generally been assumed, based largely on the fact that the extracellular loops of this protein are present at this location. Furthermore, the CNS intraperiod line is

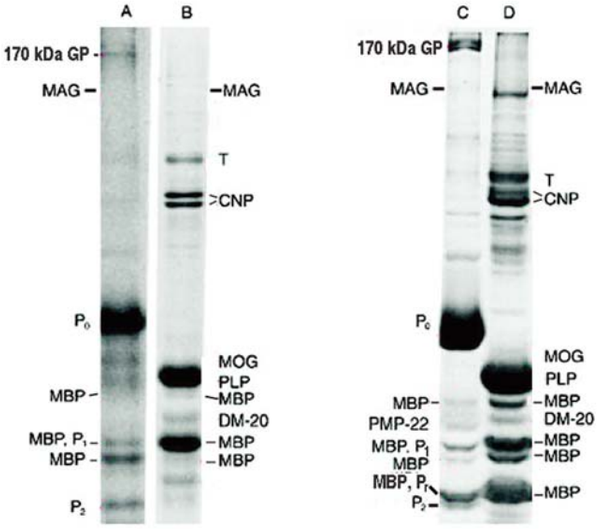

FIGURE 4-12 Polyacrylamide gel electrophoresis of myelin proteins in the presence of sodium dodecyl sulfate (SDS). The proteins of human PNS myelin (**A**), human CNS myelin (**B**), rat PNS myelin (**C**) and rat CNS myelin (**D**) were solubilized with the detergent SDS, electrophoresed and stained with Coomassie brilliant blue. The electrophoretic system separates proteins primarily according to their molecular size with the smallest proteins migrating the farthest toward the bottom of the gel. Abbreviations for the proteins are the same as in the text or defined below. The three MBP bands in lanes **A** and **B** are the 17.2, 18.5, and 21.5 kDa isoforms generated by alternative splicing of the mRNA in humans, and the four MBP bands in lanes **C** and **D** are the 14.0, 17.0, 18.5, and 21.5 kDa isoforms generated in rats (see Fig. 4-13). The 18.5 kDa MBP and the 14 kDa MBP are also called P_1 and P_2, respectively, in the terminology for the PNS. The 26 kDa MOG is probably the faint band just above PLP that is most apparent in lane **D**. CNP migrates as a tight doublet, and the lower and upper bands are sometimes referred to as CNP1 and CNP2, respectively. Note that the location shown for MAG (which stains too faintly to be seen well on the gels) is just above a discrete Coomassie-blue-stained band in lane **D**, which is probably the 96 kDa subunit of Na^+, K^+-ATPase. T, tubulin. 170 kDa GP, 170 kDa glycoprotein.

abnormally condensed both in the PLP knockout mice and in spontaneously occurring PLP mutants [10] (Table 4-2), confirming a structural role for PLP in determining the membrane spacing at the intraperiod line. PLP has an alternatively spliced isoform, DM20 (M_r = 20,000), which is present in CNS myelin at lower concentration than PLP (Fig. 4-12). DM20 has similar physical properties to PLP and is identical in sequence, except for a deletion of 35 amino acids in the intracellular domain [8, 9]. PLP/DM20 contains about 4–6 mol of fatty acids (primarily palmitate, oleate or stearate) per mole of protein in ester linkage at several cysteines. There is rapid turnover of the fatty acids independent of the peptide backbone.

The PLP gene is expressed very early in development, and in fact DM20 mRNA appears earlier than PLP during development, even before myelin formation in embryos and in premyelinating oligodendrocytes [9]. It is thought that it might have a role in oligodendrocyte migration or differentiation in addition to a structural role in myelin. The *PLP/DM20* gene may have evolved from an ancestral gene encoding a pore-forming polypeptide, lending support to the hypothesis that myelin may be involved in ion movement. Although PLP and DM20 serve important functions, they are not essential. Contrary to the general expectation that PLP would be needed for formation of compact, multilamellar myelin, a knockout mouse for *PLP/DM20* is initially relatively normal with respect to myelin formation (except for the difference in the intraperiod line spacing), life span and motor performance [9]. This suggests that other proteins or lipids of myelin may contribute to adherence of the extracellular faces of the bilayers at the intraperiod line. On the other hand, myelin in the PLP-null mutant is extra sensitive to osmotic shock during fixation, suggesting that PLP does enhance the stability of myelin, possibly by forming a 'zipper-like'

TABLE 4-2 Some spontaneously occurring animal mutants affecting myelin

Names of mutants	Inheritance*	Affected gene	Comments	References
Jimpy mouse, *rumpshaker* mouse, myelin-deficient (md) rat, shaking dog	X-linked	Proteolipid protein (PLP)	Variable degrees of oligodendrocyte death and CNS myelin deficiency; decreased spacing at intraperiod line of compact CNS myelin; see text	1, 9, 10, 43, 44
Shiverer mouse, myelin-deficient mouse	AR	Myelin basic protein (MBP)	Deletion or inversion of several MBP exons; very little functional MBP expressed; severe CNS hypomyelination and failure of compaction of major dense line; see text	1, 10, 43
Trembler mouse (PMP-22)	AD	Peripheral myelin protein-22 (PMP-22)	Hypomyelination specific for the PNS; caused by point mutations in transmembrane domains; see text	1, 45
Quaking mouse	AR	QKI family of proteins (QKI5, QKI6, QKI7 expressed in oligodendrocytes)	Hypomyelination more severe in CNS than PNS; abnormal expression of RNA-binding proteins likely to interfere with normal splicing or transport of mRNAs for myelin proteins; see text	1, 46–48
Taiep rat (acronym: **t**rembling, **a**taxia, **i**mmobility, **e**pilepsy, **p**aralysis)	AR	Unknown	Impaired myelin formation followed by demyelination in the CNS; accumulation of microtubules in oligodendrocytes interferes with transport of myelin proteins or mRNAs; see text	49

*AD, autosomal dominant; AR, autosomal recessive; CNS, central nervous system; PNS, peripheral nervous system.

structure after it is compacted. Furthermore, in older *PLP/DM20* knockout mice, there is significant axonal degeneration, suggesting that while myelin can form in the absence of PLP/DM20, CNS myelin devoid of PLP/DM20 cannot sustain normal axonal function. Despite the apparent similarity of the PLP and DM20, DM20 cannot replace PLP in transgenic mice [11] – the same long-term axonal degeneration occurs in mice expressing exclusively DM20 protein. This may be because PLP uniquely interacts both with inositol hexakisphosphate [12], a molecule involved in vesicle transport, and with integrins, modulating interaction with the extracellular matrix [13]. Thus, PLP has selective and apparently important functions in the CNS relative to DM20. While the loss of PLP/DM20 has clear neuropathological consequences in older animals, the loss of these proteins is significantly less serious than expression of mutated or excess PLP/DM20. Both human patients (see Ch. 38) and genetically engineered or naturally occurring animal mutants (Table 4-2) with defects in the PLP gene exhibit hypomyelination and often early death. This may result from production of either abnormal protein that cannot fold correctly or simply increased amounts of normal PLP [9], which induce an unfolded protein response and are toxic to oligodendrocytes.

While PLP/DM20 expression is highest in oligodendrocytes in the CNS, PLP/DM20 mRNA is also expressed in myelinating Schwann cells in the PNS [9], where small amounts of protein are synthesized although not incorporated into myelin in appreciable amounts. It is also expressed in nonmyelinating Schwann cells of the PNS. The levels of PLP and DM20 mRNA are differentially regulated in myelinating and nonmyelinating Schwann cells, with DM20 mRNA being expressed more in nonmyelinating Schwann cells and PLP mRNA being expressed more in myelinating Schwann cells. In addition to expression in the CNS and PNS, low levels of DM20 expression have been found in thymus and heart [10], again suggesting that this protein has unique functions unrelated to formation and maintenance of compact myelin. Furthermore, a novel alternatively spliced form of the protein that is soluble has recently been identified in neurons and oligodendrocytes [10]. This protein may have yet other functions.

Myelin basic proteins. The MBP of myelin has long been of interest because it was the initial myelin antigen, which, when injected into an animal, elicited a cellular immune response that produced the CNS autoimmune disease called *experimental allergic encephalomyelitis* (EAE, see Ch. 38). MBP can be extracted from myelin as well as from white matter with either dilute acid or salt solutions; once extracted, it is very soluble in water. The MBP genes from a number of species are highly conserved, and as with the PLP gene, the MBP gene is alternatively spliced [10, 14, 15]. The classical MBP gene has seven exons, with the full length MBP (21,500 M_r) containing all seven exons, although this protein is one of the minor MBP proteins in myelin. Exons 2, 5B and 6 are present or absent in four other MBP proteins found in myelin. The most abundant MBP in human myelin contains exons 1B, 3, 4, 6 and 7 (18.5 kDa MBP), whereas in rodent myelin both the 18.5 kDa MBP and a 14 kDa MBP containing exons 1B, 3, 4, 5 and 7 are the most abundant. Two different minor MBPs of approximately 17 kDa exist, which are encoded by exons 1B, 2, 3, 4, 5B and 7 or 1B, 3, 4, 6 and 7 respectively. A diagrammatic representation of some of these alternative splicing schemes is presented in Figure 4-13. The ratio of the MBPs changes with development, with more 14 kDa MBP found in mature rodent tissue. In immature oligodendrocytes, the MBP mRNA is localized in the cell body. However, as the cell matures, the MBP mRNA is localized in the myelin processes, far from the cell body, presumably because newly translated MBP associates rapidly with membranes at its site of synthesis [16].

The MBPs are extrinsic proteins localized exclusively at the cytoplasmic surface in the major dense line (Fig. 4-11), a conclusion based on their amino acid sequence, inaccessibility to surface probes and direct localization at the electron microscope level by immunocytochemistry. There is evidence to suggest that MBP forms dimers, and it is believed to be the principal protein stabilizing the major dense line of CNS myelin, possibly by interacting with negatively charged lipids. A severe hypomyelination and failure of compaction of the major dense line in MBP deficient *shiverer* mutants supports this hypothesis (Table 4-2).

The MBPs are highly unfolded in solution, with essentially no tertiary structure. They show microheterogeneity upon electrophoresis in alkaline conditions. This is due to a combination of phosphorylation, loss of the C-terminal arginine, and deamidation. There is also heterogeneity in the degree of methylation of an arginine at residue 106. The rapid turnover of the phosphate groups present on many of the MBP molecules [17] suggests that this post-translational modification might influence the close apposition of the cytoplasmic faces of the membrane (whether phosphorylation modifies this process in a dynamic manner is a topic of speculation). The physiological significance of the heterogeneity of MBPs, which results from alternative splicing and from unique post-translational modifications, is an open question.

Intriguingly, the classical MBP gene is actually part of a larger gene, *golli* (**g**ene of the **ol**igodendrocyte **li**neage), which is more than 100 kb in length [14]. This gene has three transcription start sites, two of which are used to transcribe the MBP mRNAs, while the most 5′ transcription start site generates *golli* mRNAs (Fig. 4-13). Transcripts from this upstream promoter are expressed more ubiquitously than MBP mRNAs. Thus, they are expressed in neurons and oligodendrocytes in the nervous system and in T cells in the immune system. Most interestingly from an evolutionary perspective, the *golli* proteins contain a 133 amino acid domain that contains both unique *golli* sequences and classic MBP sequences. The *golli* proteins are expressed during embryonic development and in

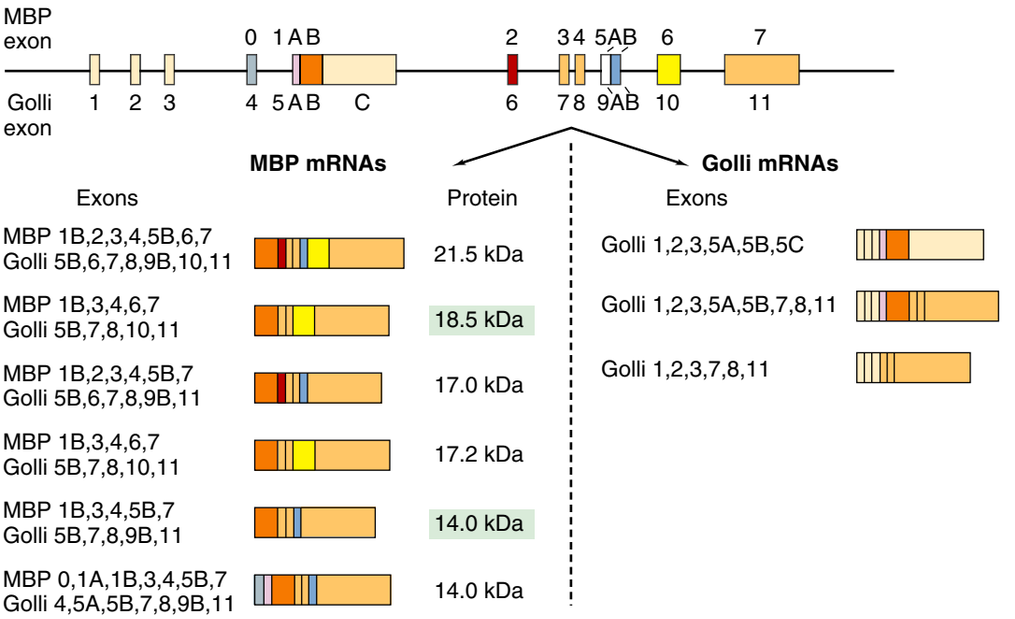

FIGURE 4-13 The amino acid sequences corresponding to the various mouse MBPs are encoded in a gene containing at least 11 exons (separated by introns – DNA regions whose base sequence does not code directly for proteins). This gene is depicted here but the sizes of the exons or introns are not accurately represented. The exons are depicted in boxes with the original *MBP* exon numbering above, and the *golli*/*MBP* exon numbering below. Some of the introns are over 100,000 bases in length and could not be shown accurately here. This gene can be spliced into two sets of mRNAs: the MBP mRNAs and the *golli* mRNAs. The *MBP* exons can be spliced to give an mRNA containing the original seven *MBP* exons, which are exons 5B, 6, 7, 8, 9B, 10 and 11 of the *golli/MBP* gene; this mRNA encodes the 21.5 kDa MBP. Alternative MBP mRNA splicings result primarily in mRNA species with deletions of *MBP* exons 2 (red) and/or 6 (yellow) (*golli* exons 6 and/or 10), which encode the other MBPs, although in humans, elimination of *MBP* exons 2 and 5B (blue) (*golli* exons 6 and 9B) can generate a 17.2 kDa MBP. A unique *MBP* mRNA (M41) encoding a 14 kDa MBP (**bottom**) was identified in which a novel *MBP* transcription site was used (exon 0/4, gray), and *MBP* exons 1A and 1B (*golli* exons 5A and 5B). Additionally, a unique *MBP* sequence upstream of the classical *MBP* exon 5 was identified (exon 5A/9A, white), which may be spliced into some *MBP* mRNAs, although the full sequence of these mRNAs has not been determined [15]. The exons forming the various *MBP* mRNA species and proteins are indicated. There are three well-characterized *golli* mRNAs (BG21, J37 and TP8 [14]), which are transcribed from *golli* exon 1, and which may or may not contain exons from the *MBP* exons 3, 4, 7. (Adapted from a figure published in reference [14].)

postnatal tissue, and the proteins are found in multiple subcellular localizations, including nuclei, cytoplasm and cellular processes. Their function is not yet understood, although there is the suggestion that they may be involved in process extension in neural cells [10, 14].

2′:3′-Cyclic nucleotide 3′-phosphodiesterase: In addition to PLP and MBP, there are many higher-molecular-weight proteins present in myelin (Fig. 4-12). These vary in amount depending on species (rodents generally have more than larger mammals) and age (immature myelin has more). A doublet with $M_r \approx 46$ kDa and 48 kDa is present in CNS myelin, which comprises several percent of total myelin protein and has the enzyme activity, 2′:3′-cyclic nucleotide 3′-phosphodiesterase (CNP) [18]. Although there are low levels of CNP associated with other cell types, it is greatly enriched in CNS myelin and oligodendrocytes, for which it is a commonly used biochemical marker. It is expressed at a much lower concentration in Schwann cells at the onset of myelination and does not increase during development with the accumulation of myelin as in the CNS. The enzyme is extremely active with the substrate 2′, 3′-cAMP, as well as cGMP, cCMP and cUMP analogs, which are all hydrolyzed to the corresponding 2′-isomer. This may be a nonphysiological activity, because only the 3′:5′ cyclic nucleotides have been shown to have biological activity. Nevertheless, evolutionary conservation of the catalytic site indicates that its amino acid sequence probably has an important function, although the precise role of CNP has remained elusive over the many years since it was discovered. Two CNP polypeptides are generated by alternative splicing of the mRNA, with the larger polypeptide having an extra 20 amino acids at the N-terminus. Immunocytochemistry demonstrates that CNP is not a major component of compact myelin, but is concentrated in specific regions of the myelin sheaths associated with cytoplasm, such as the oligodendroglial processes, inner and outer tongue processes, and lateral loops. The protein is in the cytoplasm but much of it associates with membranes, because both isoforms are isoprenylated at the C-terminus and acylated. Some clues about its function have come from reports that it binds to cytoskeletal elements such as F-actin and tubulin and that overexpression in cultured non-neural cells promotes outgrowth of processes. Such findings suggest that its function may be in regulating cytoskeletal dynamics to promote process outgrowth and

differentiation in oligodendrocytes. Furthermore, aberrant myelination occurring *in vivo* in transgenic mice overexpressing CNP similarly suggests that it could be an early regulator of cellular events that culminate in CNS myelination. However, it is also important to note that the amino acid sequence of CNP puts it in a superfamily of RNA-processing enzymes whose physiological roles are unclear, so the relevance of this to oligodendrocytes and myelination is also unclear. An interesting possibility combining some of the above information is that CNP could be involved in some specialized aspects of RNA transport and/or processing in oligodendrocytes. Yet most puzzling of all is the phenotype displayed by the recently generated CNP-null mice, which appear to myelinate entirely normally but as adults exhibit axonal swelling, neurodegeneration and premature death. It has been speculated that CNP is a multifunctional protein with an initial role in oligodendroglial differentiation that can be compensated for by another protein, and a second function essential for the normal interaction of oligodendrocytes with axons leading to axonal degeneration in its absence [18]. Clearly, more research is needed to fully understand the functions of this intriguing myelin/oligodendrocyte-related protein.

Myelin-associated glycoprotein and other glycoproteins of CNS myelin. The myelin-associated glycoprotein (MAG) is a quantitatively minor, 100 kDa glycoprotein in purified CNS and PNS myelin [19, 20] that electrophoreses at the position shown in Figure 4-12. However, because of its small amount (<1% of total protein) and weak staining by Coomassie blue, it does not correspond to one of the discrete protein bands visible in the figure. MAG has a single transmembrane domain that separates a heavily glycosylated extracellular part of the molecule, composed of five Ig-like domains and eight or nine sites for N-linked glycosylation, from an intracellular carboxy-terminal domain. Its overall structure is similar to that of neural-cell adhesion molecule (N-CAM). MAG in rodents occurs in two developmentally regulated isoforms, which differ in their cytoplasmic domains and are generated by alternative splicing of its mRNA. The isoform with a longer C-terminal tail (L-MAG) predominates early in development during active myelination of the CNS, whereas the isoform with a shorter cytoplasmic tail (S-MAG) increases during development to become prominent in adult rodents.

MAG is not present in compact, multilamellar myelin but is located in the periaxonal glial membranes of myelin sheaths. This location next to the axon and its membership in the Ig superfamily (see Ch. 7) suggest that it functions in adhesion and signaling between myelin-forming cells and the axolemma. Indeed, substantial evidence has now accumulated that MAG is involved in signaling in both directions between glia and axons, although its most important functions appear to be different in the CNS and the PNS. MAG is in the 'siglec' [**s**ialic acid –binding **i**mmuno**g**lobulin-like **lec**tins] subgroup of the Ig superfamily and binds to glycoproteins and gangliosides with terminal α2–3 linked sialic acid moieties. Thus, some of the axolemmal binding partner(s) for MAG are likely to be sialoglycoconjugates. A relationship of MAG to other adhesion proteins also is demonstrated by the presence in most species of a sulfate-containing epitope in its oligosaccharide moieties that reacts with the HNK-1 monoclonal antibody. The carbohydrate HNK-1 epitope is expressed on many neural adhesion proteins, including N-CAM and MAG, and has been shown to function in cell–cell interactions.

MAG had long been thought to function in important signaling mechanisms from axons to oligodendrocytes during myelination. However, it is now known that MAG is not essential for myelin formation because MAG-null mice myelinate relatively normally. Nevertheless, in the CNS, these knockouts exhibit a significant delay of myelination, periaxonal and paranodal structural abnormalities, redundant myelin loops and supernumerary myelin sheaths. In addition, there is degeneration of periaxonal oligodendroglial processes in aging MAG-null mice, suggesting the occurrence of a 'dying-back oligodendrogliopathy'. Therefore, the absence of MAG causes oligodendrocytes to form myelin less efficiently during development and become dystrophic with aging. Furthermore, although the neurological deficit in MAG-null mice is mild, double knockouts in which the absence of MAG is combined with the genetic ablation of other proteins result in more severe CNS phenotypes than either knockout alone. These *in vivo* findings suggest that MAG-mediated signaling from axons to oligodendrocytes is needed for efficient myelination and maintenance of healthy mature oligodendroglia. As with other proteins in the Ig superfamily, it is likely that the interaction of MAG with its ligand(s) on the axolemma mediates cell–cell signaling by mechanisms involving phosphorylation. The cytoplasmic domains of MAG are phosphorylated on serine and theonine residues by protein kinase C, and L-MAG is also phosphorylated on tyrosine-620. Furthermore, the cytoplasmic domain of L-MAG has been shown to interact with fyn tyrosine kinase, phospholipase Cγ and other oligodendroglial proteins. The L-MAG isoform appears to be particularly important for CNS myelination, because genetically engineered mice lacking only the L-isoform exhibit the same CNS abnormalities as total knockouts but not the PNS pathology of total knockouts described below.

There are a large number of other glycoproteins associated with white matter and myelin, and a few in addition to MAG that have been cloned and characterized. One of these is a minor 26 kDa protein called the myelin-oligodendrocyte glycoprotein (MOG) [21]. MOG is also a transmembrane glycoprotein, contains a single Ig-like domain and one site for N-linked glycosylation, and expresses the adhesion-related HNK-1 epitope. Unlike MAG, which is sequestered at the interior of CNS myelin

sheaths, MOG is localized on the outside surface of myelin sheaths and oligodendrocytes, apparently directed by a basolateral membrane targeting signal in its cytoplasmic domain. Consistent with its surface localization, MOG has been implicated as a target antigen in autoimmune aspects of demyelinating diseases of the CNS and is a leading candidate to be an important antigen in multiple sclerosis (see Ch. 38). Its surface location also suggests that it may function in signal transduction, transmitting information from the extracellular matrix or adjacent myelin sheaths to oligodendrocytes. This role is further suggested by changes in cultured oligodendrocytes when MOG is cross-linked on the cell surface with anti-MOG antibodies [7]. However, its physiological function remains obscure, because the recent generation of MOG-null mice yielded an apparently normal phenotype.

Another glycoprotein with a similar name to MOG is the oligodendrocyte-myelin glycoprotein (OMgp) [19, 22]. It was first characterized as a 120 kDa phosphatidylinositol-linked glycoprotein in human white matter and subsequently cloned. It is not a member of the Ig superfamily but is characterized by a cysteine-rich motif at the N-terminus, a series of tandem leucine-rich repeats and the HNK-1 epitope. These properties suggest that it may function in cell–cell interactions. However, unlike MAG and MOG, it is not specific to myelin-forming cells and is also expressed in neurons. It has attracted substantial interest in recent years because it is one of the myelin-associated inhibitors of axonal regeneration (see below), but its function with regard to myelination is unclear at this time.

Peripheral nervous system myelin also contains unique proteins.

P_0 glycoprotein. Gel electrophoretic analysis (Fig. 4-12A, C) shows that a single 30 kDa protein, P_0, accounts for more than half of the PNS myelin protein. P_0 is a type 1 membrane glycoprotein containing about 220 amino acids after removal of its signal sequence. Rat P_0 contains a single extracellular Ig-like domain of 124 amino acids, a hydrophobic transmembrane domain of 26 amino acids and an intracellular domain of 69 amino acids [19, 23]. The amino-terminal extracellular domain has a single site for N-linked glycosylation, and the glycans at that site are very heterogeneous, with many containing sialic acid and sulfate. In addition to glycosylation, other posttranslational modifications of P_0 include phosphorylation and acylation.

The principal difference in the overall protein composition of PNS and CNS myelin is that P_0 replaces PLP as the major protein, although myelin-forming Schwann cells do express very low levels of PLP. It is interesting to note that PLP and P_0 proteins, which are so different in sequence, post-translational modifications and membrane topology, may have similar roles in the formation of structures as closely related as myelin of the CNS and PNS respectively. Expression of P_0 in transfected cells results in cell–cell interactions that are due to homophilic binding of its extracellular domains, suggesting that P_0 stabilizes the intraperiod line of PNS myelin by similar homophilic binding (Fig. 4-11). The relatively large, glycosylated, extracellular Ig-like domain of P_0 probably accounts for the greater separation of extracellular surfaces in PNS myelin relative to CNS myelin where closer apposition of these surfaces is possible in the presence of the smaller extracellular domains of PLP. Evidence reviewed by Kirschner *et al.* [23] suggests that homophilic interactions between P_0 molecules involve both protein–protein and protein–carbohydrate interactions. Furthermore, investigation of the crystal structure of the P_0 extracellular domain suggests that P_0 molecules cluster on each membrane surface as tetramers. The crystal structure also suggested that a tryptophan residue at the apex of the extracellular domain could interact directly with the lipid bilayer of the apposing membrane. P_0 protein also has a relatively large positively charged domain on the cytoplasmic side of the membrane that contributes significantly to stabilization of the major dense line in the PNS. The complete knockout of P_0 has profound consequences for myelin structure, in contradistinction to the previously noted, relatively benign CNS consequence of deletion of the PLP gene. P_0-null mice exhibit abnormal motor coordination, tremors, occasional convulsions and a severe hypomyelination with thin, noncompacted myelin sheaths.

Expression of the correct amount of P_0 is apparently essential for normal myelin formation and maintenance. Young mice heterozygous for the P_0 -null mutation appear normal but develop progressive demyelination with age, which resembles chronic inflammatory demyelinating neuropathy and may involve inflammatory mechanisms. Furthermore, transgenic mice overexpressing P_0 exhibit a dose-dependent dysmyelinating neuropathy ranging from transient hypomyelination to severe arrest of myelination and impaired sorting of axons. The critical dosage of P_0 required for normal myelin formation is similar to observations with other myelin proteins and may reflect the necessity for appropriate amounts of myelin proteins to form stoichiometric complexes in compact myelin. However, in the case of P_0, the pathology that occurs with overexpression may also reflect a mistargeting of the protein and an interesting misuse of its obligate homophilic adhesive properties. Some of the extra P_0 is inappropriately located in normally dynamic mesaxonal membranes, causing them to adhere like compact myelin and halting myelination. It is clear that control of P_0 expression is complex, involving interactions with the axon and basal lamina, rate of cell division, inhibitory and stimulatory growth factors, cAMP levels and transcription factors. It also should be noted that low basal levels of P_0 are expressed in Schwann cells and neural crest cells early in embryonic development well before myelination, which suggests that P_0 could have other functions, potentially involving Schwann-cell–axon interactions and signal transduction. The cytoplasmic domain of P_0 is phosphorylated on serine and tyrosine residues and this might be indicative

of signaling mechanisms within Schwann cells during early development as well as later during myelination [17].

Peripheral myelin protein-22. In addition to the major P_0 glycoprotein, compact PNS myelin contains a 22 kDa protein called peripheral myelin protein-22 (PMP-22) that accounts for less than 5% of the total protein (Fig. 4-12C) [19, 24]. Similarly to P_0, PMP-22 has a single site for N-linked glycosylation. However, unlike P_0, which is nerve-specific, PMP-22 is expressed in many other tissues. It has four hydrophobic potential transmembrane domains and is a tetraspan protein like the major PLP of CNS myelin, but there is no sequence homology to PLP. It is in a highly homologous family of small hydrophobic tetraspan proteins that also include epithelial membrane proteins (EMP-1, -2 and –3). It is referred to as a 'growth arrest protein' because its cDNA was first cloned from nondividing fibroblasts, and the synthesis of PMP-22 and other myelin proteins ceases when Schwann cells begin to proliferate following nerve transection. Although the tetraspan PMP-22 is localized primarily in compact PNS myelin, as shown in Fig. 4-11, it is not known if its extracellular or cytoplasmic domains play an important structural role for myelin. The relatively small amount of PMP-22 and the fact that it is present in the plasma membranes of both myelinating and nonmyelinating Schwann cells suggest that it may have a dynamic function in myelin assembly or maintenance rather than a major structural role. Its tetraspan structure, similar to that of PLP, suggests that one of its roles might be similar to one of the functions of PLP in CNS myelin. PMP-22 has been shown to form complexes with P_0, and this interaction with P_0 may be relevant to its function. Also, as is the case with P_0 and PLP, any significant deviation in gene dosage for PMP-22, or disruption caused by point mutations, has severe functional consequences. Mutations of the PMP-22 gene cause the dysmyelinating phenotypes in *trembler* mice (Table 4-2) and some neuropathies in humans (see Ch. 38). In addition, the association of PMP-22 with growth arrest in Schwann cells and other cell types suggests that it may have an unknown role in regulation of growth or differentiation.

P_2 protein. PNS myelin contains a positively charged protein different from MBP that is referred to as P_2 (M_r ≃15,000). It is unrelated in sequence to MBP and is a member of a family of cytoplasmic fatty acid binding proteins (FABP) that are present in a variety of cell types [25]. The amount of P_2 protein is variable among species, accounting for about 15% of total protein in bovine PNS myelin, 5% in humans and less than 1% in rodents. P_2 protein is generally considered a PNS myelin protein but it is expressed in small amounts in CNS myelin sheaths of some species. P_2 is an antigen for experimental allergic neuritis, the PNS counterpart of EAE (see Chs 36 and 38). P_2 appears to be present in the major dense line of myelin sheaths, where it may play a structural role similar to MBP (Fig. 4-11). Interestingly, the larger amounts of P_2 protein that are in myelin of some species correlate with increased widths of the major dense lines as determined by X-ray diffraction, and there appears to be substantially more P_2 in large sheaths than small ones [4]. The large variation in the amount and distribution of the protein from species to species and sheath to sheath raises so far unanswered questions about its function. Its similarities to cytoplasmic proteins in other cells, whose functions appear to involve solubilization and transport of fatty acids and retinoids, suggest that it might function similarly in myelin assembly or turnover, but there is currently no direct experimental evidence to support this hypothesis.

Some classically defined myelin proteins are common to both peripheral and central myelin.

Myelin basic protein. In PNS myelin, MBP varies from approximately 5% to 18% of total protein, in contrast to the CNS, where it is close to 30% [1]. In rodents, the same four 21, 18.5, 17 and 14 kDa MBPs found in the CNS are present in the PNS. In adult rodents, the 14 kDa MBP is the most prominent component and is termed P_r in the PNS nomenclature. The 18.5 kDa component is present and is often referred to as the P_1 protein in the nomenclature of peripheral myelin proteins. Another species-specific variation in human PNS is that the major basic protein is not the 18.5 kDa isoform that is most prominent in the CNS but rather a form of about 17 kDa. It appears that MBP does not play as critical a role in myelin structure in the PNS as it does in the CNS. For example, the *shiverer* mutant mouse, which expresses no MBP (Table 4-2), has a greatly reduced amount of CNS myelin, with no compaction of the major dense line. By contrast, *shiverer* PNS has essentially normal myelin, both in amount and structure, despite the absence of MBP. This CNS/PNS difference in the role of MBP is probably because the cytoplasmic domain of P_0 has an important role in stabilizing the major dense line of PNS myelin. Animals doubly deficient for P_0 and MBP have a more severe defect in compaction of the PNS major dense line than P_0-null mice, which indicates that both proteins contribute to compaction of the cytoplasmic surfaces in PNS myelin [23].

Myelin-associated glycoprotein. As in the CNS, MAG is present in the periaxonal membranes of myelin-forming Schwann cells, but it is also present in the Schwann cell membranes of the Schmidt–Lanterman incisures, paranodal loops and the outer mesaxon [19, 20]. Therefore, in addition to a role in Schwann-cell–axon interactions, MAG may also function in interactions between adjacent Schwann cell membranes at these other locations in the PNS. Both isoforms of MAG are present in the rodent PNS, although S-MAG is the predominant isoform at all ages. PNS myelination in MAG-null mice is initially more normal than CNS myelination. However, as the mice age they develop a peripheral neuropathy characterized by degeneration of myelinated axons, which is the most

severe phenotypic abnormality displayed by the knockout mice. The pathology is associated with decreased axonal caliber, increased neurofilament density, reduced expression and phosphorylation of neurofilaments and eventually axonal degeneration. These findings demonstrate an essential role for MAG in signaling from Schwann cells to axons that is necessary for the maintenance of normal myelinated axons in the PNS. Thus, MAG is another example of a myelin-related glial protein whose absence has profound effects on the ensheathed axon.

In this regard, it is noteworthy that MAG is one of several neural proteins (also including Nogo and OMgp) that inhibit neurite outgrowth in tissue culture and axonal regeneration *in vivo* (see Ch. 30). This inhibitory activity has been studied intensively in recent years, since it is extremely important for understanding factors that prevent axonal regeneration following neural injury [26]. This area of research has led to remarkable progress in identifying neuronal MAG receptors, and to the identification of a MAG-mediated signaling mechanism that affects neurons and also could be important for the normal maintenance of myelinated axons. Thus, a physiologically important signal promoting the stability of mature myelinated axons could be interpreted inappropriately by a plastic developing neurite *in vitro* or a regenerating neurite *in vivo*, thereby inhibiting its growth. The MAG receptor on neurites that transmits this inhibitory signal appears to be a complex localized in raft-like signaling domains, which consists of gangliosides, the glycosylphosphatidylinositol-anchored Nogo receptor and the p75 neurotrophin receptor. This neuronal receptor complex involved in MAG's effects on neurite outgrowth is also likely to function within myelinated axons to promote axonal stability, but this remains to be established.

It is noteworthy that the axonal degeneration that occurs in the PNS of MAG-null mice is not observed in the CNS, possibly because other CNS myelin proteins enhance axonal stability. These could include PLP and/or CNP, both of which are needed for axonal stability in the CNS where they are present in much higher concentration. In summary, it appears that the most important function of MAG in the PNS is transmitting a signal from Schwann cells to axons that is needed for the stability of myelinated axons, whereas its principal function in the CNS is to transmit a signal in the reverse direction that promotes efficient myelination and oligodendrocyte vitality.

Myelin sheaths contain other proteins, some of which have only recently been established as myelin-related. The proteins described above represent most of the well-established myelin proteins that are myelin-specific or have been studied primarily in the context of myelin and demyelinating diseases. However, myelin sheaths contain numerous other proteins in smaller amounts that are also in many other cells and/or have only been identified relatively recently. Some of these are in compact myelin but others are enriched in specialized structures within myelin sheaths that are distinct from compact myelin. Some of these proteins, which may be among the many minor bands seen on myelin protein gels (Fig. 4-12), are described here briefly.

Tetraspan proteins. Intriguingly, there are numerous tetraspan proteins (containing four transmembrane spanning domains) in myelin and related glial membranes [27], including PLP/DM20, PMP-22, myelin and lymphocyte protein (MAL/MVP17/VIP17) and plasmolipin in compact myelin; and oligodendrocyte-specific protein (OSP)/claudin-11, CD9 and connexins in the specialized associated structures of the myelin sheaths, such as the tight junctions or the paranodal loops. The presence or absence of these proteins can be essential to the specialized structure and function of myelin. The paranodal loops, which form the tight junctions between glial processes and axons in the paranodal regions of the sheaths (Figs 4-3, 4-9), are crucial for normal firing of myelinated axons. Rapid saltatory conduction of nerve impulses in myelinated fibers is thus dependent on the structural integrity of nodes of Ranvier and of the tight junctions at this location, which prevent ion leaking into the internodes.

Other than PLP/DM20 and PMP22, one of the earliest myelin tetraspan proteins characterized was the 17 kDa **m**yelin **a**nd **l**ymphocyte tetraspan protein (MAL). This protein was initially identified in compact myelin as MVP17, a novel myelin membrane protein [28], which was quickly demonstrated to be identical to MAL and VIP17. MAL (MVP17/VIP17) is part of the apical sorting machinery in non-neural polarized cells and it has been proposed to be involved in protein sorting in myelin membrane domains. It associates with glycosphingolipid-enriched protein/lipid rafts and may function in their sorting and transport to myelin [29, 30]. MAL has been established to be part of an extended gene family, which includes plasmolipin, another myelin tetraspan protein [31]. Plasmolipin is also associated with glycosphingolipid-enriched membrane domains from myelin. Thus, this family of proteins, two of which are found in compact myelin, may be involved in sorting of proteins or in signal transduction through lipid rafts in myelin.

Many of the other myelin tetraspan proteins are localized in specialized myelin structures. Claudins are a family of tight junction proteins found in many tissues, which form barriers to the diffusion of solutes between adjacent cells. Tight junctions in the paranodal regions of the PNS that act as barriers for diffusion of small ions involve the tetraspan claudin-5 [32]. OSP is found in the radial component of myelin; it was initially identified by differential screening as a novel tetraspan protein found in oligodendrocytes but was quickly established to be also a member of the claudin family, i.e., claudin-11 [33]. The radial component is a specialized ultrastructural feature in CNS myelin but not PNS myelin, which appears as lines of tight junctions with reduced spacing between extracellular leaflets. These lines of tight junctions extend in spiraled

fashion across the whole thickness of CNS myelin sheaths from one paranodal region to the other. The CNS myelin tight junctions between adjacent layers of spiraled membranes probably contribute stability and, most importantly, act as a barrier to the diffusion of ions that is essential for the normal electrophysiological function of myelinated axons. The principal protein component of these tight junctions is OSP/claudin-11 [33] and, in OSP/claudin-11 null mice, these tight junctions are missing from CNS myelin. Thus, OSP/claudin-11 is essential for formation of the radial component in CNS myelin. In addition to its role in formation of tight junctions, OSP/claudin-11 is also involved in oligodendrocyte migration, possibly through its interactions with OSP/claudin-11 associated protein (OAP)-1 and β_1 integrin [33].

CD9 is a well-characterized hematopoietic tetraspan protein that has been shown to be present in CNS and PNS myelin, although it is present at higher levels in PNS myelin. In other cells, it is involved in integrin signaling and cell adhesion and motility. It is expressed at late stages of myelination and in the CNS is primarily found in paranodal junctions [34]. While compact CNS myelin is apparently normal in CD9-null animals, the paranodal loops are often disconnected from axonal membranes, and the transverse bands of the paranodal loops are lost. In the PNS, in addition to altered paranodes, hypermyelination occurs. Thus, this tetraspan protein appears to act primarily at paranodes, where it is crucial for normal paranodal junctions.

Another type of membrane contact in the paranodal regions is gap junctions, which provide a radial pathway for diffusion of small molecules across the lateral loops. In particular the tetraspan proteins connexin-32 and connexin-29 are found in myelin [35], predominantly in noncompact domains of myelin, including paranodes and Schmidt–Lanterman incisures. While gap junctions typically form between adjacent cells, in myelin they form between adjacent layers of membrane. In Schwann cells, functional gap junctions provide a radial pathway of interconnection throughout the myelin. It has been proposed that this radial pathway through the myelin mediates spatial buffering of extracellular potassium during action potential activity as well as communication from the adaxonal domain of myelin to the cell body. Similar radial pathways containing gap junctions probably also exist in CNS myelin. Connexin-32 mutations are associated with the peripheral neuropathy Charcot–Marie–Tooth disease (see Ch. 38) but, interestingly, have little CNS pathology.

Paranodal proteins other than tetraspan proteins. The overall structure of the axonal membrane at the nodes of Ranvier themselves is essential for normal axonal firing, and this appears to be regulated in *trans* by the proteins and lipids in the paranodal myelin membranes. The axonal and glial membranes in this region of the fiber demonstrate an exquisite division into highly specialized domains, whose biochemical structures are currently a very active subject of research. The correct positioning of sodium channels exclusively at the nodes and not in the internodes is necessary for generating action potentials. Similarly, the potassium channels are localized very specifically to the juxtaparanodal axonal membrane and, as noted above, cerebroside- and sulfatide-null mice have disorganized paranodes and consequently altered nodal membranes, for example altered sodium channel organization. A variety of membrane proteins, including several members of the immunoglobulin superfamily, are selectively localized in these nodal and paranodal domains and must play important roles in the formation and stabilization of these complex structures. For example, an important *trans* interaction at the paranode occurs between neurofascin-155 on the glial membrane and contactin/Caspr (contactin-associated protein) multimers on the axonal membrane to form septate-like junctions. A detailed description of the proteins and lipids in these structures is beyond the scope of this chapter, and the reader is referred to excellent recent reviews of this area that are available elsewhere [32, 36].

Enzymes associated with myelin. Several decades ago it was generally believed that myelin was an inert membrane that did not carry out any biochemical functions. More recently, however, a large number of enzymes have been discovered in myelin [37]. These findings imply that myelin is metabolically active in synthesis, processing and metabolic turnover of some of its own components. Additionally, it may play an active role in ion transport with respect not only to maintenance of its own structure but also to participation in ion buffering near the axon.

A few enzymes, such as the previously mentioned CNP, are believed to be fairly specific for myelin/oligodendrocytes. There is much more in the CNS than in peripheral nerve, suggesting some function more specialized to the CNS. In addition, a unique pH 7.2 cholesterol ester hydrolase is also enriched in myelin. On the other hand, there are many enzymes that are not myelin-specific but appear to be intrinsic to myelin and not contaminants. These include cAMP-stimulated kinase, calcium/calmodulin-dependent kinase, protein kinase C, a neutral protease activity and phosphoprotein phosphatases. The protein kinase C and phosphatase activities are presumed to be responsible for the rapid turnover of MBP phosphate groups, and the PLP acylation enzyme activity is also intrinsic to myelin.

Myelin enzymes involved in structural lipid metabolism consist of a number of steroid-modifying enzymes and cholesterol-esterifying enzymes, UDP-galactose:ceramide galactosyl-transferase and many enzymes of glycerophospholipid metabolism, including all the enzymes necessary for phosphatidyl ethanolamine synthesis from diradyl-*sn*-glycerol and ethanolamine. It is likely that phosphatidylcholine can also be synthesized within myelin. Perhaps even more elemental building blocks can be assembled

into lipids by myelin enzymes, since acyl-coenzyme A (CoA) synthetase is present in myelin, suggesting the capacity to integrate free fatty acids into myelin lipids. The extent of the contribution of these enzymes in myelin (relative to enzymes within the oligodendroglial perikaryon) to metabolism of myelin lipids is not known.

Other enzymes present in myelin include those involved in phosphoinositide metabolism; phosphatidylinositol kinase, diphosphoinositide kinase, the corresponding phosphatases and diglyceride kinases. These are of interest because of the high concentration of polyphosphoinositides of myelin and the rapid turnover of their phosphate groups. This area of research has expanded towards characterization of signal transduction system(s), with evidence of G proteins and phospholipases C and D in myelin.

Certain enzymes shown to be present in myelin could be involved in ion transport. Carbonic anhydrase has generally been considered a soluble enzyme and a glial marker but myelin accounts for a large part of the membrane-bound form in brain. This enzyme may play a role in removal of carbonic acid from metabolically active axons. The enzymes 5′-nucleotidase and Na^+, K^+-ATPase have long been considered specific markers for plasma membranes and are found in myelin at low levels. The 5′-nucleotidase activity may be related to a transport mechanism for adenosine, and Na^+, K^+-ATPase could well be involved in transport of monovalent cations. The presence of these enzymes suggests that myelin may have an active role in ion transport in and out of the axon. In connection with this hypothesis, it is of interest that the PLP gene family may have evolved from a pore-forming polypeptide [9].

Neurotransmitter receptors associated with myelin. Neurotransmitter receptors have been identified on oligodendrocytes and oligodendrocyte progenitor cells as well as in compact myelin [37, 38]. Their functional role has not been established but some intriguing hypotheses have been put forth. A wide variety of these receptors has been found, including muscarinic acetylcholine (mACh) receptors, α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptors, *N*-methyl-D-aspartate (NMDA) receptors and kainate receptors. It has been proposed that muscarinic receptors may be involved in phosphatidylinositol signaling in myelin or oligodendrocytes. There is recent evidence that muscarinic receptor activation alters integrin function in oligodendrocytes by modulating binding to extracellular matrix molecules [13]. With regard to adult pathologies, there is an increasing literature indicating that AMPA receptors may mediate glutamate cytotoxicity in oligodendrocyte progenitor cells.

Other myelin-related proteins. Another protein in compact CNS myelin is the myelin-associated oligodendrocytic basic protein, which is localized in the major dense line in several 8–12 kDa isoforms and appears to function in controlling axonal diameter and the arrangement of the radial component [39]. PNS myelin sheaths have long been known to contain a 170 kDa glycoprotein (see earlier editions of this chapter) that accounts for about 5% of the total myelin protein and may be related to the recently characterized L-periaxin-dystrophin-related protein 2-dystroglycan (PDG) complex associated with the Schwann plasma membrane [36, 40]. This PDG complex is essential for stable axon–glia interactions and mutations of the periaxin gene lead to profound disruptions of axonal ensheathment and segmental demyelination.

Small amounts of proteins characteristic of cells and membranes in general can also be found in myelin. There is evidence that tubulin is an authentic myelin-related component (**Fig. 4-12B, D,** CNS myelin). The 48 kDa myelin/oligodendrocyte-specific protein (MOSP) is a component found only in CNS myelin and oligodendroglial membranes, which appears to associate with tubulin [41].

DEVELOPMENTAL AND METABOLIC ASPECTS OF MYELIN

The developmental progress of myelination varies between regions and species. As the nervous system matures, portions of the PNS myelinate first, then the spinal cord, and the brain last [1]. In all parts of the nervous system there are many small axons that are never myelinated. It is generally true that large neural pathways become myelinated before they are completely functional. A relevant observation is that rats and other nest-building animals are quite helpless at birth and myelinate predominantly postnatally. By contrast, grazing animals such as horses, cows and sheep have considerably more CNS myelin at birth and a correspondingly higher level of complex activity immediately postnatally.

Synthesis of myelin components is very rapid during deposition of myelin. Nervous system development is marked by several overlapping periods, each defined by a major event in brain growth and structural maturation [1]. In the rat, whose CNS undergoes considerable development postnatally, the maximal rate of cellular proliferation (much of this involving oligodendroglial precursor cells) occurs at 10 days. The rat brain begins to form myelin postnatally at about 10–12 days. The maximal rate of accumulation of myelin in the rat occurs at about 20 days of age, although accumulation continues at a decreasing rate throughout adulthood. A remarkable amount of membrane biogenesis occurs in oligodendrocytes during the period of maximum myelination. Myelin accumulates in a 20-day-old rat brain at a rate of about 3.5 mg/day. Rough calculations based on the number of oligodendrocytes and the amount of myelin deposited indicate that on average the amount of myelin membrane made by each cell per day is more than three times the weight of its own perikaryon. This very rapid myelin synthesis early in development has been demonstrated biochemically by the

very rapid incorporation of radioactive precursors into myelin and substantial increases of enzymes involved in synthesizing myelin components.

Sorting and transport of lipids and proteins takes place during myelin assembly. After myelin components have been synthesized they must be assembled to form the membranes making up myelin sheaths [16]. The biogenesis of these sheaths is an extraordinary process of membrane formation and modeling. In the CNS, this requires the spiraling of numerous oligodendroglial processes around axons and their tight layering to form compact myelin. Furthermore, there is additional modeling of specialized membrane domains with different composition at the inside and outside of the sheaths and in the paranodal glia–axon junctions. The two major proteins of compact CNS myelin, PLP and MBP, enter the myelin by different routes. PLP is synthesized on membrane-bound polysomes in the perikaryon and transported in membranous vesicles to the myelin being formed at the end of the oligodendroglial processes. By contrast, MBP is synthesized on free polysomes, which are actually located in very close proximity to the newly forming myelin at the end of oligodendroglial processes [16]. Its mRNA is transported from the perikaryon to the vicinity of myelin formation in ribonucleoprotein granules by a microtubule-based translocation system. These differences in the route of entry are reflected in different kinetics of incorporation of proteins into myelin membranes in experiments involving labeling with radioactive amino acids after intracranial injection or incubation of brain slices. Radioactive MBP is synthesized and integrated into myelin very rapidly with a lag time of only a few minutes, whereas substantial amounts of radioactive PLP do not appear in myelin until after about 45 minutes [1]. Other proteins that are selectively localized in specialized regions of the myelin sheath such as the inner and outer surfaces (e.g. MAG and MOG, respectively) or in the paranodal regions (e.g. neurofascin-155) must be sorted and transported by different mechanisms involving specific sorting signals. It is likely that the sorting mechanisms are related to the apical and basolateral targeting that occurs in simple polarized epithelial cells. Using the model system of transfected Madin–Darby canine kidney (MDCK) epithelial cells, it was shown that MOG sorts exclusively to MDCK basolateral membranes, whereas PLP sorts exclusively to MDCK apical membrane [42]. However, sorting in myelin-forming cells probably also involves more complicated mechanisms because of the complex variety of membrane domains in myelin sheaths. Furthermore, some of the lipids and proteins in myelin forming cells are associated with raft-like domains, which are enriched in cholesterol, glycosphingolipids and glycosylphosphatidylinositol-linked proteins [7]. These rafts are likely to play an important role in the trafficking of membrane components and signal transduction mechanisms involved in the assembly of myelin sheaths. Much research designed to elucidate these phenomena and other aspects of myelin assembly is ongoing. However, a more detailed description of this research is beyond the scope of this chapter, and the reader is referred to more comprehensive references [7, 16].

The composition of myelin changes during development. The composition of myelin isolated from immature, rapidly developing brain is different from that of the adult [1]. As rat brain matures, the content of galactolipids, MBP and PLP in purified myelin increases, whereas phosphatidylcholine and high-molecular-weight proteins decrease. These studies on the composition of myelin from immature brains are consistent with the concept that myelin first laid down by oligodendrocytes may represent a transitional form with properties intermediate between those of mature compact myelin and the oligodendroglial plasma membrane. However, interpretation of biochemical studies on purified myelin is complicated by the fact that myelin fractions isolated by conventional procedures can be separated into subfractions of different densities. The lighter fractions are enriched in multilamellar myelin, whereas the denser fractions contain a large proportion of single membrane vesicles that morphologically resemble microsomes or plasma membrane fragments. Generally speaking, as one goes from light myelin subfractions to heavier ones, the lipid:protein ratio and the amount of MBP decrease, the amount of PLP decreases or remains relatively constant, and the amounts of MAG, CNP and other high-molecular-weight proteins increase. The interpretation of these findings is that the light subfractions contain primarily compact myelin while the heavier fractions are enriched in other oligodendroglial-derived membranes from the cell processes, the inner and outer surfaces of the sheaths, and the paranodal loops. Therefore, the differing lipid and protein composition of isolated immature myelin may reflect either transitional forms of developing myelin or a greater content of associated oligodendroglial membranes relative to compact myelin recovered from the thinner immature myelin sheaths, or a combination of these factors. Nevertheless, metabolic studies with radioactive precursors lend support to the view that the heavier fractions isolated from developing brain represent at least in part transitional membranes in the process of conversion to compact myelin. For example, PLP appears first in the heavier fractions and later in lighter fractions in a manner that suggests a precursor–product relationship.

Spontaneous mutations in experimental animals provide insights about the structure and assembly of myelin. The myelin mutants often have names relating to their characteristic tremor due to the myelin deficit, e.g. *shiverer*, *jimpy*, *quaking* and *trembler* mice (Table 4-2). Although some of the mutants have been studied for many years [1], it is only recently that recombinant DNA techniques have led to identification of the primary genetic defects in most of them. Some of them are good

models for inherited human diseases affecting myelin, as described in Ch. 38. Furthermore, the naturally occurring mouse mutants, which may express abnormal myelin proteins, sometimes have phenotypes that differ from null mutants produced experimentally by homologous recombination and are thereby instructive with regard to the mechanisms of myelin formation and loss.

Mutation of either of the major structural proteins of CNS myelin can lead to a severe hypomyelination; MBP in *shiverer* or myelin-deficient (mld) mice and PLP in *jimpy* mice and several other animal mutants [10, 43, 44] (Table 4-2). Ultrastructural abnormalities in the small amount of myelin that is formed by these mutants have been informative with regard to the structural roles of these proteins in compact CNS myelin. Thus the cytoplasmic surfaces of the spiraled oligodendrocyte membranes do not compact to form a major dense line in the absence of MBP in *shiverer* mutants, and the intraperiod line is more condensed than normal in *jimpy* mice, which express very little PLP. The ultrastructure of PNS myelin is normal in both of these mutants since PLP is virtually absent from peripheral myelin and P_0 appears to be capable of stabilizing both the intraperiod and major dense lines of myelin of the PNS in the absence of MBP. The *shiverer* phenotype can be corrected by introducing normal MBP into transgenic mutant mice, resulting in almost complete correction of the shivering, early death and failure of CNS myelin compaction.

The severity of the myelin deficiency in PLP mutants varies. Most PLP mutations are quite severe, but the PLP mutation in *rumpshaker* mice causes a relatively mild hindlimb shaking phenotype. By contrast, there is severe reduction and abnormal structure of CNS myelin in *jimpy* mice, along with a profound loss of oligodendrocytes. Furthermore, attempts to correct the *jimpy* phenotype by introducing the normal gene have not been successful. Thus the *jimpy* PLP mutation appears to be dominant, causing a misfolded protein response that leads eventually to oligodendrocyte death with morphological features of apoptosis. These oligodendroglial abnormalities appear to be the primary cause of the severe hypomyelination in *jimpy* mice rather than the absence of PLP in the myelin, since, as noted above, the PLP-null mouse has relatively normal myelin. The PLP mutants demonstrate the fact that protein mutations may be far more severe than simple loss of the protein. It must be noted that mutation of the minor isoforms of these proteins expressed in glia, neurons and other cell types may also impact these phenotypes [10].

Two allelic *trembler* mutations, which affect only the PNS, result from different point mutations in transmembrane domains of peripheral myelin protein-22 (PMP-22) [1, 45] (Table 4-2). The *trembler* phenotypes are characterized by hypomyelination, continued Schwann cell proliferation and partial paralysis of the limbs. These murine mutants are animal models for some of the inherited human neuropathies caused by abnormalities of the PMP-22 gene (Ch. 38). Because the function of PMP-22 is uncertain, the mechanisms by which the point mutations in this protein cause the *trembler* phenotype are unclear. However, as with the PLP mutations, the pathology may result from an unfolded protein response to abnormal protein that is retained in the endoplasmic reticulum.

A number of spontaneous animal mutants are not direct mutations of compact myelin protein genes but rather appear to cause defects in cellular processes needed for myelin assembly or maintenance. One example is the *quaking* mouse, with hypomyelination in both the CNS and PNS but a greater deficiency of CNS myelin [1, 46] (Table 4-2). Unlike the *shiverer* and *jimpy* mice, which form almost no myelin and die early, *quaking* mice generate more myelin and live to adulthood. However, the myelin sheaths are thin and poorly compacted, especially in the CNS. The myelin isolated from the CNS of this mutant has all the known myelin proteins but its overall composition resembles that of very immature normal mice. Although the *quaking* mouse was one of the first dysmyelinating mutants to be described and has been extensively studied, the genetic lesion was identified only recently. The *quaking* gene encodes a family of RNA-binding proteins generated by mRNA splicing. These QKI proteins appear to regulate the alternative splicing and/or transport of oligodendroglial mRNAs for myelin proteins such as MBP and MAG [46–48].

The more recently identified 'taiep' rat mutant (Table 4-2) has impaired accumulation of CNS myelin for up to 2 months followed by a period of demyelination [49]. Adult taiep rats have only 10–25% of the normal amount of CNS myelin. The primary genetic lesion has not yet been identified but the mutant oligodendrocytes exhibit an abnormal accumulation of microtubules during development, suggesting that the mutation may involve a microtubule-associated protein. Biochemical and immunocytochemical studies indicate that excessive microtubule accumulation interferes with transport of myelin proteins and/or their mRNAs, eventually leading to a failure of myelin maintenance [49].

Myelin components exhibit great heterogeneity of metabolic turnover. One of the novel characteristics of myelin demonstrated in early biochemical studies was that its overall rate of metabolic turnover is substantially slower than that of other neural membranes [1]. A standard type of experiment was to evaluate lipid or protein turnover by injecting rat brains with a radioactive metabolic precursor and then follow loss of radioactivity from individual components as a function of time. Structural lipid components of myelin, notably cholesterol, cerebroside and sulfatide, as well as proteins of compact myelin, are relatively stable, with half-lives of the order of many months. One complication in interpreting these studies is that the metabolic turnover of individual myelin components is multiphasic – consisting of an initial rapid loss of radioactivity followed by a much longer slower loss.

For example, initially MBP and PLP exhibit half-lives of 2–3 weeks, but later their half-lives are too long to be calculated accurately. A possible interpretation of these data is that some of the newly formed myelin remains in outer layers or near cytoplasmic pockets (incisures and lateral loops) where it is accessible for catabolism – thus accounting for the rapidly turning-over pool. The more stable metabolic pool would consist of deeper layers of myelin less accessible for metabolic turnover.

By contrast to the relatively slow rate of overall metabolism, the presence of signal transduction systems in myelin sheaths [7, 16] indicates that some aspects of myelin metabolism probably involve rapid events with half-lives on the order of minutes. For example, the monoesterified phosphate groups of polyphosphatidylinositol (those at positions 4 and 5) are labeled very quickly even in mature animals, and this is presumably related to the function of phosphoinositides in signal transduction (see Ch. 20). Additionally, the phosphate groups on MBP turn over rapidly [17]. Although the representation of myelin structure in **Figure 4-11** is static, studies that demonstrate relatively rapid metabolism of certain myelin components suggest that there may be some dynamic aspect of myelin structure, such as occasional separation of the cytoplasmic faces of the membranes. The dynamic nature of myelin sheaths probably contributes to the maintenance and functional state of axons. Clearly recent studies on the pathology of multiple sclerosis demonstrate the crucial nature of myelin both for nerve conduction and axonal survival (see Ch. 38). A more complete understanding of the formation and maintenance of myelin sheaths awaits conceptual and analytical advances.

ACKNOWLEDGMENTS

We thank Dr Cedric Raine for the elegant photomicrographs in this chapter and Jeffrey Hammer for help in preparing **Figure 4-11** showing the molecular organization of compact myelin.

George J. Siegel

INTRODUCTION 73
Primary active cation transporters energize many of the most basic neural functions 73

PRIMARY ION TRANSPORTERS 74
The primary transporters discussed in this chapter belong to three distinct genomic superfamilies that differ markedly in structure and reaction mechanism 74
P-type transporters share the same general reaction mechanism 74
A major fraction of cerebral energy production is consumed by the Na^+,K^+ pump 75
Na,K-ATPase is a heterodimer consisting of a catalytic α-subunit and an accessory β-subunit 75
In the central nervous system, Na,K-ATPase is most highly expressed in regions where high levels of Na^+/K^+ exchange are expected 76
The α-subunit isoforms are products of separate genes that differ in their 5′-flanking regulatory sequences 76
Na,K-pump activity can be controlled by rapid endocytic removal and insertion in response to GPCR-regulated phosphorylation of α subunits 77
Na,K pumps may function as signal transducers 79

Ca^{2+} PUMPS 79
ATP-dependent Ca^{2+} pumps and Na^+,Ca^{2+} antiporters act in concert to maintain a low concentration of free cytosolic Ca^{2+} 79
The uniquely high resolution structural data available for the SERCA1a Ca^{2+} pump illuminates the structure of all P-type transporters 81
P-type copper transporters are important for neural function 82

V_0V_1-PROTON PUMPS 82
The V-ATPase pumps protons into Golgi-derived organelles 82

ATP-BINDING CASSETTES 82
The ABC transporters are products of one of the largest gene superfamilies 82

SECONDARY ACTIVE TRANSPORT 84
Secondary transporters employ energy stored in ion gradients to transport other ions and molecules 84
The recovery of neurotransmitters from synaptic clefts and their storage in cytoplasmic vesicles is accomplished by the tandem actions of the secondary transporters in plasma and vesicular membranes 84
Packaging neurotransmitters into presynaptic vesicles is mediated by proton-coupled antiporters 86

PHYSIOLOGICAL ASPECTS OF THE NEUROTRANSMITTER TRANSPORTERS 86
Cytoplasmic chloride must be transported outward to generate the gradient that allows GABA- or glycine-gated channels to hyperpolarize neurons 87

CATION ANTIPORTERS 87
Na^+,Ca^{2+} exchangers are important for rapidly lowering high pulses of cytoplasmic Ca^{2+} 87
Intracellular pH in brain is regulated by Na^+,H^+ antiporters, anion antiporters and Na^+, HCO_3^- symporters 87
Rapid clearance of K^+ from neuronal extracellular space is critical because high extracellular K^+ depolarizes neurons 88
Cell-volume regulation involves control of the content of osmotically active impermeant molecules and ions 88

FACILITATORS 89
Simple diffusion of the polar water molecules through lipid bilayers is too slow to account for observed rates in some cells 89
AQP4 is the major water facilitator in brain and is most concentrated in astrocyte endfeet, but AQP4 has not been found in neurons 89
Facilitated diffusion of glucose across the blood–brain barrier and into brain cells is catalyzed by GLUT1,- 2 and -3, products of the SLC2 gene superfamily 90
Brain capillary endothelial cells and some neurons also express a Na^+-dependent D-glucose symporter, SGLT1 91

INTRODUCTION

Primary active cation transporters energize many of the most basic neural functions. They transform free energy from ATP hydrolysis into electrochemical energy that is stored in the transmembrane concentration gradients of Na^+, K^+, Ca^{2+} and protons. These energy stores are employed via membrane channel proteins for signaling, and also by *secondary transporters* that selectively concentrate many other ions and molecules. Secondary transporters subserve many different neural functions such as packaging neurotransmitters into vesicles and terminating signals at synapses. Also classified as transporters are *facilitator*

Basic Neurochemistry: Molecular, Cellular and Medical Aspects

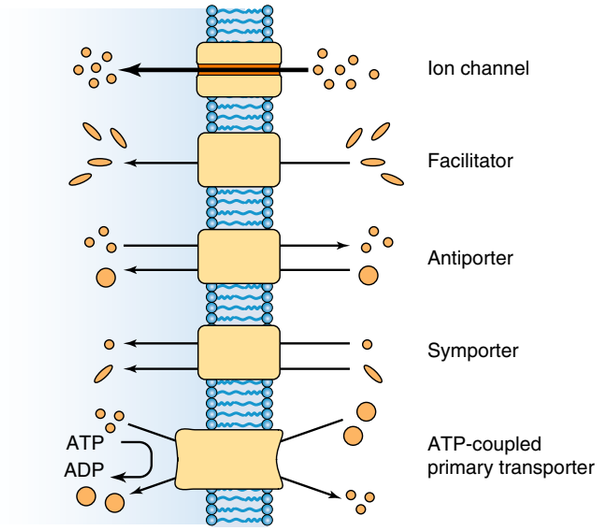

FIGURE 5-1 Types of membrane transport proteins. Ion channels provide gated diffusion paths across cell membranes that are regulated by membrane voltage, interactions with ligands, and/or by phosphorylation (see Ch. 6). Facilitators or uncoupled transporters provide highly selective pathways, e.g. for D-glucose or water, but are not coupled to energy sources and therefore cannot concentrate their substrates. Transporters that are coupled to energy sources can alter the steady-state distribution of their substrate ions and/or molecules. Secondary transporters derive energy from existing ion gradients to transport a second ion or molecule in a direction that is either the same as (symport) or opposite to (antiport) that of the energizing ion. Primary transporters couple a chemical reaction to protein conformational transitions, which supply energy to generate concentration gradients of one or more substrates across cell membranes. For identifying and classifying transporters and channels, see online databases [41].

proteins; they enable specific molecules to diffuse across membranes, often under regulatory control, but are incapable of 'uphill' transport (Fig. 5-1).

Relative to ion channels which, when open, allow diffusion of thousands of ions per channel per millisecond (Ch. 6), transporters typically require milliseconds to move 1–3 ions or molecules per reaction cycle in the uphill direction. Thus transporters are usually expressed at much higher densities in membranes than are ion channels.

PRIMARY ION TRANSPORTERS

The primary transporters discussed in this chapter belong to three distinct genomic superfamilies that differ markedly in structure and reaction mechanism. These P-, V_0V_1- and ABC-superfamily members all catalyze reactions with ATP that drive conformational cycles to move substrates across membranes and 'uphill' to higher concentrations.

P-type transporters share the same general reaction mechanism. Most pumps belonging to the P-type transporter superfamily have evolved to create cation gradients. In the case of the P-type Na^+,K^+ pumps, the Na^+ and K^+ concentration gradients generated across all eukaryotic plasma membranes constitute a large potential energy store that is employed for electrical signaling and for driving secondary transporters. Ca^{2+} gradients are also generated by P-type transporters, but these gradients are employed primarily for intracellular signaling (Ch. 22). The structures and reaction mechanisms of the Na^+,K^+ and Ca^{2+} pumps are similar and have provided insights into the functioning of the whole class of P-type transporters.

Because of the distinct roles of the two different substrate cations in its reaction mechanism, the Na^+,K^+ pump most conveniently illustrates the mechanism of P-type pumps. The Na^+,K^+ pumps are driven by a cycle of conformational transitions that is driven by phosphorylation of their catalytic sites, activated by cytoplasmic Na^+, and hydrolysis of the same phosphorylated sites, activated by extracellular K^+ (Fig. 5-2).

The cycle is initiated by ATP binding to the catalytic site and cytoplasmic Na^+ binding to all three ionophoric sites. The catalytic sites contain an aspartyl residue, which becomes phosphorylated only when all three Na^+ binding sites are occupied by sodium ions. Phosphorylation of the aspartyl is readily reversible when the pump molecule is in the E1 conformation; that is, the energy states of the E1 aspartylphosphate bond and of the ATP phosphate bond are similar. This is demonstrated by the ability of the phosphorylated enzyme to rephosphorylate ADP to ATP under conditions that inhibit step 3 in Figure 5-2. However, the active pump formation of the aspartylphosphate bond initiates a rapid transition to the E2-P conformation, in which the ionophoric sites have changed their selectivity, causing the three Na^+ to be discharged extracellularly in exchange for binding two K^+. This initiates hydrolysis of the aspartylphosphate bond in the E2 state which, in concert with ATP binding, causes E2 to revert to E1. In consequence of this the ionophoric sites discharge the two K^+ into the cytoplasm. ATP binding initiates the next transport cycle. This transport reaction can occur at a rate of ≈10,000 cycles per minute.

As noted above, a Na^+,K^+ pump exchanges three Na^+ for two K^+ per transport cycle. This produces a net outward flow of positive charge, which can generate an electrogenic potential. The extent of membrane hyperpolarization by the pump can be evaluated by measuring the reduction in membrane potential produced by selective Na^+,K^+ pump inhibitors such as ouabain. The electrogenic potential is usually small, 10 mV or less, because opposing ion currents flow through channels or secondary transporters in the contiguous membrane. However, in some neurons and muscle cells, sodium pump hyperpolarization can shorten the duration of an action potential and contribute to negative afterpotentials. In heart muscle, hyperpolarization due to Na^+ pumping occurs after sustained increases in firing rate and may be a factor in cardiac arrhythmias. [1].

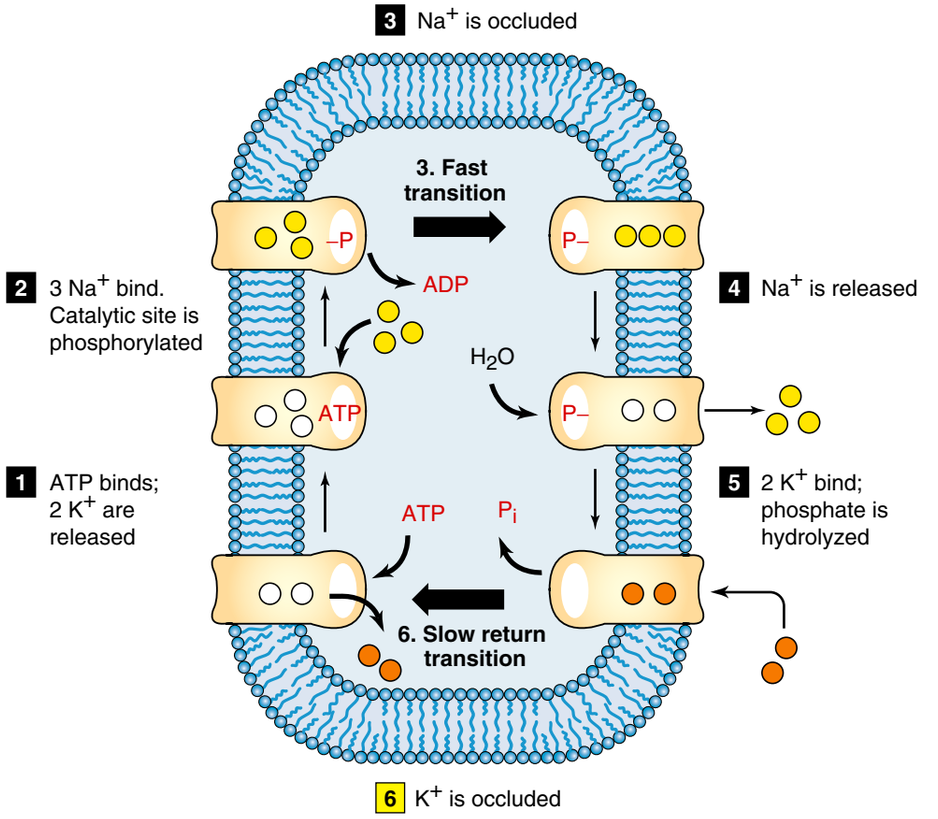

FIGURE 5-2 The mechanism of the ATP-dependent sodium pump. The sequence of reaction steps is indicated by the *large arrows*. On the left side, pump molecules are in the E1 conformation, which has high affinity for Na^+ and ATP and low affinity for K^+. Ionophoric sites are accessible only from the cytoplasmic side. *Step 1.* K^+ is discharged as metabolic energy is added to the system by ATP binding. *Step 2.* Three Na^+ bind and the enzyme is reversibly phosphorylated. *Step 3.* The conformational transition from E1~P to E2–P, shown at the top, is the 'power stroke' of the pump during which the ionophoric sites, with their three bound Na^+, become accessible to the extracellular side and decrease their affinity for Na^+. Part of the free energy of the enzyme acylphosphate has been dissipated in this process. *Step 4.* Three Na^+ dissociate from E2-P. *Step 5.* Two K^+ bind and more free energy is dissipated as the enzyme acylphosphate is hydrolyzed. At this point the two K^+ become tightly bound ('occluded') and in *step 6* E2 reverts to E1, carrying the K^+ to the cytoplasmic side. Each step of this cycle is experimentally reversible.

A major fraction of cerebral energy production is consumed by the Na^+,K^+ pump. Most of this is required to compensate for extrusion of intracellular Na^+ that enters through channels during electrical activity and through Na^+-dependent secondary transporters during neurotransmitter recovery. Assuming typical values for Na^+ and K^+ concentration gradients, that is, $[Na^+]_e/[Na^+]_i \approx 12$ and $[K^+]_i/[K^+]_e \approx 50$, then ΔG is about 3.8 kcal (16 kJ) per mole of Na^+ exchanged for K^+. Hydrolysis of a high-energy phosphate bond of ATP may yield as much as 12≈kcal/mol under physiological conditions, thus permitting the exchange of about three equivalents of cation for each mole of ATP hydrolyzed. From this stoichiometry, it appears that the chemical free energy of ATP hydrolysis must be utilized with about 95% efficiency ($3 \times 3.8/12$) to operate the sodium pump under physiological conditions. Other processes utilizing energy stores are listed in Table 31-1.

Na,K-ATPase is a heterodimer consisting of a catalytic α-subunit and an accessory β-subunit. Four isoforms of the α-subunit and three of the β-subunit are expressed in mammals. Three of the α-subunit isoforms are expressed in brain and will be discussed in a later section.

The β-subunits (≈40 kDa) are monotopic glycoproteins and exhibit some characteristics of cell adhesion molecules. At least one of the three β-subunit isoforms must be coexpressed to translocate an α-subunit from the endoplasmic reticulum (ER) to the plasmalemma. The three β-subunit isoforms have about 45% sequence identity. The β1 is most generally expressed [2]. The β2 was initially described as an 'adhesion molecule on glia' (AMOG) because it is transiently expressed on the surface of cerebellar Bergmann glia during the differentiation of granule cells. As the brain matures, it becomes widely expressed on astrocytes and disappears from most neurons. The particular β-subunit isoform paired with an α subunit

has little effect on pump parameters [3]. However, the different β isoforms may influence the ultimate cellular and subcellular localizations of the Na^+ pumps [4].

There are also Na^+ pump γ-subunits, a family of ≈15 kDa proteolipids that can associate with sodium pump α-subunits. However they are not necessary for pump activity nor are they expressed in all cells. The γ-subunits are classed as members of the FXYD gene family and several are expressed in brain [5]. The kidney expresses almost exclusively Na^+,K^+ pumps with α_1-subunits throughout the functionally diverse segments of the nephron, but different γ-subunits are expressed in different segments. From this it is inferred that different γ-subunits optimize the sodium pump for operation under the varying ionic environments [6].

In the central nervous system, Na,K-ATPase is most highly expressed in regions where high levels of Na^+/K^+ exchange are expected. These include axonal terminals, nodes of Ranvier, dendritic processes and neuronal soma, but not in myelin wrappings. In the spinal cord, neuronal α1 expression is restricted to a set of laterally situated anterior horn cells and to intermediolateral thoracic cord cells. Different dorsal root ganglion cells express α3 alone or together with α1 but do not express α1 alone. In retinal pigment epithelium and choroid plexus ependyma, the Na^+ pump is most concentrated on apical (luminal) surfaces (Fig. 5-3). With these exceptions, epithelial cells adapted for secretion or reabsorption express the Na^+ pump exclusively on the basolateral or abluminal surfaces.

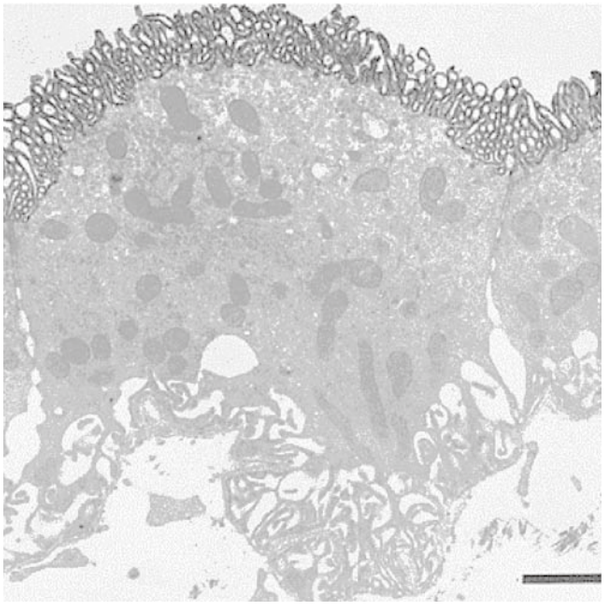

FIGURE 5-3 Immunocytochemical localization of the Na,K pump in choroid plexus. Choroid plexus contains epithelial cells with intensely stained microvillar and intermicrovillar plasma membranes. The basal and lateral plasma membrane surfaces are not stained. Bar = 2 μm. (With permission from reference [81].)

Na,K-ATPase expression patterns change with development, aging and dementia. The Na,K-ATPase activity, relative to total protein, increases about tenfold just prior to the stage of rapid myelination in rats. This occurs 2–12 days postnatally and corresponds to the time of glial proliferation, elaboration of neuronal and glial processes and increasing neuronal excitability. Neurons may play a role in upregulating glial expression of the α2 isoform during peak periods of myelination and the effect is probably dependent on contact [7]. Developmental changes in Na,K-ATPase in brain appears to depend on thyroidal influences. Glial cell cultures from 1-day old rat brain express progressively increasing amounts of α1, α2, β1 and β2 isoforms as a function of increasing triiodothyronine exposure [8].

In cerebral cortex of human (Fig. 5-4) and rat, α3 mRNA is found clustered over pyramidal and other neuronal soma while α1 mRNA is distributed diffusely through the neuropil. In non-demented, aged humans the expression of α1 mRNA does not significantly change, although there are significant but small reductions in α3 mRNA of neuronal perikarya. In contrast, in dementing Alzheimer's disease (Ch. 47), the contents of α3 mRNA in neuronal perikarya and neuropil are markedly diminished early in the neurodegenerative process, prior to neuronal dystrophic changes (Fig. 5-4).

The α-subunit isoforms are products of separate genes that differ in their 5′-flanking regulatory sequences. These may enhance or obstruct the assembly of the preinitiation complex of RNA polymerase and relevant transcription factors [9]. Physiological isoform expression varies with cell type and maturity. In rat heart, the predominant form shifts from neonatal α3 to adult α2.

The α3 isoform is expressed mainly in adult neurons and neonatal cardiomyocytes. The α3 gene exhibits three positively regulating *cis* elements that bind NP-Y, Sp1 and Sp2 [10]. Its neuron specificity appears to be related to a neural-restrictive silencer element and a positively acting *cis* element [11].

The 'basal promoter,' required for constitutive expression of the α1 gene, is a positive regulatory element termed ARE [12] containing binding sites for several transcription factors, including the cAMP-responsive element (CRE). CRE occurs within promoters of many cAMP-inducible genes and can interact with CRE-binding (CREB) and CRE–modulatory (CREM) proteins and with activating transcription factor (ATF)-1. These are a subgroup within the leucine zipper family defined by their amino acid-sequence similarity and ability to dimerize with each other. The CRE site is subject to regulation by several pathways, some involving cAMP, Ca^{2+} and transforming growth factor (TGF)β. Phosphorylation of ATF-1 and CREB by PKA or PKC enhances their binding to the

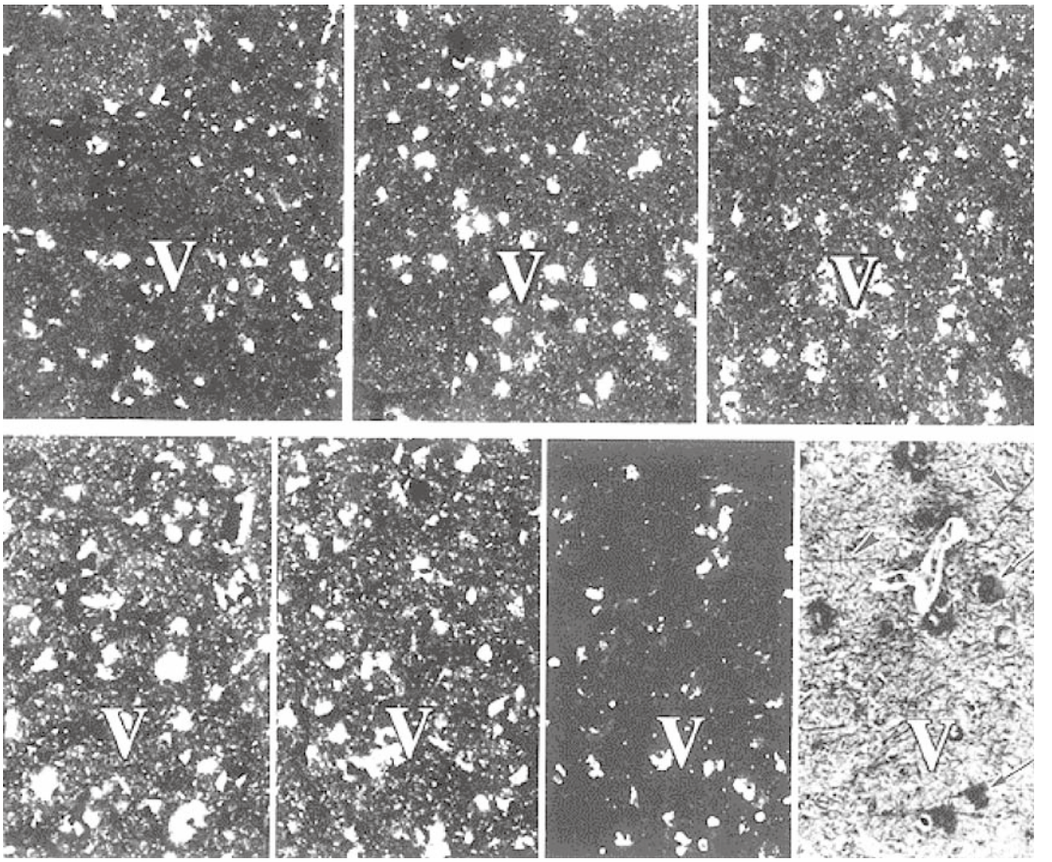

FIGURE 5-4 In situ hybridization detection of α1- and α3-mRNAs of Na,K-ATPase in human superior frontal cortex (layers IV, V). **Top row, α1.** Left to right: 39-year-old normal, 78-year-old normal, 78-year-old Alzheimer's disease (AD) subject. Note the mildly increased hybridization signal for α1-mRNA in the normal age-matched and AD brains compared to the young control brain. **Bottom row, α3.** Sections adjacent to those in the top row. *Far right:* Bielschowsky stain of adjacent AD cortex. Note the small decrease in hybridization signal in the aged normal relative to the young control and the large decrease in signal in AD relative to young and age-matched control brains. The Bielschowsky silver stain shows dark-appearing amyloid plaques in the AD brain. (With permission from reference [82].)

ATF/CRE site and may be required for transcription of the ATPase α1 gene [13].

Na,K-ATPase is subject to hormonal regulation. In the rat hippocampus, the dentate granular cells express the α1 and α3 isoforms and, in adrenalectomized rats, aldosterone can selectively regulate α3 in these neurons. In other cortical neurons that express both mRNAs, however, aldosterone has no effect on either [14], and, in kidney, aldosterone regulates the level of expression of α1. Isoform regulation by aldosterone is evidently determined by local factors such as cell type and location. These positive or negative local factors in gene regulation have been termed the 'cell context'. The cAMP or CREB protein system also interacts with the mineralocorticoid receptor system to modify α-subunit transcription [15]. In rat renal cortex, aldosterone increases α-1 subunit mRNA and this was shown to be directly due to aldosterone rather than to increased Na^+ flux [16]. Aldosterone also upregulates α3 and β1 isoform mRNAs in brains of adrenalectomized rats [17].

Na^+ can also regulate Na,K-pump expression. Alterations in the local ionic environment, through changes in cytoplasmic $Ca^{2+}$and Na^+, can affect expression of the Na,K pump via early-response genes [18].

Na,K-pump activity can be controlled by rapid endocytic removal and insertion in response to GPCR-regulated phosphorylation of α-subunits. For example, renal proximal tubule epithelia secrete dopamine, which acts on autocrine-D1-like receptors to remove Na,K pumps from their basolateral plasma membrane (Fig. 5-5). Pump endocytosis is initiated by phosphorylation at ser-18 of its α1 subunit by ζ-PKC, which permits interaction of PI3K-IA with the α-subunit and AP-2, thus inducing clathrin binding (see Ch. 9). Upregulation of Na,K pumps by recruitment requires α1 phosphorylation at both ser-11 and ser-18, which can be via β-PKC in response to serotonin- or angiotensin-activated GPCRs that leads to AP-1 binding. Another activation path for Na,K-pump

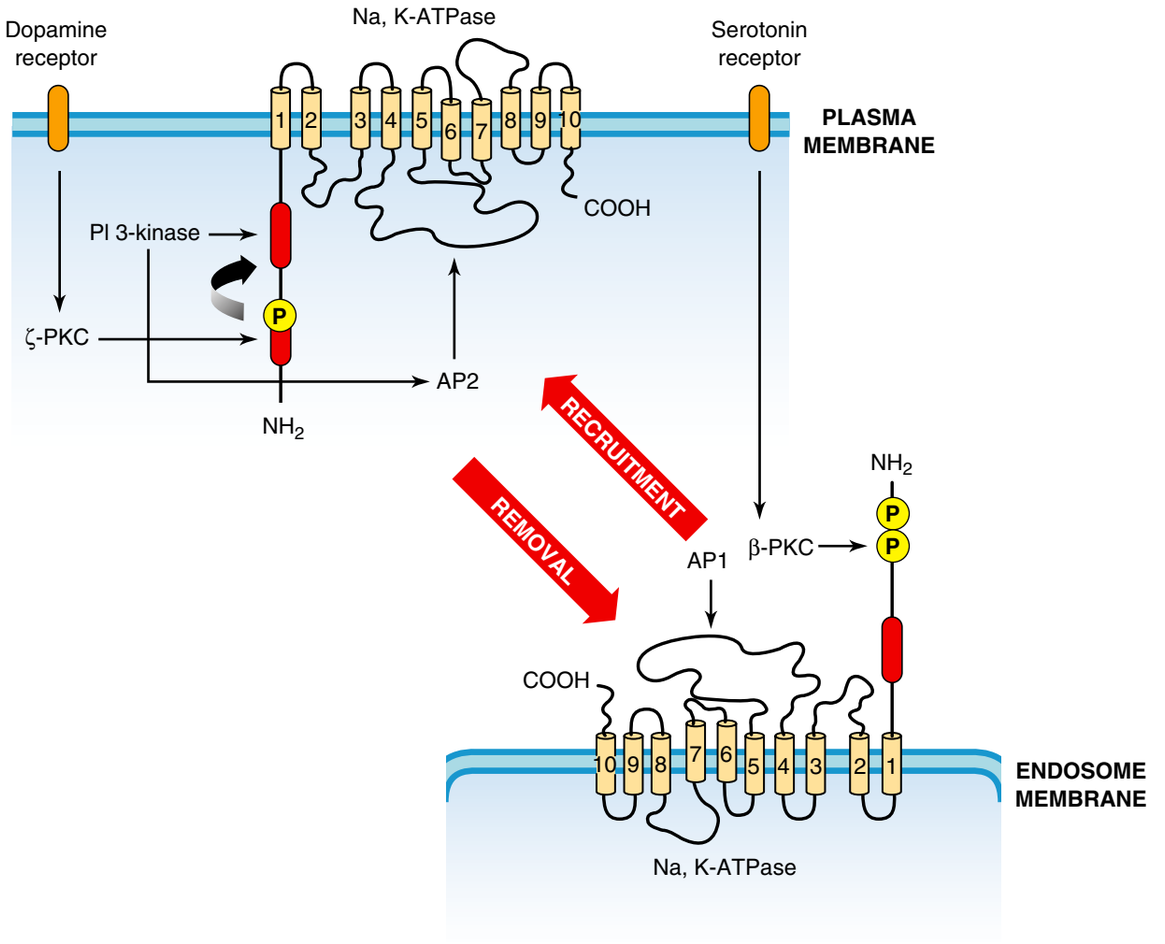

FIGURE 5-5 In kidney epithelial cells, which express only the α1 isoform, down-regulation of Na,K pumps can be initiated by dopamine via GPCR activation of endocytosis and this is controlled by phosphorylation of a single Ser-residue within the N-termini of the Na,K-ATPase α1-subunits to be internalized. Mutation analysis suggests that PI3K-IA activation ensues from its binding to a proline-rich domain present in the Na,K-ATPase α1-subunit, but which only becomes accessible to the kinase after ζ-PKC-dependent Ser-phosphorylation. PI3K-IA activation recruits the AP-2 adaptors that transfer plasma membrane vesicles into early endosomes. Thus, the Na,K-ATPase serves as its own scaffold, organizing the receptor signals that ultimately down-regulate its activity. Serotonin, acting through GPCR, can activate β-PKC phosphorylation of two serines within the N-termini of the endocytosed Na,K-ATPase α1-subunits. This evidently recruits AP-1 adaptors that initiate re-incorporation of Na,K pumps into plasma membrane. However, in the case of cultured striatal spiny neurons, which express all three Na,K-pump isoforms, regulation is more complex: although dopamine produces endocytosis-based down-regulation, this can be prevented by glutamate and glutamate can produce net pump activation by recruiting the α2 isoform [20]. (Adapted with permission from Fig. 4 of reference [83]).

recruitment to plasma membranes appears to involve α1 subunit phosphorylation on tyr-527 [19].

Endocytosis and recruitment of Na,K pumps occurs in primary isolates of striatal neurons. However in these neurons only α2 subunits were removed in response to dopamine whereas α1 subunits were selectively recruited in response to glutamate [20].

The cellular and subcellular distributions of α-subunit isoforms provide clues to their different physiological functions. The four isoforms exhibit about 85% sequence identity. The most substantial differences occur in their N-terminal regions and in an 11-residue sequence of the large cytoplasmic loop. When measured in cell cultures, the isoforms differ in their apparent affinities for intracellular Na^+ ($\alpha1 < \alpha2 < \alpha3$) [21] and extracellular K^+ ($\alpha3 < \alpha2 = \alpha1$) [22]. In adult tissues, α1 is the major isoform in most cells and functions as the 'housekeeping' or 'bulk Na extrusion' isoform. The α2, α3 and α4 isoforms are subject to unique forms of regulation and subcellular localization. In adult mammalian brains α1 is expressed in both neurons and glia, α2 is expressed in glia and some neurons, and α3 is expressed in most neurons.

In tissue culture, astrocytes, hippocampal neurons and arterial myocytes all express α1 diffusely in their plasmalemma. In contrast, immunocytochemically stained α2 in astroglia and α3 in myocytes and neurons display reticular patterns and colocalize with the Na^+/Ca^{2+} exchanger (NCX) (Fig. 5-6). These plasmalemma reticular patterns coincide with the patterns of staining for junctional complexes on sarcoplasmic reticulum and, in astroglia and neurons, junctional complexes on endoplasmic reticulum [23].

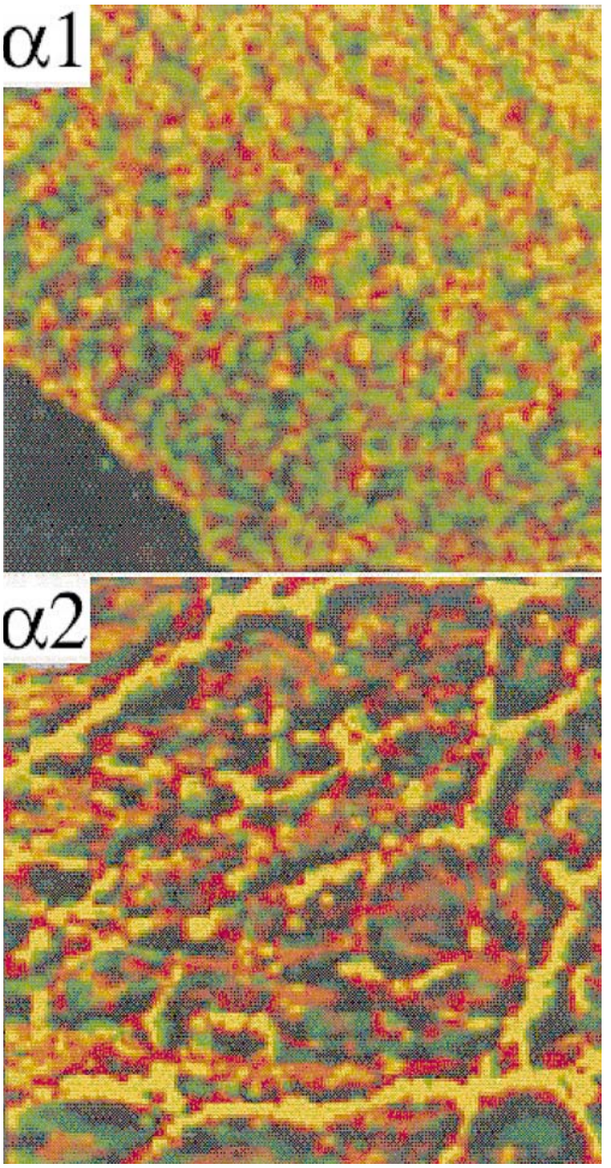

FIGURE 5-6 Localization of Na^+ pump α1 and α2 isoforms in primary cultured astrocytes. Cells were incubated with monoclonal antibodies specific for α1 or α2. The original fluorescent images were filtered by 'nearest neighbor' deblurring and the restored images compare portions of two astrocytes labeled with these antibodies. Both cells were later treated with a fluorescent dye, DiOC, to stain ER and mitochondria. When the respective antibody-labeled images (green) and DiOC-stained images (red) are superimposed, a yellow reticular pattern is observed where the ER and Na,K pumps coincide. (Adapted with permission from Fig. 4 of reference [23]).

The Ca^{2+} pumps of smooth reticulum and ER normally reduce cytoplasmic $[Ca^{2+}]$ to <1 μM. However, rapid restoration of such low $[Ca^{2+}]$ subsequent to plasma membrane depolarizations requires coordinate activity of the plasmalemma Na^+/Ca^{2+} exchanger (see discussion below). Because the energy source for driving this exchanger is the plasmalemma Na^+ gradient, inhibition of the Na,K-ATPase by a cardiac glycoside or an endogenous regulatory molecule [24] will increase cytosolic $[Na^+]$ and, secondarily, increase cytosolic $[Ca^{2+}]$, which then increases heart muscle contractility. This is the presumed cardiotonic mechanism of digitalis and related cardiosteroids.

Genetic evidence supports the importance of coordinated expression and distributions of α2 or α3 Na^+/K^+ pump isoforms with the Na^+/Ca^{2+} exchanger (NCX) and Ca^{2+} pumps to function in excitable and contractile cells: deletion of one copy of the α2 Na^+/K^+ pump gene in mice leads to *increased* contractile force in cardiac and skeletal muscle while deletion of one copy of the α1 gene leads to *reduction* of contractile force [25]. In rat optic nerve astrocytes, deletion of the α2 gene or ouabain treatment of cells expressing α2 leads to increased 'capacitative calcium entrance' responses, which reflect a decreased ability to rapidly remove cytosolic Ca^{2+} [26].

Na,K pumps may function as signal transducers. As discussed above, cardioactive steroids have long been employed to increase cardiac force. This occurs because they inhibit Na^+/K^+ pumps, thus increasing cytoplasmic $[Na^+]$, slowing Na^+/Ca^{2+} exchanger activity and increasing cytosolic $[Ca^{2+}]$. That sodium pumps have an evolutionarily conserved and highly selective binding site for cardioactive steroids has prompted a search for a possible endogenous 'ouabain-like substance' or OLS. Such substances have, in fact, been identified in brain, adrenal cortex, plasma and urine, although at very low concentrations. Elevated levels of OLS have been associated, experimentally and clinically, with salt retention, hypertension and cardiac hypertrophy. Their chemical structures appear very similar to ouabain [27].

Recent work has linked cardioactive steroid binding to the sodium pump, not only with pump inhibition but also with activation of the extracellular-receptor-activated protein kinase (ERK) signaling cascade. After exposure of contracting rat hearts to a positive inotropic dose of ouabain, the content of phosphorylated/activated ERK1/2 increases two- to threefold whereas Src and the α2 isoform of Na,K-ATPase increase by 50–60% in isolated caveolae. Isolated caveolin-enriched membrane fractions from rat cardiac myocytes contain nearly all of the cardiac-specific caveolin-3, 20–30% of the total sodium pumps and they are enriched in the signaling proteins, Src, epidermal growth factor receptor (EGFR) and ERK1/2 [28]. Such observations suggest that OLS may act on signaling systems involving some of these proteins.

Ca^{2+} PUMPS

ATP-dependent Ca^{2+} pumps and Na^+,Ca^{2+} antiporters act in concert to maintain a low concentration of free cytosolic Ca^{2+}. The concentration of cytosolic free calcium ion, $[Ca^{2+}]_i$, in unstimulated cells is between 10^{-8} and 10^{-7} mol/l, which is more than 10,000-fold lower than extracellular free Ca^{2+}. Most intracellular Ca^{2+} is stored in

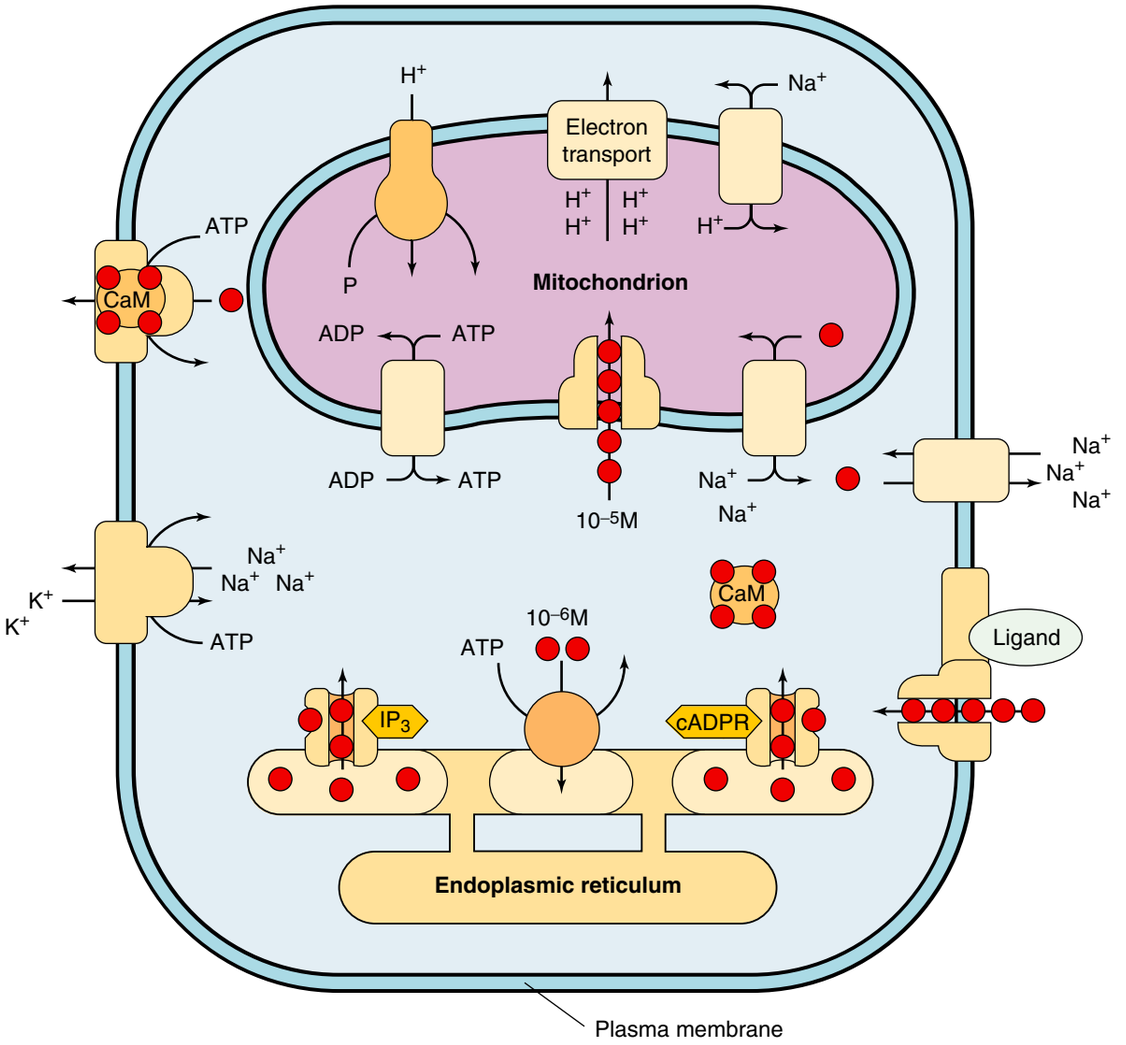

FIGURE 5-7 Calcium homeostasis. In the figure, calcium ions are represented by filled red circles. Ca^{2+} enters cells through a variety of ligand- and voltage-regulated channels, but basal cytoplasmic free Ca^{2+} is maintained at less than micromolar levels. Cytoplasmic Ca^{2+} is regulated coordinately by a Na^+/Ca^{2+} antiporter in plasma membranes and by P-type Ca-ATPases in plasma membranes and endoplasmic reticulum. The driving force for Na^+/Ca^{2+} antiporter exchange is the inwardly directed Na^+ gradient, which is maintained by α2 or α3 Na,K-ATPases. Mitochondria can participate transiently in Ca^{2+} homeostasis if the capacities of these other systems are exceeded. ER stores of Ca^{2+} can be released by second messengers, such as IP_3 or Ca^{2+} itself, in response to various receptor systems.

the endoplasmic reticulum. Because cytoplasmic $[Ca^{2+}]$ has many different intracellular signaling functions, its regulation is complex. and its impairment can be catastrophic (Fig. 5-7).

The primary plasma-membrane Ca^{2+} transporter (PMCA) is a P-type pump with high affinity for Ca^{2+} (K_m = 100–200 nmol/l) but relatively low transport capacity [19]. The stoichiometry of PMCA is one Ca^{2+} transported for each ATP hydrolyzed. These pumps probably do not carry out bulk movements of Ca^{2+} but are most effective in maintaining very low concentrations of cytosolic Ca^{2+} in resting cells. A distinguishing characteristic of the PMCAs is that, in addition to binding Ca^{2+} as a substrate, they are further activated by binding Ca^{2+}/calmodulin. The effect of calmodulin binding is to increase the affinity of the substrate Ca^{2+} site by 20- to 30-fold. This highly cooperative activation mechanism makes the PMCAs very sensitive to small changes in $[Ca^{2+}]_i$. A group of at least five PMCAs forms a multigene family. Three isoforms, PMCA1–3, occur in brain and each has a distinct distribution [20].

The smooth endoplasmic reticulum calcium pumps (SERCA) found in brain were first identified in sarcoplasmic reticulum. The three isoforms of SERCA are products of separate genes: SERCA-1 is expressed in fast-twitch skeletal muscle; SERCA-2a in cardiac/slow-twitch muscle; SERCA-2b, an alternatively spliced form, is expressed in smooth muscle and non-muscle tissues; SERCA-3 is

expressed in endothelial, epithelial, and lymphocytic cells and platelets. SERCA-2b is the major form expressed in brain, predominantly in neurons.

The uniquely high resolution structural data available for the SERCA1a Ca^{2+} pump illuminates the structure of all P-type transporters. Unlike the Na,K pump, the catalytic subunit of the SERCA Ca^{2+} pumps is active and does not require association with another subunit. However, the cardiac isoform, SERCA-2a, associates with a small membrane protein, phospholamban, that can regulate heartbeat strength and rate. The Ca^{2+}-pump reaction mechanism is essentially the same as that illustrated in Figure 5-2 for Na,K pumps except that two Ca^{2+} are exchanged in each cycle, probably for four protons. The primary sequences for the α-subunits of the Na,K- and H,K-ATPases can be superimposed on these Ca^{2+}-pump structures with only minor adjustments necessary to allow for small deletions and insertions.

Notice, in Figure 5-8, that the substrate cations are bound to ionophoric sites consisting of side chains contributed by four adjacent transmembrane helices, and

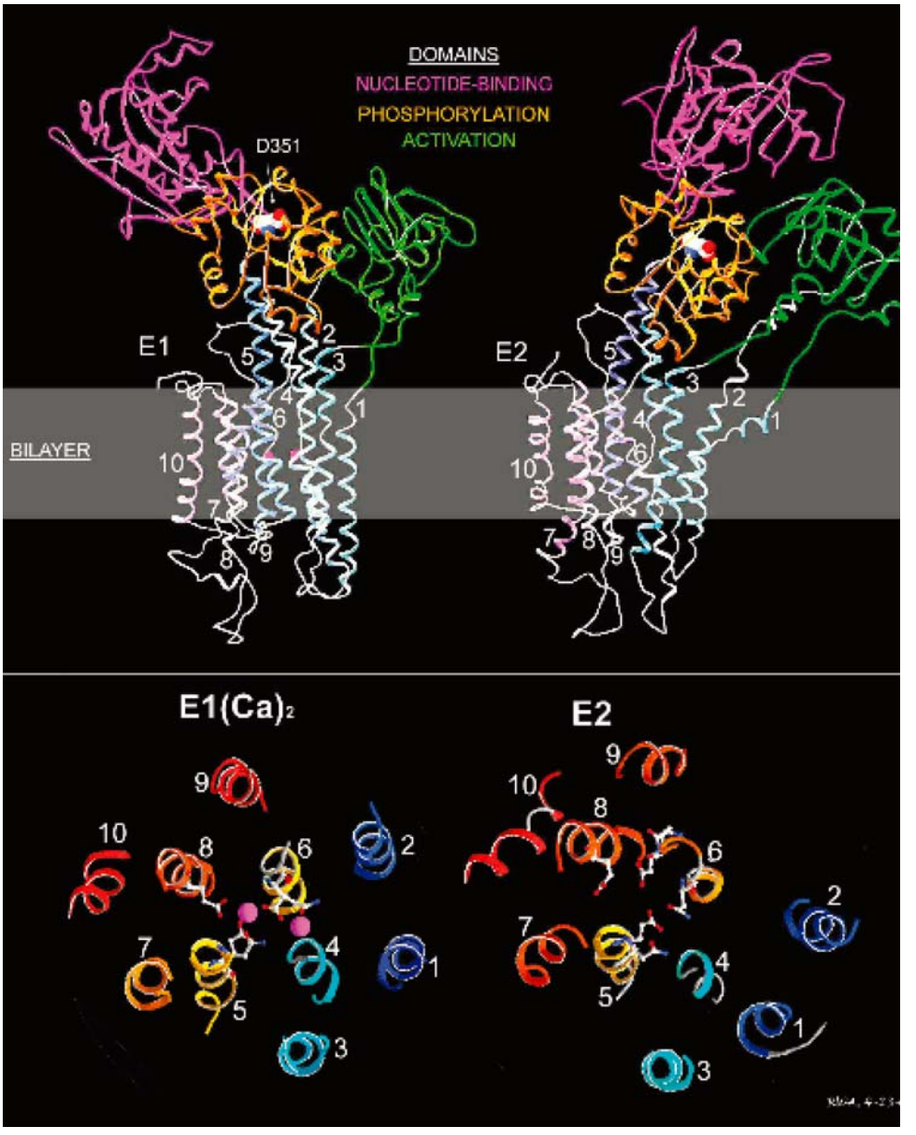

FIGURE 5-8 Structures of the SERCA1a calcium pump: $E1(Ca)_2$ was obtained from crystals formed in the presence of Ca^{2+}; E2 was obtained from crystals formed in the absence of Ca^{2+} and in the presence of the selective inhibitor, thapsigargin [84]. The two conformations are viewed in a plane perpendicular to (*top*) and parallel within (*bottom*) the lipid bilayer. The ten transmembrane segments are numbered in their order from N- to C-terminal, and colored sequentially from blue to red. The magenta spheres represent the two Ca^{2+}-binding sites in the E1 structures and, in the lower figures, the side chains that interact with Ca^{2+} are shown in stick form for both conformations. In the top figures, the N, A, and P cytoplasmic domains are colored magenta, orange and green. The aspartyl residue, D351, that is phosphorylated and dephosphorylated in each pump cycle, is shown as a space-filling model. (Models constructed from Protein Data Base coordinates 1eul and 1iwo using DeepView 3.7.) [85].

that the E2 configurations of these helices are rotated relative to the E1 configurations. Examination of the paths of these helices through the bilayer does not reveal any obvious 'channel' through the membrane. This is consistent with studies of the reaction mechanism, which have shown that, at successive stages of the cycle, the cations either have access from only one side of the membrane or are 'occluded' within the pump molecule.

The P pumps have three clearly demarcated cytoplasmic domains, which in Figure 5-8 are colored magenta (N or nucleotide-binding), orange (P or phosphoryl), and green (A or activator). Notice that transmembrane helix 5, which contributes to the ionophoric domain, extends as a helix well into the cytoplasmic P domain, transforming into a β-sheet structure just at its boundary with the 'signature sequence', ICSDKTGTL. This is conserved in all P pumps and includes the aspartyl residue (space-filled residue in Fig. 5-8), which reacts with ATP and water within each catalytic cycle.

The sodium and calcium pumps can be isolated to near purity and still exhibit most of the biochemical properties of the 'native' pump. Some kinetic properties of these pumps in 'native membranes' are altered or disappear as membrane preparations are purified. For example, when measured in intact membranes, the time-dependencies of phosphorylation and dephosphorylation of the pump catalytic sites exhibit biphasic fast to slow rate transition; this characteristic progressively disappears as the membranes are treated with mild detergents. One suggested explanation is that, as the pumps begin to cycle, the catalytic subunits associate into higher oligomers that may permit more efficient transfer of the energy from ATP into the ion transport process [29, 30]. Some structural evidence indicates that Na,K pumps exist in cell membranes as multimers of $(\alpha\beta)_2$ [31].

P-type copper transporters are important for neural function. Wilson's and Menke's diseases have major neurological components (Ch. 45). The Wilson's disease gene codes for a transporter, expressed chiefly in liver, that probably functions in Cu^{2+} excretion. The Menke's disease gene codes for a closely related transporter that regulates intestinal Cu^{2+} absorption [32].

V_0V_1-PROTON PUMPS

The V-ATPase pumps protons into Golgi-derived organelles. Its specialized neuronal function is to generate the electrochemical gradient that energizes the H^+-antiporters that load neurotransmitters into presynaptic vesicles (Ch. 10). The V_0V_1 structure of these pumps (Fig. 5-9) is similar to that of the F_0F_1-ATP synthases and they pump protons via a similar rotor and stator mechanism. Unlike F_0F_1, which animals express only in mitochondria, the particular Golgi organelle that V_0V_1 targets depends on the isoform of subunit a that is expressed [33].

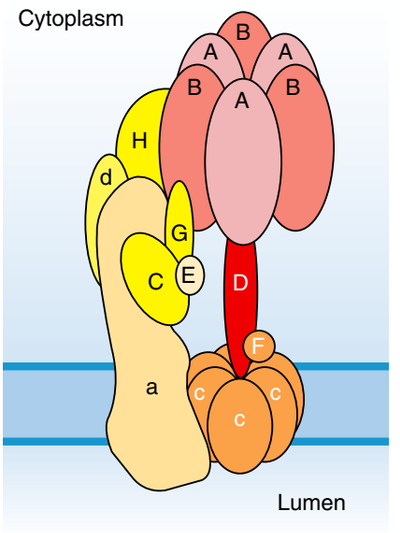

FIGURE 5-9 Structural organization of the vesicular proton pump, V-ATPase: V-ATPase is composed of numerous subunits organized as illustrated by color coding: the cytoplasmic domain, V1, contains eight different subunits (A–H), with three copies of the ATP binding subunits A and B; the membrane domain, termed V_0, is a hexameric ring composed of proteolipid subunits (5 c and 1 c″) and single copies of subunits a and d. Functionally, V-ATPase consists of a rotor (*white lettering*) and a stator domain (*black lettering*). The rotor consists of the hexameric proteolipid c ring and a stalk made of subunits D and F; the stator consists of the remaining subunits, which are fixed to the membrane via subunit a. Expression of different subunit a isoforms targets the V-ATPase to different membranes. ATP binding to and hydrolysis by the three subunits A presumably act on subunit D to induce rotation via asymmetric conformational transitions as has been described for the F_0F_1 ATP synthase. Rotation of the hexameric c ring translocates protons from the cytoplasmic interface of the proteolipid hexamer into the lumen of synaptic or Golgi-derived vesicles. The V_1 domain reversibly dissociates, in physiological conditions, to regulate V-ATPase activity. (With permission from reference [86].)

ATP-BINDING CASSETTES

The ABC transporters are products of one of the largest gene superfamilies. Each consists of two cytoplasmic nucleotide-binding domains (NBDs) and two transmembrane domains (TMDs). The NBDs are highly conserved across the ABC family and contain motifs typical of ATP-binding sites, whereas the TMD structures vary, probably because they are adapted to the wide variety of substrates. In eukaryotes the C-terminal of each NBD is linked to a TMD. In some cases the functional unit is $(NBD\text{-}TMD)_2$ and, in others, the first TMD is covalently linked to the second NBD.

The three-dimensional structures of several ABC transporters from prokaryotes have been determined.

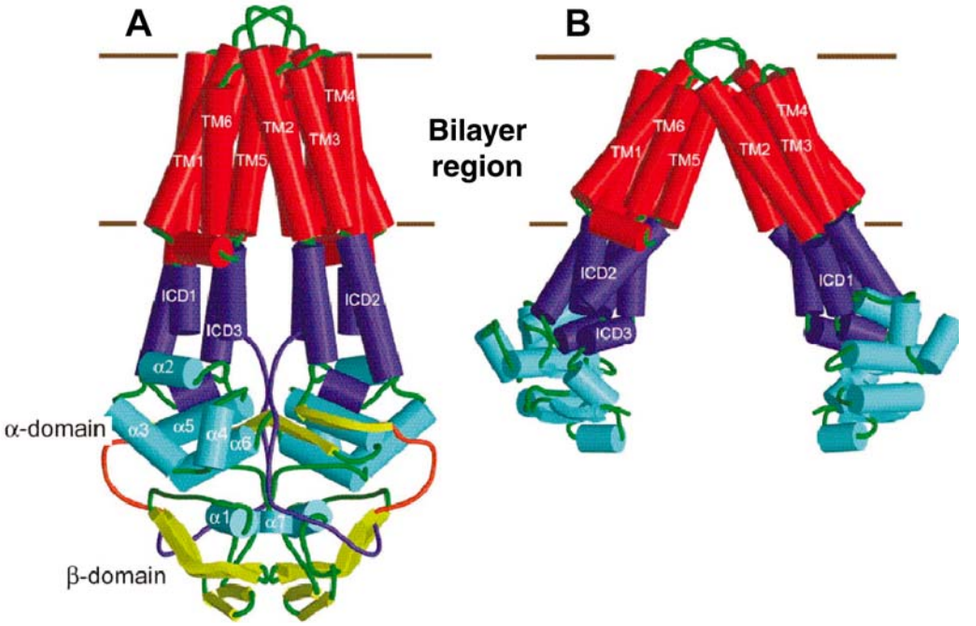

FIGURE 5-10 (**A**) Structure of a multidrug resistance ABC transporter, VC-MsbA, expressed by *Vibrio cholerae*. View looking into the chamber opening (side view). The transmembrane domain (TMD), intracellular domain (ICD) and nucleotide-binding domain (NBD) are colored red, dark blue and pale blue respectively. The transmembrane and NBD α-helices are indicated and the connecting loops are shown in green. The loop connecting the α- and β-domains of the NBD is shown in orange. The ATP-binding β-sheets are highlighted in yellow. Brown lines indicate the approximate location of the cell membrane. (**B**) A corresponding view of a very similar ABC transporter expressed by *Escherichia coli*, Eco-MsbA. Crystals of these two protein were obtained that exhibit closed and open conformations, respectively. (With permission from Fig. 2 of reference [87].)

Figure 5-10 compares NBD structures from nearly identical transporters from *Vibrio cholerae* and *Escherichia coli* that crystallized with their TMDs in two 'closed' and 'open' conformations respectively. Hypothetically, substrate would be acquired and transported as a result of energizing a conformational cycle by coupling it to ATP hydrolysis.

In the closed conformation (Fig. 5-10A) the two NBD domains bind to each other and, as shown in Figure 5-11, nucleotide binding occurs in pockets formed between these two domains. The stoichiometry and nucleotide selectivity of these binding pockets have been determined for an ABC transporter that functions to export peptides from yeast mitochondria [34]. The results of this study has led to the proposed reaction cycle diagrammed and described in Figure 5-12.

ABCA1 functions to translocate cholesterol and phospholipids outward across the plasma membrane after their delivery to the inner plasma membrane leaflet via vesicular pathways [35]. This occurs in astrocytes and developing neurons. Astrocytes also secrete apoE. Extracellular apoE binds and interacts with ABCA1 to promote cholesterol and PC efflux from cultured astrocytes through a mechanism that results in apoE-stabilized

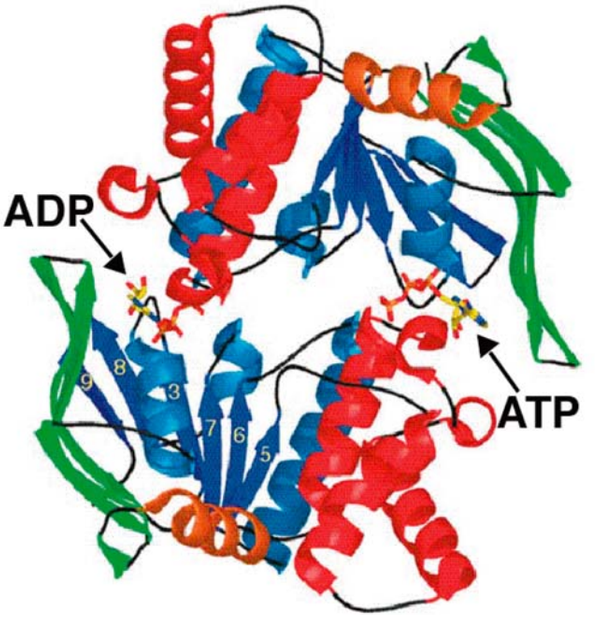

FIGURE 5-11 Ribbon diagram of an NBD dimer (PDB 1f30). β strands are depicted as arrows and α helices as coiled ribbons. The two nucleotides, shown as stick models, bind to form part of the interface that stabilizes the dimeric interaction. (With permission from Fig. 5 of reference [88].)

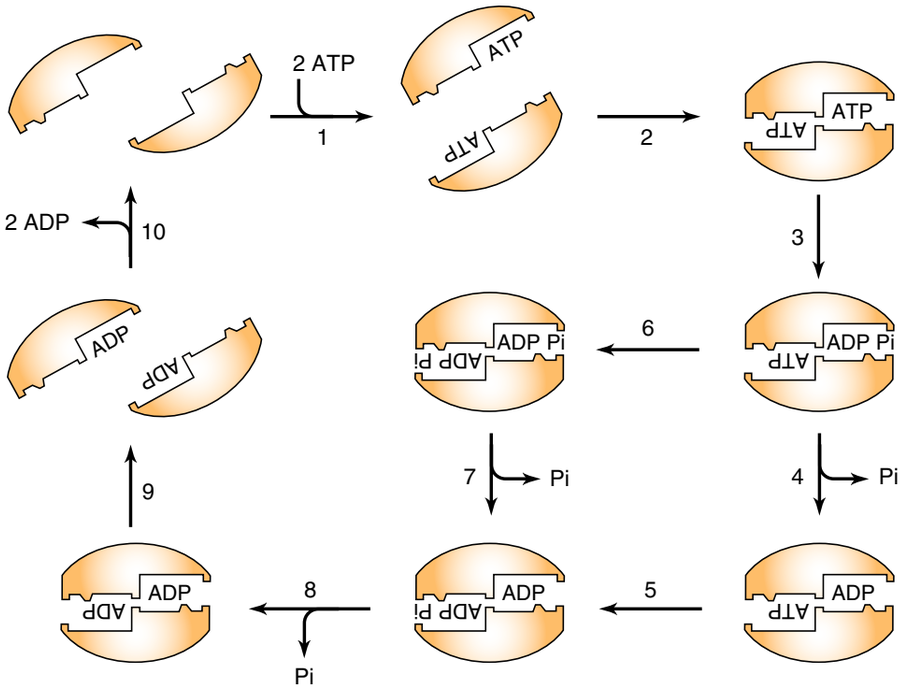

FIGURE 5-12 A processive clamp model for the ATPase cycle of the ABC transporter Mdl1p. ATP binding (*step 1*) on NBD domains of both monomers induces formation of the dimer (*step 2*). After ATP hydrolysis by the first NBD (*step 3*), either the P_i is released first (*step 4*), followed by hydrolysis of the second ATP (*step 5*) and release of the second P_i (*step 8*), or the second ATP is hydrolyzed first (*step 6*) and then both phosphates are set free (*steps 7* and *8*). After both ATPs are hydrolyzed to ADP and both phosphates are released, the dimeric complex dissociates (*step 9*) and ADP (*step 10*) is released. The hydrolysis cycle can then start again with ATP binding. (With permission from Fig. 7 of reference [34].)

HDL-like particles (see Fig. 2–7). In the absence of apolipoprotein, ABCA1 is rapidly proteolyzed by calpain with a $T_{1/2}$ of only about 20 minutes in some cells. However, apolipoproteins protect ABC1A from calpain and increase its level of expression [36]. Thus the interaction of apolipoprotein with ABCA1 is part of the regulatory process of cholesterol efflux. A closely related transporter, ABCA2, is expressed in oligodendrocytes and is markedly upregulated during myelinization [37].

Another ABC subfamily, the multidrug-resistance proteins (MDR), can 'flip' amphipathic molecules, including membrane phospholipids and sphingolipids, from the inner to the outer leaflet of plasma membranes [38]. One member, MDR3, can selectively transport phosphatidylcholine [39]. MDR1or 'P-glycoprotein' is the classic MDR, consisting of two cassettes within a single peptide chain. By pumping the drugs out of the cells its elevated expression during chemotherapy can decrease the chemosensitivity of cancer cells. P-glycoprotein is expressed at high concentrations in the luminal membranes of brain capillaries [40] and probably accounts for many drug-exclusion functions of the blood–brain barrier. Adrenoleukodystrophy and the Zellweger's syndrome (Ch. 41) result from defects in two different genes that specify 'single cassette' proteins targeted to peroxisomes.

SECONDARY ACTIVE TRANSPORT

Secondary transporters employ energy stored in ion gradients to transport other ions and molecules. Many of these are symporters or antiporters linked to Na^+ or proton gradients (Fig. 5-1). However the situation is often more complex, involving more than one ion gradient. A more systematic nomenclature for secondary transporters has recently been adopted. It is based on genomic analyses of the evolutionary relationships among these transporters which are members of a large 'solute carrier family'(SLC) [41]. Examples are discussed in the following sections.

The recovery of neurotransmitters from synaptic clefts and their storage in cytoplasmic vesicles is accomplished by the tandem actions of the secondary transporters in plasma and vesicular membranes. Sodium-dependent symporters mediate neurotransmitter reuptake from synaptic clefts into neurons and glia, whereas proton-dependent antiporters concentrate neurotransmitters from neuronal cytoplasm into synaptic vesicles (Fig. 5-13).

While the extent of the demands on cerebral energy metabolism of neurotransmitter reuptake is still somewhat controversial, it contributes substantially to the

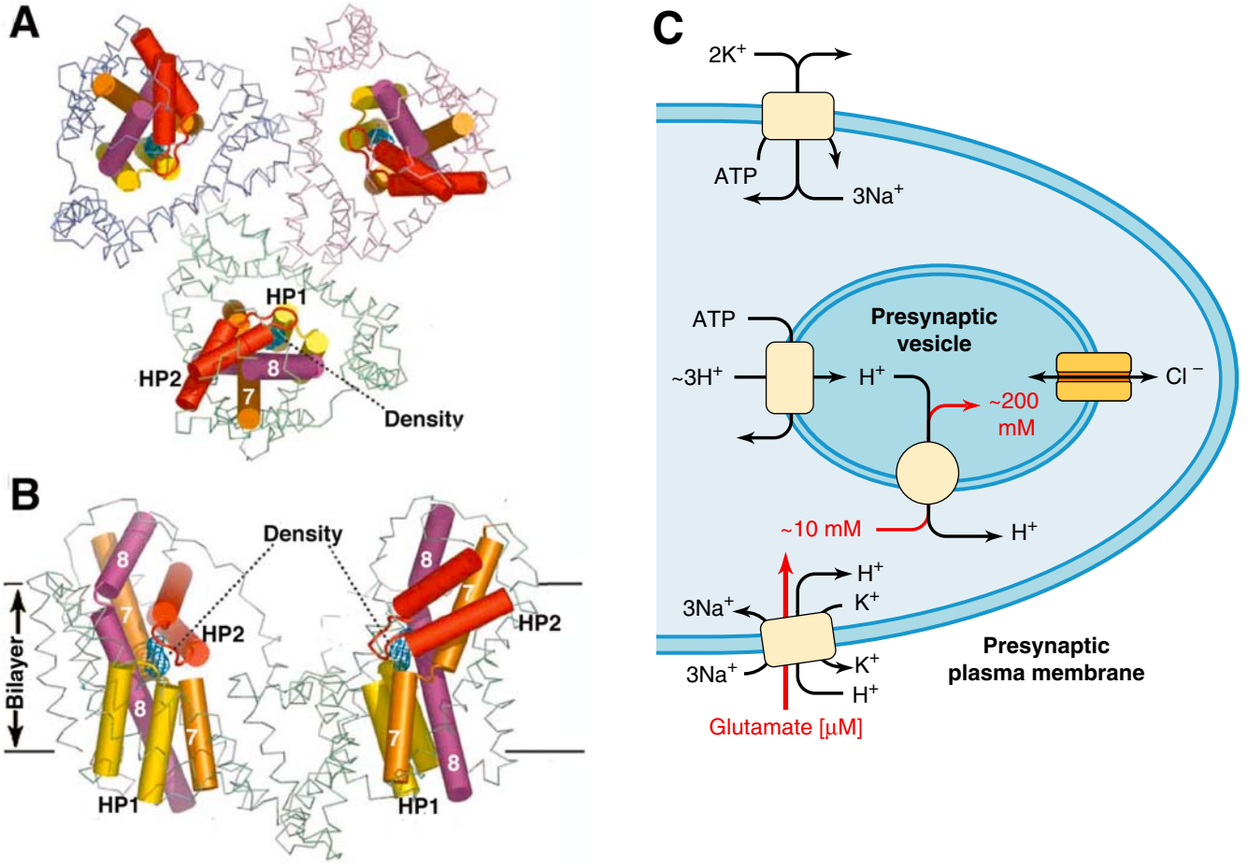

FIGURE 5-13 (**A, B**) Structure of a glutamate transporter. This bacterial glutamate transporter provides the first high-resolution model of a glutamate transporter [88]. The X-ray data indicate a trimeric structure. (**A**) A view of the trimer extracellularly and perpendicular to the bilayer. (**B**) A view from the bilayer plane. The trimer forms a deep bowl that allows extracellular solutes to access the extracellular glutamate-binding site located near the center of the bilayer plane. The helices represented by colored cylinders are those involved in the structure of the ionophoric sites, which involve transmembrane helices 7 and 8 and two re-entrant loops, HP1 (yellow) and HP2 (red), that enter from opposite sides of the bowl. The objects marked 'Density' appear to be glutamates bound at the ionophoric sites. The authors discuss this structure in terms of a model in which each bound glutamate is carried into the cytoplasm by obligatory coupling to the symport of 3 Na^+ and 1 H^+. (With permission from reference [88].) (**C**) Processes involved in neurotransmitter uptake and packaging at nerve endings. Concentration into the cytoplasm is achieved by means of Na^+ symporters with high affinity and specificity for the neurotransmitter in the plasmalemma. As indicated in red, μM extracellular glutamate is concentrated in mM levels in cytoplasm and to about 200 mM in the vesicles. Synaptic vesicle membranes contain the V-ATPase proton pump (Fig. 5-9) and chloride channels, which together acidify the internal vesicle space and generate a proton gradient that drives the neurotransmitter-selective antiporters.

increased metabolism associated with neuronal activity [42] (see Ch. 31). There are two distinct subfamilies of Na^+-dependent transporters that function in plasma membranes. One subfamily, SLC6, is characterized by 12 transmembrane segments and includes the (Na^+,Cl^-)-dependent transporters for gamma-amino butyric acid (GABA), glycine, norepinephrine, dopamine, serotonin and histamine.

The other subfamily, SLC1, includes the Na^+-dependent glutamate transporters. It encompasses some amino- and carboxylic-acid transporters including glutamate transporters that are expressed in bacteria. X-ray diffraction data have been obtained from crystals of one of these [43] (Fig. 5-13). Analysis of multiple sequence alignments indicates that this molecule has a high degree of structural similarity to the glutamate transporters that are expressed in brain. Each subunit appears to contain an ionophoric site that can bind glutamate, probably in association with three Na^+ and one H^+. This site is located near the central plane of the bilayer and involves two of the eight transmembrane helices plus two 're-entrant loops', one from each side, which may act as 'access gates' that open sequentially to permit binding and dissociation within each transport cycle.

Glutamate transporters in brain are coded by five different but closely related genes, *SLC1A1–4* and *SLC1A6*. There are several trivial names for each of the corresponding proteins. The transporters can all symport one Glu, with three Na^+ and one H^+, and antiport one K^+ within each cycle, but they differ in their cellular expression.

Different isoforms have different regulatory interactions and are expressed in different cell types. Astrocytes recover most of the synaptically released glutamate via the transporters GLT1/EAAT2 (SLC1A2) and GLAST/EAAT1 (SLC1A3). They convert much of this to glutamine, which is recycled to neurons (see Chs 15 and 31), probably by Na^+- or H^+-coupled members of the SLC38 gene family. A mutant form of SLC1A2 has been associated with amyotrophic lateral sclerosis (see Ch. 44). Mice [34] and rats [35] deficient in GLAST or GLT-1 have elevated extracellular glutamate and, in the case of mice, have lethal seizures [44].

Regulation of glutamate concentration is of special interest because its extracellular accumulation is a factor in various pathologies (see Ch. 32). While brain total glutamate concentration is about 10 mmol/l, extracellular glutamate, as measured by *in vivo* microdialysis, is normally only 3–4 μmol/l. Glutamate within the synaptic cleft must be maintained at still lower concentrations in the resting state. With 'normal' membrane potentials and ion concentrations, the glutamate transporter can theoretically reduce this value to 0.6 μmol/l or less. However, under depolarizing or anoxic conditions, the membrane potential and the Na^+ and K^+ gradients can decrease to levels that cause the symporter to fail or to operate in reverse, producing 100- to 1,000-fold increases in extracellular glutamate.

In addition to their transporter function, perisynaptic transporters function as buffers to confine the extracellular free glutamate to receptors nearest the postsynaptic release sites. The total concentration of glial transporters in some CNS synaptic regions is estimated to be sufficient to bind the glutamate content of three to five vesicles per synapse [45]. This 'buffering', which occurs mostly in endfeet of astrocytes, is essential for reliable synaptic transmission of high-frequency signals [46].

GABA reuptake is mediated by the secondary transporters, GAT1–4 (SLC6A1–4), that are expressed in GABAergic neurons. The SLC6 family also includes the transporter genes for catecholamines, serotonin, histamine and glycine. All are energized by Na^+ symport. Chloride is cotransported but, because in most cells it is passively distributed across the plasma membrane, chloride diffusion does not supply energy to the system. Many of these transporters are expressed at high densities in perisynaptic neuronal plasma membrane. However, as much as half of the transporters are found within small endocytotic vesicles that recycle in parallel with the neurotransmitter vesicles [47, 48]. Recycling between vesicles and membranes appears to be a mechanism for rapidly regulating the populations of many different integral membrane proteins. The catecholamine and serotonin transporters are inhibited by a variety of drugs, both therapeutic and addictive [49].

The synaptic action of acetylcholine is unique among neurotransmitters in that it is terminated by hydrolysis rather than by transport (Ch. 11). Consequently, cholinergic neurons recover choline, rather than acetylcholine, via a high-affinity choline transporter, CHT-1. A major fraction of these CHT-1 transporters reside in presynaptic vesicles and are only incorporated into the presynaptic membranes concurrently with the release of acetylcholine [50]. This is a form of regulation somewhat analogous to that observed for the SLC6 family noted above. Structurally, CHT-1 is most similar to the Na^+-dependent glucose transporters and is classified within the SLC5 gene family.

Packaging neurotransmitters into presynaptic vesicles is mediated by proton-coupled antiporters. As discussed above, Golgi-derived membranes, including presynaptic vesicle membranes, contain V-type primary transporters that pump protons into the lumen of these membranes and vesicles.

Glutamate packaging antiporters are VGLUT1, -2, and -3. VGLUT1 and -2 are principally localized in glutamatergic neurons and exhibit high specificity, but low affinity (≈1 mmol/l) for cytoplasmic glutamate because the concentration of cytoplasmic glutamate is high. Some indication of the functional significance of different isoforms can be inferred from demonstrations that VGLUT2 is expressed in some dopaminergic neurons whereas VGLUT3 vesicles occur in some serotonergic and GABAergic interneurons. It has been suggested that such neurons may release glutamate as an autoregulator acting on metabotropic presynaptic receptors [51].

The GABA-packaging antiporter, VGAT or VIAAT, was first identified by the characterization of a *Caenorhabditis elegans* mutant gene that produced a phenotype that mimicked ablation of an identified GABA neuron. The mammalian ortholog of this gene functions in both GABAergic and glycinergic neurons. It is a proton antiporter and, like the VGLUTs, has relatively low affinity for its substrates, GABA and glycine.

The various monoamine neurotransmitters are packaged in vesicles by the relatively nonspecific antiporters VMAT1 (SLC18A1) and VMAT2 (SLC18A2). Neurotransmitter selectivity in these cases is evidently determined by the expression of the biosynthetic enzymes. Acetylcholine packaging in synaptic vesicles of both central and peripheral neurons is mediated by the same antiporter, VAChT (SLC18A3) [52]

PHYSIOLOGICAL ASPECTS OF THE NEUROTRANSMITTER TRANSPORTERS

Presynaptic vesicles are estimated to each contain approximately 3,000–5,000 transmitter molecules; the internal volume of a vesicle is such that its internal transmitter concentration may be ≈0.5 mol/l; vesicle contents may be released within less than 1 ms and this occurs within <0.02 μm of the postsynaptic receptors. The space within

a synaptic cleft of ≈1 μm² will be ≈1000-fold greater than the vesicle volume, so that the instantaneous concentration is more than 1 mmol/l. Because only 3–4 free molecules within the volume of such a cleft is effectively ≈1 μmol/l, rapid inactivation of a postsynaptic receptor requires removal of essentially all the transmitter. Glutamate transporters have affinity constants of more than 10 μmol/l, and transport reaction cycles are slow relative to impulse rates. This problem appears to be solved by having an extremely high density of transporters in the astroglial processes immediately adjacent to CNS glutamatergic synapses. The densities of astroglial transporters in processes near glutamatergic synapses are estimated to be 5,000–10,000/μm² [45]; binding of glutamate to transporters is an important factor in the rapid (ms) removal of glutamate and thus the distribution of transporters can regulate the accessibility of glutamate to extrasynaptic receptors [53].

Cytoplasmic chloride must be transported outward to generate the gradient that allows GABA- or glycine-gated channels to hyperpolarize neurons. This transport, in mature neurons, is mediated by a K^+,Cl^- symporter, KCC2. However, immature neurons accumulate chloride via a Na^+,Cl^- symporter, NKCC1, and thus activation of $GABA_A$ channels is depolarizing [54]. The ratio of KCC2/NKCC1 expression increases with maturation in most neurons. However this ratio can be regulated in mature neurons: For example, in suprachiasmatic neurons this ratio is controlled by clock genes and in other neurons by endocrine cycles.

In the 'normal' state of mature neurons, the K^+ diffusion potential is similar to the membrane resting potential and thus has little ability to energize KCC2. However, K^+ released during membrane depolarization may transiently activate KCC2 symport, lower cytoplasmic [Cl^-] and increase the inhibitory postsynaptic current through $GABA_A$ channels. However, excitation also elevates cytoplasmic [Ca^{2+}]; this elevation apparently regulates KCC2 and is the basis of inhibitory 'coincidence detection' that has been demonstrated in hippocampal neurons: this coincidence is that of excitatory impulses arriving 'simultaneously' with $GABA_A$ channel activation at inhibitory synapses [55].

The anion antiporters comprising the SLC8 gene family all transport bicarbonate [56]. CNS energy production derives almost entirely from aerobic glycolysis resulting in a rate of metabolic CO_2 production nearly equal to the rate of oxygen consumption. In adult human brain, this is about 1.5 mmol/l per minute (Ch.31). Because most neurons express only low concentrations of carbonic anhydrase, CO_2 diffuses out of neurons mostly unhydrated, but is converted to HCO_3^- before it enters the blood. The Cl^-/HCO_3^- antiporter, AE1/(SLC4A1), also known as band 3 protein, is a major protein of erythrocytes, where it mediates rapid uptake of HCO_3^- in exchange for Cl^- and functions in the reverse direction in lungs to exchange HCO_3^-. An isoform of this antiporter (AE3) is expressed in neurons, which suggests that significant anion exchange occurs across neuronal and/or glial membranes. Since some neurons express significant concentrations of cytoplasmic carbonic anhydrase, Cl^-/HCO_3^- exchange may have unrecognized functions: its operation in neurons could influence both Cl^- potentials and cytoplasmic pH.

CATION ANTIPORTERS

Na^+,Ca^{2+} exchangers are important for rapidly lowering high pulses of cytoplasmic Ca^{2+}. They can remove cytoplasmic Ca^{2+} up to ten times faster that SERCA or PMCA pumps. Three Na^+,Ca^{2+} antiporter isoforms, NCX1–3, are expressed in brain: NCX1 and NCX3 in neurons, NCX2 predominantly in glia. As discussed above, these exchangers colocalize with the sodium pump isoforms α2 and α3 in neurons and astrocytes to form junctional complexes with the ER (Fig. 5-6). The NCX exchange process is electrogenic with three Na^+ exchanged for one Ca^{2+}.

Intracellular pH in brain is regulated by Na^+, H^+ antiporters, anion antiporters and Na^+,HCO_3^- symporters. In principle the products of cerebral energy metabolism, primarily water and CO_2, may leave the brain and enter the circulation without disturbing the ionic balance. However processes such as incomplete oxidation, CO_2 hydration or Ca^{2+} influx can change local pH. Neuronal activity is accompanied by intracellular acidification and extracellular alkalinization. Cerebral metabolic rate decreases with decreasing pH so that, without adequate pH control, local metabolic deficits can be amplified and propagated [57]. The pH response of astrocytes to membrane depolarization is opposite to the neuronal response: intracellular alkalinization and extracellular acidification occur [58]. The neuronal acidification appears to involve antiporter exchange of HCO_3^- for Cl^-, whereas astrocytic alkalinization is probably mediated by a Na^+, HCO_3^- symporter. This is an oversimplification of CNS pH regulation in view of the fact that additional secondary transporters are involved in various aspects of local pH regulation [59].

Na^+,H^+ antiporters (NHE) occur in synaptosomes, glia and neuroblastoma cells [60] (Fig. 5-8B). They are relatively inactive at neutral pH but with a decrease in intracellular pH they produce an efflux of protons at the expense of the Na^+ gradient. The NHE transport stoichiometry is 1:1. Activation by an internal pH decrement apparently results from protonation of a cytoplasmic site, which allosterically increases the affinity of the proton ionophoric site. In some cells, the NHE is under additional control by receptor mechanisms. Several growth factors and hormones produce transient cytoplasmic alkalinization, probably by mediating a protein kinase

phosphorylation of the antiporter, which increases its affinity for cytoplasmic protons.

Rapid clearance of K^+ from neuronal extracellular space is critical because high extracellular K^+ depolarizes neurons. Neural activity discharges K^+ which, if not rapidly removed, lowers the membrane potential of adjacent neurons. Normal neuronal activity can lead to elevations of 1–3 mmol/l in extracellular K^+ ($[K^+]_e$) but, during epileptogenesis, concentrations can be three to four times higher (see Ch. 37). Usually, the upper limit of axonal impulse-conduction frequency is set by a conduction block that occurs when extracellular K^+ accumulates to a concentration of 25–30 mmol/l (see Ch. 37). Both neurons and astroglia are involved in K^+ uptake but their relative contributions remains controversial. It is clear that neurons accumulate K^+ almost exclusively by means of active transport, but the Na,K pump is slow relative to the channel-mediated K^+ release from neurons and to the rates of K^+ increase in the extracellular space. Moreover, the neuronal Na^+,K^+ pump is saturated at low $[K^+]_e$, making it an ineffective regulator for this purpose.

Glial processes invest nearly all extrasynaptic neuronal surfaces (see Ch. 1), and one of their principal functions is to regulate $[K^+]_e$. The extracellular space of the brain consists primarily of the 150–250 Å clefts separating glia and neurons. Astrocytes have higher K^+ permeability than most neurons, and they are extensively interconnected by gap junctions. K^+ efflux from a neuron can diffuse into the local glial cytoplasm, and compensatory K^+ efflux can occur from more distal reaches of the glial syncytium, where the $[K^+]_e$ is lower (Fig. 5-14). It should be noted that this 'spatial buffering' is a diffusion process that requires no energy input. Measurements on retinal Müller cells have provided relevant data. These are specialized astrocytes that do not form syncytia. Rather, they extend from the deep layers of the retina to form endfeet at the retinal interface with the vitreous body (see Fig. 49-1). The K^+ conductance of these cells is about 30 times higher at the endfeet in contact with the vitreous fluid than elsewhere. Moreover, K^+ currents through plasma membranes other than endfeet are carried by inward-rectifying channels, whereas the K^+ channels at the endfeet are high-conductance and nonrectifying [40]. This seems designed to facilitate diffusive currents of K^+ from the retina into the Müller cell, which are balanced by K^+ efflux into the vitreous space and constitute a relatively 'infinite' sink, equivalent to the syncytium of the generalized astrocytes. Normally Na,K pumps in neurons and glia set the baseline extracellular $[K^+]$, and partial inhibition of these pumps can markedly slow its return to baseline levels following high-frequency neuronal activity [61].

Although spatial buffering can effectively prevent accumulation of moderate concentrations of extracellular K^+, this diffusion process may be inadequate at very high rates of neuronal K^+ efflux. Several K^+ symporters occur in astrocytes and probably broaden the range of effective $[K^+]_e$ regulation. Glial swelling accompanies neural activity. This reflects the operation of an NKCC symporter in response to the volume-regulation mechanism discussed below.

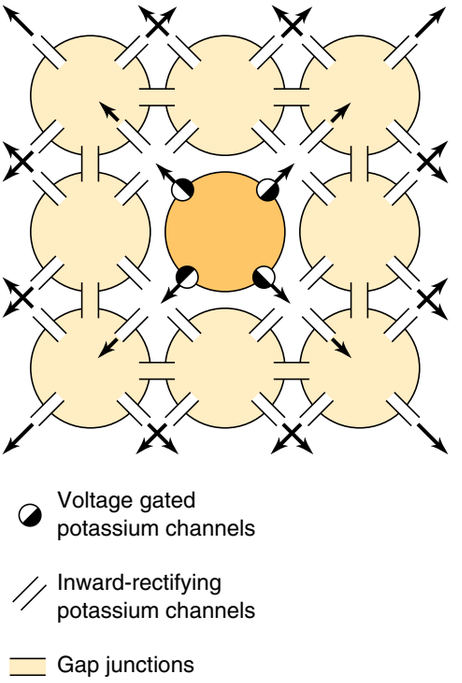

FIGURE 5-14 Spatial buffering by astrocytes. This conceptual diagram indicates the pathways available for potassium ions to diffuse through the glial syncytium (light red) subsequent to their release from neuronal membranes (dark red) during neural activity.

Cell-volume regulation involves control of the content of osmotically active impermeant molecules and ions. Brain oxidative glycolysis produces water at about 10 mmol/l per minute or ≈20 ml per brain-minute. Accordingly, water must be able to move rather freely between cells and blood. Normally most of this flow is through the choroid epithelia and enters the venous blood under positive pressure via valves in the arachnoid villi. Brain volume may change because of altered internal solute content, termed an isotonic response, or because of altered extracellular solute concentration, termed hyper- or hypotonic responses. Impairment of brain energy metabolism, such as may ensue from ischemia, anoxia or trauma, produces an isotonic cellular swelling called 'cytotoxic edema' and other effects (see Chs 32 and 34). Cellular swelling is also produced by extracellular hypotonicity, often caused by hyponatremia, which can result acutely from postsurgical fluid therapies. Chronic hyponatremia can arise from congestive heart failure, Addison's disease

or a 'syndrome of inappropriate vasopressin release'. A general reduction in brain size resulting from acute extracellular hypertonicity may produce neurological disturbances. This condition may be a component of pathology originating outside the brain, such as kidney disease (uremia) and diabetes mellitus (hyperglycemia). Central pontine myelinolysis, which is produced experimentally by acute infusion of hypertonic saline, can occur as a complication of liver transplantation and of too rapid reversal of hyponatremia in clinical situations.

Cells have short-term mechanisms that tend to restore their volume toward 'normal', primarily by shifting the distributions of Na^+, K^+ and Cl^-. The details of the mechanisms appear to vary with cell type. Subsequent to cell swelling, regulatory volume decrease usually involves opening ion channels. Subsequent to hyperosmotic shrinking, regulatory volume increase frequently involves activation of NHE and NKCC. The primary detectors of volume and osmotic changes are presently unknown. Although cell membranes can readily change shape, they do not stretch significantly. However, cytoskeletal proteins attached to membrane proteins might form tensile elements that could mediate volume changes. Cell shape is determined by interactions of cytoskeletal elements, membranes and components of the extracellular matrix. Stretch-activated cation channels have been detected in neuroblastoma cells and in cultured astrocytes. Activation of a Cl^- channel by cellular swelling is part of the regulatory volume decrease process, but the identity of the channel remains elusive [62]. Altered extracellular tonicity can induce compensatory changes in the concentrations of certain intracellular osmolytes through mechanisms involving gene regulation. Glioma cells in culture have been shown to respond after a few hours of exposure to hypertonic medium by transcribing high levels of the Na^+, inositol symporter. In brain, active osmolytes include taurine, glutamine, glutamate, myo-inositol, creatine, glycerophosphoryl-choline and choline. Na^+-dependent symporters for most of these compounds have been identified [63].

FACILITATORS

Simple diffusion of the polar water molecules through lipid bilayers is too slow to account for observed rates in some cells. Therefore, it was hypothesized that specific transporters or channels regulate rapid water movement across cell membranes. Peter Agre and colleagues in 1992 isolated and identified the first member of a family of water transport molecules, now called aquaporin1 (AQP1). Now, this family is known to have 11 members found in mammals and about 150 members found throughout all biological species. The aquaporin family consists of two subsets of channel proteins, the classical group permeated only by water, and a second group, aquaglyceroporins, permeated by water or glycerol and other small molecules such as urea [64, 65].

Cell membranes or synthetic lipid vesicles with normal low permeability to water will, if reconstituted with AQP1, absorb water, swell and burst upon exposure to hypoosmotic solutions. The water permeability of membranes containing AQP1 can be about 100 times greater than that of membranes without aquaporins. The water permeability conferred by AQP1 (about 3 billion water molecules per subunit per second) is reversibly inhibited by Hg^{2+}, exhibits low activation energy and is not accompanied by ionic currents or translocation of any other solutes, ions or protons. Thus, the movement of water through aquaporins is an example of facilitated diffusion, in this case driven by osmotic gradients.

The most crystallographic and architectural data are available for AQP1, which is a prototype for the other aquaporins. The 28 kDa protein consists of six membrane-spanning α-helixes with both the carboxyl and amino terminals on the cytoplasmic surface. It exists in membranes as a homotetramer. Each monomer contains a central water channel. Water molecules can enter the channel from either the extracellular or intracellular vestibules. The narrowest segment of the channel, near its center, is 2.8 Å in diameter, which is the van der Waals diameter of a single water molecule. Passage of molecules through this pore is controlled by size restriction and electrostatic repulsion. A positively charged arginine residue near the pore obstructs protonated water and other cations while two positively charged dipoles at the midpoint of the pore disrupt hydrogen bonds and prevent protons from passing through the pore.

The aquaporin isoforms have different distributions in various tissues or organs and often the site of localization suggests the function. The aquaporins so far found in brain are: AQP1 in choroid plexus; AQP4 in astrocytic processes; and AQP9, an aquaglycerol transporter, in astrocytes. Neurons have not yet been found to contain any aquaporin.

Cerebrospinal fluid formation and regulation of its rate and composition are dependent on a number of transporters. In choroid plexus, AQP1 is localized to the apical surface of the epithelium where Na,K-ATPase, $Na^+/K^+/2Cl^-$ co-transporter and HCO_3^- channels are also situated. The basolateral membranes contain Cl^-/HCO_3^- and Na^+/H^+ exchangers. The Na,K-ATPase pumping Na^+ out of the epithelial apical surfaces into the ventricle provides the energy driving the osmotic gradient that extrudes water from epithelial cell apical surfaces through the AQP1 transporter.

AQP4 is the major water facilitator in brain and is most concentrated in astrocyte endfeet, but AQP4 has not been found in neurons. It is localized to basolateral surfaces of ependymal cells and along the entire plasmalemma of astrocytes, including processes that ensheath

synapses. It is not found in oligodendrocytes or microglia but is observed in brain endothelial cells. The presence of AQP4 in perivascular and subpial membranes suggest that it functions in the exchange of water between brain and blood and that it may be a component of the blood–brain barrier. In AQP4 knockout mice, brain edema after experimental stroke or hypoosmotic stress is less than in wild type mice, indicating that the influx of water into brain is at least partially through the AQP4 channels, and that AQP4 channels facilitate water influx under conditions that produce edema. But, in contrast, after intraparenchymal fluid infusion, freeze injury or implanted neoplasm, mice lacking AQP4 develop even greater brain edema and have worse clinical outcomes than do wild type mice after similar treatment [66, 67].

The distribution of AQP4 is localized to astrocytic endfeet membranes by anchoring to a complex of proteins, including dystrophin or α-syntrophin (α-syn), that connects the cell cytoskeleton to the extracellular matrix (see Chs 2 and 8). The anchoring proteins maintain the AQP4 in regular orthogonal arrays that can be visualized by electron microscopy in the endfeet membranes. In dystrophin- or α-syn-null mice, AQP4 content is not reduced but it is diffusely distributed in astrocyte membranes, largely reduced in perivascular endfeet but not from subpial endfeet, other astrocytic processes or ependymal cells. In these animals, development of brain edema after hypoosmotic stress or ischemia is delayed and attenuated relative to the edema in wild-type mice. In addition, in hippocampus of α-syn-null mice, in which 90% AQP4 of perivascular end feet is lost, recovery of extracellular K^+ concentrations after stimulation is delayed. This condition can decrease the threshold for seizures. Perivascular endfeet in α-syn-null mice under basal conditions consistently exhibit swelling, suggesting that the AQP4 in endfeet facilitates efflux of the water generated by glucose metabolism. Hence, AQP4 can facilitate water transport in either direction depending on the osmotic gradient. In retinal Mueller glia, AQP4 is colocalized with Kir4.1 channels involved in K^+ clearance, suggesting that these molecules function in concert to promote K^+ and water flow from extracellular fluid through these cells into the peripheral 'sink'. In this view, water can flow from the extracellular compartment through the AQP4 on non-endfeet plasmalemma into astrocytes and through the endfeet pool of AQP4 into the blood circulation [67]). This water flux together with K^+ flux through Kir4.1 channels constitute the K^+- buffering function of astrocytes discussed above and represented in Figure 5-14.

The binding of α-syn to AQP4 is sensitive to ischemia, such that, in the postischemic stage, the othogonal arrays of AQP4 normally characteristic of the endfeet perivascular membranes are lost, although the total level of α-syn is unchanged. Edema is attenuated in the α-syn-null mice. This loss of AQP4 from perivascular endfeet might retard the extent of water influx but would delay the resolution of edema through perivascular membranes. Further information regarding the kinetics of edema formation and resolution under these conditions is necessary to understand the regulation. Since the anchoring protein is critical to the specific localization of the AQP4, its level or binding characteristics also may be involved in regulating the AQP4 activity and function.

AQP4 is also distributed in a nonpolarized pattern in astroglial lamellae of the osmosensitive supraoptic nuclei and circumventricular organs. These glia, when subjected to hypoosmotic stress, release taurine on to glycine receptors on osmosensitive neurons, which, when activated, in turn lead to reduced secretion of antidiuretic hormone [68]. AQP9 is found in third ventricle ependyma, including the tanycytes, while mRNA for AQP9 is also seen in astrocytes and endothelial cells. Its function in brain is not understood.

A number of toxic conditions beside hypoosmotic stress and hypoxia/ischemia produce brain edema and the causes may be related to regulation of the aquaporins (see Ch. 34). AQP1 and AQP4 are intensely upregulated in reactive astrocytes in subarachnoid hemorrhage [69], in human glioma and astrocytoma [70] and AQP4 in endothelia and reactive astrocytes in metastatic carcinoma [71, 72].

Knowledge of the regulation of aquaporins is expected to provide clues as to potential therapy for brain edema. Mannitol is often used clinically as an hyperosmotic agent to reduce cerebral edema. The mannitol effect might be related to its induction of expression of AQP4 and AQP9 in cultured astrocytes and in cortex after intraperitoneal infusion. An inhibitor of p38 MAPK suppressed expression of these aquaporins in cultured astrocytes [73]. Anchoring proteins that regulate aquaporin localization are also targets for therapeutic intervention. New pathways for a molecular classification of brain edema and investigation of possible means for treating brain edema have been opened by these discoveries.

Facilitated diffusion of glucose across the blood–brain barrier and into brain cells is catalyzed by GLUT1, -2 and -3, products of the SLC2 gene superfamily. The SLC2 (solute carrier) superfamily consists of 12 glucose transporters (GLUT1–12) and one H^+-myo-inositol cotransporter (HMIT or GLUT13). They all have 12 transmembrane segments with the N- and C-termini both on the cytoplasmic aspect and a specific N-linked oligosaccharide side-chain on either the first or fourth extracellular loop.

The K_m of GLUT1 is 1–2 mmol/l for glucose influx and 20–30 mmol/l for efflux. A proposed transport mechanism evokes mutually exclusive glucose binding to sites internal and external to the plasmalemma; glucose binding to the extracellular side would induce a conformational change involving transport of the glucose. Possibly GLUT1 exists in membranes as a conformationally asymmetric dimer or tetramer (see [74] for a complete review).

GLUT1 is predominantly expressed in brain endothelial cells of the blood–brain barrier and on the astrocytic endfeet covering the abluminal surface of capillaries. GLUT1 is expressed also in Schwann cells and perineurium. GLUT1 is essential for glucose delivery from blood into brain through the astrocyte endfeet. Astrocytes metabolize glucose to lactate, which can be transferred into neurons via the monocarboxylate transporters, MCT1 and MCT2 (see also Ch. 31). A hereditable mutation in the gene for GLUT1 results in a limited glucose supply to the brain and a syndrome of infantile epilepsy, acquired microcephaly and hypoglycorrhachia. A number of milder phenotypic variants have been described [75]. It is noteworthy that, despite its vital dependence on an adequate glucose supply (Ch. 31), the brain relies for its supply of glucose on facilitators rather than active transport, and this is largely regulated by local blood flow (Chs. 31, 58).

GLUT3 occurs in neurons, mainly in plasmalemma and to a lesser extent in nonsynaptic intracellular vesicles. GLUT2 and glucokinase are believed to be part of a glucose-sensor system in certain neurons that modulate feeding behavior and regulate glucose uptake by peripheral tissues: their mRNAs are expressed in human ventromedial and arcuate nuclei of the hypothalamus [76]. GLUT8 is expressed in certain brain regions, including hippocampus, amygdala, olfactory cortex, hypothalamus, brainstem and posterior pituitary nerve endings. It is mainly observed in intracellular vesicles and may be translocated to the plasmalemma by as yet unknown regulatory stimuli. This endocytic recycling model of regulation may apply to others of the GLUT family. For example, GLUT 4, in skeletal and cardiac muscle and adipose tissue, occurs mostly in an intracellular vesicle compartment. Insulin activates its rapid translocation to the cell surface resulting in increased cellular uptake of glucose. Exercise also regulates glucose uptake through trafficking of GLUT4 to the cell surface, but by an insulin-independent mechanism. Deficiencies in GLUT4 may underlie some variants of diabetes type 2 and insulin resistance as well as some skeletal or cardiac muscle disorders [74].

HMIT is a H^+-coupled myo-inositol symporter. High levels of its expression are observed in neurons and glia of hippocampus, hypothalamus, cerebellum and brainstem. Since *myo*-inositol is a precursor for phosphatidyl inositol, which itself is a critical regulator of many neuronal processes (Ch. 20), HMIT regulation is possibly involved in various mood and behavior patterns that are affected by inositol metabolism and by pharmacologic agents that modify inositol metabolism (see Chs 54 and 55).

Brain capillary endothelial cells and some neurons also express a Na^+-dependent D-glucose symporter, SGLT1. SGLT1 (SLC5A1) was the first characterized of the large SLC5 family of Na-dependent symporters (SSSF) which transport various solutes and ions into cells [77, 78]. SGLT1 is found mainly in the intestine, trachea, kidney and heart. It cotransports both glucose and galactose. A genetic disease producing glucose–galactose malabsorption and severe diarrhea is related to mutations in the SGLT1 gene [79]. In brain endothelium, SGLT1 expression is limited to the luminal membranes of brain capillary endothelial cells. This suggests that SGLT1 and GLUT1 are both involved in blood glucose transport into capillary endothelia whereas glucose efflux from the endothelia into astrocytes and neurons depends primarily on GLUT1. The low affinity of GLUT1 for intracellular glucose ($K_m \approx 25$ mmol/l) may require SGLT1 to accumulate sufficiently high intracellular glucose to maintain an adequate rate of supply to the astrocytic endfeet [77]. It is of interest that SGLT1 expressed in oocytes transports water into cells in stoichiometric relation to the glucose symport. This is calculated to account for half of the 8 liters of water absorbed by human small intestine per day. This provides a rationale for the treatment of secretory diarrhea with oral salt solutions containing glucose. It has been proposed that cotransport of water is a general property of symporters [80].

CHAPTER

6

Electrical Excitability and Ion Channels

Bertil Hille

William A. Catterall

MEMBRANE POTENTIALS AND ELECTRICAL SIGNALS IN EXCITABLE CELLS 95
Excitable cells have a negative membrane potential 95
Real cells are not at equilibrium 97
Transport systems may also produce membrane potentials 97
Electrical signals recorded from cells are of two types: stereotyped action potentials and a variety of slow potentials 97

ACTION POTENTIALS IN ELECTRICALLY EXCITABLE CELLS 98
During excitation, ion channels open and close and a few ions flow 98
Gating mechanisms for Na^+ and K^+ channels in the axolemma are voltage-dependent 98
The action potential is propagated by local spread of depolarization 99
Membranes at nodes of Ranvier have high concentrations of Na^+ channels 99

FUNCTIONAL PROPERTIES OF VOLTAGE-GATED ION CHANNELS 99
Ion channels are macromolecular complexes that form aqueous pores in the lipid membrane 99
Voltage-dependent gating requires voltage-dependent conformational changes in the protein component(s) of ion channels 100
Pharmacological agents acting on ion channels help define their functions 101

THE VOLTAGE-GATED ION CHANNEL SUPERFAMILY 101
Na^+ channels were identified by neurotoxin labeling and their primary structures were established by cDNA cloning 101
Ca^{2+} channels have a structure similar to Na^+ channels 103
Voltage-gated K^+ channels were identified by genetic means 103
Inwardly rectifying K^+ channels were cloned by expression methods 103

THE MOLECULAR BASIS FOR ION CHANNEL FUNCTION 103
We begin to know structural determinants of the ion selectivity filter and pore 103
Voltage-dependent activation requires moving charges 105
The fast inactivation gate is on the inside 106

ION CHANNEL DIVERSITY 107
Na^+ channels are primarily a single family 107
Three subfamilies of Ca^{2+} channels serve distinct functions 107
There are many families of K^+ channels 107
More ion channels are related to the Na_v, Ca_v and K_v families 108
There are many other kinds of ion channels with different structural backbones and topologies 108

Basic Neurochemistry: Molecular, Cellular and Medical Aspects
0-12-088397-X

The nervous system enables animals to receive and act on internal and external stimuli with speed and coordination. Activities of the nervous system are reflected in ongoing electrical and chemical signals. Consider a simple reflex arc mediating reflex withdrawal of the leg from a painful stimulus. Several cell types are involved in a network shown diagrammatically in Figure 6-1. Messages travel from skin receptors through the network as a volley of electrical disturbances, terminating in contraction of some muscles. This chapter concerns the origin of electrical potentials in such excitable cells, potentials generated by the passive diffusion of Na^+, K^+, Ca^{2+} and Cl^- ions through highly selective molecular pores in the cell plasma membrane called ion channels. Such channels play a role in membrane excitation as central as the role of enzymes in metabolism. The opening and closing of specific ion channels shape the membrane potential changes. (The interested reader is referred to Hodgkin [1], Armstrong [2], Nicholls *et al.* [3] and Hille [4, 5] for more detailed treatment of this subject.) Over 500 human genes coding for subunits of ion channels have been identified.

MEMBRANE POTENTIALS AND ELECTRICAL SIGNALS IN EXCITABLE CELLS

Excitable cells have a negative membrane potential. Before examining the variety of electrical signals, let us consider the electrochemical theory behind their

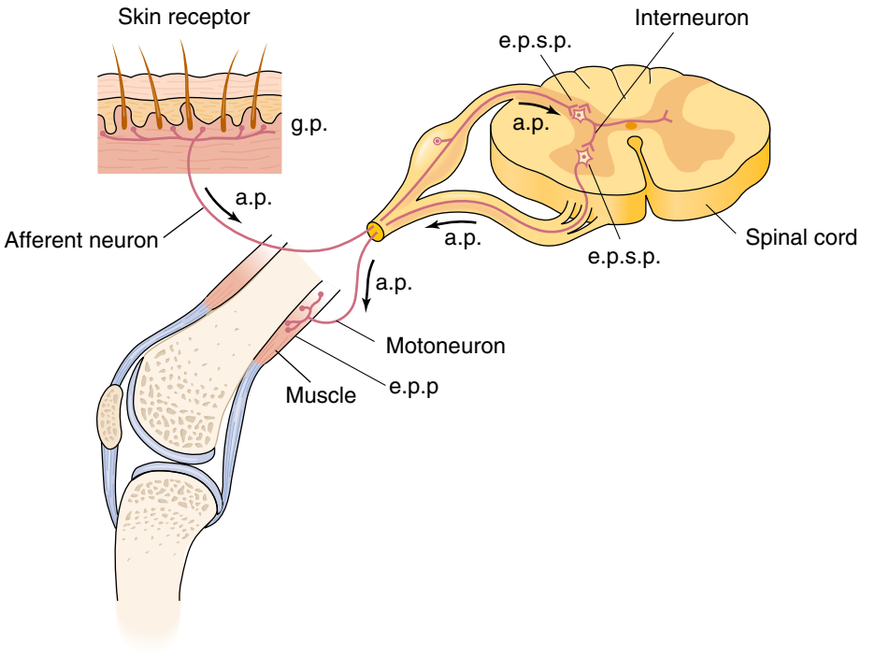

FIGURE 6-1 Path of excitation in a simplified spinal reflex that mediates withdrawal of the leg from a painful stimulus. In each of the three neurons and in the muscle cell, excitation starts with a localized slow potential and is propagated via an action potential (*a.p.*). Slow potentials are generator potential (*g.p.*) at the skin receptor; the excitatory postsynaptic potentials (*e.p.s.p.*) in the interneuron and the motoneuron and end-plate potential (*e.p.p.*) at the neuromuscular junction. Each neuron makes additional connections to other pathways that are not shown.

generation. At rest, the cytoplasm is electrically more negative than the external bathing fluid by 30–100 mV. This potential drop appears across the cell's plasma membrane, as is revealed by recording with an electrolyte-filled glass pipette microelectrode. When the narrow tip of such an electrode passes through the plasma membrane, one sees a sudden negative drop, the resting potential of the cell. By convention, the membrane potential is defined as 'inside' minus 'outside,' so the resting potential is a negative number. Signals that make the cytoplasm more positive than at rest are said to depolarize the membrane, and those making it more negative are said to hyperpolarize the membrane.

Membrane potentials arise from the diffusion of ions [3–5]. Consider the electrolyte system represented in Figure 6-2 (left), where a porous membrane separates aqueous solutions of unequal concentrations of a fictitious salt KA. Assume that the membrane pores are permeable exclusively to K^+ so that K^+ begins to diffuse across the membrane but A^- does not. Initially the movement of K^+ from the concentrated side to the dilute side exceeds the movement in the reverse direction, so a few K^+ ions flow down their concentration gradient. This process does not continue long because each K^+ ion carries a positive charge from one compartment to the other and leaves a net negative charge behind. The growing separation of charge creates an electrical potential difference (the membrane potential) between the two solutions. The accumulated positive charge on the side into which the K^+ ions diffuse sets up an electrical force that opposes further net movement of K^+, and soon the membrane potential stops changing.

The membrane potential reached in a system with only one permeant ion and no perturbing forces is called the equilibrium, or Nernst, potential for that ion; thus, the final membrane potential for the system in Figure 6-2 is

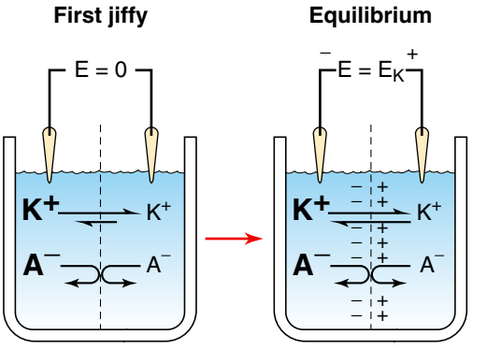

FIGURE 6-2 Origin of the membrane potential in a purely K^+-permeable membrane. The porous membrane separates unequal concentrations of the dissociated salt K^+A^-. In the first 'jiffy', the membrane potential, E, recorded by the electrodes above is zero and K^+ diffuses to the right down the concentration gradient. The anion A^- cannot cross the membrane, so a net positive charge builds up on the right and a negative charge on the left. At equilibrium, the membrane potential, caused by the charge separation, has built up to the Nernst potential, E_K, where the fluxes of K^+ become equal in the two directions.

the K^+ equilibrium potential E_K. At that potential, there is no further net movement of K^+, and unless otherwise disturbed, the membrane potential and ion gradient will remain stable indefinitely. The value of the Nernst potential is derived from thermodynamics by recognizing that the change of electrochemical potential $\Delta\mu_j$, for moving the permeant ion j^{+z} across the membrane, must be zero at equilibrium:

$$\Delta\mu_j = 0 = RT \ln \frac{[j]_o}{[j]_i} - zFE \qquad (1)$$

where R is the gas constant (8.31 J)/°/mol, T is absolute temperature in kelvin (°C + 273.2), and F is Faraday's constant (96,500 C/mol). Using terms appropriate to biology, $[j]_o$ and $[j]_i$ represent activities of ion j^{+z} outside and inside a cell; z is the ionic valence and E the membrane potential defined as 'inside minus outside'. Solving for E, and calling it E_j to denote the ion at equilibrium gives the Nernst equation for j:

$$E_j = \frac{RT}{zF} \ln \frac{[j]_o}{[j]_i}. \qquad (2)$$

For practical use at 20°C, the Nernst equation can be rewritten

$$E_j = \frac{58\,\text{mV}}{z} \log_{10} \frac{[j]_o}{[j]_i}, \qquad (3)$$

showing that for a 10:1 transmembrane gradient, a monovalent ion can give 58 mV of membrane potential. Table 6-1 gives approximate intracellular and extracellular concentrations of the four electrically most important ions in a mammalian skeletal muscle cell and the Nernst potentials calculated from these numbers at 37°C (neglecting possible activity coefficient corrections). Experimentally it is found that the resting muscle membrane is primarily permeable to K^+ and Cl^- and, therefore, the resting potential in muscle is −90 mV, close to the equilibrium potentials E_K and E_{Cl}. To summarize, membrane potentials arise by diffusion of a small number of ions down their concentration gradient across a permselective membrane.

TABLE 6-1 Approximate free ion concentrations in mammalian skeletal muscle

Ion	Extracellular concentration (mmol/l)	Intracellular concentration (mmol/l)	$[Ion]_o/[Ion]_i$	Nernst potential* (mV)
Na^+	145	12	12	+66
K^+	4	155	0.026	−97
Ca^{2+}	1.5	$<10^{-3}$	>1,500	>97
Cl^-	120	4†	30†	−90†

*Equilibrium potentials calculated at 37°C from the Nernst equation.
†Calculated assuming a −90 mV resting potential for the muscle membrane and assuming that chloride ions are at equilibrium at rest.

Real cells are not at equilibrium. Although the concept of equilibrium potentials is essential to understanding and predicting the membrane potentials generated by ion permeability, real cells actually never are at equilibrium, because different ion channels open and close during excitation and even at rest several types of channels are open simultaneously. Under these circumstances, the ion gradients are dissipated constantly, albeit slowly, and ion pumps are always needed in the long run to maintain a steady state (see Ch. 5). When the membrane is permeable to several ions, the steady-state potential is given by the sum of contributions of the permeant ions, weighted according to their relative permeabilities P_j:

$$E = \frac{RT}{F} \ln \frac{P_{Na}[Na^+]_o + P_K[K^+]_o + P_{Cl}[Cl^-]_i}{P_{Na}[Na^+]_i + P_K[K^+]_i + P_{Cl}[Cl^-]_o}. \qquad (4)$$

This Goldman–Hodgkin–Katz voltage equation is often used to determine the relative permeabilities of ions from experiments where the bathing ion concentrations are varied and changes in the membrane potential are recorded [5].

Transport systems may also produce membrane potentials. The equations just discussed describe passive electrodiffusion in ion channels where the only motive forces on ions are thermal and electrical, and they explain almost all the potentials of excitable cells. However, another class of electric current source in cells can generate potentials: the ion pumps and other membrane transporters that couple ion movements to the movements of other molecules. In excitable cells, the most prominent is the Na^+/K^+ pump (see Ch. 5), which gives a net export of positive charge and hence can hyperpolarize the plasma membrane slightly in proportion to the rate of pumping [3]; but hyperpolarization from this electrogenic pumping is at most a few millivolts. By contrast, mitochondria (and plant, algal and fungal cells) have powerful current sources in their proton transport system. Their membrane potentials are often dominated by this electrogenic system and cannot be described in terms of diffusion in passive ion channels.

Electrical signals recorded from cells are of two types: stereotyped action potentials and a variety of slow potentials. The action potential of axons is a brief, spike-like depolarization that propagates regeneratively as an electrical wave without decrement and at a high, constant velocity from one end of the axon to the other [1, 3]. It is used for all rapid signaling over a distance. For example, in the reflex arc of Figure 6-1 action potentials in motor axons would carry the message from spinal cord to leg, telling some muscle fibers of the biceps femoris to contract. In large mammalian axons at body temperature, the action potential at any one patch of membrane may last only 0.4 ms as it propagates at a speed of 100 m/s.

The action potential is normally elicited when the cell membrane is depolarized beyond a threshold level; and it is said to arise in an all-or-nothing manner because a subthreshold stimulus gives no propagated response, whereas every suprathreshold stimulus elicits the stereotyped propagating wave. Underlying the propagated action potential is a regenerative wave of opening and closing of voltage-gated ion channels that sweeps along the axon. Action potentials are also frequently referred to as spikes, or impulses. Most nerve and muscle cells and many endocrine cells can make action potentials.

By contrast, slow potentials are localized membrane depolarizations and hyperpolarizations, with time courses ranging from several milliseconds to minutes. They are associated with a variety of transduction mechanisms. For example, slow potentials arise postsynaptically at the sites of action of neurotransmitter molecules (see Ch. 10) and in transduction sites of sensory receptors (see Chs 49–51). Slow potentials are graded in relation to their stimulus and sum with each other within the cell while decaying passively over a distance of no more than a few millimeters from their site of generation. Underlying the slow potential is a graded and local opening or closing of ion channels reflecting the intensity of the stimulus. These channels are gated by stimuli other than voltage. The natural stimulus for the initiation of propagated action potentials is a depolarizing slow potential exceeding the firing threshold. In each of the cell types involved in the reflex arc in Figure 6-1, depolarizing slow potentials initiate propagating action potentials as the message moves forward.

ACTION POTENTIALS IN ELECTRICALLY EXCITABLE CELLS

During excitation, ion channels open and close and a few ions flow. The membrane potential does not change unless there is a net charge movement across the membrane. During a propagated action potential, ion channels permeable to Na^+ open, some Na^+ enters the fiber, and the membrane potential swings transiently toward E_{Na}. When these pores close again, the membrane potential returns to rest near E_K and E_{Cl}. During activity the extra ion fluxes impose an extra load on the Na^+/K^+ pump and the Ca^{2+} pump, consuming ATP and stimulating an extra burst of cellular oxygen consumption until the original gradients are restored. How large are these fluxes? The physical minimum, calculated from the rules of electricity, is very small. Only 10^{-12} equivalents of charge need be moved to polarize 1 cm^2 of membrane by 100 mV, meaning that, ideally, the movement of 1 pmol/cm^2 of monovalent ion would be enough to depolarize the membrane fully. With this kind of Na^+ gain, a squid giant axon of 1 mm diameter could be stimulated 10^5 times and a mammalian unmyelinated fiber of 0.2 µm diameter only 10–15 times before the internal Na^+ concentration would be doubled, assuming that the Na^+/K^+ pump had been blocked.

Gating mechanisms for Na^+ and K^+ channels in the axolemma are voltage-dependent. The breakthrough in explaining the action potential came with an electrical method to study the kinetics of ion permeability changes directly. In a classic series of experiments, Hodgkin, Huxley and Katz [1, 3–6] studied squid giant-axon membranes by a method they called the voltage clamp. Their method controls the membrane voltage electrically while ion movements are recorded as electric current flowing across the membrane. The recorded current can be resolved into individual ionic components by changing the ion content of the solutions that bathe the membrane. The voltage clamp is a rapid and sensitive assay for studying the opening and closing of ion channels. Today, a widely used miniature version of the voltage clamp is the patch clamp, which has sufficient sensitivity to study the current flow in a single ion channel [7]. A glass micropipette, the patch pipette, with a tip diameter <1 µm, is fire polished at the tip and then pressed against the membrane of a cell. Because the tip is smooth, it seals to the membrane in the annular contact zone, rather than piercing the membrane, and defines a tiny patch of the cell surface whose few ion channels can be detected easily by the currents flowing through them. The patch clamp readily measures fluxes of as little as 10^{-20} mol of ion in less than 1 ms.

With the voltage clamp, Hodgkin and Huxley [1, 6, 8] discovered that the opening and closing conformational changes of axonal Na^+ and K^+ channels are directly controlled by the membrane potential. Hence, channel gating (these conformational changes) derives its energy from the work done by the electric field on charges associated with the channel macromolecule. Hodgkin and Huxley [6] identified currents from two types of ion-selective channel – Na^+ channels and K^+ channels – that account for almost all the current in axon membranes. Then they made a kinetic model of the opening and closing steps, simplified in Figure 6-3. Depolarization of the membrane

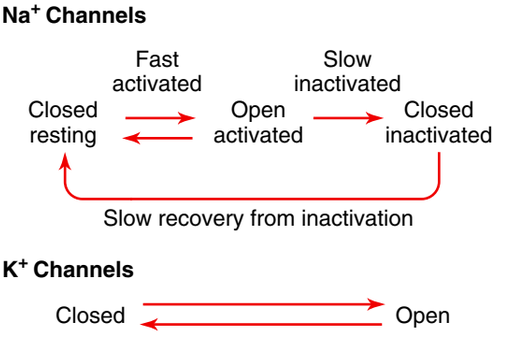

FIGURE 6-3 Simplified kinetic model for opening and closing steps of Na^+ and K^+ channels. (Adapted from Hodgkin and Huxley [6].)

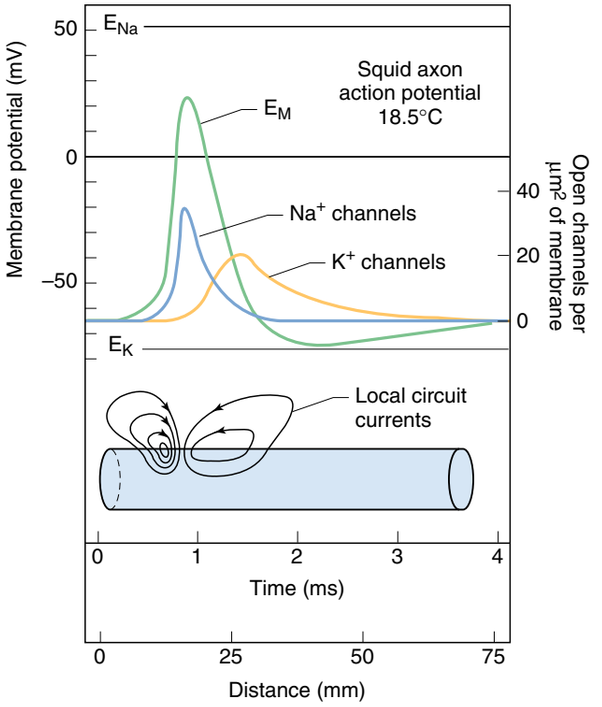

FIGURE 6-4 Events of the propagated action potential calculated from the Hodgkin and Huxley [6] kinetic model. Because the action potential is a nondecrementing wave, the diagram shows equivalently the time course of events at one point in the axon, or the spatial distribution of events at one time as the excitation propagates to the left. **Upper.** Action potential (E_M) and the opening and closing of Na^+ and K^+ channels. The Nernst potentials for Na^+ and K^+ are indicated by E_{Na} and E_K. **Lower.** Local circuit currents. The intense loop on the left spreads the depolarization to the left into the unexcited membrane.

is sensed by the voltage sensors of each channel and causes the conformational reactions to proceed to the right. Repolarization or hyperpolarization causes them to proceed to the left. We can understand the action potential in these terms. The action potential, caused by a depolarizing stimulus, begins with a transient, voltage-gated opening of Na^+ channels that allows Na^+ to enter the fiber and depolarize the membrane fully, followed by a transient, voltage-gated opening of K^+ channels that allows K^+ to leave and repolarize the membrane. Figure 6-4 shows a calculation of the temporal relation between channel-opening and membrane-potential changes in an axon at 18.5°C, using the full kinetic model of Hodgkin and Huxley [6].

The action potential is propagated by local spread of depolarization. How does the action potential propagate smoothly down an axon, bringing new channels into play ahead of it? Any electrical depolarization or hyperpolarization of a cell membrane spreads a small distance in either direction from its source by a purely passive process often called cable or electrotonic spread. The spread occurs because the intracellular and extracellular media are much better conductors than is the membrane, so that any charges injected at one point across the membrane repel each other and disperse along the membrane surface. The lower part of Figure 6-4 shows diagrammatically the so-called local circuit currents that spread the depolarization forward. In this way, an excited depolarized membrane area smoothly depolarizes the next unexcited region ahead of the action potential, bringing it above firing threshold, opening Na^+ channels there, and advancing the wave of excitation. The action potential in the upper part of Figure 6-4 is calculated by combining the known geometry of the squid giant axon with the rules of ionic electricity and the Hodgkin and Huxley kinetic equations for the voltage-dependent gating of Na^+ and K^+ channels. The success of the calculations means that the factors described are sufficient to account for action-potential propagation.

Membranes at nodes of Ranvier have high concentrations of Na^+ channels. A wide variety of cells have now been studied by voltage clamp methods, and quantitative descriptions of their permeability changes are available. All axons, whether vertebrate or invertebrate, operate on the same principles: They have a small background permeability, primarily to K^+, that sets the resting potential and display brief, dramatic openings of Na^+ and K^+ channels in sequence to shape the action potentials. Chapter 4 describes myelin, a special adaptation of large (1–20 μm diameter) vertebrate nerve fibers for higher conduction speed. In myelinated nerves, like unmyelinated ones, the depolarization spreads from one excitable membrane patch to another by local circuit currents; but, because of the insulating properties of the coating myelin, the excitable patches of axon membrane (the nodes of Ranvier) may be more than 1 mm apart, so the rate of progression of the impulse is faster. Nodes of Ranvier have at least ten times as many Na^+ channels per unit area as other axons to depolarize the long, passive internodal myelin. The Na^+/K^+ pump is also concentrated at nodes (see Ch. 5). Between nodes, the internodal axon membrane has K^+ channels but far fewer Na^+ channels.

FUNCTIONAL PROPERTIES OF VOLTAGE-GATED ION CHANNELS

Ion channels are macromolecular complexes that form aqueous pores in the lipid membrane. We have learned much about ion channel function from voltage clamp and patch clamp studies on channels still imbedded in native cell membranes [1–6, 8]. A diversity of channel types was discovered in the different cells in the body, where the repertoire of functioning channels is adapted to the special roles each cell plays [5]. The principal voltage-gated ones are the Na^+, K^+ and Ca^{2+} channels, and most of these are opened by membrane depolarizations. Figure 6-5A summarizes the major functional properties of a voltage-gated

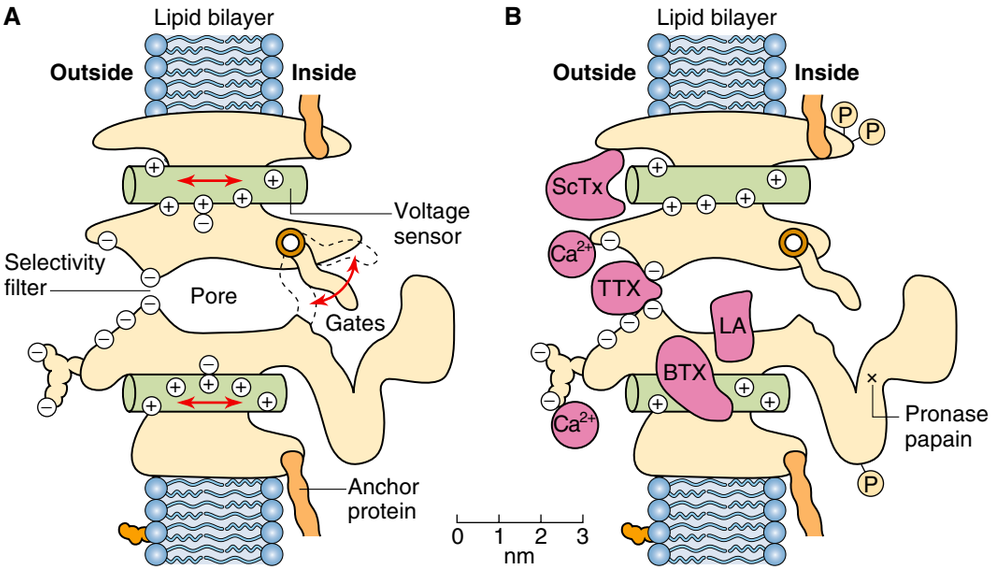

FIGURE 6-5 (**A**) Diagram of the functional units of a voltage-gated ion channel and (**B**) the hypothesized binding sites for several drugs and toxins affecting Na^+ channels. The drawing is fanciful, and the dimension and shapes of many parts are not known. Drug receptors: *TTX*, tetrodotoxin and saxitoxin; *ScTx*, scorpion toxins and anemone toxins; *BTX*, batrachotoxin, aconitine, veratridine and grayanotoxin; *LA*, local anesthetics; *Ca^{2+}*, divalent ions screening and associating with surface negative charge.

channel in terms of a fanciful cartoon drawn before the availability of crystal structures. The pore is narrow enough in one place, the ionic selectivity filter, to 'feel' each ion and to distinguish among Na^+, K^+, Ca^{2+} and Cl^-. The channel also contains charged components that sense the electric field in the membrane and drive conformational changes that open and close gates controlling the permeability of the pore. In voltage-gated Na^+, K^+ and Ca^{2+} channels, the gates close the axoplasmic mouth of the pore and the selectivity filter is near the outer end of the pore.

How did the voltage clamp show that a channel is a pore? The most convincing evidence was the large ion flux a single channel can handle. In patch-clamp studies, it is common to observe ionic currents of 2–10 pA flowing each time one channel in the patch is open. This would correspond to $12–60\times10^6$ monovalent ions moving per second. Such a turnover number is several orders of magnitude faster than known carrier mechanisms and agrees well with the theoretical properties of a pore of atomic dimensions.

Water molecules break and make hydrogen bonds with other waters 10^{11}–10^{12} times per second, and alkali ions exchange water molecules or other oxygen ligands at least 10^9 times per second. In these terms, the progress of an ion across the membrane is not the movement of a fixed hydrated complex; rather it is a continual exchange of oxygen ligands as the ion dances through the sea of relatively free water molecules and polar groups that form the wall of the pore. Dipoles and charged groups in the pore provide stabilization energy to the permeating ion, compensating for those water molecules that must be left behind as the ion enters into the pore. Evidence for important negative charges in the selectivity filter of Na^+, K^+ and Ca^{2+} channels comes from a block of their permeability as the pH of the external medium is lowered below pH 5.5 [5] and from site-directed mutagenesis of aspartate and glutamate residues in cloned channels.

The minimum pore size of ion channels was first determined from the van der Waals dimensions of ions that will pass through them [5]. The voltage-gated channels, which show considerable ion selectivity, are so narrow that ions need to shed several (not all) water molecules to pass through. The ion fluxes are often described by models with temporary binding to attractive sites and jumps over energy barriers. Formally, the kinetics of flux through channels can be formulated similarly to enzyme kinetics. It is assumed that the channel passes through a sequence of 'channel-ion complexes' as it catalyzes the progression of an ion across the membrane. Such theories also can describe other properties of ion channels, such as selectivity, saturation, competition and block by permeant ions [5].

Voltage-dependent gating requires voltage-dependent conformational changes in the protein component(s) of ion channels. On theoretical grounds, a membrane protein that responds to a change in membrane potential must have charged or dipolar amino acid residues, located within the membrane electric field, acting as voltage sensors as illustrated in Figure 6-5A [5, 6, 8]. Changes in the membrane potential then exert a force on these charged residues. If the energy of the field-charge interactions is

great enough, the protein may be induced to undergo a change to a new, stable conformational state in which the net charge or the location of charge within the membrane electric field has been altered. For such a voltage-driven change of state, the steepness of the state function versus membrane potential curve defines the equivalent number of charges that move, according to a Boltzmann distribution. On this basis, activation of Na^+ channels would require the movement of as many as 12 positive charges from the intracellular to the extracellular side of the membrane. The movement of a larger number of charges through a proportionately smaller fraction of the membrane electrical field would be equivalent.

Such movements of membrane-bound charge give rise to tiny 'gating' currents that can be detected electrophysiologically [9]. Their voltage and time dependence are consistent with the multistep changes of channel state from resting to active. In contrast to activation, fast inactivation from the open state of Na^+ channels and certain K^+ channels does not seem to be a strongly voltage-sensitive process. This inactivation can be blocked irreversibly by proteolytic enzymes acting from the intracellular side of the channel and it requires regions of the channel that are exposed at the intracellular surface of the membrane.

Pharmacological agents acting on ion channels help define their functions. The Na^+ channel is so essential to successful body function that it has become the target in evolution of several potent poisons. The pharmacology of these agents has provided important insights into the further definition of functional regions of the channel [2, 5, 10]. Figure 6-5B shows the supposed sites of action of four prominent classes of Na^+ channel agents. At the outer end of the channel pore is a site where the puffer fish poison, tetrodotoxin (TTX), a small, lipid-insoluble charged molecule binds with a K_i of 1–10 nmol/l and blocks Na^+ permeability. A second important class of Na^+ channel blockers includes such clinically useful local anesthetics as lidocaine and procaine and related antiarrhythmic agents. They are lipid-soluble amines with a hydrophobic end and a polar end, and they bind to a hydrophobic site on the channel protein where they also interact with the inactivation gating machinery. The relevant clinical actions of local anesthetics are fully explained by their mode of blocking Na^+ channels. Two other classes of toxins either open Na^+ channels spontaneously or prevent them from closing normally once they have opened. These are lipid-soluble steroids, such as the frog-skin poison batrachotoxin (BTX), the plant alkaloids aconitine and veratridine, all three acting at a site within the membrane, and peptide toxins from scorpion and anemone venoms, which act at two sites on the outer surface of the membrane. Most scorpion and anemone toxins block the inactivation gating step specifically. Interestingly, the affinity of the channel for each of these classes of toxins depends on the gating conformational state of the channel.

Similarly specific agents affect K^+ channels or Ca^{2+} channels. Most K^+ channels can be blocked by tetraethylammonium ion, Cs^{2+}, Ba^{2+}, and 4-aminopyridine [2, 5]. Except for 4-aminopyridine, there is good evidence that these ions become lodged within the channel at a narrow place from which they may be dislodged by K^+ coming from the other side. In addition, certain K^+ channels can be distinguished by their ability to be blocked near the outer mouth by polypeptide toxins from scorpion (charybdotoxin), bee (apamin), or snake (dendrotoxin) venoms. Ca^{2+} channels can be blocked by externally applied divalent ions, including Mn^{2+}, Co^{2+}, Cd^{2+} and Ni^{2+}. Different Ca^{2+} channel subtypes can be distinguished by their block by dihydropyridines (nifedipine), cone snail toxins (ω-conotoxins) and spider toxins (agatoxins).

THE VOLTAGE-GATED ION CHANNEL SUPERFAMILY

Why should we study the structural properties of the channel macromolecules themselves? Although biophysical techniques define the functional properties of voltage-sensitive ion channels clearly, it is important to relate those functional properties to the structure of the channel proteins. We focus first on the discovery of the ion channel proteins, in which three different experimental approaches were used

Na^+ channels were identified by neurotoxin labeling and their primary structures were established by cDNA cloning. Neurotoxins act at several different sites on Na^+ channels to modify their properties (Figs 6-5B, 6-6A, B. Photoreactive derivatives of the polypeptide toxins of scorpion venom were covalently attached to Na^+ channels in intact cell membranes allowing direct identification of channel components. Reversible binding of saxitoxin and tetrodotoxin to their common receptor was used as a biochemical assay for the channel protein. Solubilization of excitable membranes with nonionic detergents released the Na^+ channel, and the solubilized channel was purified by chromatographic techniques that separate glycoproteins by size, charge and composition of covalently attached carbohydrate [11–13]. Na^+ channels consist of a large α-subunit, a glycoprotein with molecular mass of 260,000, usually in association with glycoprotein β-subunits with molecular masses of 33,000–36,000 (Fig. 6-6A). An important step in the study of a purified membrane transport protein is to reconstitute its function in the pure state. This was accomplished in two ways for the Na^+ channel. In the first approach, purified channels were incorporated into vesicles of pure phospholipid. Activation of the reconstituted channels by treatment with the neurotoxins veratridine or batrachotoxin markedly increased the permeability of the vesicles to Na^+. The purified channels retained the ion selectivity and pharmacological properties of native channels. In the second

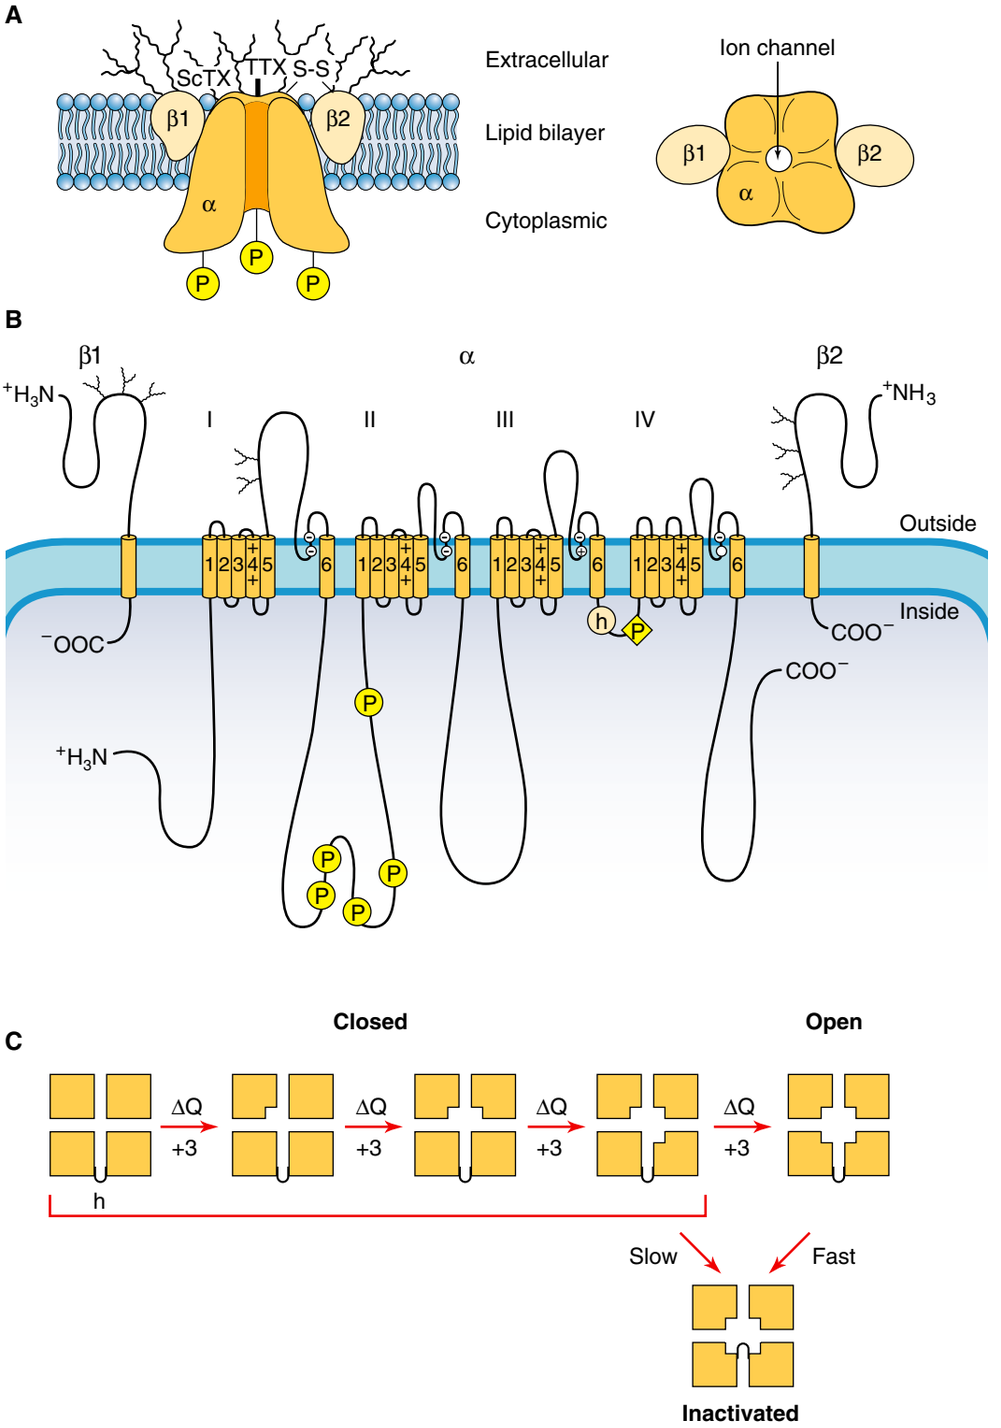

FIGURE 6-6 Structural model of the Na^+ channel. (**A**) **Left.** A topological model of the rat brain Na^+ channel illustrating the probable transmembrane orientation of the three subunits, the binding sites for tetrodotoxin (*TTX*) and scorpion toxin (*ScTX*), oligosaccharide chains (*wavy lines*) and cAMP-dependent phosphorylation sites (*P*). **Right.** An *en face* view of the protein from the extracellular side illustrating the formation of a transmembrane ion pore in the midst of a square array of four transmembrane domains of the α subunit. (**B**) A transmembrane folding model of the α and β subunits of the Na^+ channel. The amino acid sequence is illustrated as a *narrow line*, with each segment approximately proportional to its length in the molecule. Transmembrane α-helices are illustrated as cylinders. The positions of amino acids required for specific functions of Na^+ channels are indicated: ++, positively charged voltage sensors in the S4 transmembrane segments; *O*, residues required for high affinity binding of TTX with their charge characteristics indicated by –, + or open field; *h*, residues required for fast inactivation; *P in a circle*, sites for phosphorylation by cAMP-dependent protein kinase; and *P in a diamond*, sites for phosphorylation by protein kinase C. (**C**) Sequential gating of the Na^+ channel. A reaction pathway from closed to open Na^+ channels is depicted. Each square represents one homologous domain of the α subunit. Each domain undergoes a conformational change initiated by a voltage-driven movement of its S4 segment, leading eventually to an open channel. Inactivation of the channel occurs from the final closed state and the open state, by folding of the intracellular loop connecting domains III and IV into the intracellular mouth of the transmembrane pore.

approach, ion conductance mediated by single purified channels was measured electrically. Channels reconstituted in phospholipid vesicles were studied directly using patch clamp methods or incorporated into planar, phospholipid bilayer membranes by fusion. The individual purified channels observed retained the single-channel conductance, ion selectivity, and voltage dependence of activation and inactivation that are characteristic of native Na^+ channels.

The amino acid sequences of the Na^+ channel α, β1 and β2 subunits were determined by cloning DNA complementary to their mRNAs, using antibodies and oligonucleotides developed from work on purified Na^+ channels [14, 15, 16]. The primary structures of these subunits are illustrated as transmembrane folding models in Figure 6-6B. The large α subunits are composed of 1,800–2,000 amino acids and contain four repeated domains having greater than 50% internal sequence identity. Each domain contains six segments that form transmembrane α-helices and an additional membrane reentrant loop that forms the outer mouth of the transmembrane pore (see below). In contrast, the smaller β1 and β2 subunits consist of a large extracellular N-terminal segment having a structure similar to antigen-binding regions of immunoglobulin, a single transmembrane segment and a short intracellular segment (Fig. 6-6B).

Ca^{2+} channels have a structure similar to Na^+ channels. The same general experimental strategy was successfully applied to voltage-gated Ca^{2+} channels. Drugs and neurotoxins that act on Ca^{2+} channels were used to identify and purify their protein components, and the ion transport function of the purified channels was restored by reconstitution (Fig. 6-7A) [17, 18]. Like Na^+ channels, Ca^{2+} channels have a principal subunit, designated α1, which is structurally homologous to the Na^+ channel α subunit. They have associated α2 and δ subunits, which form a disulfide-linked transmembrane glycoprotein complex, and β subunits, which are intracellular (Fig. 6-7A). In addition, Ca^{2+} channels in skeletal muscle have a transmembrane γ subunit. The auxiliary subunits of Ca^{2+} channels are not related in primary structure to the Na^+ channel β subunits.

Voltage-gated K^+ channels were identified by genetic means. Genes that harbor mutations causing an easily detectable altered phenotype can be cloned directly from genomic DNA without information about the protein they encode. The *Shaker* mutation in *Drosophila* causes flies to shake when under ether anesthesia and is accompanied by loss of a specific K^+ current in the nerve and muscle of the mutant flies. Cloning successive pieces of genomic DNA from the region of the chromosome that specifies this mutation allowed isolation of DNA clones encoding a protein related in amino acid sequence to the α subunit of Na^+ channels [19]. The K^+ channel protein is analogous to one of the homologous domains of Na^+ or Ca^{2+} channels [19] and functions as a tetramer of four separate subunits, analogous to the structure of Na^+ and Ca^{2+} channels (Fig. 6-7B). Like the Na^+ channels and the Ca^{2+} channels, the K^+ channels have auxiliary subunits, which include intracellularly located β subunits as well as minK or minK-related subunits having a single transmembrane segment [19, 20].

Inwardly rectifying K^+ channels were cloned by expression methods. A third experimental approach was used to clone and characterize inwardly rectifying K^+ channels, the simplest member of the ion channel protein family [19, 21]. DNA complementary to mRNAs from brain or heart was prepared and separated into pools. mRNA was prepared from each pool and its ability to direct the synthesis of K^+ channels in *Xenopus* oocytes was measured. The active cDNA was isolated by repeatedly dividing the pool of cDNAs until only a single one remained. The amino acid sequence that it encoded showed that inwardly rectifying K^+ channels have only two transmembrane segments (Fig. 6-7B), analogous to the S5 and S6 segments of voltage-gated Na^+, Ca^{2+} or K^+ channels. Four subunits are required to form an ion channel. Thus, these two segments must also form the transmembrane pores of voltage-gated Na^+, Ca^{2+} or K^+ channels.

THE MOLECULAR BASIS FOR ION CHANNEL FUNCTION

The cloning of the cDNA encoding the ion channel subunits permitted detailed tests of the functional properties of the polypeptides. cDNA clones can be expressed in recipient cells and the resulting ion channels can be studied by voltage-clamp methods. Only the principal α subunits of the Na^+, Ca^{2+} or K^+ channels are required for function [22, 23]. However, co-expression of the auxiliary subunits increases the level of expression and modifies the voltage-dependent gating, conferring more physiologically correct functional properties on the expressed channels [15]. These results indicate that the principal subunits of the voltage-gated ion channels are functionally autonomous, but the auxiliary subunits improve expression and modulate physiological properties.

We begin to know structural determinants of the ion selectivity filter and pore. Which amino acid sequences are involved in forming the ion selectivity filter and pore? Insight into this question first came from studies of the amino acid residues required for binding of tetrodotoxin, which blocks the ion selectivity filter at the outer mouth of the pore (Fig. 6-5B). Site-directed mutagenesis experiments showed that pairs of amino acid residues required for high-affinity tetrodotoxin binding are located in analogous positions in all four domains near the carboxyl ends of the short membrane-re-entrant segments between

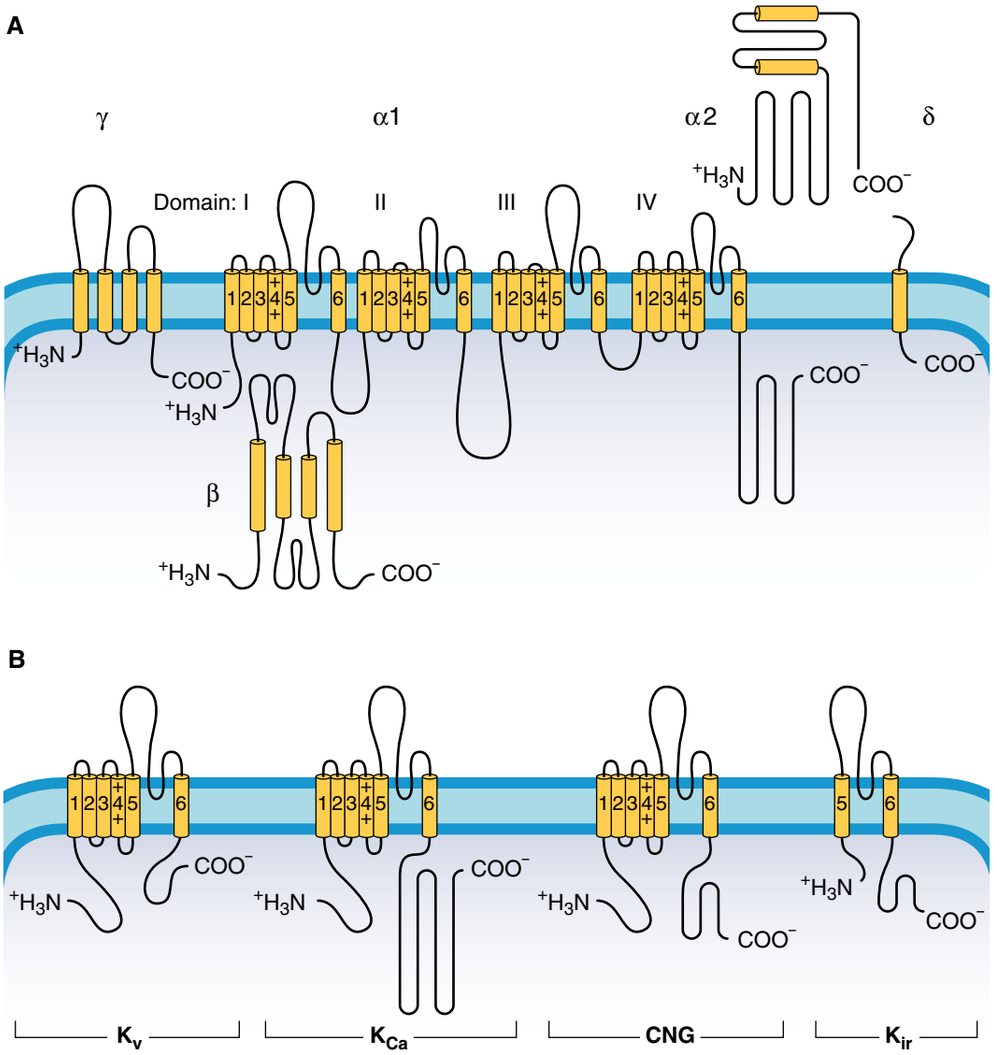

FIGURE 6-7 Transmembrane organization of voltage-gated Ca^{2+} channels, K^+ channels and relatives. (**A**) The primary structures of the subunits of voltage-gated Ca^{2+} channels are illustrated. *Cylinders* represent probable α-helical transmembrane segments. *Bold lines* represent the polypeptide chains of each subunit, with length approximately proportional to the number of amino acid residues. **B:** The primary structures of the plasma membrane cation channels related to K^+ channels are illustrated as transmembrane folding diagrams based on analysis of the hydrophobicity of the amino acid sequence. Predicted transmembrane α-helices are illustrated as *cylinders*. The remainder of the polypeptide chain is illustrated as a *bold line*, with the length of each segment approximately proportional to the length of its amino acid sequence. K_v, voltage-gated K^+ channel; K_{Ca}, Ca^{2+}-activated K^+ channel types 2 and 3; *CNG*, cyclic nucleotide-gated channel; K_{ir}, inward rectifying K^+ channel.

transmembrane α-helices S5 and S6 [24] (Fig. 6-6B). Six of these eight residues are negatively charged and may interact with permeant ions as they approach and move through the channel. In agreement with this idea, mutation of the only two of these residues that are not negatively charged (see domains III and IV, Fig. 6-6B) to glutamic acid residues, as present in the analogous positions in the Ca^{2+} channel, confers Ca^{2+} selectivity on the Na^+ channel [25]. Parallel results implicated these same regions of the K^+ channel in determining ion selectivity and conductance [26]. These results led to the idea that these segments, often called the P loops, form the ion selectivity filter. The three-dimensional structure of the pore formed from the S5 and S6 segments and the intervening P loop was elegantly determined by X-ray crystallography of a bacterial K^+ channel [27]. As in inward rectifier K^+ channels (Fig. 6-7B), the subunits of this bacterial channel have just two transmembrane segments (analogous to S5 and S6), which form α-helices that cross the membrane at an angle to form an 'inverted teepee' structure (Fig. 6-8A, left). The P loops are cradled in this structure to form the narrow ion selectivity filter at the extracellular end of the pore. This remarkable structure elucidates the molecular basis for the formation of a transmembrane pore and suggests a mechanism for ion conduction (see below).

How does the pore open? The structure illustrated in Figure 6-8A (left) may represent the closed state because

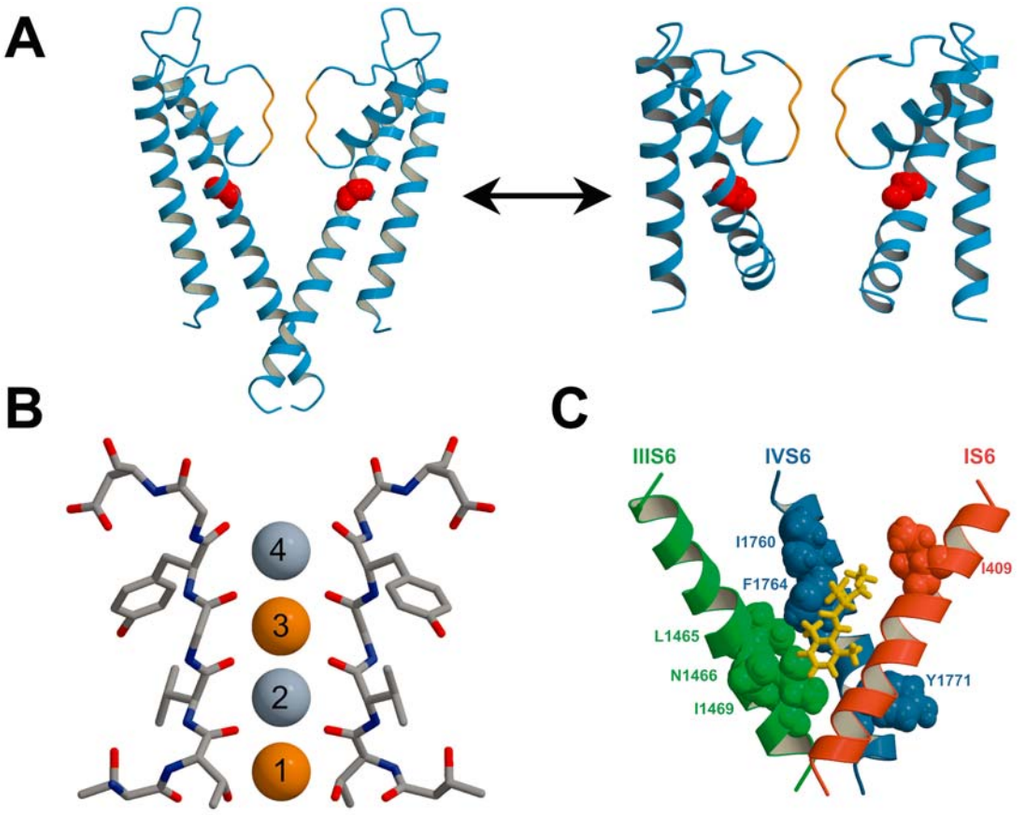

FIGURE 6-8 The ion selectivity filter and pore of Na^+ and K^+ channel illustrated with the extracellular side upwards. (**A**) A drawing of the three-dimensional structures of K^+ channels in the closed and open states, adapted from the three-dimensional structures of the K^+ channel from the bacterium *Streptococcus lividans* (closed, left) and *Methanococcus thermolytiyum* (open, right). Only two subunits are shown for clarity. (**B**) A drawing of K^+ ions moving single file through the ion selectivity filter of the K^+ channel from *S. lividans*. The four ion-coordination sites are thought to work in pairs. In one cycle of outward K^+ conductance, K^+ ions occupy sites 1 and 3 (orange), shift to sites 2 and 4 (gray), and then the K^+ ion in site 4 moves into the extracellular space while a new K^+ ion occupies site 1 and the K^+ ion in site 2 moves to site 3, re-establishing the initial state. (**C**) A drawing of the local anesthetic receptor site in the pore of the Na^+ channel. The amino acid residues that are thought to contact a bound etidocaine molecule (yellow) are indicated in a space-filling format for the S6 segments in domains I (red), III (green) and IV (blue).

the α-helices lining the inner pore cross at their intracellular ends, apparently closing the pore. In contrast, the structure of a distantly related bacterial K^+ channel [28], which is gated open by binding of Ca^{2+}, has a bend of approximately 30° in the inner pore helix (analogous to S6) at the position of a highly conserved glycine residue (Fig. 6-8A, right). This conformational change appears to open the pore at its intracellular end by splaying open the bundle of inner pore helices. Mutational studies of Na^+ channels support this pore-opening model because replacement of the conserved glycine with proline, which strongly favors a bend in the α-helix, also strongly favors pore opening and greatly slows closure [29].

Once the pore is open, K^+ ions appear to move outward in single file. Analysis of crystals shows four K^+ ions interacting with the backbone carbonyl groups of the amino acid residues that form the ion selectivity filter (Fig. 6-8B). It is thought that two K^+ ions occupy sites 1 and 3 (Fig. 6-8B, orange) and then switch to sites 2 and 4 (gray). The K^+ ion in site 4 would dissociate into the extracellular space, the K^+ ion in site 2 would move to site 3 and another K^+ ion from the intracellular space would bind to site 1. In this way, the pore remains occupied by two ions, during steady outward conduction.

Local anesthetics bind in the inner pore of Na^+ channels and block them (Fig. 6-5B). What is the structure of the local anesthetic binding site? A combination of site-directed mutagenesis and molecular modeling [16] reveals that local anesthetics and related antiepileptic drugs bind to a receptor formed by amino acid residues at specific positions in the S6 segments in domains I, III and IV of the Na^+ channel, as illustrated in Figure 6-8C. The aromatic and hydrophobic side chains of these amino acids contact the aromatic and substituted amino groups of the drug molecules and hold them in the receptor site, where they block ion movement through the pore.

Voltage-dependent activation requires moving charges. Structural models for voltage-dependent gating of ion channels must identify the voltage-sensors or gating charges (Fig. 6-5A) within the channel structure and suggest a plausible mechanism for transmembrane movement

of gating charge and its coupling to the opening of a transmembrane pore. The S4 segments of the homologous domains have been proposed as voltage sensors [13, 30]. These segments, which are conserved among Na^+, Ca^{2+} and K^+ channels, consist of repeated triplets of two hydrophobic amino acids followed by a positively charged residue. In the α-helical configuration, these segments would form a spiral of positive charge across the membrane, a structure that is well suited for transmembrane movement of gating charge (Fig. 6-5A). The positive charges are thought to be neutralized by negative charges in the nearby S2 and S3 segments. Much direct evidence in favor of designating the S4 segments as voltage sensors comes from mutagenesis studies [8, 19, 31]. Neutralization of positive charges results in progressive reduction of the steepness of voltage-dependent gating and of the apparent gating charge, as expected if indeed the S4 segments are the voltage sensors. At the resting membrane potential, the force of the electric field would pull the positive charges inward. Depolarization would abolish this force and allow an outward movement of the S4 helix. This outward movement has been detected in clever experiments that measure the movement of chemically reactive cysteine residues substituted for the native amino acids in S4 by analyzing the functional effects of specific chemical reactions at those substituted cysteines or the fluorescence of chemical probes located there [8, 32, 33]. This movement of the S4 helix is proposed to initiate a more general conformational change in each domain. After conformational changes have occurred in all four domains, the transmembrane pore can open and conduct ions (Fig. 6-6C).

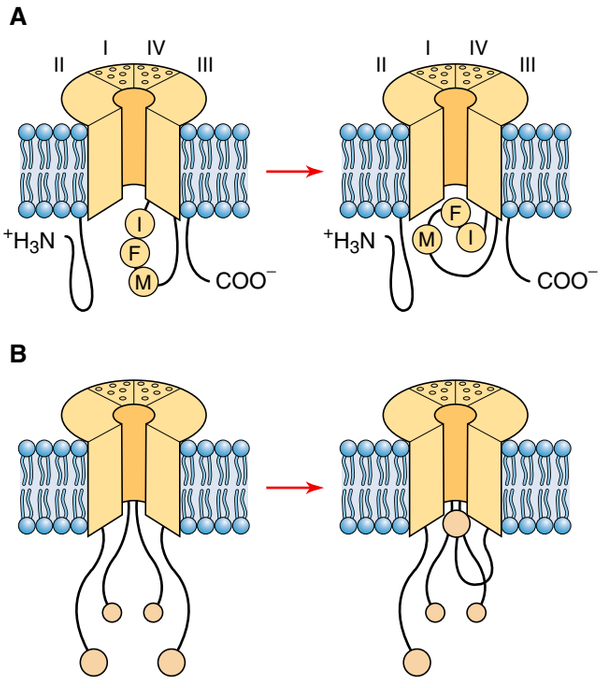

FIGURE 6-9 Mechanisms of inactivation of Na^+ and K^+ channels. (**A**) A hinged-lid model for Na^+ channel inactivation, illustrating the inactivation gate formed by the intracellular segment connecting domains III and IV and the critical cluster of hydrophobic residues that forms a latch holding the inactivation gate closed. *IFM*, isoleucine-phenylalanine-methionine. (**B**) A ball-and-chain model of K^+ channel inactivation. Each of the four subunits of a K^+ channel has a ball-and-chain structure at its N-terminus. Any one of the four can bind to the intracellular mouth of the open channel and inactivate it.

The fast inactivation gate is on the inside. Shortly after opening, many voltage-gated ion channels inactivate. The inactivation process of Na^+ channels can be prevented by treatment of the intracellular surface of the channel with proteolytic enzymes [2] or antibodies against the intracellular segment connecting domains III and IV (h, Fig. 6-6B) [23, 34], and expression of the Na^+ channel as two pieces with a cut between domains III and IV greatly slows inactivation [31]. A single cluster of three hydrophobic residues in this intracellular loop is required for fast inactivation [35] and inactivation is eliminated if these three hydrophobic residues are mutated to hydrophilic ones. Mutation of a single phenylalanine in the center of this motif nearly completely blocks fast inactivation of the channel. The segment of the Na^+ channel between domains III and IV is therefore proposed to serve as the inactivation gate by forming a hinged lid which folds over the intracellular mouth of the pore after activation [16] (Figs 6-6C and 6-9A). The cluster of hydrophobic residues may bind to the intracellular mouth of the pore like a latch to keep the channel inactivated.

A detailed model of K^+ channel inactivation has been derived from mutagenesis experiments on the original *Shaker* K^+ channels from *Drosophila* [36, 37]. The N-terminal of the K^+ channel serves as an inactivation particle and both charged and hydrophobic residues are involved. A ball-and-chain mechanism [9, 36, 37] has been proposed in which the N-terminal segment serves as a loosely tethered ball and inactivates the channel by diffusion and binding in the intracellular mouth of the pore (Fig. 6-9B). Consistent with this mechanism, synthetic peptides whose amino acid sequences correspond to that of the inactivation particle region can restore inactivation to channel mutants whose N-terminus has been removed. The mechanisms of inactivation of Na^+ and K^+ channels are similar in that in each case hydrophobic amino acid residues seem to mediate binding of an inactivation particle to the intracellular mouth of the pore. They differ in that charged amino acid residues are important in the inactivation particle of K^+ channels but not Na^+ channels, and that the inactivation particle is located over 200 residues away from the membrane at the N-terminus of the K^+ channel, compared to only 12 residues away from the membrane between domains III and IV of the Na^+ channel. It is likely that the hinged-lid mechanism of Na^+ channel inactivation evolved from the ball-and-chain mechanism of K^+ channels.

ION CHANNEL DIVERSITY

There are a surprisingly large number of evolutionarily and structurally related ion channel proteins— in the human genome more than 140 genes encode these proteins (Table 6-2) [5, 38]. What do they all do? Experiments in progress in many laboratories are beginning to reveal the meaning of this exceptional ion channel diversity.

Na^+ channels are primarily a single family. There are ten human genes encoding voltage-gated Na^+ channels (Table 6-2), and at least nine of the ten encode members of a single family ($Na_v1.1$–1.9) [38]. These Na^+ channels are expressed in different tissues and cells but their function is almost always to initiate action potentials in response to membrane depolarization.

Three subfamilies of Ca^{2+} channels serve distinct functions. In many cell types, it is not uncommon to find several Ca^{2+} channels that open with depolarization. The inflow of Ca^{2+} can assist in depolarizing cells but it also performs an important messenger role. The entering Ca^{2+} may activate exocytosis (secretion), contraction, gating of other channels, ciliary reorientation, metabolic pathways, gene expression, etc. (see Ch. 22). Indeed, whenever an electrical message activates any non-electrical event, a change of the intracellular free Ca^{2+} concentration acts as an intermediary. Genes that encode voltage-gated Ca^{2+} channels (Table 6-2) are grouped in three subfamilies that have distinct functions. In general, the members of a subfamily are greater than 75% identical in amino acid sequence in their conserved transmembrane regions while there is only 25–50% amino acid sequence identity between subfamilies [38]. The Ca_v1 subfamily of Ca channels conducts L-type Ca currents that initiate excitation–contraction coupling in muscle cells and secretion in endocrine cells, control gene transcription and regulate many enzymes. The Ca_v2 subfamily conducts N-, P/Q-, and R-type Ca^{2+} currents and are particularly concentrated in nerve terminals where a Ca^{2+} influx is required for release of chemical neurotransmitters (see Ch. 10). The Ca_v3 subfamily conducts T-type Ca currents that are activated at negative membrane potentials and are transient. These channels are important in repetitively firing cells, like the sinoatrial nodal cells that serve as pacemakers in the heart and the neurons in the thalamus that generate sleep rhythms. This division of Ca^{2+} channels is ancient – the worm *Caenorhabditis elegans* has a single member of each of these Ca^{2+} channel subfamilies. Evidently, specialization of Ca^{2+} signaling is crucial for even simple nervous systems.

There are many families of K^+ channels. K^+ channels have many different roles in cells. For example, in neurons they terminate the action potential by repolarizing cells, set the resting membrane potential by dominating the resting membrane conductance, determine the length and frequency of bursts of action potentials and respond to neurotransmitters by opening or closing and causing prolonged changes in membrane potential [5]. These channels are regulated by a combination of voltage, G proteins and intracellular second messengers. Many K^+ channels are gated primarily by voltage (K_v, Table 6-2). They can be divided into 12 subfamilies based on their amino acid sequence relationships [38]. In neurons, all the K_v channels are primarily involved in repolarizing the membrane to terminate action potentials.

In addition to the K_v family, the inward rectifier family, K_{ir} (Table 6-2), comprises seven subfamilies of channels [19, 38] that are primarily involved in setting the resting membrane potential. The $K_{ir}3$ subfamily is strikingly activated by G protein βγ subunits released by activation of G-protein-coupled receptors (see Ch. 19). This has an important regulatory influence on the resting membrane potential in many neurons. The $K_{ir}6$ subfamily forms a complex with a large nucleotide binding protein (the sulfonylurea receptor, SUR) to form ATP-gated K^+ channels that couple changes in intracellular ATP and ADP to changes in the resting membrane potential.

TABLE 6-2 The voltage-gated ion channel protein superfamily

Channel family	Symbol	No. in human genome	Primary activators	Primary physiological roles in neurons
Voltage-gated Na^+ channel	Na_v	10	Depolarization	Initiate action potentials
Voltage-gated Ca^{2+} channel	Ca_v	10	Depolarization	Couple depolarization to Ca^{2+} entry; repetitive firing
Voltage-gated K^+ channel	K_v	40	Depolarization	Repolarization
Inwardly rectifying K^+ channels	K_{ir}	15	G protein βγ-subunits, ATP	Set and regulate resting membrane potential
Two-pore K^+ channels	K_{2P}	15	Constitutively open	Set resting membrane potential
Calcium-activated K^+ channel	K_{Ca}	8	Depolarization and Ca^{2+}	Repolarization; regulation of repetitive firing
Cyclic nucleotide-gated channels	CNG	6	Cyclic AMP and cyclic GMP	Visual and olfactory sensory transduction
Hyperpolarization and cyclic nucleotide-gated channels	HCN	4	Hyperpolarization; cyclic AMP and cyclic GMP	Regulation of firing rate and pattern; regulation of pacemaking
Transient receptor potential channels	TRP	32	Lipid messengers; heat and cold	Ca^{2+} homeostasis, thermal and pain sensation

A third type of K^+ channel, K_{2P}, has a structure similar to two fused K_{ir} subunits, and only two subunits are required to form a pore (Table 6-2) [39, 40]. These channels are often called leak channels or open rectifiers because they are continuously open. Like the K_{ir} channels they are important in setting the resting membrane potential. Their activity is often regulated by kinases.

More ion channels are related to the Na_v, Ca_v and K_v families. Remarkably, evolution has created an even more diverse array of ion channels based on variations of the structure of voltage-gated K^+ channels (Fig. 6-7B) [38]. Ca^{2+}-activated K^+ channels (K_{Ca}) have a core, six-transmembrane-segment architecture similar to K_v channels, and they also contain regions in their C-terminal domain that can bind Ca^{2+} itself or the ubiquitous regulatory protein calmodulin. Binding of Ca^{2+} or Ca^{2+}/calmodulin to the C-terminal domain acts synergistically with membrane depolarization to activate the channel. These channels couple changes in intracellular Ca^{2+} concentration to repolarization of the membrane potential.

Cyclic nucleotide-modulated ion channels (Table 6-2) are not K^+-selective. Nevertheless, their inward current of Na^+ and Ca^{2+} ions is conducted through a channel that is similar in overall architecture to *Shaker* K^+ channels. This protein family includes the CNG channels, which respond only to cyclic nucleotides, and the HCN channels, which are activated synergistically by hyperpolarization and cyclic nucleotide binding [38, 40]. The CNG channels are involved in signaling of visual and olfactory information and serve as cyclic nucleotide-gated Ca^{2+} channels. In contrast, the HCN channels are required for normal rhythmic electrical discharges by the sinoatrial node in the heart and the pacemaker cells of the thalamus.

There is also a large family of transient receptor potential (TRP) channels [38, 41] (Table 6-2). These channels, first discovered as the target of a mutation in the *Drosophila* eye, also resemble K_v channels in architecture. However, they are nonselective in most cases, allowing both Na^+ and Ca^{2+} to enter cells when they are active, and they are not strongly affected by membrane potential, even though they have an S4 segment with some positive charges. The activity of this diverse group of channels is regulated in numerous ways, including by lipid messengers, protons and temperature. These channels conduct Ca^{2+} into cells in response to activation of G-protein-coupled receptors, initiate physiological responses to heat and cold, and may serve as mechanosensory channels under some circumstances. It is likely that we have much more to learn about the physiological roles of this interesting family of ion channels

There are many other kinds of ion channels with different structural backbones and topologies. The channels used in the action potential contrast with those generating slow potentials at synapses and sensory receptors by having strongly voltage-dependent gating. The other channels have gates controlled by chemical transmitters, intracellular messengers or other energies such as mechanical deformations in touch and hearing. In general, less is known about these channels than about Na^+, Ca^{2+} and K^+ channels of action potentials, with the exception of the nicotinic acetylcholine receptor channel of the neuromuscular junction (see Ch. 10). The ionic selectivity of these channels includes a very broad, monovalent anion permeability at inhibitory synapses, a cation permeability (about equal for Na^+ and K^+) at excitatory synapses at the neuromuscular junction and at many sensory transducers, and other more selective K^+ and Na^+ permeabilities in other synapses. The acetylcholine receptors of the neuromuscular junction and brain, the excitatory glutamate receptors and the inhibitory GABA and glycine receptors all have been solubilized and chemically purified, and the amino-acid sequences of their subunits have been determined by methods of molecular genetics (see Ch. 10). The structural features that are responsible for the function of these ligand-gated channels are being elucidated rapidly.

Recent research shows there is a great diversity of ion channels playing a great diversity of roles in cells throughout the body. We know now that hundreds of genes code for structural components of channels. Beyond their functions in the nervous system, channel activity in endocrine cells regulates the episodes of secretion of insulin from the pancreas and epinephrine from the adrenal gland. Channels initiate and regulate muscle contraction and cell motility. Channels form part of the regulated pathway for the ion movements underlying absorption and secretion of electrolytes by epithelia. Channels also participate in cellular signaling pathways in many other electrically inexcitable cells. Thus while they are especially prominent in the function of the nervous system, ion channels are actually a basic and ancient component of all cellular life, even bacteria [5].

CELL ADHESION MOLECULES IN MYELINATION 118

SUMMARY 120

OVERVIEW

Cell adhesion molecules (CAMs) play critical roles in all facets of nervous system development and maintenance. Important phenomena in which CAMs are involved include initial formation of the neural tube and the neural crest, migration of all neurons and glial cells, axonal outgrowth and guidance, target selection, synaptic stabilization and plasticity, myelination and nerve regeneration after injury (see Chs 4, 24, 28–30 and 53). Adhesion molecules interact with each other and with nonadhesive cell-surface and/or cytoplasmic molecules, and, in the two most extreme situations, may produce diametrically opposite results. For example, under certain circumstances, adhesion can vigorously encourage movement or growth along a preferred pathway, or, in contrast, it can completely immobilize a cell or membrane and prevent further movement or growth. How can membrane adhesion molecules mediate these very different effects? The answer to this question is not straightforward but, to reduce the answer to simple terms, a number of factors sum to yield the net effect of all adhesive forces acting on cell surfaces. There are always many adhesion molecules expressed at the same time on a given cell surface but in different concentrations. Furthermore, each adhesion molecule subtype is unique in terms of adhesive preference and adhesive strength. An additional complication is that, in some cases, an individual adhesion molecule may display more than one binding site, with each site specific for a different peptide ligand protruding from an opposing cell surface or membrane. Also, the post-translational addition of certain charged carbohydrate moieties, for example sialic acid, to adhesion proteins may interfere with the adhesive properties of the polypeptide. The post-translationally modified protein is rendered nonadhesive through charge repulsion and may actually repel abutting membrane surfaces. The reality in many systems is that the net result of all adhesion molecule interactions on the cell surface at a given time yields an averaged effect.

Cell adhesion molecules comprise several 'families'. These families are defined by individual members, which are related to each other by common primary sequences, structural motifs and binding properties (e.g. Fig. 7-1). In spite of differences in the biochemistry and function of each CAM, we can make certain generalizations about how they function in nervous tissue. First, CAMs act at

the cell surface, where they interact with either identical molecules, termed *homophilic interaction,* or different molecules, termed *heterophilic interaction*, expressed on an opposing cell surface or in the extracellular matrix (ECM). Second, adhesion has consequences for the cells involved, usually by virtue of adhesion molecule interactions with the underlying cytoskeleton [1]. Third, adhesive events between cells vary in strength, 'strong' vs. 'weak' adhesion, and the strength of adhesion is influenced by a wide range of factors. For example, the sum of all adhesive forces acting on a growing neurite is likely to be weaker than that of all the forces causing permanent adherence of pre- and postsynaptic membranes. Fourth, intercellular adhesion may be modulated, depending on the situation (Fig. 7-2). Last, because the nervous system is not a homogeneous organ, it is important to consider when and where each CAM is expressed. In other words, the temporal and spatial expression patterns of CAMs sharply focus and limit their interactions.

The three major groups of CAMs found in the nervous system are the members of the immunoglobulin (Ig) gene superfamily (IgCAMs, **Figs 7-1, 7-2**), the integrins (Fig. 7-3) and the cadherins (Fig. 7-4). Another family of carbohydrate-binding CAMs, the selectins, is important in other tissues, particularly in the immune system [2]. However, the selectins seem not to be expressed by neurons or glia. To date, these proteins have been detected only in the nervous system when expressed by invading immune cells in pathological states. The cadherins and IgCAMs engage exclusively in cell–cell or membrane–membrane interactions, while integrins, for the most part, interact with components of the ECM. Integrins appear to be more important in the PNS than the CNS, but play a critical role in early axonal growth in both CNS and PNS [3, 4]. In adult CNS, ECM is less well developed; this might explain the low profile integrins have in the mature CNS. However, it should be noted that within the CNS, integrins do operate to maintain the integrity of the cerebrovascular system, and when the functions of these adhesion molecules are compromised, severe cerebral hemorrhage is the result [5].

Within each of these adhesion molecule families, membership has been defined largely by amino-acid sequence similarity, which is reflected in common structural features. Consequently, distinct binding requirements also characterize each family. For example, cadherins interact in a Ca^{2+}-dependent, usually homophilic manner. Binding of the members of the Ig family is Ca^{2+}-independent and, although frequently homophilic, can be heterophilic. Integrin binding is also divalent cation-dependent (Ca^{2+}, Mg^{2+}) but always heterophilic.

Another, but less well defined, class of molecules, some of whose members mediate adhesion interaction, is the four-transmembrane domain family, which shares similar hydropathy plots and may have similar dispositions with respect to the phospholipid bilayer, for example the myelin proteolipid proteins, the connexins of gap junctions, the ryanodine receptor and others.

THE IMMUNOGLOBULIN GENE SUPERFAMILY

The best studied group of recognition/adhesion molecules expressed in the nervous system is that of the IgCAMs (Fig. 7-1), which are defined by regions that have sequence similarity with Igs, termed the Ig domains [6, 7]. Ig domains contain alternating hydrophobic and hydrophilic stretches of residues, which form a series of antiparallel β strands. The β strands come together to form two β sheets. The folding of the β sheets is, in most cases, stabilized by the formation of a disulfide bond between the sheets. There are three subclasses of Ig-like domains, which are defined by their similarity to variable (V) or constant (C) regions of Igs. For V-like domains, there are 70–110 amino acids spanning the two cysteines that form the disulfide bond, allowing formation of seven to nine β strands. C-like domains have about 50 amino acids spanning the stabilizing cysteines and, consequently, carry seven β sheets. The third class of Ig-like domains is termed a C2 domain. This class of IgCAM has the β strand distribution of a C-like domain but bears more sequence similarity to V-like domains.

The formation of immunoglobulin-like domains may confer characteristics important for extracellular presentation and interaction with other molecules. First, because of the folding pattern, Ig domains are stabilized by both inward-pointing hydrophobic amino acids and the intersheet disulfide bond, making them relatively resistant to proteolysis and, hence, ideal molecules to present to the external cellular environment. Second, the folding of the β strands provides a good platform for the presentation of amino acids, carried in the loops between the strands, for interaction with an opposing molecule. The loops between β strands, in antibodies, carry the antigen-recognition sites and, in Ig-like domains, contain the regions of greatest variability, allowing for distinct and specific interactions.

Members of this family of molecules may have only one Ig-like domain, as is the case for the myelin protein P_0, or, as for most of the family, have many Ig domains. In addition to the subclassification of Ig domains into V-, C- and C2-like domains, Ig family members can be broadly divided into three general classes [8]: (a) those that have only Ig-like domains; (b) those that have Ig domains and additional domains that resemble regions of the ECM component fibronectin, termed FN-like domains; and (c) those that have Ig domains and motifs other than FN-like domains. Moreover, any one Ig family member may have many isoforms, which may differ in the length of the cytoplasmic domain, in their post-translational modifications and whether they are membrane-spanning or glycosylphosphatidylinositol (GPI)-anchored proteins (see Box 3-1). Also, additional amino acid sequences inserted in the extracellular domain may distinguish isoforms of a particular IgCAM. While it is not known how the majority

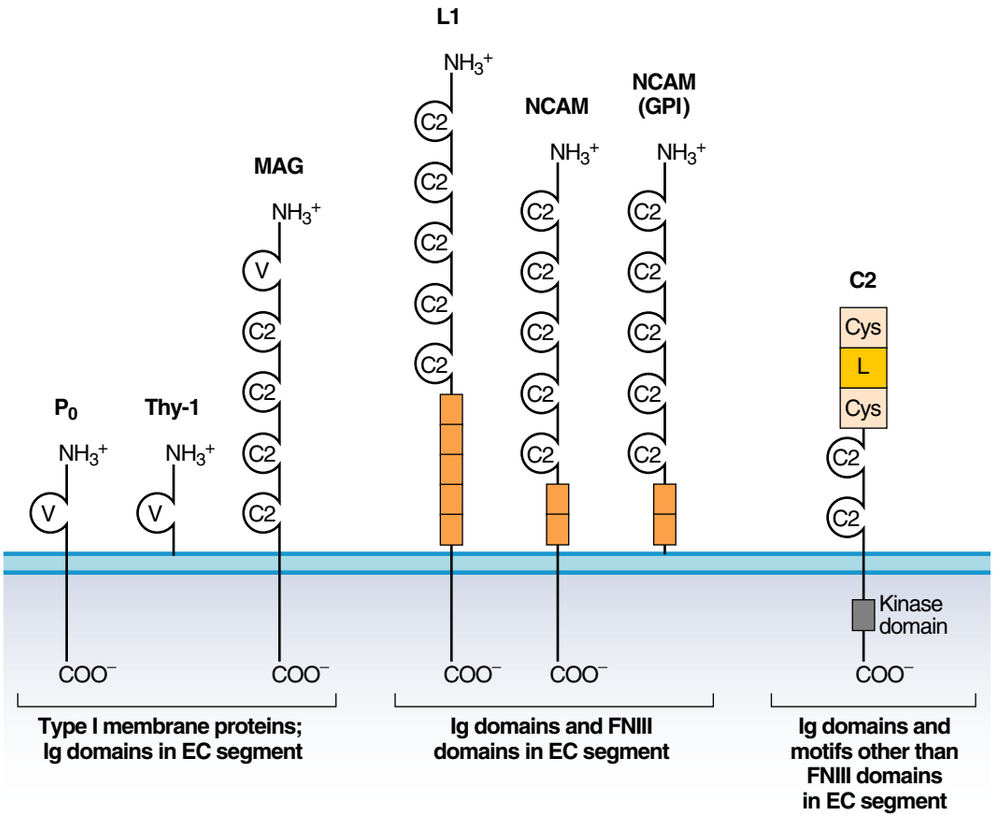

FIGURE 7-1 The immunoglobulin (Ig) gene family of molecules. Several varieties of Ig domain-containing molecules are contained within the Ig gene superfamily. Most are type I membrane proteins; some have only Ig domains or other moieties that may convey function (see text). *V*, variable Ig domain; *C*, constant Ig domain; *MAG*, myelin-associated glycoprotein; *NCAM*, neural cell adhesion molecule; *GPI*, glycosylphosphatidyl-inositol; *EC*, extracellular domain; *FN*, fibronectin.

of different isoforms of a particular IgCAM affect its functioning, differences in effect have been described for molecules that carry some of the isoform-distinguishing amino acid sequences in the extracellular domain of the neural cell adhesion molecule (NCAM). For example, a sequence of ten amino acids, termed the variable alternative spliced exon (VASE) sequence, in the fourth Ig domain of some isoforms of NCAM alters the response of axonal growth to this adhesion molecule; NCAM proteins with the VASE sequence are much less effective at promoting axonal growth than are NCAM proteins without this sequence. However, a puzzling question is: How do IgCAMs that have identical extracellular domains but are either GPI-linked or membrane-spanning, differ in function? Similarly, how differences in the cytoplasmic domain affect function is still not known. Presumably, the cytoplasmic domains interact with signal-transduction cascades and cytoskeletal proteins and in this way transduce adhesion into an intracellular response.

The siglecs constitute a novel subfamily of immunoglobulin-like molecules that bind to sialosides. These molecules, previously termed sialoadhesins, share considerable sequence similarity among the first four amino-terminal Ig domains [8, 9]. More importantly, all members of this subfamily bind to sialoglycoconjugates. To date, only two siglecs have been identified in the nervous system: the myelin-associated glycoprotein (MAG) (see Ch. 4) and the Schwann cell myelin protein (SMP). All other family members are specific to the immune system. An additional common feature of this IgCAM subfamily is that they bind sialic acid with relatively low affinity. Because of this, it is suggested that siglecs must be clustered within the membrane and that the molecule(s) with which siglecs interact must either be clustered or carry multimeric sialic acid residues to be effective. It should be noted, however, that, although both MAG and SMP have been shown to be sialic acid-binding proteins, the identity of a possible sialoglycoconjugate(s) with which they interact and the functional relevance of such an interaction have yet to be described.

Immunoglobulin-like cell adhesion molecules signal to the cytoplasm. In some instances, adhesion may act primarily to bind membranes to surfaces but it now seems clear that some IgCAMs act via the cytoplasmic domain after engaging with a cognate partner molecule to initiate a signal-transduction cascade as a direct consequence of an adhesive interaction. A good example of this is the Trk receptors, which have two Ig domains in their

extracellular sequences, or the fibroblast growth factor (FGF) receptor with four Ig-like domains, which first bind a neurotrophin, such as nerve growth factor (NGF), brain-derived growth factor (BDNF), neurotrophin 3 (NT3) or FGF (Ch. 27), after which signal transduction is triggered by dimerization and autophosphorylation of the cytoplasmic domains by endogenous tyrosine kinases (see Ch. 24). In contrast, in molecules such as NCAM and L1, which have multiple Ig domains, and P_0, which has a single Ig domain, all of which are known to interact homophilically, there is no obvious mechanism whereby a signaling cascade could be initiated after interaction. None of these proteins carries endogenous tyrosine kinase activity or any motifs that might indicate an interaction with G proteins. A novel mechanism for signaling [10, 11] has been suggested for NCAM, L1 and N-cadherin (see below) in that these molecules are believed, in certain circumstances, to cluster with the FGF receptor and induce autophosphorylation of that receptor in the absence of its usual ligand, FGF (Fig. 7-2). Each of these molecules has been implicated in neurite outgrowth [10–13]. In contrast, the myelin P_0 protein, although it has been suggested [14] to cluster within its membrane and interact, initially, with the cytoskeleton, is unlikely to initiate a signal-transduction cascade. The primary, if not the only, role of P_0 is to hold the myelin membranes in a tightly compacted state (Ch. 4).

THE CADHERIN FAMILY

The cadherins (Fig. 7-4) are a superfamily of adhesion molecules that function in cell recognition [15, 16], tissue morphogenesis and tumor suppression [17]. As a group, the cadherins are Ca^{2+}-dependent adhesion molecules and, within the group, the classic cadherins are the best studied. These include neural cadherin (N-cadherin), epithelial cadherin (E-cadherin), placental cadherin (P-cadherin) and retinal cadherin (R-cadherin). Although the classic cadherins were originally named for the tissue in which they were first found, their distributions are in no way limited to these tissues. Brain tissue expresses at least 20 [18, 19], and possibly many more, individual cadherins, which are used in differential neurite outgrowth, cell–cell interactions and 'locking in' pre- and postsynaptic membranes at the synaptic junctional complex.

In general, the cadherins have a common primary structure in that they all contain an amino-terminal

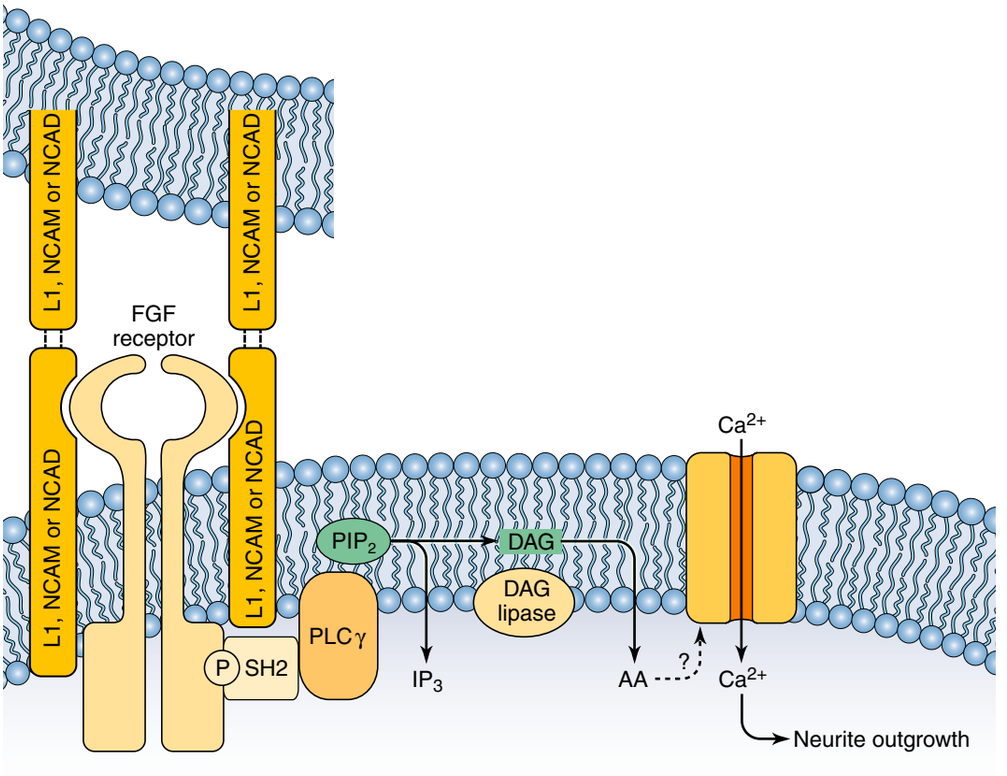

FIGURE 7-2 Signaling events in cell adhesion molecule (*CAM*)-stimulated neurite outgrowth. It has been postulated that a signaling cascade is stimulated by homophilic interactions of neural cell adhesion molecule (*NCAM*), N-cadherin (*NCAD*) or L1 adhesion molecule, which dimerizes the fibroblast growth factor (*FGF*) receptor and activates phospholipase C-γ (*PLCγ*) to generate diacylglycerol (*DAG*), conversion of DAG to arachidonic acid (*AA*) by a DAG lipase and an AA-induced increase in Ca^{2+} influx into the neurons via Ca^{2+} channels. *SH2*, src homology 2 domain; *PIP_2*, phosphatidyl-inositol 4,5-bisphosphate; *IP_3*, inositol (1,4,5)-trisphosphate.

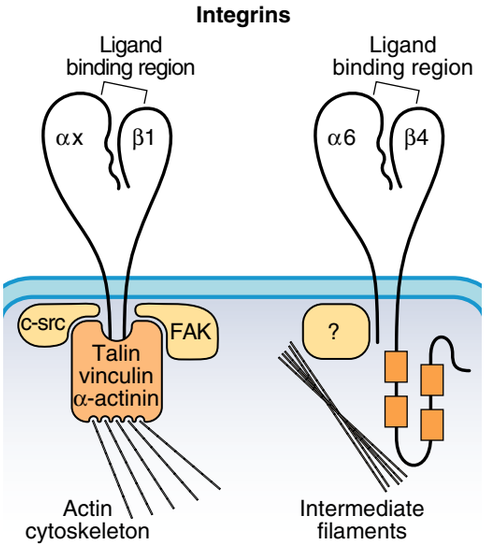

FIGURE 7-3 Integrins are heterodimers. Integrins consist of α and β subunits noncovalently linked, which interact via their cytoplasmic domains with a number of cytoplasmic proteins. The α*x*β1 integrin complex on the left binds to a complex which includes focal adhesion kinase (*FAK*). The α6β4 integrin complex contains fibronectin *(FN)* III repeats, which mediate binding to intermediate filaments.

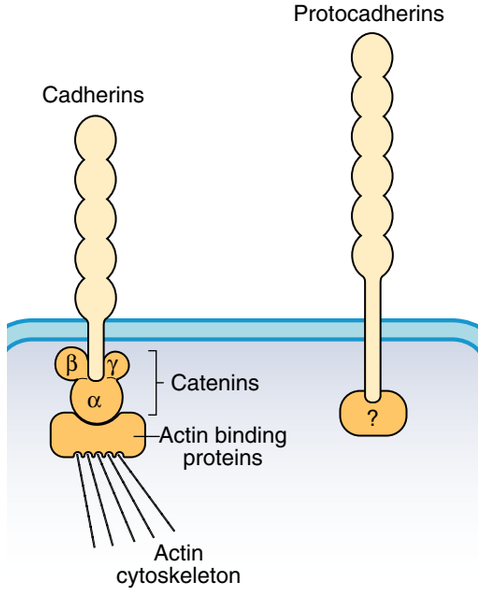

FIGURE 7-4 Basic cadherin structure. Two types of cadherin are present in the nervous system: the classic cadherins with five extracellular domains and the protocadherins with six extracellular domains. For the classic cadherins, the binding partners on the cytoplasmic side include the α, β and γ catenins. The binding partners for the protocadherins have not yet been identified.

extracellular domain, a single transmembrane domain and a conserved carboxyl-terminal cytoplasmic region, which is responsible for interactions with signaling pathways and with cytoplasmic and cytoskeletal proteins. The extracellular domain can be divided into five homologous regions, referred to as extracellular domains 1–5 (EC1–EC5). All of the extracellular domains are highly homologous to one another and, between the extracellular domains, Ca^{2+} articulates with binding sites and serves to rigidify the extracellular domain into a rod-like conformation.

The classic cadherins are homophilic adhesion molecules. That is, E-cadherin expressed on one cell surface binds to E-cadherin expressed on an apposed cell surface, N-cadherin binds to N, P to P and so forth. It was originally thought that all cadherins would behave completely homophilically but it is now clear that, for example, N-cadherin can bind to R-cadherin, although perhaps more weakly than it would to N-cadherin.

A recent crystal structure based model [20] for the structure of C-cadherin postulates that the five extracellular domains EC1–EC5 protrude from the cell surface as a curved rod. The structural analysis of C-cadherin reveals that the molecules facing each other across apposed cell surfaces are antiparallel to one another, forming a dimeric interaction termed a 'strand dimer' (Fig. 7-5). This forms the functional unit that is likely to mediate adhesion between cell surfaces. The structure from this recent paper allows the prediction of both *cis* and *trans* interfaces that together result in a lattice and not, as previously believed, an adhesion zipper. This new model allows for a mechanism by which adhesion 'plates' or puncta might be generated, such as are formed at CNS synapses [21, 22], adherens junctions and desmosomes [23], all cadherin based organelles.

The first cadherin to be expressed in the nervous system is N-cadherin. This molecule appears around the time the neural tube closes [24]. As the neural tube expands and develops, a variety of cadherins can be detected in cell bodies, outgrowing neurites and synaptic endings [25]. Many adhesion/recognition molecules have been implicated in guiding axons to their appropriate targets. Once the target axon has arrived in the vicinity of its ultimate destination, it has been suggested [26, 27] that expression of identical cadherin molecules on both pre- and postsynaptic membranes ultimately links up and locks in these membranes to the synaptic junctional complex. According to this proposed mechanism, neurons in the brain would utilize the same mechanisms to produce pre- and postsynaptic membrane adhesion as do other cells in forming junctions, such as the cadherin-based mechanisms of the epithelial adherens junction. In the brain, neural transmitter release mechanisms, neurotransmitter receptors, second-messenger systems and other uniquely synaptic elements are superimposed on this adhesive scaffold.

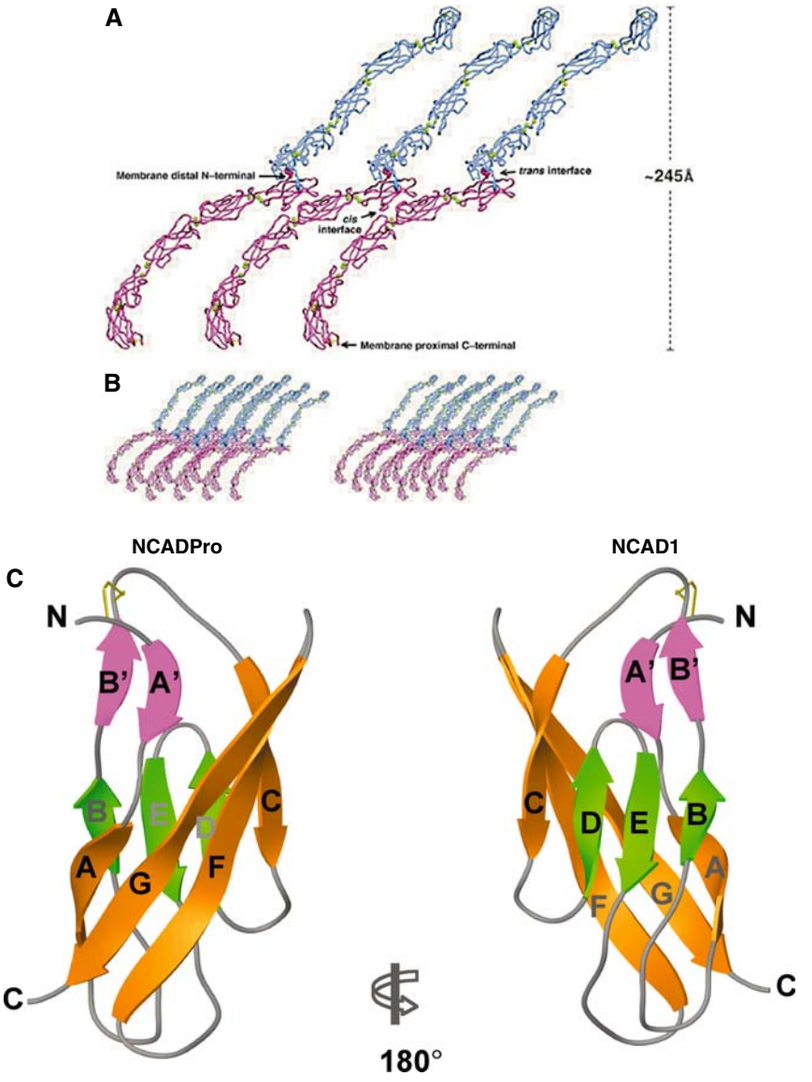

FIGURE 7-5 Cadherin structure. (**A**) Cadherin extracellular domains are illustrated as if protruding from two conjoined cell surfaces (a *pink* and a *blue* surface). The *green* dots are calcium ions. The *cis* and *trans* interfaces together determine the lattice. (**B**) Stereo view of the three-dimensional cadherin lattice. (**A** and **B** from reference [18].) (**C**) This is a ribbon diagram of a representative low-energy NMR structure of NPro (residues 31–124). β strands of the three sheets are depicted as *magenta*, *green* and *orange* arrows and the disulfide bridge between Cys32 and Cys63 is depicted in *yellow*. Loop regions are shown in *gray* and N- and C-termini are indicated.

These complex elements expand the function of this 'neural adherens junction'.

CELL ADHESION MOLECULES AND AXONAL OUTGROWTH

Cell adhesion molecules influence axonal outgrowth. During development, axons extend from the neuronal cell body and grow, frequently over long distances, in order to make very precise connections with a target. Despite the complexity of the nervous system, where over 10^{12} axons must find their targets, the pattern of axonal outgrowth for any one axon is highly reproducible from one individual to another. The flattened tip of a growing axon is called the growth cone, which resembles the palm of the hand, with processes extending from it like fingers (see Chs 8 and 25). It is the growth cone that responds to the environment and determines what direction the growing axon will take. Environmental cues that the growth cone encounters can be either fixed or diffusible, and it is the integration of these signals that determines the final direction. The majority of fixed signals are CAMs, expressed by glia, other cells or older axons that have already traversed that particular pathway. In addition, growth cones use integrins to select a pathway of ECM molecules on which to extend processes.

This has been demonstrated from both tissue culture studies and studies *in vivo* [28–30]. In culture, members of all three families of adhesion molecules found in the nervous system have been shown to promote axonal growth. This was carried out by transfecting the cDNA for the molecule to be tested in a cell line that does not normally express it, usually a fibroblast cell line. Isolated neurons are then grown on a monolayer of the CAM-expressing cells, and neurite length is compared to that obtained by contact with cells not expressing the adhesion molecule. Experiments like these have shown that CAMs, including the cadherins, the integrins and members of the Ig family, in particular NCAM and L1, are very potent promoters of axonal growth from a variety of primary neurons. The same neuron has been shown to respond to different CAMs, indicating that there is not any one unique 'CAM cue' for a particular neuron. Instead, it is likely that a variety of CAMs contribute to the effect on axonal growth. As well as being able to promote axonal growth when fixed in the ECM, some CAMs, such as L1, have been shown to promote axonal growth when added in a soluble form to neurons in culture. This strengthens the suggestion that CAMs are not just 'sticky' molecules but can exert their effects by activation of a signal-transduction pathway. Indeed, a number of soluble forms of various CAMs, including L1, NCAM, MAG and cadherins, have been found in the extracellular milieu of living cells. It remains to be determined whether these soluble CAMs in fact influence axonal growth *in vivo.*

In addition to CAM-expressing fibroblasts, another more physiological cell substrate has been used to demonstrate the effects of CAMs on axonal growth in culture. When dorsal root ganglion neurons are grown on a monolayer of nonmyelinating Schwann cells, which are very permissive for growth *in vivo* when not synthesizing myelin proteins, there is robust axonal outgrowth. Only when a combination of antibodies against NCAM, L1, cadherins and integrins was added to the cultures was outgrowth significantly reduced. Together, these experiments indicate that axonal outgrowth at any one time can be influenced by several CAMs.

This concept is supported by observations *in vivo.* Knockout mice lacking NCAM expression are viable and display subtle abnormalities in the nervous system. These abnormalities include a reduction in the size of the olfactory bulb, which is attributed to a decrease in migration of the neuronal cells that form this structure. Possibly, the inability to migrate normally reflects an increase in cellular adhesiveness, due to the absence of the highly sialylated form of NCAM, which in the wild-type or normal animal tends to repel apposed membranes on which it is expressed. Also, a reduction in the density of mossy fibers in the hippocampus has been noted in the NCAM knockout mouse, revealing a defect in axonal growth. The subtle phenotype in these mice, relative to the dramatic effect of NCAM on axonal growth in culture, suggests that there may be a certain amount of redundancy in nervous tissue, whereby another CAM or combination of CAMs can in part compensate for the absence of NCAM.

Cell adhesion molecules are responsible for axonal fasciculation. Usually, when growing toward their target, axons fasciculate (Fig. 7-6) and grow in bundles. However, there are points along the pathway where axons must defasciculate and different axons must take different paths. Hence, in addition to promoting axonal outgrowth, CAMs can affect the direction an axon takes at key decision points along the way. One model that has been proposed for explaining how an axon is selected to remain fasciculated with respect to other axons or to separate from the bundle and grow alone is based on the relative adhesiveness of the substrate vs. the adhesiveness of other axons. This model was proposed based on observations of adhesion and axonal growth with two forms of NCAM: one form that carries the highly charged sialic acid and polysialic acid (PSA) and another form with very little or no PSA. It has been suggested that the high negative charge on PSA–NCAM renders it less adhesive than its unsialylated counterpart [31]. Because the negatively charged sialic acid moieties tend to sequester water, occupy a large volume in the extracellular space and strongly repel one another across the bilayer, they probably keep plasma membranes sufficiently far apart so as to prevent other adhesion molecules, such as L1 and the cadherins, from

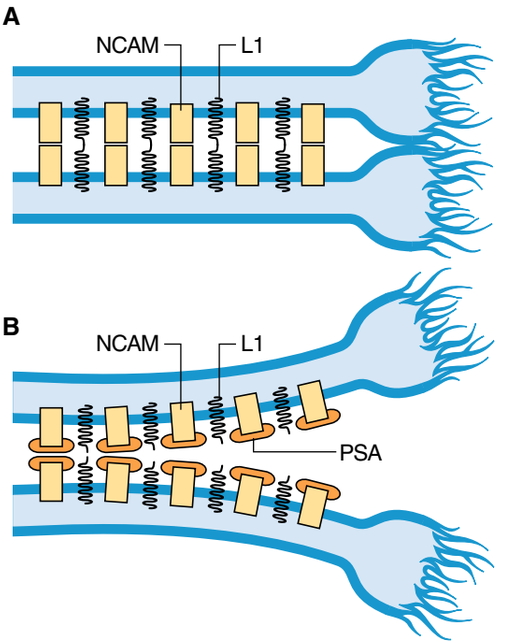

FIGURE 7-6 Neural cell adhesion molecule (*NCAM*) carries different levels of polysialic acid. (**A**) NCAM is depicted on a growing axon, without polysialic acid. Under these conditions, NCAM and L1 molecules interact homophilically and axons fasciculate. (**B**) NCAM carries polysialic acid (*PSA*), and NCAM and L1 molecules are far apart and cannot, therefore, interact. Growing axons do not fasciculate under these circumstances.

getting close enough to interact. Following from this, fasciculated axons, which adhere tightly to each other, express the adhesive form of NCAM that does not carry PSA. In contrast, the PSA form of NCAM is more effective than the unsialylated form at promoting axonal growth.

As stated above, the complexity and precision of connections within the nervous system would appear to require a very rigid set of rules or cues. The ubiquitous expression of individual CAMs throughout the nervous system and during development implies that they could not provide the specificity required for such a precise signal for individual neurons. However, the full repertoire of CAMs used *in vivo* for any single axon to reach its target has yet to be characterized. It is likely, as suggested from both *in vivo* and *in vitro* results, that many CAMs affect the growth of any one axon. In addition, as demonstrated by studies with different isoforms of NCAM, i.e. with and without the VASE sequence or with and without PSA, it is highly likely that subtle differences in isoform expression of any single CAM can have dramatic effects on axonal response. What has been determined regarding the role of adhesion molecules in axonal guidance during development to date is most probably an underestimate of their full involvement.

Cell adhesion molecules may also function in regeneration. As well as growing during development, axons grow and regenerate under certain conditions after injury [32]. Axonal regeneration is often successful in the PNS, where it may be accompanied by full restoration of function. In contrast, in the mammalian CNS, there is usually little or no regrowth and function is often lost. The main difference between axonal growth during development and during regeneration is in whether the damaged axon is allowed by the existing conditions to regrow, not whether it is able (Ch. 30). In the PNS, after injury, damaged tissue, consisting mostly of myelin debris, is cleared away by macrophages. Coincident with this event, Schwann cells downregulate the expression of the myelin-specific proteins and upregulate a number of growth-promoting adhesion molecules, including L1 and NCAM. These Schwann cells now resemble Schwann cells in the developing nervous system and are very permissive for axonal growth (Fig. 7-7). In contrast, myelin is not cleared from the CNS after injury and the myelin-forming cells in the CNS, oligodendrocytes, continue to express myelin proteins and do not upregulate any growth-promoting adhesion molecules. There is now substantial evidence to support the idea that the presence of myelin and the absence of growth-promoting molecules are two factors largely responsible for the lack of regeneration in the mammalian CNS [33]. Myelin membranes have been shown to be inhibitory for regeneration both *in vitro* and *in vivo*, and a number of myelin-specific molecules have been shown to be potent inhibitors of axonal growth. One of these is MAG, which is a member of the siglec subfamily. MAG can promote as well as inhibit axonal growth depending on the age and type of neuron. The ability of MAG to inhibit or promote regeneration when presented to the neuron either as a substrate or in a soluble form strongly suggests that MAG binds to a neuronal receptor and activates a signal-transduction mechanism in the neuron that effects changes in axonal growth [34, 35].

CELL ADHESION MOLECULES IN MYELINATION

Myelin is formed by the compaction of oligodendrocyte plasma membranes in the CNS or Schwann cell plasma membranes in the PNS as the plasma membrane spirals around the axon. For myelin to function efficiently, a tight apposition of these membranes must be maintained, which, when viewed by electron microscopy, displays a uniform and reproducible spacing between the layers (see Ch. 4). Given the close association of myelin membranes, it is not surprising that CAMs play major roles in the formation and maintenance of this plasma membrane organelle. There is strong evidence supporting a role for CAMs in the initiation of myelination, in the compaction of myelin membranes and in the stability of the noncompacted as well as the compact layers of myelin, the axon–myelin interface and the nodes of Ranvier.

The myelinating cell, when brought into contact with a large axon, begins to synthesize vast amounts of plasma membrane. The molecular trigger that starts this process is not yet known but the interaction of MAG with some axonal component has been suggested to play an important role. The next steps in myelin formation are membrane synthesis, axonal wrapping and compaction. While MAG in both the CNS and PNS is located at the axon–myelin interface and is therefore likely to play a role in membrane spiraling, different molecules are responsible for membrane compaction in the two systems. In PNS myelin, the most abundant protein is P_0, a small protein containing a single extracellular Ig domain [36] (see Ch. 4). The P_0 protein is responsible for adhesion at the apposition of extracellular surfaces, or intraperiod line, via homophilic interactions of its Ig domain and at the major dense line, where cytoplasmic surfaces come together via interactions of the highly negatively charged cytoplasmic domain of P_0 with the acidic lipids, mostly phosphatidylserine, of the opposing membrane. Therefore, P_0 protein can be regarded as a 'bifunctional' adhesion molecule. It is interesting that P_0 is an 'obligatory' adhesion molecule in that it induces strong cell–cell adhesion between any cells in which it is expressed [37–39].

In the CNS of mammals, two proteins are needed to accomplish the dual role of adhesion at both myelin bilayer surfaces that P_0 effects in the PNS. The four-transmembrane-domain proteolipid protein (PLP) is likely to be responsible for adhesion of the extracellular surfaces, while the very basic cytoplasmic myelin basic protein

(MBP) holds membranes together at the inner cytoplasmic surfaces in the CNS. Although MBP is also present in the PNS, it is much less abundant than in the CNS and its absence does not have a dramatic effect on PNS myelin compaction.

The importance of P_0 in PNS myelin has been clearly demonstrated. In P_0 gene knockout experiments in mice [40], severe hypomyelination and a virtual absence of compact myelin in the PNS is observed. In humans, there are two disease states associated with mutations in the P_0 gene: Charcot–Marie–Tooth type I disease (see Ch. 38) and Dejerine–Sottas disease, both dysmyelinating diseases that exhibit a spectrum of severity depending on the particular mutation.

The crystal structure of the extracellular domain of P_0 has also been determined [41]. The arrangement of molecules in the crystal indicates that P_0 may exist on the membrane surface as a tetramer (Fig. 7-7) that can link to other tetramers from the opposing membrane to form an adhesive lattice, like a 'molecular Velcro'. The structure also suggests that P_0 mediates adhesion through the direct interaction of apically directed tryptophan side chains with the opposing membrane [42], in addition to homophilic protein–protein interaction.

Functional myelin not only depends on compact myelin in the internodes but also requires maintenance of a stable structure in the membranes adjacent to the nodes of Ranvier, termed the paranodes, which are sinuous, open cytoplasmic channels that are continuous with each other throughout the myelin sheath. In the plasma membrane subdomains that surround these channels, a number of adhesion molecules have been localized, namely MAG, certain integrins [43] and cadherins. The paranodal loops interact across their extracellular surfaces and it is clear that certain cadherins at least participate in holding them firmly in place against each other [44]. In particular, E-cadherin is expressed by Schwann cells and is localized to these cytoplasmic compartments. This cadherin is not present in the underlying axon. Thus, in peripheral nerve, E-cadherin is unusual in that it does not mediate adhesion between two cells but instead mediates adhesion between two regions of a single plasma membrane elaborated by a single Schwann cell.

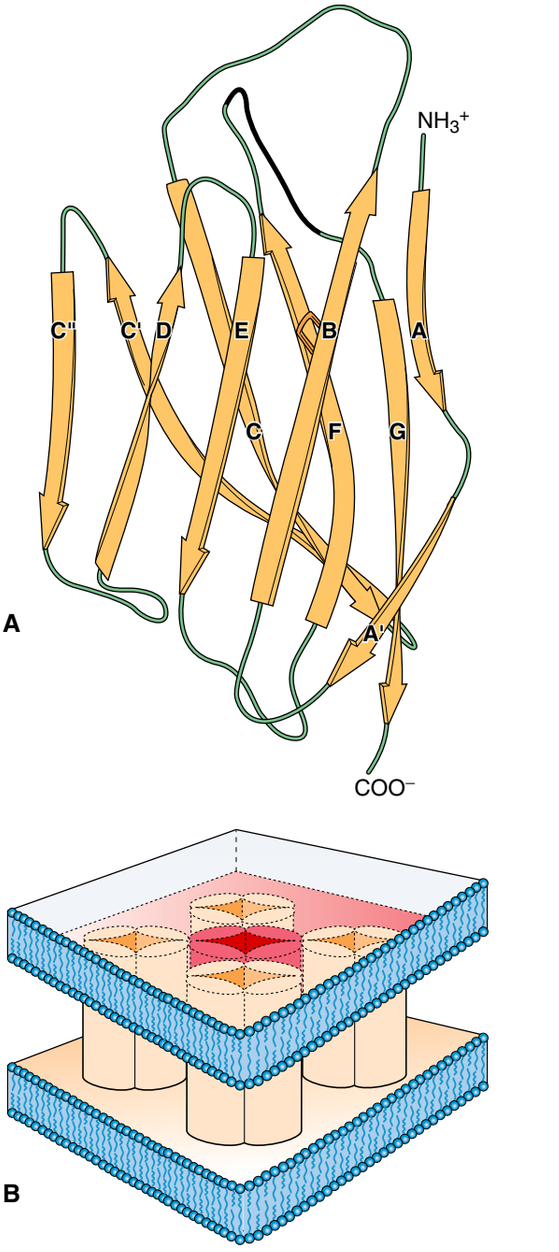

FIGURE 7-7 Structure of the P_0 glycoprotein protomer. (**A**) In this ribbon diagram of the extracellular domain of P_0, each β strand is labeled with a letter and two antiparallel β sheets are formed. The disulfide bridge is indicated in *dark orange* and a hypothetical path for disordered amino acids 103–106 is shown in *black* in the FG loop. (**B**) Lattice formation by P_0. A view of the intraperiod line, or extracellular apposition, of myelin in the PNS. The *orange* tetramer sets emanate from one bilayer and the *blue* tetramer interacts with all four of them. This is a view perpendicular to the plane of the myelin membrane.

SUMMARY

Adhesion molecules are indispensable components of nervous tissue. They adhere cell membranes to each other with varying degrees of strength and 'translate' adhesion into cellular responses via signal-transduction pathways (see, for example, [45]). The major classes of adhesion molecules, the integrins, IgCAMs and cadherins, act cooperatively [46] and in concert to coordinate brain development and maturation and, in adulthood, to maintain the normal tissue architecture.

MOLECULAR COMPONENTS OF THE NEURONAL CYTOSKELETON 124

The cytoskeleton is one of several biological elements that define eukaryotic cells 124

Microtubules act as both dynamic structural elements and tracks for organelle traffic 124

Neuronal and glial intermediate filaments provide support for neuronal and glial morphologies 127

Actin microfilaments and the membrane cytoskeleton play critical roles in neuronal growth and secretion 129

ULTRASTRUCTURE AND MOLECULAR ORGANIZATION OF NEURONS AND GLIA 131

A dynamic neuronal cytoskeleton provides for specialized functions in different regions of the neuron 131

Both the composition and organization of cytoskeletal elements in axons and dendrites become specialized early in differentiation 131

CYTOSKELETAL STRUCTURES IN THE NEURON HAVE COMPLEMENTARY DISTRIBUTIONS AND FUNCTIONS 132

Microfilament and microtubule dynamics underlie growth cone motility and function 132

The axonal cytoskeleton may be influenced by glia 133

Levels of cytoskeletal protein expression change after injury and during regeneration 134

Alterations in the cytoskeleton are frequent hallmarks of neuropathology 134

Phosphorylation of cytoskeletal proteins is involved both in normal function and in neuropathology 135

CONCLUSIONS 135

Neurons and glia exhibit a remarkable diversity of shapes. These different morphologies are so characteristic and distinctive that they have been used since the time of Cajal to define functional neural functions. For example, Purkinje cells in the cerebellum have such distinctive morphologies that they are readily identifiable in any vertebrate. Neurons do not divide, so their distinctive morphologies are maintained throughout life. Biochemical and immunological markers are used to delineate neuronal populations. Their distributions are found to correlate well with populations previously defined on morphological grounds. This evidence indicates that the shape of cells in the nervous system is closely connected to their functions. Understanding the proteins and cellular structures that underlie cell morphology is essential for understanding the neural functions.

Proteins of the cytoskeleton play a central role in the creation and maintenance of cell shapes in all tissues. They serve multiple roles in eukaryotic cells. First, they provide structural organization for the cell interior, helping to establish metabolic compartments. Second, cytoskeletal structures serve as tracks for intracellular transport, which creates and maintains differentiated cellular functions. Finally, the cytoskeleton comprises the core framework of cellular morphologies.

Methods for visualizing individual neurons and glia *in vivo* have depended for more than 100 years on histochemical reactions with cytoskeletal elements and even now these methods have not been surpassed. Because cytoskeletal structures play a particularly prominent role in the nervous system, cytoskeletal proteins represent a large fraction of total brain protein, comprising perhaps a third or more of the total. In fact, much of our knowledge about cytoskeletal biochemistry is based on studies of proteins purified from brain. The aims of this chapter are twofold: first to provide an introduction to the cytoskeletal elements themselves and second to examine their role in neuronal function. Throughout, the emphasis will be on the cytoskeleton as a vital, dynamic component of the nervous system.

MOLECULAR COMPONENTS OF THE NEURONAL CYTOSKELETON

The cytoskeleton is one of several biological elements that define eukaryotic cells (others include the nucleus and mitochondria). The term 'cytoskeleton' is often used as if it described a single, unified structure, but the cytoskeleton of neurons and other eukaryotic cells comprises three distinct, interacting structural complexes that have very different properties: microtubules (MTs), neurofilaments (NFs) and microfilaments (MFs). Each has a characteristic composition, structure and organization that may be further specialized in a particular cell type or subcellular domain. The defining structural elements have long been identifiable in electron micrographs (Fig. 8-1), and a considerable amount is known about the detailed organization of these components in neurons and glia. Each set of cytoskeletal structures will be considered in turn.

Microtubules act as both dynamic structural elements and tracks for organelle traffic. Neuronal MTs are structurally similar to those found in other eukaryotic cells (reviewed in [1]). The core structure is a polymer of 50 kDa tubulin subunits. Heterodimers of α- and β-tubulin align end-to-end to form protofilaments, 13 of which join laterally to form a hollow tube with an outer diameter of 25 nm (Fig. 8-2). Examples also exist of MTs with 12 and 14 protofilaments. The α- and β-tubulins are the best-known members of a unique protein family that have significant sequence similarity [2]. There is approximately 40% sequence identity between α- and β-tubulins, and even greater identity within the α and β gene subfamilies [3]. Conservation of primary sequence for tubulins is also high across species so that tubulins from yeast can readily coassemble with tubulins from human brain. Tubulin dimers bind two GTPs and exhibit GTPase activity that is closely linked to assembly and disassembly of microtubules [1]. While many questions remain about tubulin and its interactions, the structure of

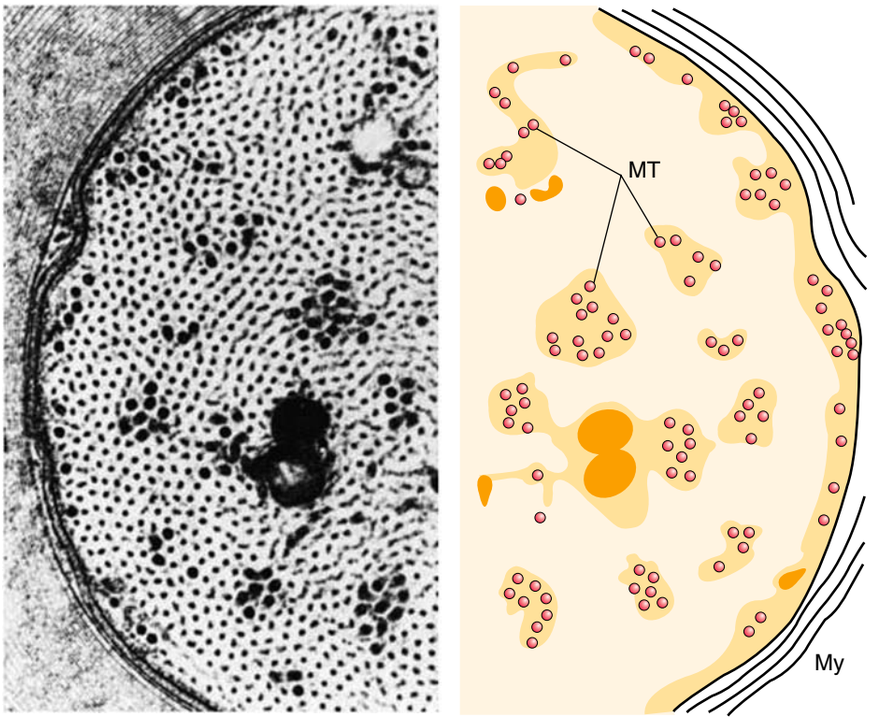

FIGURE 8-1 The cytoskeleton and organization of the axon in cross-section. **Left.** Electron micrograph of a myelinated toad axon in cross-section taken near a Schmidt–Lanterman cleft; axon diameter is slightly reduced and the different domains within the axoplasm are emphasized. **Right.** Diagram highlighting key features of the axoplasm. Portions of the myelin sheath surrounding the axon can be seen (*My*). Most of the axonal diameter is taken up by the neurofilaments (*clear area*). There is a minimum distance between neurofilaments and other cytoskeletal structures that is determined by the side arms of the neurofilaments. (These side arms are visible between some of the neurofilaments in the electron micrograph, **left.**) The microtubules (*MT*) tend to be found in bundles and are more irregularly spaced. They are surrounded by a fuzzy material that is also visible in the region just below the plasma membrane (*stippled areas*, **right**). These areas are thought to be enriched in actin microfilaments and presumably contain other slow component b (SCb) proteins as well. The *stippled regions* with embedded microtubules are also the location of membranous organelles in fast axonal transport (*larger, filled, irregular shapes*, **right**). Both microtubule and microfilament networks need to be intact for the efficient movement of organelles in fast transport. (Electron micrograph provided by Dr Alan Hodge. From Hodge, A. and Adelman, W. In: *Structure and Function in Excitable Cells*. New York: Plenum, 1983, pp. 75-111, with permission.)

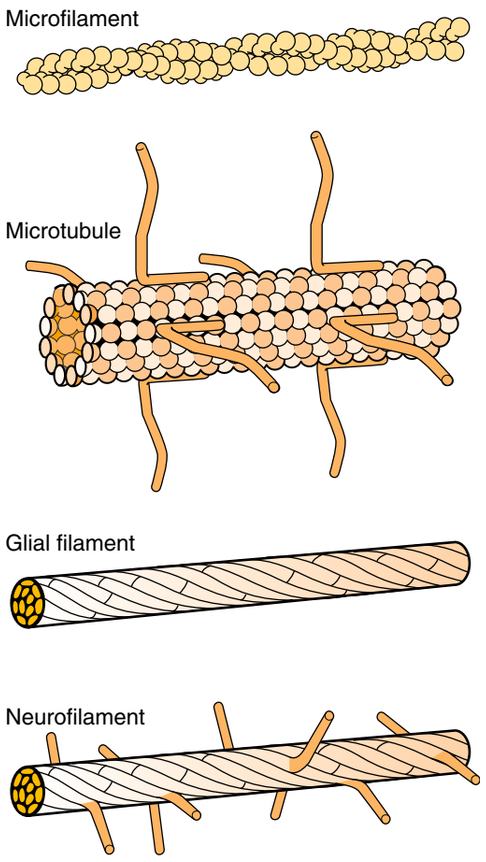

FIGURE 8-2 Microfilaments, microtubules and intermediate filaments in the nervous system. Each cytoskeletal structure has a distinctive ultrastructure. This schematic illustrates the major features of the core fibrils. The microfilament consists of two strands of actin subunits twisted around each other like strings of pearls. The individual subunits are asymmetrical, globular proteins that give the microfilament its polarity. The microtubule is also made from globular subunits, but in this case the basic building block is a heterodimer of α- and β-tubulins. These αβ dimers are organized into linear strands, or protofilaments, with β-tubulin subunits oriented toward the plus end of the microtubule. Protofilaments form sheets *in vitro* that roll up into a cylinder with 13 protofilaments forming the wall of the microtubule. Assembly of both microfilaments and microtubules is coupled to slow nucleotide hydrolysis, ATP for microfilaments and GTP for microtubules. The subunits of both glial filaments and neurofilaments are rod-shaped molecules that will self-assemble without nucleotides. The core filament structure is thought to be a ropelike arrangement of individual subunits. Glial filaments are typical type III intermediate filaments in that they form homopolymers without side arms. In contrast, neurofilaments are heteropolymers formed from three subunits, NFH, NFM and NFL for the high-, medium- and low-molecular-weight subunits. The NFH and NFM subunits have extended carboxy-terminal tails that project from the sides of the core filament and may be heavily phosphorylated.

the αβ-tubulin dimer has recently been derived from electron diffraction studies [4], providing a basis for dissection of MT functional architecture.

Heterodimers in a MT are oriented in the same direction, so the resulting MT has asymmetric ends that differ in their assembly properties [5]. The β-tubulin subunit is exposed at the 'plus' end, which is the preferred end for addition of tubulin dimers. The opposite 'minus' end grows more slowly at physiological concentrations of tubulin. In the case of free microtubules, the balance between assembly and disassembly at each end defines a critical concentration for net microtubule growth. MT assembly under *in vitro* conditions involves a slow nucleation step followed by a more rapid, net growth phase; a kinetic pattern described as dynamic instability. In glia and most other non-neuronal cells, however, the minus-ends of MTs are usually bound at the site of nucleation which is associated with the centrosome or pericentriolar complex of the cell [6], a site often called the microtubule-organizing center (MTOC) [7]. Anchoring of MT minus-ends helps establish and maintain the polarity of cellular MTs. Anchoring and nucleation of microtubules appears to require a third class of tubulin, γ-tubulin, which is detectable only as part of the pericentriolar complex [7, 8].

The organization of MTs in neurons differs several ways from that seen in non-neuronal cells (Fig. 8-3) [9]. Axonal and dendritic MTs are not continuous back to the cell body nor are they associated with any visible MTOC. Axonal MTs can be more than 100 μm long, but they have uniform polarity, with all plus-ends distal to the cell body. Dendritic MTs are typically shorter and often exhibit mixed polarity, with only about 50% oriented plus-end distal. Recent work suggests that MTs in both axons and dendrites are nucleated normally at the MTOC, but they are then released from the MTOC and delivered to neurites [10].

While MTs in neurons are composed of the same basic constituents as those in non-neuronal cells, they are strikingly more diverse (Table 8-1). Brain MTs contain tubulins of many different isotypes, with many different post-translational modifications, and also have a variety of associated proteins (MAPs) [11]. MT composition varies according to location, such as in axons or dendrites, suggesting that brain MTs exist in specialized forms to perform designated tasks in the unique environments of the neuron. For example, axonal MTs contain stable segments that are unusually resistant to treatments that depolymerize MTs in other cells [12]. Such stable domains are preserved as short MT segments and may serve to nucleate or organize MTs in axons [13], particularly during regeneration. This and other specializations of axonal microtubules (see below) may reflect the unusual requirements of the neuronal cytoskeleton, where remarkably long microtubules are maintained at considerable distances from sites of new protein synthesis in the cell body.

Multiple genes exist for both α- and β-tubulins. Tubulin isotypes differ primarily at the carboxy-terminus, the region where most post-translational modifications and MAP interactions occur. While most α- and β-tubulin isotypes are expressed in all tissues, some are expressed preferentially in different tissues. For example, class III and IVa β-tubulins are neuron-specific (reviewed in [3, 14]). It is not known if such examples of tissue-specific

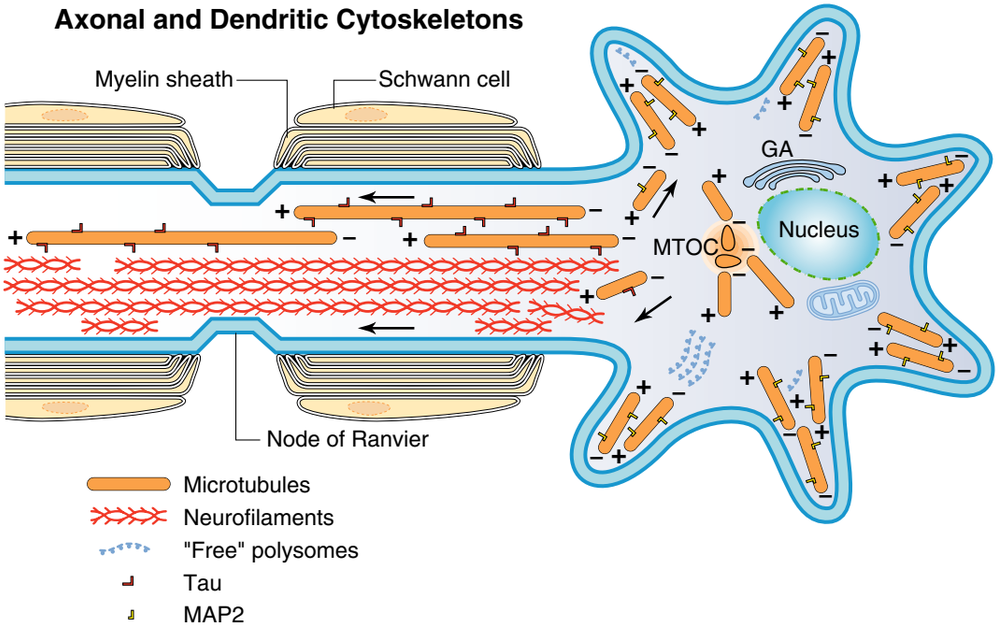

FIGURE 8-3 The axonal and dendritic cytoskeletons differ in both composition and organization. The major differences are illustrated diagrammatically in this diagram. With one exception, all cytoskeletal proteins are synthesized on free polysomes in the cell body, then transported to their different cellular compartments. The exception is MAP2, which is the major microtubule-associated protein of dendrites. While some MAP2 is synthesized in the cell body, MAP2 mRNA is specifically enriched in the dendritic compartment and a significant fraction is thought to be synthesized there. The microtubules of cell bodies, dendrites and axons are thought to be nucleated at the microtubule-organizing center (*MTOC*), then released and delivered to either the dendrites or axon. In the dendrite, microtubules often have mixed polarities with both plus and minus ends distal to the cell body. The functional consequence of this organization is uncertain but may help explain why dendrites taper with distance from the cell body. In contrast, all axonal microtubules are oriented with the plus end distal to the cell body and exhibit uniform distribution across the axon. Although some tau protein can be detected in cell bodies and dendrites, axonal microtubules are enriched in tau and axonal tau is differentially phosphorylated. MAP2 appears to be absent from the axon. Neurofilaments are largely excluded from the dendritic compartments but are abundant in large axons. The spacing of neurofilaments is sensitive to the level of phosphorylation. Microtubules and neurofilaments both stop and start in the axon rather than being continuous back to the cell body. The microfilaments are more dispersed in their organization and may be difficult to visualize in the mature neuron. They are most abundant near the plasma membrane but are also enriched in presynaptic terminals and dendritic spines. *GA*, Golgi apparatus.

TABLE 8-1 Major microtubule cytoskeletal proteins of the nervous system

Protein	Expression pattern and distribution	Modifications
α–tubulin (multigene family)	In all cells, but some isoforms are preferentially expressed in brain	Acetylation Tyrosination
β–tubulin (multigene family)	In all cells, but some isoforms are preferentially expressed in brain	Phosphorylation Polyglutamylation
γ-tubulin	In all cells, pericentriolar region/MTOC	
MAP1a	Appears late, preferentially in dendrites	Phosphorylation
MAP1b (multigene family)	Appears early then declines, enriched in axons	Phosphorylation
MAP2a	High molecular weight, dendritic in mature neurons	Phosphorylation
MAP2b	High molecular weight, dendritic expressed throughout lifetime	Phosphorylation
MAP2c (single gene)	Low molecular weight, dendritic in developing neurons	Phosphorylation
Tau – high MW – low MW (single gene)	Peripheral axons with distinctive phosphorylation pattern Enriched in CNS axons with distinctive phosphorylation pattern	Phosphorylation Phosphorylation
MAP4	Primarily nonneuronal, multiple forms, widespread distribution	Phosphorylation at mitosis
Katanin	Widespread distribution, enriched at MTOC, severs MT	
Stathmin	Widespread distribution, destabilizes MT	Phosphorylation

expression imply that different isotypes are structurally suited to function in different tissues, or merely that different tubulin genes are part of different tissue-specific developmental programs. Where it can be evaluated, all isotypes available in a given cell appear capable of coassembly and typically can be detected in all cellular MTs.

Brain MTs also contain a variety of post-translational modifications. When purified mammalian tubulin is analyzed by isoelectric focusing, over 20 different isoforms can be seen [3]. These are explained by a combination of multiple genes and various post-translational modifications. The two best-studied post-translational modifications of tubulin are α-tubulin detyrosination and acetylation (reviewed in [3]). Most α-tubulins are expressed with a carboxy-terminal tyrosine residue. This tyrosine can be removed by tubulin carboxypeptidase and then replaced by tubulin tyrosine ligase, in a rapid cycle that occurs on the majority of available tubulin. Since the carboxypeptidase acts only on assembled tubulin and the ligase acts on unassembled tubulin, this tyrosination/detyrosination cycle is linked to MT dynamics. Typically, newly assembled MTs will contain Tyr-tubulin. The longer a MT remains polymerized, the higher its content of de-Tyr-tubulin, or Glu-tubulin. A second prominent post-translational modification of neuronal α-tubulin is lysine-ε-acetylation. The enzyme responsible for acetylation, tubulin acetyltransferase, like tubulin carboxypeptidase, acts only on assembled tubulin. Neuronal β-tubulin isotypes appear to be subject to fewer post-translational modifications [3]. The β_{III} isotype of brain is phosphorylated, and while the function of this modification is not clear, correlations with neurite outgrowth in neuroblastoma cells have been made. Another modification of β–tubulin is polyglutamylation, the addition of 1–5 glutamyl units to the γ-carboxyl group of a glutamate residue near the C-terminus [15]. Despite the plethora of neuronal tubulin post-translational modifications, none are known to have a direct effect on MT properties although they correlate with specific states (i.e. assembly, microtubule age, etc.).

MTs *in vivo* invariably include members of a heterogeneous set of proteins known as microtubule-associated proteins [11, 16]. MAPs interact with MTs rather than with free tubulin and maintain constant stoichiometry with the tubulin in MTs through cycles of assembly and disassembly. Several categories of brain MAPs can be distinguished: the high-molecular-weight MAPs, which include MAPs 1A, 1B, 2A and 2B (>270 kDa); the tau proteins; MAPs of intermediate molecular weight, such as MAP3 and MAP4, and the molecular motor MAPs kinesin and dynein, which drive the intracellular transport of membrane-bounded organelles along MT tracts (see Ch. 28). The other groups of MAPs are collectively known as 'fibrous' or 'structural' MAPs because they have been observed to form lateral extensions between adjacent MTs and between MTs and other cytoskeletal elements [16]. Such extensions do not generally represent stable cross-links but rather reflect transient interactions that facilitate MT function. One exception is the formation of stably crosslinked axonemal microtubules of cilia and flagella; such as occur on ependymal cells in the CNS.

The high molar ratio of MAPs to tubulin in brain suggests that MAPs may play an important role in determining MT properties. Some MAPs are differentially distributed in neurons [11]. For example, MAP 2 is found primarily in cell bodies and dendrites, and tau is enriched in axons. Additionally, changes in MAP expression and MAP phosphorylation during development suggest they may play a role in modulating MT function in the developing brain [16]. For example, MAPs 1A and 1B occur in both axons and somatodendritic domains, but MAP 1B is preferentially phosphorylated in axons and especially in developing axons. As many as six different tau proteins may be derived by alternative splicing from a single tau gene [17]. Both the expression and phosphorylation of the different tau isoforms are regulated throughout development. While MAPs affect nucleation and stability of MTs *in vitro*, these may not be their primary functions *in vivo*. Other likely functions include roles in MT spacing and organization, compartmentation, scaffolds for signaling molecules and interaction with other cellular structures.

Recently, another class of MAPs has been identified that lead to depolymerization of MT, stathmin and katanin [11]. Stathmin destabilizes MT either by reducing available tubulin dimer or by altering the frequency of catastrophe at MT plus ends [18]. In contrast, katanin is an ATP-ase that severs MT [19]. In neurons, one important role of katanin is to release the MT from the MTOC and allow transport of the assembled MT into axons and dendrites.

MTs serve multiple roles in neurons. Besides acting as the substrate for the transport of membrane-bounded organelles, MTs are necessary for the extension of neurites during development; they provide the structural basis for maintaining neurites after extension and they also help maintain the definition and integrity of intracellular compartments. The diversity of these functions is reflected in differences in the biochemistry and metabolic stability of different MTs.

Neuronal and glial intermediate filaments provide support for neuronal and glial morphologies. As a class of cytoskeletal structures, intermediate filaments (IFs) display an unusual degree of cell specificity and are often used as markers of cellular differentiation. They comprise a family of related genes that have been classified in five types [20]. All five share homology in a core rod domain, which contains multiple α-helical domains that can form coiled/coils. The sequence homology in this conserved domain is sufficient that some antibodies recognize all known IFs from mammals through a wide range of invertebrates. IFs are also ultrastructurally similar regardless of type, forming 8–10 nm rope-like filaments that may be

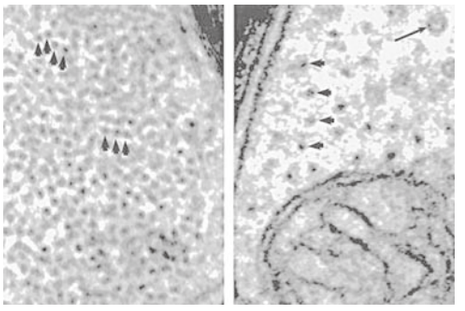

FIGURE 8-4 Glial filaments and neurofilaments are easily recognized in electron micrographs. The glial filaments lack side arms and often appear to be densely packed, with neighboring subunits almost touching (*large arrows* in **left** panel). In contrast, the spacing between neurofilaments is typically much greater (*large arrows* in **right** panel). This spacing is due to the side arms of neurofilaments formed by the tails of the high- and medium-molecular-weight neurofilaments (NFH and NFM, respectively). These tails are heavily phosphorylated in large axons such that NFH tails may have 50 or more phosphates added to the multiple repeats of a consensus phosphorylation site. NFM tails have fewer sites and typically only ten to 12 phosphates. Charges on the surface of phosphorylated neurofilaments are thought to repel neighboring filaments, creating the large spacing. For comparison, a 25 nm microtubule is indicated in the **right** panel (*thin arrow*). (Micrograph provided by H. Ross Payne and Scott Brady.)

several micrometers long. However, NFs differ from the other IFs because they have sidearms that project from their surface. The result is that IFs in non-neuronal cells are often seen in densely packed bundles, while NFs are widely spaced (Fig. 8-4).

Types I and II are the keratins that are found in various combinations in epithelial cells throughout the body. Keratin IFs must include representative subunits of both type I and type II IF subunits with each tissue having a characteristic combination. In contrast, type III IF subunits typically form homopolymers. They include IFs that are characteristic of less differentiated cells like glial or neuronal precursors, as well as those seen in more specialized cell types like smooth muscle cells and mature astrocytes. These three types of IF not only share sequence homology within their rod domains but their genes exhibit similar exon and intron structure. Type IV IFs are all neuron-specific and have a common pattern of exons and introns that differs from that seen in types I–III. Finally, type V polypeptides are the nuclear lamins, which form the walls of the nuclear envelope structure rather than typical IF structures. Although all eukaryotes express type V lamins, plants, many unicellular organisms and arthropods do not express other IF types. Cytoplasmic IFs are nearly ubiquitous in vertebrate cells and some cells contain more than one type of IF in their cytoplasm. Curiously, oligodendrocyte precursors contain vimentin IFs, but these are lost during differentiation, making mature oligodendrocytes one of the few vertebrate cell types that lack cytoplasmic IFs.

The nervous system contains an unusually diverse set of intermediate filaments (Table 8-2) with distinctive cellular distributions and developmental expression [21, 22]. Despite their molecular heterogeneity, all intermediate filaments appear as solid, rope-like fibers 8–12 nm in diameter. Neuronal intermediate filaments (NFs) can be hundreds of micrometers long and have characteristic sidearm projections, while filaments in glia or other non-neuronal cells are shorter and lack sidearms (Fig. 8-2). The existence of NFs was established long before much was known about their biochemistry or properties. As stable cytoskeletal structures, NFs were noted in early electron micrographs, and many traditional histological procedures that visualize neurons are based on a specific interaction of metal stains with NFs.

The primary type of IF in large myelinated axons is formed from three subunit proteins known as the neurofilament triplet: NF high-molecular-weight subunit (NFH, 180–200 kDa); NF middle-molecular-weight subunit (NFM, 130–170 kDa); and NF low-molecular-weight subunit (NFL, 60–70 kDa) [21–23]. A separate gene encodes each of the subunit proteins. The NF triplet proteins are type IV IF proteins that are expressed only in neurons and have a characteristic domain structure. The amino-terminal regions of all three subunits interact via α-helical coiled-coils to form the core of the filament. NFM and NFH also have long carboxy-terminal regions, which project from the core filaments as sidearms.

TABLE 8-2 IF proteins of the nervous system

IF Type	Subunit	Cell type
Type III	Vimentin	Neural and glial precursors
	GFAP	Astrocytes, some Schwann cells
	peripherin	Subset of neurons, particularly in PNS, may co-assemble with NFH/NFM/NFL
	Desmin	Smooth muscle cells in vasculature
Type IV	NFH	
	NFM	
	NFL	Most neurons, most abundant in large neurons
	α–internexin	Subset of neurons, particularly parallel fibers in cerebellum, may also coassemble with NFH/NFM/NFL
Type V	Nuclear lamins	Nuclear envelope
Type VI	nestin	Neuroectodermal precursors in developing brain

NFH, and to a lesser extent NFM, has a large number of consensus phosphorylation sites for proline-directed kinases in this carboxy-terminal extension (>50 on NFH and >10 on NFM in many species). In large myelinated axons, most, if not all, of these sites are phosphorylated [21, 22]. This phosphorylation of NFH and NFM sidearms alters the charge density on the NF surface, repelling adjacent NFs with similar charge. Such mutual repulsion by the sidearms of NFs is thought to be a major determinant of axonal caliber [24].

Other IFs are also found in the nervous system [21, 22]. Vimentin is the most widely expressed type III IF and is found in a variety of cell types like fibroblasts, microglia and smooth muscle cells as well as in embryonic cell types including neuronal and glia precursors. Astrocytes and some Schwann cells contain the type III IF glial fibrillary acidic protein (GFAP). This distribution has led to the widespread use of GFAP immunoreactivity to identify astrocytes in culture and in tissue. In contrast to NFs, type III IFs like GFAP lack sidearms and often appear to be tightly bundled.

At least three other IFs occur in selected neurons or neuronal precursors: α-internexin, peripherin and nestin. All of these are most prominently expressed during development, then downregulated. Based on sequence and gene structure, peripherin is a type III IF, while α-internexin is a type IV IF. Nestin is the most divergent of the IFs that form filaments and nestin sequence has characteristics of both type III and type IV IFs [21]. As a result, nestin is sometimes considered to be a distinct IF type (type VI). While the NF triplet proteins and α-internexin may be components of both CNS and PNS neurons, peripherin appears to be expressed preferentially in PNS neurons. Both can co-assemble with the NF triplet proteins *in vitro* and may do so *in vivo*, but can also form homopolymeric filaments. Both are expressed at higher levels in a variety of developing neurons, and expression becomes more restricted as neurons mature. Many neurons cease to express α-internexin during maturation. However, a few neurons retain the expression of IFs containing α-internexin. Notably, IFs of parallel fibers in the cerebellar cortex contain only α-internexin subunits. Peripherin continues to be expressed in some peripheral neurons in maturity. Although nestin is specific to the nervous system, it is expressed in multipotent neuroectodermal precursors and suppressed during subsequent development. For this reason it can be used as an early marker for differentiation of precursor cells.

Not all neurons have NFs. Indeed, one entire phylum in the animal kingdom, arthropods, expresses only type V nuclear lamins so arthropod cells have no IF cytoskeletal structures at all. In addition, mature oligodendrocytes lack IFs although their embryonic precursors contain vimentin. Clearly, the IFs are not essential for cell survival. Yet, in large myelinated fibers, NFs make up the bulk of axonal volume and represent a substantial fraction of the total protein in brain. In most organisms, IFs in both glia and neurons contribute to the distinctive morphologies of these cells. They are thought to provide mechanical strength and a stable cytoskeletal framework. In neurons, NFs play an important role in regulating cellular and axonal volumes and are a primary determinant of axonal caliber in large fibers. Finally, NFs exhibit an unusual degree of metabolic stability, which makes them well suited for a role in stabilizing and maintaining neuronal morphology [25].

Actin microfilaments and the membrane cytoskeleton play critical roles in neuronal growth and secretion. This major class of cytoskeletal elements is perhaps the oldest. Certainly, the actin cytoskeleton has the most diverse composition and organization. MFs are formed from 43 kDa actin monomers that are arranged like two strings of pearls intertwined into fibrils 4–6 nm diameter (Fig. 8-2) [26]. A remarkable variety of proteins have been found to interact with actin MFs, ranging from myosin motors to cross-linkers, bundling proteins to anchoring proteins, and sequestration proteins to small GTPase regulatory proteins [27, 28].

Actin MFs are found throughout neurons and glia, but they are enriched in cortical regions near the plasmalemma and are particularly concentrated in presynaptic terminals, dendritic spines and growth cones. Under most circumstances in the nervous system, MFs are short oligomers organized into a meshwork most apparent near the plasma membrane and in the vicinity of axonal MTs. MFs are the main components of the membrane cytoskeleton and this may be their primary role in mature neurons. The actin cytoskeleton also plays an important role in the Golgi complex (GC) morphology. Actin and actin-associated proteins, like spectrin and myosin, are associated with the GC, although their exact functions are not fully understood. However, the cytoplasmic arrangement of actin filaments is directly involved in the subcellular localization and the shape of GC [29, 30]. Spectrin is thought to provide a cross-linked matrix surrounding GC membranes, similar to its role at the plasma membrane, providing structural integrity, as well as defining putative GC microdomains and possibly mediating interactions with dynactin and dynein [31, 32]. The prominent actin bundles (stress fibers) seen in fibroblasts and many other non-neuronal cells in culture are not characteristic of neurons *in vivo* or *in vitro*. Most neuronal MFs are less than a micron in length. However growth cones contain many longer MFs, with bundles of MFs in the filopodia and lamellipodia in addition to the typical more dispersed actin network (Fig. 8-4) [33]. The role of actin MFs in the growth cone will be considered in greater detail below.

Many MF-associated proteins [28] have been described in the nervous system (Table 8-3). In general, a good deal is known about their distribution and function in primary cultures of neurons and glia, but less is known about their role in the mature nervous system. Two that have been characterized more extensively are the major non-actin

TABLE 8-3 Selected microfilament-associated proteins expressed in the nervous system

Protein	Activity	Cellular location
Actin	Core subunit of MFs	Throughout neurons and glia, enriched in growth cones and in membrane cytoskeleton
Tropomyosin	Stabilize MFs	Co-distributed with most MFs
Spectrin/fodrin	Cross-link MFs in membrane cytoskeleton	Enriched in membrane cytoskeleton
Ankyrin	Links MF/spectrin to membrane proteins	Membrane cytoskeleton, distinct forms in axon, dendrite and nodes of Ranvier
Fimbrin	MF bundling and cross-linking	Growing neurites
Gelsolin	Fragments MFs and nucleates assembly, regulated by Ca^{2+}	Growing neurites, glia, mature neurons
β–thymosins	Binds actin monomers and regulates MF assembly	Growing neurites
Profilin	Binds actin monomers, inhibits MF formation, regulated by selected signal transduction pathways	Growing neurites, glia, mature neurons
Arp2/3 complex	Nucleation of actin MF assembly in cortex and initiation of MF branches	Enriched in cell cortex where MF assembly is active
N-WASP	Interacts with Arp2/3 complex to nucleate actin MF assembly	Enriched in cell cortex where MF assembly is active, binds to Cdc42 and Arp2/3 complexes

structural elements of the membrane cytoskeleton: spectrin and ankyrin. Spectrin is a flexible rod-shaped molecule composed of homologous α- and β-subunits that was originally characterized as a component of the erythrocyte membrane cytoskeleton. Neurons were the first cell type, other than erythrocytes, shown to contain spectrins and the brain form was initially called fodrin. Spectrin heterodimers align end-to-end to form tetramers, which are cross-linked by short actin MFs. This spectrin-actin meshwork is tightly coupled to the plasma membrane through direct binding to membrane proteins [34]. Some of these interactions occur via the protein ankyrin, which has separate binding sites for specific membrane proteins and β-spectrin (Fig. 8-5). In neurons, specific isoforms of spectrin and ankyrin are localized to axons, dendrites and paranodal regions. The spectrin and ankyrin isoforms in perikarya and dendrites tend to be highly homologous to the erythrocyte forms and distinct from the spectrin and ankyrin isoforms that occur in axons.

A variety of additional MF bundling or linking proteins have been described in the nervous system. For example, fimbrin may play a role in the formation of microfilament

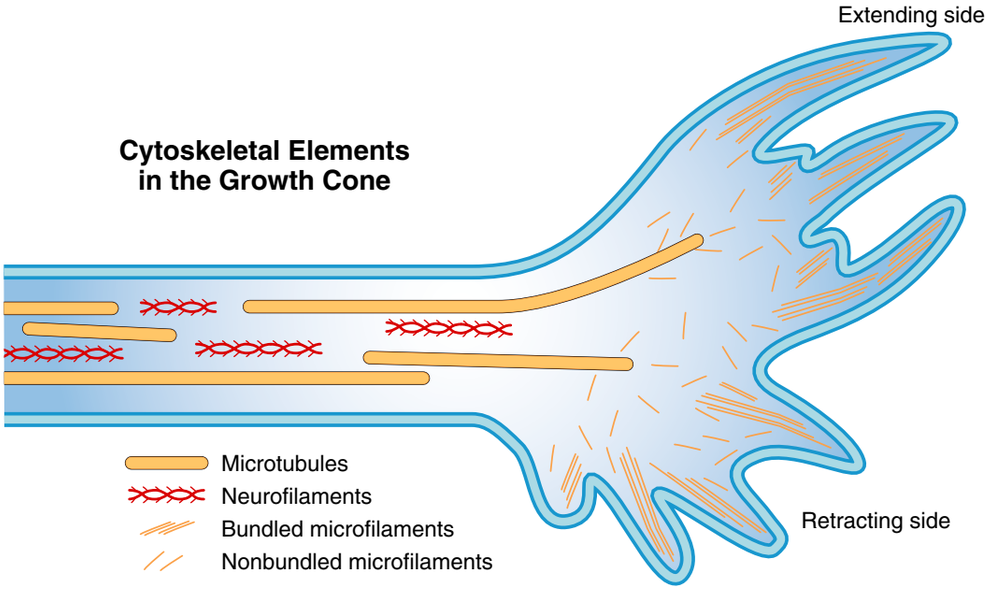

FIGURE 8-5 The cytoskeletal elements of a growth cone are organized for motility. In this diagram of a growth cone, a typical distribution of major cytoskeletal structures is shown. The microfilaments are longer and more prominent in the growth cone than in other regions of a neuron. They are bundled in the lamellipodia and particularly in the filopodia. A combination of actin assembly, microfilament cross-linking and myosin motors (see Ch. 28) is thought to mediate this movement. In the central core of the growth cone, the microfilaments may interact with axonal microtubules which do not extend to the periphery. These microtubules may be pulled toward the preferred direction of growth and appear to be necessary for net advance. In the absence of microtubules, filopodia extend and retract but the growth cone does not advance. Microtubule movements are thought to be a combination of assembly and contractility. Finally, the neurofilaments appear to stabilize the neurite and consolidate advances but appear to be excluded from the growth cone proper.

bundles in growth cone filopodia. Still other actin binding proteins may regulate MF assembly. Gelsolin fragments MFs in a Ca^{2+}-sensitive manner, but also caps and nucleates MFs. In contrast, profilin and β-thymosins bind to actin monomers and may act in part by sequestering actin subunits, although this oversimplifies the effects of these proteins. The list of actin MF-associated proteins has become quite long and this diversity reflects the many forms of MF-based cytoskeletal structures.

Recent studies on mechanisms for regulation of MF assembly have identified a number of components critical for creating and maintaining the actin membrane cytoskeleton including Arp2/3 and the WASp/Scar family [35, 36]. Arp2 and Arp3 are actin-related proteins that form a complex with five other unique polypeptides [28, 36]. The first member of the WASP/Scar family was isolated from hematopoietic cells and was mutated in a rare disease known as Wiskott–Aldrich syndrome. Other family members were expressed at high levels in brain and other tissues [28]. Briefly, members of the Cdc/Rac family of small GTPases activate WASp/Scar proteins. Activated WASp/Scars bind to the Arp2/3 complex to initiate a new MF or a branch off an existing MF [28, 35, 36]. Often actin monomer is sequestered in association with profilin to limit assembly. A second signal (PIP or PIP_2) stimulates dissociation of actin and profilin and rapid MF assembly occurs. This pathway is particularly important in neuronal activities like growth cone motility.

MFs in the nervous system appear to have a variety of functions. The neuronal membrane cytoskeleton plays a role in maintaining the distribution of plasma membrane proteins, establishing cell morphologies and segregating axonal and dendritic proteins into their respective compartments. MFs and the membrane cytoskeleton also mediate the interactions between neurons and the external world, including extracellular matrix components and neighboring cells (see Ch. 7). In neurons and glia, cell adhesion sites such as tight junctions and focal adhesion plaques interact with the MF cytoskeleton either directly or indirectly. The cortical MF meshwork also restricts access of organelles to the plasma membrane and is involved in both regulated and constitutive secretion. Finally, MFs are the basis of filopodia and lamellipodia, which are essential for cell migrations, growth cone motility and myelination.

ULTRASTRUCTURE AND MOLECULAR ORGANIZATION OF NEURONS AND GLIA

A dynamic neuronal cytoskeleton provides for specialized functions in different regions of the neuron. The cytoskeleton in different regions of a neuron differs with regard to both composition and function. While both neurons and glia exhibit distinctive specializations in their cytoskeletal elements, distinct domains are most easily visualized within the neuron. In order to maintain the polarized morphology of a neuron, cytoskeletal, cytoplasmic and membranous elements must be assembled and targeted in a characteristic and consistent manner. The biochemical diversity of each of these elements is striking, as the composition of proteins in the axon differs significantly from that in cell bodies and dendrites. There is diversity even along the length of a single axon. In this section, several examples are given that illustrate how characteristic features of the somatodendritic and axonal cytoskeletons are generated and maintained. A common theme underlying each example is the dynamic nature of the cytoskeleton.

Both the composition and organization of cytoskeletal elements in axons and dendrites become specialized early in differentiation. A brief description of how the cytoskeletal elements within axons and dendrites are established illustrates the dynamic nature of the cytoskeleton. The sequence of events has been described for neurons in primary culture [9, 37]. Postmitotic neurons initially extend and retract multiple neuritic processes. These early short neurites are of comparable length and growth rate. All contain MTs oriented with plus-ends distal to the cell body and all have both MAP2 and tau microtubule-associated proteins. Eventually, in neurons that elaborate an axon, one neurite outgrows the others. This first long neurite continues to grow without tapering and becomes the single axon. Under culture conditions that lack directional information, the choice of neurite that becomes the axon appears to be stochastic. Cues in the local environment are likely to specify a particular direction for neurite outgrowth *in vivo*. As the axon grows, it loses MAP2 while tau is enriched and become differentially phosphorylated. Subsequent to axonal outgrowth, some of the other neurites are stabilized and begin to extend. The number of dendrites varies with type of neuron, ranging from the single dendritic process that partially fuses with the axon to produce the single branched process of dorsal root ganglion pseudo-unipolar neuron to the elaborate branching dendrite of the Purkinje cell and to multipolar motor neurons with both apical and basal dendritic arbors. Most neurites that develop into dendrites become tapered as they grow. When dendrites reach this stage, they begin to contain MTs in both orientations. More or less concurrently, MAP2 becomes enriched in the dendritic processes. Initially, the smallest form of MAP2 is abundant, but a shift to predominantly high molecular weight isoforms occurs with maturation.

As axons and dendrites mature, their differences become more apparent [9]. In axons, MTs have a uniform orientation with plus-ends distal to the cell body, but dendrites contain MTs in both orientations. Dendrites and to a lesser extent perikarya contain MAP2, which is excluded from axons at an early stage. Curiously, MAP2 mRNA is one of several mRNAs that are specifically transported

into the dendrite and translated locally. No other cytoskeletal protein has been found to display a similar expression pattern and protein synthetic machinery is excluded from the axon. Expression of dendritic mRNAs is affected by synaptic activity, but its physiological function is uncertain. In contrast, tau is enriched in axons and NFs similarly occur primarily in axons. The phosphorylation of MAP 1B, tau and NFs is maintained at a high level in axons [16, 23]. Neuron-specific isoforms of spectrin and ankyrin exist only in axons [34].

While tau is not restricted to the growing axonal process, tau expression appears to be critical for the initial elongation event that defines an axon-to-be. If tau expression is blocked before the commitment to axonal outgrowth through use of antisense oligonucleotides, no axon is formed [46]. If tau expression is blocked after commitment, the axon is retracted, suggesting that tau-MT interactions are necessary for axonal differentiation. Similarly, reduction in MAP2 expression inhibits dendrite differentiation. That MAP2 and tau seem to bestow upon MTs the ability to form 'dendrite-like' or 'axon-like' processes respectively has also been suggested by experiments in which these MAPs have been expressed in non-neuronal cells. MAP2 and tau differentially affect the packing density of MTs, so, while these MAPs may not trigger the initial polarization of neurons, they no doubt contribute to maintenance of the polarized phenotype [37]. For both axons and dendrites, cytoskeletal composition and organization are carefully orchestrated during differentiation and maturation.

Although axonal and dendritic microtubules differ in their associated proteins and organization, both are thought to originate in the cell body. Microtubules are likely to continue to grow after entry in the axon or dendrite, but there is little evidence for *de novo* formation of microtubules in either region. The evidence suggests that both are nucleated at the MTOC as another cell types. Instead of remaining associated with the MTOC, neuritic MTs are released from the MTOC and transported into the neurite. The sites where most elongation occurs and where specific microtubule-associated proteins are added remains a matter of dispute. Similarly, the molecular mechanisms by which different cytoskeletal compositions are maintained in different neuronal compartments are unknown.

As the size and shape of neurons change during development, the composition of the IF cytoskeleton varies coordinately. Different types of neurons and neurons in different stages of development vary in the number and composition of their IFs [23]. For example, in many neurons peripherin and α-internexin are expressed very early in neuronal differentiation, then downregulated. NFL and NFM are detectable during initial neurite outgrowth, while NFH is not expressed at significant levels until much later. Phosphorylation of NFH and NFM occurs even later in development, and only reaches its full extent in large myelinated axons. Additionally, NFs in different neuronal populations may not contain the same subunit stoichiometry for NFL, NFM and NFH.

CYTOSKELETAL STRUCTURES IN THE NEURON HAVE COMPLEMENTARY DISTRIBUTIONS AND FUNCTIONS

While each set of cytoskeletal elements has a distinctive spectrum of composition, stability and distribution, all three interact with each other. They have complementary functions and may be coordinately regulated. Such interactions can be seen during development of the nervous system, in mature neuron/glia interactions and in neuropathologies.

Microfilament and microtubule dynamics underlie growth cone motility and function. The mechanisms by which neurons make appropriate synaptic connections are a subject of great interest. The first stages of this process are neurite elongation and pathfinding. As the growing tip of a growth cone advances across a substrate, the growth cone must interpret extracellular cues to steer the growing neurite in the right direction [33, 38]. Growth cones receive both attractive and repulsive cues and respond by selectively stabilizing, destabilizing or rearranging actin and MT cytoskeletons to allow for directed growth. This section briefly describes how extracellular signals mediate rearrangements of the cytoskeleton.

Growth cones can be roughly divided into three domains: *filopodia* are long, thin, spike-like projections that grow and retreat rapidly from the growth cone surface; *lamellipodia* are web-like veils of cytoplasm that also spread and retract, often between filopodia; and the *body* itself of the growth cone is the area of cytoplasm beyond the cylindrical neurite that adheres to the substratum. Filopodia and lamellipodia sample the environment for favorable conditions, then the body of the growth cone will move forward as the axon elongates. The distribution of the three cytoskeletal elements in the growth cone is well established (Fig. 8-4) [33, 38]. In neurites MTs occur as bundles, which then splay out into single filaments in the body of the growth cone, but MTs do not extend into the filopodia. NFs are limited to the shaft of the neurite and do not extend beyond the proximal edge of the growth cone body. Actin MFs make up the majority of the growth cone cytoskeleton. They form a complex meshwork that includes a number of actin-associated proteins beneath the entire plasma membrane of lamellipodia and the growth cone body. Bundles of actin MFs form the cores of filopodia. Forces generated by rearrangement of the actin MFs help realign the MTs, and eventually the NFs, to the preferred direction for growth.

The diameter of a growth cone is often much greater than that of the neurite, allowing it to sample a large

volume of the environment. Typically, the shape of a growth cone is constantly changing, with filopodia and lamellipodia extending and retracting, receiving signals from the surface of other cells, the extracellular matrix or the surrounding media. A number of factors may elicit a growth response including soluble neurotrophins and membrane or matrix-bound ligands. In addition, repulsive signals have been identified that lead to collapse of filopodia or lamellipodia and to retraction of growth cones. The extension of filopodia and lamellipodia are regulated in part by members of the Rho and Rac family of low-molecular-weight GTPases [27].

Signals in response to extracellular guidance cues cause growth cones to steer probably involve multiple pathways [38]. When one or a few filopodia receive an attractive cue, the growth cone will turn in that direction. At least two things occur in the region of the growth cone chosen for further growth. First, extracellular signals activate cell surface receptors to recruit a multiprotein complex that links the receptor to the actin meshwork beneath the surface. This is likely to involve a variety of signals including local Ca^{2+} transients, release of PIP and PIP_2, activation of Cdc42/Rac small GTPases, and phosphorylation of cytoskeletal proteins in the vicinity. Rapid polymerization of actin MFs leads to a protrusion of the membrane at the site of growth. This burst of actin polymerization is probably due to the concerted actions of a number of different actin-binding proteins [36] and the membrane protrusion may also involve actin-based motors like myosins [39] (see Ch. 28). More or less concurrent with MF rearrangements, the splayed MTs in the growth cone body begin to invade the selected site [33, 40]. This invasion may involve both MT elongation and MT movements. Once MTs form an ordered bundle oriented in the new direction, the membrane of the growth cone collapses around the MT bundle to create an extension of the neurite cylinder and the NFs are advanced to consolidate new growth. Then the growth cone begins looking for the next signal. While this description is an oversimplification of growth cone steering events, it nevertheless illustrates that growth cones are highly motile and very dynamic entities.

The axonal cytoskeleton may be influenced by glia. In cross sections of large myelinated axons, most of the volume is occupied by NFs separated from each other by sidearm spacers. Spaces between fields of NFs are occupied by one of two specialized regions: MTs with membrane-bounded organelles or electron-dense regions adjacent to MTs and to the plasma membrane cortex (Fig. 8-1). These electron-dense areas are enriched in short actin MFs. Such images suggest a static cross-linked cytoskeleton and do not reveal the underlying dynamics of the axonal cytoskeleton. In fact, fully mature neurons also have a dynamic cytoskeleton that is both engaged in axonal transport (Ch. 28) and responsive to the local environment.

The relationships between an axon and its myelinating glia are both intimate and extensive. Originally, these relationships were thought to be specified by signals from the axon that elicited specific responses in glial cells after contact, including proliferation and myelination [12]. Little thought was given to the possibility of glia influencing neurons. However, more recent studies indicate that the axonal cytoskeleton is also altered locally by glial contacts. Axonal cytoskeletal elements are subject to constant modulation via signals from the axonal environment including both target cells and cells forming the myelin sheath. Such signals appear to influence axonal branching, synapse formation and axonal caliber.

The response of the axon to loss of myelin is instructive. In the *trembler* mutant mouse, the axon undergoes a continuing cycle of partial myelination followed by demyelination. The result is a thin or absent peripheral myelin sheath and a reduction in axonal caliber (Fig. 8-6). Remarkably, this reduction in axonal caliber is highly localized to segments of axon with disrupted myelin.

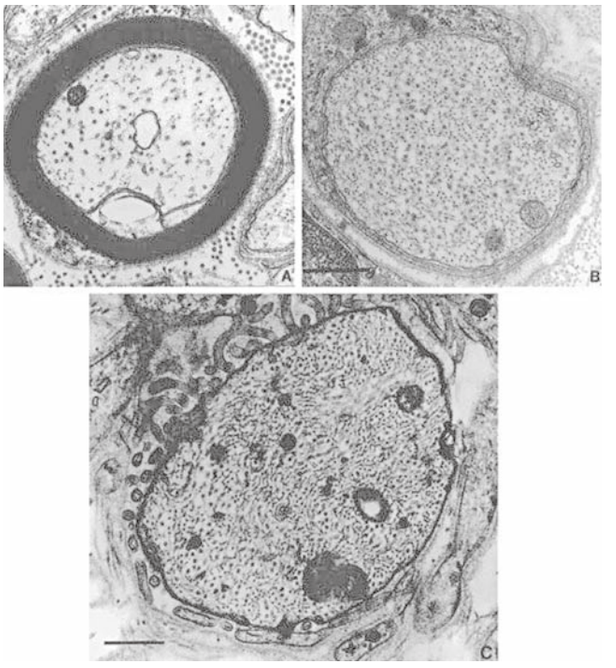

FIGURE 8-6 The local environment can alter the organization of the axonal cytoskeleton. (**A**) In a normal myelinated axon of the sciatic nerve, neurofilaments and microtubules are widely spaced, so they occupy considerable volume. (**B**) In contrast, a comparably sized axon from the sciatic nerve of the demyelinating *trembler* mutant mouse has a denser cytoplasm, with neurofilaments densely packed. This has been shown to result from a shift in the net dephosphorylation of neurofilaments produced by demyelination. This effect on the axonal cytoskeleton is highly localized. (**C**) Similar changes in the organization and phosphorylation of the axonal cytoskeleton occur even over the short gap in the myelin sheath which occurs at the node of Ranvier. Such changes illustrate the dynamic nature of the axonal cytoskeleton. Bars represent 0.5 µm with (**A**) and (**B**) at the same magnification. (Micrographs supplied by Sylvie de Waegh and Scott Brady.)

The local nature of these changes was proven by studies in which regions of *trembler* sciatic nerve were grafted into normal nerves. Only those axon segments surrounded by *trembler* Schwann cells have reduced diameters. More importantly, the reduction in axon caliber is due to an increase in NF density in *trembler* nerves by a factor of two, even though the actual amount of NF protein is not changed. The increased NF packing density means that the same number of NFs now occupies a smaller volume producing a smaller axon. This change in density appears to be due to a reduction in the phosphorylation of NFH and NFM tail domains, which allows the individual NFs to be packed more tightly [24]. Such changes are restricted to axons in contact with *trembler* Schwann cells. Thus, it is the direct interaction between the axons and the Schwann cells that modulates the axonal cytoskeleton. The influence of myelinating Schwann cells is not restricted to NFs, because the stability, organization and composition of the MT cytoskeleton are also altered in *trembler* nerves.

The effects of myelin can be observed in intact normal nerve as well. A similar change in cytoskeletal organization occurs in normal myelinated nerves at nodes of Ranvier [41]. Beginning in the paranodal regions where compact myelin is lost, the diameter of the axon is reduced; the packing density of NFs in increased; and NF phosphorylation is reduced. Thus, the axonal cytoskeleton is constantly influenced by the myelinating glial environment, providing a dramatic example of the dynamic nature of the neuronal cytoskeleton.

Levels of cytoskeletal protein expression change after injury and during regeneration. As described above there are substantial changes in the composition and organization of neuronal and glial cytoskeletal elements during development. Changes are equally dramatic following injury to the nervous system. Some of these changes reflect the switch from maintaining cellular structures to growth or repair modes. The response of PNS neurons during regeneration may fall into this category. In other cases, the response is incomplete or may be a reactive response to the injury. For example, after CNS injury, astrocytes become reactive, rapidly proliferate and frequently form a glial scar. The hallmark of this glial scar is a dramatic increase in GFAP IF bundles, which allows the astrocytes to fill the injured zone and provide mechanical support for surrounding uninjured tissues. Unfortunately, the glial scar often represents a physical barrier to neuronal elongation and repair.

The neuronal response to injury has been studied in some detail to gain a better understanding of why mammalian CNS neurons regenerate poorly or not at all, while PNS neurons regenerate effectively. Although regeneration is often described as paralleling developmental growth of neurons, the distinctive pattern of changes in the neuronal cytoskeleton during regeneration differs in some important ways from changes during development. First, there is a coordinate downregulation in NF subunit expression following injury. NFH, NFM and NFL protein and mRNA levels in the perikarya decline rapidly after injury and do not recover until after reconnection with an appropriate target cell has occurred. Unlike the case during development, where NFH expression lags behind the other two, all three NF subunits decline and recover coordinately during regeneration. Concurrent with the reduction in NF protein levels following injury, both tubulin and actin increase significantly. While NF proteins are low throughout the elongation phase of regeneration, tubulin and actin expression remains high during neurite growth and synaptogenesis. As might be expected, there are associated changes in the expression of MAPs and MF-associated proteins during regeneration as well.

The observation that selected tubulin genes are preferentially upregulated during regeneration has led to proposals that some tubulin isoforms are better suited for neurite growth. While this idea is attractive, there is little evidence for a significant functional difference among the various tubulin genes [3, 14]. Nonetheless, the idea that changes in cytoskeletal protein are required for effective regeneration is consistent with observations that changes in cytoskeletal protein expression after injury are limited or altered in CNS neurons that fail to regenerate after injury. The precise regulation of cytoskeletal gene expression during both development and regeneration suggests the importance of these structures for neuronal growth.

Alterations in the cytoskeleton are frequent hallmarks of neuropathology. A definitive diagnosis for many neurological disorders depends on a histological examination. The identifying characteristic for a number of neuropathologies is a disrupted or aberrant cytoskeleton. This is a feature of many toxic neuropathies and a number of neurodegenerative conditions, including motor neuron disease, frontotemporal dementia (FTDP-17) and Alzheimer's disease. Although other neuronal functions may also be affected and the initial cause of the disease may not directly involve the cytoskeleton, the associated pathogenic disruption of cytoskeletal function maybe a key element in the loss of neurons or neuronal function [42]. In recent years, a new class of neurological disorders captured a lot of attention in the neuroscience community. Both sporadic and familial forms of these puzzling disorders exist, but all of them exhibit a characteristic accumulation of tau protein aggregates and they have come to be known as tauopathies [17]. Several mutations in the tau gene have now been linked to these tauopathies, with differences in the severity of symptoms and the cellular location of tau accumulations depending on the specific mutation. These mutations comprise a heterogeneous group of neurological disorders known as FTDP-17. The pathological hallmark in both sporadic and familial tauopathies is the presence of intracellular tau filamentous inclusions that are typically hyperphosphorylated.

In some cases, the primary pathogenic mechanism is an effect on one or more cytoskeletal structures. For example, some widely used chemotherapeutic agents for treatment

of tumors act by disrupting microtubule function in the spindles of rapidly dividing cancer cells. Such drugs can affect microtubules in both neuronal and non-neuronal cells. Perhaps the two best known examples are vincristine and paclitaxel (taxol). While these two compounds have opposite actions on microtubules, long-term or high-dosage treatment with either leads to a high frequency of associated neuropathies. Vincristine is a classic antimicrotubule drug that destabilizes existing microtubules and blocks assembly of new microtubules. In contrast, paclitaxel stabilizes microtubules and leads to formation of numerous short MTs in inappropriate sites. Despite these differences, peripheral neuropathies are a troublesome side effect of both drugs. Neuronal viability is compromised because microtubule function is compromised. Other environmental toxins or chemicals may interfere with neurofilaments. For example, in rabbits, exposure to some aluminum salts leads to accumulation of neurofilaments in the initial segments of the axon.

In fact, a number of neuropathologies with diverse pathogenic mechanisms have associated disruptions in axonal neurofilaments. Neurofilaments accumulate in the cell bodies of motor neurons in patients with amyotrophic lateral sclerosis and related motor neuron diseases. The example of motor neuron disease is particularly interesting, because the symptoms of motor neuron disease can be produced in animal models in several very different ways. Some of these animal models have little obvious relevance to the cytoskeleton, such as those resulting from point mutations in a superoxide dismutase gene. Others directly involve neurofilaments, such as transgenic mice that express defective NF subunits or overexpress normal NF subunits. Regardless of how these animal models are produced, a characteristic feature of motor neuropathology is the accumulation of poorly phosphorylated NFs in cell bodies and initial segments (reviewed in [22, 23]).

Other diseases with disruptions in neurofilament organization include diabetic neuropathy and Charcot–Marie–Tooth disease. For these diseases, the disruption of neurofilaments may be a secondary effect as in the case of *trembler* axons or a direct effect. For example, some forms of Charcot–Marie–Tooth peripheral neuropathy result from mutations in a neurofilament subunit [22, 43]. In most cases, neuronal degeneration is an eventual consequence, but neuronal function may be impaired prior to substantial loss of neurons. Generally, disruptions of neurofilaments have the most severe consequences in large motor neurons, which is consistent with the fact that the largest neurons have the highest levels of neurofilament expression.

Phosphorylation of cytoskeletal proteins is involved both in normal function and in neuropathology. An entire book could be devoted to research on the phosphorylation of cytoskeletal proteins. Phosphorylation of cytoskeletal components may affect their assembly and organization as well as their associated function. As described above, levels of phosphorylation on NFs are a major determinant in regulation of axonal caliber and a specific set of phosphorylations is a hallmark of tau protein in axons. The phosphorylation of other MAPs is carefully regulated during development and maturation of the nervous system. Similarly, many MF-associated proteins are regulated by phosphorylation, so that the local action of kinases and phosphatases may underlie many changes in the membrane cytoskeleton and growth cone motility.

Phosphorylation of cytoskeletal proteins has also been linked to various neuropathologies. For example, the NF accumulations seen in many diseases have aberrant phosphorylation patterns. A more significant change may be the hyperphosphorylation of brain MAP tau, which is associated with the formation of neurofibrillary tangles in Alzheimer's disease [17]. These tangles contain distinctive paired helical filaments that are extremely resistant to solubilization and analysis. They were initially thought to be aberrant NFs based on their dimensions, but a careful immunochemical and biochemical dissection showed that the primary polypeptide present in tangles was tau, the axonally enriched MAP [44]. The tau in neurofibrillary tangles is differentially phosphorylated and this misphosphorylation is thought to play a role in the formation of tangles. While the precise etiology of neurofibrillary tangles and their relationship to the deposition of amyloid are not yet certain, the appearance of these tangles is closely correlated with loss of neurons and their number is a good indication of how far the disease has advanced. Clearly, alterations in the axonal cytoskeleton are an important component of the Alzheimer's neuropathology [45] (see Ch. 46).

CONCLUSIONS

The architectures of neurons and glia are generated by the diverse specializations of MTs, NFs and MFs. Each of these components forms a set of structures that are constantly changing and subject to the influence of extracellular signals. While the importance of the cytoskeleton for development, maintenance and regeneration of nerve fibers is now well documented, many details about their activities remain to be delineated. Continued exploration of these phenomena will provide the basis for a deeper understanding of neuronal development, regeneration and neuropathology.

Scott T. Brady

GENERAL MECHANISMS OF INTRACELLULAR MEMBRANE TRAFFICKING IN MAMMALIAN CELLS INCLUDE BOTH UNIVERSAL AND HIGHLY SPECIALIZED PROCESSES 139

FUNDAMENTALS OF MEMBRANE TRAFFICKING ARE BASED ON A SET OF COMMON PRINCIPLES 141

Most transport vesicles bud off as coated vesicles, with a unique set of proteins decorating their cytosolic surface 141

GTP-binding proteins, such as the small monomeric GTPases and heterotrimeric GTPases (G proteins) facilitate membrane transport 142

SNARE proteins and Rabs control recognition of specific target membranes 143

Unloading of the transport vesicle cargo to the target membrane occurs by membrane fusion 143

THE BIOSYNTHETIC SECRETORY PATHWAY INCLUDES SYNTHETIC, PROCESSING, TARGETING AND SECRETORY STEPS 144

Historically, endoplasmic reticulum is classified as rough or smooth, based on the presence (RER) or absence (SER) of membrane-associated polysomes 144

Biosynthetic and secretory cargo leaving the ER is packaged in COPII-coated vesicles for delivery to the Golgi complex 146

The Golgi apparatus is a highly polarized structure consisting of a series of flattened cisternae, usually located near the nucleus and the centrosome 146

Processing of proteins in the Golgi complex includes sorting and glycosylation of membrane proteins and secretory proteins 148

Proteins and lipids move through Golgi cisternae from the *cis* to the *trans* direction 148

Plasma membrane proteins are sorted to their final destinations at the *trans*-Golgi network 150

Lysosomal proteins are also sorted and targeted in the *trans*-Golgi network 150

Several intracellular trafficking pathways converge at lysosomes 150

Both constitutive and regulated neuroendocrine secretion pathways exist in cells of the nervous system 151

THE ENDOCYTIC PATHWAY PLAYS MULTIPLE ROLES IN CELLS OF THE NERVOUS SYSTEM 151

Endocytosis for degradation of macromolecules and uptake of nutrients involves phagocytosis, pinocytosis and autophagy 151

The constitutive pathway is also known as the default pathway because it does not require any type of signal to enter 154

Secretory cells, including neurons, also possess a specialized regulated secretory pathway 154

Retrieval of membrane components in the secretory pathway through receptor-mediated endocytosis (RME) is a clathrin-coat-dependent process 155

SYNAPTIC VESICLE TRAFFICKING IS A SPECIALIZED FORM OF REGULATED SECRETION AND RECYCLING OPTIMIZED FOR SPEED AND EFFICIENCY 158

The organization of the presynaptic terminal is one important element for this optimization 158

In a simplistic model, the exocytosis step of neurotransmission takes place in at least three major different steps 158

Many years have passed since the concept of synaptic vesicle recycling was introduced in the early 1970s, but details of the synaptic vesicle cycle continue to be a matter for investigation and debate 160

GENERAL MECHANISMS OF INTRACELLULAR MEMBRANE TRAFFICKING IN MAMMALIAN CELLS INCLUDE BOTH UNIVERSAL AND HIGHLY SPECIALIZED PROCESSES

Eukaryotic cells have evolved a complex, intracellular membrane organization. This organization is partially achieved by compartmentalization of cellular processes within specialized membrane-bounded organelles. Each organelle has a unique protein and lipid composition. This internal membrane system allows cells to perform two essential functions: to *sort and deliver* fully processed membrane proteins, lipids and carbohydrates to specific intracellular compartments, the plasma membrane and the cell exterior, and to *uptake* macromolecules from the cell exterior (reviewed in [1, 2]). Both processes are highly developed in cells of the nervous system, playing critical roles in the function and even survival of neurons and glia.

Basic Neurochemistry: Molecular, Cellular and Medical Aspects
0-12-088397-X

The biosynthetic, secretory pathway is responsible for protein sorting and delivery and allows, among other functions, for cell–cell communication through secreted products. This delivery process starts at the endoplasmic reticulum (ER), to finish in the cell plasma membrane or, in some cases, in specific intracellular organelles. To accomplish this, specific proteins must be properly directed to the correct destination, while other proteins are retained as residents within specific organelles along the way.

The series of molecular events responsible for the uptake process constitutes the endocytic pathway, which enables cells to internalize macromolecules from the cell exterior, forming an endosome. The endosome is an intermediate organelle that serves as an essential component for many receptor-mediated signaling pathways and as a transport vector for eventual delivery to a specialized organelle known as the lysosome. Once in the lysosomal lumen, digestive enzymes provide essential metabolites from these macromolecules (i.e. free amino acids and lipids) directly to the cytosol for their use.

Intracellular membrane compartments are in a continuous, balanced and dynamic interaction. A constant, directed flow of membrane components among different compartments occurs at all times in a single cell. Transport vesicles of variable shape and composition provide the means by which membrane components and soluble molecules, generically referred as cargoes, move from a donor to a target compartment (Fig. 9-1). Such vesicles first bud off from the donor membrane and later fuse with the target membrane. In order to maintain the biochemical composition and the unique structural identities of each organelle, eukaryotic cells developed specialized retrieval and retention mechanisms. The retrieval process implies that recycling transport vesicles must take only the proteins to be recycled (i.e. proteins that are continuous residents in their original compartment, or resident proteins), while others are left behind. The specific sequence of events observed in any direction within the biosynthetic and the endocytic pathways implies that transport vesicles need to fuse only with the correct target organelle. These mechanisms allow for maintenance and proper balance of membrane flow among compartments, assuring that each protein is targeted for the correct location as well as redirecting resident membrane components to the compartment where they originated.

Neurons constitute the most striking example of membrane polarization. A single neuron typically maintains thousands of discrete, functional microdomains, each with a distinctive protein complement, location and lifetime. Synaptic terminals are highly specialized for the vesicle cycling that underlies neurotransmitter release and neurotrophin uptake. The intracellular trafficking of a specialized type of transport vesicles in the presynaptic terminal, known as synaptic vesicles, underlies the ability of neurons to receive, process and transmit information. The axonal plasma membrane is specialized for transmission of the action potential, whereas the plasma membrane of cell body and dendrites has specialized to receive signals from other nerve cells.

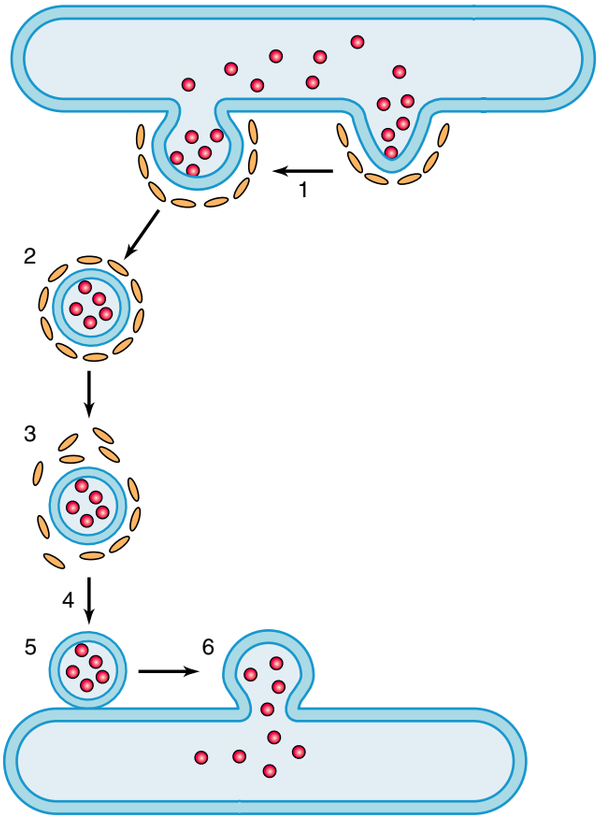

FIGURE 9-1 Fundamental steps of intracellular membrane transport. A series of basic steps allows the transfer of material (generally referred to as cargo) from the lumen and membrane of a donor compartment to a target/acceptor compartment. First, specific cargo is selected for packaging in the donor organelle (*1*). This process is concurrent with the formation of a specific protein coat on the cytosolic surface of the donor membrane, which helps molding a newly formed transport vesicle. Once a transport vesicle is formed, it buds off from the donor organelle (*2*). Transport vesicles shed their coats shortly after budding (*3*) in a an active process that involves either an ATPase/chaperone or a small GTPase. After uncoating, vesicles are actively translocated across the cytoplasm, usually through mechanisms mediated by microtubule-based molecular motors (*4*). Transport vesicles eventually reach, recognize and tether to the appropriate target organelle (*5*). Finally, unloading of the transport vesicle cargo to the target membrane occurs by membrane fusion (*6*).

Glial cells also require extensive, albeit less diverse intracellular membrane trafficking activity. This includes the delivery of myelin proteins during both the generation and maintenance of myelin. In the case of oligodendrocytes, different processes myelinating different axons may require differential trafficking of these components, similar to the situation in neurons (see Ch. 4). Finally, astrocytes must distribute a variety of transporters and channels to different astrocytic domains as part of their role in regulating the neuronal environment and delivering nutrients.

In this chapter, the basic mechanisms of membrane trafficking and the functions of the biosynthetic, secretory

and endocytic pathways in the nervous system will be examined. First, the fundamental steps of vesicle formation will be defined. Second, the diverse biosynthetic, secretory pathways and their functions will be examined, including biogenesis of organelles, delivery of plasma membrane components, and secretion. Third, endocytic pathways will be summarized including receptor-mediated endocytosis, membrane recycling and signaling. Finally, the specialized processes of synaptic vesicle trafficking serve to integrate these two pathways and represent a unique form of membrane trafficking in the nervous system.

FUNDAMENTALS OF MEMBRANE TRAFFICKING ARE BASED ON A SET OF COMMON PRINCIPLES

Although the various membrane compartments utilize a different repertoire of proteins for coat formation, vesicle budding and fusion, the basic principles behind these processes are similar (Fig. 9-1). A number of ordered, regulated molecular events allow for protein segregation into discrete, separate membrane domains [2]. Although these events are essential for functionality and survival of all cell types, they are highly specialized and often more complex in neuronal cells. The process of budding is initiated by the selection and assembly of specific components in donor membranes intended to be packaged and delivered together to the same target membranes. The formation of specific protein coats on the cytosolic face of the donor membrane gathers these common components into a single domain that can be packaged as a transport vesicle. This sequence of events provides for membrane targeting specificity.

Most transport vesicles bud off as coated vesicles, with a unique set of proteins decorating their cytosolic surface. The coat has two major known functions. First, it concentrates and selects specific membrane proteins in a discrete portion of donor organelle membrane that will serve as origin to the transport vesicle. Second, the assembly of coat proteins into curved structures delineates the area of the forming transport vesicle. The size and curvature is a function of the coat composition. Thus, vesicles with similar vesicle coat have closely similar size and shape [3].

There are at least three well-established types of coated vesicles common to all cell types, each one with a characteristic coat protein composition, and each used for different transport steps in the cell. Ultrastructural and biochemical studies first suggested a higher degree of diversity within these vesicle types [4]. In addition to these coated-vesicle types familiar from electron microscopy, video microscopic imaging in living cells identified tubulovesicular carriers, rather than spherical-shaped vesicles, budding off from endosomes, the ER and the *trans*-Golgi network. Transport vesicles important for longer distance trafficking, such as secretory vesicles, synaptic vesicles and other specialized vesicle types, are discussed in detail later in this chapter.

Clathrin-coated vesicles mediate transport from the Golgi apparatus to endosomes, and from the plasma membrane to endosomes. A multi-subunit protein, clathrin, constitutes the major protein of this vesicle type (see Ch. 2). Clathrin is composed of three large and three small polypeptide chains, which assemble to form a triskelion (Fig. 9-2). Regulatory mechanisms control the assembly and formation of a convex, polyhexa-pentagonal basket-like structure by these triskelions [5]. This structure is responsible for the formation of coated pits on the cytosolic face of plasma membranes.

Another major protein component of clathrin-coated vesicles, generally known as adaptins, bind and link clathrin coats to the membrane [5]. Multiple types of adaptins have been described, each type binding a unique set of cargo receptors and associated to a specific membrane organelle. Different sets of adaptins participate in forming the coat assembly complexes for the Golgi (AP1) and the plasma membrane (AP2). Sequential assembly and

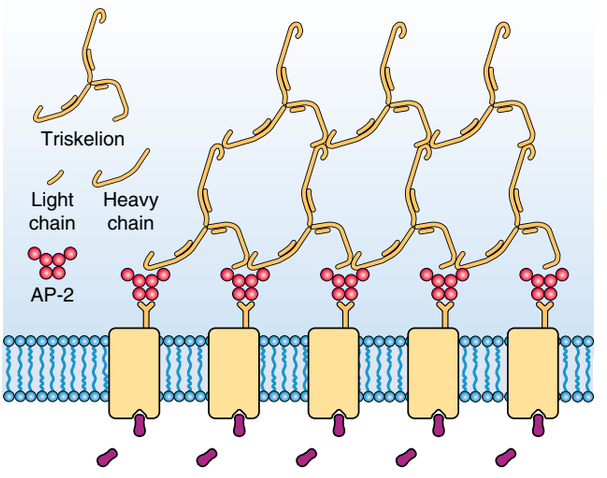

FIGURE 9-2 Endocytosis of membrane components through clathrin-coated pits. Clathrin coats are the best characterized and understood pathway for formation of vesicles either from the plasma membrane or the Golgi complex [5]. Clathrin function was initially worked out by studies of the recycling of membrane receptors for ligands such as transferrin and insulin. Recycling of synaptic vesicle membranes occurs by a similar process. Subsequent studies on Golgi trafficking revealed a parallel clathrin coat pathway. Ligand binding to the receptor appears to induce a conformational change that permits a tyrosine-containing β turn in the cytoplasmic domain to interact with one of the adaptins (AP-2). Clathrin binding to the adaptins then produces the coated pits that develop into endocytotic vesicles. Clathrin consists of three heavy chains (≈190 kDa each) that join near their C-termini to form a triskelion. Three light chains, of undetermined function, associate with the proximal segments of the heavy chains, possibly via an amphipathic α helix (heptad repeats) found in their central domains. Auxillin (not shown) is another component of the triskelion that appears to be important for removal of clathrin coats by a member of the Hsp70 chaperone family.

interactions between adaptins and clathrin aid in bud formation. Adaptins also bind and recruit transmembrane proteins known as cargo receptors, which in turn bind and recruit soluble proteins in the membrane lumen. This provides a means by which proteins may be selectively packaged into a clathrin-coated vesicle.

COPI-coated vesicles mediate intra-Golgi transport and Golgi to ER retrograde transport. The coats of these vesicles do not show the geometric forms seen with clathrin coats and have a more complex protein composition [3]. Coat protein purification first lead to the identification of a complex composed of seven individual coat-protein subunits, known as COPI or coatomer. Some of these subunits bear a sequence similarity to clathrin adaptors. In addition, there is a small GTP-binding protein, Arf1, present on COPI-coated vesicles.

COPII-coated vesicles are anterograde transport vesicles used early in the secretory pathway [3, 6]. COPII components were initially identified by using yeast mutants showing secretion defects and subsequently isolated from mammalian cells. The appearance of COPII coats in electron micrographs is readily distinguished from both clathrin and COPI coats. COPII-coated vesicles bud from the ER for transport to the Golgi, and their coat is composed of four individual coat-protein subunits. One of these is a small GTP-binding protein, SarI, exhibiting some sequence similarity to Arf1.

GTP binding proteins, such as the small monomeric GTPases and heterotrimeric GTPases (G proteins) facilitate membrane transport. GTPase proteins regulate a variety of cellular processes, including membrane trafficking in cells [7]. These proteins act as switches by alternating between an active, GTP-bound state and an inactive, GDP-bound state. Various modulator proteins affect the rate of conversion between these two states. Guanine-nucleotide exchange factors (GEFs), promote the exchange of GDP for GTP, resulting in GTPase activation. On the other hand, GTPase-activating proteins (GAPs), promote GTP to GDP hydrolysis, thus inactivating GTPases.

Although both heterotrimeric G proteins and monomeric GTPases appear to have roles in the regulation of vesicle transport, the role of monomeric GTPases is better understood. In particular, coat protein assembly is regulated by coat-recruitment GTPases, which are monomeric GTPases. In general, coat-recruitment GTPases are abundant in the cytosol, where they exist in an inactive, GDP-bound state. Hydrolysis of GTP by GTPases typically results in their translocation to membranes. Examples of such coat-recruitments GTPases are ARF proteins, which regulate clathrin and COPI coat assembly at Golgi membranes, and the SarI protein, which regulates COPII coat assembly at the ER.

COPI vesicle budding is triggered by the hydrolysis of GTP to GDP by membrane-associated ARF1. Once in the membranes, ARF–GTP recruits pre-assembled coatomers, resulting in membrane deformation. The cytoplasmic tail of an abundant transmembrane protein, known as p24, binds to COPI through an internal KKXX sequence, promoting vesicle formation [8]. As explained below, KKXX sequences represent a motif that is instrumental in retrieval mechanisms leading to retrograde transport of proteins in the secretory pathway.

Another set of proteins regulates the budding of COPII-coated vesicles. Before COPII-coated vesicles bud from the ER, a specific membrane embedded GEF binds to SarI and catalyzes the exchange of GDP to GDP by SarI. A conformational change in SarI is induced by this GTP–GDP exchange, leading SarI to expose a fatty acid tail normally hidden in the SarI core. This structural change allows SarI to insert at the ER membrane and recruit COPII subunits, which in turn starts the membrane deformation and the vesicle budding process [6]. GTP hydrolysis by SarI and other GTPases can eventually reverse this process, albeit at a slow rate in the absence of a GAP activity. This suggested that coat-recruitment GTPases might regulate temporal aspects of vesicle assembly working by hydrolyzing GTP at a slow, but predictable rate.

Once a membrane bud has formed, additional factors are required to form a discrete transport vesicle. The best-known example is seen with clathrin-coated vesicles. As budding proceeds, clathrin-coated vesicles recruit among other proteins, a soluble GTPase known as dynamin [9]. Dynamin and other binding partners form a complex that bends the membrane at the neck of the budding vesicle. This is achieved by locally distorting the membrane or by changing the lipid composition trough the actions of lipid-modifying enzymes, which are recruited to the dynamin complex. Once in close proximity, the two membranes leaflets fuse, resulting in the final pinching-off of the coated vesicle.

Chaperones of the Hsp70 family later remove the clathrin coat once vesicles are released from the donor membrane [5]. These chaperones are ATPases recruited and activated in a regulated manner by specific protein domains within the membrane-associated protein auxillin. In neuronal cell bodies, clathrin coats need to be removed before transport vesicles undergo active translocation to axonal processes from the Golgi apparatus. Presumably, uncoating allows membrane proteins exposed on the surface of vesicles to be recognized by molecular motors of the kinesin and dynein superfamilies (see Ch. 28). COPI and II coats also need to be removed to permit active translocation by molecular motors and to allow fusion of transport vesicles with a target membrane. GTP hydrolysis by the appropriate coat-recruitment GTPase causes COPI and COPII coats to disassemble. This step is catalyzed by the specific GAP protein ARF GAP in the case of COPI vesicles, and sec23 protein promotes in the case of COPII vesicles [4].

The cytoskeleton appears to have a significant role in the localization of different organelles, as well as in the active transport of vesicles (see Chs 8 and 28). Both microtubules (MTs) and actin filaments appear to be involved in these processes. For example, through its association with the minus end of MTs, the Golgi apparatus is

localized in close proximity with the centrosome. MTs also provide the tracks used by molecular motors for transport of vesicles and organelles throughout the neuron (see Ch. 28). Neuronal cells are highly dependent on these MT-based transport systems, because of their high degree of polarization and their architectural dynamics. The actin cytoskeleton also appears to play a role in vesicle tethering and transport, particularly in the event of regulated secretion, and the synaptic vesicle cycle. Finally, cytoplasmic-linker proteins, or CLIPs, appear to mediate certain types of interactions among vesicles and MTs. CLIP-170 for example, links endosomal membranes to MTs.

SNARE proteins and Rabs control recognition of specific target membranes. Rabs are a family of monomeric GTPases normally localized on the cytosolic face of membranes that aid in vesicular transport specificity [10, 11]. There are more than 30 known Rabs, each showing a distinctive organelle distribution. Targeting to specific organelles is though to be mediated by variable carboxyl terminal sequences, which appear to bind proteins specific to the surface of each organelle [12]. In their active, GTP-bound state, Rabs appear to bind other proteins in the membrane (generally known as Rab effectors), through an exposed lipid anchor.

SNAREs provide specificity to a target membrane and participate in the fusion process. SNARE proteins are transmembrane proteins with a cytoplasmic helical domain. There are more than 20 different SNAREs in each cell, each one associated to a specific membranous organelle [13]. SNAREs exist as complementary sets of v-SNAREs (in the transport vesicles) and t-SNAREs (in the target membranes). The SNARE hypothesis proposes that SNARE molecules are the basis for specificity of membrane fusion [14]. When SNAREs bind, their cytoplasmic helical domains interact to form coiled-coil interactions, which are thermodynamically highly stable. These interactions result in the formation of a stable, four-helix bundle complex known as a *trans*-SNARE pair and brings the two membranes together. Recent *in vitro* experiments indicate a high level of specificity in the interaction between v- and t-SNAREs. Three SNARES in one membrane and one in the other appear to be needed to form a functional complex containing four-helix bundle [15]. If different SNARE combinations display different specificities, this explains how a single SNARE can be involved in several transport steps. Inhibitory proteins provide another level of regulation by binding to t-SNARES, limiting their amount and availability for fusion. SNARE complexes are best characterized in neuronal cells, where they mediate the docking and fusion of synaptic vesicles, two critical steps necessary for the process of neurotransmitter release (see below). SNAREs in the nerve terminal can be targeted and cleaved by botulinum neurotoxins, which causes a block in synaptic transmission.

The *trans*-SNARE pair becomes the *cis*-SNARE pair after fusion (this name is given because after fusion, they are in the same membrane) and disassembly of the *cis*-SNARE complex is necessary for the SNAREs to be reused. An ATPase named NSF catalyzes this step. NSF acts as a chaperone, actively unfolding the coiled-coil interaction between SNAREs with the help of adaptor proteins [14]. Once *cis*-SNAREs are disassembled, v-SNAREs may be returned to the donor membrane for reuse. The regulated disassembly of SNARE complexes by NSF provides the means to control the degree and amount of membrane fusion within cell.

Rabs are also thought to regulate v/t-SNARE recognition, and ultimately vesicle fusion. Rabs and their effectors may modulate vesicle trafficking through different means. Although each Rab member has a discrete localization, a common feature of all Rabs is that they contribute to vesicle tethering near the target site and to the release of SNARE control proteins, thus facilitating v- and t-SNARE recognition. Once GTP is hydrolyzed, the inactive Rab protein moves to the cytosol and becomes available for another transport cycle [10]. GEF and GAP proteins regulate the normal intrinsically low GTPase activity of Rabs. In addition, GDP-dissociation inhibitor (GDI) and GDI-displacement factor (GDF) may regulate association of Rabs with membranes. These proteins are effectors of pathways activated by specific extracellular signaling events, thus linking transport steps to extracellular stimuli [16]. Finally, some Rabs appear to directly link specific organelles and transport vesicles to the cytoskeleton.

Unloading of the transport vesicle cargo to the target membrane occurs by membrane fusion. The fusion event need not happen immediately after vesicle docking. Depending on the target, fusion may be constitutive or regulated. Fusion events are often subject to exquisitely sensitive regulatory mechanisms, i.e., localized Ca^{2+} influx at the presynaptic terminal. Although docking indicates sufficient membrane proximity for proteins to interact, fusion requires a much higher degree of proximity. Membranes must be brought as close as 1–2 nm. This proximity eventually allows lipids to move from one membrane to another. Specific proteins facilitate this high-energy-demanding process by removing water molecules from the cytosolic face of closely opposite membranes. SNARE complex formation appears to help repel water as coiled-coil structures wrap around each other. Although *in vitro* experiments indicate that SNAREs could allow for slow membrane fusion by themselves, accessory proteins appear to assist and regulate membrane fusion events *in vivo* [17].

Fusion events may be homotypic or heterotypic. Homotypic fusion indicates fusion between membranes that originate from the same compartment (i.e. fusion of ER-derived vesicles to form tubular vesicular clusters, see below). Heterotypic membrane fusion indicates fusion of membranes originating from different compartments (i.e. synaptic vesicles and the plasma membrane). Triggered fusion like neurotransmitter release is typically heterotypic.

THE BIOSYNTHETIC SECRETORY PATHWAY INCLUDES SYNTHETIC, PROCESSING, TARGETING AND SECRETORY STEPS

The biosynthetic secretory pathway starts at the rough endoplasmic reticulum with synthesis of components, continues through the Golgi apparatus, and eventually finishes in the cell plasma membrane, secretory vesicles, or lysosomes. Along the way, a variety of processing and packaging events must occur. To facilitate understanding of each step, a functional description of each organelle along the biosynthetic pathway is useful before discussing specific transport steps within this pathway.

Historically, endoplasmic reticulum is classified as rough or smooth, based on the presence (RER) or absence (SER) of membrane-associated polysomes. The biosynthetic pathway of membrane trafficking begins with the rough endoplasmic reticulum (RER). Generally, most protein synthesis occurs on the cytosolic surface of the ER (Fig. 9-3). Shortly after initiation of synthesis, proteins destined for secretion, for service as integral membrane proteins or for residence along the biosynthetic pathway are targeted to the ER lumen by a specific amino-terminal sequence. As new polypeptide chains start to protrude from the ribosomes, they are recognized by the signal recognition particle (SRP), which targets the newly formed polypeptide chain to the cytosolic side of the ER membrane, by means of a specific SRP receptor and a protein complex known as Sec61p [18]. Soluble luminal or secretory proteins are cotranslationally translocated into the ER lumen, through the Sec61p membrane channel, while transmembrane proteins are cotranslationally inserted into the ER membrane directly.

Once in the ER lumen, proteins oligomerize and fold. Proper folding in most cases is facilitated by various isomerases and chaperones resident in the ER. Complex mechanisms exist within the ER to ensure that proteins

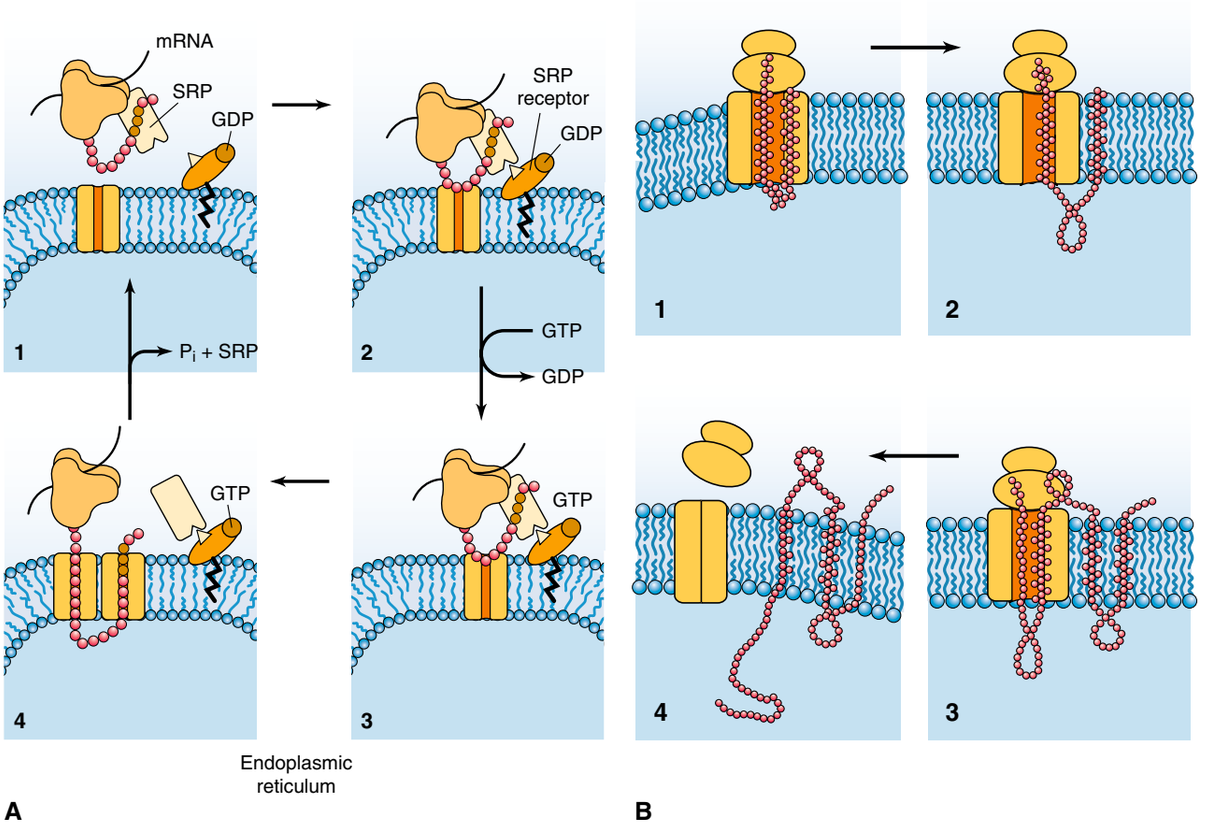

FIGURE 9-3 Insertion of proteins into a membrane. (**A**) Initiation of membrane protein insertion into the endoplasmic reticulum. *1.* Signal-recognition particles (SRP) associate with ribosomes (mRNA), and the signal sequences (darker residue) of nascent membrane proteins. *2.* These complexes associate with SRP receptors in the endoplasmic reticulum membrane. The SRP receptors contain bound GDP. *3.* Bound GDP is exchanged for cytoplasmic GTP, and (*4*) translocation of peptides occurs as GTP is hydrolyzed. The peptides are oriented N- to C-terminal outward as they insert through a membrane. (**B**) The synthesis of polytopic membrane proteins requires multiple sequential steps to generate specific domains including (*1*) the transmembrane segments that involve insertion into the membrane bilayer, (*2*) luminal domains that may eventually project into the extracellular environment and (*3*) cytoplasmic domains. During these steps, the ribosome seals the lumen of the translocator channel. As transmembrane domains are completed, they move laterally into the lipid bilayer, allowing generation of multiple transmembrane domains. *4.* Once translation is complete, the ribosome detaches and the channel closes, leaving an integral membrane protein. Translocation of proteins into the lumen of the endoplasmic reticulum occurs when no transmembrane domains are present.

are correctly folded and multimeric protein complexes correctly assembled before leaving this organelle. For example, some cargo proteins destined to move through the biosynthetic secretory pathway need to be actively recruited into vesicles. This recruitment is mediated by exit signal sequences located on their properly folded surface. ER chaperone proteins, such as Bip, recognize and cover such exit signals in incomplete or improperly folded proteins, thereby impeding their exit from the ER [19]. Such defective proteins may be sent to the cytosol, where they are degraded through the action of the proteasome. In some cases, such as the acetylcholine receptor, 90% or more of the synthesized protein is degraded before it reaches the plasma membrane. Thus, chaperone-mediated quality control mechanisms prevent defective proteins from reaching their normal destinations where they might interfere with the function of normal proteins [20]. A number of human diseases are related to defects in this quality control mechanism, including cystic fibrosis, Tay–Sachs disease (see Ch. 41), and Charcot–Marie–Tooth disease type 1a (see Ch. 36) [21].

The covalent addition of sugars (or glycosylation) is an important part of the proper folding of proteins of many membrane-associated proteins, and this is one of the major functions of the SER (Table 9-1). The majority of proteins destined to the ER itself (membrane and soluble ER proteins), secreted proteins and proteins destined to other organelles in the biosynthetic secretory pathway are in fact sugar-modified proteins, or glycoproteins. Addition of different sugar complexes may be important for the normal function of a protein or for targeting a protein to a particular organelle, but the first stages of glycosylation follow a typical pattern.

Initially, a 14-sugar oligosaccharide containing *N*-acetylglucosamine, mannose and glucose, known as the precursor oligosaccharide, is added *en bloc* to the side chain amino group of an asparagine residue of nascent proteins as they enter the ER lumen. Only asparagines within the consensus sequence NXS/T are modified (where X is any amino acid except proline). This process is also known as N-linked glycosylation, and it is catalyzed by the action of a membrane-bound enzyme known as oligosaccharyl transferase. Proteins in the cytosol are not subject to this kind of modification, because the oligosaccharyl transferase enzyme is oriented in the ER membrane with its catalytically active site facing the ER lumen. Since most proteins are co-translationally imported into the ER, N-linked oligosaccharides are almost always added during protein synthesis. It is thought that N-linked glycosylation is used as a mechanism for recognizing the extent of protein folding, allowing only properly folded proteins to leave the ER.

Most glycoproteins have one mannose and three glucoses removed by specific enzymes while still in the ER. This sugar trimming process has a role in the correct folding of N-linked glycoproteins [22]. For example, specific chaperones such as calnexin and calreticulin bind to monoglucosylated (trimmed) oligosaccharides and assist in their folding. Enzymatic hydrolysis of the remaining glucose in the monoglucosylated protein species leads to dissociation of these chaperones. Proteins not properly folded are enzymatically reglucosylated, recognized again by calnexin or calreticulin and retained in the ER. This process allows the protein to follow the right folding sequence. Improperly folded proteins that cannot be recovered are eventually translocated back to the cytosol, where they are deglycosylated, ubiquitinated and degraded in proteasomes. The abnormal accumulation of unfolded proteins in the ER can eventually trigger a pathway known as unfolded protein response, which leads to the transcription and translation of specific genes that help the ER to continue its appropriate function [23].

TABLE 9-1 Compartmentalization of glycosylation processing steps in the secretory pathway

Compartment	Processing step	Enzymes
Endoplasmic reticulum	N-linked glycosylation	ER mannosidase
	Removal of mannose	Glucosidase I
	Removal of two glucoses	Glucosidase II
cis-Golgi network	Phosphorylation of oligosaccharides in lysosomal luminal proteins	*N*-acetylgalactosaminyl transferase
	O-linked glycosylation	
cis-Golgi cisterna	Removal of mannose	Golgi mannosidase I
medial Golgi cisterna	Removal of mannose	*N*-acetyl glucosamine transferase I
	Addition of N-acetylglucosamine	
trans-Golgi cisterna	Addition of galactose	Golgi mannosidase II
	Addition of NANA	
trans-Golgi network	Sulfation of tyrosines and carbohydrates	α2,6-sialyltransferase
	Addition of sialic acid	
	Selective recognition of M6P by M6P receptor	

Immunoelectron microscopic and biochemical fractionation data on specific processing enzymes have permitted the localization of specific processing steps in the processing pathway for proteins in the Golgi complex. The distribution of many remaining enzymes and steps has not yet been determined. The distribution for each step indicated in this table reflects a significant enrichment rather than an exclusive localization.

Biosynthetic and secretory cargo leaving the ER is packaged in COPII-coated vesicles for delivery to the Golgi complex. These vesicles exit the ER from specialized regions of the ER membrane, devoid of bound ribosomes and known as ER exit sites (Fig. 9-4). These domains are specialized in the generation of COPII-coated transport vesicles. Soon after budding from the ER, COPII-coated vesicles lose their coat and fuse homotypically to form structures known as vesicular tubular clusters, transitional ER, or ER–Golgi intermediate compartment (ERGICs). ERGIC represents an independent ER-derived compartment, which lacks ER-resident proteins.

Two models have been proposed to explain the process of packaging and transport of COPII vesicles from the ER towards the Golgi: the bulk flow transport and selective transport models. Bulk transport proposes that only signals necessary for retention and recycling play a role in the selectivity of cargoes [24]. Proteins without such signals follow a default pathway, which send them to the Golgi apparatus. The selective transport model proposes that proteins are concentrated before packaging by a process involving the recognition of specific exit signals [25]. This model is consistent with the fact that approximately 90% of ERGICs are recycled back to the ER, suggesting active concentration of soluble and membrane proteins from recycling vesicles. However, with some few exceptions, exit signals directing proteins outside ER to Golgi are not well understood. More recent evidence indicates that some cargo proteins are actively recruited to vesicles through exit signals on their surface. These exit signals are recognized by receptor proteins, which also interact with components of the COPII coat. One possibility is that abundant proteins could leave the ER via bulk transport, while certain low-abundance proteins would be packaged by selective transport [26].

Specific retrieval and retention mechanisms allow for the sustained maintenance of the ER's biochemical composition. Shortly after being formed, vesicular tubular clusters start budding COPI-coated vesicles, which retrogradely carry ER-resident proteins and proteins involved in ER budding reaction back to the ER. Thus, the ERGICs sort out proteins by either recycling ER proteins or sending secretory cargo to the *cis*-Golgi. This recycling, known as retrieval transport, is essential for the maintenance of biochemical identity of specific membrane compartments. As a result of retrieval transport, vesicular tubular clusters change their composition as selected proteins are returned to the ER [27]. The retrieval of ER resident proteins depends in turn upon retrieval signals, some of which bind directly to COPI coats, thereby getting packaged in COPI-coated vesicles [28]. Examples of retrieval signals are the KKXX and the H/KDEL amino acid sequences (both names based on the single-letter amino acid code).

The KKXX sequence is present at the carboxyl terminus of ER membrane proteins, while the H/KDEL is present in soluble ER proteins, such as the aforementioned chaperone BiP. Soluble ER proteins containing these sequences bind to receptor proteins such as the Golgi-localized H/KDEL receptor. The KDEL receptor is a transmembrane protein that recognizes and recruits H/KDEL-containing proteins into COPI-coated vesicles that undergo retrograde transport. H/KDEL receptors need to cycle themselves between the ER and the Golgi. To achieve this, H/KDEL receptors affinity towards H/KDEL containing proteins needs to change from very low binding affinity in the ER, to a very high binding affinity while in vesicular tubular clusters and Golgi. Such differences in binding affinities are achieved due to pH-dependent conformational changes in the H/KDEL receptor. Whereas the pH in ER is near neutral, H^+ pumps in the Golgi create slightly acidic conditions and result in high-affinity binding of H/KDEL-containing soluble proteins.

Another potential mechanism for protein retention is that ER proteins bind to each other to form large complexes that cannot be recruited in transport vesicles [27]. This mechanism is known as kin recognition. Because the concentration of resident ER proteins can be very high (some had been estimated in the millimolar range), it can be achieved even with low-affinity interactions among resident proteins.

The Golgi apparatus is a highly polarized structure consisting of a series of flattened cisternae, usually located near the nucleus and the centrosome. Camillo Golgi first discovered the Golgi apparatus while studying neuronal cells, using a staining technique based in heavy metals [29]. Neurons have the most abundant Golgi complement as a result of the high rate of synthesis and processing of membrane proteins in neurons. Golgi localization has been shown to depend on intact microtubules and the action of microtubule motors. Each Golgi stack or cisterna has an entry (or *cis*) face, and an exit (or *trans*) face. The Golgi usually consists of three to eight cisternae, and it can be divided morphologically and functionally in *cis*, medial and *trans*-Golgi. This heterogeneity was demonstrated by the differential distribution of processing enzymes within individual cisterna, particularly for enzymes involved in the glycosylation process (Table 9-1).

The *cis* and *trans* faces of the Golgi apparatus are each associated with a specific compartment composed of interconnected tubular and vesicular structures: the *cis*-Golgi network (CGN) and the *trans*-Golgi network (TGN) respectively. The CGN is thought to originate through the fusion of multiple vesicular clusters. Sorting of proteins is an important process that takes place in these two compartments. After entering the CGN, proteins can either be retrieved to the ER or continue their travel through the Golgi apparatus. Similarly, within the TGN proteins are sorted in different transport packages and sent to their final destinations. Such destinations are specific domains of the plasma membrane (i.e. dendritic or axonal domains), lysosomes, secretory vesicles or earlier compartments in secretory pathway. The TGN is functionally

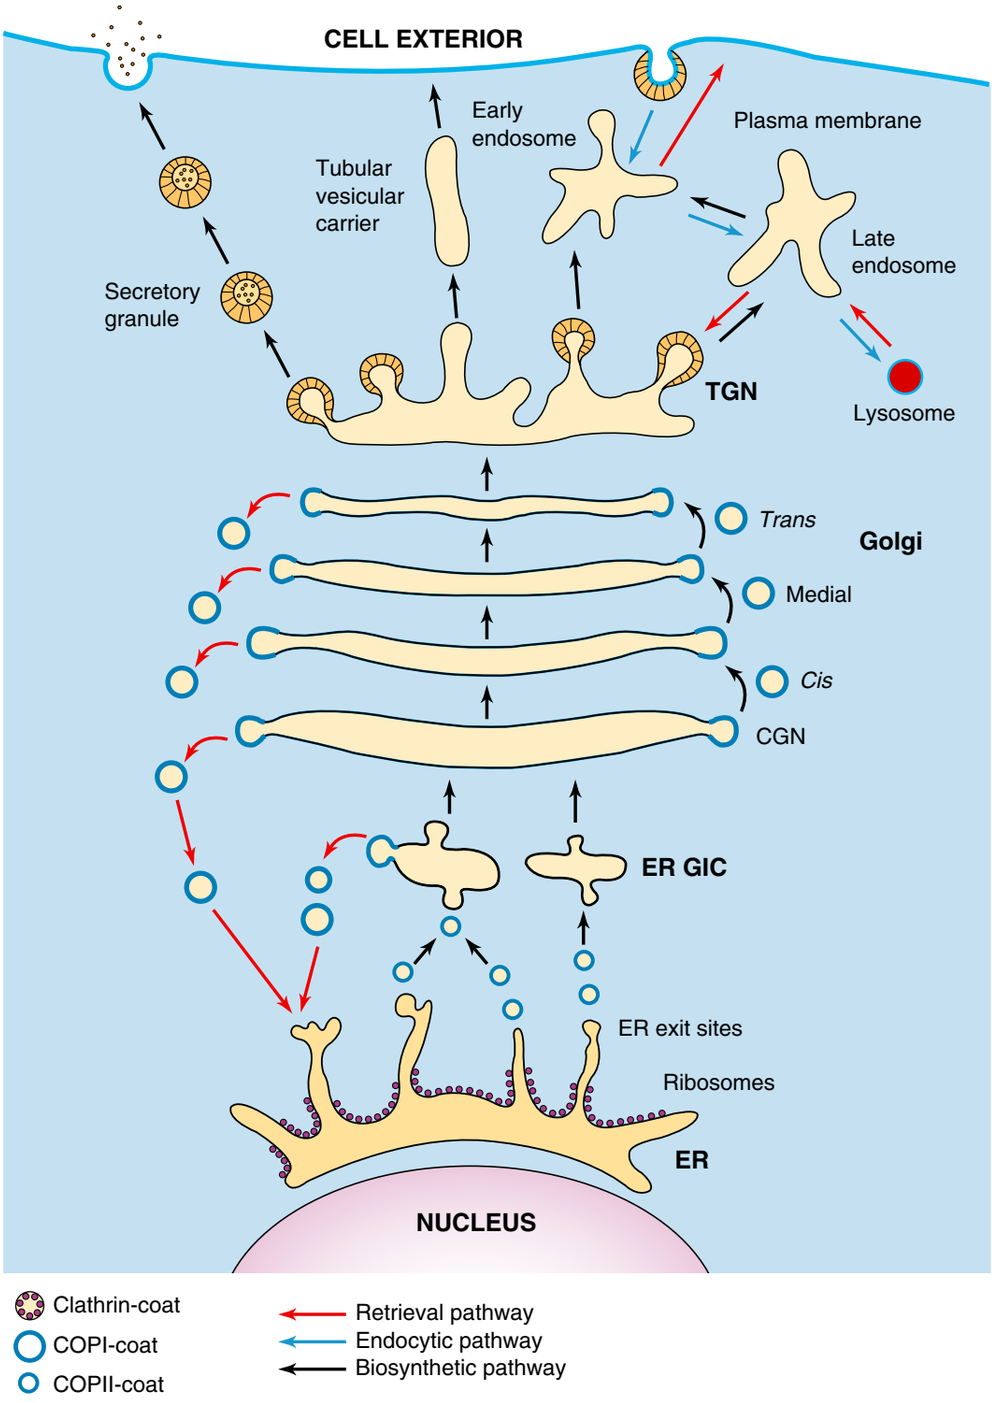

FIGURE 9-4 Schematic illustrating intracellular compartments and major transport steps along the secretory and the endocytic pathways. Intracellular organelles transfer material to each other in the form of transport vesicles. Different coat proteins help in the selection of specific cargoes during different transport steps. In the secretory pathway (black arrows), cargo proteins start their journey by budding off from ER exit sites. These are ribosome-free areas of the endoplasmic reticulum (ER). These proteins are packaged in COPII-coated vesicles, which later fuse to form vesicular clusters (ERGIC). Several ERGICs merge and fuse to form the *cis*-Golgi network (CGN). COPI-coated vesicles mediate the recycling of ER proteins and the transport of cargoes between Golgi stacks. Once in the TGN, proteins get sorted to the plasma membrane, or in some cases to lysosomes. Resident proteins of each organelle along the secretory pathway achieve their localization through specific retrieval mechanisms (*red arrows*). Different types of coated vesicles and tubulovesicular carriers transport cargo to their final destinations. For example, some cargoes reach the plasma membrane and/or the cell exterior by means of secretory granules, while others appear to travel in tubulovesicular structures, or trough recycling endosomes. In the endocytic pathway (*blue arrows*), molecules are internalized in the form of plasma-membrane-derived, clathrin-coated vesicles. These vesicles are delivered to the early endosomes, late endosomes and eventually to lysosomes, where they are degraded. Retrieval pathways allow for the recycling of proteins from the early endosome to the plasma membrane surface, and from the late endosome to the Golgi. Some differentiated cell types have additional pathways in addition to the general ones depicted in this figure, including specialized extremely rapid secretory and recycling pathways for synaptic vesicle proteins in presynaptic terminals.

and morphologically distinct from the stack cisternae in a number of ways. For example, the coat composition of buds derived from TGN (clathrin) differs from those in the Golgi stack (COPI). The TGN is also a location where specific proteins modifications occur, including tyrosine sulfation, proteolytic processing and sialylation [30].

Processing of proteins in the Golgi complex includes sorting and glycosylation of membrane proteins and secretory proteins. Many glycosidases and glycosyltransferases reside within the Golgi apparatus. The great diversity of N-linked oligosaccharide structures on mature glycoproteins results from both the trimming of the original precursor oligosaccharide originally added to proteins in the ER and the addition of further sugars (Fig. 9-3). The result is the formation of complex oligosaccharides and high-mannose oligosaccharides. These two differ in that high-mannose oligosaccharides have no new sugars added to them. High-mannose oligosaccharides contain two *N*-acetylglucosamines and many mannose residues, usually the original number added in the ER. Complex oligosaccharides can contain multiple *N*-acetylglucosamines and a variable number of galactose and sialic acid residues. The formation of both complex and high-mannose oligosaccharides depends largely on their accessibility by processing enzymes in the Golgi [31].

In the Golgi, another mode of protein glycosylation is the O-linked glycosylation. In this process, sugars are added to the OH groups of selected serine or threonine side chains by glycosyl transferase enzymes Typically, *N*-acetyl galactosamine is added first, followed by a variable amount of additional sugar residues, sometimes up to ten.

Finally, the Golgi apparatus is an organelle with an important role in lipid biosynthesis [32]. The enzyme sphingomyelin synthase catalyzes the production of both sphingomyelin and diacylglycerol from the products phosphatidylcholine and ceramide, previously generated in the ER (see Ch. 3). In addition, more complex glycosphingophospholipids are generated in the Golgi.

As these sphingolipids associate with ER-derived cholesterol, they are segregated from unsaturated glycerolipids in the lipid bilayer. These results in a *cis*- to *trans*-Golgi sphingolipid/cholesterol gradient, which translates in increased bilayer thickness. This membrane thickening serves for the selective retention of some Golgi enzymes at the TGN. Golgi-derived vesicles are richer in cholesterol, which causes their lipid bilayer to be thicker than that of the Golgi membrane itself. Thus, only proteins with transmembrane regions long enough to span this thickness can enter transport vesicles at the TGN. This mechanism is consistent with the fact that transmembrane domains of Golgi proteins are approximately five to six amino acids shorter than plasma membrane proteins [33].

The function of protein glycosylation is unknown for most proteins. However, some functional consequences had been established for the glycosylation of certain proteins [34]. In some cases, glycosylation appears to help in the folding process in the ER or to serve a role in protein sorting. For example, carbohydrate binding proteins known as lectins help in ER to Golgi transport, as well as in the sorting process occurring in the TGN [35]. In some cases, specific glycosylation patterns may serve to target a protein to a particular destination, such as the lysosome (see below). Alternatively, glycosylation can influence the stability and or turnover of a protein. Because sugar chains are not very flexible, they tend to protrude from the surface or glycoproteins, potentially limiting the approach of other molecules. For example, the high level of glycosylation on lysosomal membrane proteins makes them resistant to the action of hydrolases.

Glycosylation also plays an important role in cell–cell adhesion (see Ch. 7). Such is the case of glycosylated cell-surface proteins that are recognized by specific lectins known as selectins. The high degree of glycosylation on proteoglycan core proteins also is important on the cell surface. Many proteoglycans are secreted to become components of the extracellular matrix, and others remain attached to the plasma membrane [36].

Proteins and lipids move through Golgi cisternae from the *cis* to the *trans* direction. The addition of sugars to proteins occurs in an organized sequence in the Golgi [37] (Fig. 9-4). Each cisterna is characterized by the abundance of specific processing enzymes. As proteins travel through different cisternae, they are modified successively. In addition, each oligosaccharide-processing enzyme can only accept a glycoprotein as a substrate once a preceding enzyme has processed this protein. Therefore, the processing appears to be ordered both spatially and biochemically. Enzymes catalyzing early steps are concentrated in the *cis* face of the Golgi, with the ones catalyzing downstream processing steps being localized closer to the *trans* face. This localization of specific processing steps in the Golgi apparatus and other organelles in the biosynthetic pathway is shown in Table 9-1. Finally, the lumen of the *trans* compartment appears to be continuous with the TGN, a station where sorting of proteins occurs to target plasma membrane, lysosomes or secretory vesicles.

How the Golgi apparatus maintains its polarized structure while molecules move from one compartment to another is still a matter of debate. Two models were originally proposed based on different experimental evidence (Fig. 9-5): the vesicular transport model and the cisternal maturation model. A third model known as the dual transport model combines elements from both vesicular transport and cisternal maturation models and can better explain intra-Golgi transport.

In the vesicular transport model, individual cisternae represent static structures [38]. Cargo is transported through the Golgi in the form of transport vesicles, which bud from one cisterna and fuse with the next. The vesicular transport model is consistent with the

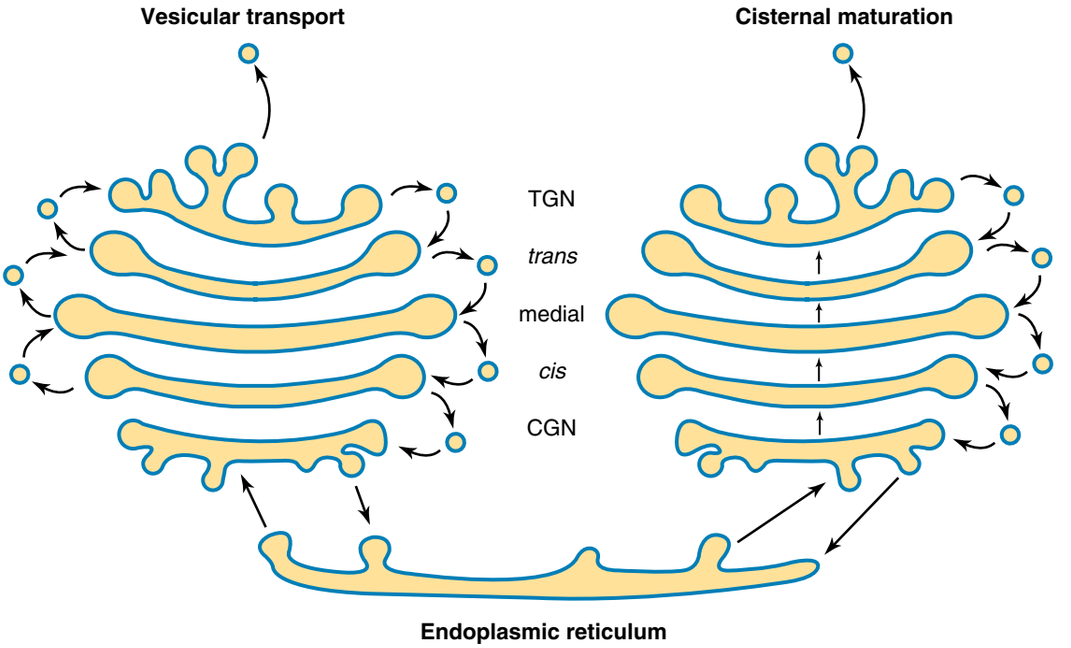

FIGURE 9-5 Two models proposed for intra-Golgi transport. In the vesicular transport model (**left**), cisternae are static, and each cisterna has a unique resident protein composition. Transport vesicles moving forward in the pathway provide the basis for the movement of molecules among cisternae throughout the Golgi. Retrieved proteins are selectively packed and returned in retrograde-moving ones. In the cisternal maturation model (**right**), an individual cisterna matures as it moves forward from the *cis* to the *trans* position in the Golgi. COPI-coated transport vesicles move resident proteins to the preceding cisterna, providing the means for specific localization of processing enzymes within the Golgi apparatus. Notice the absence of forward moving transport vesicles in the cisternal maturation model. An alternative, dual transport model (not depicted here), combines elements of both models and it is likely to represent intra-Golgi transport more accurately.

differential distribution of processing enzymes in each Golgi compartment. Forward moving proteins are selectively packed into forward-moving vesicles, while retrieved proteins are selectively packed and returned in retrograde-moving ones. Alternatively, vesicles move randomly and the flow occurs because of the continuous, specific input at the *cis* cisterna and the corresponding output at the *trans* cisterna. Experimental evidence suggested these cargo-carrying vesicles are COPI-coated vesicles. Movement of vesicles from one cisterna to another is helped by filamentous proteins, which restrict their movement and facilitate their fusion. One problem with this model is that insufficient fusion markers have been identified that would label each compartment. Such markers would be necessary for directional transport among different cisternae in the Golgi. In addition, COPI-coated vesicles appear to be the only type of transport vesicle observed within the Golgi, and they move only retrogradely in the secretory pathway [39]. This evidence is difficult to reconcile with the anterograde movement of vesicles predicted by the vesicular transport model.

These and other inconsistencies fueled the proposal of an alternative model known as the cisternal maturation/progression model [40]. In the cisternal maturation model, cargo is transported in cisternae as they progress through the stacks from *cis* to *trans*-Golgi. Vesicular tubular clusters from the ER fuse to form the *cis* face of the Golgi stack. New *cis* cisternae continuously form and migrate through the stacks as they mature. Although everything moves forward, including enzymes found mainly in early Golgi sacks, a specific distribution of processing enzymes is achieved by a continuous COPI-dependent vesicle retrograde flow [41]. Newly formed cisternae receive their complement of proteins from the one immediately ahead, and later pass them backward to still newer cisternae at the next *cis* position. Documentation of *de novo cis*-Golgi formation, as well as the movement of large molecular structures such as procollagen, which would not fit in a transport vesicle, strongly supported this model [42]. However, a major difficulty faced by the cisternal progression/maturation model is to explain the origin of the TGN, an apparent steady-state compartment that contains a unique set of resident proteins and behaves differently from Golgi stacks in many respects.

The dual-transport model combines aspects of the previous two models [43]. Molecules so large that they would not fit in transport vesicles would move inside maturing cisternae. Bidirectional transport vesicles, on the other hand, would move proteins through the Golgi

more rapidly. Molecular tethers would limit the movement of vesicles, promoting the transfer of cargo between adjacent cisternae, without the requirement for multiple sets of specific SNARE complexes. Regardless of the model proposed, proteins all complete their journey through the Golgi at the TGN, where they are sorted and packaged into specific transport vesicles that target them to specific cell domains and organelles.

Plasma membrane proteins are sorted to their final destinations at the *trans*-Golgi network. Soluble and plasma membrane proteins are delivered to axonal, dendritic or axo-dendritic plasma membrane domains by yet unidentified mechanisms. Axonal and dendritic domains appear to be analogous to the apical and basolateral plasma membrane domain of epithelial cells [44]. The selective enrichment of membrane proteins can be achieved by means of selective protein transport delivery, selective endocytosis and specific retention. Certain proteins appear to be sent directly to each plasma membrane domain by a mechanism involving selective packaging of cargoes at the TGN and attachment to specific molecular motors [44, 45]. Certain apical and basolateral proteins have been observed to leave the TGN in different membrane carriers, and sorting signals have been identified in some protein primary sequences that can direct them to apical or basolateral surfaces of epithelial cells. *In vitro* experiments first suggested that constitutive secretion was carried out entirely in the form of small vesicles. However, more recent imaging experiments using fluorescently tagged proteins in living cells revealed a much more heterogeneous repertoire of membranes moving from the TGN towards the plasma membrane, including large tubulovesicular structures [46].

However, not all proteins proceed directly to their eventual destination. Some proteins relocate from one plasma membrane compartment to another by means of transcytosis. Transcytosis involves endocytosis of selected proteins in one membrane compartment, followed by subsequent transport through early endosomes to recycling endosomes and finally translocation to a different membrane compartment, for example from the apical to the basolateral surfaces. Sorting at the TGN and endosome recycling steps appear to have a primary role in the steady state distribution of proteins in different plasma membrane domains [47]. However, selective retention of proteins at the plasma membrane by scaffolding proteins or selective removal may also contribute to normal distributions. Finally, microtubule-motor regulatory mechanisms have been discovered that might explain the specific delivery of membrane proteins to discrete plasma membrane domains [48].

Lysosomal proteins are also sorted and targeted in the *trans*-Golgi network. Lysosomes are morphologically heterogeneous organelles whose major function is the degradation and digestion of macromolecules (see also Lysosomal Diseases in Ch. 41). They are found in all eukaryotic cells and the lysosomal membrane has a unique composition. ATP-dependent H^+ pumps maintain the low pH of the lysosomal lumen, and transporter proteins move sugars, amino acids and nucleotides resulting from digestion of macromolecules from the lysosomal lumen to the cytosol, where they can be either excreted or reused. The luminal side of this membrane compartment is filled with acid hydrolases, enzymes whose optimal pH is acid to 5.0. The near-neutral pH in cytosol provides a poor environment for acid hydrolases and serves to protect cytosolic components from the activity of any hydrolases that might leak from lysosomes. Nearly 40 different types of lysosomal hydrolase have been described. These include glycosidases, lipases, nucleases, phospholipases and phosphatases. Genetic defects affecting the function of lysosomal hydrolases can lead to human disease, as they usually result in the accumulation of undigested material in lysosomes, often with severe pathological consequences [49]. Examples of these include Hurler's, Niemann–Pick and Tay–Sachs diseases (see Ch. 40).

Several intracellular trafficking pathways converge at lysosomes. Hydrolases and lysosomal membrane proteins are delivered to lysosomes from the TGN (via endosomes), whereas substances destined for digestion are provided to lysosomes by three different pathways: endocytosis, autophagy and phagocytosis (see below). Lysosomal membrane proteins and hydrolases are synthesized first in the rough ER and later transported to the TGN. In the TGN, they are packed in transport vesicles, which are delivered to late endosomes first, and subsequently to lysosomes [50]. Specific targeting mechanisms ensure that these vesicles transport lysosomal proteins while excluding others. In the case of lysosomal hydrolases, this mechanism is based on the selective recognition of a mannose 6-phosphate (M6P) tag, a unique marker for proteins destined to lysosomes [51]. M6P is added specifically to the N-linked oligosaccharides of soluble lysosomal enzymes as they pass through the lumen of the TGN. The signal to add M6P specifically to a glycoprotein is the presence of a motif in its primary sequence known as a signal dispatch. The sequential action of two enzymes then catalyzes the addition of M6P to lysosomal hydrolases. The first is GlcNAc phosphotransferase, which binds the hydrolase and adds GlcNAc-phosphate to one or two mannose residues on each oligosaccharide chain. The second enzyme removes the GlcNAc residue, leaving a M6P behind. Most hydrolases contain multiple oligosaccharides, thus finishing with several M6P. This appears to facilitate the high-affinity signal for the M6P receptor. A M6P receptor in the TGN recognizes and binds to M6P on the luminal side and to adaptins on the cytosolic side of assembling clathrin-coated pits in the Golgi [52]. This allows selective packaging of lysosomal directed

proteins in the TGN for transport to a late endosome in the form of clathrin-coated vesicles.

The retrieval mechanism for the M6P receptor resembles the one previously described for the H/KDEL receptor [53]. Optimal binding of M6P receptor to M6P occurs at pH 6.5–6.7, the pH found in the TGN. When transport vesicles arrive at late endosomes, the pH is lowered by the action of H^+ pumps. The affinity of the M6P receptor for its ligands is reduced at acid pHs, resulting in M6P receptor releasing the M6P in the late endosome. As a result, transport of lysosomal hydrolases occurs unidirectionally. Once the M6P receptor releases M6P-bearing hydrolases, the receptor can be returned to the TGN for reuse. Transport of the M6P receptor to either TGN or late endosome relies on signal peptides on the cytoplasmic tail region of the M6P receptor.

Under some circumstances, lysosomal hydrolases may fail to be properly packaged in the TGN, so they enter the default pathway to the cell surface, where they are secreted. Although these hydrolases do little harm at the nearly neutral pH of most extracellular fluids, they can also be returned to lysosomes by a pathway known as receptor-mediated endocytosis. In this pathway, M6P receptors are sent to the plasma membrane, where they bind escaped lysosomal hydrolases and bring them back to lysosomes through the early and late endosomes. Receptor-mediated endocytosis is a major component of the endocytic pathways for trafficking of membrane proteins and merit more detailed consideration.

Both constitutive and regulated neuroendocrine secretion pathways exist in cells of the nervous system. Vesicular proteins and lipids that are destined for the plasma membrane leave the TGN sorting station continuously. Incorporation into the plasma membrane is typically targeted to a particular membrane domain (dendrite, axon, presynaptic, postsynaptic membrane, etc.) but may or may not be triggered by extracellular stimuli. Exocytosis is the eukaryotic cellular process defined as the fusion of the vesicular membrane with the plasma membrane, leading to continuity between the intravesicular space and the extracellular space. Exocytosis carries out two main functions: it provides membrane proteins and lipids from the vesicle membrane to the plasma membrane and releases the soluble contents of the lumen (proteins, peptides, etc.) to the extracellular milieu. Historically, exocytosis has been subdivided into constitutive and regulated (Fig. 9-6), where release of classical neurotransmitters at the synaptic terminal is a special case of regulated secretion [54].

All eukaryotic cells possess an unspecialized exocytic pathway known as the constitutive secretion. Vesicle membranes in this pathway fuse with the plasma membrane without any extracellular signal. As noted above, proteins destined for the secretory pathway are sorted at the level of the TGN. Proteins to be transported to the plasma membrane are directed into a constitutive secretory pathway.

THE ENDOCYTIC PATHWAY PLAYS MULTIPLE ROLES IN CELLS OF THE NERVOUS SYSTEM

Most pathways in the endocytic system are shared with cells in general, but a special case exists in synaptic vesicle cycling, which is unique to neurons and a keystone in neuronal function. Three categories will be considered here: endocytic processes important for degradation of macromolecules and uptake of nutrients; constitutive and regulated neuroendocrine secretion; and receptor-mediated endocytosis. Synaptic vesicle cycling will then be considered separately and in greater detail.

Endocytosis for degradation of macromolecules and uptake of nutrients involves phagocytosis, pinocytosis and autophagy. The cellular processes by which macromolecules, particulate substances and even other cells may be taken up in a regulated fashion are an important subset of endocytic pathways [55]. These processes may also be important for invasion of the nervous system by viral vectors. There are three general mechanisms for uptake: phagocytosis for engulfing macromolecules, particles and cells or viruses; autophagy for degradation of intracellular organelles and aggregates; and pinocytosis for uptake of smaller molecules and fluids.

Phagocytosis involves the uptake of large materials such as microorganisms or dead cells via large vesicles named phagosomes. The material to be internalized is wrapped up by a special portion of the plasma membrane that invaginates first and then after a regulated molecular mechanism event pinches off forming an endocytic vesicle carrying the phagocytosed material. The usual vesicle diameter size is >200 nm. Phagocytosis of large particles was developed early in the evolution; unicellular organisms use this type of endocytosis as a way to get nutrients and the phenomenon is most familiar in macrophages. Phagocytosed particles via phagosomes fuse with lysosomes; after a digestion process the metabolized products are released into the cytosol to be consumed as nutrients by the organism.

In multicellular organisms, phagocytosis has been developed as a defensive mechanism rather than for feeding purpose and is largely carried out by specialized cells in mammalian tissues. Three different white blood cells commonly exhibit phagocytosis in mammals: macrophages, neutrophils and dendritic cells. These different cell types posses a unique and complex function; they protect us from infections by phagocytosing the invading agents and they also take care of dead or senescent cells throughout the organism. In the nervous system, phagocytosis is normally conducted only by a specific type of glial cell: microglia, which are a specialized type of macrophage [56, 57]. The function of these cells in the normal healthy brain is not very well known, but when these cells detect brain damage they proliferate, migrate to the site of

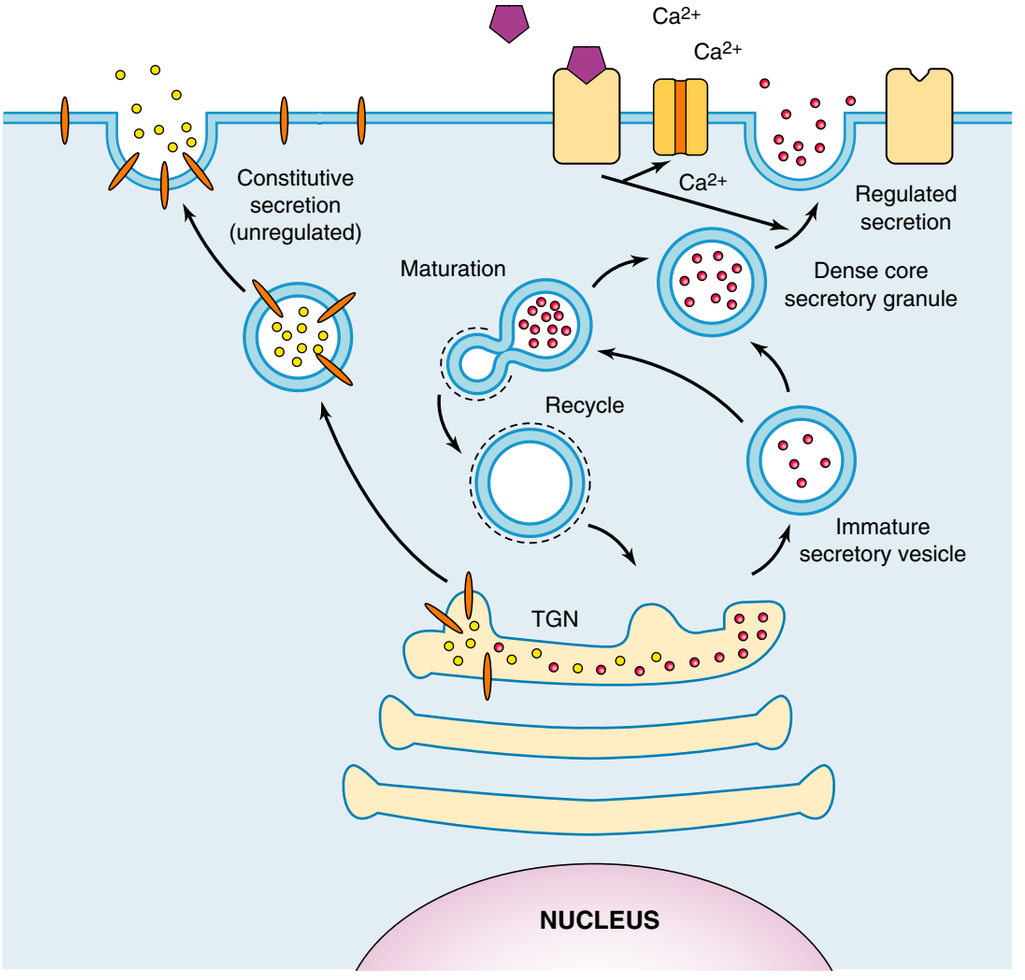

FIGURE 9-6 The constitutive and regulated secretory pathway. Eukaryotic cells determine the fate of newly synthesized proteins and lipids destined to the plasma membrane at the TGN. Eukaryotic cells developed two different exocytic pathways, one called constitutive secretion, which is an unregulated or default pathway, and a second one, which is triggered by extracellular signals, known as regulated secretory pathway because it is tightly coupled to extracellular stimuli. Lipids, secreted proteins and integral membrane proteins lacking a particular sorting signal are packaged into a common type of vesicles in the *trans*-Golgi network (TGN). Once the transport vesicle buds off, it is steadily delivered to a common domain within the plasma membrane via the constitutive secretory pathway. This constitutive pathway typically provides the cellular plasma membrane with newly synthesized lipids and integral membrane proteins (*blue*). In addition, some secreted proteins like extracellular matrix materials may be released constitutively as they are synthesized (*yellow*). Specialized secretory cells such as neurons and endocrine cells to a great extent developed more selective exocytic pathways known collectively as the regulated secretory pathway. These pathways form the basis for interneuronal communication. In this pathway the exocytic event is triggered by a specific extracellular signal, allowing for a tight regulation of secretion. The regulated secretory pathway is mainly responsible for the release of specific cellular products such as hormones, peptides and neurotransmitters. The peptides, hormones and other targeted molecules (*red*) are also sorted and concentrated in the TGN and packaged into immature secretory vesicles with a distinctive polypeptide composition. After the vesicle buds off of the TGN, they undergo a maturation process that is needed to concentrate them further and create a secretion-competent secretory granule. The secretory granules that contain protein or peptides often exhibit a dense core in electron micrographs and are called dense core secretory granules or vesicles. This maturation process often includes a series of steps that require formation of clathrin coats and recycling of membrane and membrane components to the TGN. Release of secretory granule contents requires binding of a ligand (*dark orange pentagon*) to a membrane receptor (*light orange*), which triggers movement of secretory granules closer to the plasma membrane and an influx of Ca^{2+} through a specific channel (*dark orange*) that is required for membrane fusion and release. A specialized variant of these pathways, which is extremely rapid, is found in presynaptic terminals.

injury or disease, turn on their macrophage capabilities and engulf pathogens and cellular debris (see Ch. 1). In addition, vascular macrophages and related cells may on occasion be seen in nervous tissue, particularly in response to disease or damage.

Phagocytosis is a tightly regulated process that is initiated by a specific signal at the plasma membrane that is transmitted to the cell interior, which in turn initiates and regulates the phagocytosis process [55]. There are different signaling initiators to triggers phagocytosis; the best characterized are antibodies. Antibodies bind specifically to the surface of the invader organism leaving the fc region of the antibodies exposed to the exterior. These antibody fc regions are recognized by specific surface receptors on the macrophages and neutrophils, which turn on the phagocytosis machinery. Negative charges on the cell surface of dead cells or cell debris can also trigger phagocytosis. There are also inhibitory signals displayed on the surface of living cells that prevent the activation of phagocytosis pathway. One practical use of phagocytosis is for tracing of neuronal pathways after labeling with specific markers like Fluorogold or horseradish peroxidase.

Pinocytosis involves the internalization of liquids and solutes via small pinocytic vesicles with around 40–100 nm in diameter size [55]. Unlike phagocytosis, pinocytosis is a constitutive process in almost all eukaryotic cells. Cells need to internalize fluids and solutes via small pinocytic vesicles, usually clathrin-coated vesicles around 40 nm in diameter. Many of these small membrane vesicles later return to the plasma membrane by exocytosis in non-growing or stationary cells after passage through a sorting endosome. Cells must keep endocytosis and exocytosis processes tightly balanced, otherwise within time the cell would run out of plasma membrane. Under normal circumstances, the volume and area of the cell in a stationary phase does not change during the endocytic–exocytic events even when rates of exocytosis become quite high, as in the presynaptic terminal. The two linked processes should then be viewed as a continuous endocytic–exocytic cellular cycle. The rate and extent of membrane internalization by pinocytosis varies among cell types. Some are extremely large such as secretory cells and macrophages, which may internalize as much as a quarter of its own volume in one hour. Some unicellular organisms can endocytose their entire plasma membrane even faster, in less than an hour.

Caveolae represent membrane invaginations of cholesterol- and sphingolipid-rich membrane domain. They are thought to mediate the transport of serum proteins into endothelial cells for transcellular transfer across the endothelium and may play a role in signaling pathways including nitrous oxide [55]. The major protein described in association with caveolae is caveolin, although its functions are not fully understood. Curiously, caveolin-null mice are phenotypically normal although subtle changes in specific cell types can be seen. Caveolae are particularly abundant on endothelial cells but can be detected on most cell types. They are not very abundant in neurons but may be important in NO signaling from endothelial cells of the brain.

The bulk of pinocytosis in the nervous system is mediated by clathrin-mediated endocytosis (CME) [55] and this is the best-characterized pathway. More detail about clathrin-mediated pathways will be given when receptor-mediated endocytosis and the synaptic vesicle cycle pathways are considered. Pinocytosis through CME is responsible for uptake of essential nutrients such as cholesterol bound to low density lipoprotein (LDL) and transferring, but also plays a role in regulating the levels of membrane pumps and channels in neurons. Finally, CME is critical for normal synaptic vesicle recycling.

Other pinocytotic pathways also exist that do not depend on either caveolae or clathrin, although these are not as well defined [55]. Specific receptors continue to be internalized in the absence of clathrin or caveolin and these pathways can be monitored by following glycosyl phosphatidylinositol (GPI)-anchored proteins. Nonclathrin, noncaveolin pathways may also be responsible for the reuptake of membrane in neuroendocrine cells after stimulated secretion. Some, but not all, of these pathways appear to require dynamin.

Autophagy involves the disposal of the obsolete part of the cells such as mitochondria, or SER. Three categories of autophagy have been described in cells [58] and all can be seen in the nervous system. Macroautophagy is typically accomplished by envelopment of organelles with an intracellular membrane known as an isolating membrane to form a double membrane structure known as an autophagosome [59]. The engulfment isolates the organelle from the cytoplasm and the compartment may then be acidified. Eventually, the autophagosome fuses or is engulfed by a lysosome for degradation. Macroautophagy is induced by stress and may be seen following nerve or axonal damage [58]. For example, resorption of myelin by Schwann cells in peripheral demyelination or wallerian degeneration is a dramatic example of macroautophagy.

Microautophagy is a constitutive pathway that is normally responsible for turnover of organelles [58]. Unlike macroautophagy, there is no initial isolating membrane. Instead, the organelle fuses or is directly engulfed by the lysosome and degraded. This is an important pathway for recycling amino acids and other biological building blocks. Microautophagy may also be important for degradation of protein aggregates associated with neurodegeneration. This is the only pathway available for degradation of insoluble aggregates and may be neuroprotective. Autophagic structures may be prominent in Parkinson's and Huntington's disease and amyotrophic lateral sclerosis, but the extent to which this is a neuroprotective pathway is unclear [60]. Indeed, a combination of micro- and macroautophagy plays a key role in type II/nonapoptotic programmed cell death [58, 59]. In type II programmed cell death, organelles are isolated and degraded, but the cytoskeleton is spared. Type II programmed cell death is

seen in many developmental programmed cell death events.

Chaperone-mediated autophagy is a mechanism for importing cytoplasmic proteins into lysosomes for degradation [58]. This pathway has only been documented in mammalian cells to date and its cellular functions are not well defined. This process is analogous in some respects to the ubiquitin/proteasome pathway. Proteins targeted for degradation are tagged with a particular KFERQ peptide motif, which is recognized by a chaperone. The chaperone–protein complex binds to a specific lysosomal membrane receptor for import into the lysosome and degradation. Autophagic profiles are common features of the aging brain and include some of the characteristic histological features of the aging brain (lipofuscin, ceroid, multivesicular bodies, etc.) [61]. Neuronal accumulations of autophagic profiles become even more prominent in diseases of the aging brain such as Alzheimer's and Parkinson's disease.

The constitutive pathway is also known as the default pathway because it does not require any type of signal to enter. However, proteins in this pathway are sorted into packages in which the constituents have a common destination. For example, molecular components of the active zone in the presynaptic membrane appear to be transported as a prepackaged dense core vesicle [62]. Thus, active zone scaffold proteins such as piccolo, bassoon and rim are present in the same transport vesicle, but synaptic vesicle proteins such as synaptophysin and synaptobrevin are not present. Components of other functional microdomains in the neuronal plasma membrane such as nodes of Ranvier and the postsynaptic densities may be similarly packaged into discrete vesicles with unique destinations. This is likely to be a general feature of cells with specialized functions and distinct domains, including neurons and glia in the nervous system. However, the full complement of proteins needed in a particular membrane domain may not be packaged together in the TGN and local assembly of functional complexes such as ion channels may still be necessary.

The constitutive pathway has not been studied as intensively as regulated secretion [54]. In particular, relatively little is known about targeting and regulatory mechanisms for these transport vesicles. Clathrin seems not to be directly involved in the constitutive secretory pathway. Antibodies that disrupt clathrin assembly *in vitro* inhibit endocytosis, but constitutive exocytosis is not affected [63].

Secretory cells, including neurons, also possess a specialized regulated secretory pathway. Vesicles in this pathway have soluble proteins, peptides or neurotransmitters stored and concentrated within secretory vesicles. At that point, these vesicles are actively transported to a site for extracellular delivery in response to a specific extracellular signal. Exocytosis through regulated secretion accomplishes different functions, including the release of hormones, peptides and neurotransmitters. Exocytosis through the regulated secretory pathway is the primary basis for intercellular communication in the nervous system.

At least two classes of regulated secretion can be defined [54]. The standard regulated secretion pathway is common to all secretory cells (i.e. adrenal chromaffin cells, pancreatic beta cells, etc.) and works on a time scale of minutes or even longer in terms of both secretory response to a stimulus and reuptake of membranes after secretion. The second, much faster, neuron-specific form of regulated secretion is release of neurotransmitters at the synapse. Release of neurotransmitters may occur within fractions of a second after a stimulus and reuptake is on the order of seconds. Indeed, synaptic vesicles may be recycled and ready for another round of neurotransmitter release within 1–2 minutes [64]. These two classes of regulated secretion will be discussed separately after a consideration of secretory vesicle biogenesis.

Our information about protein secretion was developed through studies with a variety of secretory cells over more than 30 years. Secretion is a multistep process that involves vesicle biogenesis, cargo loading, concentration and processing, vesicle transport and targeting, vesicle docking and Ca^{2+}-dependent vesicular fusion with the plasma membrane. In response to physiological demands, cells synthesize, concentrate and store secretory products into membrane-bounded organelles called variously secretory vesicles, secretory granules or dense core vesicles (named after dense core or electron opaque content in electron micrographs).

Regulated secretion is easily recognized and distinguished from constitutive secretion. First, regulated secretion is linked to an extracellular stimulus. Regulated exocytosis via vesicle membrane fusion is triggered by different stimuli, which in turn results in a transient local rise in intracellular Ca^{+2} that leads to fusion of the vesicle membrane with the plasma membrane and concomitant release of vesicle contents to the extracellular space. Second, the secretory products are concentrated into specialized vesicles that are morphologically distinct and abundant in secretory cells. Finally, the secretory vesicles are transported to cellular locations near release sites and significant numbers are subsequently stored in the cytoplasm as a ready releasable pool for further utilization. This means that secretory cells synthesize, package and store a few specific secretory products that are not released in significant amounts until a specific physiological stimulation is received.

Secretory vesicle biogenesis requires completion of a characteristic sequence of steps before they are competent for secretion. Secretory cells typically invest a substantial fraction of their biosynthetic capacity for generation of secretory vesicles and their secreted products. Neurons devote a particularly high fraction of their biosynthetic activity to the synthesis and assembly of secretory organelles. In secretory cells, the bulk of newly synthesized

membrane and membrane-associated proteins may be devoted to generation of the secretory vesicles, sometimes referred to as secretory or dense core granules. The extensive Nissl substance (mostly RER) and large Golgi complexes seen in neurons reflect this biosynthetic activity and both structures were first described in neurons.

Neurons have multiple types of secretory vesicles whose secretion and biogenesis differ. The typical dense core vesicles (75–95 nm), which deliver protein and neuropeptides to the extracellular space by the classic regulated secretory pathway; and more numerous smaller vesicles (40–50 nm), known as synaptic vesicles specialized in the store and delivery of small neurotransmitters such as acetylcholine, glutamate, glycine, γ amino butyric acid (GABA) and monoamines. Most small, classical synaptic vesicles are electron-lucent, but those containing noradrenalin may also have a dense core in electron micrographs. In contrast, secretory granules in endocrine or neuroendocrine cells may be significantly larger, as much as 165 nm in diameter [65].

The specific molecular signals that drive the packaging and aggregation of secreted proteins or their characteristic integral membrane proteins into distinct secretory vesicles within the TGN are currently unknown. Standard secretory vesicles emerge as immature vesicles from the TGN of the Golgi complex. The size of these immature secretory vesicles is heterogeneous but all have a dense core. This core of aggregated proteins is separated from the vesicle membrane by a space filled with undetermined material, forming a halo-like structure. As secretory vesicles mature, they lose volume and surface area and their contents become concentrated as the result of coordinated retrieval of membrane that is recycled back to the late endosomes and TGN, and the internal vesicle acidification as a consequence of progressive concentration of protons by pumps in the vesicular membrane.

Biogenesis of synaptic vesicles in neurons differs in some important respects from generation of secretory granules [66]. Most vesicles being transported from the neuronal cell body down the axon are actually tubulovesicular structures, 50 nm in diameter and with variable lengths [67] rather than the typical 50 nm synaptic vesicle profiles. Moreover, evidence suggests that not all synaptic vesicle components are transported in the same vesicle [68]. Thus, synaptic vesicle precursors may not be competent to serve as synaptic vesicles. The evidence now suggests that some or all synaptic vesicles are locally assembled in presynaptic terminal regions following an intermediate exocytosis and endocytosis event (see below). Subsequently, they are reconstituted as complete synaptic vesicles in the early endosome compartment. Consistent with this, synaptic vesicles are typically recycled many times and locally filled with neurotransmitter for reuse within minutes, unlike neuropeptide secretory granules, which can be used only once for secretion [64]. However, neurotransmitter vesicles containing noradrenalin are filled with transmitter during transport, leading to their characteristic dense core in electron micrographs. As a result, there may be some heterogeneity in synaptic vesicle biogenesis.

Once secretory vesicles are loaded with their cargo, they pinch off from the TGN and are actively transported to the specific subcellular site, in which they fuse and release the cargo. These sites may be quite far from the site of packaging and processing in the Golgi complex. For example, neurons transport secretory vesicles carrying neuropeptides from the cell body (where peptides are synthesized and packaged into secretory vesicles) down the axon to the nerve terminals, which in some neurons can be a meter or more away. Secretory vesicles are transported to sites of release through the action of microtubule-based motor proteins. In neurons, these transport processes are collectively known as axonal transport (see Ch. 28). The fates of different secretory vesicles once they reach the plasma membrane may vary. Ones carrying cargo to be constitutively secreted will fuse with the plasma membrane once they arrive at their destination. In contrast, those carrying material to be secreted via regulated exocytosis pathways remain near the plasma membrane without fusing until a signal arrives that triggers vesicle fusion with the plasma membrane.

As secretory vesicles mature, many secretory polypeptides undergo post-translational modifications. Many hormones and neuropeptides as well as hydrolytic enzymes are synthesized as inactive polypeptide precursors that need to undergo proteolysis to become active. This maturation process usually starts in the TGN and continues in the secretory vesicles, but may be completed in the extracellular space soon after exocytosis takes place in some cases. The maturation process for neuropeptides is described in Chapter 18.

Retrieval of membrane components in the secretory pathway through receptor-mediated endocytosis (RME) is a clathrin-coat-dependent process [5]. The clathrin coat provides stability to the vesicle core and allows uptake of specific membrane proteins for reuse or degradation. RME shows a remarkable degree of specificity, allowing cells to internalize with astonishing efficiency only those selected molecules independent of their extracellular concentration.

Extracellular ligands (hormones, neurotrophins, carrier protein, adhesion molecules, small molecules, etc.) will bind to specific transmembrane receptors. This binding of specific ligand induces the concentration of the receptor in coated pits and internalization via clathrin-coated vesicles. One of the best studied and characterized examples of RME is the internalization of cholesterol by mammalian cells [69]. In the nervous system, there are a plethora of different membrane receptors that bind extracellular molecules, including neurotrophins, hormones and other cell modulators, being the best studied examples. This type of clathrin-mediated endocytosis is an amazingly efficient process, capable of concentrating

receptors several hundredfold and taking up large quantities of specific molecules. As a result, even a very dilute extracellular ligand can be internalized without taking up a correspondingly large amount of extracellular fluid.

In the CNS, neurons are highly dependent on a continual supply of small polypeptide growth factors with neurotrophic activity (see Ch. 27). This process requires the binding of the secreted polypeptides to specific transmembrane receptors with an intrinsic tyrosine kinase activity on their cytoplasmic domains (Fig. 9-7). Upon binding of peptide growth factor, these receptor tyrosine kinases (RTKs) activate their intrinsic tyrosine kinase activity and induce RME [70]. The sequence of events typically follows a pattern of ligand binding, followed by RTK dimerization and activation of the kinase activity. Once activated, RTKs autophosphorylate on specific cytoplasmic tyrosines and phosphorylate other associated proteins, which recruit proteins containing Src-homology II (SH2) and phosphotyrosine-binding domains. Among these are linking proteins and adaptor proteins for assembly of a clathrin coat. The signaling induces internalization and continues as the RTKs are packaged and returned to the cell body [71].

Cells control the amount of receptors on their surface as well as the level of extracellular ligand by regulating rates of RME, balanced by insertion of new receptors. The internalization of activated receptors through clathrin-coated pits and their translocation to endosomes lowers the number of receptors in the plasma membrane, a process known as downregulation. Cells reduce or attenuate the receptor-mediated intracellular signaling via this downregulation. Alternatively, removing the extracellular ligands via RME will also attenuate intracellular signaling [72]. Thus, intracellular signaling and endocytosis are tightly linked, although many questions remain to be answered [71, 72].

Electron microscopic studies on cells stimulated simultaneously with different labeled ligands indicate that RME can concentrate up to a thousand of different transmembrane receptors in a single clathrin-coated pit. In the canonical model of clathrin-mediated endocytosis, these clathrin-coated pits of the plasma membrane bud off to form clathrin-coated vesicles. These coated vesicles rapidly lose their clathrin coats through the action of a chaperone from the Hsp70 family, an event that facilitates local fusion with early endosomes (EEs). The various endocytic vesicles fuse with the membrane of the same EEs soon after shedding their clathrin coats. However, the fate of various ligand-receptor complexes varies according to their physiological role and cellular demand.

In non-neuronal cells, electron microscopy studies reveal very complex endosomal compartments composed of a highly dynamic array of heterogeneous tubulovesicular-membrane structure extending from close vicinity to the plasma membrane to the cell interior, reaching the boundaries of the Golgi apparatus. Presynaptic terminals have similar endosomal systems, albeit less extensive [73, 74].

The endocytic pathway also contains functionally and physically discrete compartments [75]. EEs are slightly acidic (pH 6.0–6.8), which induces the dissociation of many, but not all, receptor–ligand complexes. Free receptors may then concentrate in the tubular portion of EEs, where they bud off to form recycling vesicles, which transport receptors that are directly or indirectly returned to the plasma membrane. Free ligands are kept in the vesicular portion of the EEs. Depending on the ligand and the cell, ligands that provide essential cellular components (transferrin, etc.) can be actively transported to the perinuclear region of the cell where they fuse with late endosomes (LEs) and the ligand is delivered to the appropriate compartment. Alternatively, once the ligand is transported to the perinuclear region of the cell and LE, the LE will fuse with lysosomes where ligands may be degraded by the lysosomal enzymes in an acidic environment (pH 5.0). Lysosomal enzymes are transported from the TGN to the LEs and lysosomes via the same type of clathrin-coated vesicles. Thus, clathrin-coated vesicles generate vesicular structures designed to fuse with endosomes independent of their origin, either the plasma membrane or the TGN.

EEs with their slightly reduced pH are sorting compartments responsible for the dissociation and sorting of the ligands to the LEs and lysosomes as well as for directing receptors back to the plasma membrane for reuse. So EEs act as the first sorting station in the endocytic pathway. EEs also play an important role in synaptic vesicle recycling (see below). LEs serve to concentrate and sort endocytosed material further, including for delivery to lysosomes where both endogenous and exogenous macromolecules are digested.

Ligand–receptor complexes that do not dissociate in the EEs have different fates. In some cells, they may be returned to the same plasma membrane compartment from which they originated, whereas in polarized cells such as endothelial cells or astrocytes they can be moved to a different plasma membrane domain, resulting in transcytosis. In other cases, the complexes go to LEs and lysosomes for degradation. In neurons, these vesicles may serve as signaling organelles that are transported from the EEs back to the cell body where they influence gene expression [71].

Details of the mechanisms by which endocytosed material moves from the early to the late and lysosomal compartment are still poorly understood. However, portions of the EEs tubulovesicular structures may be actively transported along microtubules towards the perinuclear region of the cell in both neurons and non-neuronal cells. These endosomes on the move may enclose invaginated membranes and also internally bud off vesicles. For that reason, these complex structures are called multivesicular bodies (MVBs) [76]. Material returning by retrograde axonal transport to the neuronal cell body includes many MVBs [67]. The eventual fate of these structures may vary. Some MVBs may fuse with LEs or they may fuse with each

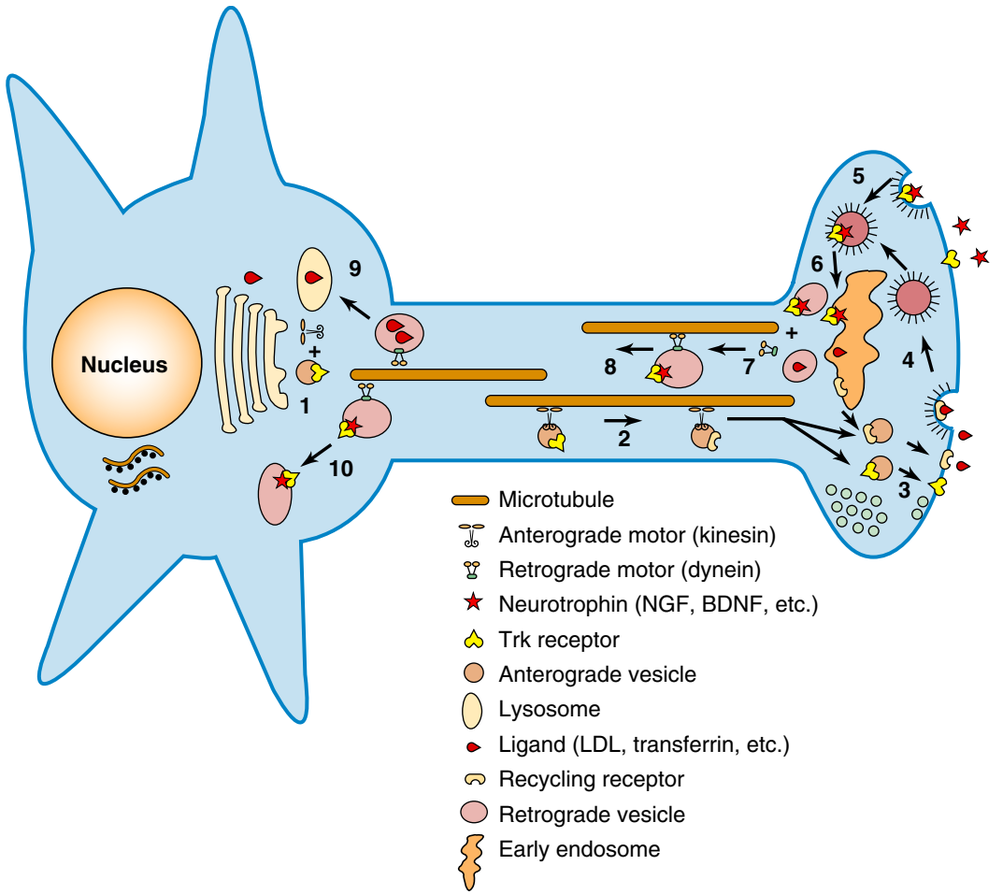

FIGURE 9-7 Receptor-mediated endocytosis. Many kinds of extracellular polypeptides and ligands (including hormones, carrier proteins, adhesion molecules, neurotrophins, etc.) are imported into the cell with a high degree of specificity via a special type of clathrin-mediated endocytosis. A high degree of molecular specificity is achieved through binding of ligands to specific receptors localized within discrete domains of the plasma membrane. The unique dependence on membrane receptors for the internalization of these different extracellular molecules led to the name of receptor-mediated endocytosis. Endocytosis through this pathway ensures the internalization of selected molecules independent of the extracellular concentration of the ligand, As a result, even very dilute extracellular ligands can be internalized without taking up a correspondingly large quantity of extracellular fluid. One of the best-studied receptor-mediated endocytosis pathways is the internalization of neurotrophins along with their specific receptor tyrosine kinase receptors (RTK). The internalization of the neurotrophins and growth factors is achieved through a well-defined sequence of events: *1*. Receptors are synthesized and packaged in the Golgi. Anterograde motors (kinesin) are added to the newly formed vesicles, then (*2*) the vesicles are transported along microtubules to the appropriate membrane domain, where (*3*) the receptors are inserted into the plasma membrane. This typically occurs through a form of targeted constitutive secretion. *4*. Binding of a suitable ligand to a typical recycling receptor like the LDL receptor or the transferrin receptor leads to formation of a coated pit and coated vesicle. The coat is removed and the interior of the endocytosed vesicle is acidified leading to dissociation of receptor and ligand, followed by fusion with an early endosome (EE). *5*. Alternatively, stimulation of cells with a neurotrophin or a growth factor results in the clustering of the growths factor-RTK into clathrin-coated pits. Ligand-RTK complexes are internalized by regulated clathrin-mediated endocytosis but the receptor ligand complex does not dissociate. Clathrin-coated vesicles carrying the growth factor-RTK complexes shed their clathrin coats soon after internalization, before being translocated and fused with EEs. *6*. In the EE, receptors are sorted. If ligands and receptors are dissociated by the slightly acidic pH in the EEs, the receptor is typically recycled back to the plasma membrane to participate in a new cycle of endocytosis. *7*. The ligands are then packaged into a vesicle for return to the cell body. However, neurotrophins remain bound to their RTKs and are sorted into a specialized retrograde endosome that may continue to signal. At this stage, the retrograde motor (dynein) is added to the vesicle. *8*. Retrograde vesicles containing ligands or growth factor-RTK complexes are actively transported returned by retrograde axonal transport (see Ch. 28) to the cell body where (*9*) ligand-containing vesicles and worn-out membrane proteins are fused with lysosomes for eventual degradation and recycling at the end of the journey. *10*. Vesicles containing neurotrophin–RTK complexes continue to signal for a period of time before degradation, leading to changes in gene expression.

other to form LEs. These LEs eventually become lysosomes, a process that requires the fusion of hydrolase-containing vesicles coming from the TGN and acidification of their lumens. In MVBs we can find internalized membrane proteins in their way to be degraded as well as others that have to be recycled and possibly some that are actively signaling organelles [76].

SYNAPTIC VESICLE TRAFFICKING IS A SPECIALIZED FORM OF REGULATED SECRETION AND RECYCLING OPTIMIZED FOR SPEED AND EFFICIENCY

Some neurons can fire several hundred times per second, secreting neurotransmitter each time. Synapses are remarkable secretion machines destined to undergo millions of repeated exocytic cycles in their lifetime. So how does this process work so fast and so efficiently? Answers have gradually emerged from the work of many different laboratories and model systems [73, 74]. An exhaustive description is beyond the scope of this chapter, but a summary of key events and specializations of the synaptic vesicle cycle is useful. This will show how synaptic transmission is optimized spatially and biochemically (see also Chs 6, 10 and 22).

The organization of the presynaptic terminal is one important element for this optimization. The presynaptic terminal is compact so vesicles may rapidly move from one compartment to another. Unlike endocrine secretion, where membrane fusion occurs randomly on a relatively large membrane area, synaptic vesicles are secreted only at active zones after docking. This means that vesicles are primed for membrane fusion in response to highly localized changes in Ca^{2+}. The ability to dock at an active zone is unique to synaptic vesicles. The peptidergic, dense core vesicles also found in most presynaptic terminals are released through unspecialized membrane regions and the kinetics of peptide secretion is similar to release of hormones from endocrine cells. The composition of synaptic vesicles, the active zone and many of the components needed for docking have been identified [73, 74] (see Table 9-2 for a list of proteins and putative functions).

One characteristic of regulated exocytosis is the ability to store secretory vesicles in a reserve pool for utilization upon stimulation. In the presynaptic terminal, this principle is expanded to define multiple pools of synaptic vesicles: a ready releasable pool, a recycled synaptic vesicle pool and a larger reserve pool. This reserve pool assures that neurotransmitter is available for release in response to even the highest physiological demands. Neurons can fire so many times per minute because synaptic vesicles from the ready releasable pool at a given synapse undergo exocytosis in response to a single action potential. Those vesicles have been primed by docking at the active zone and are therefore ready for exocytosis upon arrival of an action potential. However, for the synapse to respond rapidly and repeatedly under heavy physiological demand, these exocytosed vesicles must be rapidly replaced. This is accomplished first from the recycled pool of vesicles and, as the demand increases, from the reserve pool. To be recycled, synaptic vesicles must be reloaded quickly after they release their contents. The sequence of events that is triggered by neurotransmitter exocytosis is known as the synaptic vesicle cycle [73, 74] (Fig. 9-8).

In neurons, an action potential triggers a highly localized rise of synaptic intracellular Ca^{2+} through opening of voltage-gated Ca^{2+} channels closely apposed to the active zones [77]. These Ca^{2+} ions bind proteins that serve as Ca^{2+} sensors, among them isoforms of synaptotagmin, which in turn triggers the vesicular membrane fusion with the plasma membrane for docked synaptic vesicles [78, 79].

In a simplistic model, the exocytosis step of neurotransmission takes place in at least three major different steps. First, synaptic vesicles dock to a special region of the plasma membrane at the synapse, the active zone. Once docked, synaptic vesicle proteins and plasma membrane proteins (v- and t-SNAREs) are closely apposed but not activated. Second, after vesicle docking and prior to a vesicle fusion event, these vesicles must undergo an ATP-dependent priming process requiring the activity of NSF (NEM-sensitive factor) and phosphoinositide transfer proteins. This priming event prepares synaptic vesicles to fuse their membranes with the synaptic plasma membrane within milliseconds after an action potential has reached the synapse. The synaptic vesicle protein Munc13 and the presynaptic protein RIM, localized to the active zone, play critical roles in the priming process. Third, when an action potential reaches the synapse, voltage-gated Ca^{2+} channels open and Ca^{2+} ions flow into the synaptic terminal, raising the local intracellular Ca^{2+} concentration in the vicinity of the active zone and docked vesicles. These free Ca^{2+} ions bind Ca^{2+}-binding proteins, including synaptotagmin, which in turn initiate vesicular membrane fusion with the plasma membrane through a conformational change in both vesicle and plasma membrane proteins.

As noted above, synaptic vesicles are not typically generated at the level of the TGN. Instead, they are assembled from endocytosed material retrieved from the synaptic plasma membrane. Synaptic vesicle and plasma membrane lipids and proteins are synthesized in the endoplasmic reticulum and modified in the Golgi apparatus, where they are then packaged in secretory vesicles. These synaptic precursors are delivered to the plasma membrane from the cell body by the constitutive secretory pathway. Synaptic vesicle proteins must be retrieved by clathrin-mediated synaptic vesicle endocytosis, a variant of RME with some neuron-specific components. Once the vesicle sheds its clathrin coat, the uncoated vesicle fuses with a

TABLE 9-2 A glossary of proteins in the synapse [73, 74]

1. Synaptic vesicle proteins	
Cysteine string protein (CSP)	Peripheral membrane protein that is palmitoylated on >10 cysteines. May have a role in Ca^{2+} sensitivity of exocytosis.
Cytochrome b561	Electron-transport protein required for intravesicular monooxygenases in subsets of secretory vesicles. Required for dopamine-β_2-hydroxylase and peptide amidase activity.
Neurotransmitter transporters	There are probably at least five types of transport protein specific for glutamate, acetylcholine, catecholamines, glycine/GABA and ATP. The type of transporter contributes to determining the transmitter specificity of a synapse.
Rab and Ra1 proteins	Rab3A, Rab3C, Rab5, Rab7 and Ra1. Since Rab proteins cycle between cytosolic and membrane-bound forms, not all synaptic vesicles contain all Rab proteins at the same time. Rab proteins regulate docking and fusion processes.
Rabphilin-3A	Peripheral membrane protein that binds to Rab3A and Rab3C as a function of GTP, is substrate for multiple protein kinases and contains two C-terminal C2 domains that may bind Ca^{2+}.
Secretory carrier membrane proteins (SCAMPs)	Ubiquitous integral membrane proteins of secretory and transport vesicles of unknown function.
SV2s	Highly glycosylated proteins with at least three isoforms (SV2A, B and C) containing 12 transmembrane regions and homology to bacterial and eukaryotic transporters. May help regulate Ca^{2+} levels.
Synapsins Ia, Ib, IIa and IIb	Monotopic membrane proteins with common N-terminal domains, with phosphorylation sites for CaMKI and PKA but diverge C-terminally. Synapsins Ia/b contain C-terminal phosphorylation sites for CaMKII and CDK 5. Interact with microfilaments, neurofilaments, microtubules, SH3 domains, calmodulin and annexin VI *in vitro.*
Synaptobrevins (VAMPs)	Small-membrane proteins that are cleaved by tetanus toxin and by botulinum toxins B, D, F and G.
Synaptogyrin	Polytopic membrane protein that is tyrosine-phosphorylated. Function unknown.
Synaptophysins	Polytopic membrane proteins, including synaptoporin, that are tyrosine-phosphorylated and bind to synaptobrevins. May regulate SNARE function
Synaptotagmins	Membrane proteins with at least 15 isoforms that contain C2 domains; bind Ca^{2+} and phospholipids; and interact with neurexins, AP2 and syntaxins. Synaptotagmins 1 and 2 may function as Ca^{2+} sensors in fast Ca^{2+}-dependent neurotransmitter release
Transport proteins (channels) for chloride and zinc	Components of synaptic vesicles to mediate the chloride flux for glutamate uptake and zinc uptake in most synaptic vesicles. Zinc transporter is homologous to endosomal and plasma membrane zinc transporters; chloride transporters remain to be identified.
Vacuolar proton pump	Protein complex of more than 12 subunits. Constitutes the largest component of synaptic vesicles and establishes electrochemical gradient for neurotransmitter uptake.
2. Proteins that associate with synaptic vesicles or their precursors	
Amphiphysin	Nerve-terminal protein that associates with synaptic vesicles probably via AP2 bound to synaptotagmin. May function in endocytosis.
AP2 and clathrin	AP2 is a protein complex that binds to a specific receptor on synaptic vesicles and plasma membranes to trigger assembly of clathrin for endocytosis.
Ca^{2+},calmodulin-dependent protein kinases I and II (CaMKI and CaMKII)	May transiently associate with synaptic vesicles to phosphorylate synapsins and rabphilin-3A. May regulate various steps in neurotransmitter release.
Dynamin-1	GTPase required for endocytosis that is phosphorylated by protein kinase C and dephosphorylated by calcineurin upon membrane depolarization and binds to AP2. Important for budding and fusion pore closure.
Dynein	Motor protein mediating microtubule-based synaptic vesicle transport. May be involved in retrograde axonal transport to the cell body.
Kinesins	Motor proteins for microtubule-based synaptic vesicle transport. In *Caenorhabditis elegans*, a kinesin encoded by unc-104 is essential for transport of synaptic vesicles to nerve terminals.
GDP-dissociation inhibitors (GDIs)	Bind isoprenylated Rab proteins in the GDP-bound form, resulting in a cytoplasmic complex.
MSS4	Ubiquitous protein that tightly binds to a subgroup of Rab proteins, including Rab1, Rab3 and Rab8. Function unknown.
pp60src	Tyrosine kinase that phosphorylates synaptophysin and synaptogyrin.
3. Presynaptic plasma membrane proteins	
Munc13s	Mammalian homologs of the *C. elegans* unc-13 gene that is essential for exocytosis. Binds phorbol esters but is not a protein kinase. A component of active zones that interact with RIM, syntaxin and other proteins.
Neurexins	Cell surface proteins with more than 1,000 isoforms generated by alternative splicing from three genes. Neurexins include one of the receptors for α_1-atrotoxin and may function in cell–cell recognition between neurons.
SNAP-25	Palmitoylated peripheral membrane protein that is cleaved by botulinum toxins A and E and binds to syntaxins.
Syntaxins	Ubiquitous membrane proteins that are cleaved by botulinum toxin C1 and bind to synaptotagmins, SNAP-25, synaptobrevins, complexins, munc13s, SNAPs, Ca^{2+} channels and munc18s.
Voltage-gated Ca^{2+} channels	Mediate Ca^{2+} influx for neurotransmitter release at the active zone.
RIM	Binds to Rab3 in a GTP-dependent manner and may mediate Rab3 action in regulating fusion.
4. Proteins that reversibly associate with synaptic plasma membrane proteins	
Munc18s	Mammalian homologs of the *C. elegans unc-18* gene and the *sec-1*, *sly-1* and *slp-1* products of yeast. Bind tightly to syntaxins.
N-ethylmaleimide-sensitive factor (NSF)	Trimeric ATPase required for in vitro membrane fusion during vesicular transport. Probably function as chaperones in synaptic vesicle recycling.
$\alpha/\beta/\gamma$-SNAPs	Soluble NSF-attachment proteins required to recruit NSF to membranes in an ATP-dependent manner.

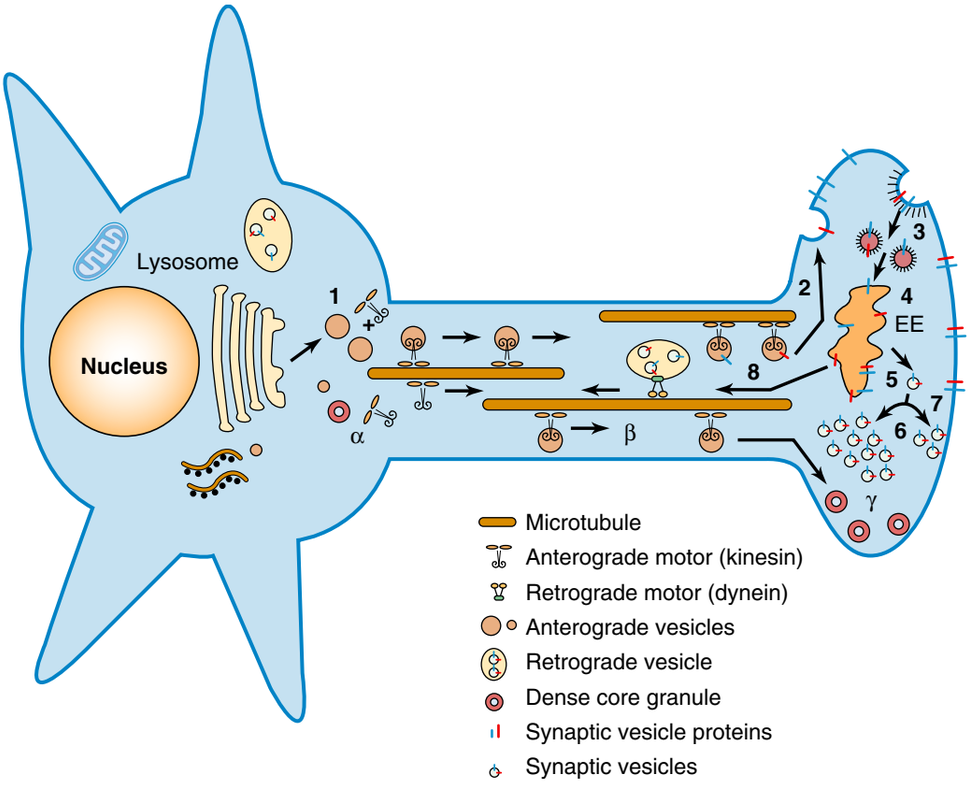

FIGURE 9-8 The life cycle of synaptic vesicles. As with other secretory vesicles, (*1*) membrane components of synaptic vesicles are synthesized in the cell body, packed into membrane-bounded transport vesicles, combined with kinesin motor proteins and actively transported down the axon to the plasma membrane via the constitutive secretory pathway. However, not all synaptic vesicle proteins (*red and blue*) are packaged together, so the synaptic vesicle requires additional steps for reconstitution. Neurons typically release neuropeptides as well as standard neurotransmitters. These are prepared as illustrated in Figure 9-7 for more typical regulated secretory vesicles (α) because their contents must be synthesized in the cell body. *2.* Once a synaptic vesicle precursor has been transported to the presynaptic terminal, where it fuses with the plasma membrane constitutively. Dense core granules are similarly transported down the axon (β). They mature during transport, but are otherwise competent for regulated secretion. *3.* Synaptic vesicle membrane proteins are then gathered efficiently through receptor mediated endocytosis in a clathrin-mediated process. *4.* Soon after the endocytosed vesicle pinches off it sheds its clathrin coat and is transported to the early endosomes (EE) where the components for a synaptic vesicle are sorted and (*5*) then they bud off from the EE to form empty synaptic vesicles. These are rapidly loaded with neurotransmitter via active transport across the membrane. *6.* At this stage, the synaptic vesicle is translocated either to the large reserve pool of synaptic vesicles or back to the plasma membrane, where it docks again to the synaptic active zone. Vesicle exocytosis is a process that requires an ATP-dependent priming process (see text) prior to membrane fusion triggered by Ca^{2+} influx in response to an action potential. The dense core granules (γ) are not associated with active zones or other specialized structures. These peptidergic vesicles typically require higher levels of intracellular Ca^{2+} and have a much slower rate of release. *7.* After release of neurotransmitter, synaptic vesicle membrane components may be recycled by repeating steps 3–6. This recycling can occur very rapidly (see below). *8.* Eventually, some synaptic vesicle components will be repackaged into retrograde vesicles for return to the cell body and degradation.

local EE, where the synaptic vesicle proteins are sorted to form synaptic vesicles. The sorted proteins bud off from the EE as an empty synaptic vesicle and neurotransmitter is taken up into the mature synaptic vesicle in the nerve terminal. The loaded synaptic vesicle is actively transported to the reserve pool of vesicles, where it waits until it is mobilized to the active zone of the synaptic terminal, where it docks with the plasma membrane. After being discharged, synaptic vesicle membrane along with the protein components are retrieved by regulated endocytosis and recycled for additional rounds of secretion.

Many years have passed since the concept of synaptic vesicle recycling was introduced in the early 1970s, but details of the synaptic vesicle cycle continue to be a matter for investigation and debate. The role of clathrin-coated vesicles and a rapid form of endocytosis is well established as a mechanism for synaptic vesicle recycling [64, 80–82] but this classical model was difficult to reconcile with some observations. In recent years, evidence has mounted to support the existence of other pathways that diverge from the classical picture. In particular, membrane fusion may not always be complete. In these cases, the clathrin-mediated endocytosis and sorting endosome steps may be bypassed under certain circumstances. Although these models were originally proposed as an alternative to the classical model, most investigators now acknowledge that these pathways are not mutually exclusive.

In the classic model of synaptic vesicle recycling in nerve terminals, synaptic vesicles fuse completely with the plasma membrane and the integrated vesicle proteins move away from the active zone to adjacent membrane regions (Fig. 9-9A). In these regions, clathrin-mediated synaptic vesicle endocytosis takes place rapidly after neurotransmitter release (within seconds) [64]. The process starts with the formation of a clathrin-coated pit that invaginates toward the interior of the cell and pinches off to form a clathrin-coated vesicle [83]. Coated vesicles are transient organelles that rapidly shed their coats in an ATP/chaperone dependent process. Once uncoated, the recycled vesicle fuses with a local EE for reconstitution as a synaptic vesicle. Subsequently, the recycled synaptic vesicle is filled with neurotransmitter and it returns to the release site ready for use. This may be the normal pathway when neurotransmitter release rates are modest. Clathrin/EE-based pathways become essential when synaptic proteins have been incorporated into the presynaptic plasma membrane.

However, an alternative pathway that bypasses clathrin-mediated endocytosis and EEs appears to be available as well. This model of endocytosis known as 'kiss and run' or its variant 'kiss and stay' have attracted increasing interest in recent years [74] (Fig. 9-9B). Kiss and run has been directly demonstrated with dense-core granules in neuroendocrine cells [84, 85], and this model would explain some observations that are not readily accommodated by the classical pathway. The kiss and run model proposes that neurotransmitters are released by a transient fusion pore, rather than by a complete fusion with integration of the synaptic vesicle components into the plasma membrane. Synaptic membrane proteins never lose their association and the vesicle reforms when the pore closes. As a result, the empty vesicle can be refilled and reused without going through clathrin-mediated endocytosis and sorting in the EEs.

Direct demonstrations of the kiss and run model in mammalian synapses have remained elusive [73], but there is sufficient evidence to suggest that there may be up

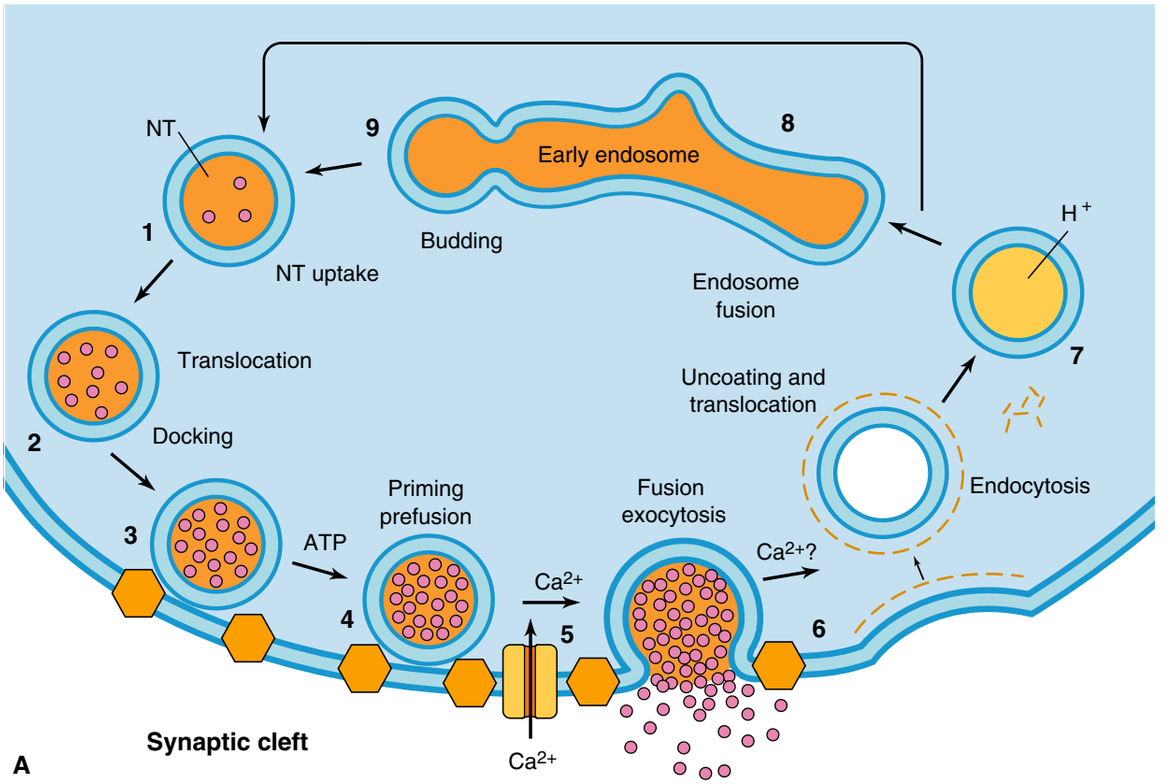

FIGURE 9-9 Release of neurotransmitter from synaptic vesicles is rapid and highly specialized. (**A**) The canonical pathway for neurotransmitter release involves a specific sequence of events. *1.* The first step in neurotransmitter release is to fill the synaptic vesicle (SV) with the appropriate neurotransmitter. This is accomplished by specific transporters in the SV membrane and is ATP-dependent. *2.* After filling, SVs may be moved to a reserve pool or to specialized regions of the presynaptic plasma membrane known as active zones (*black hexagons*). *3.* SVs dock at the active zones where (*4*) they are primed for the fusion event. When an action potential arrives at the terminal (*5*), there is a local influx of Ca^{2+} through voltage-gated channels that triggers fusion of the SV with the plasma membrane and release of neurotransmitter. In the canonical pathway (*6*), SV membrane components are rapidly displaced from the active zone and gathered into coated pits for endocytosis. *7.* The resulting coated vesicle begins to acidify and the clathrin coat is removed by a chaperone. *8.* These endocytosed vesicles fuse with an early endosome for sorting and reconstitution or may be directly refilled. *9.* with neurotransmitter for reuse. Although there is considerable evidence in support of this model, evidence exists for more rapid alternatives [73, 74].

Continued

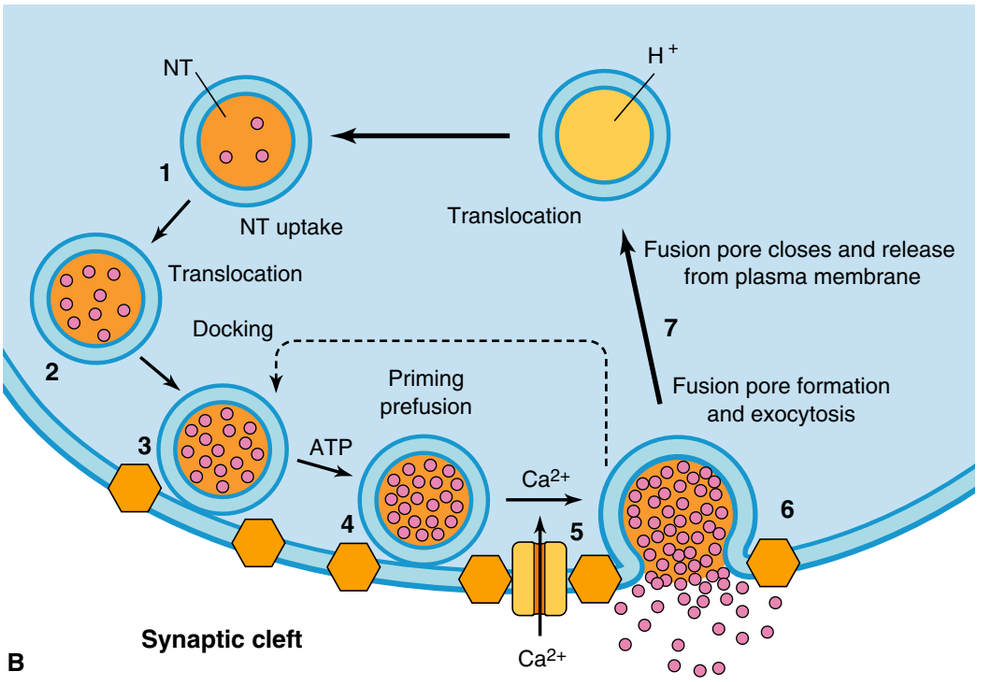

FIGURE 9-9—cont'd (**B**) Two variants of this mechanism have been proposed [74] called respectively ' kiss and run' (*solid arrows*) and 'kiss and stay' (*dashed arrow*). In both of these models, the initial steps of (*1*) filling the SV with neurotransmitter, (*2*) translocation to the active zone, (*3*) docking of the SV and (*4*) priming of the SV prior to fusion occur as in the canonical pathway. However, (*5*) influx of Ca^{2+} leads to the transient formation and rapid closure of a 'fusion pore' for release of neurotransmitter without integration of synaptic vesicle proteins into the plasma membrane. (*6*) Recycling of synaptic vesicles proceeds by a less well-understood mechanism that does not involve clathrin, formation of a coated pit or vesicle, or sorting in an early endosome. Because the SV never loses its integrity (*7*), it may be released from the plasma membrane to reenter at step (1) or may remain docked at the active zone (3) where it is refilled and reprimed (4). These pathways and the classic pathway are not mutually exclusive and both kinds of release may occur in a presynaptic terminal.

to three types of endocytic pathways operating in the presynaptic terminal: the classic, clathrin-mediated endocytic pathway and two faster pathways that do not depend on clathrin coat assembly. In the first, known as kiss and stay, the vesicles remain docked for refilling. In the second, referred to as kiss and run, vesicles recycle locally after forming a transient pore and then releasing from the membrane. Consistent with the existence of one or both of these latter models, elegant studies done with *Drosophila* indicate that flies with mutations in endophilin, a key endocytic protein required for clathrin-mediated endocytosis, have synapses that contain very few vesicles. However, these synapses can sustain synaptic transmission at low frequencies [86], suggesting that multiple pathways are operating in the presynaptic terminal.

Synaptic Transmission and Cellular Signaling: An Overview

Ronald W. Holz

Stephen K. Fisher

SYNAPTIC TRANSMISSION 167
Chemical transmission between nerve cells involves multiple steps 167
Neurotransmitter release is a highly specialized form of the secretory process that occurs in virtually all eukaryotic cells 168
A variety of methods have been developed to study exocytosis 169
The neuromuscular junction is a well defined structure that mediates the presynaptic release and postsynaptic effects of acetylcholine 170
Quantal analysis defines the mechanism of release as exocytosis 172
Ca^{2+} is necessary for transmission at the neuromuscular junction and other synapses and plays a special role in exocytosis 174
Presynaptic events during synaptic transmission are rapid, dynamic and interconnected 175
There are important differences between fast synaptic transmission at nerve terminals and the release of proteins and peptides from nerve terminals and neuroendocrine cells 177
Discrete steps in the regulated secretory pathway can be defined in neuroendocrine cells 177

CELLULAR SIGNALING MECHANISMS 177
Largely as a result of the studies of Langley, the possibility was first entertained that biological tissues possess receptor molecules specific for each neurotransmitter 177
Three phases of receptor-mediated signaling can be identified 178
Four distinct molecular mechanisms that link agonist occupancy of cell-surface receptors to functional responses have been identified 178
Cross-talk can occur between intracellular signaling pathways 179
Signaling molecules can activate gene transcription 181
Nitric oxide acts as an intercellular signaling molecule in the central nervous system 181

SYNAPTIC TRANSMISSION

Chemical transmission between nerve cells involves multiple steps. Until the late 19th century, many physiologists believed that there were direct physical connections between nerves and that an impulse from one nerve was communicated to another through a direct physical connection. However, studies by Golgi, Ramon y Cajal and others convinced many histologists that most connections, which we now know as synapses, were close but not continuous. The pioneering work of Oliver and Shäfer, of Langley and of Elliot beginning in the 1890s provided data that raised the possibility of chemical transmission between nerves. Chemical transmission was convincingly demonstrated in the historic experiments of Otto Loewi. He electrically stimulated the vagus nerve of an isolated frog heart to decrease the strength and rate of contractions. The bathing solution caused a decrease in the strength and rate of contractions when subsequently applied to a second heart. We now know that the inhibition was caused by the neurotransmitter acetylcholine (ACh), which had been released by the nerve terminals of the vagus nerve. (See Davenport [1] for an entertaining and excellent review of the early history of chemical transmission.)

Chemical transmission is the major means by which nerves communicate with one another in the nervous system. The pre- and postsynaptic events are highly regulated and subject to use-dependent changes that are the basis for plasticity and learning in the CNS. Although direct electrical connections also occur, these account for transmission of information between nerves only in specialized cases.

Chemical transmission requires the following steps:

1. Synthesis of the neurotransmitter in the presynaptic nerve terminal
2. Storage of the neurotransmitter in secretory vesicles
3. Regulated release of neurotransmitter into the synaptic space between the pre- and postsynaptic neurons

Basic Neurochemistry: Molecular, Cellular and Medical Aspects
0-12-088397-X

4. The presence of specific receptors for the neurotransmitter on the postsynaptic membrane, such that application of the neurotransmitter to the synapse mimics the effects of presynaptic nerve stimulation
5. A means for terminating the action of the released neurotransmitter.

An overview of some of the processes involved in synaptic transmission is shown in Figure 10-1. Many of the processes are discussed below or in other chapters of this book. Many different types of substance are neurotransmitters. 'Classical' neurotransmitters, such as ACh (see Ch. 11) and norepinephrine (NE; see Ch. 12), are low-molecular-weight substances that have no other function but to serve as neurotransmitters. The predominant excitatory neurotransmitter in the brain, glutamate, and the inhibitory neurotransmitter in the spinal cord, glycine, are common and essential amino acids (see Chs 15 and 16). They can function as neurotransmitters because the membranes of secretory vesicles in glutamatergic and glycinergic nerve terminals have specific transport systems that concentrate and store these amino acids so that they can be released by exocytosis in a highly regulated manner. Gamma-aminobutyric acid (GABA), the predominant inhibitory amino acid in brain, ACh and the aminergic neurotransmitters are also concentrated within synaptic vesicles through the actions of specific transport proteins. Synaptic vesicles have an acidic interior, pH ≈5.5, which is maintained by a vacuolar-type proton-translocating ATPase (see Ch. 5). The uptake of low-molecular-weight neurotransmitters is coupled via the transporters to the electrochemical H^+ gradient (for reviews, see [2, 3]).

Neurotransmitter release is a highly specialized form of the secretory process that occurs in virtually all eukaryotic cells. The fundamental similarity between the events in the nerve terminal that control neurotransmitter

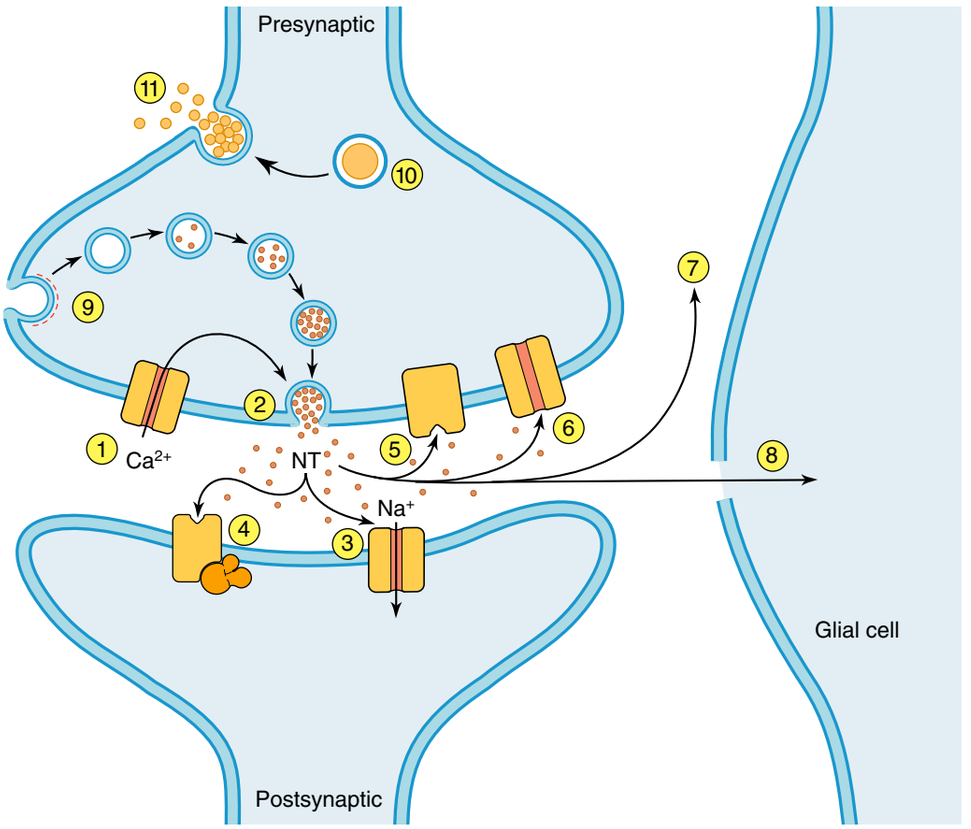

FIGURE 10-1 Depolarization opens voltage-sensitive Ca^{2+} channels in the presynaptic nerve terminal (*1*). The influx of Ca^{2+} and the resulting high Ca^{2+} concentrations at active zones on the plasmalemma trigger (*2*) the exocytosis of small synaptic vesicles that store neurotransmitter (NT) involved in fast neurotransmission. Released neurotransmitter interacts with receptors in the postsynaptic membrane that either couple directly with ion channels (*3*) or act through second messengers, such as (*4*) G-protein-coupled receptors. Neurotransmitter receptors, also in the presynaptic nerve terminal membrane (*5*), either inhibit or enhance exocytosis upon subsequent depolarization. Released neurotransmitter is inactivated by reuptake into the nerve terminal by (*6*) a transport protein coupled to the Na^+ gradient, for example, dopamine, norepinephrine, glutamate and GABA; by (*7*) degradation (acetylcholine, peptides); or by (*8*) uptake and metabolism by glial cells (glutamate). The synaptic vesicle membrane is recycled by (*9*) clathrin-mediated endocytosis. Neuropeptides and proteins are stored in (*10*) larger, dense core granules within the nerve terminal These dense core granules are released from (*11*) sites distinct from active zones after repetitive stimulation.

release and the ubiquitous vesicular trafficking reactions in all eukaryotic cells is described in Chapter 9. This similarity has important implications for the biochemistry of synaptic transmission. Many of the proteins essential for constitutive secretion and endocytosis in yeast and mammalian cells are similar to those involved in the presynaptic events of synaptic transmission (see Ch. 9).

Peptides and proteins can also be released from nerve terminals. Their biosynthetic and storage processes are similar to those in other protein secretory cells [4]. They utilize the endoplasmic reticulum, Golgi and *trans*-Golgi network, which are present in the cell body but not in the nerve terminal. The peptide- and protein-containing vesicles must be transported into the nerve terminal by axonal transport (see Ch. 28). Examples of peptide neurotransmitters include substance P, thyrotropin-releasing hormone (TRH), vasopressin, oxytocin, enkephalins and endorphins (endogenous opiate-like agonists), vasoactive intestinal peptide (VIP) and luteinizing-hormone-releasing hormone (LHRH) (see Ch. 18). The interior of mature secretory granules in neuroendocrine cells in the regulated pathway has a pH of 5.3–5.5, similar to the pH in synaptic vesicles. The low pH influences intravesicular protein processing and the conformation of the stored proteins, as well as the transport of other substances into the granules.

A variety of methods have been developed to study exocytosis. Neurotransmitter and hormone release can be measured by the electrical effects of released neurotransmitter or hormone on postsynaptic membrane receptors, such as the neuromuscular junction (NMJ; see below), and directly by biochemical assay. Another direct measure of exocytosis is the increase in membrane area due to the incorporation of the secretory granule or vesicle membrane into the plasma membrane. This can be measured by increases in membrane capacitance (C_m). C_m is directly proportional to membrane area and is defined as: $C_m = QA_m/V$, where C_m is the membrane capacitance in farads (F), Q is the charge across the membrane in coulombs (C), V is voltage (V) and A_m is the area of the plasma membrane (cm^2). The specific capacitance, Q/V, is the amount of charge that must be deposited across 1 cm^2 of membrane to change the potential by 1 V. The specific capacitance, mainly determined by the thickness and dielectric constant of the phospholipid bilayer membrane, is approximately 1 $\mu F/cm^2$ for intracellular organelles and the plasma membrane. Therefore, the increase in plasma membrane area due to exocytosis is proportional to the increase in C_m.

The electrophysiological technique used to measure changes in membrane capacitance is the patch clamp [5, 6] in the whole-cell recording mode, where the plasma membrane patch in the pipet is ruptured. In another configuration of the patch clamp, the plasma membrane patch is maintained intact. In this case, small currents due to the opening of individual channels can be measured in the membrane patch. The whole-cell patch clamp technique establishes a high resistance seal between the glass rim of the micropipet and the plasma membrane. This seal allows low-noise, high-sensitivity electrical measurements across the entire plasma membrane. An example of the use of membrane capacitance to measure exocytosis in chromaffin cells is shown in **Figure 10-2** [7].

Sensitive electrochemical techniques have also been developed to directly measure the release of oxidizable neurotransmitters such as catecholamines (CAs) and serotonin (5-hydroxytryptamine, 5-HT). Current flows in the circuit when the potential of the electrode is positive enough to withdraw electrons from, i.e. oxidize, the released neurotransmitter. The technique is very sensitive and readily detects the release of individual quanta of neurotransmitter resulting from the fusion of single secretory vesicles to the plasmalemma **(Fig. 10-2)**.

A variety of different types of tissue preparation are used to study neurosecretion and synaptic transmission. A classical preparation is the frog NMJ (discussed below). The brain slice has been used for many years for biochemical studies of CNS metabolism and is a useful preparation for electrophysiological studies of synaptic transmission in the CNS. Slices can be oriented to maintain the local neuronal circuitry and can be thin, ≈0.3 mm, to minimize anoxia. The transverse hippocampal slice is widely used as an electrophysiological preparation to study synaptic plasticity (see Ch. 53). Primary cultures of neurons from selected CNS areas and sympathetic ganglia are also frequently used. They permit excellent visual identification of individual neurons and control of the extracellular milieu, but the normal neuronal connections are disrupted.

Gentle homogenization of brain tissue results in suspensions of intracellular organelles and pinched-off nerve terminals, *synaptosomes*. Homogenization shears off nerve terminals from axons, especially in brain regions with clearly defined anatomical layers such as the cerebral cortex and hippocampus. Synaptosomes can be partially separated from other organelles by centrifugation techniques. Each of these remarkable structures is 0.5–1.0 µm in diameter, contains hundreds of synaptic vesicles and one or more mitochondria and is often associated with postsynaptic membrane fragments. Synaptosomes remain functional for several hours and can be used to study biochemical events, including energy and Ca^{2+} metabolism, neurotransmitter synthesis, transport and secretion. A related preparation is the neurosecretosome, from the posterior pituitary. These nerve terminals originate in the hypothalamus and contain vasopressin and oxytocin in large vesicles that appear as dense core granules. They are obtained in high purity from the neurohypophysis, which does not contain cell bodies. Neurosecretosomes are somewhat larger than synaptosomes and can be used for biochemical and patch clamp studies.

Several types of cells related to sympathetic neurons can be maintained and studied in tissue culture. Adrenal medullary chromaffin cells have the same precursor cells

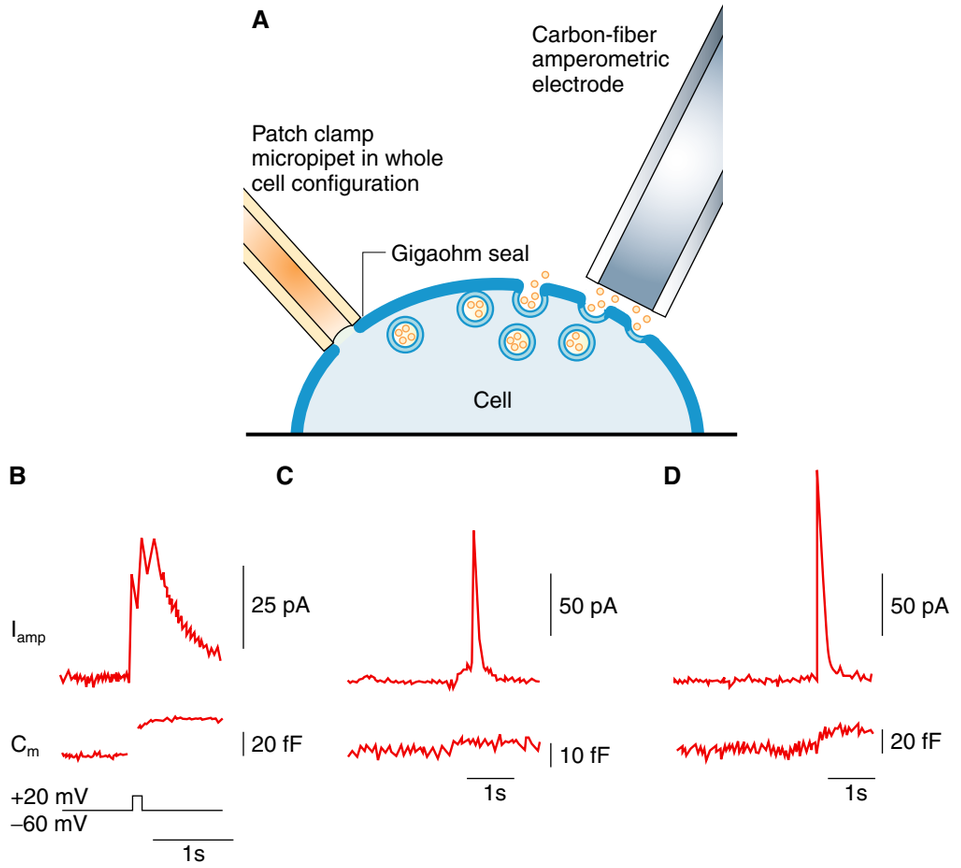

FIGURE 10-2 Secretory events monitored by simultaneous amperometric (I_{amp}) and capacitance (C_m) measurements demonstrate typical patterns of release. (**A**) Configuration of the recording setup. (**B**) Wide amperometric response composed of multiple spikes due to the fusion of several secretory vesicles triggered by a 50 ms depolarization to +20 mV from a holding potential of −60 mV. From the magnitude of the capacitance response (24 fF), it is estimated that between 2 and 24 vesicles fused with the plasmalemma. The exact number of vesicles that fused is not known since there is a distribution in their size. The amperometric response shows at least three to five discernible peaks that lag the capacitance step. However, the broad amperometric response (**B**) is likely to be composed of many more spikes. Two particularly large, isolated fusion events are shown in **C** and **D**. A clear lag between the fusion of a vesicle and the main spike of release can sometimes be observed, resulting in a foot before the spike (**C**); however, it is not always present (**D**).

as postganglionic sympathetic neurons. These excitable neuroendocrine cells store, in large dense core granules called chromaffin granules, epinephrine or NE, together with ATP and a variety of proteins (chromogranins, opiate peptides and their precursors and dopamine β-hydroxylase). Relatively pure primary cultures can be prepared by collagenase digestion of bovine adrenal glands followed by cell-purification techniques. Various aspects of neurotransmitter metabolism and secretion have been extensively studied with these cells. They are amenable to both biochemical and electrophysiological experiments. A clonal cell line, PC12, is derived from a rat pheochromocytoma, a tumor of the adrenal medulla. Upon incubation with nerve growth factor (NGF), PC12 cells differentiate within days into neurons with axons and terminals (see Ch. 27). Thus, they are used not only for biochemical and secretion studies but also for investigation of neuronal differentiation.

The neuromuscular junction is a well-defined structure that mediates the presynaptic release and postsynaptic effects of acetylcholine. The first detailed studies of synaptic transmission were performed with the NMJ. The NMJ is a beautiful example of how structure and function are intimately entwined. The myelinated axon originating from the motor neuron in the spinal cord forms unmyelinated terminals that run longitudinally along the muscle fiber. Specialized transverse release sites, or active zones, occur periodically along the terminals and are oriented opposite to invaginations of the postsynaptic membrane (Fig. 10-3). There are approximately 300 active zones per NMJ. The active zones in the nerve terminal display a cloud of clear vesicles, 50–60 nm in diameter, that contain ACh (Fig. 10-3). The active zone contains aggregates of proteins (active zone material, AZM) composed of discrete structures that link the docked granules to the plasma membrane and probably play a

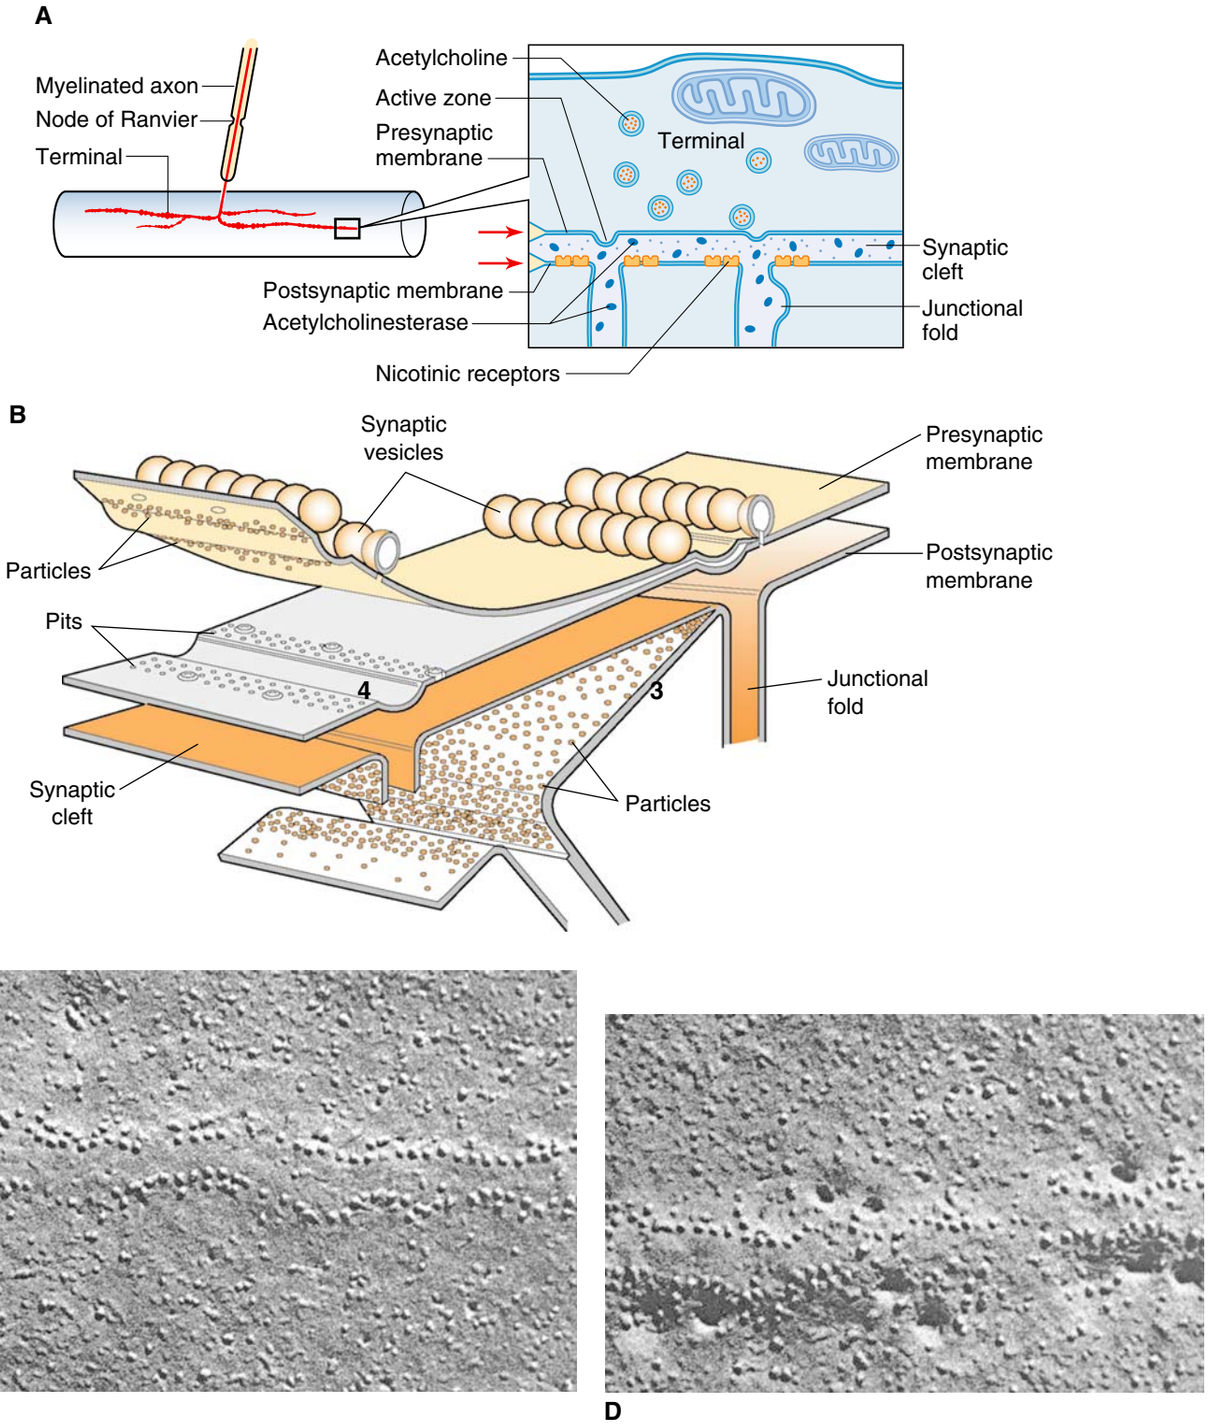

FIGURE 10-3 Synaptic membrane structure. (**A**) Entire frog neuromuscular junction (NMJ, **left**) and longitudinal section through a portion of the nerve terminal (**right**). *Arrows* indicate planes of cleavage during freeze-fracture. (**B**) Three-dimensional view of presynaptic and postsynaptic membranes with active zones and immediately adjacent rows of synaptic vesicles. Plasma membranes are split along planes indicated by the *arrows* in **A** to illustrate structures observed by freeze-fracture. The cytoplasmic half of the presynaptic membrane at the active zone shows on its fracture face protruding particles whose counterparts are seen as pits on the fracture face of the outer membrane leaflet. Vesicles that fuse with the presynaptic membrane give rise to characteristic protrusions and pores in the fracture faces. The fractured postsynaptic membrane in the region of the folds shows a high concentration of particles on the fracture face of the cytoplasmic leaflet; these are probably acetylcholine receptors (AChRs). (Courtesy of U. J. McMahan; with permission from reference [8].) Freeze-fractured active zones from frog resting and stimulated NMJ. (**C**) The active zone is the region of presynaptic membrane surrounding double rows of intramembrane particles, which may be channels for Ca^{2+} entry that initiates transmitter release. (**D**) Holes that appear in active zones during transmitter release are openings of synaptic vesicles engaged in exocytosis. This muscle was prepared by quick-freezing, and transmitter release was augmented with 4-aminopyridine so that the morphological events, such as the opening of synaptic vesicles, could be examined at the exact moment of transmitter release evoked by a single nerve shock (×120,000). (With permission from reference [9].)

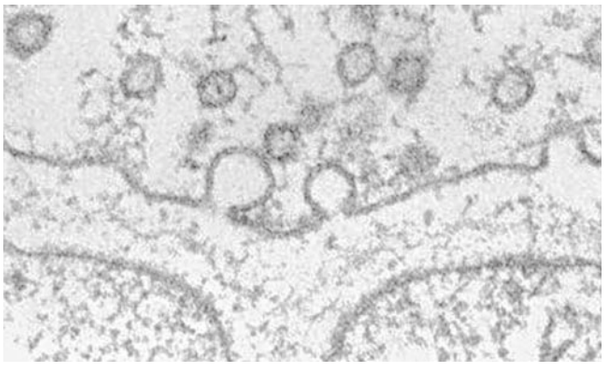

FIGURE 10-4 High-magnification (×145,000) view of freeze-substituted neuromuscular junctions in a muscle frozen during the abnormally large burst of acetylcholine release that is provoked by a single nerve stimulus in the presence of 2 mmol/l 4-aminopyridine. The stimulus was delivered 5.1 ms before the muscle was frozen. The section was cut unusually thin (≈200 Å) to show the fine structure of the presynaptic membrane, which displayed examples of synaptic vesicles apparently caught in the act of exocytosis. In all cases, these open vesicles were found just above the mouths of the postsynaptic folds, hence at the site of the presynaptic active zones. (With permission from reference [10].)

role in exocytosis. There are approximately 500,000 vesicles in all the active zones at one NMJ. It is estimated that on the average a vesicle contains 20,000 ACh molecules. A small subset of the vesicles is attached in rows to the presynaptic membrane (Fig. 10-3A, B). These are thought to be docked vesicles that are able to undergo exocytosis upon Ca^{2+} influx. In freeze fracture, these rows coincide with rows of intramembrane particles that may be Ca^{2+} channels (Fig. 10-3C). Ca^{2+} entry that occurs upon stimulation of the nerve causes exocytosis, which is seen as pits in freeze-fracture micrographs (Fig. 10-3D) or as 'omega' figures in thin-section electron microscopy (Fig. 10-4). The vesicle membranes in the nerve terminal are recycled by endocytosis (see below).

The postsynaptic membrane opposite release sites is also highly specialized, consisting of folds of plasma membrane containing a high density of nicotinic ACh receptors (nAChRs). Basal lamina matrix proteins are important for the formation and maintenance of the NMJ and are concentrated in the cleft. Acetylcholinesterase (AChE), an enzyme that hydrolyzes ACh to acetate and choline to inactivate the neurotransmitter, is associated with the basal lamina (see Ch. 11).

Quantal analysis defines the mechanism of release as exocytosis. Stimulation of the motor neuron causes a large depolarization of the motor end plate. In 1952, Fatt and Katz [11] observed that spontaneous potentials of approximately 1 mV occur at the motor endplate. Each individual potential change has a time course similar to the much larger evoked response of the muscle membrane that results from electrical stimulation of the motor nerve. These small spontaneous potentials were therefore called miniature endplate potentials (MEPPs). Because the MEPPs are reduced by the nicotinic antagonist D-tubocurarine and increased in amplitude and duration by the AChE inhibitor physostigmine, it was concluded that they are initiated by the release of ACh. Because the potential changes are too large to be accounted for by the interaction of individual molecules of ACh with the end plate, Fatt and Katz [11] postulated that they reflect the release of packets, or *quanta*, of ACh molecules from the nerve terminal.

A 'curious effect' was observed by Fatt and Katz [11]: when the Ca^{2+} concentration is reduced and the Mg^{2+} increased, the evoked end-plate potential (EPP) is diminished without altering the size of the spontaneous MEPPs. With sufficiently low Ca^{2+}, the evoked EPP is similar in size to MEPPs and varies in a stepwise manner. A single nerve impulse results in either no EPP or EPPs the approximate size of one, two, three or more MEPPs in an apparently random manner. The results of this type of experiment are displayed in Figure 10-5. The frequency histogram shows that the amplitudes of evoked potentials are clustered in multiples of the mean spontaneous MEPP value. Statistical analysis [14] demonstrates that the release is a random process described by a Poisson distribution. Each event is unaffected by the preceding events. The model assumes n release sites capable of responding to a nerve impulse, each with a probability, p, of releasing a quantum of ACh. The mean number of quanta (m), or quantal content, released per nerve impulse is $m = np$. For a Poisson distribution, p must be small, <0.05, and n large, >100. The probability of evoked release of x quanta is $p_x = (m^x/x)e^{-m}$. (See Martin [15] for a review of the Poisson distribution in the analysis of synaptic transmission.)

One critical test for the validity of the Poisson distribution as a description of release in the presence of reduced Ca^{2+} was the excellent agreement of two measures of m. One was derived empirically from the direct measurement of EPPs and MEPPs:

m = mean amplitude of EPP/mean amplitude of MEPPS.

The other was derived from the Poisson equation and the observed probability of no response, or failures, upon nerve stimulation:

$$p_0 = e^{-m} \text{ and } m = -\ln(p_0).$$

A more stringent test of the model is its ability to predict the histogram in Figure 10-5.

The number of quanta released, m, differs for different types of synapses. For a single impulse at the NMJ, 100–300 quanta are released. The large number of quanta that are released during a single impulse reflects the need for a large safety factor in the all-or-none response of muscle contraction. Where integration of inputs is important, quantal number is often less. At single terminals in sympathetic ganglia, at inhibitory and excitatory inputs on spinal motor neurons and at individual boutons of cultured hippocampal neurons, m is 1–3.

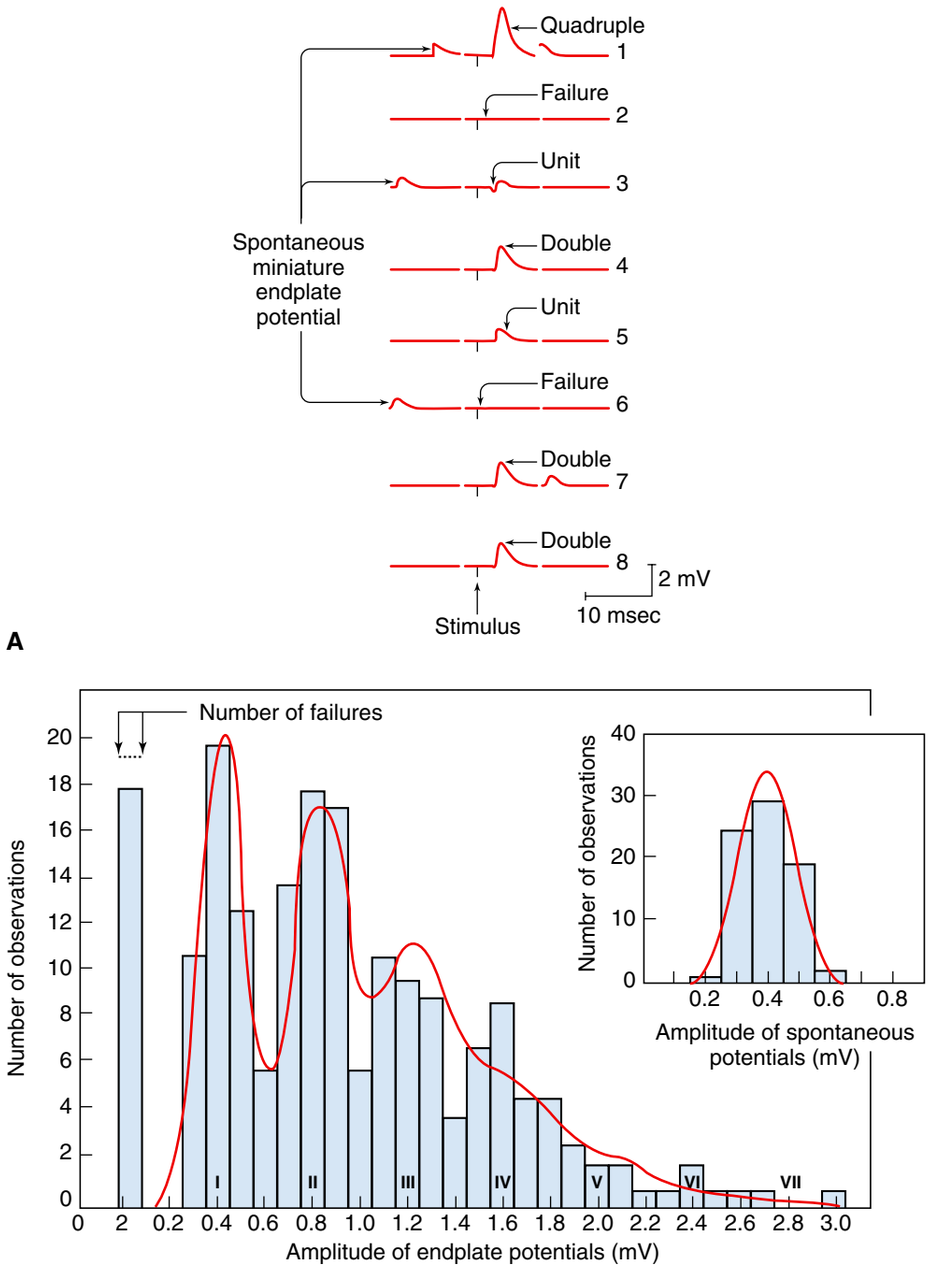

FIGURE 10-5 Comparison of the amplitudes of the spontaneous miniature endplate potentials and the evoked endplate potentials indicates that transmitter is released in quantal packages that are fixed in amplitude but variable in number. (**A**) Intracellular recording from a rat nerve–muscle synapse shows a few spontaneous miniature endplate potentials and the synaptic responses, or endplate potentials, evoked by eight consecutive stimuli to the nerve. The stimulus artifact evident in the records is produced by current flowing between the stimulating and recording electrodes in the bathing solution. In a Ca^{2+}-deficient and Mg^{2+}-rich solution designed to reduce transmitter output, the endplate potentials are small and show considerable fluctuations: two impulses produce complete failures (*2* and *6*); two produce a unit potential (*3* and *5*) and still others produce responses that are two to four times the amplitude of the unit potential. Comparison of the unit potential and the spontaneously occurring miniature endplate potential illustrates that they are the same size. (Adapted with permission from reference [12].) (**B**) Distribution of amplitudes of the spontaneous miniature endplate potentials and the evoked endplate potentials. Synaptic transmission has again been reduced, this time with only a high-Mg^{2+} solution. The histograms of the evoked endplate potential illustrate peaks that occur at 1, 2, 3 and 4 times the mean amplitude of the spontaneous potentials (0.4 mV). The distribution of the spontaneous miniature endplate potentials shown in the **inset** is fitted with a gaussian curve. The gaussian distribution for the spontaneous miniature potentials is used to calculate a theoretical distribution of the evoked endplate potential amplitudes, based on the Poisson equation, that predicts the number of failures, unit potentials, twin and triplet responses and so on. The fit of the data to the theoretical distribution is remarkably good (*solid line*). Thus, the actual number of failures (*dashed line* at 0 mV) was only slightly lower than the theoretically expected number of failures (*arrows above dashed line*). (Adapted with permission from reference [13].)

Ca^{2+} is necessary for transmission at the neuromuscular junction and other synapses and plays a special role in exocytosis. In most cases in the CNS and PNS, chemical transmission does not occur unless Ca^{2+} is present in the extracellular fluid. Katz and Miledi [16] elegantly demonstrated the critical role of Ca^{2+} in neurotransmitter release. The frog NMJ was perfused with salt solution containing Mg^{2+} but deficient in Ca^{2+}. A twin-barrel micropipet, with each barrel filled with 1.0 mmol/l of either $CaCl_2$ or NaCl, was placed immediately adjacent to the terminal. The sodium barrel was used to depolarize the nerve terminal electrically and the calcium barrel to apply Ca^{2+} ionotophoretically. Depolarization without Ca^{2+} failed to elicit an EPP (Fig. 10-6A). If Ca^{2+} was applied just before the depolarization, EPPs were evoked (Fig. 10-6B). In contrast, EPPs could not be elicited if the Ca^{2+} pulse immediately followed the depolarization (Fig. 10-6C). EPPs occurred when a Ca^{2+} pulse as short as 1 ms preceded the start of the depolarizing pulse by as little as 50–100 µs. The experiments demonstrated that Ca^{2+} must be present when a nerve terminal is depolarized in order for neurotransmitter to be released.

The normal extracellular Ca^{2+} concentration is approximately 2 mmol/l. The basal cytosolic Ca^{2+} concentration is 0.1 µmol/l or less. In nerve terminals, the rise of intracellular Ca^{2+} caused by depolarization of the plasma membrane opens voltage-sensitive Ca^{2+} channels. Ca^{2+} influx and the resultant rise in the cytosolic Ca^{2+} concentration adjacent to release sites along the plasma membrane trigger exocytosis. The sites of exocytosis are closely associated with Ca^{2+} channels (Fig. 10-3C). Ca^{2+} channels may, in fact, be components of multimeric protein complexes involved in exocytosis. Intracellular $[Ca^{2+}]$ immediately adjacent to Ca^{2+} channels is probably in the range 50–100 µmol/l [17–19]. It is this high Ca^{2+} concentration that triggers exocytosis. Neuroendocrine cells, such as chromaffin cells from the adrenal medulla, also release hormones, such as epinephrine and opioid peptides, upon Ca^{2+} influx through membrane channels. It is thought that in this type of cell, release sites are usually not closely associated with Ca^{2+} channels and that $[Ca^{2+}]$ in the 0.5–10 µmol/l range can trigger exocytosis. It should be noted that other types of cells, such as exocrine cells (for example, pancreatic acinar cells), also release stored protein by exocytosis upon a rise in cytosolic Ca^{2+}. In many cases, Ca^{2+} is released from intracellular stores by inositol trisphosphate (IP_3), which is generated by the hormonal activation of G protein-linked receptors that activate phosphoinositide-specific phospholipase C (PI-PLC) (see Ch. 20). In this case, extracellular Ca^{2+}

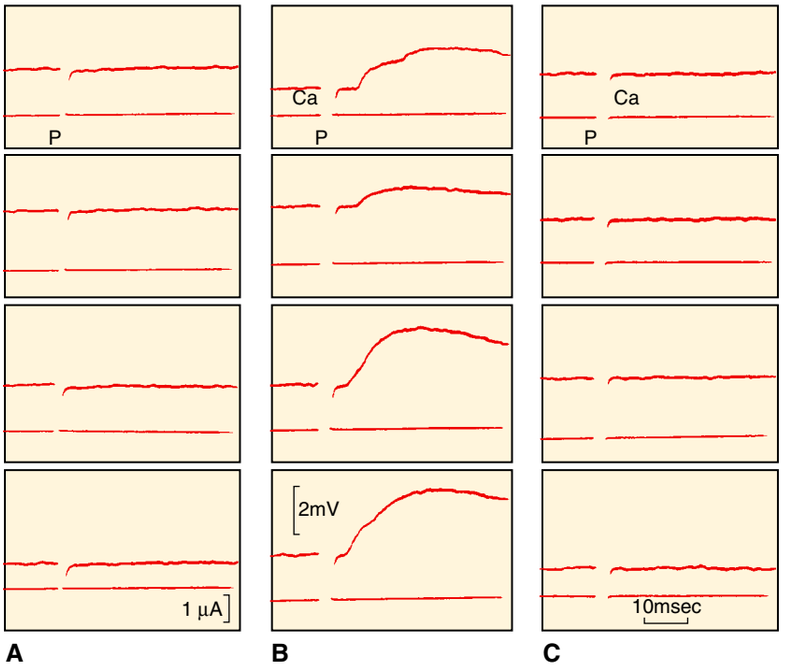

FIGURE 10-6 Synaptic transmission requires that Ca^{2+} be present during the action potential. The effects of iontophoretic pulses of Ca^{2+} on endplate response are shown. Depolarizing pulses (*P*) and Ca^{2+} were applied from a double-barrel micropipet to a small part of a frog sartorius neuromuscular junction. Intracellular recording was from the endplate region of the muscle fiber. **Top traces** show the postsynaptic membrane potential responses. **Bottom traces** show current pulses through the pipet. (**A**) Depolarizing pulses alone. (**B**) Short-duration, approximately 1 ms, Ca^{2+} pulses applied less than 1 ms before the depolarizing pulse. (**C**) Short Ca^{2+} pulses immediately following depolarizing pulses. The acetylcholinesterase inhibitor prostigmin was present to enhance the response. Temperature 3°C. Depolarization elicited endplate potentials only if the Ca^{2+} pulse preceded the depolarizing pulse (**B**). (With permission from reference [16].)

sustains secretion by refilling the intracellular, IP_3-sensitive Ca^{2+} stores rather than by directly triggering secretion.

Presynaptic events during synaptic transmission are rapid, dynamic and interconnected. The time between Ca^{2+} influx and exocytosis in the nerve terminal is very short. At the frog NMJ at room temperature, 0.5–1 ms elapses between the depolarization of the nerve terminal and the beginning of the postsynaptic response. In the squid giant synapse, recordings can be made simultaneously in the presynaptic nerve terminal and in the postsynaptic cell. Voltage-sensitive Ca^{2+} channels open toward the end of the action potential. The time between Ca^{2+} influx and the postsynaptic response as measured by the postsynaptic membrane potential is 200 µs (Fig. 10-7). However, measurements made with optical methods to record presynaptic events indicate a delay of only 60 µs between Ca^{2+} influx and the postsynaptic response at 38°C [21].

The short delays between Ca^{2+} influx and exocytosis have important implications for the mechanism of fusion of synaptic vesicles (see Ch. 9). In this short time, a synaptic vesicle cannot move significant distances and must be already at the release site. From the diffusion constant of Ca^{2+} in squid axoplasm, one can calculate that Ca^{2+} could diffuse a distance of only 850 Å, somewhat greater than the diameter of a synaptic vesicle. Therefore, in fast synapses, vesicle exocytosis sites must be close to the triggering Ca^{2+} channels.. Vesicles are exposed to $[Ca^{2+}]$ of a few hundred micromoles near the cytoplasmic mouth of the channels.

The supply of synaptic vesicles in the nerve terminal is limited. With continuous stimulation of the NMJ, the number of quanta released can be many times the number observed to be available in the nerve terminal. Transport of secretory vesicles from the cell body would be much too slow to maintain fast synaptic transmission in the terminal. Instead, the synaptic vesicle membrane that fuses with the plasmalemma membrane is rapidly recycled via clathrin-mediated endocytosis (reviewed in [22]; see Ch. 9). Hence, the vesicle membrane is a reusable container for neurotransmitter storage and exocytosis. The process of membrane recycling at the nerve terminal is closely related to the general process of endocytosis that occurs in nonneuronal cells. Strong evidence for this process came from electron micrographs of horseradish peroxidase uptake from the extracellular medium into the nerve terminal of the frog NMJ after nerve stimulation [23, 24]. Endocytosis is dispersed along the membrane away from active zones. It was originally proposed that clathrin-coated vesicles bud from the plasma membrane, lose their triskelion clathrin coat and fuse to an intermediary endosomal compartment, from which new synaptic vesicles bud. Synaptic vesicles then take up neurotransmitter and recycle to release sites. However, later studies suggested an alternative pathway that bypasses the intermediate endosomal compartment. It would allow more rapid endocytic recycling of the synaptic vesicle membrane. In this view, clathrin-coated vesicles bud from the plasmalemma, become uncoated, take up neurotransmitter and recycle to the plasmalemma. Strong stimulation of the nerve

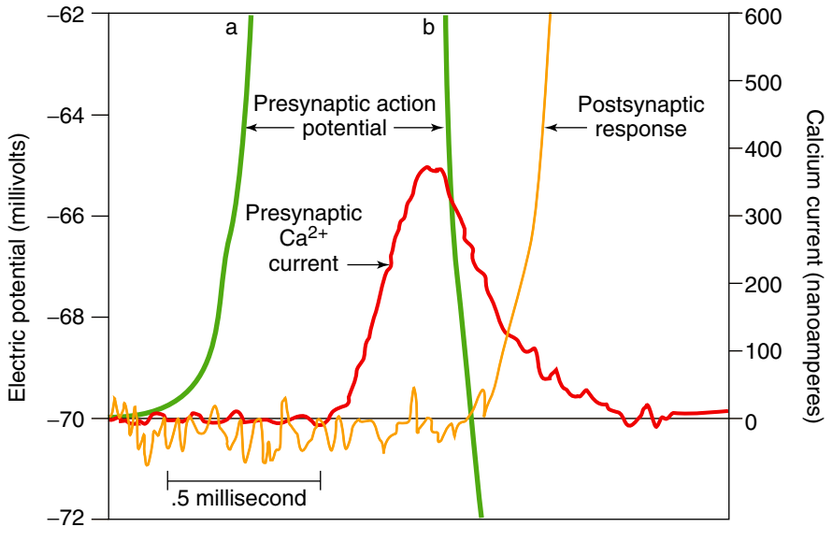

FIGURE 10-7 The delay between Ca^{2+} influx into the nerve terminal and the postsynaptic response is brief. The temporal relationships between the Ca^{2+} current and the action potential in the nerve terminal and the postsynaptic response in the squid giant synapse are shown. The rapid depolarization (*a*) and repolarization (*b*) phases of the action potential are drawn. A major fraction of the synaptic delay results from the slow-opening, voltage-sensitive Ca^{2+} channels. There is a further delay of approximately 200 µs between Ca^{2+} influx and the postsynaptic response. (With permission from reference [20].)

terminal may cause invaginations of the plasmalemma, from which clathrin-coated vesicles can also bud (see Ch. 2).

The development of amphipathic fluorescent dyes that label endocytic vesicles has permitted the study of endocytosis in nerve terminals in real time [25, 26]. The probe FM1-43 equilibrates between the aqueous phase and the membrane but is not membrane-permeating. The plasmalemma becomes fluorescent (Fig. 10-8). Upon endocytosis, the labeled membrane is internalized. When removed from the extracellular medium, the dye is retained by the endocytic vesicles but lost from the plasmalemma. Endocytic vesicles are transformed into synaptic vesicles containing FM1-43. Importantly, recycled synaptic vesicles lose the probe upon exocytosis.

This technique has permitted the dynamics of the exocytic/endocytic cycle to be investigated. At the neuromuscular junction, a readily releasable pool (RRP) and a reserve pool of vesicles coexist, the latter being released after the RRP during high-intensity stimulation. Recycling of the fused vesicle membrane requires seconds for the RRP and approximately 1 minute for the reserve pool, indicating discrete endocytic pathways. A single nerve impulse releases ≈0.1% of the total recycling pool. Readily releasable and reserve vesicle pools also occur in cultured hippocampal neurons [27]. However, in contrast to the neuromuscular junction, there is significant mixing between the pools in the hippocampus. Endocytosis follows approximately 20 seconds after exocytosis. The transformation of the endocytic vesicle into a functioning synaptic vesicle requires about 15 seconds. About 0.5% of the recycling pool is released by a nerve impulse. This corresponds to approximately one vesicle per synaptic bouton.

The importance of endocytosis for the normal function of the nerve terminal is demonstrated by the *shibire* mutant of *Drosophila*. When these mutant flies, bearing a temperature-sensitive allele, are exposed to high temperature,

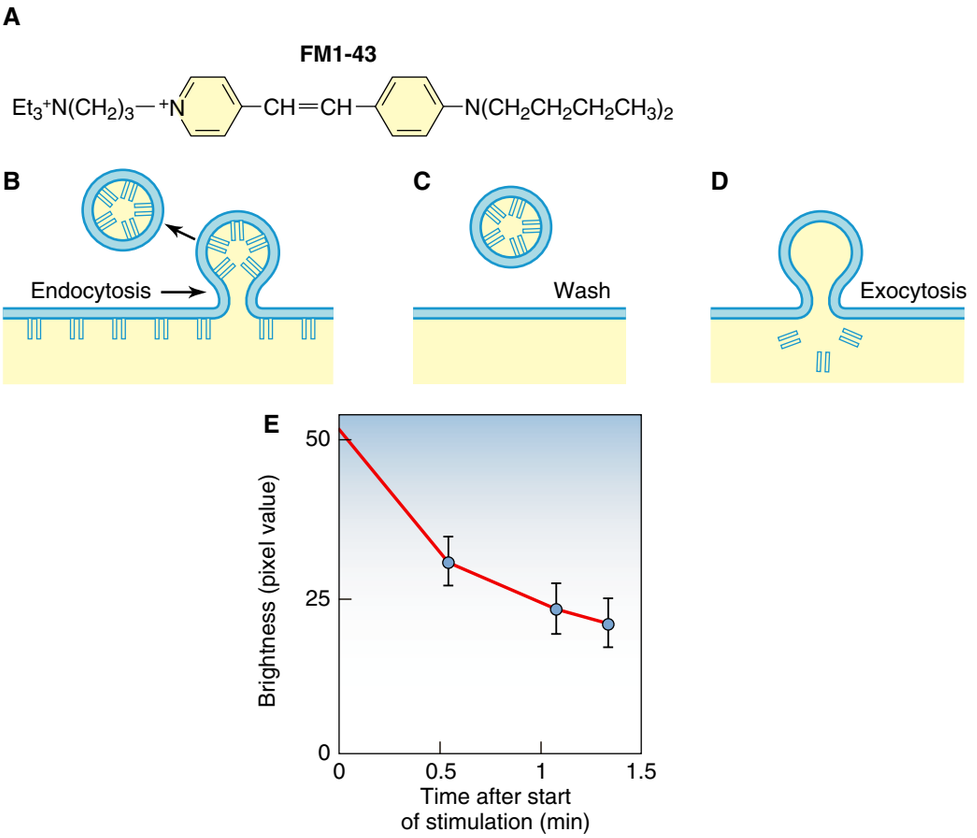

FIGURE 10-8 The probe FM1-43 was used to visualize endocytosis and exocytosis at the neuromuscular junction (NMJ). (**A**) Structure of the amphipathic membrane probe FM1-43. (**B**) Labeling of the plasmalemma by FM1-43 in the extracellular medium. The amphipathic probe is present during electrical stimulation of the NMJ. Note that membrane originating from synaptic vesicles that have undergone exocytosis is labeled. (**C**) A brief wash of the NMJ after electrical stimulation removes FM1-43 from the plasma membrane but not from intracellular endocytic vesicles that had formed following exocytosis in the presence of FM1-43. (**D**, **E**) A second round of exocytosis stimulated by exocytosis in the absence of extracellular FM1-43 results in loss of the fluorescent probe from newly formed synaptic vesicles that have undergone exocytosis. In **E,** the fluorescence intensity of vesicle populations at the NMJ was followed over time during a 10 Hz stimulation. Note the decline of fluorescence as FM1-43-labeled vesicles undergo exocytosis and release the probe into the extracellular medium [25].

they become paralyzed within 1 minute but rapidly recover when returned to the permissive temperature. Electron microscopy demonstrates that the paralysis results from a block of synaptic vesicle endocytosis at the NMJ. The *shibire* allele encodes dynamin, a GTPase that is essential for the fission of the endocytic bud from the plasmalemma.

There are important differences between fast synaptic transmission at nerve terminals and the release of proteins and peptides from nerve terminals and neuroendocrine cells. Because fast synaptic transmission involves recycling vesicles, the neurotransmitter must be replenished locally. Thus, fast synaptic transmission uses neurotransmitters such as ACh, glutamate, GABA, glycine, dopamine (DA) and NE, all of which can be synthesized within the nerve terminal or transported rapidly across the nerve terminal plasmalemma. In contrast, proteins are inserted into secretory granules in the cell body. The secretory granules must then be transported by fast axonal transport into the nerve terminal, a process that can take many hours or days depending on the distance of the nerve terminal from the soma (see Ch. 28). Nerve terminals that are specialized for fast synaptic transmission may have peptidergic granules as well as the recycling vesicles of fast synaptic transmission. For example, nerve terminals can contain VIP as well as ACh, enkephalin as well as NE and substance P as well as 5-HT. The peptidergic granules are usually far less numerous than the smaller vesicles involved in fast exocytosis and are not localized at active zones (Fig. 10-1). The exocytosis of protein-containing granules in nerve terminals may be closely related to exocytosis of protein-containing granules in endocrine and exocrine cells. While a single nerve impulse will release vesicles at active zones, exocytosis of peptidergic granules in nerve terminals can require multiple or high-frequency stimulation. This may reflect the need for sustained elevations of Ca^{2+} that extend into the interior of the nerve terminal. Peptides and proteins released from nerves may have slower and longer-lasting effects on postsynaptic cells than fast neurotransmitters and are then able to modulate the response to fast neurotransmitters.

Discrete steps in the regulated secretory pathway can be defined in neuroendocrine cells. The rapid presynaptic events of synaptic transmission produce closely coordinated exocytosis and endocytosis. Insights into the steps involved in the exocytotic limb of the pathway have come from analyzing the secretion kinetics for protein-containing granules released from adrenal chromaffin cells and PC12 cells. Adrenal chromaffin cells are excitable and contain a large number of secretory or chromaffin granules. In bovine chromaffin cells, neuronal-type nAChRs and voltage-sensitive Ca^{2+} channels permit Ca^{2+} entry, which stimulates secretion. The intracellular milieu of chromaffin cells can be directly controlled by extracellular solutions when their plasmalemmas are rendered leaky by the detergent digitonin, by streptolysin-O [28] or by mechanical disruption of the plasma membrane as cells are passed through a steel cylinder partially blocked by a precision steel bearing [29]. PC12 cells contain far fewer granules than do adrenal chromaffin cells, and many of the granules are closely associated with the plasma membrane. An analysis of the effects of Ca^{2+}, ATP and temperature suggests that ATP hydrolysis occurs before Ca^{2+} is able to cause the granules to secrete. Two distinct Ca^{2+}-dependent steps have been identified. One step enhances the ability of ATP to prime secretion, with maximal effects at approximately 1 µmol/l Ca^{2+}, whereas the other step triggers exocytosis with maximal effects at 30–300 µmol/l Ca^{2+}. Electrophysiological studies have identified additional steps associated with the triggering of exocytosis that may reflect the dynamics of inter-related pools of granules [30].

What is the function of ATP in secretion? While protein phosphorylation can modulate the secretory response, there is compelling evidence that the effect of ATP in priming involves other processes. ATP is necessary for the function of *N*-ethylmaleimide-sensitive factor (NSF). This protein is an ATPase that acts as a molecular chaperone to dissociate complexes of the SNARE proteins VAMP (synaptobrevin), syntaxin and SNAP-25 (see Ch. 9). This may permit their subsequent reassociation as part of the exocytotic response. Another function of ATP in priming exocytosis is the maintenance of the polyphosphoinositides, phosphatidylinositol 4,5-bisphosphate (PIP_2) and phosphatidylinositol 4-phosphate (PIP), by phosphorylation of lipid precursors via phosphatidylinositol 4-kinase and PIP kinase [31–33]. Interestingly, phosphatidylinositol 4-kinase is an integral membrane protein of chromaffin granules and synaptic vesicles. The polyphosphoinositides appear to function in the priming step not as precursors for the formation of IP_3 and diacylglycerol (DAG) but, rather, in some other capacity (see Ch. 20). PIP_2 binds specifically to the vesicle or granule proteins synaptotagmin and rabphilin3. PIP_2 also regulates numerous proteins that control the cytoskeleton, such as profilin, gelsolin, scinderin and myosin I. Therefore, the polyphosphoinositides on the secretory granule membrane may coordinate the secretory functions of several secretory granule proteins and may modulate dynamic changes in the cytoskeletal network. This network and its changes are important for exocytosis. PIP_2 is essential also in endocytosis at presynaptic nerve terminals through the regulation of proteins involved with coating and uncoating of endocytic vesicles and through the regulation of the actin cytoskeleton.

CELLULAR SIGNALING MECHANISMS

Largely as a result of the studies of Langley, the possibility was first entertained that biological tissues possess receptor molecules specific for each neurotransmitter. Langley in the early 1900s noted the high degree of specificity and potency with which some agents

elicit a biological response and postulated the existence of 'receptor' or 'acceptor' molecules. This concept has subsequently been fully validated. Many receptors have been isolated and purified biochemically, and many have also been cloned and sequenced. In several cases, the activity of purified receptors has been reconstituted in artificial systems.

Three phases of receptor-mediated signaling can be identified. The first is the binding component in which an extracellular ligand, usually a polar molecule, forms a complex with a cell-surface receptor, which can be localized on either a pre- or a postsynaptic membrane. The second phase is that in which the activated receptor–ligand complex elicits an increase in either the formation of second messengers, the opening or closing of ion channels or the recruitment of cytoplasmic proteins. The third phase typically involves the activation of enzymes, typically protein kinases or phosphatases, which mediate the biological response. Thus, the initial interaction of a ligand with a receptor results in amplification of the signal by means of a cascade of responses.

Four distinct molecular mechanisms that link agonist occupancy of cell-surface receptors to functional responses have been identified. Traditionally, receptors have been classified according to the mediator to which they respond. The first example, proposed by Sir Henry Dale in 1914, was that the neurotransmitter ACh can interact with two types of AChRs, termed either nicotinic or muscarinic AChRs based on the similarity of action of ACh to the plant alkaloids nicotine and muscarine. Similarly, Ahlquist proposed the division of adrenergic receptors into α and β subtypes, based on the potency of a series of natural and synthetic agonists to elicit a biological response. Although the pharmacological characterization of receptors provided a useful starting point, it rapidly became apparent that extensive subclassification of receptors would be required. For example, it is now recognized that there are both neural and non-neural forms of the nAChR, which can be distinguished pharmacologically and biochemically. In addition, multiple adrenergic receptor subtypes, including α_1, α_2, β_1, β_2 and β_3, can be distinguished based on the ability of selective agonists and antagonists to bind to them. Although the pharmacological division of receptors remains that most commonly employed, an alternative classification is based on the effector mechanism to which receptors are linked.

This classification leads to four distinct groups based on the types of primary effector to which they couple [34] (Fig. 10-9). The first group is comprised of receptors which possess intrinsic ion channels that are composed of multiple subunits. Upon the binding of an agonist to these ligand-gated ion channels, the receptors undergo a conformational change which facilitates opening of the intrinsic ion channel. The permeability to specific ions is

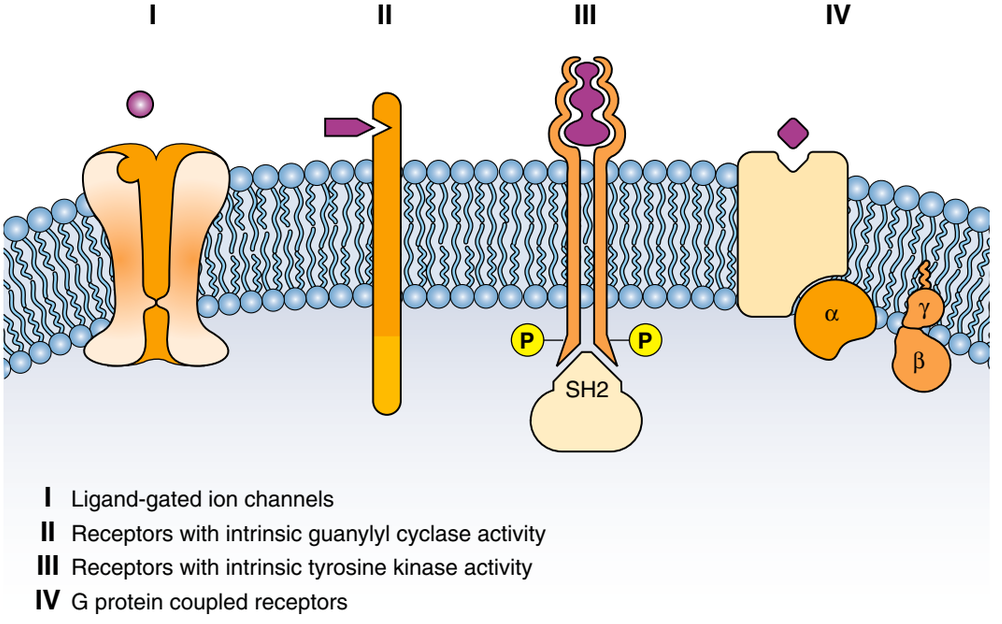

FIGURE 10-9 Cell-surface receptors utilize four distinct molecular mechanisms for transmembrane signaling. *I.* Ligand-gated ion channels. *II.* Receptors which possess intrinsic guanylyl cyclase activity. *III.* Receptors with intrinsic tyrosine kinase activity. *IV.* G-protein-coupled receptors, which are linked to the opening/closing of ion channels, modulation of adenylyl cyclase and phosphoinositide-specific phospholipase C activities. *SH2,* src homology 2 domain.

a characteristic of the receptor; for example, both the neuronal nAChR and NMDA receptors are selectively permeable to Na^+ and Ca^{2+} ions, whereas $GABA_A$ and glycine receptors are primarily permeable to Cl^- ions. As a result of the changes in ion conductance, the membrane potential may become either depolarized, as in nAChR or NMDA receptors, or hyperpolarized, as in $GABA_A$ or glycine receptors. Receptors in this category include those that are activated by synaptically released neurotransmitter and occur on the cell surface. The responses to these cell-surface receptors are extremely rapid, occurring in milliseconds, and do not require either the subsequent generation of second-messenger molecules or protein phosphorylation events. Thus, ligand-gated ion channels mediate 'fast synaptic' transmission events in the CNS. The intracellular ligand-gated receptor for IP_3 also opens within milliseconds upon binding of IP_3 (see Ch. 20).

Receptors in the second group possess intrinsic guanylyl cyclase activity and generate cGMP upon receptor activation, for example, brain natriuretic peptide receptor. These receptors consist of an extracellular binding domain, a single transmembrane-spanning domain (TMD), a protein kinase-like domain and a guanylyl cyclase catalytic domain. Ligand binding results in a conformational change in the receptor and activation of the guanylyl cyclase catalytic region. Membrane-bound guanylyl cyclase activity does not require Ca^{2+} and can be modulated by ligand addition to cell-free preparations. A different, cytoplasmic form of guanylyl cyclase is activated by micromolar concentrations of Ca^{2+}. Receptors with intrinsic guanylyl cyclase activity are often very highly phosphorylated in the absence of agonist and rapidly undergo dephosphorylation upon activation (see Ch. 23).

Receptors in the third group possess intrinsic receptor tyrosine kinase (RTK) activity. RTKs, such as epidermal growth factor receptor (EGFR) and platelet-derived growth factor receptor (PDGFR), are found in all multicellular eukaryotic organisms and are involved in the regulation of cellular growth and differentiation (see Chs 24 and 27). Structurally, RTKs possess an extracellular ligand-binding domain, a single TMD and an intracellular catalytic kinase domain. Three distinct events underlie signal transduction at RTKs. Initially, upon ligand binding to an RTK, the receptor undergoes a dimerization which results in the juxtaposition of the two cytoplasmic domains. Contact between these domains is thought to result in a stimulation of catalytic activity, which in turn results in an intermolecular autophosphorylation of tyrosine residues both within and outside of the kinase domain. The significance of the phosphorylation of tyrosine residues lies in the subsequent ability of the RTK to recruit cytoplasmic proteins which possess src homology 2 (SH2) domains. These regions of the molecule are 60–100 amino acids in length, are globular in structure, protrude from the surface of the protein and permit high-affinity protein–protein interactions to occur. In the case of the SH2 domain, a key arginine residue buried deep in a specific binding pocket interacts with the phosphate group of the tyrosine residue. The presence of an SH2 domain can increase the affinity of a peptide for a phosphorylated tyrosine residue by 1,000-fold. Once autophosphorylated, RTKs can recruit a number of cytoplasmic proteins and initiate a series of reactions involving protein–protein interactions. The best studied pathway of this type is the mitogen-activated protein kinase (MAPK) pathway. RTKs, via the recruitment of an adaptor protein complex such as growth factor receptor-binding protein 2 (Grb2)/son of sevenless (SOS) or SHC (see Ch. 27) can activate Ras, a low-molecular-weight, monomeric G protein. The role of Ras is to recruit and activate Raf (MAPKKK), a serine/threonine kinase, which in turn activates MEK (MAPKK), a dual-specificity tyrosine/ threonine kinase. MEK subsequently activates MAPK, also known as ERK or extracellular signal-regulated kinase, which is a serine/threonine kinase with multiple substrates. ERK can enter the nucleus and regulate gene transcription by phosphorylating nuclear proteins (see Ch. 23).

The fourth group of receptors involves G proteins. Numerically, more diverse types of receptors have been demonstrated to operate via an intervening G protein than by any other mechanism. These G protein-coupled receptors (GPCRs), which have a characteristic seven TMD structure, can be further divided into three categories. Some GPCRs, such as $GABA_B$, α_2-adrenergic, D_2-dopaminergic or muscarinic M_2, regulate the changes in K^+ conductance independently of second-messenger production (see Ch. 19). A second group of GPCRs is linked to the modulation of adenylyl cyclase activity. This regulation may be either positive, as in the case of activation of the β_2-adrenergic receptor, or negative, as occurs following activation of the α_2-adrenergic receptor. Changes in the concentrations of cAMP regulate the activity of protein kinase A (PKA) (see Ch. 21). A third group of GPCRs is linked to the activation of PI-PLC with the attendant breakdown of PIP_2 and formation of IP_3 and DAG (see Ch. 20). These receptors are linked to changes in Ca^{2+} homeostasis and protein phosphorylation via the action of protein kinase C (PKC). Other effector enzymes that may be regulated by IP_3-linked GPCRs include phospholipases A_2 and D.

Cross-talk can occur between intracellular signaling pathways. Most cells possess receptors that operate through each of these four distinct effector mechanisms. Receptors within each class may be subject to further regulation during persistent agonist occupancy. One way that this can occur is via phosphorylation of the receptor, which results in its uncoupling from the effector enzyme, as has been demonstrated for the β-adrenergic receptor (see Ch. 12). This has been called *homologous regulation.* In addition, signaling pathways do not operate in isolation but may regulate and be regulated by one another,

which has been termed *heterologous regulation*. In this way, the output of the cell is fine-tuned via subtle modulation of the relevant intracellular signaling mechanisms. There are numerous examples in which the activity of one receptor can regulate, either positively or negatively, the activity of a second; for example, increases in cAMP mediated by PKA can depress or potentiate PI-PLC activity (reviewed in [35]). Conversely, activation of PI-PLC can result in modulation of the activity of other pathways via the activation of PKC. An additional complexity is that the same ligand may activate multiple pathways in a given tissue. For example, NE can activate β_2-adrenergic receptors, which increase adenylyl cyclase; α_2-adrenergic receptors, which are coupled to inhibition of adenylyl cyclase; and α_1-adrenergic receptors, which are linked to the activation of PI-PLC. Similarly, ACh can activate muscarinic cholinergic receptors, which either inhibit adenylyl cyclase, activate PI-PLC or activate K^+ channels. In addition, ACh can directly activate nAChRs, which are linked to changes in Na^+ and Ca^{2+} permeability. Thus, although individual signaling mechanisms are most frequently studied in isolation, their activity *in vivo* is likely to be highly regulated and integrated by cross-talk and other signal-transduction events.

A further consideration is that receptors which primarily activate one pathway may, on occasion, activate a second pathway (Fig. 10-10). An example is the ability of GPCRs, such as α_2-adrenergic receptors or mAChRs, to activate the MAPK cascade. Activation of adenylyl cyclase-linked receptors results in the release of G protein $\beta\gamma$ subunits, which, probably via an intermediary protein tyrosine kinase (PTK-X), stimulates phosphorylation of the adaptor protein SHC [36]. This in turn recruits the Grb2-SOS complex and activates the MAPK pathway.

Activation of PI-PLC-linked receptors, such as the mAChR, results in increased PKC activity. Since the addition of phorbol esters, which are PKC agonists (see Ch. 20), results in phosphorylation of Raf, this mechanism may provide an explanation for the ability of PI-PLC-coupled receptors to activate MAPK. A recently discovered protein tyrosine kinase PYK2, which is enriched in the CNS, is also activated by PKC. Like PTK-X, PYK2 phosphorylates SHC and recruits the Grb2-SOS complex, which results in activation of the MAPK cascade. PYK2 is also activated by

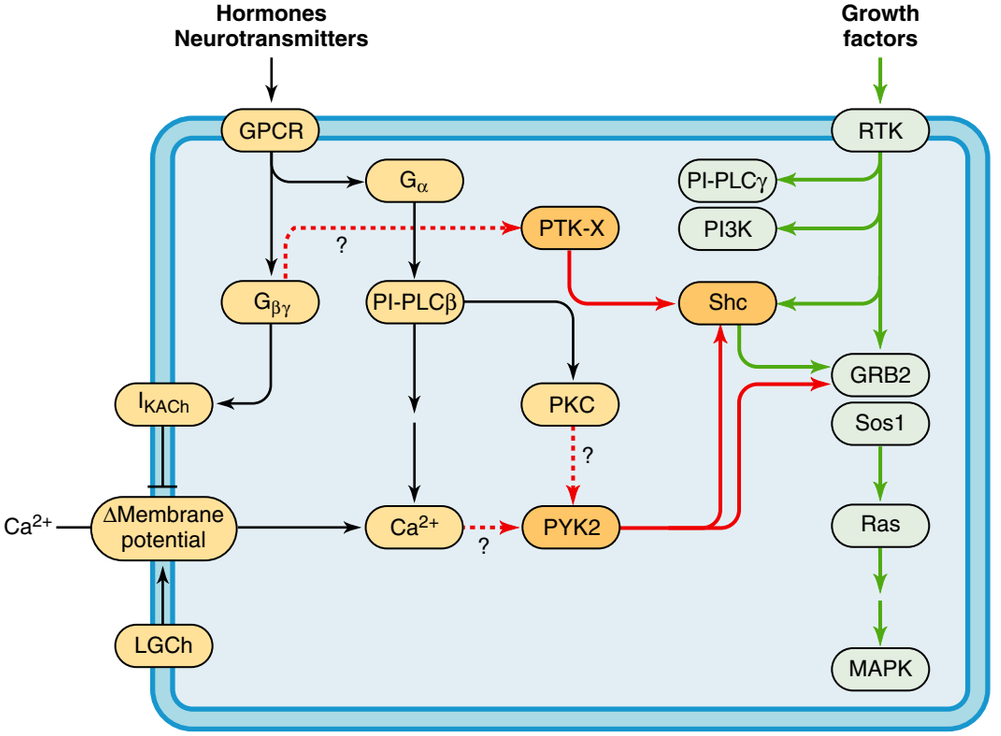

FIGURE 10-10 Cross-talk between G-protein-coupled receptors (*GPCRs*), ligand-gated ion channels (*LGChs*) and receptor protein tyrosine kinases (*RTKs*). GPCRs, via activation of PTK-X or PYK2, can activate the mitogen-activated protein kinase (*MAPK*) pathway. LGChs, via an increase in $[Ca^{2+}]_i$, may also activate PYK2. Note that the key 'go-between' molecule is the adaptor protein Shc, which in turn can interact with growth factor receptor-binding protein 2 (*GRB2*)/son of sevenless (*Sos1*) to activate the MAPK pathway. Question marks indicate that the pathways of activation still need to be firmly established, I_{KACh}, inwardly rectifying, acetylcholine-regulated channel; *PI3K*, phosphatidylinositol 3-kinase; *PKC*, protein kinase C; *PI-PLC*, phosphoinositide-specific phospholipase C. (Adapted with permission from reference [36].)

Ca^{2+}, raising the possibility that the activity of ligand-gated ion channels can also modulate the MAPK pathway. However, to date, there is no evidence to suggest that this regulation is reciprocal, that is, that activation of the MAPK pathway can modulate the activity of either GPCRs or ligand-gated ion channels.

Signaling molecules can activate gene transcription. In addition to their ability to elicit acute effects within cells, second-messenger molecules, such as cAMP, Ca^{2+} and DAG, can regulate gene transcription. The transcription factors cAMP response element-binding (CREB) protein, Fos and Jun, which respond to these signaling molecules, are members of the amphipathic helix family of proteins. Each contains a characteristic 'leucine zipper' that mediates dimerization (see Ch. 26). The best studied of these transcription factors is CREB, which becomes phosphorylated on Ser^{133} in response to increases in the intracellular concentration of cAMP and subsequent activation of PKA. CREB can also be phosphorylated by Ca^{2+}/calmodulin-dependent protein kinase IV. In its phosphorylated form, CREB binds to an eight-base *cis*-regulatory sequence called cAMP response element (CRE) and stimulates transcription. CREB has been implicated in long-term potentiation and memory (see Ch. 53). Increased concentrations of cytoplasmic Ca^{2+} and DAG activate PKC, which can also activate gene transcription via *fos* and *jun*. Activation of the MAPK pathway also leads to increased expression of Jun and Fos. Because increases in mRNA for *fos* and *jun* are observed very rapidly following a variety of stimuli, they have been termed *immediate early response genes*. The Fos–Jun heterodimers, termed AP-1, bind to a seven-base pair *cis*-regulatory element called tetradecanoyl-phorbol acetate (TPA) response element (TRE). The latter has been demonstrated to control the transcription of several genes coding for neuropeptide modulators. Thus, despite major differences in the initial molecular mechanisms that underlie activation of RTKs or receptors coupled to either adenylyl cyclase or PI-PLC, these diverse groups of receptors share at least one common end path, that of gene regulation.

Nitric oxide acts as an intercellular signaling molecule in the central nervous system. Because cells rarely act in isolation, a signaling event in one cell may have a significant impact on the activity of neighboring cells. Initial evidence for intercellular, nonsynaptic signaling was obtained from experiments with blood vessels, in which it was observed that the addition of ACh increased cGMP concentrations and resulted in relaxation of the vascular smooth muscle and vasodilation.. The increases in cGMP concentrations were dependent on the presence of Ca^{2+} and could not be demonstrated in tissue homogenates. A key observation was that removal of the endothelium abolished the relaxing effect of ACh, indicating the existence of an *endothelium-derived relaxing factor* (EDRF). Subsequently, it was discovered that EDRF was a short-lived gaseous molecule, nitric oxide (NO). NO is synthesized from arginine via the Ca^{2+} activation of nitric oxide synthase (NOS), an enzyme that requires NADPH as coenzyme and tetrahydrobiopterin as cofactor. Three distinct forms of NOS have been identified: an inducible form (iNOS), which is present in glia; a neuronal form (nNOS), which is widespread in distribution throughout the CNS; and an endothelial enzyme (eNOS) [37]. The activity of both nNOS and eNOS is Ca^{2+}/calmodulin-dependent, whereas that of iNOS is Ca^{2+}-insensitive. The activity of nNOS can be increased by brain lesions or ischemia (see Ch. 32). As a signaling molecule, NO differs from conventional neurotransmitters in that (a) it is not present in synaptic vesicles, (b) it is not released by exocytosis and (c) no specific extracellular synaptic receptors for NO exist. Rather, NO is released upon stimulation and diffuses from its site of production, which can be either neuronal or glial cells, to affect neurons up to 100 μm away. At these locations, NO activates a soluble form of guanylyl cyclase through electron transfer to the heme group on the enzyme. The increase in cGMP concentration subsequently activates cGMP-dependent protein kinases. It has been speculated that, in the CNS, NO plays a role in both long-term potentiation (LTP) and long-term depression, although the precise mechanism remains to be defined. One counterargument against a role of NO in LTP is the observation that the latter persists in transgenic mice lacking nNOS. NO can also lead to post-translational modifications of sulfhydryl groups on synaptic vesicle proteins, thereby facilitating synaptic vesicle exocytosis [38].

It is conceivable that other gaseous molecules may also act as intercellular messengers. One putative candidate is carbon monoxide, which is generated from the conversion of heme to biliverdin, a reaction catalyzed by an oxygenase. One form of the enzyme, heme oxygenase-2, is constitutive and is found in high concentrations in various brain regions. Like NO, CO increases the production of cGMP. Another putative gaseous neuromodulator, hydrogen sulfide, is thought to potentiate NMDA receptors and LTP in the hippocampus [43, 44].

Intercellular signaling may also occur via other mechanisms. For example, cell-to-cell propagation of Ca^{2+} signals can result from the gap junctional transfer of IP_3 [39]. Alternatively, the release of humoral factors such as 5-HT, glutamate and nucleotides can initiate intercellular signaling. Thus, ATP and ADP released from human neuroepithelioma cells in response to a rise in the concentration of intracellular Ca^{2+} serves to further the propagation of intercellular Ca^{2+} signals [40]. Within the CNS, glutamate released from glia can activate receptors on neurons [41]. An additional consideration is that the secreted factor may act in an autocrine fashion. Thus, prostaglandins released from myenteric neurons in response to the addition of bradykinin can modulate the subsequent Ca^{2+}

influx mediated by bradykinin receptors on the same neuron [42].

Acetylcholine

Palmer Taylor

Joan Heller Brown

CHEMISTRY OF ACETYLCHOLINE 186

ORGANIZATION OF THE CHOLINERGIC NERVOUS SYSTEM 186
Acetylcholine receptors have been classified into subtypes based on early studies of pharmacologic selectivity 186
The intrinsic complexity and the multiplicity of cholinergic receptors became evident upon elucidation of their primary structures 189

FUNCTIONAL ASPECTS OF CHOLINERGIC NEUROTRANSMISSION 189
Both muscarinic and nicotinic responses are elicited in brain and spinal cord 189
Neurotransmission in autonomic ganglia is more complex than depolarization mediated by a single transmitter 190
Muscarinic receptors are widely distributed at postsynaptic parasympathetic effector sites 190
Stimulation of the motoneuron releases acetylcholine onto the muscle endplate and results in contraction of the muscle fiber 191
Competitive blocking agents cause muscle paralysis by preventing access of acetylcholine to its binding site on the receptor 191

SYNTHESIS, STORAGE AND RELEASE OF ACETYLCHOLINE 192
Acetylcholine formation is limited by the intracellular concentration of choline, which is determined by active transport of choline into the nerve ending 192
A second transport system concentrates acetylcholine in the synaptic vesicle 193
Choline is supplied to the neuron either from plasma or by metabolism of choline-containing compounds 193
A slow release of acetylcholine from neurons at rest probably occurs at all cholinergic synapses 194
The relationship between acetylcholine content in a vesicle and the quanta of acetylcholine released can only be estimated 194
Depolarization of the nerve terminal by an action potential increases the number of quanta released per unit time 194
All the acetylcholine contained within the cholinergic neuron does not behave as if in a single compartment 194

ACETYLCHOLINESTERASE AND THE TERMINATION OF ACETYLCHOLINE ACTION 195
Cholinesterases are widely distributed throughout the body in both neuronal and non-neuronal tissues 195
The primary and tertiary structures of the cholinesterases are known 195
Acetylcholinesterases exist in several molecular forms governed by alternative splicing 195
Cholinesterase catalysis and inhibition mechanisms involve formation of reversible complexes and covalent conjugates 197
Consequences of acetylcholinesterase inhibition differ with effector site 197

NICOTINIC RECEPTORS 197
The nicotinic acetylcholine receptor (nAChR) was the first characterized neurotransmitter receptor 197
The nAChR consists of five subunits arranged around a pseudoaxis of symmetry 198
Analysis of the opening and closing events of individual channels has provided information about ligand binding and activation of the receptor 201
Continued exposure of nicotinic receptors to agonist leads to desensitization of the receptors 201
Nicotinic receptor subunits are part of a large superfamily of ligand-gated channels 202
Both nicotinic receptors and acetylcholinesterase are regulated tightly during differentiation and synapse formation 202

MUSCARINIC RECEPTORS 203
Muscarinic receptor activation causes inhibition of adenylyl cyclase, stimulation of phospholipase C and regulation of ion channels 203
Radioligand-binding studies have been used to characterize muscarinic receptors 205
The binding properties of the antagonist pirenzepine led to the initial classification of muscarinic receptors 205
Transgenic mice are being generated to assess the functions of receptor subtypes *in vivo* 207

Acetylcholine (ACh) and its targets of interaction have played a long-standing and critical role in the basic concepts of neurochemistry. At the turn of the last century, ACh emerged as a pivotal mediator in chemical neurotransmission and as a ligand for defining receptors. The natural alkaloids physostigmine (by inhibiting acetylcholinesterase) and nicotine and muscarine (for distinguishing

Basic Neurochemistry: Molecular, Cellular and Medical Aspects
0-12-088397-X

receptor subtype) were invaluable tools for identifying ACh as a transmitter and delineating its sites of action. The unusual spatial localization of nicotinic acetylcholine receptors (nAChR) at the neuromuscular junction endplates enabled the discoveries of quantal release of neurotransmitter, receptor desensitization and channel gating properties of individual receptor molecules through single channel and noise analysis.

ACh is widely distributed in the nervous system. It subserves all motor transmission in vertebrates, is the primary transmitter for peripheral ganglia, mediates parasympathetic actions of the autonomic nervous system and is a dominant transmitter in the central nervous system. Toxins from various predatory species have evolved to block motor activity of prey; others from coral and plants use paralysis induced by cholinergic agents for protection from predation. The high affinity and selectivity of these toxins enabled the nAChR to emerge as the first chemically characterized neurotransmitter receptor. Other toxins from snakes and snails have proved useful to identify receptor subtypes in various tissues. In Alzheimer's dementias, ACh-containing nerve terminals are preferentially affected and therapy is directed to extending the surface area and duration of action of released ACh (Ch. 47). Cholinergic nerve terminals are also the site of action in the treatment of certain myasthenias and disorders involving compromised or excessive smooth muscle activity and exocrine secretion in the periphery. Carbamate and organophosphate pesticides act to delay the termination of action of acetylcholine by inhibiting acetylcholinesterase, and volatile organophosphates that have been used in terrorism incidents also act in this manner.

ACh arrived within the evolutionary scheme long before the design of the nervous system and functional synapses. Bacteria, fungi, protozoa and plants store ACh and possess biosynthetic and degradative capacities for turnover of the molecule. Even in higher organisms, ACh distribution is far wider than the nervous system. For example, ACh is found in the cornea, certain ciliated epithelia, the spleen of ungulates and the human placenta [1]. Although definitive evidence is lacking, ACh has been proposed to play a role in development and tissue differentiation.

ACh was first proposed as a mediator of cellular function by Hunt in 1907, and in 1914 Dale [2] pointed out that its action closely mimicked the response of parasympathetic nerve stimulation (see Ch. 10). Loewi, in 1921, provided clear evidence for ACh release by nerve stimulation. Separate receptors that explained the variety of actions of ACh became apparent in Dale's early experiments [2]. The nicotinic ACh receptor was the first transmitter receptor to be purified and to have its primary structure determined [3, 4]. The primary structures of most subtypes of both nicotinic and muscarinic receptors, the cholinesterases (ChE), choline acetyltransferase (ChAT), the choline and ACh transporters have been ascertained. Three-dimensional structures for several of these proteins or surrogates within the same protein family are also known.

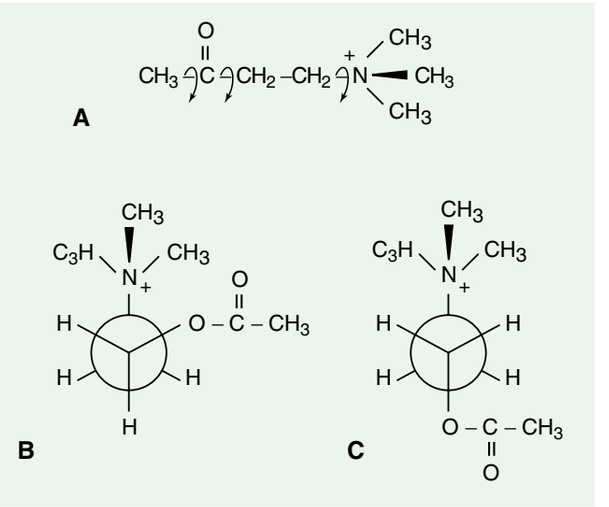

FIGURE 11-1 Structure of acetylcholine. (**A**) The three torsion angles, τ_1, τ_2 and τ_3. (**B**) Newman projection of the *gauche* conformation. (**C**) Newman projection of the *trans* conformation. The molecule is viewed in the plane of the paper from the left side, and the bond angles around τ_2 are compared.

CHEMISTRY OF ACETYLCHOLINE

Torsional rotation in the ACh molecule can occur around bonds τ_1, τ_2 and τ_3 (Fig. 11-1). Since the methyl groups are disposed symmetrically around τ_3 and constraints are placed on τ_1 by the planar acetoxy group, the most important torsion angle determining ACh conformation in solution is τ_2. A view from the β-methylene carbon of the molecule (Fig. 11-1B,C) shows the energy configurations around τ_2. Nuclear magnetic resonance (NMR) studies indicate that the *gauche* conformation is predominant in solution [5, 6]. Studies of the activities of rigid analogs of ACh suggest that the *trans* conformation may be the active conformation at muscarinic receptors [7], while results of NMR and X-ray crystallography studies suggest a change in configuration when ACh is bound to the nicotinic receptor [6, 8]. Hence the bound conformations of this flexible molecule appear to differ substantially with receptor subtype. This finding should not be a great surprise, since structural modifications of ACh that enhance or diminish activity on muscarinic receptors are very different from those modifications that influence activity on nicotinic receptors.

ORGANIZATION OF THE CHOLINERGIC NERVOUS SYSTEM

Acetylcholine receptors have been classified into subtypes based on early studies of pharmacologic selectivity. Long before structures were known, two crude alkaloid fractions, containing nicotine and muscarine (Fig. 11-2), were used to subclassify receptors in the cholinergic nervous system (Fig. 11-3). The greatly different

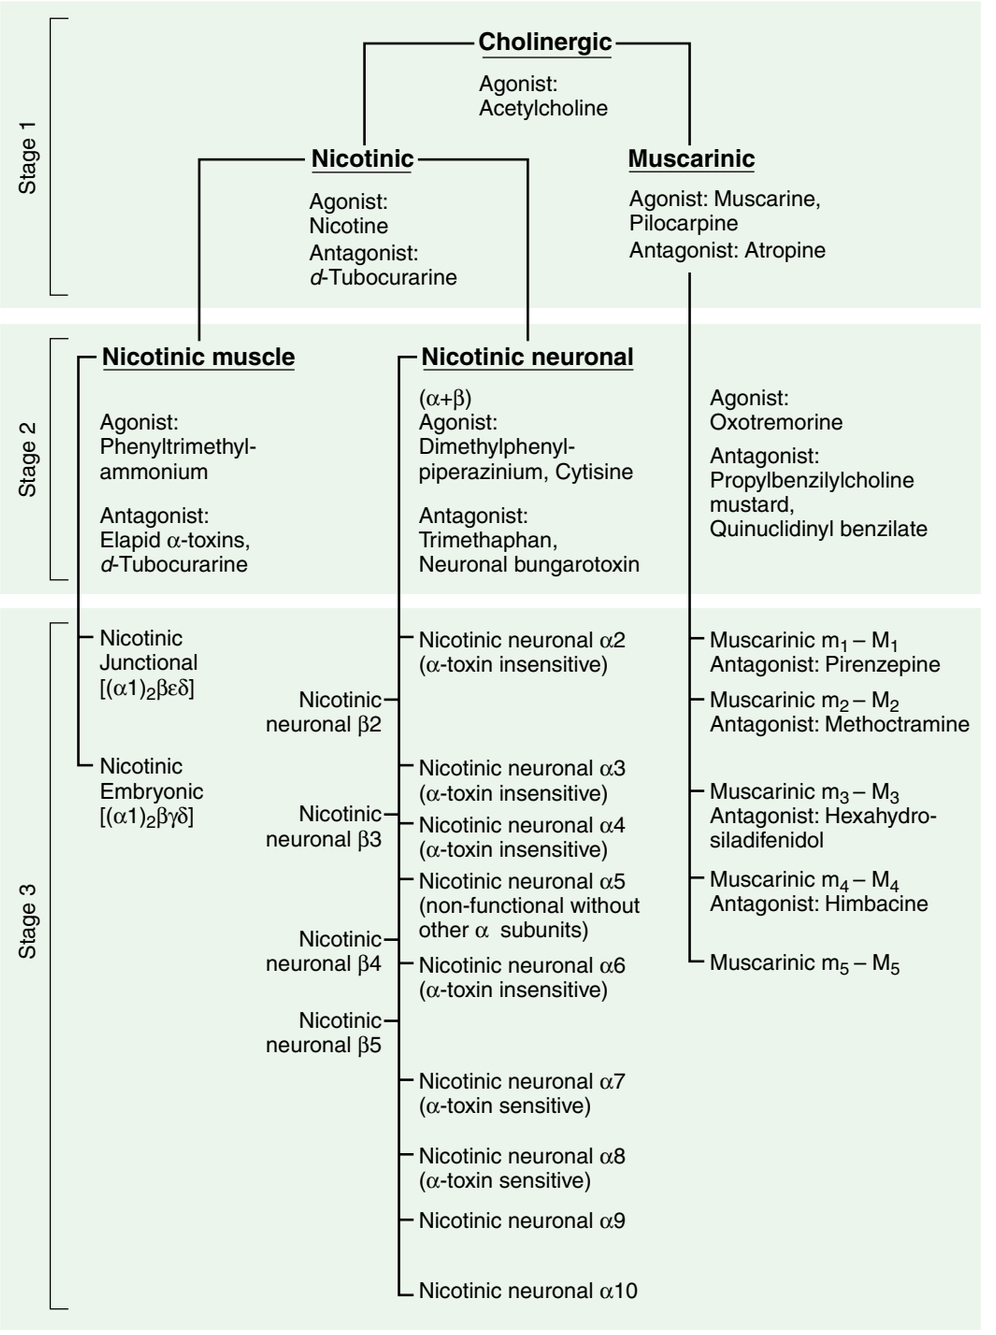

FIGURE 11-2 Classification of cholinergic receptors. The diagram shows a historical classification of receptors analyzed on the basis of distinct responses with crude alkaloids (**stage 1**), the partial resolution of receptor subtypes with chemically synthesized agonists and antagonists (**stage 2**) and the distinction of primary structures of the receptors principally through cloning by recombinant DNA techniques (**stage 3**).

activities of the antagonists atropine on muscarinic receptors and D-tubocurarine on nicotinic receptors further supported the argument that multiple classes of receptors existed for ACh. Subsequently, it was found that all nicotinic receptors are not identical. Nicotinic receptors in the neuromuscular junction, sometimes denoted as N_1 receptors, show selectivity for phenyltrimethylammonium as an agonist; elicit membrane depolarization in response to bisquaternary amines, with decamethonium being the most potent; are preferentially blocked by the competitive antagonist D-tubocurarine and are blocked irreversibly by the snake α-toxins. Nicotinic receptors in ganglia, N_2 receptors, are stimulated preferentially by 1,1-dimethyl-4-phenylpiperazinium, blocked competitively by trimethaphan, blocked noncompetitively by bisquaternary amines, with hexamethonium being the

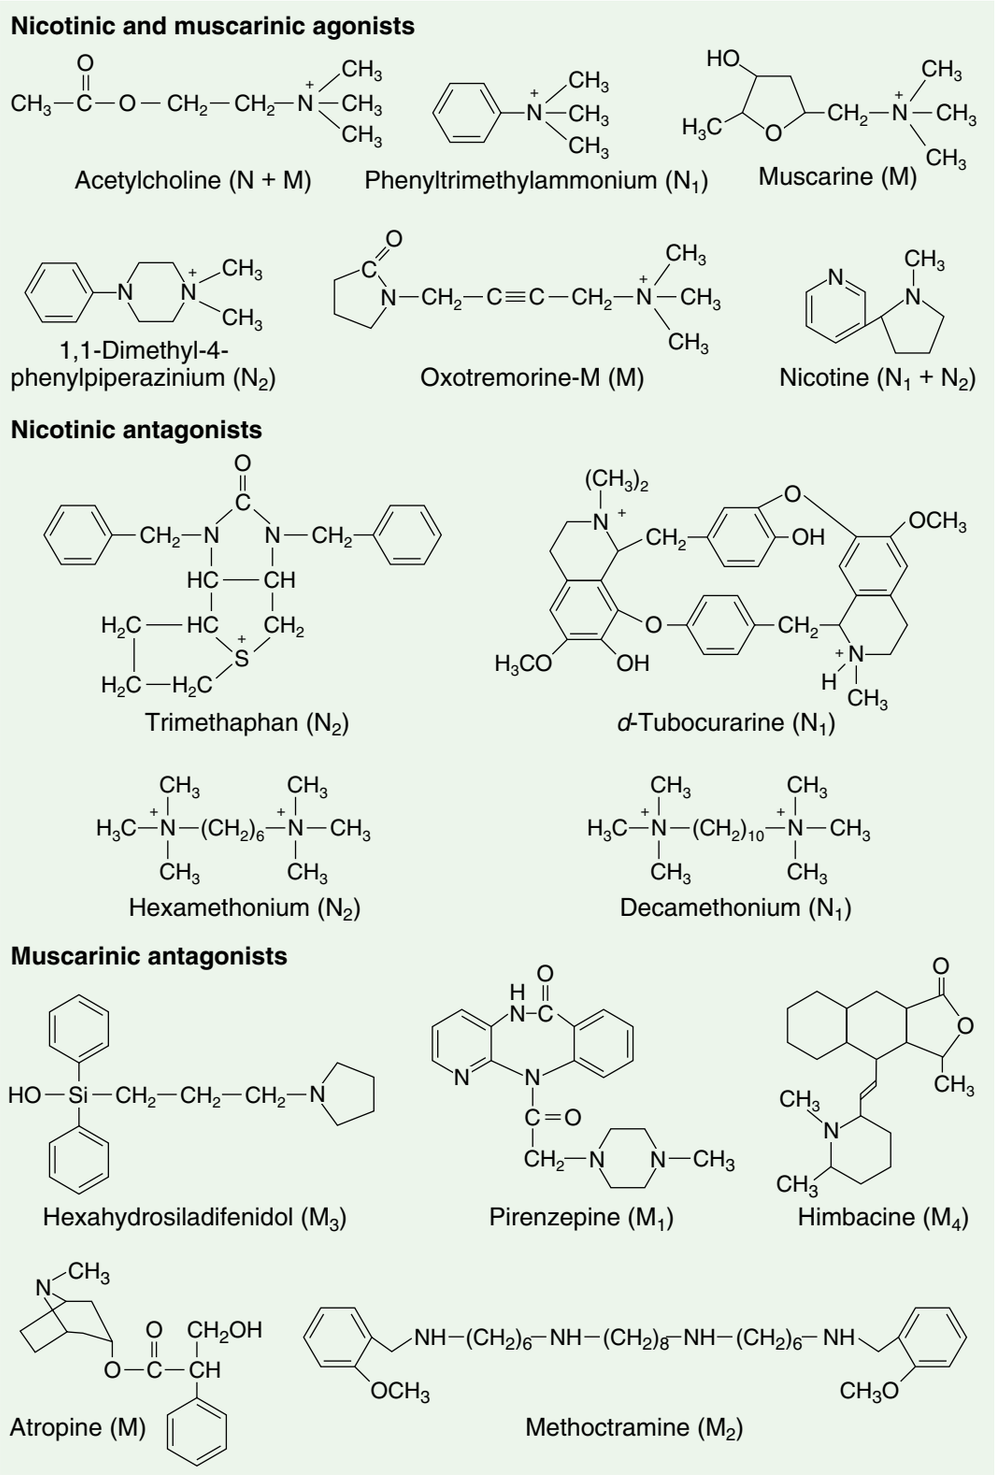

FIGURE 11-3 Structure of compounds important to the classification of receptor subtypes at cholinergic synapses. Compounds are subdivided as nicotinic (*N*) and muscarinic (*M*). The compounds interacting with nicotinic receptors are subdivided further according to whether they are neuromuscular (N_1) or ganglionic (N_2). Compounds with muscarinic subtype selectivity (M_1, M_2, M_3, M_4) are also noted.

most potent, and show resistance to the snake α-toxins [9]. A large number of distinct neuronal nicotinic receptors are found in the CNS; they are closer relatives of the nicotinic receptors in ganglia than of those in muscle.

Muscarinic receptors also exhibit distinct subtypes. The antagonist pirenzepine (PZ) has the highest affinity for one subtype, M_1, which is found mainly in neuronal tissues. Another antagonist, methoctramine, has a higher affinity for M_2 receptors, which are the predominant muscarinic receptor subtype in mammalian heart. Hexahydrosiladifenidol is relatively selective for the M_3 receptors present in smooth muscle and glands, whereas himbacine exhibits high affinity for M_4 receptors. With this level of multiplicity of receptor subtypes, limitations on specificity preclude a single antagonist defining a distinct subtype.

The intrinsic complexity and the multiplicity of cholinergic receptors became evident upon elucidation of their primary structures. In the CNS, at least nine different sequences of α subunits and three different sequences of β subunits of the nicotinic receptor have been identified [10, 11]. Expression of the cloned genes encoding certain subunit combinations yields functional receptors with different sensitivities toward various toxins and agonists.

At least five distinct muscarinic receptor genes have been cloned and sequenced. The genes are called m_1 to m_5. They correlate with the M_1 to M_5 receptors identified pharmacologically. The subtypes differ in their ability to couple to different G proteins and, hence, to elicit cellular signaling events.

Thus, cholinergic receptor classification can be considered in terms of three stages of development. Initially, Dale [2] distinguished nicotinic and muscarinic receptor subtypes with crude alkaloids. Then, chemical synthesis and structure-activity relationships clearly revealed that nicotinic and muscarinic receptors were heterogeneous, but chemical selectivity could not come close to uncovering the true diversity of receptor subtypes. Lastly, analysis of subtypes came from molecular cloning, making possible the classification of receptors on the basis of primary structure (Fig. 11-2).

FUNCTIONAL ASPECTS OF CHOLINERGIC NEUROTRANSMISSION

The individual subtypes of receptors often show discrete anatomical locations in the peripheral nervous system, and this has facilitated their classification. Nicotinic receptors are found in peripheral ganglia and skeletal muscle. Upon innervation of skeletal muscle, receptors congregate in the junctional or postsynaptic endplate area. Upon denervation or in noninnervated embryonic muscle, the receptors are distributed across the surface of the muscle, and these extrajunctional receptors are synthesized and degraded rapidly. Junctional receptors exhibit far slower rates of turnover and are distinguished by an ε subunit replacing a γ subunit in the assembled pentameric receptor.

Ganglionic nicotinic receptors are found on postsynaptic neurons in both parasympathetic and sympathetic ganglia and in the adrenal gland. Ganglionic nicotinic receptors appear in tissues of neural crest embryonic origin and exhibit identical properties in sympathetic and parasympathetic ganglia.

Muscarinic receptors are responsible for postganglionic parasympathetic neurotransmission and thus for control of a wide range of smooth muscle, cardiac muscle and secretory responses. Some responses originating in the sympathetic division of the autonomic nervous system, such as sweating and piloerection, also are mediated through muscarinic receptors.

Both muscarinic and nicotinic responses are elicited in brain and spinal cord. A few specific central cholinergic pathways have been characterized. In higher brain centers, ACh is concentrated in interneurons and long projection neurons. In the striatum, cholinergic interneurons provide critical intercircuitry for extrapyramidal motor control and implicit memory. Four predominant nuclei in the basal forebrain send projecton neurons to the hippocampus, olfactory bulb and cerebral cortex. These include the nucleus basalis of Meynert, a region of primary degeneration in Alzheimer's disease. Four areas of the brain stem send cholinergic projections to the thalamus, interpeduncular nucleus and the superior colliculus. Renshaw cells in the spinal cord play a role in modulating motoneuron activity by a feedback mechanism. Stimulation of Renshaw cells occurs through branches of the motoneuron, and the transmitter is ACh acting on nicotinic receptors.

Both nicotinic and muscarinic receptors are widespread in the CNS. Muscarinic receptors with a high affinity for pirenzepine (PZ), M_1 receptors, predominate in the hippocampus and cerebral cortex, whereas M_2 receptors predominate in the cerebellum and brainstem, and M_4 receptors are most abundant in the striatum. Central muscarinic and nicotinic receptors are targets of intense pharmacological interest for their potential roles in regulating abnormal neurological signaling in Alzheimer's disease, Parkinson's disease and certain seizure disorders. Nicotinic receptors are largely localized at prejunctional sites and control the release of neurotransmitters [10, 11].

Histochemical studies using antibodies selective for receptor subtype, ChAT and presynaptic transport proteins, along with receptor autoradiography with labeled ligands, have produced detailed maps of the CNS. In addition, the nerve cell bodies containing the mRNA encoding these proteins have been defined through *in situ* hybridization with a cDNA or antisense mRNA. Studies involving iontophoretic application of transmitter, local stimulation and intracellular or cell-surface measurements of responses establish appropriate

functional correlates. Recently, knockout mice strains, harboring deletions of M1–M5 mAChRs and various nAChR subunits, have been generated, providing a direct means of determining the localization of function of these receptors [12, 13].

Neurotransmission in autonomic ganglia is more complex than depolarization mediated by a single transmitter. In autonomic ganglia, the primary electrophysiological event following preganglionic nerve stimulation is the rapid depolarization of postsynaptic sites by released ACh acting on nicotinic receptors. This activation gives rise to an initial excitatory postsynaptic potential (EPSP), which is due to an inward current through a cation channel (see Chs 6 and 10). This mechanism is virtually identical to that in the neuromuscular junction, with an immediate onset of the depolarization and decay within a few milliseconds. Nicotinic antagonists such as trimethaphan competitively block ganglionic transmission, whereas agents such as hexamethonium produce blockade by occluding the channel. An action potential is generated in the postganglionic nerve when the initial EPSP attains a threshold amplitude.

Several secondary events amplify or suppress this signal. These include the slow EPSP, the late, slow EPSP and an inhibitory postsynaptic potential (IPSP). The slow EPSP is generated by ACh acting on muscarinic receptors and is blocked by atropine. It has a latency of approximately 1 sec and a duration of 30–60 seconds. The late, slow EPSP can last for several minutes and is mediated by peptides found in ganglia, including substance P, angiotensin, luteinizing-hormone-releasing hormone (LHRH) and the enkephalins. The slow EPSP and late, slow EPSP result from decreased K^+ conductance and are believed to regulate the sensitivity of the postsynaptic neuron to repetitive depolarization [14]. The IPSP seems to be mediated by the catecholamines dopamine and/or norepinephrine and is blocked by α-adrenergic antagonists as well as by atropine. ACh released from presynaptic terminals may act on a catecholamine-containing interneuron to release dopamine and perhaps norepinephrine. Similar to the slow EPSP, the IPSP has a prolonged latency and duration of action. These secondary events vary with the individual ganglia and are believed to modulate the sensitivity to the primary event. Hence, drugs that selectively block the slow EPSP, such as atropine, will diminish the efficiency of ganglionic transmission rather than eliminate it. Similarly, agonists such as muscarine and the ganglion-selective muscarinic agent, McN-A-343, are not thought of as primary ganglionic stimulants. Rather, they enhance the initial EPSP under conditions of repetitive stimulation.

Since parasympathetic and sympathetic ganglia exhibit comparable sensitivities to nicotinic agonists such as nicotine and ACh in producing the initial EPSP, the pharmacological effect of ganglionic stimulation depends on the profile of innervation to particular organs or tissues (Table 11-1). For example, blood vessels are innervated only by the sympathetic nervous system; thus, ganglionic stimulation should produce only vasoconstriction. Similarly, the pharmacological effects of ganglionic blockade will depend on which component of the autonomic nervous system is exerting the predominant tone at the effector organ.

Muscarinic receptors are widely distributed at postsynaptic parasympathetic effector sites. The response to systemically administered ACh is characteristic of stimulation of postganglionic effector sites rather than of ganglia. This is a consequence of the greater abundance of muscarinic receptors at effector sites in innervated tissues and the limited blood flow to ganglia. Muscarinic receptors are found in visceral smooth muscle, cardiac muscle, secretory glands and endothelial cells of the vasculature. Except for endothelial cells, each of these sites receives cholinergic innervation. Responses can be excitatory or inhibitory, depending on the tissue. Even within a single tissue the responses may vary. For example, muscarinic stimulation causes gastrointestinal smooth muscle to depolarize and contract, except at sphincters, where hyperpolarization and relaxation are seen (Table 11-2). In most tissues innervated by the cholinergic nervous system, smooth muscle exhibits intrinsic electrical and/or mechanical activity. This activity is modulated rather than initiated by cholinergic nerve stimulation. Cardiac muscle and smooth muscle exhibit spikes of electrical activity that are propagated between cells. These spikes are initiated by rhythmic fluctuations in resting membrane potential. In intestinal smooth muscle, cholinergic stimulation

TABLE 11-1 Predominance of sympathetic or parasympathetic tone at effector sites: effects of autonomic ganglionic blockade

Site	Predominant tone	Primary effects of ganglionic blockade
Arterioles	Sympathetic (adrenergic)	Vasodilation, increased peripheral blood flow, hypotension
Veins	Sympathetic (adrenergic)	Dilation, pooling of blood, decreased venous return, decreased cardiac output
Heart	Parasympathetic (cholinergic)	Tachycardia
Iris	Parasympathetic (cholinergic)	Mydriasis
Ciliary muscle	Parasympathetic (cholinergic)	Cycloplegia (focus to far vision)
Gastrointestinal tract	Parasympathetic (cholinergic)	Reduced tone and motility of smooth muscle, constipation, decreased gastric and pancreatic secretions
Urinary bladder	Parasympathetic (cholinergic)	Urinary retention
Salivary glands	Parasympathetic (cholinergic)	Xerostomia
Sweat glands	Sympathetic (cholinergic)	Anhidrosis

TABLE 11-2 Effects of acetylcholine (ACh) stimulation on peripheral tissues

Tissue	Effects of ACh
Vasculature (endothelial cells)	Release of endothelium-derived relaxing factor (nitric oxide) and vasodilation
Eye iris (pupillae sphincter muscle)	Contraction and miosis
Ciliary muscle	Contraction and accommodation of lens to near vision
Salivary glands and lacrimal glands	Secretion – thin and watery
Bronchi	Constriction, increased secretions
Heart	Bradycardia, decreased conduction (atrioventricular block at high doses), small negative inotropic action
Gastrointestinal tract	Increased tone, increased gastrointestinal secretions, relaxation at sphincters
Urinary bladder	Contraction of detrusor muscle, relaxation of the sphincter
Sweat glands	Diaphoresis
Reproductive tract, male	Erection
Uterus	Variable, dependent on hormonal influence

will cause a partial depolarization and increase the frequency of spike production. In contrast, cholinergic stimulation of atria will decrease the generation of spikes through hyperpolarization of the membrane.

Membrane depolarization typically results from an increase in Na^+ conductance. In addition, mobilization of intracellular Ca^{2+} from the endoplasmic or sarcoplasmic reticulum and the influx of extracellular Ca^{2+} appear to be elicited by ACh acting on muscarinic receptors (see Ch. 22). The resulting increase in intracellular free Ca^{2+} is involved in activation of contractile, metabolic and secretory events. Stimulation of muscarinic receptors has been linked to changes in cyclic nucleotide concentrations. Reductions in cAMP concentrations and increases in cGMP concentrations are typical responses (see Ch. 21). These cyclic nucleotides may facilitate contraction or relaxation, depending on the particular tissue. Inhibitory responses also are associated with membrane hyperpolarization, and this is a consequence of an increased K^+ conductance. Increases in K^+ conductance may be mediated by a direct receptor linkage to a K^+ channel or by increases in intracellular Ca^{2+}, which in turn activate K^+ channels. Mechanisms by which muscarinic receptors couple to multiple cellular responses are considered later.

Stimulation of the motoneuron releases acetylcholine onto the muscle endplate and results in contraction of the muscle fiber. Contraction and associated electrical events can be produced by intra-arterial injection of ACh close to the muscle. Since skeletal muscle does not possess inherent myogenic tone, the tone of apparently resting muscle is maintained by spontaneous and intermittent release of ACh. The consequences of spontaneous release at the motor endplate of skeletal muscle are small depolarizations from the quantized release of ACh, termed *miniature endplate potentials* (MEPPs) [15] (see Ch. 10). Decay times for the MEPPs range between 1 and 2 ms, a duration similar to the mean channel open time seen with ACh stimulation of individual receptor molecules. Stimulation of the motoneuron results in the release of several hundred quanta of ACh. The summation of MEPPs gives rise to a postsynaptic excitatory potential (PSEP), also termed *motor endplate potential*. A sufficiently large and abrupt potential change at the endplate will elicit an action potential by activating voltage-sensitive Na^+ channels. The action potential propagates in two-dimensional space across the surface of the muscle to release Ca^{2+} and elicit contraction. Therefore, the PSEP may be thought of as a generator potential, found only in junctional regions and arising from the opening of multiple receptor channels. Normal resting potentials in endplates are about −70 mV. The PSEP causes the endplate to depolarize partially to about −55 mV. It is the rapid and transient changes from −70 to −55 mV in localized areas of the endplate that trigger action potential generation [9, 15].

Competitive blocking agents cause muscle paralysis by preventing access of acetylcholine to its binding site on the receptor. Competitive blockade with agents such as D-tubocurarine result in maintenance of the endplate potential at −70 mV. Without frequent PSEPs, action potentials are not triggered and flaccid paralysis of the muscle results. The actions of competitive blocking agents can be surmounted by excess ACh. Depolarizing neuromuscular blocking agents, such as decamethonium and succinylcholine, produce depolarization of the endplate such that the endplate potential is −55 mV. The high concentrations of depolarizing agent that are maintained in this synapse do not allow regions of the endplate to repolarize, as would occur with a labile transmitter such as ACh. Since it is the transition in membrane potential between −70 and −55 mV that triggers the action potential, flaccid paralysis also will occur with a depolarizing block [9]. Excess ACh will not reverse the paralysis by depolarizing blocking agents. As might be expected if depolarization occurs in a non-uniform manner in microscopic areas within individual endplates and in individual motor units, the onset of depolarization blockade is characterized by muscle twitching and fasciculations that are not evident in competitive block. Once paralysis occurs, the overall pharmacological actions of competitive and depolarizing blocking agents are similar, yet intracellular measurements of endplate potential can distinguish these two classes of agent.

SYNTHESIS, STORAGE AND RELEASE OF ACETYLCHOLINE

The biosynthesis and storage of ACh can be divided into three processes that allow for recovery of hydrolyzed transmitter by choline transport back into the nerve ending, conversion by acetylation to active transmitter and then storage in a vesicle for subsequent release [16–21] (Fig. 11-4).

The synthesis reaction is a single step catalyzed by the enzyme choline acetyl transferase (ChAT):

$$\text{Choline} + \text{Acetyl coenzyme A} \rightleftharpoons \text{Acetylcholine} + \text{Coenzyme A}.$$

ChAT, first assayed in a cell-free preparation in 1943, has subsequently been purified and cloned from several sources [16]. The purification of ChAT has allowed production of specific antibodies. Whereas acetylcholinesterase (AChE), the enzyme responsible for degradation of ACh, is produced by cells containing cholinoreceptive sites as well as in cholinergic neurons, ChAT is found in the nervous system specifically at sites where ACh synthesis takes place. Within cholinergic neurons, ChAT is concentrated in nerve terminals, although it is also present in axons, where it is transported from its site of synthesis in the soma. When subcellular fractionation studies are carried out, ChAT is recovered in the synaptosomal fraction, and within synaptosomes it is primarily cytoplasmic. It has been suggested that ChAT also binds to the outside of the storage vesicle under physiological conditions and that ACh synthesized in that location may be situated favorably to enter the vesicle.

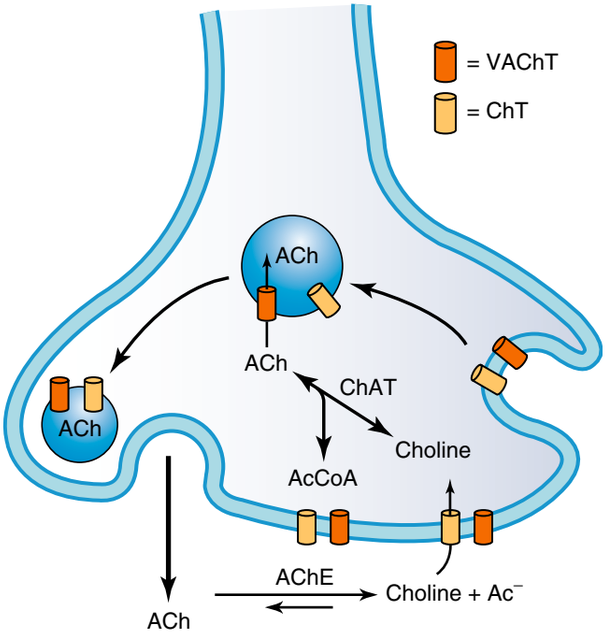

FIGURE 11-4 Transport, synthesis and degradative processes in a cholinergic presynaptic nerve terminal and synapse. The choline transport protein (*ChT*) functions at the nerve ending membrane to transport choline into the cytoplasm, where its acetylation by acetyl CoA is catalyzed by choline acetyltransferase (*ChAT*) to generate acetylcholine (*ACh*) in the vicinity of the synaptic vesicle. The vesicular acetylcholine transporter (*VAChT*) concentrates acetylcholine in the vesicle. ChT is also found on the vesicle but in a functionally inactive state. Upon nerve stimulation, depolarization and Ca^{2+} entry, ACh-containing vesicles fuse with the membrane and release their contents. The fusion of the membrane results in more ChT being exposed to the synaptic gap, where it becomes active. ACh is hydrolyzed to acetate and choline catalyzed by acetylcholinesterase (*AChE*), allowing for recapture of much of the choline by ChT. Because of the differing ionic compositions in the extracellular milieu and within the cell, ChT is thought to be active only when situated on the nerve cell membrane. Similarly, the VAChT may only be active when encapsulated in the synaptic vesicle [19].

Brain ChAT has a K_D for choline of approximately 1 mmol/l and for acetyl coenzyme A (CoA) of approximately 10 µmol/l. The activity of the isolated enzyme, assayed in the presence of optimal concentrations of cofactors and substrates, appears far greater than the rate at which choline is converted to ACh *in vivo*. This suggests that the activity of ChAT is repressed *in vivo*. Surprisingly, inhibitors of ChAT do not decrease ACh synthesis when used *in vivo*; this may reflect a failure to achieve a sufficient local concentration of inhibitor, but also suggests that this step is not rate-limiting in the synthesis of ACh [18–20].

The acetyl CoA used for ACh synthesis in mammalian brain comes from pyruvate formed from glucose. It is unclear how the acetyl CoA, generally thought to be formed at the inner membrane of the mitochondria, accesses the cytoplasmic ChAT. This may also be a regulated, rate-limiting step.

Acetylcholine formation is limited by the intracellular concentration of choline, which is determined by active transport of choline into the nerve ending. Choline is present in the plasma at a concentration of about 10 µmol/l. A 'low-affinity' choline uptake system with a K_m of 10–100 µmol/l is present in all tissues, but cholinergic neurons also have a Na^+-dependent 'high-affinity' choline uptake system, with a K_m for choline of 1–5 µmol/l [17–20]. The high-affinity uptake mechanisms should be saturated at 10 µmol/l choline, so the plasma choline concentration is probably adequate for sustained ACh synthesis even under conditions of high demand, as observed in ganglia. Since the plasma concentration of choline is above the K_m of the high-affinity choline-transport system, it is not expected that choline concentrations in the nerve ending would be increased by increasing the plasma concentration of choline or by changing the K_m of the uptake system. However, neuronal choline content can be influenced by altering the capacity of the high-affinity choline-uptake mechanism, i.e. by changing the maximum velocity (V_{max}) for transport. The cloning of the high affinity choline transporter has provided considerable insight into the mechanisms by which events associated with neuronal

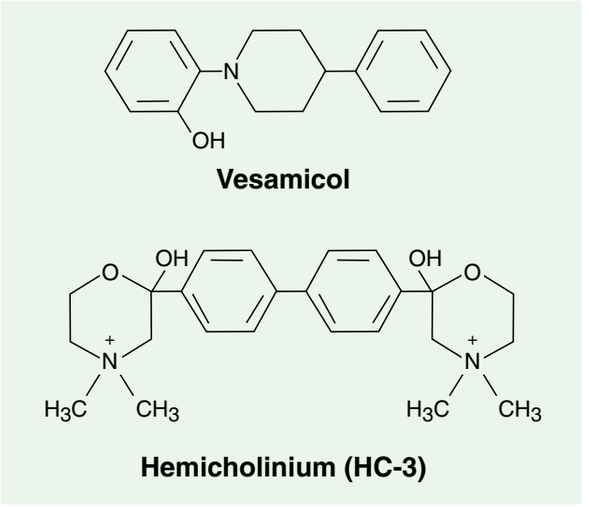

FIGURE 11-5 Structures of hemicholinium (HC-3) and vesamicol.

activity enhance choline entry into neurons [17, 19]. If the K_m of ChAT for choline *in vivo* is as high as that seen with the purified enzyme, one would expect ACh synthesis to increase in proportion to the greater availability of choline. Conversely, ACh synthesis should be diminished when high-affinity choline uptake is blocked. Hemicholinium-3 is a potent inhibitor of the high-affinity choline-uptake system, with a K_i in the submicromolar range (Fig. 11-5). Indeed, treatment with this drug decreases ACh synthesis and leads to a reduction in ACh release during prolonged stimulation; these findings lend support to the notion that choline uptake is the rate-limiting factor in the biosynthesis of ACh [18].

Characterization and regulation of the high affinity choline transporter. The successful cloning of the high affinity choline transporter [17], now referred to as the CHT, was spurred by the discovery of a *Caenorhabditis elegans* transporter exhibiting cholinergic neuron specificity. The homologous rat CHT cDNA conferred high affinity Na^+ and Cl^- dependent choline transport when expressed in *Xenopus* oocytes, and subsequently homologous cDNAs were cloned from numerous species including mice and humans [19]. The gene structure is highly conserved amongst the species, and the encoded protein is a member of a family of Na^+-dependent transporters. The structure reveals 13 transmembrane spans, glycosylation sites on the extracellular surface and several potential sites for phosphorylation on intracellular loops and at the C-terminus. The development of antibodies to CHT revealed the anticipated localization of CHT at presynaptic sites and exclusively in cholinergic neurons. Surprisingly, however, much of the CHT immunoreactivity was found associated with intracellular vesicles rather than at the presynaptic plasma membrane. These vesicles appear to be those involved in ACh synthesis (and its subsequent storage and release) as CHT is co-localized with the vesicular ACh transporter (VAChT) described below. Interestingly, blocking endocytosis leads to CHT accumulation at the plasma membrane and an enhanced capacity for choline uptake [19]. Thus, it appears that the transporter is normally removed from the plasma membrane and recycled. Conversely, stimuli that trigger ACh release have been shown to increase CHT density at the plasma membrane, providing a mechanism by which uptake can be tightly coupled to the rate of ACh release. It is likely that post-translational modification, e.g. phosphorylation, also serves to regulate the transporter in response to altered synaptic activity. Whether this occurs via activation of a resident plasma membrane pool of CHT or alterations in activity or recycling of the vesicular CHT pool remains to be determined. The transporter precursor progresses down the axons by axoplasmic transport and is localized to the vesicular environment by poorly understood mechanisms.

A second transport system concentrates acetylcholine in the synaptic vesicle. The vesicular ACh transporter (VAChT) also has been cloned and expressed (see also Ch. 5). Its sequence places it in the 12-membrane-spanning family characteristic of the other biogenic amine transporters found in adrenergic nerve endings [18, 20, 21]. Interestingly, the gene encoding the transporter is located within an intron of the ChAT gene, suggesting a mechanism for coregulation of gene expression for ChAT and VAChT [20]. ACh uptake into the vesicle is driven by a proton-pumping ATPase. Coupled countertransport of H^+ and ACh allows the vesicle to remain isoosmotic and electroneutral [18].

A selective inhibitor of ACh transport, vesamicol (Fig. 11-5), inhibits vesicular ACh uptake with an IC_{50} of 40 nnol/l [16–18]. Inhibition appears noncompetitive, suggesting that this inhibitor acts on a site other than the ACh-binding site on the transporter. Vesamicol blocks the evoked release of newly synthesized ACh without significantly affecting high-affinity choline uptake, ACh synthesis or Ca^{2+} influx. The fact that ACh release is lost secondary to the blockade of uptake by the vesicle supports the concept that the vesicle is the site of ACh release. The activity of the recombinant transporter also is inhibited by vesamicol [19, 20].

Choline is supplied to the neuron either from plasma or by metabolism of choline-containing compounds. The majority of the choline used in ACh synthesis is thought to come directly from recycling of released ACh, hydrolyzed to choline by acetylcholinesterase (Fig. 11-4). Presumably, uptake of this neurotransmitter-derived choline occurs rapidly, before the choline diffuses away from the synaptic cleft. Another source of choline is the breakdown of phosphatidylcholine, which may be stimulated by locally released ACh. Choline derived from these two sources is then subject to high-affinity uptake into the

nerve ending. In the CNS, these metabolic sources of choline appear to be particularly important because choline in the plasma cannot readily pass the blood–brain barrier. Thus, the high-affinity uptake of choline into cholinergic neurons in the CNS might not always be saturated, and ACh synthesis could be limited by the supply of choline, at least during sustained activity. This would be consistent with the finding that ACh stores in the brain are subject to variation, whereas ACh stores in ganglia and muscles remain relatively constant.

A slow release of acetylcholine from neurons at rest probably occurs at all cholinergic synapses. Quantized ACh release was described first by Fatt and Katz, who recorded small, spontaneous depolarizations at frog neuromuscular junctions that were subthreshold for triggering action potentials. These MEPPs were shown to be due to the release of ACh. When the nerve was stimulated and endplate potentials recorded and analyzed, the magnitude of these potentials always was found to be some multiple of the magnitude of the individual MEPPs. It was suggested that each MEPP resulted from a finite quantity or quantum of released ACh and that the endplate potentials resulted from release of greater numbers of quanta during nerve stimulation (see Ch. 10).

A possible structural basis for these discrete units of transmitter was discovered shortly thereafter when independent electron microscopic and subcellular fractionation studies by de Robertis and Whittaker revealed the presence of vesicles in cholinergic nerve endings. These investigators defined procedures for subcellular fractionation of mammalian brain and *Torpedo* electric organs that yield resealed nerve endings, or synaptosomes, that can be lysed to release a fraction enriched in vesicles. More than half of the ACh in the synaptosome is associated with particles that look like the vesicles seen under an electron microscope. Therefore, it is clear that ACh is associated with a vesicle fraction, and it is likely that it is contained within the vesicle. The origin of the free ACh within the synaptosome is less clear. It may be ACh that is normally in the cytosol of the nerve ending, or it may be an artifact of release from the vesicles during their preparation (see Ch. 10).

The relationship between acetylcholine content in a vesicle and the quanta of acetylcholine released can only be estimated. Estimates of the amount of ACh contained within cholinergic vesicles vary considerably [22]. Whittaker estimated that there are about 2,000 molecules of ACh in a cholinergic vesicle from the CNS. A similar estimate of about 1,600 molecules of ACh per vesicle was made using sympathetic ganglia. The most abundant source of cholinergic synaptic vesicles is the electric organ of *Torpedo*. Vesicles from *Torpedo* are far larger than those from mammalian species and are estimated to contain up to 100 times more ACh per vesicle. The *Torpedo* vesicle also contains ATP and, in its core, a proteoglycan of the heparin sulfate type. Both of these constituents may serve as counter-ions for ACh, which otherwise would be at a hyperosmotic concentration.

The amount of ACh in a quantum has been estimated by comparing the potential changes associated with MEPPs to those obtained by iontophoresis of known quantities of ACh. Based on such analysis, the amount of ACh per quantum at the snake neuromuscular junction was estimated to be something less than 10,000 molecules [22]. Since this compares with estimates of vesicle content, quanta are likely defined by the amount of releasable ACh in the vesicle. An alternative favored by some investigators is that ACh is released directly from the cytoplasm. In this model, definable quanta are evident because channels in the membrane are open for finite periods of time when Ca^{2+} is elevated. A presynaptic membrane protein suggested to mediate Ca^{2+}-dependent translocation of ACh has been isolated [21]. Although some arguments support this model, most investigators favor the notion that the vesicle serves not only as a unit of storage but also as a unit of release. The vesicle hypothesis and release of neurotransmitters are discussed also in Chapter 10.

Depolarization of the nerve terminal by an action potential increases the number of quanta released per unit time. Release of ACh requires the presence of extracellular Ca^{2+}, which enters the neuron when it is depolarized. Most investigators are of the opinion that a voltage-dependent Ca^{2+} current is the initial event responsible for transmitter release, which occurs about 200 μs later. The mechanism through which elevated Ca^{2+} increases the probability of ACh release is not yet known; presumably activation of proteins in the synaptic vesicle membrane fusion complex causes the vesicle to fuse with the neuronal membrane. Dependence on Ca^{2+} is a common feature of all exocytotic release mechanisms and it is likely that exocytosis is a conserved mechanism for transmitter release. There is good evidence that adrenergic vesicles empty their contents into the synaptic cleft because norepinephrine and epinephrine are released along with other contents of the storage vesicle. Although less rigorous data are available for cholinergic systems, cholinergic vesicles contain ATP, and release of ATP has been shown to accompany ACh secretion from these vesicles. Furthermore, Heuser and Reese demonstrated, in electron microscopic studies at frog nerve terminals, that vesicles fuse with the nerve membrane and that vesicular contents appear to be released by exocytosis; it has been difficult to ascertain, however, whether the fusions are sufficiently frequent to account for release on stimulation. The nerve ending also appears to endocytose the outer vesicle membrane to form vesicles that subsequently are refilled with ACh [19, 23].

All the acetylcholine contained within the cholinergic neuron does not behave as if in a single compartment. Results of a variety of neurophysiological and biochemical experiments suggest the presence of two distinguishable

pools of ACh, only one of which is readily available for release. These have been referred to as the 'readily available' or 'depot' pool and the 'reserve' or 'stationary' pool. The reserve pool refills the readily available pool as it is utilized. Unless the rate of mobilization of ACh into the readily available pool is adequate, the amount of ACh that can be released may be limited. It is also likely that newly synthesized ACh is used to fill the readily available pool of ACh because it is the newly synthesized ACh that is released preferentially during nerve stimulation. The precise relationship between these functionally defined pools and ACh storage vesicles is not known. It is possible that the readily available pool resides in vesicles poised for release near the nerve ending membrane, whereas the reserve pool is in more distant vesicles.

ACETYLCHOLINESTERASE AND THE TERMINATION OF ACETYLCHOLINE ACTION

Cholinesterases are widely distributed throughout the body in both neuronal and non-neuronal tissues. Based largely on substrate specificity, the cholinesterases are subdivided into the acetylcholinesterases (AChEs) (EC 3.1.1.7) and the butyrylcholinesterase (BuChE) (EC 3.1.1.8) [24–26]. Choline esters with acyl groups of the size of butyric acid or larger are hydrolyzed very slowly by AChE; selective inhibitors for each enzyme have been identified. AChE and BuChE are encoded by single but distinct genes. BuChE is synthesized primarily in the liver and appears in plasma; however, it is highly unlikely that appreciable concentrations of ACh diffuse from the locality of the synapse and elicit a systemic response. That the population distribution of BuChE mutations correlates with resistance of the enzyme to naturally occurring inhibitors suggests that this enzyme hydrolyzes dietary esters of potential toxicity. Although BuChE is localized in the nervous system during development, the existence of nonexpressing mutations in the BuChE gene within the human population also demonstrates that this enzyme is not essential for nervous system function. In general, AChE distribution correlates with innervation and development in the nervous system. The AChEs also exhibit synaptic localization upon synapse formation. Total knock out of the AChE gene in mice gives rise to an animal with continuous tremors, stunted growth and deficits in neurologic function [27].

The primary and tertiary structures of the cholinesterases are known. The primary structures of the cholinesterases initially defined a large and functionally eclectic superfamily of proteins, the α,β hydrolase fold family, that function not only catalytically as hydrolases but also as surface adhesion molecules forming heterologous cell contacts, as seen in the structurally related proteins neuroligin and the tactins. A sequence homologous to the cholinesterases and a presumed common structural matrix are found in thyroglobulin, in which tyrosine residues become iodinated and conjugated to form thyroid hormone [24, 25].

The initial solution of the crystal structure of the *Torpedo* enzyme [28], followed by the mammalian AChE structure [29], revealed that the active center serine lies at the base of a rather narrow gorge that is lined heavily with aromatic residues (Fig. 11-6). The enzyme carries a net negative charge, and an electrostatic dipole is oriented on the enzyme to facilitate diffusional entry of cationic ligands. Crystal structures of several inhibitors in a complex with AChE also have been elucidated [25].

Acetylcholinesterases exist in several molecular forms governed by alternative splicing. The open reading frame in mammalian AChE genes is encoded by three invariant exons (exons 2, 3 and 4) followed by three splicing alternatives. Continuation through exon 4 gives rise to a monomeric species. Splicing to exon 5 gives rise to the carboxyl-terminal sequence signal for addition of glycophospholipid, while splicing to exon 6 encodes a sequence containing a cysteine that links to other catalytic or structural subunits. These species of AChE differ only in the last 40 residues in their C-termini.

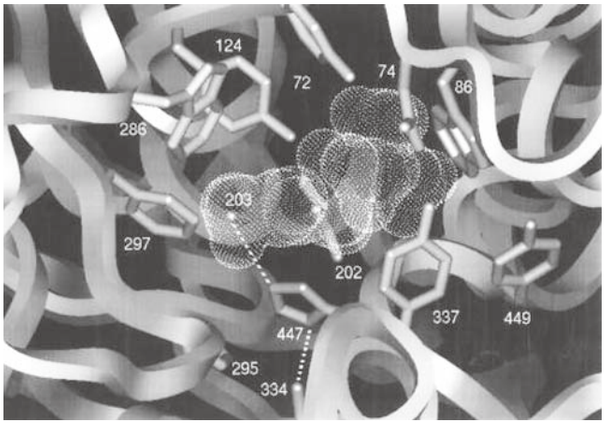

FIGURE 11-6 View of the active center gorge of mammalian acetylcholinesterase looking into the gorge cavity. The gorge is 18–20 Å in depth in a molecule of 40 Å diameter and is heavily lined with aromatic amino acid side chains. Side chains from several sets of critical residues are shown emanating from the α carbon of the α carbon-amide backbone: (a) A catalytic triad between Glu 334, His 447 and Ser 203 is shown by dotted lines to denote the hydrogen-bonding pattern. This renders Ser 203 more nucleophilic to attack the carbon of acetylcholine (shown in white with the van der Waals surface). This leads to formation of an acetyl enzyme, which is deacetylated rapidly. (b) The acyl pocket outline by Phe 295 and 297 is of restricted size in acetylcholinesterase. In butyrylcholinesterase, these side chains are aliphatic, increasing the size and flexibility in the acyl pocket. (c) The choline subsite lined by the aromatic residues Trp 86, Tyr 337 and Tyr 449 and the anionic residue Glu 202. (d) A peripheral site which resides at the rim of the gorge encompasses Trp 286, Tyr 72, Tyr 124 and Asp 74. This site modulates catalysis by binding inhibitors or, at high concentrations, a second substrate molecule.

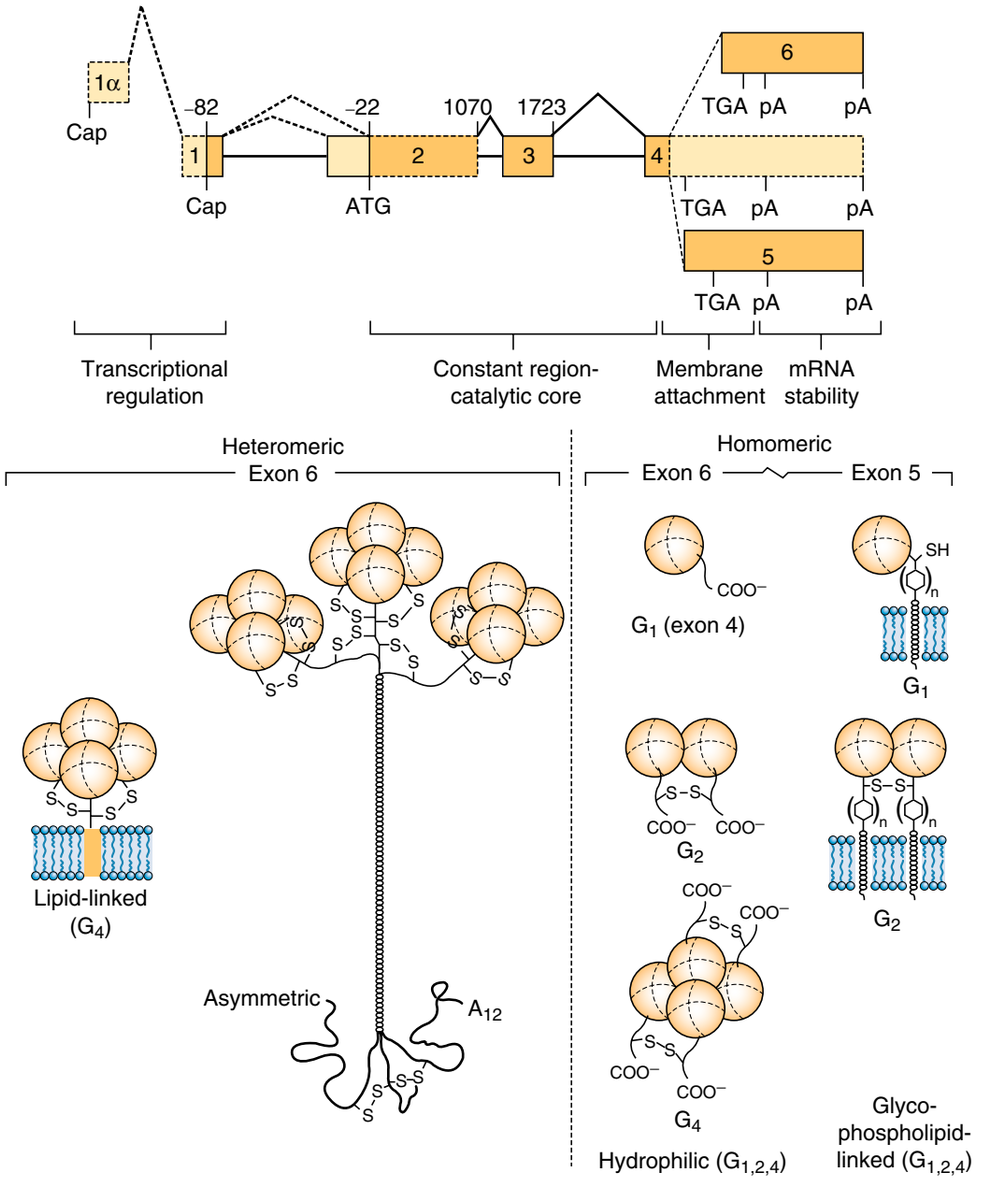

FIGURE 11-7 Gene structure of AChE. Alternative cap sites in the 5′ end of the gene allow for alternative promoter usage in different tissues. Skeletal-muscle-specific regulation is controlled by the intron region between Exons 1 and 2. Exons 2, 3 and 4 encode an invariant core of the molecule that contains the essential catalytic residues. Just prior to the stop codon, three splicing alternatives are evident: *1*, a continuation of exon 4; *2*, the 4–5 splice; and *3*, the 4–6 splice. The catalytic subunits produced differ only in their carboxy-termini and are shown in the lower panel. (Modified with permission from reference [24].)

These AChE forms differ in solubility and mode of membrane attachment rather than in catalytic activity. One class of molecular forms exists as homomeric assemblies of catalytic subunits that appear as monomers, dimers or tetramers (Fig. 11-7). These forms also differ in hydrophobicity, and their amphiphilic character arises from either exposure of an amphipathic helix or post-translational addition of a glycophospholipid on the carboxyl-terminal amino acid. The glycophospholipid allows the enzyme to be tethered on the external surface of the cell membrane.

The second class of AChEs exists as heteromeric assemblies of catalytic and structural subunits. One form consists of up to 12 catalytic subunits linked by disulfide bonds to filamentous, collagen-containing structural subunits. These forms are often termed *asymmetric*, since the tail unit imparts substantial dimensional asymmetry to the molecule. The collagenous tail unit links by disulfide bonding at its proline rich N-terminus through a coiled coil arrangement to the C-terminus of two of the catalytic subunits [30]. The tail unit associates with the basal lamina of the synapse rather than the plasma membrane.

Asymmetric forms are present in high density at the neuromuscular junction. A second type of structural subunit, found primarily in the CNS, has a similar proline-rich attachment domain but contains covalently attached lipid, enabling this form of the enzyme to associate with cell membranes. The different C-termini and attachment modes lead to distinctive extracellular localizations of AChE but do not affect the intrinsic catalytic activities of the individual forms.

Cholinesterase catalysis and inhibition mechanisms involve formation of reversible complexes and covalent conjugates. In ester catalysis, an initial acylation step proceeds through the formation of a tetrahedral transition state; acylation is rapidly followed by deacylation. Alkylphosphate inhibitors are tetrahedral in configuration and their geometric resemblance to the transition state in part accounts for their effectiveness as inhibitors of AChE. Acylation occurs on the active-site Ser 202, which is rendered nucleophilic by proton withdrawal by Glu 334 through His 447. The acetyl enzyme that is formed is short-lived, lasting approximately 10 μs; this accounts for the high catalytic efficiency of the enzyme (Fig. 11-6). The availability of a crystal structure of AChE has enabled investigators to assign residues and domains in the cholinesterase responsible for catalysis and inhibitor specificity [26, 28, 29].

Several AChE inhibitors are used therapeutically in glaucoma, myasthenia gravis and smooth muscle atony, whereas others have proved useful as insecticides. Still others have been produced for more insidious uses in terrorism and chemical warfare. Inhibitors such as edrophonium bind reversibly to the active center of AChE at the base of the gorge (Fig. 11-6). Other reversible inhibitors, such as gallamine, propidium and the three-fingered peptide from snake venom, fasciculin, bind to a peripheral site located at the gorge rim. The carbamoylating agents, such as neostigmine and physostigmine, form a carbamoyl enzyme by reacting with the active-site serine. The carbamoyl enzymes are more stable than the acetyl enzyme; their decarbamoylation occurs over several minutes. Since the carbamoyl enzyme will not hydrolyze ACh, the carbamoylating agents are alternative substrates that are effective inhibitors of ACh hydrolysis. The alkylphosphates, such as diisopropylfluorophosphate or echothiophate, act in a similar manner; however, the alkylphosphorates and alkylphosphonates form extremely stable bonds with the active-site serine on the enzyme. The time required for their hydrolysis often exceeds that for biosynthesis and turnover of the enzyme. Accordingly, inhibition with the alkylphosphates is effectively irreversible.

Consequences of acetylcholinesterase inhibition differ with effector site. At postganglionic parasympathetic effector sites, AChE inhibition enhances or potentiates the action of administered ACh or ACh released by nerve activity. In part, this is a consequence of diffusion of transmitter and stimulation of receptors extending over a larger area from the point of transmitter release. Similarly, ganglionic transmission is enhanced by cholinesterase inhibitors. Since atropine and other muscarinic antagonists are effective antidotes of AChE inhibitor toxicity, some CNS manifestations result largely from excessive muscarinic stimulation.

By prolonging the residence time of ACh in the synapse, AChE inhibition in the neuromuscular junction promotes a persistent depolarization of the motor endplate. The decay of endplate currents or potentials resulting from spontaneous release of ACh is prolonged from 1–2 ms to 5–30 ms. This indicates that the transmitter activates multiple receptors before diffusing from the synapse. Excessive depolarization of the endplate, resulting from slower rates of decay of endplate currents, leads to a diminished capacity to initiate coordinated action potentials. In a fashion similar to depolarizing blocking agents, fasciculations and muscle twitching are observed initially with AChE inhibition, followed by flaccid paralysis.

NICOTINIC RECEPTORS

The nicotinic acetylcholine receptor (nAChR) was the first characterized neurotransmitter receptor. The nAChR was purified a decade earlier than other neurotransmitter receptors. The electric organ of *Torpedo*, consisting of stacks of electrocytes, tissue of common embryonic origin to skeletal muscle, is a rich source of nicotinic receptors. Upon differentiation, the electrogenic bud in the electrocyte proliferates but the contractile elements are not expressed. The excitable membrane encompasses the entire ventral surface of the electrocyte rather than being localized to focal junctional areas covering ≈0.1% of the cell surface as found in skeletal muscle. The electrical discharge in *Torpedo* relies solely on a PSEP resulting from depolarization of the postsynaptic membrane, rather than propagation from an action potential. The density of receptors in the *Torpedo* electric organ approaches 100 pmol/mg protein, which may be compared with 0.1 pmol/mg protein in skeletal muscle.

In the early 1960s, it was established that snake α-toxins, such as α-bungarotoxin, irreversibly inactivate receptor function in intact skeletal muscle, and this finding led directly to the identification and subsequent isolation of the nicotinic ACh receptor from *Torpedo* [3]. By virtue of their high affinity and very slow rates of dissociation, labeled α-toxins serve as markers of the receptor during solubilization and purification. Sufficient amino acid sequence of the receptor was obtained to permit the cloning and sequencing of the genes encoding the individual subunits of the receptor, first in *Torpedo* and then in other species [4]. As a consequence of the high density of nicotinic ACh receptors in the postsynaptic membranes of *Torpedo*, sufficient order of the receptor molecules is achieved in isolated membrane fragments such that image

reconstructions from electron microscopy have allowed a more detailed analysis of structure [31]. Labeling of functional sites, determination of subunit composition and structure modification through mutagenesis contributed to our understanding of the structure of nicotinic receptors [32]. Recently, a soluble acetylcholine binding protein (AChBP) from mollusks was purified and its three dimensional structure determined (Fig. 11-8) [33]). Not only are these pentameric proteins structural surrogates of the extracellular domain of the nAChR [33] but, when appropriately linked to the transmembrane spans of nAChR family, they gate ions in response to agonists and are blocked by antagonists [34].

The nAChR consists of five subunits arranged around a pseudoaxis of symmetry. The subunits display homologous amino acid sequences with 30–40% identity of amino acid residues [4, 11, 32]. In muscle, one subunit, designated α, is expressed in two copies; the other three, β, γ and δ, are present as single copies (Fig. 11-9). Thus, the receptor is a pentamer of molecular mass of approximately 280 kDa. Structural studies show the subunits to be arranged around a central cavity, with the largest portion of the protein exposed toward the extracellular surface. The central cavity is believed to lead to the ion channel, which in the resting state is impermeable to ions; upon activation, however, it opens to a diameter of 6.5 Å. The open channel is selective for cations. The two α subunits and the opposing face of the γ and δ subunits form the two sites for binding of agonists and competitive antagonists and provide the primary surfaces with which the larger snake α-toxins associate. A similar pentameric ring of subunits is found for AChBP [8, 33, 34] with the binding sites located at the five interfaces between the identical subunits of this homomeric pentamer (Fig. 11-8). The sites for ligand binding are localized toward the external perimeter of each of the ligand binding subunit interfaces; occupation of multiple sites on the pentamer is necessary for receptor activation. Electrophysiological and ligand-binding measurements together with analysis of the functional states of the receptor indicate positive cooperativity in the association of agonists; Hill coefficients greater than unity have been described for agonist-elicited channel opening, agonist binding and agonist-induced desensitization of the receptor [3, 32]. Noncompetitive inhibitor sites within various depths of the internal channel also have been defined and are the sites of local anesthetic inhibition of receptor function.

Sequence identity among the subunits appears to be greatest in the hydrophobic regions. Various models for the disposition of the peptide chains and subunit assembly have been proposed on the basis of hydropathy plots, electron microscopic reconstruction analysis of *Torpedo* receptor membranes and the AChBP crystal structure [30, 33] (Figs 11-8, 11-9). Homology among the four subunits strongly suggests that the same folding pattern is found in all subunits.

A disulfide loop between Cys 128 and 142 in the α subunit is conserved in the entire receptor channel family (Fig. 11-8). A second disulfide is found in the α subunits between vicinal Cys 192 and 193, and this structural feature is also found in AChBP. Early studies showed that reduction of the Cys 192–193 bond allowed for labeling by the site-directed sulfhydryl-reactive agonist and antagonist, respectively, bromoacetylcholine and *m*-maleimidobenzyl trimethylammonium [32]. Subsequent studies involving photolytic labeling, labeling by the natural coral toxin, lophotoxin, and site-specific mutagenesis identified the region between residues 185 and 200 in the α subunit as being important for forming part of the agonist- and

FIGURE 11-8 Features of the sequence of the acetylcholine receptor. (**A**) Schematic drawing of the sequence showing candidate regions for spanning the membrane. The region M_2 is believed to be an α helical segment and lines the internal pore of the receptor. M_1, M_3 and M_4 contain hydrophobic sequences but it is not certain whether they traverse the membrane as full α helices. The nicotinic β, γ and δ subunits contain homologous M_1 through M_4 hydrophobic domains at similar positions in the linear sequence. Two disulfide loops, 128–142 and 192–193, in the α subunits are shown. While the other subunits contain the larger disulfide loop, they lack cysteines 192 and 193 and tyrosine 190. Sequence features of other homologous subunits in ligand-gated channel (5-hydroxytryptamine [*5-HT*$_3$], GABA and glycine) receptors are shown. The amino-terminal portion is found on the extracellular (synaptic) surface. The soluble ACh binding proteins characterized from *Lymnaea* and *Aplysia* have truncated sequences ending at residue 202–204 and an absence of hydrophobic domains designed to interact with sequences that span the membrane or interact with membrane lipids. (**B**) Structure of the acetylcholine binding protein from *Lymnaea* as a model of the extracellular domain of the nicotinic acetylcholine receptor. Structures are developed from the crystallographic coordinates of Sixma and colleagues [33]. **B-1**. View of the pentameric protein from the apical surface. The protein is a pentamer of five identical subunits surrounding a central cavity, which in the receptor is the vestibule to the ion channel pore. Although the subunits are identical, they are distinguished by color. **B-2**. View of subunit interfaces from the outer perimeter. The C loop, containing the second disulfide bond with vicinal cysteines, overlaps the complementary face on the adjacent subunit. The subunit interfaces (shown in gray, orange and blue and located apical to the C loop) contain binding locations of nicotine and α-neurotoxin (ribbon diagram, shown in red and largely on the membrane side of the C loop) [33]. **B-3**. Interface of the binding protein to the transmembrane spans of the ion channel. Modification of selected residues allowed the acetylcholine binding protein, when linked to the transmembrane spans of the channel, to become a functional ligand-gated ion channel with the expected ligand specificity and channel gating kinetics. **Top** (**a**): Schematic diagram of a chimaeric subunit composed of AChBP and 5-HT_{3A} sequences. The amino terminus contains AChBP (white bars and black font) and 5-HT_{3A} sequences (loop β1-β2, orange; Cys loop , green; β8-β9 loop, magenta). The 5-HT_{3A} pore domain follows, with transmembrane helices M1-M4 (red) and the M2-M3 linker (blue). Red font indicates the start of the M1 domain. **Middle** (**b**): Homology model of the chimaeric receptor with key regions of one subunit colour-coded as in **Top** figure. **Bottom** (**c**): View of the coupling zone from the pore showing the network of binding and pore domain loops. FIGURE 11-9 (**A**) Longitudinal view of the muscle nicotinic acetylcholine receptor with the γ subunit removed. The remaining subunits, two copies of α, one of β and one of δ, surround an internal channel with outer vestibule and its constriction or gating locus deep within the membrane bilayer region. Spans of α helices with bowed structures from the M_2 region of the sequence form the perimeter of the channel (see C). Acetylcholine-binding sites, denoted by *arrows*, are found at the αγ- and αδ (not visible)-subunit interfaces. (**C** shows the data on which this structure is based.) (Adapted with permission from references [25, 59, 60].) (**B**) Image reconstruction of electron micrographs yielding a structure at 9 Å resolution. Shown are side and synaptic views. (Adapted with permission from reference [25, 59, 60].) (**C**) Longitudinal view of the electron density of the receptor. The transmembrane area is shown between the *dots.* The visible transmembrane-spanning helixes are shown by the *V-shaped solid lines.* This helix is believed to be the M_2 region, the sequence of which is shown. The area inside the rectangle is the transmembrane-spanning region. The 'X' denotes the conserved leucine. The additional density in the cytoplasmic region arises from an associated 43 kDa protein, rapsyn. The *shaded area* to the right indicates the zone of narrowest constriction.

antagonist-binding surface. The loop containing the vicinal cysteines overlaps with the neighboring subunit at the outer perimeter of the receptor, and internal to this loop is nested the ligand-binding site. Two other segments of sequence in the α subunit and four discrete segments on the opposing face of the γ and δ subunits also have been identified as forming regions that contribute to the binding surfaces at the αγ and αδ interfaces [34], findings that have now been confirmed from the AChBP–ligand complexes.

Four candidate membrane-spanning regions are found after residue 210 with a large cytoplasmic loop between membrane spans 3 and 4 (Figs 11-8, 11-9). Based on labeling experiments and site-specific mutagenesis, membrane span 2 was found to be proximal to the ion channel. This span, when constructed as an α helix, is amphipathic, with an abundance of serine and threonine residues pointed toward the channel lumen. Positions corresponding to α-Thr 244, α-Leu 251, α-Val 255 and α-Glu 262 in this transmembrane span have been labeled with the noncompetitive, channel-blocking inhibitors chlorpromazine and tetraphenyl phosphonium [3, 32]. Mutation of several of the hydroxyl groups on residues at these positions affects channel kinetics. The channel gate, or constriction, is thought to lie deep within the channel or even close to the cytoplasmic side. The ion selectivity of the channels appears to be controlled in part by rings of charges formed by all five subunits at the extracellular surface of the channel corresponding to α-Glu 262 and at the cytoplasmic surface corresponding to α-Glu241. Exposed amide backbone hydrogens and carbonyl groups and a ring of hydroxylated amino acids corresponding to α-Thr 244 also contribute to ion selectivity and permeation [11, 32, 35].

Analysis of the opening and closing events of individual channels has provided information about ligand binding and activation of the receptor. Electrophysiological studies use high-resistance patch electrodes of 1–2 μm diameter, which form tight seals on the membrane surface [36]. They have the capacity to record conductance changes of individual channels within the lumen of the electrode (see Ch. 10). The patch of membrane affixed to the electrode may be excised, inverted or studied on the intact cell. The individual opening events for ACh achieve a conductance of 25 pS across the membrane and have an opening duration that is distributed exponentially around a value of about 1 ms. The duration of channel opening is dependent on the particular agonist, whereas the conductance of the open-channel state is usually agonist-independent. Analyses of the frequencies of opening events have permitted an estimation of the kinetic constants for channel opening and ligand binding, and these numbers are in reasonable agreement with estimates of ligand binding and activation from rapid kinetic, or stopped-flow, studies. Overall, activation events for the muscle receptor may be described by scheme 1 [3, 11, 36]:

$$2L + R \underset{k\text{-}1}{\overset{2k+1}{\rightleftharpoons}} LR \underset{2k\text{-}1}{\overset{k+1}{\rightleftharpoons}} L_2R \underset{k\text{-}2}{\overset{k\text{-}2}{\rightleftharpoons}} L_2R^*$$

(Closed) (Closed) (Closed) (Open)

Scheme 1

Two ligands (L) associate with the receptor (R) prior to the isomerization step to form the open-channel state L_2R^*. For ACh, the forward rate constant for binding, k_{+1}, is $1–2\times10^8$ mol^{-1} l^{-1} s^{-1}; k_{+2} and k_{-2}, forward and reverse rate constants for isomerization, yield rates of isomerization consistent with opening events in the millisecond time frame. Since k_{+2} and k_{-2} are greater than k_{-1}, the rate constant for ligand dissociation, several opening and closing events with the fully liganded receptor occur prior to dissociation of the first ligand. Binding of the first and second ligands appears not to be identical, even allowing for the statistical differences arising from the two sites. Such a conclusion is consistent with receptor structure since different subunits, such as the γ and δ subunits in muscle, are adjacent to the same face of the α subunits in the muscle receptor pentamer.

Continued exposure of nicotinic receptors to agonist leads to desensitization of the receptors. This diminution of the response occurs even though the concentration of agonist available to the receptor has not changed. Katz and Thesleff examined the kinetics of desensitization with microelectrodes and found that a cyclic scheme in which the receptor existed in two states, R and R′, prior to exposure to the ligand best described the process.

To achieve receptor desensitization and activation by ligand, multiple conformational states of the receptor are required. The binding steps represented in horizontal equilibria are rapid; vertical steps reflect the slow, unimolecular isomerizations involved in desensitization (scheme 2). Rapid isomerization to the open channel state (scheme 1) should be added. To accommodate the additional complexities of the observed fast and slow steps of desensitization, additional states have to be included.

A simplified scheme, in which only one desensitized and one open-channel state of the receptor exist, is represented in scheme 2, where R is the resting (activatable) state, R* the active (open channel) state and R′ the desensitized state of the receptor; M is an allosteric constant defined by R′/R, and K and K' are equilibrium dissociation constants for the ligand.

$$\begin{array}{ccccccc} 2L + R & \underset{}{\overset{k/2}{\rightleftharpoons}} & LR & \underset{}{\overset{2k}{\rightleftharpoons}} & L_2R & \longleftrightarrow & L_2R^* \\ {\scriptstyle M}\uparrow\downarrow & & \uparrow\downarrow & & \uparrow\downarrow & & \\ 2L + R' & \underset{}{\overset{k'/2}{\rightleftharpoons}} & LR' & \underset{}{\overset{2k'}{\rightleftharpoons}} & L_2R' & & \end{array}$$

Scheme 2

In this scheme, $M < 1$ and $K' < K$. Addition of ligand eventually will result in an increased fraction of R′ species because of the values dictated by the equilibrium constants. Direct binding experiments have confirmed the generality of this scheme for nicotinic receptors. Thus, distinct conformational states govern the different temporal responses that ensue upon addition of a ligand to the nicotinic receptor. No direct energy input or covalent modification of the receptor channel is required.

Nicotinic receptor subunits are part of a large superfamily of ligand-gated channels. Nicotinic receptors on neurons, such as those originating in the CNS or neural crest, show ligand specificities distinct from the nicotinic receptor in the neuromuscular junction. One of the most remarkable differences is the resistance of most nicotinic neuronal receptors containing α2–α6 subunits to α-bungarotoxin and related snake α-toxins. This fact and the lack of an abundant source of neuronal CNS receptors limited initial progress in their isolation and characterization. However, low-stringency hybridization with cDNAs encoding the subunits of electric organ and muscle receptors provided a means to clone neuronal nicotinic receptor genes. Isolation of the candidate cDNA clones, their expression in cell systems to yield functional receptors and the discrete regional localizations of the endogenous mRNAs encoding these receptor subunits revealed that the nicotinic receptor subunits are part of a large and widely distributed gene family. They are related in structure and sequence to receptors for inhibitory amino acids (GABA and glycine), to 5-hydroxytryptamine type 3 ($5HT_3$) receptors and, somewhat more distantly, to glutamate receptors (32).

At least 12 distinct genes encoding neuronal nicotinic receptor subunits α2–α10 and β2–β4 have been identified in the central and peripheral nervous systems (Fig. 11-2). The α subunits are similar in sequence to the muscle α1 subunit and contribute to the ligand-binding interface. The β subunits fulfill the role of β1, γ and δ subunits in the muscle receptor. When certain pairs or triplets of cDNAs encoding neuronal α and β subunits are cotransfected into cells or their corresponding mRNAs are injected into oocytes, characteristic ACh-gated channel function can be achieved. The α3 subunit is prevalent in peripheral ganglia, usually with β2, β4, and α5 subunits. The α4β2 subunit combination predominates in the CNS, yet its elimination in knockout studies causes surprisingly limited changes in function. The α5 subunit appears unique in that it will not contribute to function in the absence of other α subunits; its global sequence features are more similar to those of the β subunits. Four permutations of subunits containing α4, α5, α6, β2 and β3 subunits are found in the striatum that mediate dopamine release [36]. The α7 and α8 subunits display function as homologous pentamers. Receptors containing α7 subunits have a high Ca^{2+} permeability, and Ca^{2+} entry may be integral to their function *in vivo*. These receptors also show characteristically rapid rates of desensitization and a high sensitivity to choline as antagonist. α9 and α10 subtypes function in vestibular and cochlear mechanosensory hair cells [37]. While not all combinations of α and β mRNAs lead to the expression of functional receptors on the cell surface, the number of permutations is large [11]. A future challenge is the assignment of pharmacological and biophysical signatures to all of the subunit combinations found *in vivo*.

Substantial evidence points to nicotinic receptors in the CNS functioning at presynaptic locations to regulate release of several CNS transmitters [10]. Electrophysiological and microdialysis studies provide evidence that glutamatergic, dopaminergic, serotonergic, peptidergic and cholinergic pathways are under the control of presynaptic nicotinic receptors. Hence, nicotinic receptors appear to play an important amplification and modulatory role in the CNS. A prime example is the influence of presynaptic nicotinic receptors influencing the release of dopamine that appears to underlie the addictive actions of nicotine [10, 40]. See also Ch. 56.

Both nicotinic receptors and acetylcholinesterase are regulated tightly during differentiation and synapse formation. At present, we understand more about tissue-specific gene expression in muscle than in nerve [41–45]. Both the above proteins show enhanced expression during myogenesis upon differentiating from a mononucleated myoblast to a multinucleated myotube. Curiously, enhanced receptor expression occurs largely by transcriptional activation, while the increase in cholinesterase expression arises to a large extent from stabilization of the mRNA. The receptor appears to cluster spontaneously, which involves a protein on the cytoplasmic side of the membrane, termed 43K or rapsyn (see in Ch. 43) [43, 44]. This protein links the receptor to cytoskeletal elements and restricts its diffusional mobility. Following innervation and synaptic activity, expression of the receptor and AChE persists in endplate, or junctional, regions and disappears in extrajunctional regions. The collagen-tail-containing species of AChE is localized to the basal lamina in the neuromuscular synapse; it links at its distal end to the proteoglycan perlecan [45].

With innervation and the development of electrically excitable synapses, the γ subunit of the receptor is replaced by an ε subunit; small changes in the biophysical properties of the receptor occur concomitantly. Upon denervation, many of the developmental changes associated with innervation are reversed and there is again an increase in expression of extrajunctional receptors containing the γ subunit. In multinucleated muscle cells, particular subsynaptic nuclei drive the expression of these synapse-specific proteins. The factors controlling these regulatory events are incompletely understood, but calcitonin gene-related peptide (CGRP) and the protein ACh receptor-inducing activity (ARIA) may be extracellular mediators of expression. In addition, intracellular Ca^{2+},

membrane depolarization and protein kinase C play distinct roles in maintaining junctional expression of synapse-localized proteins [42–44].

A neurally derived signaling protein, agrin, acts through a receptor tyrosine kinase, MuSK, in the formation of the specialized postsynaptic endplate by interaction with rapsyn. Thus, MuSK–rapsyn interactions are critical in forming the local scaffold for postsynaptic components in the motor endplate [43, 44].

An extensive variety of neuromuscular diseases have been uncovered as congenital conditions involving not only the nAChR and AChE but also proteins that control their expression and synaptic localization. These are discussed in Ch. 43. Study of the underlying genotype or sequence differences has also proved helpful in unraveling the involvement of various amino acid residue determinants in function [41].

MUSCARINIC RECEPTORS

Muscarinic and nicotinic receptors are related more closely to other receptors in their respective families than to one another, both structurally and functionally. The nicotinic receptor is far more similar to other ligand-gated ion channels than to the muscarinic receptor. The muscarinic receptor in turn belongs to a group of seven transmembrane-spanning receptors [46], which transduce their signals across membranes by interacting with GTP-binding proteins (see Ch. 19). Several macromolecular interactions are involved in the responses triggered by activation of the muscarinic receptor. These associations contribute to the 100–250 ms latency characteristic of muscarinic responses, which are slow compared with those mediated by nicotinic receptors.

Muscarinic receptor activation causes inhibition of adenylyl cyclase, stimulation of phospholipase C and regulation of ion channels. Many types of neuron and effector cell respond to muscarinic receptor stimulation. Despite the diversity of responses that ensue, the initial event that follows ligand binding to the muscarinic receptor is, in all cases, the interaction of the receptor with a G protein. Depending on the nature of the G protein and the available effectors, the receptor–G-protein interaction can initiate any of several early biochemical events. Common responses elicited by muscarinic receptor occupation are inhibition of adenylyl cyclase, stimulation of phosphoinositide hydrolysis and regulation of potassium or other ion channels [47] (Fig. 11-10). The particular receptor subtypes eliciting those responses are discussed below. (See also Chs 20 and 21.)

Inhibition of adenylyl cyclase by mAChR activation results in decreased cAMP formation. A decrease in cAMP is most apparent when adenylyl cyclase is stimulated, for example, by activation of adrenergic receptors with catecholamines or by forskolin. Simultaneous addition of cholinergic agonists decreases the amount of cAMP formed in response to the catecholamine, in some tissues almost completely. The result is diminished activation of cAMP-dependent protein kinase (PKA) and decreased substrate phosphorylation catalyzed by this kinase. The mechanism by which the muscarinic receptor inhibits adenylyl cyclase is through activation of an inhibitory GTP-binding protein, G_i. The α subunit of G_i competes with the α subunit of the G protein activated by stimulatory agonists (G_S) for regulation of adenylyl cyclase (see Chs 19, 21). Although muscarinic receptors do not interact with G_s, increases in cAMP formation are seen in response to mAChR stimulation under some circumstances. These may result from stimulatory effects of $\beta\gamma$ subunits released from G_i proteins or from elevated intracellular Ca^{2+} on specific isoforms of adenylyl cyclase or phosphodiesterase.

Activation of phosphoinositide-specific phospholipase C by muscarinic agonists elicits phosphatidylinositol 4,5-bisphosphate stimulates phosphoinositide hydrolysis. The β_1 isoform of phosphoinositide-specific phospholipase C (PI-PLC) is activated by its interaction with the α subunit of a GTP-binding protein, $G_{q/11}$ [48]. This is the primary mechanism by which muscarinic receptors regulate this enzyme. However, some PLC isoforms, most clearly β_2, also are activated by $\beta\gamma$ subunits. This probably accounts for the pertussis-toxin-sensitive, G_i/G_o-mediated activation of PI-PLC seen when high levels of mAChR subtypes that normally couple to G_i (see below) are expressed in heterologous cell lines. The hydrolysis of phosphatidylinositol 4,5-bisphosphate yields two potential second messengers, inositol 1,4,5-trisphosphate (IP_3) and diacylglycerol (DAG) (see Ch. 20). DAG increases the activity of the Ca^{2+} and phospholipid-dependent protein kinase (PKC). IP_3 mobilizes Ca^{2+} from intracellular stores in the endoplasmic reticulum and thereby elevates cytosolic free Ca^{2+}. Subsequent responses are triggered by direct effects of Ca^{2+} on Ca^{2+}-regulated proteins and by phosphorylation mediated through Ca^{2+}/calmodulin-dependent kinases and PKC. Stimulation of a phospholipase D, which hydrolyzes phosphatidylcholine, also occurs in response to muscarinic receptor activation. This appears to be secondary to activation of PKC and contributes to a secondary rise in DAG.

Regulation of K^+ channels. Muscarinic agonists cause rapid activation of G-protein-coupled, inwardly rectifying potassium channels (GIRKs). This muscarinic effect can be mimicked by GTP analogs in whole-cell clamp experiments, and the response is sensitive to pertussis toxin, which ribosylates and inactivates G_i and a related protein, G_o (see Ch. 19). It is now generally agreed that GIRK1 and GIRK2 are activated directly by binding $\beta\gamma$ subunits released from G_i or G_o. This is a primary mechanism by which muscarinic agonists cause hyperpolarization of

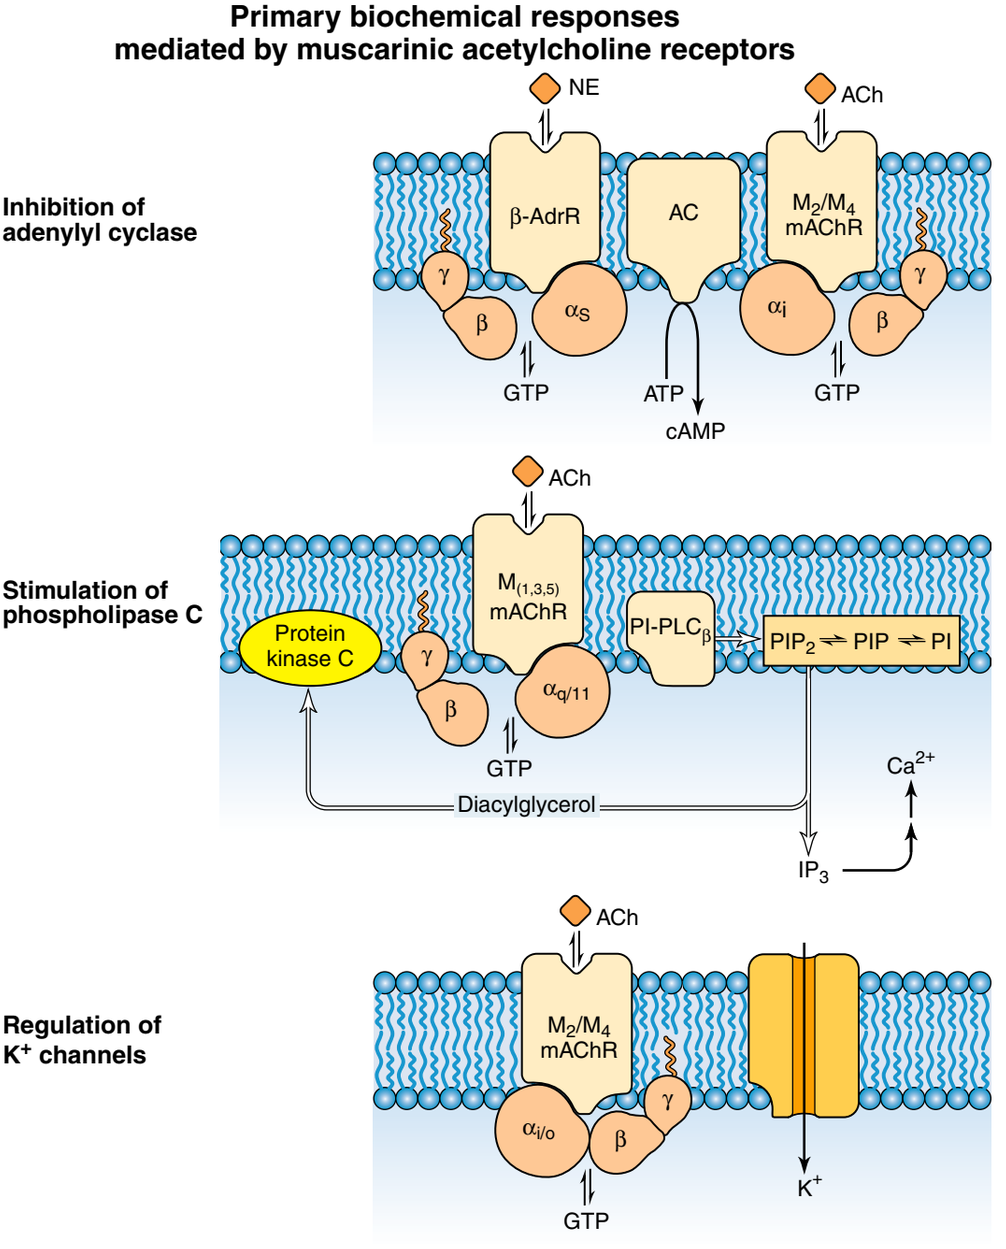

FIGURE 11-10 Acetylcholine (*ACh*) interacts with a muscarinic receptor of the subtypes indicated to induce various responses. The M_2 and M_4 muscarinic acetylcholine receptors (*mAChR*) interact with the α subunit of GTP-binding protein, G_i. When ACh binds, $G\alpha_i$ dissociates from βγ and inhibits adenylyl cyclase (*AC*). The M_1, M_3 and M_5 mAChRs interact with GTP-binding proteins in the G_q and G_{11} family. The $G\alpha_q$ and α_{11} subunits activate phosphoinositide-specific phospholipase C (*PI-PLC*). The M_2 and M_4 mAChRs regulate inwardly rectifying K^+ channels through the βγ subunit of G_i or G_o. Diffusible second messengers formed within the cell include cAMP, inositol trisphosphate (*IP_3*) and diacylglycerol (DAG). IP_3 is generated from phosphatidylinositol bisphosphate (PIP_2). *NE*, norepinephrine; *β-AdrR*, β-adrenergic receptor; *PI*, phosphatidylinositol; *PIP*, phosphatidylinositol-4-phosphate; *PIP_2*, phosphatidylinositol-4,5-bisphosphate.

cardiac atrial cells, as well as of neurons [49]. This pathway contrasts with muscarinic inhibition of the M-current in sympathetic ganglia; suppression of this K^+ channel is mediated indirectly through muscarinic formation of a diffusible second messenger.

Intracellular mediators of muscarinic receptor action. The three events described above, inhibition of adenylyl cyclase, stimulation of PLC and regulation of K^+ channels, occur within the plasma membrane. They can be triggered directly by muscarinic receptor occupation independent of changes in cytosolic mediators. However, these primary events in turn affect the generation of diffusible second messengers such as cAMP, DAG, IP_3 and Ca^{2+}, which generate other metabolic sequelae. For example, an increase in cytosolic free Ca^{2+} probably contributes to activation of phospholipase A_2, generating arachidonic acid, prostaglandins and related eicosanoids (see Ch. 33). These products in turn can stimulate cGMP formation and can regulate ion channel activity. Increased Ca^{2+} also can activate Ca^{2+}-dependent ion channels (K^+, Cl^-), regulate cAMP phosphodiesterase and activate Ca^{2+}/calmodulin kinase-dependent protein phosphorylation. PKC is activated by DAG, generally in concert with Ca^{2+} for conventional PKC isoforms, and has effects on ion channel activity, as well as on cholinergic secretory and contractile responses. Given the obviously complex set of possible interactions between these intracellular mediators, it is easy to explain how diverse cellular responses can be mediated through a single receptor activating relatively few primary responses (see Ch. 10).

Radioligand-binding studies have been used to characterize muscarinic receptors. In membranes or homogenates from heart, brain and other tissues, muscarinic agonists compete for antagonist-binding sites with Hill slopes of less than unity, suggesting that these agonists interact with more than a single population of muscarinic receptors [46]. Direct binding experiments with radiolabeled agonists also show multiple binding sites for agonists. Competition curves are best fitted by a model in which there are sites with low, high and, in some cases, super-high affinity for agonists. Addition of GTP to the binding assay can have a dramatic effect on the agonist competition curve or on direct agonist binding. The effect of GTP is to decrease the apparent affinity of the receptor for agonists. This results from a change in the interaction of the receptor with the GTP-binding protein that transduces its effects.

Agonists vary in their binding properties. Some, like ACh, carbamylcholine and methacholine, bind with high affinity to a large percentage of the total sites and with low affinity to the remainder. In contrast, agonists such as oxotremorine and pilocarpine appear to bind to a single class of sites and may show relatively little high-affinity binding. The capacity of an agonist to induce high-affinity binding correlates with the efficacy of that agonist for eliciting responses such as contraction or phosphoinositide breakdown. It therefore appears that interaction of the receptor and G protein, as reflected in high-affinity agonist binding, is critical to production of the cellular response.

Unlike agonists, most muscarinic antagonists, such as quinuclidinylbenzilate, *N*-methylscopolamine and atropine, bind to the receptor with Hill slopes of unity, as expected for a mass-action interaction with a single receptor type. There is little difference in affinity for these ligands in various tissues. Similar findings with other antagonists initially suggested that all muscarinic receptors were the same. However, a number of functional studies suggested that muscarinic receptors were heterogeneous, and putative subtype-selective antagonists have been described throughout the years.

The binding properties of the antagonist pirenzepine led to the initial classification of muscarinic receptors. Pirenzepine (PZ), in contrast to other known mAChR antagonists, binds to muscarinic receptors in cortex, hippocampus and ganglia with relatively high affinity; these sites have been termed M_1. Heart, gland and smooth muscle mAChR muscarinic receptors, as well as those in brainstem, cerebellum and thalamus, show 30–50-fold lower affinity for PZ [46, 47]. The affinity for classic antagonists like *N*-methylscopolamine is the same in all of these regions, emphasizing the unique selectivity of PZ. Direct binding studies using [^{3}H]-PZ confirmed that only certain tissues and brain regions had receptors with high affinity for this antagonist. Results of pharmacological studies also demonstrated that PZ blocks muscarinic responses in ganglia better than responses in heart. Brain and heart were subsequently used to purify distinct receptors, termed M_1 and M_2 muscarinic receptors, and cDNA clones corresponding to these receptors were isolated from rat brain and heart libraries.

The cDNAs for the muscarinic receptors encode apparent glycoproteins of 55–70 kDa, which contain seven predicted transmembrane-spanning regions, similar to what is seen for the β-adrenergic receptor and other receptors that couple to G proteins (Fig. 11-11). There is only 38% amino acid identity between the proteins cloned from porcine brain and heart. The cDNA encoding the receptor initially cloned from the brain has been termed m_1, whereas that cloned from the heart has been termed m_2, in keeping with the names (M_1 and M_2) applied to the purified recombinant receptors.

The human and rat homologs of these receptor genes, as well as three additional subtypes termed m_3, m_4 and m_5, were subsequently cloned and expressed. Comparison of the amino acid sequences of the five muscarinic receptor subtypes suggests that they are members of a highly conserved gene family. The greatest sequence identity is in the transmembrane-spanning regions, whereas the long cytoplasmic loop (i_3) between transmembrane domains V and VI varies among the receptor subtypes [46, 50]. The

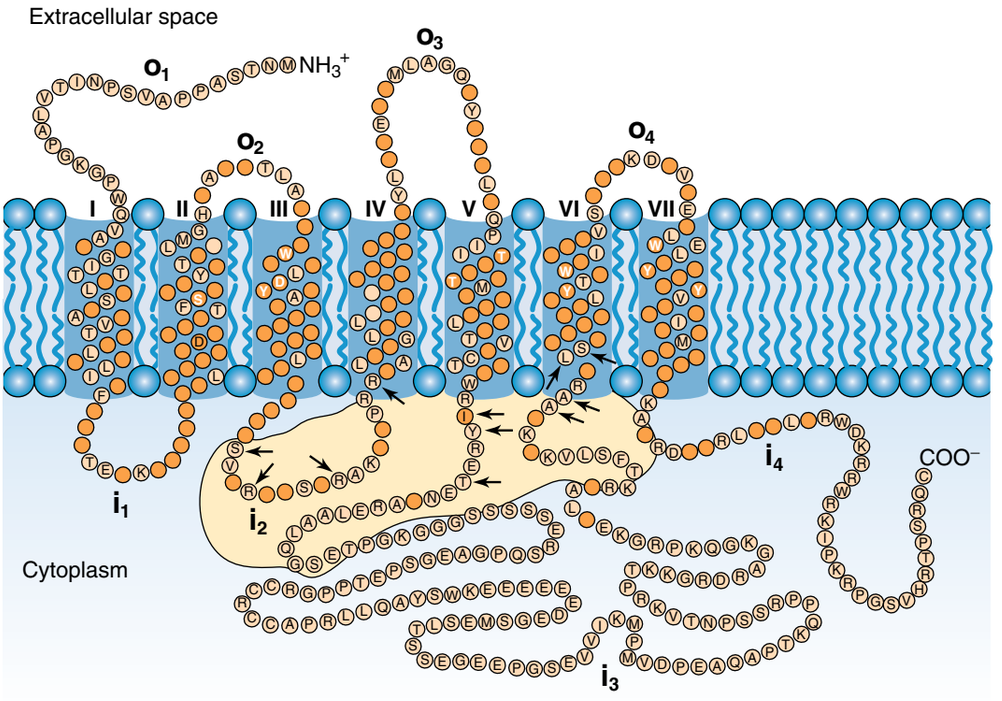

FIGURE 11-11 Predicted amino acid sequence and transmembrane domain structure of the human M_1 muscarinic receptor. Amino acids that are identical among the m_1, m_2, m_3 and m_4 receptors are *dark orange*. The *shaded cloud* represents the approximate region that determines receptor–G-protein coupling. *Arrows* denote amino acids important for specifying G protein coupling. Amino acids predicted to be involved in agonist or antagonist binding are denoted by *white letters* [50].

cloned receptors, expressed in mammalian cells, show differences in antagonist affinity similar to the differences of the pharmacologically defined receptors. Thus, the expressed M_1 receptor is blocked selectively by PZ, the M_2 receptor is blocked by AFDX-116 and methoctramine and the M_3 receptor is blocked by hexahydrosiladifenidol [47]. The regions in the receptor responsible for differences in antagonist affinity have not yet been identified clearly. Ligands are believed to bind to the receptor at sites facing the extracellular space but located in a central cavity deep within the bundle formed by transmembrane domains III–VII. The binding site for the covalent antagonist propylbenzilylcholine mustard has been mapped to a particular aspartic acid residue in the third transmembrane region. This amino acid is conserved in all biogenic amine G-protein-coupled receptors. Mutagenesis of this amino acid profoundly affects both agonist and antagonist binding to muscarinic receptors. It is hypothesized that this residue participates in ionic bonding with the ammonium headgroup of the cholinergic ligand [46].

Expression of the cloned receptors in Chinese hamster ovary cells, other mammalian cells and *Xenopus* oocytes has demonstrated differential coupling of these receptors to cellular responses. In general the M_1, M_3 and M_5 receptors regulate phosphoinositide hydrolysis by stimulating PLC. This occurs through selective coupling of the receptor to the pertussis-toxin-insensitive G protein $G_{q/11}$, which can activate the β isoform of PLC [48]. Calcium-dependent K^+ and Cl^- channels are activated secondarily to the PLC-mediated increase in intracellular Ca^{2+}. In contrast, the M_2 and M_4 receptors couple through a pertussis-toxin-sensitive G protein (G_i) to inhibition of adenylyl cyclase. Regulation of K^+ channels also is mediated through M_2 or M_4 receptor interaction with specific pertussis-toxin-sensitive G proteins.

Chimeric receptors have been used to determine the regions critical for specifying coupling to particular responses. These studies demonstrate that it is the third intracellular (i_3) loop that defines functional specificity [47, 50]. A series of amino acids proximal to the transmembrane domain, that is, at the N- and C- termini of the i_3 loop, carry most of this information. These particular regions are similar in the M_1, M_3 and M_5 receptors and in the M_2 and M_4 receptors but distinguish these two groups from one another. Both site-directed and random mutagenesis studies have identified specific amino acids at the amino-terminus of the i_3 loop which are required for G protein recognition and activation [50, 51]. These critical noncharged amino acids are predicted to reside on the hydrophobic face of an α-helical extension of transmembrane domain V. Conserved amino acids in the carboxy-terminus of the i_3 loop and adjacent transmembrane domain VI also have been demonstrated to specify coupling to G_i- versus G_q-mediated responses. The hydrophobic

regions at the two ends of the i_3 loop thus are suggested to form a surface that binds to and discriminates between different classes of G protein [50]. Other regions, including a portion of the second intracellular loop, also contribute to specifying correct G protein coupling. The early and detailed characterization of distinct regions involved in selective G-protein coupling of mAChR provides a paradigm for analysis of other GPCRs.

The selectivity in muscarinic receptor coupling is not, however, absolute. Overexpression of receptors or of particular G proteins supports interactions that may differ from those described above. For example, M_2 receptors expressed in Chinese hamster ovary cells not only inhibit adenylyl cyclase but also can stimulate phosphoinositide hydrolysis through a pertussis-toxin-sensitive G protein [52]; this is not seen, however, when M_2 receptors are expressed in Y1 cells. These findings indicate that caution must be exercised in interpreting data obtained when receptors are expressed, often at high levels, in cells in which they normally do not function.

Muscarinic receptors of the M_1, M_3 and M_5 subclasses induce transformation or cell proliferation, a feature not shared by M_2 and M_4 receptors [53]. This property has been exploited to develop a high-throughput assay for screening effects of receptor mutations [51]. Mitogen-activated protein kinases (MAP kinases) also are activated by muscarinic receptors but, unlike transformation, this response occurs with receptors of the M_2/M_4 subtype as well as of the M_1/M_3 subtype. Notably, induction of cell growth by muscarinic receptor stimulation is cell-type-specific, however, and is seen only at high levels of receptor expression [53]. Thus, it is questionable whether there is a physiological role for ACh in growth regulation.

Transgenic mice are being generated to assess the functions of receptor subtypes *in vivo*. Knowledge of the anatomical distribution and coupling properties of receptor subtypes can indicate which physiological responses they mediate *in vivo*. However, the lack of good subtype-selective antagonists limits the use of pharmacological approaches to address this question. Generation of transgenic mice in which muscarinic receptors are overexpressed or knockout mice in which receptor genes are disrupted by homologous recombination provides a powerful and necessary approach for evaluation of muscarinic receptor function. The *m_1* gene was the first to have been targeted selectively, eliminating M_1-receptor expression in the forebrain where it is abundantly expressed [54]. Homozygous M_1-receptor-deficient mice are completely resistant to seizures produced by pilocarpine, implicating the M_1 receptor in this model of epilepsy. Furthermore, inhibition of the M-current in sympathetic ganglia, suggested by previous pharmacological experiments to be M_1-receptor-coupled, is ablated in knockout mice. Interestingly, despite the abundance of M_1 receptors in the forebrain, most learning and memory tasks are not impaired in mice lacking M_1 receptors. With regard to the biochemical signaling pathways delineated above, mAChR-stimulated phosphoinositide hydrolysis is attenuated and MAP kinase activation lost in hippocampus and pyramidal neurons. The conclusion that brain M_1 mAChR selectively regulate these responses is supported by the observation that these responses are unaffected in the M_2-, M_3- and M_4-receptor knockout mice described below.

Both the M_2 and M_4 receptors are, as indicated above, coupled to G_i pathways and appear to mediate similar responses. The M_2 receptor is widely expressed in the CNS but also present in heart and smooth muscle, while M_4 is preferentially expressed in the CNS, especially in forebrain. Ablation of the M_2 receptor leads to complete loss of muscarinic-agonist-stimulated bradycardia [55]. In the CNS, deletion of the M_2 receptor abolishes oxotremorine induced akinesia and tremors [56]. Memory and learning tasks including passive avoidance and working memory are impaired in M_2-receptor knockout mice, and there is decreased LTP in hippocampal slices [12].

M_2 receptors are also predominant in the mouse spinal cord and here this receptor subtype appears, from knockout studies, to play a major role in signaling muscarinic-agonist-induced analgesia (although M_4 receptors can also mediate this response) [56]. A major role for M_2 (and M_4) receptors is as presynaptic auto- (or hetero-)receptors. Thus studies using M_2-receptor knockout mice reveal that the M_2 receptor plays a prominent role in inhibiting NE release from sympathetic nerves in atria and other peripheral tissues and that M_2 and M_4 autoreceptors regulate ACh release from atria, urinary bladder and cholinergic neurons in the hippocampus and striatum [12, 57].

Muscarinic and dopaminergic pathways in the CNS interact in control of numerous pathways implicated in diseases, especially those controlling involuntary motor systems. Muscarinic effects on dopamine release are mediated in several ways via different mAChR subtypes. Thus mAChR facilitation of DA release appears to involve M_4 receptors on GABA projection neurons to the striatum, while M_3 receptors on striatal DA neurons are predicted to inhibit striatal DA release [12].

The role of the M_3 mAChR in the CNS remains unclear. The phenotype of the M_3 receptor knockout is hypophagic and lean. This appears to result from altered hypothalamic appetite regulation, as M_3 receptors are relatively highly expressed in this region [12]. The most striking changes in the M_3-receptor knockout animal are peripheral, specifically loss of contractile responses of tracheal, urinary bladder and pupillary smooth muscle to muscarinic agonists. The M_5 receptor also has an uncertain role in the CNS, where it is present at low levels. Recent studies using M_5-receptor knockout mice suggest that these receptors may reside primarily on endothelial cells of brain arteries and arterioles, mediating cholinergic relaxation of these vessels [58].

The information gleaned from studies with mAChR knockout mice is encouraging in demonstrating striking phenotypes that indicate that mAChR agonists and

antagonists have potential for the treatment of Alzheimer's disease, Parkinson's disease, epilepsy and pain. The evidence that the distribution and functions of the various mAChR subtypes are highly specific provides further hope for the design of therapeutic agents without limiting side effects. That mice are not humans means that the general principles learned from these studies are germane, but that much additional work will be needed to define the utility of selective mAChR agents in human disease.

DOPAMINE RECEPTORS 218
There are five primary dopamine receptor subtypes 218

ADRENERGIC RECEPTORS 220
There are nine primary adrenergic receptor subtypes 220

DYNAMICS OF CATECHOLAMINE RECEPTORS 221
Chronic exposure to agonists often results in diminished responsiveness 221
Chronic exposure to antagonists often results in increased responsiveness 221
Changes in receptor density are associated with altered synaptic activity 222
The number of D_1 and D_2 receptors can be modulated by antagonists 222
Dopamine D_2-like receptors appear to mediate the actions of antipsychotic drugs 222
Changes in dopamine receptor density may be involved in the side effects of antipsychotic drugs 222

INTRODUCTION

The catecholamines dopamine, norepinephrine and epinephrine are neurotransmitters and/or hormones in the periphery and in the CNS. Norepinephrine is a neurotransmitter in the brain as well as in postganglionic, sympathetic neurons. Dopamine, the precursor of norepinephrine, has biological activity in the periphery, most particularly in the kidney, and serves as a neurotransmitter in several important pathways in the CNS. Epinephrine, formed by the *N*-methylation of norepinephrine, is a hormone released from the adrenal gland, and it stimulates catecholamine receptors in a variety of organs. Small amounts of epinephrine are also found in the CNS, particularly in the brainstem.

BIOSYNTHESIS OF CATECHOLAMINES

The enzymatic processes involved in the formation of catecholamines have been characterized. The component enzymes in the pathway have been purified to homogeneity, which has allowed for detailed analysis of their kinetics, substrate specificity and cofactor requirements and for the development of inhibitors (Fig. 12-1). Their cDNAs have been cloned, and studies with knockout mice clearly indicate the importance of these enzymes since their

absence results in a variety of abnormalities, including loss of viability (Table 12-1).

Tyrosine hydroxylase is the rate-limiting enzyme for the biosynthesis of catecholamines. Tyrosine hydroxylase (TH) is found in all cells that synthesize catecholamines and is a mixed-function oxidase that uses molecular oxygen and tyrosine as its substrates and biopterin as its cofactor [1]. TH is a homotetramer, each subunit of which has a molecular weight of approximately 60,000. It catalyzes the addition of a hydroxyl group to the *meta* position of tyrosine, thus forming 3,4-dihydroxy-L-phenylalanine (L-DOPA).

TABLE 12-1 Studies with knockout mice

VMAT2	Not viable	[54]
DAT	Growth retardation and hyperactivity	[54]
NET	Enhanced opiate-mediated analgesia and responses to psychostimulants	[56]

TH can also hydroxylate phenylalanine to form tyrosine, which is then converted to L-DOPA; this alternative synthetic route may be of significance in patients affected with phenylketonuria, a condition in which phenylalanine hydroxylase activity is depressed. TH has a K_m for tyrosine in the micromolar range. As a result, it is virtually saturated by the high tissue concentrations of endogenous tyrosine. The cofactor, biopterin, may be at subsaturating concentrations within catecholamine-containing neurons and thus may play an important role in regulating catecholamine biosynthesis. TH is primarily a soluble enzyme; however, interactions with membrane constituents, such as phosphatidylserine, or with polyanions, such as heparin sulfate, have been shown to alter its kinetic characteristics. Analogs of tyrosine, such as α-methyl-*p*-tyrosine (AMPT), are competitive inhibitors of TH. Sequence analysis [2] reveals consensus sequences for phosphorylation primarily in the N-terminal portion of the molecule (Fig. 12-2). The gene reveals considerable sequence homology with phenylalanine hydroxylase and tryptophan hydroxylase.

DOPA decarboxylase catalyzes the removal of the carboxyl group from DOPA to form dopamine. DOPA decarboxylase (DDC) is a pyridoxine-dependent enzyme that has a low K_m and a high V_{max} with respect to L-DOPA; thus, endogenous L-DOPA is efficiently converted to dopamine. DDC can also decarboxylate 5-hydroxytryptophan, the precursor of serotonin, as well as other aromatic amino acids; accordingly, it has also been called aromatic amino acid decarboxylase (AADC). DDC is widely distributed throughout the body, where it is found both in catecholamine- and serotonin-containing neurons and in non-neuronal tissues, such as kidney and blood vessels. In dopamine-containing neurons, this enzyme is the final step in the pathway and this is exploited clinically in the treatment of Parkinson's disease by giving patients excess L-DOPA to boost the production of dopamine in the remaining dopaminergic axon terminals. α-Methyldopa inhibits DDC *in vitro* and leads to a reduction in blood pressure after being converted to the false transmitter α-methylnorepinephrine *in vivo*. A false neurotransmitter is a substance stored and released like the authentic transmitter but has lower efficacy.

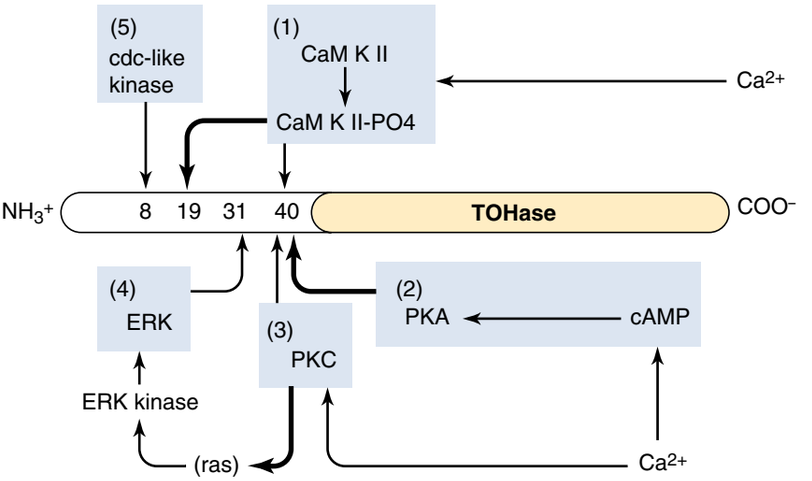

FIGURE 12-2 Schematic diagram of the phosphorylation sites on each of the four 60 kDa subunits of tyrosine hydroxylase (TOHase). Serine residues at the N-terminus of each of the four subunits of TOHase can be phosphorylated by at least five protein kinases. (*1*), Calcium/calmodulin-dependent protein kinase II (CaM KII) phosphorylates serine residue 19 and to a lesser extent serine 40. (*2*), cAMP-dependent protein kinase (PKA) phosphorylates serine residue 40. (*3*), Calcium/phosphatidylserine-activated protein kinase (PKC) phosphorylates serine 40. (*4*), Extracellular receptor-activated protein kinase (ERK) phosphorylates serine 31. (*5*), A cdc-like protein kinase phosphorylates serine 8. Phosphorylation on either serine 19 or 40 increases the activity of TOHase. Serine 19 phosphorylation requires the presence of an 'activator protein', also known as 14-3-3 protein, for the expression of increased activity. Phosphorylation of serines 8 and 31 has little effect on catalytic activity. The model shown includes the activation of ERK by an ERK kinase. The ERK kinase is activated by phosphorylation by PKC. (With permission from reference [72].)

For neurons that synthesize epinephrine or norepinephrine, dopamine β-hydroxylase is the next step in the biosynthetic pathway. Like TH, dopamine β-hydroxylase (DBH) is a mixed-function oxidase that uses molecular oxygen to form the hydroxyl group added to the carbon on the side chain of dopamine [3]. Ascorbate, reduced to dihydroascorbate during the reaction, provides a source of electrons. DBH contains Cu^{2+}, which is involved in electron transfer in the reaction; accordingly, copper chelators, such as diethyldithiocarbamate, are potent inhibitors of the enzyme. DBH is a tetrameric glycoprotein containing subunits of 77 and 73 kDa, as determined by sodium dodecyl sulfate (SDS) gel electrophoresis. A full-length clone encodes a polypeptide chain of 578 amino acids [4]. The enzyme is concentrated within the vesicles that store catecholamines; most of the DBH is bound to the inner vesicular membrane but some is free within the vesicles. DBH is released along with catecholamines from nerves and from the adrenal gland and is found in plasma.

In cells that synthesize epinephrine, the final step in the pathway is catalyzed by the enzyme phenylethanolamine *N*-methyltransferase. This enzyme is found in a small group of neurons in the brainstem that use epinephrine as their neurotransmitter and in the adrenal medullary cells, for which epinephrine is the primary hormone secreted. Phenylethanolamine *N*-methyltransferase (PNMT) transfers a methyl group from *S*-adenosylmethionine to the nitrogen of norepinephrine, forming a secondary amine [5]. The coding sequence of bovine PNMT is contained in a single open reading frame encoding a protein of 284 amino acids [6]. PNMT activity is regulated by corticosteroids in the adrenal gland and superior cervical ganglia [7].

STORAGE AND RELEASE OF CATECHOLAMINES

Catecholamines are concentrated in storage vesicles that are present at high density within nerve terminals. Ordinarily, low concentrations of catecholamines are free in the cytosol, where they may be metabolized by enzymes including monoamine oxidase (MAO). Thus, conversion of tyrosine to L-DOPA and L-DOPA to dopamine occurs in the cytosol; dopamine then is taken up into the storage vesicles. In norepinephrine-containing neurons, the final β-hydroxylation occurs within the vesicles. In the adrenal gland, norepinephrine is *N*-methylated by PNMT in the cytoplasm. Epinephrine is then transported back into chromaffin granules for storage.

cDNA clones encoding vesicular amine transporters have been obtained. The sequences suggest that the proteins have 12 transmembrane domains and are homologous to a family of bacterial drug-resistance transporters (Ch. 5). The expressed protein, referred to as vesicular membrane transporter 2 (VMAT2), has a high affinity for reserpine, which blocks vesicular uptake *in vivo*. The mechanism that concentrates catecholamines within the vesicles is an ATP-dependent process linked to a proton pump. The intravesicular concentration of catecholamines

is approximately 0.5 mol/l, and they exist in a complex with ATP and acidic proteins known as chromogranins. The vesicular uptake process has broad substrate specificity and can transport a variety of biogenic amines, including tryptamine, tyramine and amphetamines; these amines may compete with endogenous catecholamines for vesicular storage sites. Reserpine is a specific, irreversible inhibitor of the vesicular amine pump that blocks the ability of the vesicles to concentrate the amines. Treatment with reserpine causes a profound depletion of endogenous catecholamines in neurons. Knockout mice lacking VMAT2 are not viable (Table 12-1). Altered levels of VMAT2 have been associated with bipolar disorder in humans [8] and lithium, a treatment for this disorder, modulates VMAT2 expression in the brain [9].

The vesicles play a dual role: they maintain a ready supply of catecholamines at the nerve terminal that is available for release, and they mediate the process of release. When an action potential reaches the nerve terminal, Ca^{2+} channels open, allowing an influx of the cation into the terminal; increased intracellular Ca^{2+} promotes the fusion of vesicles with the neuronal membrane (see Ch. 10). The vesicles then discharge their soluble contents–for example, at norepinephrine neurons, norepinephrine, ATP, chromogranin and DBH – into the extraneuronal space [10]. The demonstration that DBH is released concurrently and proportionately with norepinephrine established the fact that release occurs by the process of exocytosis, since proteins would not be expected to diffuse across cell membranes. Exocytotic release from sympathetic neurons may be the source of some of the DBH found in the plasma and cerebrospinal fluid (CSF) of animals and humans. Indirectly acting sympathomimetics, like tyramine and amphetamine, release catecholamines by a mechanism that is neither dependent on Ca^{2+} nor associated with release of DBH. These drugs displace catecholamines from storage vesicles, resulting in leakage of neurotransmitter from the nerve terminals.

The concentration of catecholamines within nerve terminals remains relatively constant. Despite the marked fluctuations in the activity of catecholamine-containing neurons, efficient regulatory mechanisms modulate the rate of synthesis of catecholamines [11]. A long-term process affecting catecholamine synthesis involves alterations in the amounts of TH and DBH present in nerve terminals. When sympathetic neuronal activity is increased for a prolonged period of time, the amounts of mRNA coding for TH and DBH are increased in the neuronal perikarya. DDC does not appear to be modulated by this process. The newly synthesized enzyme molecules are then transported down the axon to the nerve terminals.

In addition, two mechanisms operative at the level of the nerve terminal play important roles in the short-term modulation of catecholamine synthesis and are responsive to momentary changes in neuronal activity [12]. TH, the rate-limiting enzyme in the synthesis pathway, is modulated by end-product inhibition [11]. Thus, free intraneuronal catecholamines inhibit the further activity of TH by competing at the site that binds the pterin cofactor; conversely, neuronal activity results in the release of catecholamines, a decrease in cytoplasmic concentrations and disinhibition of the enzyme. An additional and probably more important effect of depolarization of catecholaminergic terminals is activation of TH, resulting from reversible phosphorylation of the enzyme (Fig. 12-2) [13]. Protein kinase C (PKC), cAMP-dependent protein kinase (PKA) and Ca^{2+}/calmodulin-dependent protein kinases (CaMKs) are all capable of inducing phosphorylation of the enzyme, leading to an increase in its activity (see Chs 20 and 21). When phosphorylated, the kinetic characteristics of the enzyme change so that it has a higher affinity for the pterin cofactor and is less sensitive to end-product inhibition.

Monoamine oxidase and catechol-*O*-methyltransferase are primarily responsible for the inactivation of catecholamines. MAO and catechol-*O*-methyltransferase (COMT) are widely distributed throughout the body (Fig. 12-3). MAO is a flavin-containing enzyme located on the outer membrane of the mitochondria [14]. This enzyme oxidatively deaminates catecholamines to their corresponding aldehydes; these can be converted, in turn, by aldehyde dehydrogenase to acids or by aldehyde reductase to form glycols. Because of its intracellular localization, MAO plays a strategic role in inactivating catecholamines that are free within the nerve terminal and not protected by storage vesicles. Accordingly, drugs that interfere with vesicular storage, such as reserpine, or indirectly acting sympathomimetics, such as amphetamines, which displace catecholamines from vesicles, cause a marked increase in deaminated metabolites. Isozymes of MAO with differential substrate specificities have been identified: MAO-A preferentially deaminates norepinephrine and serotonin and is selectively inhibited by clorgyline, whereas MAO-B acts on a broad spectrum of phenylethylamines, including β-phenylethylamine. MAO-B is selectively inhibited by deprenyl. MAO in the gastrointestinal tract and liver plays an important protective role by preventing access to the general circulation of ingested, indirectly acting amines, such as tyramine and phenylethylamine, that are contained in food; however, patients being treated for depression or hypertension with MAO inhibitors are not afforded this protection and can suffer severe hypertensive crises after ingesting foods that contain large amounts of tyramine. Such foods include port wine, Stilton cheese and herring. Drugs that selectively inhibit MAO isozymes are less prone to produce hypertensive crisis and the MAO-A inhibitor moclobemide is an effective antidepressant [15], while the MAO-B inhibitor deprenyl is used in Parkinson's disease.

A methyl substituent on the α carbon of the phenylethylamine side chain protects against deamination by MAO; the prolonged action of amphetamine and related

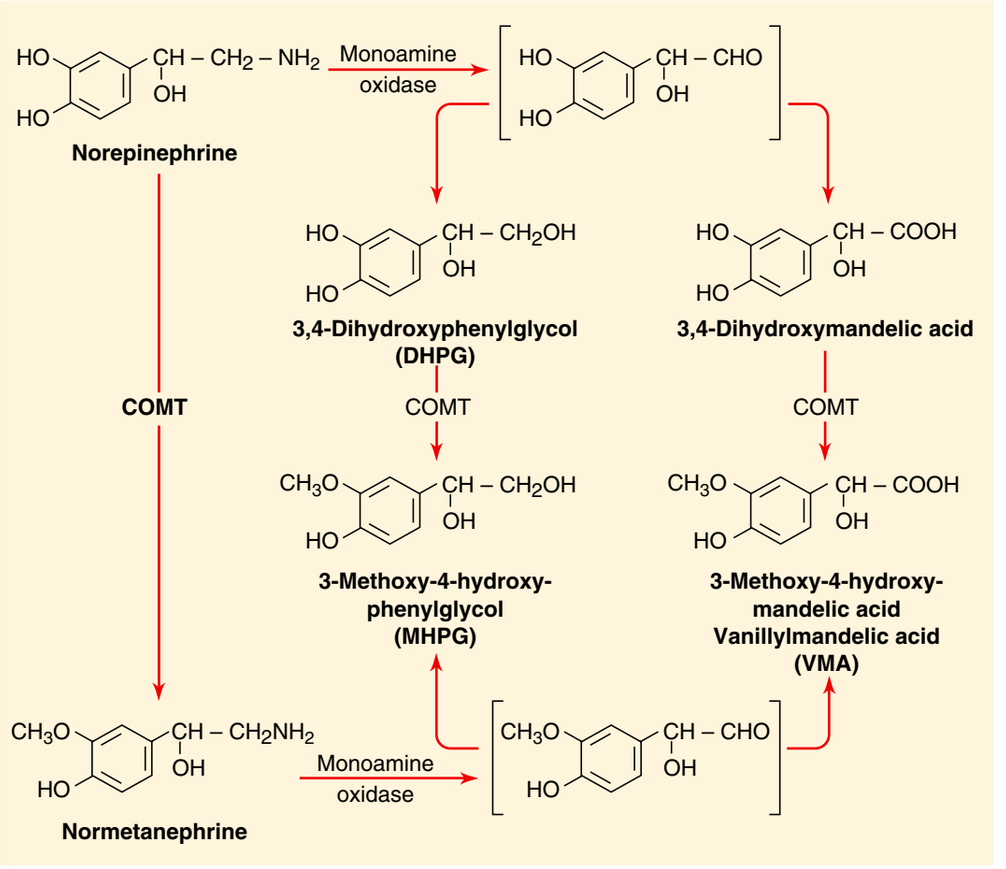

FIGURE 12-3 Pathways of norepinephrine degradation. Unstable glycol aldehydes are shown in brackets. COMT, catechol-*O*-methyltransferase.

indirectly acting stimulants is in part a consequence of the presence of an α-methyl group, which prevents their inactivation by MAO.

COMT is found in nearly all cells, including erythrocytes; thus, this enzyme can also act on extraneuronal catecholamines. Most studies of COMT are carried out with enzyme purified from homogenates of liver. The enzyme, which requires Mg^{2+}, transfers a methyl group from the co-substrate *S*-adenosylmethionine to the 3-hydroxy group on the catecholamine ring. This enzyme has broad substrate specificity, methylating virtually any catechol regardless of the side-chain constituents; for this reason, competitive inhibitors of the enzyme that are of pharmacological significance have not been developed. COMT knockout mice exhibit increased dopamine levels in frontal cortex, but not striatum, and complex, sexually dimorphic behavioral alterations [16]. In humans, a functional polymorphism of the COMT gene has been identified, in which valine (val) is substituted for methionine (met). The met containing enzyme has reduced enzymatic activity compared with the val containing protein. The higher activity, COMT(val) enzyme has been correlated with impaired prefrontal cortical functioning and an increase in risk for schizophrenia [17].

Measurement of catecholamine metabolites can provide insight into the rate of release or turnover of catecholamines in the brain. In clinical studies, metabolites of catecholamines are generally assayed in the CSF because the large quantities derived from the peripheral sympathomedullary system obscure the small contribution from the brain to urinary concentrations. However, acid metabolites are actively excreted from the CSF; more reliable estimates of turnover in the brain are obtained when this transport process is blocked by pretreatment with the drug probenecid.

4-hydroxy-3-methoxy-phenylacetic acid, more commonly known as homovanillic acid (HVA), is a major metabolite of dopamine. Spinal fluid concentrations of HVA provide insight into the turnover of dopamine in the striatum. Concentrations of HVA are decreased, for example, in the CSF of patients with Parkinson's disease (see Ch. 46). A metabolite of norepinephrine formed relatively selectively in the brain is 3-methoxy-4-hydroxyphenylglycol (MHPG). Because this is a minor metabolite of the much larger amounts of norepinephrine metabolized in the periphery, it is estimated that between 30% and 50% of the MHPG excreted in urine is derived from the brain. MHPG has been measured in CSF

and in urine to provide an index of norepinephrine turnover in the brain, and concentrations of MHPG have been shown to be decreased in certain forms of depression (see Ch. 55) and increased in generalized anxiety disorder.

The action of catecholamines released at the synapse is modulated by diffusion and reuptake into presynaptic nerve terminals. Catecholamines diffuse from the site of release, interact with receptors and are transported back into the nerve terminal. Some of the catecholamine molecules may be catabolized by MAO and COMT. The catecholamine-reuptake process was originally described by Axelrod [18]. He observed that, when radioactive norepinephrine was injected intravenously, it accumulated in tissues in direct proportion to the density of the sympathetic innervation in the tissue. The amine taken up into the tissues was protected from catabolic degradation, and studies of the subcellular distribution of catecholamines showed that they were localized to synaptic vesicles. Ablation of the sympathetic input to organs abolished the ability of vesicles to accumulate and store radioactive norepinephrine. Subsequent studies demonstrated that this Na^+- and Cl^--dependent uptake process is a characteristic feature of catecholamine-containing neurons in both the periphery and the brain (Table 12-2).

The uptake process is mediated by a carrier or transporter located on the outer membrane of the catecholaminergic neurons. It is saturable and obeys Michaelis–Menten kinetics. A unique transporter for norepinephrine is found only in noradrenergic neurons, whereas a different transporter is found in dopamine-containing neurons. The genes for transporters responsible for uptake of norepinephrine and dopamine have been cloned, revealing proteins that belong to a larger family of neurotransporters (see Ch. 5) and that display many conserved structural features [19]. The proteins are thought to have 12 transmembrane domains with intracellularly oriented N- and C-termini and a large glycosylated extracellular loop between transmembrane domains 3 and 4. The proteins show the most homology in their transmembrane spanning domains, particularly domains 1, 2, and 4–8, which may be involved in moving the transmitter across the membrane. The transporters are substrates for PKC-dependent phosphorylation, which reduces their activity. The dopamine transporter is phosphorylated on the extreme end of the N-terminal tail, and consensus phosphorylation sites for various other kinases are present in the intracellular loops and domains [20–22] (Fig. 12-4). The dopamine and norepinephrine transporters form functional homo-oligomers, although it is not known if this is required for transport activity, and the transporters also interact with many other membrane proteins that may control their cell-surface expression or other properties.

The uptake process is energy-dependent since it can be inhibited by incubation at a low temperature or by metabolic inhibitors. The energy requirements reflect a coupling of the uptake process with the Na^+ gradient across the

TABLE 12-2 Properties of amine transporters

The neuronal membrane norepinephrine transporter (NET), the dopamine transporter (DAT) and the vesicular membrane transporter (VMAT-2), which is the same in all catecholamine-containing neurons, have similar numbers of predicted transmembrane segments. They have different numbers of amino acids, pharmacological properties and chromosomal localizations.

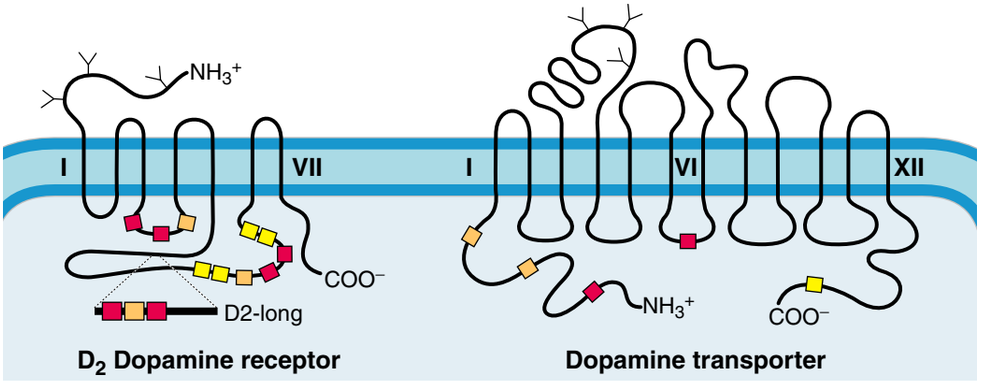

FIGURE 12-4 Schematic of the D_2 receptor and dopamine transporter. The amino acid chain is depicted as a line crossing the membrane. The D_2 receptor has the typical seven transmembrane domains, while the dopamine transporter has approximately 12. The D_2 dopamine receptor has two alternatively spliced mRNA variants that result in a short and a long form of the receptor. The longer variant has the insertion in the third intracellular loop. Putative glycosylation sites are indicated with *Y-shaped symbols* on extracellular sequences. Possible phosphorylation sites are indicated with boxes for various protein kinases: *gray boxes*, protein kinase A; *orange boxes*, protein kinase C; *white boxes*, calcium-calmodulin protein kinase. The dopamine transporter has a large glycosylated extracellular loop between transmembrane regions III and IV.

neuronal membrane. The process is also Cl^--dependent. Drugs such as ouabain, which inhibits Na,K-ATPase, or veratridine, which opens Na^+ channels, inhibit the uptake process.

The linkage of uptake to the Na^+ gradient may be of physiological significance since transport temporarily ceases at the time of depolarization-induced release of catecholamines. The transport of catecholamines can be inhibited selectively by such drugs as tricyclic antidepressants and cocaine. In addition, a variety of phenylethylamines, such as amphetamine, are substrates for carrier; thus, they can be concentrated within catecholamine-containing neurons and can compete with the catecholamines for transport.

Neurotoxins such as mercaptopyrazide pyrimidine (MPP+) and 6-hydroxydopamine are also taken up by transporters, and this is required for their neurotoxic effects. Mice have been prepared with their transporter genes 'knocked out'. Extensive studies with these mice confirm the important role of transporters (Table 12-1). Once an amine has been taken up across the neuronal membrane, it can be taken up by intracellular adrenergic storage vesicles as described above.

The reuptake process does not capture all of the released catecholamine. Diffusion away from the nerve terminal to distant sites can occur and has been termed 'volume transmission' [23]. Volume transmission allows the stimulation of extrasynaptic receptors, which has been described for dopamine [24] and norepinephrine [25]. Brain regions differ in their capacity for catecholamine reuptake; thus, whereas extracellular dopamine concentrations are dominated by release in the cerebral cortex, in the striatum dopamine concentrations are dominated by reuptake [26]. These regional differences in extracellular dopamine kinetics correlate with levels of dopamine transporter [27].

ANATOMY OF CATECHOLAMINERGIC SYSTEMS

The anatomy of catecholaminergic systems has been elucidated. After several decades of research, using a variety of both light and electron microscopic techniques, the anatomical organizations of dopaminergic, noradrenergic and adrenergic neurons have been elucidated [28]. The most important techniques include histofluorescence and immunohistochemistry, which can visualize either the catecholamines themselves or enzymes involved in their synthesis. There appear to be 16 dopamine- and noradrenaline-containing cell groups, and 3 adrenaline-containing cell groups in the CNS. In general, cell bodies containing these transmitters are found in clusters throughout the subcortical brain. In many instances, axons from these cells project to widespread areas and are believed to have broad effects in the CNS, while some of the cell groups have more focused projections and more specific functional effects. Also, other neurotransmitters often colocalize with these catecholaminergic transmitters.

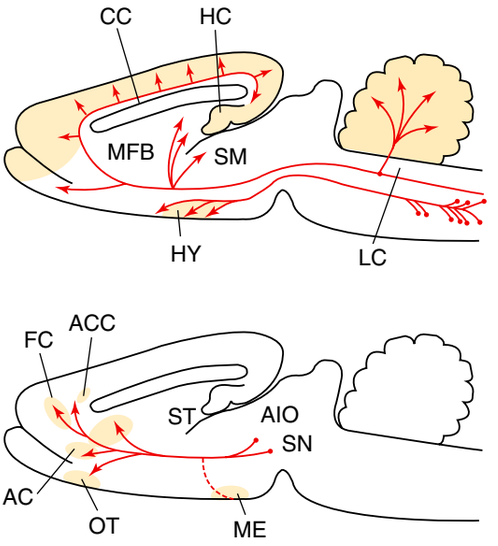

FIGURE 12-5 Some catecholaminergic neuronal pathways in the rat brain. **Upper.** Noradrenergic neuronal pathways. **Lower.** Some dopaminergic neuronal pathways. *A10*, ventral tegmental cell group; *AC*, nucleus accumbens; *ACC*, anterior cingulate cortex; *CC*, corpus callosum; *FC*, frontal cortex; *HC*, hippocampus; *HY*, hypothalamus; *LC*, locus ceruleus; *ME*, median eminence; *MFB*, median forebrain bundle; *OT*, olfactory tubercle; *SM*, stria medullaris; *SN*, substantia nigra; *ST*, striatum. (Courtesy of J. T. Coyle and S. H. Snyder.)

Six groups of cell bodies of noradrenergic neurons are clustered in the medulla oblongata, pons and midbrain. They are considered part of the reticular formation and extend from the spinal cord to the lateral pontine reticular formation. One of the best-studied of these groups is the locus ceruleus (Fig. 12-5), which has many ascending and descending projections from the pons.

Ten groups of dopaminergic neurons are broadly distributed from the retina and olfactory bulb to ventral midbrain and lemniscal area. Some of the most studied of these groups include the tuberoinfundibular neurons involved in endocrine regulation, the nigrostriatal neurons involved in body movement and Parkinson's disease and the mesolimbic and mesocortical ventral tegmental neurons involved in the action of antipsychotic, antihyperactivity and abused drugs (Fig. 12-5). Aside from these brief comments, the functional involvements of these catecholaminergic pathways cannot be summarized here, and the reader is referred to other reviews [29–32] and chapters in Part VIII, Neural Processing and Behavior.

CATECHOLAMINE RECEPTORS

The brain contains many different catecholamine receptors. The effects of dopamine are mediated through interaction with five different receptors; usually referred to as D_1-like (D_1, D_5) and D_2-like (D_2, D_3, D_4) [33] (Table 12-3).

TABLE 12-3 Properties of human dopamine receptor subtypes

The effects of norepinephrine and epinephrine are mediated through nine distinct receptors grouped into three families (α_1, α_2, β), each containing three subtypes encoded by separate genes [35] (Tables 12-4–12-6). Knockout mice lacking each of these receptors have now been produced and characterized. Knockouts of individual receptors sometimes, but not always, cause overt phenotypical changes (Table 12-7). Because there are so many receptors for each transmitter, it is perhaps not particularly surprising that loss of a single subtype often results in apparently only mild phenotypes.

The postsynaptic receptors on any given neuron receive information from transmitters released from another neuron. Typically, postsynaptic receptors are located on dendrites or cell bodies of neurons, but may also occur on axons or nerve terminals; in the latter case, an axoaxonic synaptic relationship may cause increases or decreases in transmitter release. In contrast, autoreceptors are found on certain neurons and respond to transmitter molecules released from the same neuron. Autoreceptors may be widely distributed on the surface of the neuron. At the nerve terminal, they respond to transmitter molecules released into the synaptic cleft; on the cell body, they may respond to transmitter molecules released by dendrites. Functionally, most autoreceptors appear to decrease further transmitter release in a kind of negative feedback loop. Autoreceptors have been identified for all the catecholamines, as well as for several other neurotransmitters. α_2-adrenergic receptors are often found on noradrenergic nerve terminals of postganglionic sympathetic nerves, as well as on noradrenergic neurons in the CNS [36], and activation of these receptors decreases further norepinephrine release. Dopamine autoreceptors, primarily of the D_2 subtype, are found in the nigrostriatal pathway and also reduce further transmitter release. There is also evidence for other dopamine autoreceptors in the brain and both β and α_1-adrenergic autoreceptors on peripheral sympathetic nerves [37]. However, these are much less common than α_2 and D_2 autoreceptors and can sometimes increase, rather than decrease, further transmitter release.

DOPAMINE RECEPTORS

There are five primary dopamine receptor subtypes. Dopamine receptors are found primarily in brain, although they also exist in kidney [33]. Two subtypes of dopamine receptor were initially identified based primarily on differences in their drug specificities and signaling mechanisms. D_1 receptors were found to stimulate adenylyl cyclase activity, while D_2 receptors inhibited this enzyme (Fig. 12-6). Subsequently, multiple D_1- and D_2-like receptors were identified by molecular cloning (Table 12-3) [33]. All dopamine receptor subtypes are

TABLE 12-7 Characteristics of catecholamine receptor knockout mice

Knockout	Phenotype	Reference
α_{1A}-adrenergic receptor	Decreased blood pressure	[58]
α_{1B}-adrenergic receptor	Decreased blood pressure, decreased response to CNS stimulants	[59]
α_{1D}-adrenergic receptor	Decreased blood pressure	[60]
α_{2A}-adrenergic receptor	Increased sympathetic activity, tachycardia, loss of hypotensive response to α_2 agonists	[61]
α_{2B}-adrenergic receptor	Decreased vasoconstrictor response to α_2 agonists	[62]
α_{2C}-adrenergic receptor	No overt phenotype	[63]
β_1-adrenergic receptor	Most die prenatally, survivors have impaired cardiac response	[64]
β_2-adrenergic receptor	Changes in vascular tone and energy metabolism during stress	[65]
β_3-adrenergic receptor	Altered leptin and insulin concentrations after agonist treatment	[66]
D_1-dopamine receptor	Reduced agonist responses, hyperlocomotion	[67]
D_2-dopamine receptor	Parkinsonian-like motor impairment	[68]
D_3-dopamine receptor	Hyperactivity	[69]
D_4-dopamine receptor	Reduced locomotion, hypersensitivity to ethanol and stimulants	[70]
D_5-dopamine receptor	Reduced agonist induced locomotion, startle, and prepulse inhibition	[71]

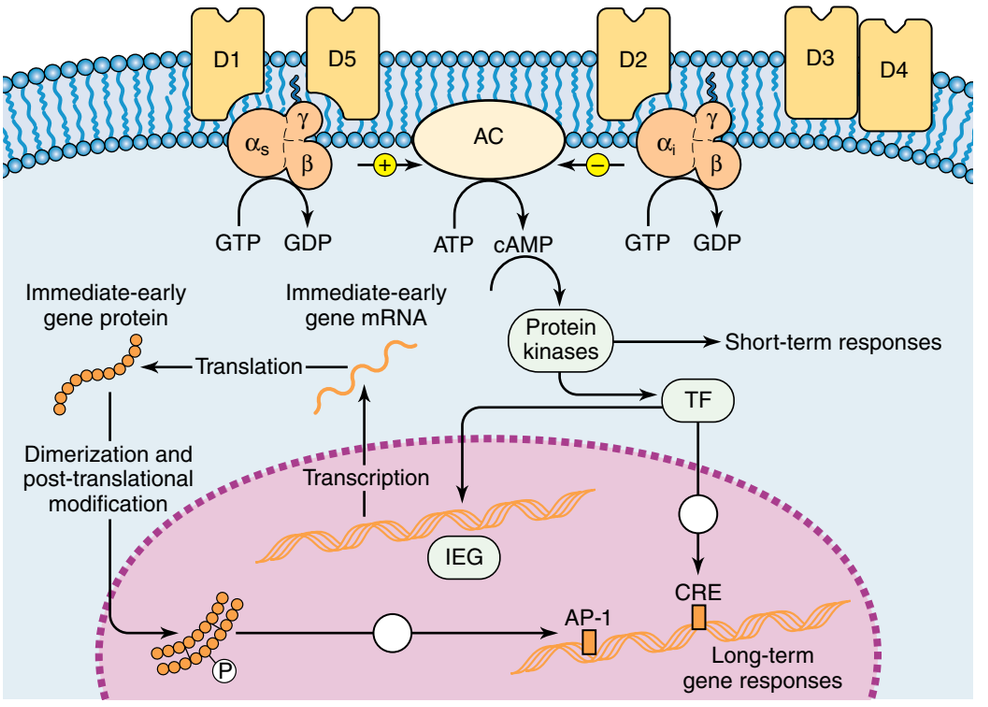

FIGURE 12-6 Effect of dopamine on intracellular signaling pathways. Stimulation of receptors by agonists can change enzyme activities as well as gene expression. Five subtypes of dopamine receptor have been identified. The D_1 and D_5 receptors are coupled to adenylyl cyclase (*AC*) via a stimulatory G protein (G_S). The D_2 receptor inhibits cyclase activity via coupling to an inhibitory G protein (G_i). Activation of D_3 and D_4 receptors also inhibits cAMP production. Adenylyl cyclase catalyzes the conversion of ATP into cAMP, which in turn causes dissociation of the regulatory and catalytic subunits of protein kinase A. The activated catalytic subunit catalyzes conversion of protein substrates into phosphoproteins. For example, PKA phosphorylates and activates DARPP-32 which in turn inhibits protein phosphatase-1 (PP-1). The phosphoproteins activated by the kinase in turn can lead to short-term responses within the cell or activate transcription factors (*TF*) which enter the nucleus and alter gene expression. Long-term gene responses can be initiated by the action of constitutively expressed TFs either directly on DNA or via a mechanism involving transcription of an immediate-early gene (*IEG*) and cytoplasmic production of its protein. This protein can then act on DNA via an adaptor protein 1 (*AP-1*)-binding site. *TF*, constitutively expressed transcription factors, such as a cAMP-response element (CRE), *IEG*, immediate-early genes, such as c-*fos*, c-*jun* and *knox*. For detailed discussion of the regulation of DARRP-32 phosphorylation by D_1 and D_2 receptors see reference [34], and for PP-1 functions, see Ch. 23.

members of the large G-protein-coupled receptor superfamily, which is characterized by seven hydrophobic, transmembrane domains, an extracellular N terminus and an intracellular C terminus (Fig. 12-4). These receptors are subject to post-translational modifications, including glycosylation, palmitoylation and phosphorylation. Consensus sequences for phosphorylation are found in the second (i_2) and third (i_3) intracellular loops and the C-terminal tail. D_1-like receptors have relatively small i_3 loops and long C-tails, while D_2-like receptors have large i_3 loops and short C-tails.

D_1-like receptors include the D_1 and D_5 receptors, have a high affinity for benzazepines like SCH-23390 and a low affinity for benzamides, and are coupled to stimulation of adenylyl cyclase activity through G_S, leading to increases in cyclic AMP and activation of PKA (see Chs 19 and 21). One of the consequences of dopamine receptor activation of PKA is the phosphorylation of DARPP-32, a protein phosphatase inhibitor enriched in dopaminoceptive neurons (see Ch. 23). The most striking pharmacological difference among D_1 and D_5 receptors is the high affinity of D_5 receptors for dopamine. The activity of D_1-like receptors modulates the functioning of the prefrontal cortex [38] and these receptors are increased in the prefrontal cortex of patients with schizophrenia [39].

D_2-like receptors include the D_2, D_3 and D_4 receptors. In addition, molecular cloning has demonstrated the presence of two isoforms of D_2 receptors, designated D_2L and D_2S [40]. These two isoforms differ by a 29-amino-acid insert in the i_3 loop of the receptor (Fig. 12-4), which appears to arise through alternative splicing. Although most (90%) G-protein-coupled receptors contain no introns in their protein coding blocks [41], D_2 receptors are an exception and contain multiple introns, allowing for alternative splicing. Both D_2L and D_2S receptors inhibit adenylyl cyclase activity through G_I, leading to decreased production of cyclic AMP (see Chs 19 and 21). The function of these splice variants has recently been elegantly elucidated by the use of transgenic animals, where D_2L appears to act mainly at postsynaptic sites and D_2S is primarily a presynaptic autoreceptor [42]. Interestingly, the cataleptic effects of the widely used antipsychotic drug haloperidol are absent in D_2L-deficient mice [42], suggesting that this receptor may be one of the main targets for haloperidol. D_2, D_3 and D_4 receptors are found in a variety of brain regions (Table 12-3). Pharmacologically, D_3 receptors have a relatively high affinity for atypical antipsychotics and for dopamine autoreceptor inhibitors, including (+)-UH232 and (+)-AJ76, while D_4 receptors have a particularly high affinity for the atypical antipsychotic drug clozapine. D_3 and D_4 receptors also inhibit adenylyl cyclase through G_i, and D_4 receptors have also been reported to be positively coupled to K^+ channels.

ADRENERGIC RECEPTORS

There are nine primary adrenergic receptor subtypes. Since norepinephrine and epinephrine are important messengers in both the peripheral sympathetic nervous system and the brain, adrenergic receptors are widely distributed in peripheral tissues as well as existing in high concentrations in the brain. Two subtypes of adrenergic receptor were first identified in the 1940s by differences in the relative potencies of catecholamine agonists [43]. α-adrenergic receptors were found to be potently activated by the natural catecholamines norepinephrine and epinephrine but not by the synthetic analog isoproterenol. Conversely, β-adrenergic receptors were potently stimulated by all three agonists. Subtypes of β-adrenergic receptor were first discovered in the 1960s and subtypes of α-adrenergic receptor in the 1970s [44]. Further pharmacological analysis and molecular cloning approaches have now shown that there are nine distinct adrenergic receptors, subclassified into three major families (α_1, α_2, β) based on their pharmacological properties, amino acid sequences and signaling mechanisms [35, 44] (Tables 12-4–12-6). All the adrenergic receptors, like the dopamine receptors, are members of the G-protein coupled receptor superfamily and are thought to have similar seven-transmembrane domain structures.

All subtypes within each adrenergic receptor family appear to be linked to the same primary signaling mechanism, raising the question of whether these receptors are redundant or have distinct functions. α_1-adrenergic receptor subtypes all activate $G_{q/11}$, increasing phospholipase Cβ activity and releasing inositol 1,4,5 trisphosphate and diacylglycerol (see Ch. 20). These actions synergistically increase the activity of protein kinase C, as well as causing many other effects due to increased intracellular calcium. α_2-adrenergic receptor subtypes all activate G_i to inhibit adenylyl cyclase (as do D_2-like receptors), leading to decreases in cyclic AMP and decreased phosphorylation of proteins by PKA. α_2-adrenergic receptor subtypes also appear to be linked to N-type calcium channels, inhibiting their function [45], particularly when they function as autoreceptors. Conversely, β-adrenergic receptor subtypes all activate G_S to increase adenylyl cyclase activity (as do D_1-like receptors), thereby increasing cyclic AMP and subsequent PKA activity.

All three α_1-adrenergic receptor genes contain a conserved intron in their protein coding sequence near the end of the sixth transmembrane domain [41]. Four splice variants have been reported for α_{1A}-adrenergic receptors, which appear to differ only in their final six to 53 amino acids at the distal end of the C-tail. The functional importance of these splice variants are not yet understood, and it is not yet known whether similar splice variants occur for the other two members of this family. Interestingly, the β_3- but not the β_1- or β_2-adrenergic receptor also contains an intron in its protein coding block only a few amino acids from the C-terminus [41]. C-terminal splice variants of this receptor have also been reported, although their function remains unclear.

Adrenergic receptors are also subject to multiple post-translational modifications. Like dopamine receptors, they are glycosylated, palmitoylated and phosphorylated on various residues. There are multiple consensus

phosphorylation sites for serine and threonine residues in the i_3 loops and C termini, and phosphorylation may be important in agonist-induced receptor sequestration and desensitization [46] (see also below). Both cAMP-dependent and non-cAMP-dependent phosphorylations of β-adrenergic receptors have been observed and in many cases the phosphorylated receptor is functionally uncoupled from G_S. Tyrosine phosphorylation of β-adrenergic receptors has also been reported. Other receptors coupled to activation of adenylyl cyclase can also cause what is known as heterologous desensitization. In addition, occupancy of β-adrenergic receptors by agonists results in the activation of β-adrenergic receptor kinase (βARK), which leads to phosphorylation of the receptor. The uncoupling of the receptor from G_S also appears to involve a protein called β-arrestin [46], which is similar to the 48 kDa arrestin protein in the retina (see Ch. 49).

The widespread distribution and the important functional activities of adrenergic receptors have made them attractive therapeutic targets for drug development. All adrenergic receptors are found in brain, although in widely varying patterns. In peripheral tissues, different subtypes often coexist in tissues and cells, but one subtype is often dominant. For example, α_1-adrenergic receptors are most important in smooth muscle contraction, and α_2- receptors in decreasing pancreatic insulin secretion. β_1-receptors are dominant in cardiac muscle, while β_2-receptors are most important in bronchial smooth muscle. Therefore, selective β_1 antagonists such as atenolol are widely used for cardiovascular problems, without the undesirable effect of promoting bronchoconstriction, which is mediated by the β_2-subtype. Conversely, selective β_2-agonists such as albuterol are useful in treating asthma and chronic obstructive pulmonary disease, without undesirable cardiovascular actions. Selective α_1-blockers such as prazosin are used for treating hypertension by blocking sympathetic vasoconstriction and reducing total peripheral resistance. Surprisingly, selective α_2-agonists such as clonidine are also used for treating hypertension by stimulating CNS control centers to reduce total sympathetic outflow. Unfortunately, highly selective agonists and antagonists have not yet been developed for the closely related subtypes within these subfamilies, greatly limiting their therapeutic utility.

The role of particular adrenergic receptor subtypes in brain function is still poorly understood. There is clearly a differential distribution of subtypes within different brain regions, determined primarily by radioligand binding, quantitative autoradiography, and/or *in situ* hybridization with specific mRNA sequences. α_1-adrenergic receptor subtypes are enriched in most brain regions, with the density of α_{1A} and α_{1B} subtypes generally much higher than α_{1D}; α_{2A} and α_{2C} receptors are found in most brain regions while α_{2B} is found primarily in thalamus; β_1 and β_2 subtypes are widely distributed but there is evidence for only low levels of β_3-adrenergic receptor expression in brain [47]. Elucidation of the functional importance of adrenergic receptor subtypes in CNS has been hampered by the lack of subtype-selective agonists and antagonists that cross the blood–brain barrier, but has recently been at least partially clarified by the use of knockout mice. For example, such studies suggest that the α_{2A} subtype is primarily responsible for the central hypotensive effects of α_2-adrenergic receptor agonists [48]. Interestingly, α_{1B} knockout mice show dramatically reduced stimulation of locomotor activity and reward responses to psychostimulants and opiate-type drugs of abuse [49], suggesting an important role for this subtype in vulnerability to addiction.

DYNAMICS OF CATECHOLAMINE RECEPTORS

Chronic exposure to agonists often results in diminished responsiveness. Neurotransmitter receptors are not static entities and, in both the peripheral sympathetic nervous system and the brain, receptor numbers can be modulated by chronic increases or decreases in agonist activation. The phenomenon of desensitization refers to a loss in cellular responsiveness caused by chronic agonist stimulation, often due to uncoupling of the receptor from its immediate effector mechanism. A related phenomenon is termed downregulation, which usually occurs with a slower time course and involves much more extensive cellular adaptations such as receptor degradation. Although occurring with most receptor subtypes, the mechanisms involved in desensitization and downregulation have been most extensively explored for β_2-adrenergic receptors. As mentioned above, within minutes of exposure to agonist, β_2-adrenergic receptors are phosphorylated by a specific kinase, βARK, which phosphorylates only agonist-occupied receptors [46]. Agonist-dependent phosphorylation by βARK promotes binding of β-arrestin to the receptor, which uncouples the receptor from G_S, thereby stopping signaling. This functional uncoupling is followed by a sequestration of cell-surface β_2-adrenergic receptors into intracellular compartments, with partial recycling to the cell surface and partial degradation. Similar, but independent, cAMP-dependent phosphorylation of the receptor has also been observed, and there appears to be a complex interplay between different types of phosphorylation events and the multiple molecular mechanisms involved in desensitization. These events also appear to involve both transcriptional and post-transcriptional regulatory mechanisms, including changes in transcription factor availability and receptor mRNA levels, feedback phosphorylation, changes in mRNA stability and targeting of receptors to particular cellular compartments for recycling or degradation (see also Chs 9 and 21). It now seems likely that similar mechanisms of desensitization occur with many, if not all, of the catecholamine receptors to different extents [50], although this has yet to be definitively proved.

Chronic exposure to antagonists often results in increased responsiveness. It is also well established that chronic treatment with antagonists to block receptor

stimulation, or surgical or chemical denervation, can result in compensatory increases in receptor density and/or responsiveness. This phenomenon, commonly referred to as supersensitivity or sensitization, was first observed after sympathetic denervation of peripheral organs in the early 20th century and has now also been observed extensively in brain [51]. Supersensitivity can result from a rapid loss of release sites for catecholamines following denervation, a more slowly occurring increase in receptor density on postsynaptic cells due to diminished stimulation, or from other compensatory processes resulting in increases in the efficiency of signal transduction from the activated receptor to downstream effectors [51]. Like desensitization, different degrees of supersensitivity have been observed with most of the catecholamine receptors when they are deprived of their normal tonic stimulatory tone.

Changes in receptor density are associated with altered synaptic activity. Destruction of catecholamine-containing nerves can be accomplished by treatment with selective neurotoxins such as 6-hydroxydopamine and usually causes functional supersensitivity of postsynaptic effector cells. Conversely, administration of tricyclic antidepressants or inhibitors of MAO, which would increase the concentrations of catecholamines within the synaptic cleft, often leads to functional subsensitivity. Many of these changes appear to be a compensatory response and involve changes in catecholamine receptor density. Destruction of the dopamine-containing nigrostriatal pathway can be accomplished surgically and has well described behavioral consequences. Unilateral nigrostriatal lesion causes asymmetry in dopamine innervation between the two cerebral hemispheres. Behavioral studies have demonstrated that the dopamine receptors in the denervated corpus striatum are supersensitive. Apomorphine, a dopamine agonist that stimulates dopamine receptors selectively, causes rotational behavior in rats with unilateral lesions in a direction contralateral to the lesion. In contrast, indirect agonists such as cocaine cause rotation in the opposite direction, since they act by releasing or blocking reuptake of dopamine. Thus, these agents will only activate receptors on the side with an intact dopaminergic input (see Ch. 46).

The extent of receptor supersensitivity after unilateral nigrostriatal lesions can be quantified by measuring the extent of rotational behavior. After selective nigrostriatal lesions have been produced in rats by injections of 6-hydroxydopamine into the substantia nigra, the number of dopamine receptors in the ipsilateral corpus striatum increases markedly, and the increase in the number of receptors may correlate with the extent of behavioral supersensitivity as monitored by rotational behavior [52]. Thus, the increase in receptor density appears to play a role in the behavioral supersensitivity of these animals.

The number of D_1 and D_2 receptors can be modulated by antagonists. The density of both D_1 and D_2 receptors can also be increased by chronic administration of antagonists [53]. Different subtypes of dopamine receptor may be coregulated since the D_2 antagonist sulpiride attenuated the ability of SCH-23390 to increase the density of D_1 receptors. The increase in the density of D_2 receptors following chronic administration of antagonists may be responsible for the development of a movement disorder called tardive dyskinesia (see Ch. 46). For example, when either acute or repeated doses of agonists acting at dopamine receptors are administered to rats, the result is an augmentation of the behavioral effects of the drugs. This phenomenon, known as reverse tolerance or sensitization, is characterized by a selective increase in the intensity or duration or a shift to an earlier time of onset of stereotypical behaviors such as locomotion, sniffing, rearing, licking and gnawing. Sensitization to indirect dopamine agonists such as amphetamine or cocaine also occurs. The mechanisms underlying behavioral sensitization are likely to be complex. It is known, for example, that stereotypical behavior and locomotor hyperactivity are critically dependent on activation of both D_1 and D_2 receptors.

Dopamine D_2-like receptors appear to mediate the actions of antipsychotic drugs. A strong correlation exists between the clinical potencies of antipsychotic drugs and their affinity for brain D_2 receptors [53]. This has led to the hypothesis that psychotic disorders result from overstimulation of D_2-like receptors (Chs 46 and 54). Long-term administration of antipsychotic drugs to humans or experimental animals can result in an increase in the density of striatal D_2 receptors and in the appearance of extrapyramidal side effects, including parkinsonian movement disorders and tardive dyskinesia. Certain antipsychotic drugs such as clozapine, olanzapine and quetiapine, referred to as atypical antipsychotics, have been reported to produce fewer extrapyramidal side effects than typical antipsychotics. They have been useful in treatment of patients with schizophrenia who respond poorly to typical antipsychotics such as haloperidol. The relative affinities of D_2, D_3 and D_4 receptors for typical and atypical antipsychotics together with the selective expression of D_3 receptor mRNA in limbic areas of the brain have led to the hypothesis that the clinical utility of antipsychotics in the treatment of psychiatric illness may be due, at least in part, to their ability to antagonize stimulation of D_3 or D_4 receptors, while the motor dysfunction observed following chronic treatment with typical antipsychotics could be due to alterations in the density of D_2 receptors in the striatum.

Changes in dopamine receptor density may be involved in the side effects of antipsychotic drugs. One of the most serious side effects of the antipsychotic drugs is tardive dyskinesia, a disfiguring, excessive motor activity of the tongue, face, arms and legs in patients treated chronically with large doses of the drugs (see Ch. 46). Paradoxically, reduction of the dosage worsens the

symptoms, whereas increasing the dosage alleviates the symptoms. It has been suggested that tardive dyskinesia reflects a supersensitivity of dopamine receptors that have been chronically blocked. This hypothesis gains support from the direct demonstration that chronic treatment with antipsychotics leads to an increase in the number of dopamine receptors in the corpus striatum. Moreover, the ability of antipsychotics to elicit this increase correlates with their ability to block dopamine receptors. The recently introduced antipsychotic aripiprazole is a partial D_2 agonist and has been associated with a very low incidence of extrapyramidal side effects. If this is borne out after more extensive use in the clinic, partial agonists may represent an important and novel avenue for future development of drugs to modulate catecholaminergic neural systems.

Serotonin

Julie G. Hensler

SEROTONIN, THE NEUROTRANSMITTER 227
The indolealkylamine 5-hydroxytryptamine was initially identified because of its effects on smooth muscle 227
Understanding the neuroanatomical organization of serotonergic neurons and projections provides insight into this neurotransmitter's functions and possible roles in mental processes 228
The amino acid L-tryptophan serves as the precursor for the synthesis of 5-HT 231
The synthesis of 5-HT can increase markedly under conditions requiring more neurotransmitter 233
5-HT is stored primarily in vesicles and is released into the synaptic cleft by an exocytotic mechanism 233
The activity of 5-HT in the synapse is terminated primarily by its re-uptake into serotonergic terminals 234
Acute and chronic regulation of serotonin transporter function provides means for altering synaptic 5-HT concentrations and neurotransmission 236
The primary catabolic pathway for 5-HT is oxidative deamination by the enzyme monoamine oxidase 237
In addition to classical synaptic transmission, 5-HT may relay information by volume transmission or paracrine neurotransmission 238
5-HT may be involved in a wide variety of behaviors by setting the tone of brain activity in relationship to the state of behavioral arousal/activity 238
5-HT modulates neuroendocrine function 239
5-HT modulates circadian rhythmicity 239
5-HT modulates feeding behavior and food intake 239
Not only does 5-HT have important physiological effects of its own but it is also the precursor of the hormone melatonin 240

SEROTONIN RECEPTORS 240
Pharmacological and physiological studies have contributed to the definition of the many receptor subtypes for serotonin 240
Molecular biology techniques led to the discovery of additional 5-HT receptor subtypes and furthered our understanding of their structure and function 241
The 5-HT_1 receptor family comprises the 5-HT_{1A}, 5-HT_{1B}, 5-HT_{1D}, 5-ht_{1E} and 5-ht_{1F} receptors 241
The 5-HT_2 receptor family comprises the 5-HT_{2A}, 5-HT_{2B} and 5HT_{2C} receptors 244
Unlike the other subtypes of receptor for 5-HT, the 5-HT_3 receptor is a ligand-gated ion channel 245
The 5-HT_4, 5-ht_6 and 5-HT_7 receptors are coupled to the stimulation of adenylyl cyclase 246
'Orphan' receptors include the 5-ht_5 receptor and the 5-HT_{1P} receptor 247

SEROTONIN, THE NEUROTRANSMITTER

The indolealkylamine 5-hydroxytryptamine was initially identified because of its effects on smooth muscle. Since the mid-19th century, scientists have known that after blood clots, a substance in the resulting serum constricts vascular smooth muscle and increases vascular tone. Around the turn of the century, platelets were identified as the source of this substance. It wasn't until 1948 that Rapport, Green and Page isolated and correctly identified the serum vasoconstrictor factor as the substituted indole 5-hydroxytryptamine (5-HT) [1]. Quite appropriately, this serum tonic factor, released into sera from platelets during the clotting of blood, was named 'serotonin'. Independently, Esparmer characterized a substance found in large amounts in the enterochromaffin cells of the gastrointestinal tract, which also constricted smooth muscle. He called this substance 'enteramine'. In 1952, Esparmer and Areso reported that serotonin and enteramine were the same substance. Twarog and Page, in 1953, detected serotonin in extracts of brain using a sensitive bioassay, the mollusk heart. Thus, serotonin was localized to three key systems in the body: platelets, gastrointestinal tract and brain.

The structures of serotonin (5-HT) and related compounds are shown in Figure 13-1. The combination of the hydroxyl group in the 5 position of the indole nucleus and a primary amine nitrogen serving as a proton acceptor at physiological pH makes 5-HT a hydrophilic substance. Therefore, it does not pass the lipophilic blood–brain barrier readily. For this reason, its discovery in brain in 1953 by Twarog and Page was exciting in that it indicated that 5-HT was being synthesized in brain. At about the same time the observation was made that (+)lysergic acid diethylamide (LSD), which was known to have psychedelic or psychotomimetic effects, antagonized a response to 5-HT

(i.e. the contraction of gastrointestinal smooth muscle produced by serotonin) (see detailed discussion in Ch. 56). This further substantiated an important role of 5-HT in brain function. The idea that 5-HT had important behavioral effects stimulated much thought about a central role for 5-HT in mental illness. Subsequently, various theories arose linking abnormalities of 5-HT function in brain to the development of a number of psychiatric disorders, particularly schizophrenia and depression. Psychotherapeutic drugs are now available that are effective in depression, anxiety disorders and schizophrenia, and have potent, and in some cases selective, effects on serotonergic neurons in brain (see Chs 54 and 55).

Understanding the neuroanatomical organization of serotonergic neurons and projections provides insight into this neurotransmitter's functions and possible roles in mental processes. Serotonin-containing neuronal cell bodies are restricted to discrete clusters or groups of cells located along the midline of the brainstem. Their axons, however, innervate nearly every area of the central nervous system (Fig. 13-2). In 1964, Dahlstrom and Fuxe, using the Falck–Hillarp technique of histofluorescence, observed that the majority of serotonergic soma were found in cell body groups that had been previously designated by Taber, Brodal and Walberg as the raphe nuclei. This earlier description of the raphe

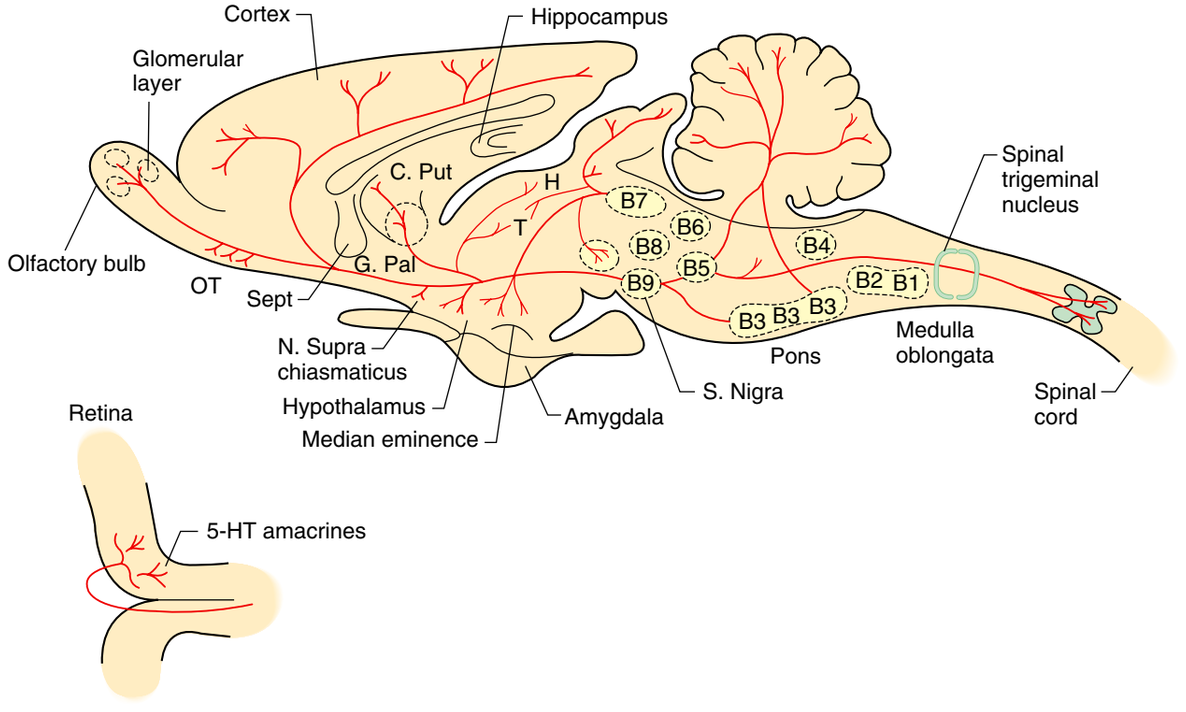

FIGURE 13-2 Schematic drawing depicting the location of the serotonergic cell body groups in a sagittal section of the rat central nervous system and their major projections. *OT*, olfactory tuberculum; *Sept*, septum; *C. In: *The Biology of Serotonergic Transmission.* New York: John Wiley & Sons, 1982, pp 29–61.)

nuclei was based on cytoarchitectural criteria, i.e. on cell body structural characteristics and organization. Dahlstrom and Fuxe described nine groups of serotonin-containing cell bodies, which they designated B_1–B_9 and which correspond for the most part with the raphe nuclei [2] (Table 13-1). Some serotonergic neuronal cell bodies, however, are found outside the raphe nuclei, and not all the cell bodies in the raphe nuclei are serotonergic. In most of the raphe nuclei, the majority of neurons are nonserotonergic. For example, the dorsal raphe contains the largest number of serotonergic neurons; however, only 40–50% of the cell bodies in the dorsal raphe are serotonergic (Fig. 13-3).

Over the course of the last three decades, a variety of techniques have been used to characterize the circuitry of serotonergic neurons in the central nervous system. The density of serotonergic innervation in the forebrain was initially underestimated because the original histofluorescence method was limited in sensitivity and did not permit the detection of many fine axons and terminals.

TABLE 13-1 Classification of serotonergic cell body groups according to Dahlstrom and Fuxe and corresponding anatomical structure

Groups of serotonin-containing cell bodies	Anatomical structure
B_1	Raphe pallidus nucleus
	Caudal ventrolateral medulla
B_2	Raphe obscurus nucleus
B_3	Raphe magnus nucleus
	Rostral ventrolateral medulla
	Lateral paragigantocellular reticular nucleus
B_4	Raphe obscurus nucleus, dorsolateral part
B_5	Median raphe nucleus, caudal part
B_6	Dorsal raphe nucleus, caudal part
B_7	Dorsal raphe nucleus principal, rostral part
B_8	Median raphe nucleus, rostral main part
	Caudal linear nucleus
	Nucleus pontis oralis
B_9	Nucleus pontis oralis
	Supralemniscal region

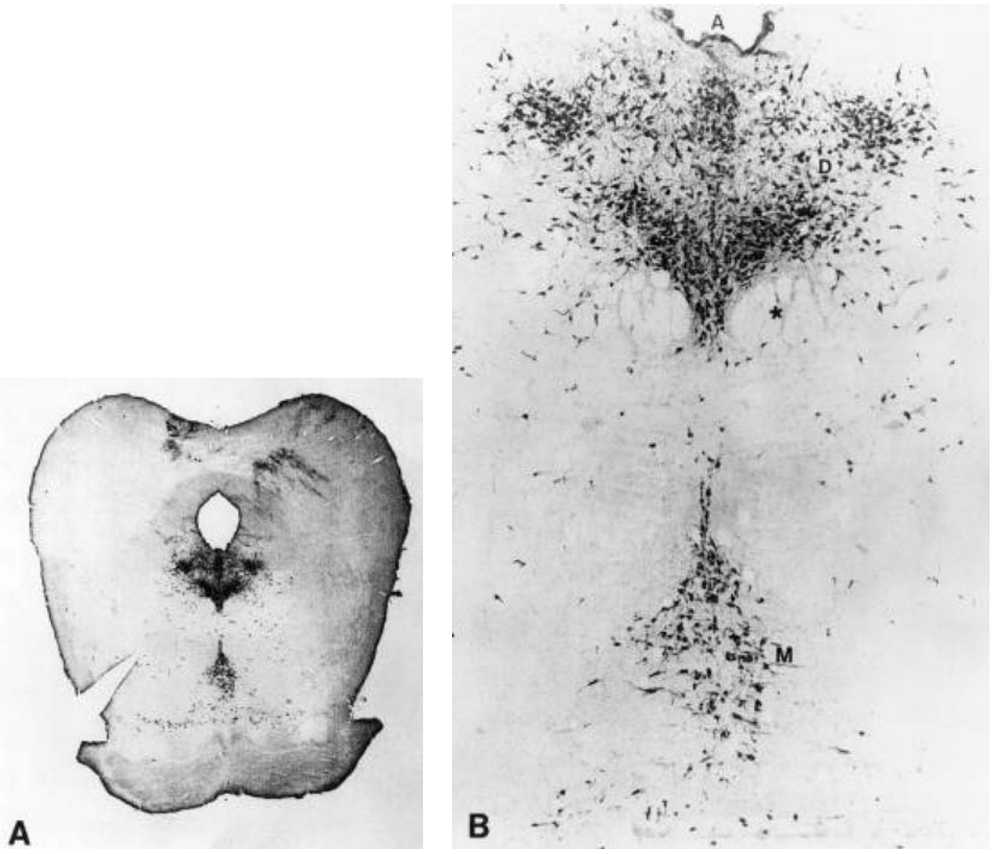

FIGURE 13-3 Serotonergic cell bodies in the midbrain raphe nuclei demonstrated by 5-HT immunocytochemistry. (**A**) Low magnification of transverse section through rat midbrain. The serotonergic cell body groups shown give rise to widespread serotonergic projections to cerebral cortex and forebrain structures. (**B**) Higher magnification micrograph showing serotonergic cell bodies in dorsal and median raphe nuclei. The dorsal raphe nucleus lies in the central gray matter just beneath the cerebral aqueduct. In the transverse plane, the dorsal raphe can be further subdivided into a ventromedial cell cluster between and just above the medial longitudinal fasciculus (MLF), a smaller dorsomedial group just below the aqueduct, and large bilateral cell groups. The median raphe nucleus lies in the central core of the midbrain, below the MLF. *D*, dorsal raphe; *M*, median raphe, *A*, aqueduct. (With permission from Molliver [4].)

Subsequent anatomical techniques (e.g. immunohistochemistry of 5-HT or tryptophan hydroxylase, an enzyme unique to the synthesis of 5-HT; retrograde and anterograde axonal transport studies) have allowed a more complete and accurate characterization of the serotonergic innervation of forebrain areas.

The largest group of serotonergic cells is group B_7 of Dahlstrom and Fuxe. B_7 is continuous with a smaller group of serotonergic cells, B_6. Groups B_6 and B_7 are often considered together as the dorsal raphe nucleus, with B_6 being its caudal extension. Another prominent serotonergic cell body group is B_8, which corresponds to the median raphe nucleus, also termed the nucleus central superior. Group B_9, part of the ventrolateral tegmentum of the pons and midbrain, forms a lateral extension of the median raphe and therefore is not considered one of the midline raphe nuclei. Ascending serotonergic projections innervating the cerebral cortex and other regions of the forebrain arise primarily from the dorsal raphe, median raphe, and B_9 cell group. The serotonergic neurons of the median and dorsal raphe nucleus differ in their electrophysiological characteristics and in their inhibition by somatodendritic autoreceptor activation [3], as well as in the morphology and topographical organization of their axonal projections to the forebrain (see below). These differences may be extremely important in understanding the role of these two distinct serotonergic systems, arising from the dorsal and median raphe nuclei, in normal brain function and in mental illness.

The two main ascending serotonergic pathways from the midbrain raphe nuclei to the forebrain are the dorsal periventricular path and the ventral tegmental radiations. Both pathways converge in the caudal hypothalamus where they join the medial forebrain bundle. Axons of dopaminergic (A8, A9, A10) and noradrenergic (A6) cell body groups also course anteriorly through the medial forebrain bundle.

Ascending projections from the raphe nuclei to forebrain structures are organized in a topographical manner. The dorsal and median raphe nuclei give rise to distinct projections to forebrain regions (Fig. 13-4). The median raphe projects heavily to hippocampus, septum and hypothalamus, whereas the striatum is innervated predominantly by the dorsal raphe. The dorsal and median raphe nuclei send overlapping neuronal projections to the neocortex. Within the dorsal and median raphe, cells are organized in particular zones or groups that send axons to specific areas of brain. For example, the frontal cortex receives heavy innervation from the rostral and lateral subregions of the dorsal raphe nucleus. Moreover, raphe

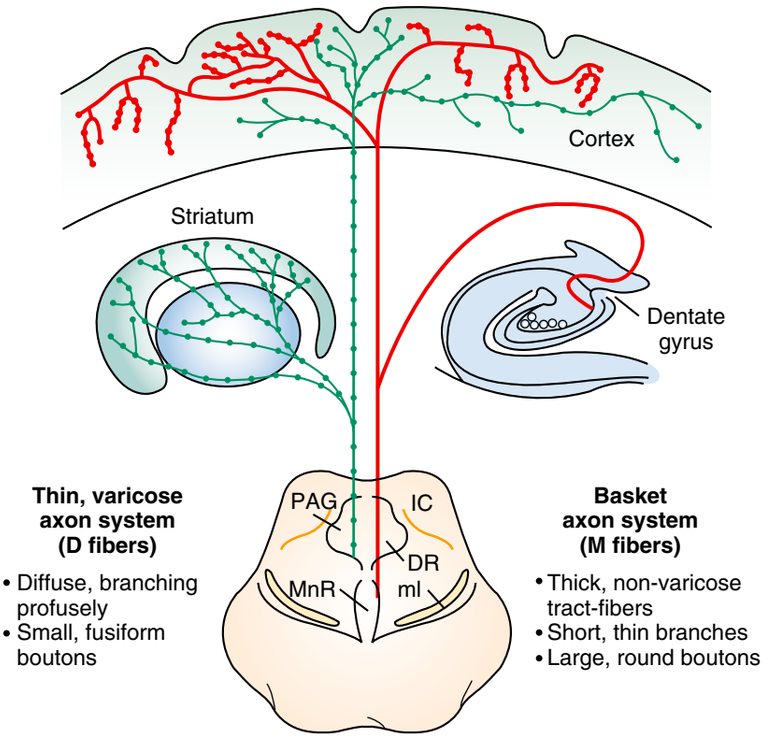

FIGURE 13-4 Simplified diagram of the main features of the dual serotonergic system innervating the forebrain. The fine varicose axon system (*D fibers*) arises from the dorsal raphe (*DR*) nucleus with fibers that branch profusely in their target areas. It is difficult to demonstrate the synaptic connections of these fibers and therefore the incidence of synapses on these fibers is still being debated. The basket axon system (*M fibers*) arises from the median raphe (*MnR*) nucleus with thick, nonvaricose axons, giving rise to branches with characteristic axons that appear beaded, with round or oval varicosities. These large terminals make well-defined synapses with target cells. *PAG*, periaqueductal gray matter; *IC*, inferior colliculus; *ml*, medial lemniscus. (With permission from Tork [2].)

neurons send collateral axons to areas of brain that are related in function such as the amygdala and hippocampus, or substantia nigra and caudate putamen. The highly organized innervation of forebrain structures by serotonergic neurons of the raphe is quite interesting in that it implies independent functions of sets of serotonergic neurons dependent on their origin and terminal projections, as opposed to a nonselective or general role for 5-HT in the central nervous system.

Serotonergic axon terminals appear to exhibit morphological differences related to the raphe nucleus of origin (Fig. 13-4). Serotonergic axons from the median raphe nucleus (type M) look relatively coarse with large spherical varicosities. By contrast, axons from the dorsal raphe (type D) are very fine and typically have small, pleomorphic varicosities. Dorsal raphe axons appear to be more vulnerable to certain neurotoxic amphetamine derivatives, e.g. 3,4-methylenedioxymethamphetamine (MDMA, or 'Ecstasy') and parachloroamphetamine (PCA) (see also Ch. 56). Median raphe axons appear to be more resistant to the neurotoxic effects of these drugs. Blockade of the serotonin transporter (SERT) prevents the neurotoxic effects of these amphetamine derivatives, indicating that activity of this transporter is critical for the neurotoxic effects of these drugs.

The other raphe nuclei, B_1–B_4, are more caudally situated (mid-pons to caudal medulla) and contain a smaller number of serotonergic cells. These cell body groups give rise to serotonergic axons that project within the brainstem and to the spinal cord (Fig. 13-2). The spinal cord receives a strong serotonergic innervation. Three principal descending pathways have been described: (1) from the raphe magnus nucleus (B_3) to laminae I and II of the dorsal horn; (2) from the raphe obscurus nucleus (B_2, B_4) to lamina IX of the ventral horn; (3) from the rostral ventrolateral medulla and the lateral paragigantocellular reticular nucleus (B_3) to the intermediolateral cell column. Projections from the caudal ventrolateral medulla (B_1) are not known at present [2].

Afferent connections to the raphe nuclei include connections between the dorsal and median raphe nuclei, B_9, B_1 and B_3. Connections between the raphe nuclei have been described by retrograde tracing techniques using horseradish peroxidase and wheat germ agglutinin. Such innervation may have considerable physiological and/or pharmacological importance as serotonin released in the vicinity of serotonergic cell bodies regulates the firing of serotonergic neurons through the activation of somatodendritic autoreceptors. The raphe nuclei also receive input from other cell body groups in the brainstem such as the substantia nigra and ventral tegmental area (dopamine), superior vestibular nucleus (acetylcholine), locus ceruleus (norepinephrine), nucleus prepositus hypoglossi and nucleus of the solitary tract (epinephrine). Other afferents include neurons from the hypothalamus, cortex, and limbic forebrain structures such as the amygdala [2, 4].

The amino acid L-tryptophan is the precursor for the synthesis of 5-HT. The synthesis and primary metabolic pathways of 5-HT are shown in Figure 13-5. The initial step in the synthesis of serotonin is the facilitated transport of the amino acid L-tryptophan from blood into brain. The primary source of tryptophan is dietary protein. Other neutral amino acids, such as phenylalanine, leucine and methionine, are transported by the same carrier into the brain. Therefore, the entry of tryptophan into brain is not only related to its concentration in blood but is also a function of its concentration in relation to the concentrations of other neutral amino acids. Consequently, lowering the dietary intake of tryptophan while raising the intake of the amino acids with which it competes for transport into brain lowers the content of 5-HT in brain and changes certain behaviors associated with 5-HT function. This strategy for lowering the brain content of 5-HT has been used clinically to evaluate the importance of brain 5-HT in the mechanism of action of psychotherapeutic drugs.

Serotonergic neurons contain the enzyme L-tryptophan-5-monooxygenase (EC 1.14.16.4), more commonly termed tryptophan hydroxylase, which converts tryptophan to 5-hydroxytryptophan (5-HTP) (Fig. 13-5). Tryptophan hydroxylase contains 444 amino acids, corresponding to a molecular weight of about 51 Da. This enzyme is synthesized in serotonergic cell bodies of the raphe nuclei and is found only in cells that synthesize 5-HT. Therefore its distribution in brain is similar to that of 5-HT itself. The K_m of tryptophan hydroxylase for tryptophan is approximately 30–60 µmol/l, a concentration comparable to that of tryptophan in brain. If the concentration of tryptophan in serotonergic neurons is assumed to be comparable to that in whole brain, the enzyme would not be saturated with substrate, and the formation of 5-HT in brain would be expected to rise as the brain concentration of tryptophan increases. This has been found to occur in response to raising the dietary intake of tryptophan specifically.

The other enzyme involved in the synthesis of 5-HT, aromatic L-amino acid decarboxylase (AADC) (EC 4.1.1.28), is a soluble pyridoxal-5′-phosphate-dependent enzyme, which converts 5-HTP to 5-HT (Fig. 13-5). It has been demonstrated that administration of pyridoxine increases the rate of synthesis of 5-HT in monkey brain, as revealed using position emission tomography (this technique is discussed in Ch. 58). This presumably reflects a regulatory effect of pyridoxine on AADC activity and raises the interesting issue of the use of pyridoxine supplementation in situations associated with 5-HT deficiency.

AADC is present not only in serotonergic neurons but also in catecholaminergic neurons, where it converts 3,4-dihydroxyphenylalanine (DOPA) to dopamine (see Ch. 12). However, different pH optima or concentrations of substrate or cofactor are required for optimum activity of the enzyme in brain homogenates when using either 5-HTP or DOPA as the substrate. cDNAs encoding AADC

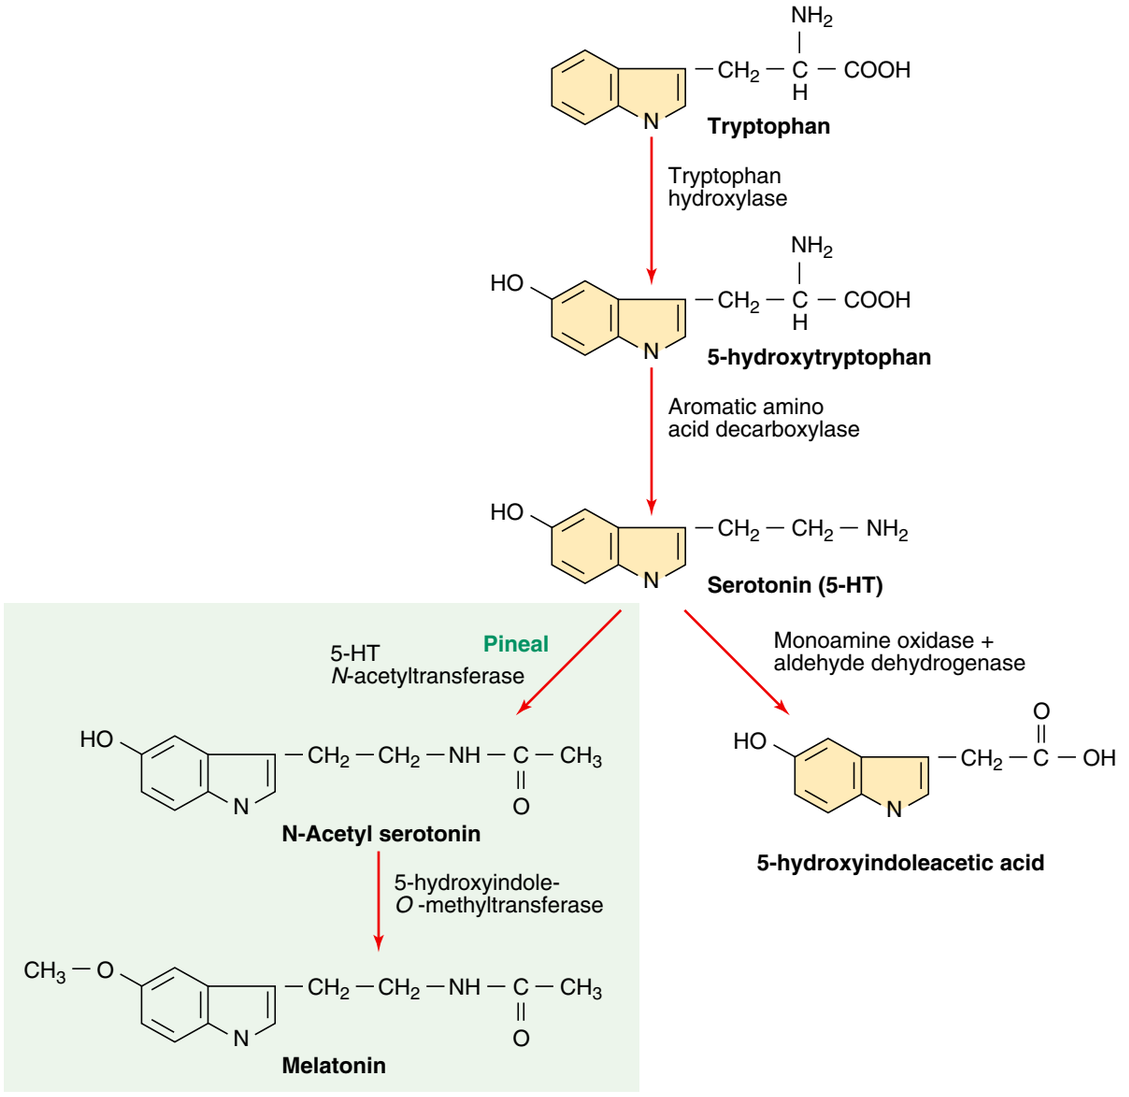

FIGURE 13-5 The biosynthesis and catabolism of serotonin. Note that in the pineal gland, serotonin is converted enzymatically to melatonin.

have been cloned from various species. The encoded protein contains 380 amino acids and has a molecular weight of 54 kDa, but it appears to exist as a dimer. Characterization of the protein expressed in cells transfected with the cDNA shows that it decarboxylates either DOPA or 5-HTP. Also, *in situ* hybridization of the mRNA for the enzyme revealed its presence both in serotonergic cells in the dorsal raphe nucleus and in catecholaminergic cells in brain regions containing catecholaminergic soma [5]. Taken together, these results support the idea that the decarboxylation of both DOPA and 5-HTP are catalyzed by the same enzyme.

Because AADC is not saturated with 5-HTP under physiological conditions, (i.e. the concentration of 5-HTP is much less than the enzyme's K_m of 10 µmol/l), it is possible to raise the content of 5-HT in brain not only by increasing the dietary intake of tryptophan but also by raising the intake of 5-HTP. This procedure, though, results in the formation of 5-HT in cells that would not normally contain it (e.g. catecholaminergic neurons) because of the nonselective nature of AADC.

The initial hydroxylation of tryptophan, rather than the decarboxylation of 5-HTP, appears to be the rate-limiting step in serotonin synthesis. Therefore, the inhibition of this reaction results in a marked depletion of the content of 5-HT in brain. The enzyme inhibitor most widely used in experiments is parachlorophenylalanine (PCPA). *In vivo,* PCPA irreversibly inhibits tryptophan hydroxylase, presumably by incorporating itself into the enzyme to produce an inactive protein. This results in a long-lasting reduction of 5-HT levels. Recovery of enzyme activity, and 5-HT biosynthesis, requires the synthesis of new enzyme. Marked increases in mRNA for tryptophan hydroxylase are found in the raphe nuclei 1–3 days after administration of PCPA [6].

The synthesis of 5-HT can increase markedly under conditions requiring more neurotransmitter. Plasticity is an important concept in neurobiology. In general, this refers to the ability of neuronal systems to conform to either short- or long-term demands placed upon their activity or function (see Plasticity in Ch. 53). One of the processes contributing to neuronal plasticity is the ability to increase the rate of neurotransmitter synthesis and release in response to increased neuronal activity. Serotonergic neurons have this capability; the synthesis of 5-HT from tryptophan is increased in a frequency-dependent manner in response to electrical stimulation of serotonergic soma [7]. The increase in synthesis results from the enhanced conversion of tryptophan to 5-HTP and is dependent on extracellular calcium ion. It is likely that the increased 5-HT synthesis results in part from alterations in the kinetic properties of tryptophan hydroxylase, perhaps due to calcium-dependent phosphorylation of the enzyme by calmodulin-dependent protein kinase II or cAMP-dependent protein kinase (PKA; see Ch. 23).

Short-term requirements for increases in the synthesis of 5-HT can be met by post-translational processes, such as phosphorylation, that change the kinetic properties of tryptophan hydroxylase without necessitating the synthesis of more molecules of tryptophan hydroxylase. By contrast, situations requiring long-term increases in the synthesis and release of 5-HT result in the synthesis of tryptophan hydroxylase protein. For example, partial but substantial destruction (>60%) of central serotonergic neurons results in an increase in the synthesis of 5-HT in residual terminals. Although the increase in synthesis initially results from activation of existing tryptophan hydroxylase molecules, the increased synthesis of 5-HT seen weeks after the lesion results from more tryptophan hydroxylase being present in the residual terminals. An increase in tryptophan hydroxylase mRNA has been reported in residual serotonergic neurons after partial lesion with the neurotoxins 5,7-dihydroxytryptamine or MDMA [8, 9], consistent with the idea of an increase in the synthesis of tryptophan hydroxylase molecules in residual neurons.

5-HT is stored primarily in vesicles and is released into the synaptic cleft by an exocytotic mechanism. Peripheral sources of monoamine-containing cells have been utilized to study the properties of storage vesicles, for example chromaffin cells of the adrenal medulla for catecholamines and parafollicular cells of the thyroid gland for 5-HT [10]. In some respects, the vesicles that store 5-HT resemble those that store catecholamines. For example, drugs such as reserpine and tetrabenazine, which inhibit the activity of the transporter localized to the vesicular membrane, deplete the brain content of 5-HT as well as catecholamines. Storage of 5-HT in vesicles requires its active transport from the cytoplasm. The vesicular 'transporter' uses the electrochemical gradient generated by a vesicular H^+-ATPase to drive transport, such that a cytoplasmic amine is exchanged for a luminal proton – i.e. the uptake of 5-HT is coupled to the efflux of H^+ (Fig. 13-6A) (see also Ch. 5).

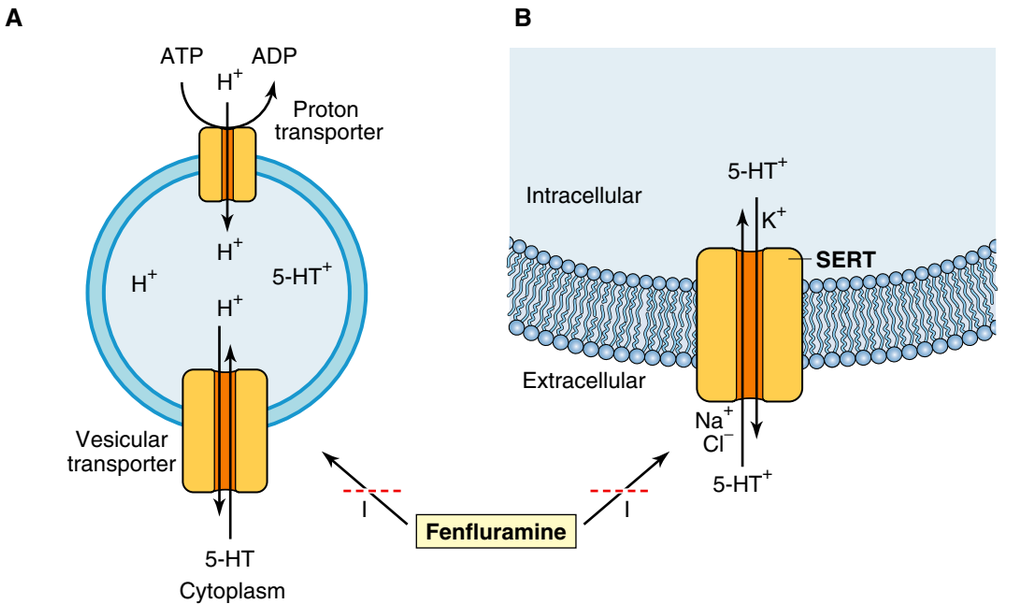

FIGURE 13-6 The substituted amphetamine fenfluramine inhibits the transport of 5-HT by both (**A**) the vesicular transporter, and (**B**) the serotonin transporter (*SERT*). Substituted amphetamines such as fenfluramine and MDMA stimulate the release of 5-HT from serotonergic terminals. These drugs block the vesicular transporter and disrupt the proton gradient across the vesicle membrane. The increase in intracellular 5-HT favors the release of 5-HT by the reverse action of the SERT. These drugs also act as substrates for the SERT so as to inhibit the transport of 5-HT into cells.

Drugs that inhibit the vesicular transporter do not generally block the plasma membrane transporter (serotonin transporter, SERT) and *vice versa*. However, two drugs that have effects at both the vesicular transporter and the SERT are MDMA or 'Ecstasy', and the anorexic agent fenfluramine. Fenfluramine and MDMA inhibit the vesicular transporter directly by competing for its substrate binding site. These agents also dissipate the transmembrane pH gradient to further inhibit 5-HT uptake into the vesicle (Fig. 13-6A). The effects of these drugs on the vesicles storing 5-HT raises cytoplasmic 5-HT and facilitates SERT-mediated efflux of 5-HT. Both fenfluramine and MDMA act as substrates for the SERT and not only inhibit the transport of 5-HT into the cell but also facilitate its outward transport by the SERT (Fig. 13-6B). The consequence of such dual pharmacological actions on both the vesicle pump and the plasmalemma transporter is the stimulation of the release of 5-HT by a calcium ion-independent (i.e. non-exocytotic) process. In contrast to exocytotic release, this release process is not modulated by terminal auto- or heteroreceptors. The release of 5-HT caused by drugs such as fenfluramine is prevented by drugs that block the SERT.

Vesicles storing 5-HT exhibit some differences from those storing catecholamines. In contrast to catecholamine-containing vesicles, there is virtually no ATP in serotonin vesicles. Also, serotonergic synaptic vesicles, but not chromaffin granules, contain a specific protein that binds 5-HT with high affinity in the presence of Fe^{2+}. This serotonin-binding protein (SPB) is packaged in secretory vesicles along with 5-HT, which probably accounts for the observation that newly taken up ^{3}H-5-HT is rapidly complexed with this protein in brain *in situ*. SPB is secreted along with 5-HT by a calcium-dependent process.

There is considerable evidence that the release of 5-HT occurs by exocytosis, i.e. by the discharge from the cell of the entire content of individual storage vesicles. First, 5-HT is sufficiently ionized at physiological pH so that it does not cross plasma membranes by simple diffusion. Second, most intraneuronal 5-HT is contained in storage vesicles and other contents of the vesicle including SPB are released together with serotonin. By contrast, cytosolic proteins do not accompany electrical stimulation-elicited release of 5-HT. Third, the depolarization-induced release of 5-HT occurs by a calcium-dependent process; indeed, it appears that the influx of extracellular calcium ions with or without membrane depolarization can increase the release of 5-HT. Calcium stimulates the fusion of vesicular membranes with the plasma membrane (see Chs 9, 10).

Serotonin release is regulated in part by the firing rate of serotonergic soma in the raphe nuclei. Numerous studies utilizing a variety of techniques have revealed that an increase in raphe cell firing enhances the release of 5-HT in terminal fields. The opposite effect is observed when raphe cell firing decreases. This means that drugs that change the firing rate of serotonergic soma modify the release of 5-HT as well. Important targets for such drugs are somatodendritic autoreceptors, which, as is discussed later, are 5-HT_{1A} receptors (see Fig. 13-8). Activation of these receptors by 5-HT or exogenous agonist slows the rate of firing of serotonergic soma. As discussed below, serotonergic autoreceptors on terminals appear to be either the 5-HT_{1B} or 5-HT_{1D} subtype, depending on the species. Activation of these receptors decreases the synthesis and release of 5-HT. However, in contrast to the activation of somatodendritic autoreceptors, such effects are not due to decreases in the firing rate of serotonergic soma.

The activity of 5-HT in the synapse is terminated primarily by its re-uptake into serotonergic terminals. The synaptic effects of many amino acid and monoaminergic neurotransmitters, including 5-HT, are terminated by the binding of these molecules to specific transporter proteins. The serotonin transporter (SERT) is located on serotonergic neurons. Evidence for this comes from studies showing that the selective lesion of serotonergic neurons in brain markedly reduces both the high-affinity uptake of ^{3}H-5-HT in areas of brain receiving serotonergic innervation and the specific binding of radioligands to the SERT. The mRNA for the SERT has been localized in brain exclusively to the serotonergic cells in the raphe nuclei. Of interest is the fact that mRNA for the SERT has not yet been detected in glia, even though primary cultures of astrocytes *in vitro* can take up 5-HT. Activity of the SERT regulates the concentration of 5-HT in the synapse, thereby influencing synaptic transmission.

The uptake system for 5-HT is saturable and of high affinity, with a K_m value for 5-HT of approximately 0.2–0.5 µmol/l. The uptake of 5-HT is an active process that is temperature-dependent and has an absolute requirement for external Na^+ and Cl^- it is inhibited by metabolic inhibitors as well as by inhibitors of Na^+/K^+-ATPase activity. From these and other data it has been inferred that the energy requirement for 5-HT uptake is not directly used to transport 5-HT but rather is necessary to maintain the gradient of Na^+ across the plasma membrane upon which 5-HT uptake is dependent (see Ch. 5). The current model of transport has one Na^+, one Cl^- and one protonated 5-HT binding to the transporter extracellularly to form a quaternary complex that subsequently undergoes a conformational change to release the neurotransmitter and the ions into the cytoplasm. In the cytoplasm, K^+ associates with the SERT to promote the reorientation of the unloaded carrier for another transport cycle (Fig. 13-6B). This 'alternating access' hypothesis of serotonin transport, however, does not adequately account for electrophysiological data that are better explained by a channel model of coupled transport [11].

The cloning, sequencing and expression of several transporter proteins, including that for 5-HT, has aided considerably in understanding structure/function relationships of transporter proteins [12]. The cDNA for the SERT isolated from rat brain predicts a protein containing

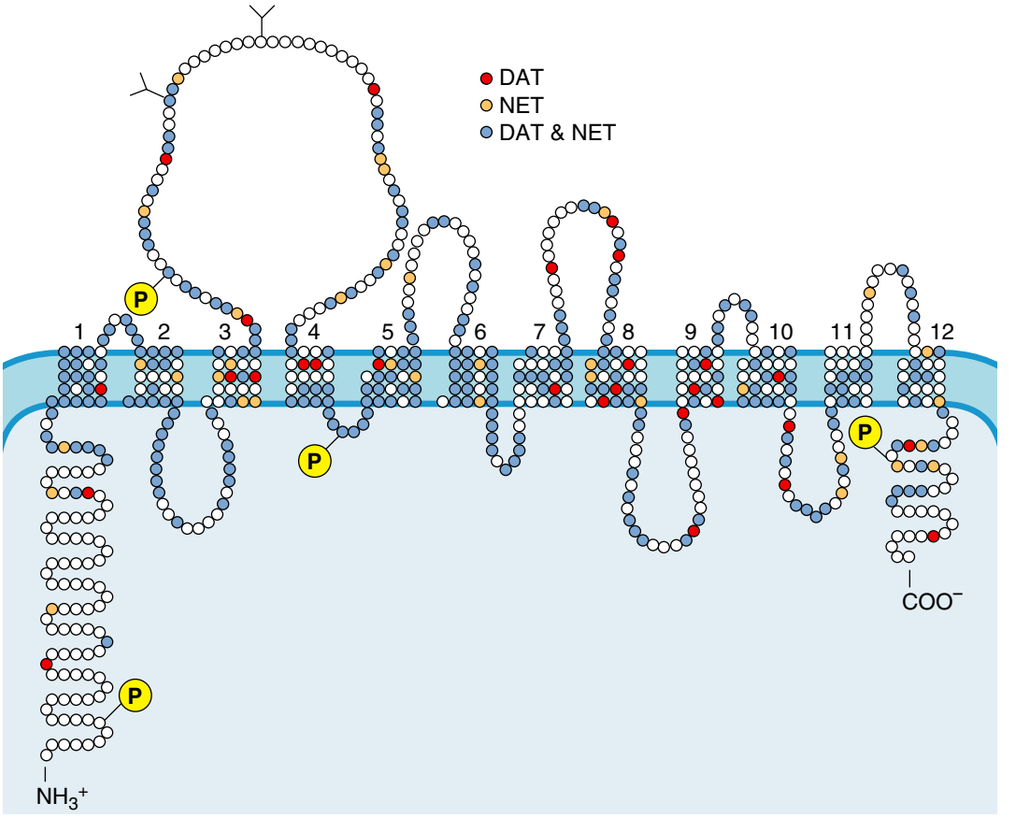

FIGURE 13-7 Putative structure of the rat serotonin transporter (SERT) showing homologous amino acids with the rat dopamine transporter (*DAT*), human norepinephrine transporter (*NET*) or both. Possible phosphorylation (*P*) sites are shown, as are possible glycosylation sites on the large second extracellular loop. Note the considerable degree of homology in the 12 transmembrane-spanning regions. (Courtesy of Dr Beth J. Hoffman, Amgen, Thousand Oaks, CA.)

630 amino acids with a molecular weight of about 68,000 Daltons or 68 kDa. The putative structure of the SERT has 12 transmembrane domains (TMDs), with both the amino- and carboxy-termini being intracellular, and a large extracellular loop containing glycosylation sites connecting TMDs 3 and 4 (Fig. 13-7). Glycosylation seems necessary for optimal stability of the transporter in the membrane but not for 5-HT transport or ligand binding. There are also six potential sites of phosphorylation by protein kinase A (PKA) and protein kinase C (PKC) on the human SERT (see Ch. 23). The predicted structure of the SERT is similar to the predicted structure of other cloned neurotransmitter transporters and quite distinct, for example, from the seven-transmembrane-domain structure of G-protein-linked receptors. These transporters are considered to be members of the Na^+ and Cl^- dependent neurotransporter family, distinct from the vesicular transporter family described earlier. All members of this family are fragmented by multiple introns, raising the possibility of multiple transcripts by alternative RNA processing.

The serotonin transporter exhibits about 50% absolute homology with the transporters for norepinephrine (NET) and dopamine (DAT), with the greatest homology being found in TMDs 1 and 2, and TMDs 4–8. The least conserved regions are the intracellular amino- and carboxy-terminal tails (Fig. 13-7). It has been proposed that the conserved regions may be involved in general transport functions and the least conserved regions in the unique attributes of each carrier, i.e. pharmacological specificity. However, studies in which the terminal regions were exchanged between the SERT and the NET revealed no alteration in substrate or antagonist selectivity, suggesting that the NH_2 and COOH termini may not, in fact, be important for ligand recognition. There is evidence for a lack of strict substrate selectivity among biogenic amine transporters, particularly in situations where the function of one transporter is compromised. For example, studies using *in vivo* chronoamperometry to measure the clearance of 5-HT from the extracellular fluid, indicate that 5-HT can be taken up by the NET [12].

Although there is structural homology among the transporters for 5-HT, norepinephrine and dopamine, some drugs exhibit great selectivity at inhibiting the activity of just one of these proteins. For example, the selective norepinephrine re-uptake inhibitor reboxetine is 150 times more potent at inhibiting norepinephrine transport

than that of 5-HT. By contrast, the selective serotonin reuptake inhibitors (SSRIs), such as fluoxetine, sertraline or paroxetine, are 25–100 times more potent in inhibiting the uptake of 5-HT than the uptake of norepinephrine. There are also drugs, such as cocaine, that are nonselective inhibitors of all three transporters.

It has been known for over 25 years that many of the tricyclic antidepressants (TCAs), e.g. imipramine and amitriptyline, are potent inhibitors of both norepinephrine and 5-HT reuptake. Some tricyclic antidepressants, e.g. desipramine, inhibit the uptake of norepinephrine much more potently than the uptake of 5-HT. Thus, it was unclear for some time whether the inhibition of 5-HT uptake played any role in the antidepressant action of those TCAs that possessed this pharmacological property. Recently, however, effective antidepressants such as fluoxetine, paroxetine and sertraline have been marketed and these SSRIs are much more potent inhibitors of the uptake of 5-HT than that of norepinephrine (Fig. 13-8). Thus, selective inhibition of the uptake of either norepinephrine or 5-HT can result in an antidepressant effect (Ch. 55).

The SSRIs, which were initially developed as antidepressants, are now the most widely used agents in the treatment of many additional neuropsychiatric disorders (e.g. eating disorders, anxiety, obsessive–compulsive disorder) (Fig. 13-8). Clomipramine, a TCA that is somewhat selective *in vivo* as an inhibitor of 5-HT uptake, also produces clinically significant amelioration of the symptoms associated with obsessive–compulsive disorder. Thus, the inhibition of 5-HT uptake, not only has an antidepressant effect, but also reduces the symptoms of anxiety disorders, including obsessive–compulsive disorder. This clinical effect is not found with drugs such as desipramine that selectively inhibit the uptake of norepinephrine (see also Ch. 55).

Acute and chronic regulation of serotonin transporter function provides means for altering synaptic 5-HT concentrations and neurotransmission. Long-term exposure to drugs that block the SERT have been shown to downregulate the SERT. A number of studies have shown that chronic administration of SSRIs produces a reduction in SERT activity and expression. In postmortem samples of dorsal raphe nucleus from cocaine users, SERT binding sites are reduced in number, suggesting a downregulation of the SERT with chronic cocaine exposure. In addition to this long-term regulation of SERT function by drugs that block the SERT, there is a

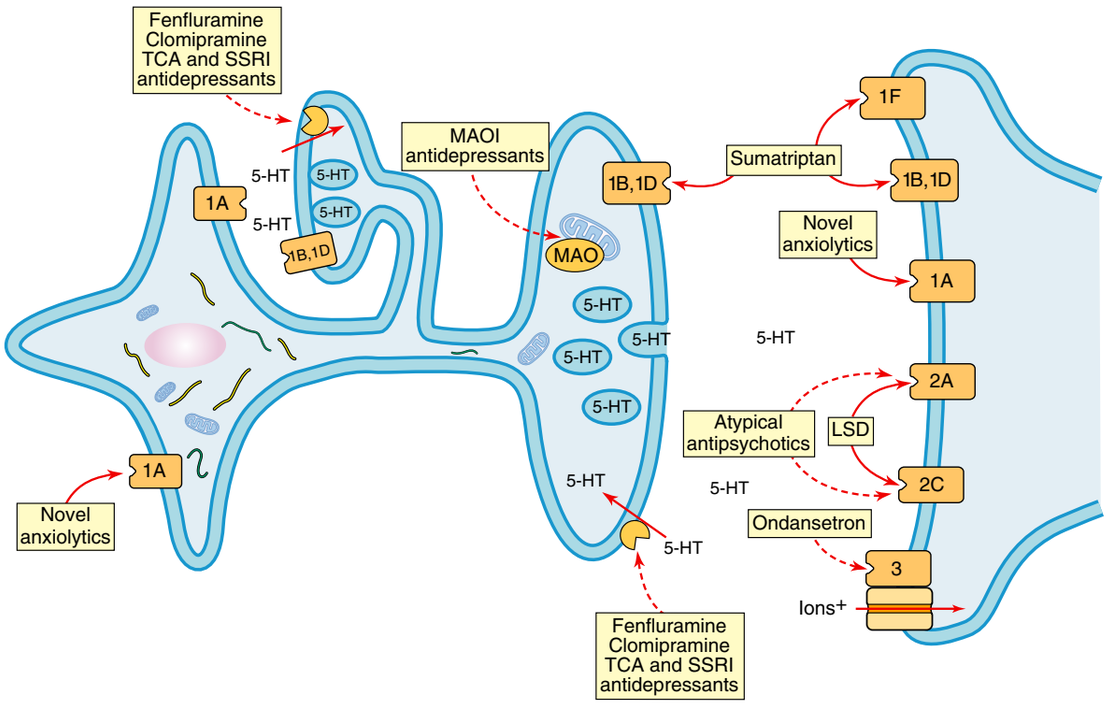

FIGURE 13-8 Serotonin neurons and receptors are targets for a wide variety of therapeutic drugs. Drugs that act as agonists to activate receptors are indicated by *solid-line arrows*, whereas antagonists or inhibitors are shown with *broken-line arrows*. The 5-HT_{1A} receptor acts as both the somatodendritic autoreceptor and a postsynaptic receptor; anxiolytic drugs such as buspirone are agonists at this receptor. In terminal fields, the autoreceptor is either the 5-HT_{1B} or 5-HT_{1D} subtype; these receptors also function as postsynaptic receptors. The antimigraine drug sumatriptan is an agonist at these receptors as well as the 5-ht_{1F} receptor. Hallucinogenic drugs such as LSD are agonists at 5-HT_{2A} and 5-HT_{2C} receptors whereas atypical antipsychotic drugs such as clozapine and olanzapine are antagonists. The 5-HT_3 receptor, a ligand-gated ion channel, is blocked by drugs effective in the treatment of chemotherapy-induced nausea and emesis, such as ondansetron. Another important target for psychotherapeutic drugs is the serotonin transporter, which is blocked by drugs effective in the treatment of depression or obsessive-compulsive disorder (clomipramine). The enzyme responsible for the catabolism of serotonin, MAO, is inhibited by another class of antidepressants.

more dynamic, short-term regulation of SERT function by substrate exposure, membrane potential changes and presynaptic receptor activation/inhibition. Depolarization of the plasma membrane is associated with reduced transport velocity, whereas hyperpolarization results in enhanced transport. The transient inhibition of uptake during neuronal depolarization may allow 5-HT to diffuse away from the presynaptic terminal to interact with postsynaptic receptors. Substrate occupancy and/or transport activity promotes retention of the SERT on the cell surface, thereby maintaining SERT function [12]. Acute presynaptic receptor-mediated regulation of SERT function has been demonstrated in experiments using *in vivo* chronoamperometry; the activation of 5-HT_{1B} terminal autoreceptors increases SERT activity [13].

The regulation of SERT number or function by cyclic changes in estrogen and/or progesterone is a current area of research interest. The number of SERT binding sites is increased in many areas of the brain by estrogen [14]. Because the modulation of SERT function and/or number provides means for altering synaptic 5-HT concentrations and serotonergic neurotransmission, hormonal regulation of the SERT may underlie changes in mood that occur during the reproductive cycle, or increased incidence of major depression in women *versus* men.

The regulation of SERT function can occur at the level of transcription or translation, or by post-translational modifications (e.g. glycosylation or phosphorylation). Research carried out *in vitro* using cells that express the SERT has indicated that second-messenger systems, particularly those activating protein kinases, play a role in the regulation of SERT function. SERT gene expression is influenced by cAMP-dependent pathways and rapidly regulated by changes in intracellular calcium, treatment with calmodulin inhibitors, or activation of protein kinase C (PKC) as well as NOS/cyclic GMP pathways. Most of the changes in enzyme kinetics reflect change in maximal transport capacity (V_{max}) rather than changes in apparent affinity (K_m). Recent work indicates that activation of PKC causes a loss of SERT protein on the cell surface. Thus, occupancy of the SERT by substrate (5-HT) may induce a conformational change of the transporter that either prohibits phosphorylation by PKC (thereby inhibiting PKC-induced internalization of the SERT), or enhances access of phosphatases (thereby reducing phosphorylation and internalization) [12].

The SERT is encoded by a single gene located on the long arm of chromosome 17. The human serotonin transporter gene possesses a functional polymorphism within the promotor region, which affects the transcription and therefore expression of the gene. The long (l/l) variant, compared to the short (s/s) or heterozygous (s/l) forms, is associated with greater SERT expression and function. Alterations in the expression and function of the SERT would be expected to affect 5-HT neurotransmission. The discovery of these polymorphisms has led to much research examining the potentially exciting association of these polymorphisms with different personality traits, a variety of neuropsychiatric disorders, and differing responses to drugs, in particular the SSRIs [15, 16].

The primary catabolic pathway for 5-HT is oxidative deamination by the enzyme monoamine oxidase. Monoamine oxidase (MAO) (E.C.1.4.3.4.) converts serotonin to 5-hydroxy-indoleacetaldehyde, and this product is oxidized by an NAD^+-dependent aldehyde dehydrogenase to form 5-hydroxyindoleacetic acid (5-HIAA) (see Fig. 13-5). There are at least two isoenzymes of MAO, referred to as type A and type B. These isoenzymes are integral flavoproteins of outer mitochondrial membranes in neurons, glia and other cells. Evidence for the existence of isoenzymes of MAO was based initially on differing substrate specificities and sensitivities to inhibitors of MAO. For example, 5-HT and norepinephrine are metabolized preferentially by type A MAO. Selective inhibitors of each form of MAO exist, e.g. clorgyline or moclobemide for type A or deprenyl for type B. Definitive proof of the existence of these two forms of MAO comes from the cloning of cDNAs encoding type A and type B MAO from human liver [17]. The deduced amino acid sequences of type A and type B MAOs show about 70% homology and have masses of 59.7 kDa and 58.8 kDa respectively. The activity of the proteins expressed in recombinant cell systems resembles that of the endogenous enzymes from human brain, e.g. the expressed type A MAO prefers 5-HT as a substrate and is preferentially inhibited by clorgyline (see also Chs 12 and 46).

Several different techniques have been used to study the neuroanatomical localization of the two forms of MAO in brain. Originally, both histochemical and immunohistochemical techniques were used. More recently, *in situ* hybridization histochemistry has been used to demonstrate the location of the mRNAs for the two isoenzymes of MAO. The development of radioligands selective for each form of MAO has enabled their distribution to be revealed by quantitative autoradiography. In general, the results from the use of these different techniques are similar. It is of some interest that there is more type A enzyme than type B enzyme throughout rat brain whereas human brain contains more type B MAO than type A. Interestingly, serotonergic cell bodies contain predominantly type B MAO so that serotonergic neurons contain the form of MAO (type B) that does not preferentially metabolize 5-HT. This has led to the hypothesis that type B MAO in serotonergic neurons prevents the cell from accumulating various natural substrates (e.g. dopamine) that could interfere with the storage, release and uptake of 5-HT. Furthermore, treatment of rats with clorgyline, a selective inhibitor of type A MAO, raises the brain content of 5-HT and reduces the conversion of 5-HT to 5-HIAA in brain. Thus, 5-HT may well be oxidized preferentially by type A MAO *in vivo*, as it is *in vitro*, even though serotonergic neurons do not contain much of this form of the enzyme.

Techniques have been developed that permit the selective elimination, or 'knockout' of genes encoding specific proteins in mice. Mice that have either type A or type B MAO knocked out have been developed with this methodology [18]. In the brains of mice deficient in type A MAO, the content of 5-HT remains markedly elevated for about 12 days after birth and then slowly declines, reaching values comparable to those in normal mice after about 7 months. In the type A MAO-deficient mice, the selective inhibitor of type B MAO, deprenyl, had a greater effect on serotonin metabolism than it did in normal mice. Such observations indicate that, in the absence of type A MAO, the type B isoform can metabolize 5-HT *in vivo*. However, mice lacking the MAO B isoenzyme do not have elevated levels of 5-HT in brain. Of interest are the aggressive behaviors exhibited by the mice deficient in type A MAO, consistent with a postulated role of serotonergic neurons in human aggressive behaviors.

Another class of antidepressant drug is the monoamine oxidase inhibitors (MAOIs), e.g. phenelzine or tranylcypromine. These drugs are nonselective in that they irreversibly inhibit the activity of MAO type A and type B (Fig. 13-8). Because MAO metabolizes biogenic amines such as 5-HT, dopamine and norepinephrine, these neurotransmitters have been implicated in the mechanism of action of these drugs. Interestingly, studies have been carried out from which it was inferred that 5-HT is needed for SSRIs or MAOIs to produce a beneficial clinical response in depressed patients. Such data are consistent with the idea that drug-induced enhancement of serotonergic transmission can produce amelioration of depressive symptomatology (see Ch. 55).

In addition to classical synaptic transmission, 5-HT may relay information by volume transmission or paracrine neurotransmission. As expected, serotonergic terminals make the usual specialized synaptic contacts with target neurons and release 5-HT following nerve stimulation. In some areas of the mammalian CNS, however, there are sites where 5-HT is released and there is no evidence for synaptic specializations. For example, it is difficult to demonstrate the synaptic contacts of fine varicose fibers whereas large terminals make well-defined synapses with target cells. The percentage of 5-HT terminals associated with synaptic specializations appears to vary in particular brain regions. This may have important implications for the type of information processing in which 5-HT is involved in these brain areas. The appearance of specialized synaptic contacts suggests relatively stable and strong associations between a presynaptic neuron and its target. Conversely, the lack of synaptic specialization implies a dynamic and perhaps less specific interaction with target neurons. For example, neurotransmitter is released and then diffuses over some distance (as great as several hundred microns); this is termed *volume transmission*. It is also seen in dopamine targets areas (Ch. 12).

Consistent with the idea that a significant mode of transmission for 5-HT is through volume or extra-synaptic transmission is the observation that the SERT is localized perisynaptically and along axons and dendrites, and not confined to the terminals [19]. Thus 5-HT may diffuse away from the site of release before its action is terminated by re-uptake into serotonergic neurons. 5-HT_{1B} receptors, which function as both auto- and heteroreceptors in serotonergic terminal field areas, are also found predominantly at extrasynaptic and nonsynaptic sites [20]. The fact that serotonergic neurons contain predominantly type B MAO, the form of MAO that does not preferentially metabolize 5-HT, is also consistent with the volume or extrasynaptic transmission of 5-HT. As discussed above, 5-HT is oxidized preferentially by type A MAO, even though serotonergic neurons do not contain this form of the enzyme. Thus 5-HT may have a paracrine or neuromodulatory role in brain, adjusting or tuning ongoing activity at synapses some distance from the serotonergic terminal.

5-HT may be involved in a wide variety of behaviors by setting the tone of brain activity in relationship to the state of behavioral arousal/activity. Serotonin has been implicated in practically every type of behavior, e.g. appetitive, emotional, motoric, cognitive, autonomic. However, from a physiologic perspective, it is not clear whether 5-HT affects such behaviors specifically, or more generally by coordinating the activity of the nervous system, particularly to set the tone of activity in conjunction with the organism's level of arousal.

The primary body of data that has contributed to the view that 5-HT has a general effect on behavior by modulating the tone of nervous system activity comes from studies of the firing rate of serotonergic soma in raphe nuclei [21]. Under quiet waking conditions, serotonergic neurons display a slow, clock-like activity of about 1–5 spikes per second, which shows a gradual decline as the animal becomes drowsy and enters slow-wave sleep. A decrease in the regularity of firing accompanies this overall slowing of neuronal activity. During REM (rapid eye movement) sleep, the activity of these neurons becomes silent. In response to certain types of arousing stimulus, the firing rate of these serotonergic neurons increases. Not surprisingly, such data led to the idea that the activity of serotonergic neurons is related to the level of behavioral arousal/activity. These data have contributed also to the idea that the activity of serotonergic neurons is associated with motoric output, since atonia of the major skeletal muscle groups occurs during REM sleep. Also oral–buccal motor activity, such as chewing, biting, licking or grooming, causes a marked increase in the firing rate of a subgroup of serotonergic somata that are also activated by somatosensory stimuli applied to the head, neck and face. However, exposing a cat to environmental stressors such as a loud noise or seeing a dog, although producing strong sympathetic activation and typical

behavioral responses, does not alter the firing rate of serotonergic neurons. Thus, the type of motoric activity that activates serotonergic cell bodies seems to be repetitive, of the type known to be mediated by central pattern generators. Furthermore, activation of serotonergic transmission inhibits information processing in afferent systems. From all such data, it has been suggested that the serotonergic neuronal system functions at the organismic level to integrate functions needed for the animal's behavioral output, i.e. facilitation of motor output with suppression of activity in sensory systems irrelevant to the ongoing behavior.

Perturbation of the 5-HT system can elicit changes in a wide variety of behaviors. Furthermore, drugs that act on serotonergic neurons and their receptors are used to treat diseases such as depression, anxiety disorders and schizophrenia. Thus, 5-HT has been implicated in the regulation of many behaviors and physiological processes. The involvement of 5-HT in three areas – neuroendocrine function, circadian rhythms and feeding behavior – will be highlighted for illustrative purposes.

5-HT modulates neuroendocrine function. The hypothalamus secretes several releasing factors and release-inhibiting factors to control the secretion of hormones from the anterior pituitary gland (see details in Ch. 52). 5-HT is among the many neurotransmitters that participate in the hypothalamic control of pituitary secretion, particularly in the regulation of the secretion of adrenocorticotropin (ACTH), prolactin and growth hormone. A direct synaptic connection between serotonergic terminals and corticotropin-releasing-hormone (CRH)-containing neurons in the paraventricular nucleus of the hypothalamus has been described. Precursors of 5-HT or drugs that enhance the effect of 5-HT increase CRH in portal blood and ACTH in plasma. In addition to effects at the hypothalamus, 5-HT may also have direct effects on the anterior pituitary to stimulate the release of ACTH, and at the level of the adrenal cortex to regulate release of corticosterone or cortisol. However, what role, if any, is played by 5-HT in regulating stress-induced elevations of CRH or the circadian periodicity of the HPA axis is unclear.

Measurement of these endocrine responses after administration of drugs that increase brain serotonin function provides one of the few methods currently available for assessing such function in humans. Precursors of 5-HT, releasing agents, reuptake inhibitors, and receptor agonists and antagonists have all been used to probe serotonergic function. For example, intravenous administration of the serotonin precursor L-tryptophan increases plasma concentrations of prolactin and growth hormone consistently, but not ACTH or cortisol. Fenfluramine (Fig. 13-6) causes a dose-dependent increase in plasma prolactin. When administered to humans, 5-HT receptor agonists that stimulate 5-HT_{1A} or 5-HT_2 receptors also increase plasma ACTH, cortisol, prolactin and perhaps growth hormone levels. The neuroendocrine response in humans to such agents has been used clinically to assess the functioning of the central serotonergic system in patients with psychiatric disorders.

5-HT modulates circadian rhythmicity. Serotonin also appears to be involved in the regulation of *circadian* rhythms. The suprachiasmatic nucleus (SCN) of the hypothalamus generates electrophysiological and metabolic cycles that repeat approximately every 24 hours. When isolated *in vitro*, the SCN continues to produce 24 hour rhythms in metabolism, vasopressin secretion and spontaneous electrical activity, indicating that circadian time-keeping functions or pacemaker activity are endogenous characteristics of the SCN. Ordinarily, this rhythm is synchronized or entrained to the environmental photoperiod, also about 24 hours. A serotonergic contribution to circadian rhythm regulation has been postulated because the SCN receive a very dense serotonergic innervation from the midbrain raphe nuclei. In addition, there is a serotonergic innervation to the intergeniculate leaflet, an area of brain through which photic information indirectly accesses the SCN.

Serotonin appears to function as an inhibitory transmitter that modulates the effects of light on circadian rhythmicity. Direct application of 5-HT or receptor agonists to the SCN block light-induced phase shifts during the subjective night but cause phase advances during the subjective day. Such agents inhibit the excitatory effect of light, measured electrophysiologically, in either the SCN or the lateral geniculate complex. The nonselective 5-HT agonist quipazine has been shown to reset or shift the rhythm of spontaneous electrical activity of single cells recorded extracellularly in SCN isolated in brain slices.

Lesions of serotonergic neurons in laboratory animals have been reported by some, but not all, investigators to disrupt locomotor rhythms or to result in the loss of the daily rhythm of corticosterone. There is evidence that, in the hamster, the median raphe nucleus projects to the SCN whereas the dorsal raphe nucleus innervates the IGL; furthermore, the serotonergic innervation to the SCN and not the IGL is necessary for the photic entrainment of locomotor activity [22]. It appears then, that the SCN circadian pacemaker or clock is modulated by stimulation of serotonergic receptors in the SCN and that serotonergic projections to the SCN may modulate the phase of the SCN in intact animals.

5-HT modulates feeding behavior and food intake. Pharmacological studies primarily have contributed to the idea that 5-HT has an inhibitory effect on feeding behavior. Drugs that either directly or indirectly activate postsynaptic 5-HT receptors decrease food consumption whereas agents that inhibit serotonergic transmission increase food intake. Precisely how this occurs is controversial, with claims that 5-HT governs the selection of macronutrients in the diet, or influences responses to the taste qualities of food, or modulates gastric activity to

reduce feeding. Perhaps the most comprehensive and enduring view is that enhanced serotonergic activity enhances satiety, particularly by increasing the rate of satiation and prolonging the state of satiety [23].

Fenfluramine, originally the racemate and more recently the D-isomer, has been the prototypical drug for studying serotonergic mechanisms in feeding behavior. As mentioned previously, fenfluramine elicits the release of 5-HT and inhibits its reuptake (Fig. 13-7). D-fenfluramine has an active metabolite, D-norfenfluramine, that contributes to the anorectic (appetite suppressant) effects of the parent compound. Fenfluramine decreases meal size, the rate of eating and eating between meals. This is probably related to its ability in humans to decrease the sensation of hunger and to increase the feeling of 'fullness'. Serotonin reuptake inhibitors such as fluoxetine and serotonin precursors mimic these effects of fenfluramine. Fenfluramine's effects on feeding behavior are blocked by the nonselective serotonin receptor antagonist metergoline. Multiple mechanisms in brain appear to be responsible for the effects of serotonergic drugs on satiety; for example, postsynaptic 5-HT_{1B} receptors are involved in regulating the size of meals but 5-HT_{2C} receptors influence the rate of eating.

The sites in brain where these drugs, and presumably 5-HT as well, act to cause such effects remain to be identified. The paraventricular nucleus (PVN) of the hypothalamus may be an important site, although some data indicate that actions on the PVN may be sufficient but not necessary to reduce caloric intake. In addition to brain mechanisms, 5-HT may also act through peripheral mechanisms to produce satiety.

The pharmacological effects produced by drugs such as fenfluramine on feeding behavior in animals has led to its use in the treatment of obesity in humans. In many double-blind placebo-controlled trials, chronic administration of fenfluramine causes greater weight loss than placebo. Although not studied as extensively clinically, fluoxetine produces similar effects. Given all the medical problems associated with obesity, anorectic agents are valuable tools to be used in association with other modalities (diet, exercise) in the treatment of the truly obese individual.

Not only does 5-HT have important physiological effects of its own but it is also the precursor of the hormone melatonin. The pineal gland occupies the depression between the superior colliculi at the posterior border of the corpus callosum and lies 'outside' the blood–brain barrier. Extracts of the pineal gland were reported as early as 1917 to lighten frog skin *in vitro*; in the late 1950s, Lerner and associates isolated the pineal hormone that produced this effect and described its chemical structure, 5-methoxy-*N*-acetyltryptamine (melatonin) (Fig. 13-5). Melatonin is synthesized from serotonin, and the pineal gland contains all the enzymes necessary to synthesize serotonin from tryptophan as well as two additional enzymes required to convert serotonin to melatonin (Fig. 13-5). The rate-limiting enzyme serotonin *N*-acetyl transferase (EC 2.31.87) (arlylalkylamine *N*-acetyltransferase; AANAT) converts serotonin to *N*-acetylserotonin and this product is methylated to form melatonin by the enzyme 5-hydroxyindole-*O*-methyltransferase (HIOMT), which uses *S*-adenosyl methionine as the methyl donor. The human AANAT gene has been cloned and found to have considerable sequence identity to the sheep and rat genes. The human gene is localized on chromosome 17. The gene product is a 23.2 kDa protein that contains putative phosphorylation sites. Such sites are likely to be involved in the cAMP-dependent regulation of enzyme activity.

A unique feature of pineal gland physiology is that the synthesis and secretion of melatonin is markedly influenced by the light–dark cycle, acting through a multisynaptic pathway that relays in the superior cervical ganglia of the sympathetic nervous system. During daylight, the synthesis and secretion of melatonin are reduced, as is impulse flow along the sympathetic nerves innervating the pineal gland. At the onset of darkness, there is activation of these nerves, and the increased release of norepinephrine from them activates β-adrenergic receptors on the pineal to increase the formation of cAMP, with activation of α_1-adrenergic receptors further amplifying the response. This second messenger causes activation of AANAT so as to increase the synthesis of melatonin.

Thus, the pineal gland functions as a neuroendocrine transducer. In mammals, photosensory information impinging on the retina influences the activity of its neuronal projections, which serves ultimately to inhibit or to stimulate the secretion of melatonin. A circadian rhythm of melatonin secretion persists in animals housed in continuous darkness. Thus, melatonin synthesis is turned on by an endogenous 'clock', probably located within the SCN of the hypothalamus, with the daily rhythm normally being entrained to the day–night, light–dark cycle [24]. Melatonin, which provides circadian and seasonal timing cues through activation of G-protein-coupled receptors [25], has been implicated in not only the regulation of biological rhythms but also in sleep and affective disorders.

SEROTONIN RECEPTORS

Pharmacological and physiological studies have contributed to the definition of the many receptor subtypes for serotonin. The initial suggestion that there might be more than one type of receptor for serotonin came from experiments of Gaddum and Picarelli in 1957. Using the isolated guinea pig ileum, they demonstrated that only a portion of the contractile response to 5-HT was blocked by high concentrations of morphine. The remainder of the response to 5-HT was blocked by low concentrations of Dibenzyline (phenoxybenzamine). In the presence of

maximally effective concentrations of Dibenzyline, the remaining contractile response elicited by 5-HT was blocked by low concentrations of morphine. They speculated that there were two different receptors for 5-HT in the ileum, one blocked by morphine (termed the M receptor) and one blocked by Dibenzyline (termed the D receptor). The D receptor was thought to be on the smooth muscle of the ileum whereas the M receptor was considered to be on ganglia or nerves within the muscle.

In the 1970s, the development of radioligand binding assays furthered our understanding of subtypes of receptor for 5-HT. Initially, a number of radioligands, such as ^{3}H-5-HT, ^{3}H-LSD and ^{3}H-spiroperidol, were used to label sites related to 5-HT receptors. In 1972, Farrow and Van Vunakis observed high-affinity, stereospecific binding of ^{3}H-LSD in cortex that was inhibited more potently by serotonin than by other neurotransmitters. Peroutka and Snyder in 1979 demonstrated the presence of two classes of serotonin receptors in brain. Binding sites that were labeled with high affinity by ^{3}H-5-HT were designated the 5-HT$_1$ receptor; binding sites labeled with high affinity by ^{3}H-spiroperidol were termed the 5-HT$_2$ receptor [26].

The binding of ^{3}H-5-HT to 5-HT$_1$ receptors was shown to be displaced by spiperone in a biphasic manner, suggesting that what was termed the 5-HT$_1$ receptor might be a heterogeneous population of receptors. The ^{3}H-5-HT binding site that showed high affinity for spiperone was termed the 5-HT$_{1A}$ subtype, whereas the component of ^{3}H-5-HT binding that showed low affinity for spiperone was called the 5-HT$_{1B}$ subtype. The different neuroanatomical localization of these two 5-HT binding sites, as demonstrated by quantitative autoradiography, was further evidence that these were distinct subtypes of receptor for 5-HT. For example, the 5-HT$_{1A}$ subtype was shown to be present in high density in the hippocampus; the 5-HT$_{1B}$ subtype was shown to be present in high density in the globus pallidus and substantia nigra. A high density of binding sites for ^{3}H-5-HT was also found in the choroid plexus. These ^{3}H-5-HT binding sites were termed the 5-HT$_{1C}$ subtype as they did not show the pharmacological characteristics used to classify the 5-HT$_{1A}$ or 5-HT$_{1B}$ binding site, or the 5-HT$_2$ binding site. Subsequently, a fourth binding site for ^{3}H-5-HT was identified in bovine brain and was called the 5-HT$_{1D}$ receptor. The 5-HT$_{1D}$ receptor was identified by pharmacological criteria only in brains of species devoid of the 5-HT$_{1B}$ receptor such as pig, cow, guinea pig and human.

Bradley and associates in 1986 proposed a classification scheme with three major types of receptors for serotonin, using pharmacological criteria and functional responses primarily in peripheral tissues. The receptors were called '5-HT$_1$-like', 5-HT$_2$ and 5-HT$_3$. The development of potent and selective antagonists of the 5-HT$_2$ receptor, such as ketanserin, facilitated the assignment of certain effects mediated by 5-HT to the 5-HT$_2$ receptor. The D receptor of Gaddum and Picarrelli, originally described in guinea pig ileum, and the 5-HT$_2$ receptor were shown to be pharmacologically indistinguishable. The M receptor of Gaddum and Picarelli, which is pharmacologically distinct from all of the binding sites associated with 5-HT receptors just described, was renamed the 5-HT$_3$ receptor. The development of potent selective antagonists and an agonist, 2-methyl-5-HT, provided useful tools for the pharmacological characterization of 5-HT$_3$ receptors.

Molecular biology techniques led to the discovery of additional 5-HT receptor subtypes and furthered our understanding of their structure and function. The first 5-HT receptor to be cloned and fully sequenced was the 5-HT$_{1A}$ receptor, by Kobilka and co-workers in 1987. Over the course of the next 5 years, the 5-HT$_{1B}$, 5-HT$_{1C}$, 5-HT$_{1D}$, 5-HT$_2$ and 5-HT$_3$ receptors were also cloned. Techniques used in molecular biology also led to the rapid discovery of additional subtypes of receptor for 5-HT, making it necessary to establish an unambiguous system of nomenclature for serotonin receptors. The current classification scheme takes into account not only operational criteria (drug-related characteristics such as selective agonists, selective antagonists, ligand-binding affinities) but also information about intracellular signal transduction mechanisms and molecular structure (amino acid sequence of the receptor protein) [27]. For example, the 5-HT$_{1C}$ receptor was reclassified as a 5-HT$_2$ receptor based on the sequence homology, similar pharmacological characteristics and effector coupling of the 5-HT$_2$ and 5-HT$_{1C}$ receptors. The 5-HT$_2$ receptor was renamed the 5-HT$_{2A}$ receptor and the 5-HT$_{1C}$ was renamed the 5-HT$_{2C}$ receptor. The amino acid sequence of many new 5-HT receptors has been reported. However, the classification of several of these receptors remains tentative because of limited knowledge of their operational and transductional characteristics, which have only been described for these recombinant receptors in transfected cell systems. Because the functions mediated by these 5-HT receptors in intact tissue are unknown, lower case appellations are presently used [27] (Table 13-2).

Three families of serotonin receptor, the 5-HT$_1$ family, the 5-HT$_2$ family and the family that includes the 5-HT$_4$, 5-ht$_6$ and 5-HT$_7$ receptors represent the three major classes of 5-HT receptor that are G-protein-coupled receptors (Ch. 19). The 5-HT$_3$ receptor is a ligand-gated ion channel and is a separate family. Although each serotonin receptor can be potently activated by 5-HT, differences in signal transduction mechanisms, neuroanatomical distribution and affinities for synthetic chemicals create opportunities for drug discovery and make each 5-HT receptor subtype a potential therapeutic target.

The 5-HT$_1$ receptor family comprises the 5-HT$_{1A}$, 5-HT$_{1B}$, 5-HT$_{1D}$, 5-ht$_{1E}$ and 5-ht$_{1F}$ receptors. The five receptor subtypes in the 5-HT$_1$ receptor family share 40–63% overall sequence homology. These 5-HT receptors couple preferentially to the inhibition of adenylyl cyclase via the G$_{i/o}$ family of G proteins (see Ch. 21).

TABLE 13-2 Serotonin receptors present in the central nervous system.

Receptor	Distribution	Effector mechanism
5-HT$_1$ receptor family		
5-HT$_{1A}$	Hippocampus, amygdala, septum entorhinal cortex, hypothalamus, raphe nuclei	Inhibition of adenylyl cyclase; opening of K^+ channels
5-HT$_{1B}$	Substantia nigra, basal ganglia	Inhibition of adenylyl cyclase
(5-HT$_{1D\beta}$)	Frontal cortex, superior colliculus, lateral geniculate, deep nuclei of the cerebellum	
5-HT$_{1D}$	Globus pallidus, substantia nigra, caudate putamen	Inhibition of adenylyl cyclase
(5-HT$_{1D\alpha}$)	Hippocampus and cortex	
5-ht$_{1E}$	?	Inhibition of adenylyl cyclase
5-ht$_{1F}$	Cerebral cortex, striatum, hippocampus,	Inhibition of adenylyl cyclase
5-HT$_2$ receptor family		
5-HT$_{2A}$ 13q14–21	Claustrum, cerebral cortex, olfactory tubercle, striatum, nucleus accumbens	Stimulation of phospholipase C; closing of K^+ channels
5-HT$_{2B}$ 2q36.3–37.1	?	Stimulation of phospholipase C
5-HT$_{2C}$ Xq24	Choroid plexus, globus pallidus, cerebral cortex, hypothalamus septum, substantia nigra, spinal cord	Stimulation of phospholipase C
5-HT$_3$ receptor family		
5-HT$_3$ (5-HT$_{3A}$) (5-HT$_{3B}$)	Hippocampus, entorhinal cortex, amygdala, nucleus, accumbens, solitary tract nerve, trigeminal nerve, motor nucleus of the dorsal vagal nerve, area postrema, spinal cord	Ligand-gated cation channel
5-HT$_4$	Hippocampus, striatum, olfactory tubercle, substantia nigra	Stimulation of adenylyl cyclase
5-ht$_{5A}$	?	Inhibition of adenylyl cyclase
5-ht$_{5B}$	?	?
5-ht$_6$	?	Stimulation of adenylyl cyclase
5-HT$_7$	Cerebral cortex, septum, thalamus hypothalamus, amygdala, hippocampus	Stimulation of adenylyl cyclase

The 5-HT$_{1C}$ receptor appellation is vacant because, as described above, this receptor was renamed the 5-HT$_{2C}$ receptor due to structural, operational and transductional similarities with the 5-HT$_2$ receptor family. A lower case appellation is used for the 5-ht$_{1E}$ and 5-ht$_{1F}$ receptors because a physiological role for these receptors in intact tissue has not been found [28].

The 5-HT$_{1A}$ receptor is present in high density in cortical and limbic structures (i.e. hippocampus, entorhinal cortex, septum, amygdala, frontal cortex). The distribution of the 5-HT$_{1A}$ receptor in brain suggests that this 5-HT receptor subtype may have a role in cognitive or integrative functions as well as in emotional states. The 5-HT$_{1A}$ receptors in terminal field areas of serotonergic innervation are located postsynaptically. 5-HT$_{1A}$ receptors are also present in high density on serotonergic cell body areas, particularly in the dorsal and median raphe nuclei. Here they function as somatodendritic autoreceptors, involved in the negative feedback modulation of serotonergic neuronal activity. Therefore somatodendritic 5-HT$_{1A}$ autoreceptors play a key role in regulating serotonergic neurotransmission. In terminal field areas of serotonergic innervation such as the hippocampus, 5-HT$_{1A}$ receptors are coupled to the inhibition of adenylyl cyclase activity, as well as to the opening of potassium channels, which results in neuronal hyperpolarization (Table 13-2). However, in the dorsal raphe nucleus, 5-HT$_{1A}$ receptors are coupled to the opening of potassium channels but do not appear to be coupled to the inhibition of adenylyl cyclase.

Activation of 5-HT$_{1A}$ receptors in the central nervous system results in a variety of physiological and behavioral responses. 5-HT$_{1A}$ receptors modulate feeding, sexual behavior and body temperature. Activation of 5-HT$_{1A}$ receptors stimulates the release of adrenocorticotrophic hormone (ACTH). The 5-HT$_{1A}$ receptor has been implicated in affective disorders such as anxiety and depression. Newer antianxiety medications, specifically the substituted azapirones (e.g. buspirone), are agonists with high affinity for the 5-HT$_{1A}$ receptor (Fig. 13-8). The sensitivity and function of the 5-HT$_{1A}$ receptor is decreased following chronic administration of a variety of antidepressant drugs as well as 5-HT$_{1A}$ receptor agonists. Because of the critical role of the somatodendritic 5-HT$_{1A}$ autoreceptor in regulating serotonergic neuronal firing, and therefore serotonergic neurotransmission, the desensitization of this receptor by drugs used to treat anxiety and depression is of great interest, particularly in regard to the role of serotonin in these mental disorders (Ch. 55). Drugs with agonist activity at the 5-HT$_{1A}$ receptor are also of interest in the treatment of schizophrenia, and behavioral disorders such as impulsivity and aggression (Chs 54, 55).

The 5-HT$_{1B}$ and 5-HT$_{1D}$ receptor subtypes are also linked to inhibition of adenylyl cyclase activity (Table 13-2). Binding sites, pharmacologically defined as 5-HT$_{1B}$ receptors, were originally characterized in certain rodents (rat, mouse, hamster), whereas the 5-HT$_{1D}$ receptor was characterized using pharmacological criteria in species such as guinea pig, dog, pig, cow and human. The 5-HT$_{1B}$ and 5-HT$_{1D}$ receptors were considered to be species variants of the same receptor because the pharmacological profiles of these two receptors are similar, although not identical, and the distribution of these two receptors in brain is very similar.

Although biochemical, pharmacological and functional data suggest that the 5-HT$_{1B}$ receptor found in rats and mice, and the 5-HT$_{1D}$ receptor found in other species, including human, are functionally equivalent species homologues of the same receptor, the story has been somewhat complicated by the discovery of two genes encoding the human 5-HT$_{1D}$ receptor, 5-HT$_{1D\alpha}$ and 5-HT$_{1D\beta}$. The human 5-HT$_{1D\beta}$ receptor was shown to have a high degree of homology with the rodent 5-HT$_{1B}$ receptor. Subsequently, a gene homologous to the human 5-HT$_{1D\alpha}$ was discovered in the rat. This gene encoded a receptor with the pharmacological profile of the 5-HT$_{1D}$. Thus, both rat and human express a 5-HT$_{1B}$ and 5-HT$_{1D}$ receptor. As a result, the nomenclature for the 5-HT$_{1B/1D}$ receptors was reassessed [29]. This new nomenclature scheme recognizes that the human 5-HT$_{1D\beta}$ receptor is a species equivalent of the rodent 5-HT$_{1B}$ receptor, as discussed above, despite differing pharmacology, and realigned the 5-HT$_{1D\beta}$ to the 5-HT$_{1B}$ receptor classification. Prefixes are often used to denote species-specific 5-HT$_{1B}$ receptors because of the significant differences in the pharmacology of the 5-HT$_{1B}$ receptor across species, e.g. r5-HT$_{1B}$ and h5-HT$_{1B}$ denote the rat and human receptors respectively. The 5-HT$_{1D\alpha}$ receptor expressed in both rat and human is reclassified as the 5-HT$_{1D}$ receptor (Table 13-2).

Much of what is known about the function and neuroanatomical distribution of the 5-HT$_{1B}$ receptor is attributed to the receptor designated under the older classification scheme as the 5-HT$_{1B}$ receptor in rodents and the 5-HT$_{1D}$ receptor in bovine, guinea pig and human brain. The 5-HT$_{1B}$ (5-HT$_{1D_JA\beta}$, r5-HT$_{1B}$, h5-HT$_{1B}$) receptor is located in high density in the basal ganglia, particularly in the globus pallidus and the substantia nigra (Table 13-2). The neuroanatomical localization of 5-HT$_{1B}$ receptor raises the interesting possibility that this receptor may be involved in diseases of the brain that involve the basal ganglia, such as Parkinson's disease (see Ch. 46). Functional studies indicate that 5-HT$_{1B}$ receptors are located on presynaptic terminals of serotonergic neurons and modulate the release of serotonin. 5-HT$_{1B}$ receptors are also located postsynaptically where they may modulate the release of other neurotransmitters, such as acetylcholine in the hippocampus and dopamine in the prefrontal cortex. Postsynaptic 5-HT$_{1B}$ receptors are also located on cerebral arteries and other vascular tissues. Agonists at the 5-HT$_{1A}$ and 5-HT$_{1B}$ receptors have been termed 'serenics' because of their selective ability to inhibit aggressive behavior without sedation in rats and mice. Drugs that are agonists at 5-HT$_{1B/1D}$ receptors (e.g. sumatriptan, zolmitriptan) (Fig. 13-8) are currently used clinically in the treatment of migraine. These drugs constrict cranial blood vessels and inhibit the neurogenic inflammation in the dura mater that gives rise to plasma extravasation. Activation of 5-HT$_{1B/1D}$ receptors in the nucleus tractus solitarius may alleviate symptoms of nausea and vomiting in patients having a migraine attack [30].

It has been difficult to determine the distribution of the 5-HT$_{1D}$ (5-HT$_{1D\alpha}$,) receptor in brain because of the lack of selective radioligands. Receptor binding sites attributed to the 5-HT$_{1D}$ receptor are present in basal ganglia (globus pallidus, substantia nigra, caudate putamen) and hippocampus and cortex [31]. With the cloning of the various subtypes of receptors for 5-HT, knowledge of receptor sequences can be used to generate radioactive probes for mRNAs encoding individual serotonin receptor subtypes. Using the technique of *in situ* hybridization histochemistry, the localization of these mRNAs and, thus, the distribution of cells expressing the mRNAs for 5-HT receptors can be established in brain. 5-HT$_{1D}$ receptor mRNA is expressed at low levels in the basal ganglia, dorsal raphe nucleus and locus ceruleus, indicative of the 5-HT$_{1D}$ receptor being located predominantly on axon terminals of both serotonergic and nonserotonergic neurons. The release of 5-HT from dorsal raphe nucleus appears to be under the control of 5-HT$_{1D}$ receptors, presumably located on serotonergic terminals. It has been proposed that neurogenic inflammation and trigeminal nociception may be 5-HT$_{1D}$-receptor-mediated. Therefore, there is much interest in the 5-HT$_{1D}$ receptor as a useful therapeutic target for migraine.

The 5-ht$_{1E}$ receptor was originally identified in homogenates of human frontal cortex by radioligand binding studies using ^{3}H-5-HT in the presence of 5-CT to block 5-HT$_{1A}$ and 5-HT$_{1D}$ receptor sites. Because of the lack of specific radioligands for the 5-ht$_{1E}$ receptor, the overall distribution of this receptor in brain is unknown. 5-ht$_{1E}$ receptor mRNA has been found in the cortex (particularly entorhinal cortex) and caudate putamen. The function of the 5-ht$_{1E}$ receptor in intact tissue is not known due to the lack of selective agonists or antagonists. In transfected cells, the 5-ht$_{1E}$ receptor is coupled to the inhibition of adenylyl cyclase activity [32]. The 5-ht$_{1E}$ receptor displays a higher degree of homology with the 5-HT$_{1D}$ receptor (64%) than any other 5-HT$_{1}$ receptors. Although 5-ht$_{1E}$ receptor mRNA and binding sites have been mapped in the rodent and human brain, confirmation of a true physiological role for 5-ht$_{1E}$ receptors is still lacking; hence, they retain their lower case appellation.

The 5-ht$_{1F}$ receptor was cloned and sequenced in 1993 and shares the greatest sequence homology with the 5-ht$_{1E}$

receptor (61%). 5-ht$_{1F}$ receptor mRNA is found in cortex, hippocampus, dentate gyrus, nucleus of the solitary tract, spinal cord, uterus and mesentery. In transfected cells, the 5-ht$_{1F}$ receptor is coupled to the inhibition of adenylyl cyclase. Because selective agonists or antagonists for the 5-ht$_{1F}$ receptor have not been available until very recently, little is known about the distribution or function of the 5-ht$_{1F}$ receptor in brain. Binding sites attributed to the 5-ht$_{1F}$ receptor have been found in cortex, striatum and hippocampus. Activation of 5-ht$_{1F}$ receptors *in vivo* does not mediate constriction of human vasculature (unlike 5-HT$_{1B/1D}$ receptors), but may be associated with the blockade of dura extravasation. Because 5-ht$_{1F}$ receptor mRNA has been detected in the trigeminal ganglia, 5-ht$_{1F}$ receptor agonists are also of great interest as potential therapeutic drugs in the treatment of migraine.

The 5-HT$_2$ receptor family comprises the 5-HT$_{2A}$, 5-HT$_{2B}$ and 5HT$_{2C}$ receptors. The three receptor subtypes in the 5-HT$_2$ receptor family share 46–50% overall sequence homology. Members of the 5-HT$_2$ receptor family are coupled via the G$_{q/11}$ family of G proteins to the phospholipase C signaling cascade, which involves the hydrolysis of membrane phosphatidylinositol 4,5-bisphosphate (PIP$_2$) and increases in intracellular calcium ion (see Ch. 20). The 5-HT$_{2A}$ receptor nomenclature refers to the classical D receptor of Gaddum and Picarelli, and 5-HT$_2$ receptor of Peroutka and Snyder [26]. The 5-HT$_{2C}$ receptor was formerly the 5-HT$_{1C}$ receptor. It is important to note that because selective drugs able to differentiate between members of the 5-HT$_2$ receptor family have not been available until very recently, many of the functional and clinical correlates of the 5-HT$_{2A}$ receptor may very well involve or be attributed to the 5-HT$_{2C}$ or 5-HT$_{2B}$ receptor.

5-HT$_{2A}$ receptors are found postsynaptically to serotonergic neurons and are particularly concentrated in the frontal cortex. 5-HT$_{2A}$ receptors are also found in high density in the claustrum, a region that is connected to the visual cortex, in parts of the limbic system (i.e. amygdala and hippocampus) and in the basal ganglia (Table 13-2). In the cortex, the 5-HT$_{2A}$ receptor is located on local GABAergic interneurons, as well as on pyramidal projection neurons, which are known to be glutamatergic. The high level of 5-HT$_{2A}$ receptor expression throughout the cortex suggests that this 5-HT receptor subtype may play a role in higher cognitive or integrative functions. Activation of 5-HT$_{2A}$ receptors in the central nervous system results in an increase in body temperature (hyperthermia) and increased secretion of ACTH. In the periphery, 5-HT$_{2A}$ receptors mediate the contractile responses of vascular smooth muscle, and a component of the contractile response of smooth muscle in the gut, to 5-HT. The 5-HT$_{2A}$ receptor has been implicated in the hallucinogenic effects of 5-HT$_2$ receptor agonists. There is also considerable interest in the role of the 5-HT$_{2A}$ receptor in antipsychotic drug action. The so-called 'atypical' antipsychotic medications (e.g. clozapine, olanzepine) (Fig. 13-8) are antagonists with high affinity for the 5-HT$_{2A}$ and D$_2$ receptors (see Ch. 54).

The cloning of the 5-HT$_{2A}$ receptor has been used to gain insight into a controversy over the nature of agonist binding to the 5-HT$_{2A}$ receptor. The hallucinogenic amphetamine derivative ^{3}H-DOB, an agonist, has been shown to bind to receptor sites with properties very similar to those of the receptor labeled with the antagonist ^{3}H-ketanserin. Some investigators interpreted these and other data as evidence for the existence of a new subtype of 5-HT$_{2A}$ receptor, whereas others interpreted these data as indicative of agonist high-affinity and agonist low-affinity states of the 5-HT$_{2A}$ receptor. In experiments in which the cDNA encoding the 5-HT$_{2A}$ receptor was transfected into clonal cells, binding sites for both the 5-HT$_{2A}$ receptor antagonist ^{3}H-ketanserin and the 5-HT$_2$ receptor agonist ^{3}H-DOB were found. Furthermore, agonists had higher affinities for ^{3}H-DOB binding than for ^{3}H-ketanserin binding. Thus, a single gene produces a protein with both binding sites substantiating the view that agonist and antagonist binding are to different states of the 5-HT$_{2A}$ receptor rather than two different subtypes of the 5-HT$_{2A}$ receptor.

5-HT$_{2B}$ receptor. Although the 5-HT$_{2B}$ receptor is the most recently cloned of the 5-HT$_2$ receptor class, it was among the first of the 5-HT receptors to be characterized using pharmacological criteria. The first report of the sensitivity of rat stomach fundus to 5-HT was published by Vane in 1959. This receptor, whose activation results in the contraction of fundus smooth muscle, was originally placed in the 5-HT$_1$ receptor class because of its sensitivity to serotonin and because responses mediated by this receptor were not blocked by 5-HT$_2$ or 5-HT$_3$ receptor antagonists. It has been reclassified as a 5-HT$_2$ receptor because of its similar pharmacological profile to the 5-HT$_{2C}$ receptor (Table 13-2). The recombinant receptor expressed in clonal cells is coupled to hydrolysis of membrane PIP$_2$. However, in rat stomach fundus, the 5-HT$_{2B}$ receptor appears not to be coupled to PIP$_2$ hydrolysis. 5-HT$_{2B}$-receptor-mediated contraction of rat stomach fundus is dependent upon the influx of calcium ion through voltage-sensitive channels, intracellular calcium release and activation of PKC [33]. The effector system to which this receptor is coupled in the CNS is a subject of research.

5-HT$_{2B}$ receptor mRNA has been detected in the stomach fundus, intestine, kidney, heart and lung, as well as in the brain (cerebellum, cerebral cortex, amygdala, substantia nigra, caudate, thalamus, hypothalamus and retina). The lack of truly selective 5-HT$_{2B}$ receptor agonists and antagonists until recently has limited our knowledge about the functional role of the 5-HT$_{2B}$ receptor in brain and in the periphery. The 5-HT$_{2B}$ receptor is also expressed in a number of blood vessels. Contraction of the renal

artery is mediated in part by the 5-HT_{2B} receptor [34]. Given the vasodilatory role of the 5-HT_{2B} receptor, recently developed 5-HT_{2B} receptor antagonists may be indicated for the treatment of migraine. In addition, the 5-HT_{2B} receptor, which is expressed in heart valves, appears to be responsible for the cardiac valve defects reported in obese patients treated with dex-fenfluramine-containing preparations such as 'fen-phen' [28].

The 5-HT_{2C} receptor is present in high density in the choroid plexus. High-resolution autoradiography has shown that they are enriched on the epithelial cells of the choroid plexus. It has been proposed that 5-HT-induced activation of 5-HT_{2C} receptors could regulate the composition and volume of the cerebrospinal fluid. 5-HT_{2C} receptors are also found throughout the brain, in particular in areas of the limbic system (hypothalamus, hippocampus, septum, neocortex) and those associated with motor behavior (substantia nigra, globus pallidus). 5-HT_{2C} receptors are present in these areas in much lower concentrations than in the choroid plexus (Table 13-2). The lack of truly selective 5-HT_{2C} receptor agonists and antagonists has limited our knowledge about the functional role of the 5-HT_{2C} receptor in brain.

RNA editing is the term applied to the process of altering gene transcripts co- or post-transcriptionally (see Ch. 26). 5-HT_{2C} receptor mRNA undergoes post-transcriptional editing to yield multiple 5-HT_{2C} receptor isoforms with different distributions in brain [35, 36]. Messenger RNA editing alters the binding affinity of the resulting recombinant 5-HT_{2C} receptor isoforms for agonists and therefore alters the functional potency of the agonists. This is potentially of great significance as the isoforms expressed endogenously may have different functional and regulatory properties, and thus provide a novel mechanism for the regulation 5-HT synaptic signaling and plasticity.

5-HT_2 receptors are thought to mediate hallucinogenic properties of some 5-HT agonists, such as LSD (Fig. 13-8) (see Ch. 56). Evidence for this comes from experiments in which animals are trained to discriminate 5-HT_2 receptor agonists and are therefore able to recognize or discriminate other 5-HT_2 receptor agonists but not, for example, 5-HT_1 receptor agonists. Thus, activation of 5-HT_2 receptors is said to lead to a discriminative stimulus. The production of drug discriminative stimulus properties of 5-HT_2 receptor agonists, such as the hallucinogenic amphetamine derivatives, can be blocked by 5-HT_2 receptor antagonists. There is also a close correlation between the human hallucinogenic potency of 5-HT_2 receptor agonists and their affinity for 5-HT_2 (i.e. both 5-HT_{2A} and 5-HT_{2C}) receptor binding sites.

Unlike the other subtypes of receptor for 5-HT, the 5-HT_3 receptor is a ligand-gated ion channel.

The 5-HT_3 receptor refers to the classical M receptor of Gaddum and Picarelli. Based on its overall electrophysiological features and sequence, it is a member of the ligand-gated ion channel superfamily of receptors. This receptor is a cation channel that is gated by 5-HT. Like other members of this receptor superfamily, it possesses additional pharmacologically distinct recognition sites whereby the function of the receptor can be modulated by alcohols and anesthetic agents [37].

5-HT_3 receptors are located postsynaptically to serotonergic neurons in the central and peripheral nervous systems. 5-HT_3 receptors initially appeared to be confined to peripheral neurons, where they mediate depolarizing actions of 5-HT and modulate neurotransmitter release. Serotonin throughout the gastrointestinal tract regulates both motility and intestinal secretion through activation of 5-HT_3 receptors. 5-HT_3 receptors are found in high density in peripheral ganglia and nerves (superior cervical ganglion and vagus nerve) as well as in the substantia gelatinosa of the spinal cord. Their localization in spinal cord and medulla suggest that 5-HT could modulate nociceptive mechanisms via the 5-HT_3 receptor. 5-HT_3 receptors facilitate the release of substance P (see Ch. 18) in the spinal cord. The localization of 5-HT_3 receptor binding sites in cortical and limbic areas of the brain is consistent with behavioral studies in animals that suggest that 5-HT_3 receptor antagonists (Fig. 13-8) may have potential anxiolytic, antidepressant and cognitive effects. In the cortex and hippocampus the majority of neurons expressing 5-HT_3 receptor mRNA are GABAergic. The observation that 5-HT_3 receptors modulate the activity of dopaminergic neurons in the ventral tegmental area has led to the hypothesis that 5-HT_3 receptor antagonists may have potential as antipsychotic drugs and may posses the ability to reduce the rewarding effects of alcohol and certain drugs of abuse (Fig. 13-8). The highest density of 5-HT_3 receptor sites in the brain is in the area postrema, the site of the chemoreceptor trigger zone (Table 13-2).

Antagonists at 5-HT_3 receptors, such as ondansetron or granisetron (Fig. 13-8), are an important class of drugs for the treatment of nausea and vomiting in cancer patients receiving chemotherapy. Chemotherapeutic drugs such as cisplatin and dacarbazine induce the release of 5-HT from enterochromaffin cells of the gastrointestinal tract. The released 5-HT activates 5-HT_3 receptors located on the enteric nerves innervating the smooth muscle of the gut, causing depolarization of visceral afferent nerves and increases in their rate of firing. The enhanced afferent input leads to stimulation of the chemoreceptor trigger zone, which produces nausea and vomiting. Antagonism of 5-HT_3 receptors prevents or attenuates this chain of events. The site of action of these drugs appears to be 5-HT_3 receptors in the gastrointestinal tract, even though the central area regulating emesis, i.e. the chemoreceptor trigger zone, possesses a high density of 5-HT_3 receptors. Unfortunately, there is a more prolonged, often milder, form of emesis caused by chemotherapeutic drugs that is not dependent on the release of 5-HT and is resistant to amelioration with 5-HT_3 receptor antagonists.

The 5-HT_3 receptor is a pentamer made up of five subunits. Julius and co-workers cloned a single subunit of the 5-HT_3 receptor (5-HT_{3A} receptor subunit) in 1991. The cloned receptor subunit exhibits sequence similarity to the alpha subunit of the nicotinic acetylcholine receptor. Later, a second subunit, 5-HT_{3B}, was cloned [38]. Although single subunits of members of the ligand-gated ion channel receptor family can form functional homomeric receptors (receptors composed of subunits of a single type), they generally lack some of the properties of the native receptor. This appears to be the case for the 5-HT_3 receptor. In electrophysiological studies using *Xenopus* oocytes injected with mRNA encoding 5-HT_{3A} and/or 5-HT_{3B} receptor subunits, the heteromeric combination of 5-HT_{3A} and 5-HT_{3B} subunits is necessary to provide the functional characteristics of the native 5-HT_3 receptor. Homomeric receptors composed of either subunit do not display the characteristics of native 5-HT_3 receptors. The exact subunit composition of the native 5-HT_3 receptor is not known. It is entirely possible that the subunit composition of native 5-HT_3 receptors may vary with their location in the body, raising the exciting possibility of differences in the pharmacology and regulation of native 5-HT_3 receptors depending on the tissue or brain region in which they are expressed.

The 5-HT_4, 5-ht_6 and 5-HT_7 receptors are coupled to the stimulation of adenylyl cyclase. 5-HT_4, 5-ht_6 and 5-HT_7 receptors preferentially couple to the stimulation of adenylyl cyclase, increasing cAMP formation, via the Gs family of G proteins (see Chs 19 and 21). These receptors, however, share only >35% overall sequence homology. For this reason, they are classified as distinct receptor groups or classes and not subtypes of a family. The grouping of these receptors together is considered to be somewhat arbitrary and may be modified in the future. A lower-case appellation is used for the 5-ht_6 receptor because a physiological role for these receptors in intact tissue has not been found [28].

The 5-HT_4 receptor was originally described in cultured mouse collicular neurons, and subsequently in mouse and guinea pig brain, by Bockaert and co-workers in the late 1980s. This 5-HT receptor coupled to the stimulation of adenylyl cyclase activity and possessed pharmacological characteristics distinct from that of the 5-HT_1, 5-HT_2 or 5-HT_3 receptors. It had been known for a number of years prior to the pharmacological definition of the 5-HT_4 receptor that 5-HT could stimulate adenylyl cyclase in brain. Studies of the 5-HT_4 receptor were hampered by the absence of a high-affinity radioligand. The synthesis and development of specific radioligands provided the necessary tools for the study and characterization of the 5-HT_4 receptor. 5-HT_4 receptor binding sites are localized with high density in the striatum, substantia nigra and olfactory tubercle, and have been reported in the hippocampus as well (Table 13-2). The 5-HT_4 receptor is located postsynaptically to serotonergic neurons and this receptor modulates the release of several neurotransmitters (including acetylcholine, dopamine and GABA) and, indirectly, 5-HT release as well. 5-HT_4 receptor activation enhances cognitive performance in rats and monkeys. In humans, a role for the 5-HT_4 receptor in memory enhancement remains to be demonstrated in clinical studies [39].

In the periphery, 5-HT_4 receptor mRNA is found in vascular smooth muscle. Newly developed drugs that activate 5-HT_4 receptors are of interest for their potential in treating cardiac arrhythmia. The 5-HT_4 receptor is also located on neurons of the alimentary tract, for example the myenteric plexus of the ileum, and on smooth muscle cells and secretory cells of the gastrointestinal tract, where they evoke secretions and the peristaltic reflex. 5-HT_4 receptor agonists (e.g. cisapride, prucalopride, tegaserod) are used therapeutically in the treatment of constipation-predominant irritable bowel syndrome and in functional motility disorders of the upper gastrointestinal tract.

Multiple isoforms of the 5-HT_4 receptor have been shown to exist, the result of alternative splicing of 5-HT_4 receptor mRNA. Studies indicate specificity in the pattern of expression of these splice variants in different tissues. For example, the human 5-HT_{4a}, 5-HT_{4b} and 5-HT_{4c} receptor isoforms are expressed in the brain, atrium and gut, whereas expression of the 5-HT_{4d} receptor isoform appears to be restricted to the gut. The physiological significance of the differential distribution of many splice variants of the 5-HT_4 receptor in the body remains to be understood. The existence of different isoforms of the 5-HT_4 receptor raises interesting possibilities as to the distinct pharmacological characteristics and regulation of these different receptor isoforms.

The 5-ht_6 receptor, when expressed in transfected cells, shows a pharmacological profile that is unique. Interestingly, this receptor has high affinity for various antipsychotic and antidepressant drugs such as clozapine, amitriptyline, clomipramine, mianserin and ritanserin. The 5-ht_6 receptor stimulates adenylyl cyclase when expressed in recombinant cell systems. The function of the 5-ht_6 receptor in intact tissue has not been characterized because of the lack of selective agonists or antagonists. Expression of 5-ht_6 receptor mRNA has been detected in the striatum, nucleus accumbens, olfactory tubercle, hippocampus and cerebral cortex The recent development of the selective antagonist radioligand [^{125}I] SB 258585 has allowed the visualization of the distribution of 5-ht_6 receptor sites in brain using quantitative autoradiography [40].

The 5-HT_7 receptor is the most recently identified member of the family of G-protein-coupled 5-HT receptors. Although there is no selective agonist or antagonist currently available for the 5-HT_7 receptor, the distinct pharmacological profile of 5-HT_7 receptor sites has been used to delineate the function and distribution of this

receptor *in vivo*. 5-HT_7 receptor binding sites in the rat brain have been described using non-selective radioligands in the presence of drugs to mask 5-HT_{1A} and 5-HT_{1B} receptors. Recently, the distribution of 5-HT_7 receptors has been confirmed in autoradiographic studies using nonselective ligands, and in the brains of mice lacking 5-$HT_{1A/1B}$ receptors. Analysis of the binding of nonselective radioligands in the brains of 5-HT_{1A} and 5-$HT_{1A/1B}$ knockout mice revealed the presence of low densities of 5-HT_7 receptors in the cortex, septum, thalamus, hypothalamus, amygdala and hippocampus [41] (Table 13-2).

A role for the 5-HT_7 receptor in the regulation of circadian rhythms has been implicated. As discussed above, 5-HT has been known for some time to induce phase shifts in behavioral circadian rhythms and modulate neuronal activity in the suprachiasmatic nucleus, the likely site of the mammalian circadian clock. The pharmacological characteristics of the effect of 5-HT on circadian rhythms are consistent with 5-HT_7 receptor. Moreover, mRNA for the 5-HT_7 receptor is found in the suprachiasmatic nucleus. There is also increasing evidence that the 5-HT_7 receptor may play a role in psychiatric disorders. The regional distribution of 5-HT_7 receptors in brain includes limbic areas and cortex. Atypical antipsychotics, such as clozapine and risperidone, and some antidepressants display high affinity for this receptor. In the periphery, 5-HT_7 receptors have been shown to mediate relaxation of vascular smooth muscle.

Alternative mRNA splicing has been reported to generate four 5-HT_7 receptor isoforms. However, these isoforms have not been shown to differ in their respective pharmacology, signal transduction or tissue distribution.

'Orphan' receptors include the 5-ht$_5$ receptor and the 5-HT_{1P} receptor.

5-ht$_5$ receptor. Two subtypes of the 5-ht$_5$ receptor have been cloned (5-ht$_{5A}$ and 5-ht$_{5B}$ receptors). These receptor proteins are 77% identical to each other whereas the homology with other serotonin receptors is low. 5-ht$_{5A}$ receptor mRNA transcripts have been detected by *in situ* hybridization in the cerebral cortex, hippocampus, granule cells of the cerebellum, medial habenula, amygdala, septum, several thalamic nuclei and olfactory bulb of the rat and mouse. 5-ht$_{5B}$ mRNA has been detected by *in situ* hybridization in the hippocampus, habenula and dorsal raphe nucleus of rat and human [27]. Immunohistochemical studies using antibodies to the 5-ht$_{5A}$ receptor have shown this receptor to be expressed predominantly by astrocytes, although some neurons in cortex were labeled as well. When expressed in recombinant cell systems, the 5-ht$_{5A}$ receptor is coupled to the inhibition of adenylyl cyclase. At the present time, the functional correlate and transductional properties of the 5-ht$_{5B}$ receptor are unknown. Because no evidence has been obtained to confirm that the recombinant 5-ht$_5$ receptor is expressed and functions in an endogenous tissue, this receptor retains its lower case appellation [28].

The existence of an atypical 5-HT receptor on the enteric neurons of the gut has been shown in a series of investigations by Gershon and associates. This receptor has high affinity for ^{3}H-5-HT and mediates a slow depolarization of particular myenteric neurons that is not blocked by selective 5-HT_3 antagonists. This receptor has been termed the 5-HT_{1P} receptor as it has a high affinity for 5-HT and is found in the periphery, in high density in the gut. The pharmacology of this receptor is somewhat similar to that of the 5-HT_4 receptor. The available functional and radioligand binding data confirm the orphan status of the 5-HT_{1P} receptor and emphasize the need to establish a rigorous basis for its positive identification [27, 28].

Rob Leurs

HISTAMINE: THE MESSENGER AND THE MOLECULE 249
Histamine is a mediator of several physiological and pathological processes within and outside the nervous system 249
The chemical structure of histamine has similarities to the structure of other biogenic amines, but important differences also exist 250

HISTAMINERGIC CELLS OF THE CENTRAL NERVOUS SYSTEM: ANATOMY AND MORPHOLOGY 250
The brain stores and releases histamine from more than one type of cell 250
Histaminergic fibers originate from the tuberomammillary region of the posterior hypothalamus 251
Histaminergic neurons have morphological and membrane properties that are similar to those of neurons storing other biogenic amines 251
Histaminergic fibers project widely to most regions of the central nervous system 252
Histaminergic neurons are present in many species 252

DYNAMICS OF HISTAMINE IN THE BRAIN 253
Specific enzymes control histamine synthesis and breakdown 253
Several forms of histidine decarboxylase may derive from a single gene 254
Histamine synthesis in the brain is controlled by the availability of L-histidine and the activity of histidine decarboxylase 254
Histamine is stored within and released from neurons but a neuronal transporter for histamine has not been found 254
In the vertebrate brain, histamine metabolism occurs predominately by methylation 254
Neuronal histamine can be methylated outside of histaminergic nerve terminals 254
The activity of histaminergic neurons is regulated by H_3 autoreceptors and by other transmitter receptors 255

MOLECULAR SITES OF HISTAMINE ACTION 256
Histamine acts on four G-protein-coupled receptors, three of which are clearly important in the brain 256
H_1 receptors are intronless GPCRs linked to G_q and calcium mobilization 256
H_2 receptors are intronless GPCRs linked to G_s proteins and cyclic AMP synthesis 256
H_3 receptors are a family of GPCRs produced by gene splicing and are linked to $G_{i/o}$ 257
H_4 receptors are very similar to H_3 receptors in gene structure and signal transductions but show limited expression in the brain 260
Histamine can modify ionotropic transmission at identified and unidentified sites 260

HISTAMINE ACTIONS ON THE NERVOUS SYSTEM 261
Histamine in the brain may act as both a neuromodulator and a classical transmitter 261
Histaminergic neurons can regulate and be regulated by other transmitter systems 261
Histamine in the nervous system may participate in a variety of brain functions 261
Histamine may contribute to nervous system diseases or disorders 262

SIGNIFICANCE OF BRAIN HISTAMINE FOR DRUG ACTION 262
Many clinically available drugs that modify sleep–wake cycles and appetite act through the histaminergic system 262
Drugs that modify pain perception act in part through the histaminergic system 262
Drugs that act on the H_3 receptor are being developed for treating obesity, sleep disturbances, epilepsy and cognitive disorders 262

HISTAMINE: THE MESSENGER AND THE MOLECULE

Histamine is a mediator of several physiological and pathological processes within and outside the nervous system. Although the existence of histamine in the brain was known over 50 years ago, a role for this substance in brain function was not widely appreciated until relatively recently. It is now clear that histamine is formed within and released from central nervous system neurons and is an important regulator of several brain functions [1–3]. Paradoxically, the existence of well-established roles for histamine outside the nervous system is one factor that hampered the acceptance of this amine as a neuronal messenger. As a physiological mediator, histamine is best known as an endogenous stimulant of gastric secretion. Histamine is also released from mast cells and basophils by antigens, certain peptides and small basic drugs. In addition, histamine participates in inflammation and in the regulation of immune responses. Cardiac stores of

Basic Neurochemistry: Molecular, Cellular and Medical Aspects

FIGURE 14-1 Chemical structure of histamine, illustrating the two tautomeric forms. The names of the nitrogen atoms are shown on the left tautomer and the numbering scheme for carbon atoms is on the right. For example, *N*$^{\pi}$-methylhistamine, *N*α-methylhistamine and α-methylhistamine are distinct substances and have very different properties (Fig. 14-3 and Table 14-1). This nomenclature system avoids references to the ring nitrogens as 1- and 3-, a designation that becomes confused by the tautomerism.

histamine probably play no physiological role but may be of pathological significance. Endogenous peripheral histamine may also participate in the modulation of sympathetic and/or afferent nerve activity; the storage of this histamine is probably non-neuronal.

The chemical structure of histamine has similarities to the structures of other biogenic amines, but important differences also exist. Chemically, histamine is 2-(4-imidazolyl)ethylamine (Fig. 14-1). The ethylamine 'backbone' is a common feature of many of the amine transmitters (e.g. dopamine, norepinephrine and serotonin). However, the imidazole nucleus, absent from other known transmitters, endows histamine with several distinct chemical properties. Among these is prototypic tautomerism, a property that permits it to exist in two different chemical forms (Fig. 14-1). The tautomeric properties of histamine are thought to be critical in the ability of this molecule to activate some of its receptors. Although histamine has more than one basic center, both tautomers exist predominantly as monocations at physiological pH. This tautomerism has also contributed to confusion in naming histamine congeners (Fig. 14-1).

HISTAMINERGIC CELLS OF THE CENTRAL NERVOUS SYSTEM: ANATOMY AND MORPHOLOGY

The brain stores and releases histamine from more than one type of cell. Mast cells are a family of bone marrow-derived secretory cells that store and release high concentrations of histamine. They are found throughout many connective tissues of the body, but are also present within and surrounding the brain of many species [4, 5]. In many

TABLE 14-1 Interactions between histamine and other transmitters

	Histaminergic modulation of transmitter			*Transmitter's modulation of histamine*		
Transmitter	**Transmitter parameter**	**Receptor**	**Effect**	**Histamine parameter**	**Receptor**	**Effect**

(but not all) species, they are prevalent in thalamus and hypothalamus, as well as in the dura mater, leptomeninges and choroid plexus [4]. The quantitative contribution made by mast cells to brain histamine levels can be substantial in some cases (e.g. rat thalamus). Earlier biochemical studies suggested that histamine in brain mast cells could be distinguished from neuronal histamine by characteristics such as histamine turnover rates, subcellular fractionation and ontogenic pattern [5]. However, activated mast cells may not show a slow histamine turnover rate. Brain and dural mast cells have been characterized histologically and histochemically in detail. Characterization of neuronal and non-neuronal histamine has been facilitated by the study of mast-cell deficient mice and rats.

The functions for brain and dural mast cells are not certain but several interesting hypotheses are being investigated. The close proximity of many of these cells to blood vessels, along with the potent vascular actions of their contents, has led to the suggestion that they regulate blood flow, permeability and/or immunological access to the brain. Dural mast cells are localized in close proximity with sensory nerve fibers and may modulate the release of inflammatory mediators from these cells (Table 14-1). Perhaps most intriguing are recent findings showing that chemosensory cues associated with estrus induction can trigger mast cell infiltration into distinct brain areas [6]. Brain and/or dural mast cells may also participate in neurodegenerative diseases such as multiple sclerosis, Alzheimer's disease or Wernicke's encephalopathy [7, 8]. In addition to mast cells and neurons, other brain cells (e.g. cerebrovascular endothelial cells [5, 9]) may also synthesize and/or store histamine.

Histaminergic fibers originate from the tuberomammillary region of the posterior hypothalamus. The inability to visualize histaminergic neurons greatly limited the understanding and acceptance of this neuronal system. This situation changed in 1984, when antibodies raised against histamine [10] or its biosynthetic enzyme [11] provided the first detailed anatomical studies of these cells and their distribution. In all vertebrates studied, including humans, histaminergic neurons are found in the tuberomammillary (TM)nucleus of the posterior basal hypothalamus (Fig. 14-2A).

Histaminergic neurons have morphological and membrane properties that are similar to those of neurons storing other biogenic amines. Histaminergic perikarya can be of medium size but most are large, bipolar or multipolar cells with diameters of up to 30 µm. Ultrastructural characteristics resemble those of noradrenergic and serotonergic cell bodies [1]. Some of the most ventrally located cells may make direct contact with cerebrospinal fluid.

Electrophysiological properties of histaminergic neurons show spontaneous activity of about 2 Hz. A combination of sodium, calcium and potassium conductances account for their pacemaker properties [1]. Noradrenergic and serotonergic neurons show similar properties. TM histaminergic neuron firing is high during waking or attention, and much lower or absent during slow wave sleep, findings that strongly support a role for histamine in wakefulness.

(Modified with permission from reference [2].)

Histaminergic fibers project widely to most regions of the central nervous system. Both ascending and descending efferent pathways account for the histaminergic innervation of the mammalian brain and spinal cord (Fig. 14-2B). The ascending tracts are predominantly ipsilateral. All cell groups appear to contribute to all pathways. Although nearly all CNS areas contain some histaminergic fibers, the density of innervation is heterogeneous [1, 12, 13] and somewhat phylogenetically distinct. The highest densities are found in several hypothalamic nuclei, the medial septum, the nucleus of the diagonal band and the ventral tegmental area. Moderate densities are found in cerebral cortex, amygdala, striatum and substantia nigra. Innervation of the hippocampus and thalamus is substantial is some species. Most areas of the brainstem, as well as retina, cerebellum and spinal cord, contain only small numbers of fibers. These densities follow closely the tissue concentrations of histamine and its biosynthetic enzyme found throughout the brain [14]. In the monkey brain, a homogeneous innervation of several areas of the visual system (including lateral geniculate and superior colliculus) has been documented. Ultrastructural studies in rat show that histaminergic varicosities form only a few synaptic contacts, implying that most neuronal histamine is released by nonsynaptic mechanisms; this seems to be the case for the other amine transmitter systems as well. However, histaminergic synapses have been characterized in some detail, such as in the innervation of the mesencephalic trigeminal nucleus. Histaminergic varicosities also appear to make contact with glia and blood vessels.

A number of substances are colocalized with histamine and its biosynthetic enzyme in hypothalamic tuberomammillary neurons [15]. These include glutamate decarboxylase, GABA, GABA-transaminase, adenosine deaminase, monoamine oxidase-B and the neuropeptide Met-Enk-Arg^6-Phe^7. A subset of cells in rat brain also contain galanin. Thyrotropin-releasing hormone (TRH) is present in some histaminergic neurons of some species. These findings suggest that some of these peptides, as well as GABA and/or adenosine, may function as co-transmitters in this system. Galanin may be a presynaptic inhibitor of neuronal histamine release, similar to its proposed actions on cholinergic and serotonergic fibers. Endogenous GABA appears to regulate neuronal histamine release, but the cellular origin of this GABA is not known (Table 14-1). A recent study found that GABA storage within TM neurons is separate from that of histamine [16].

TM histaminergic cells receive innervation from several brain areas, including the infralimbic prefrontal cortex, several areas within the septum/diagonal band complex and the medial preoptic area of the hypothalamus. These or other afferents seem to contain neuropeptide Y (NPY) or substance P. TM cells receive monoaminergic input from adrenergic (C1–C3), noradrenergic (A1–A2) and serotonergic (B5–B9) cells, but the innervation from dopamine-containing ventral tegmental area is sparse [1]. Since some of these areas seem to have both input and output connections with histaminergic areas, the possibility of reciprocal control has been considered [5]. Orexinergic inputs to the TM cells have also been recently described [1].

Histaminergic neurons are present in many species. Histaminergic neurons have been found in the hypothalamus or diencephalon of a variety of vertebrate brains, including those of fish, snake, turtle and bird. The brain histaminergic system of zebrafish has been studied in

detail, since this species apparently lacks any non-neuronal stores of histamine, such as those found in gastric mucosa or mast cells in mammals [1]. In invertebrates, histamine functions as an important transmitter, for example in arthropod and insect photoreceptors [17, 18]. It is well established that the C2 neuron of *Aplysia* uses histamine as a transmitter [19].

DYNAMICS OF HISTAMINE IN THE BRAIN

Specific enzymes control histamine synthesis and breakdown. Figure 14-3 summarizes the major mechanisms for the synthesis and metabolism of histamine. Biosynthesis is performed in one step by the enzyme L-histidine decarboxylase (HDC, E.C. 4.1.1.22). Histamine metabolism occurs mainly by two pathways. Oxidation is carried out by diamine oxidase (DAO, E.C. 1.4.3.6), leading to imidazole acetic acid (IAA), whereas methylation is effected by histamine *N*-methyltransferase (HMT, E.C. 2.1.1.8), producing *tele*-methylhistamine (t-MH). IAA can exist as a riboside or ribotide conjugate. t-MH is further metabolized by monoamine oxidase (MAO)-B, producing *tele*-methylimidazole acetic acid (t-MIAA). Note that histamine is a substrate for DAO but not for MAO. Aldehyde intermediates, formed by the oxidation of both histamine and t-MH, are thought to be quickly oxidized to acids under normal circumstances. In the vertebrate CNS, histamine is almost exclusively methylated

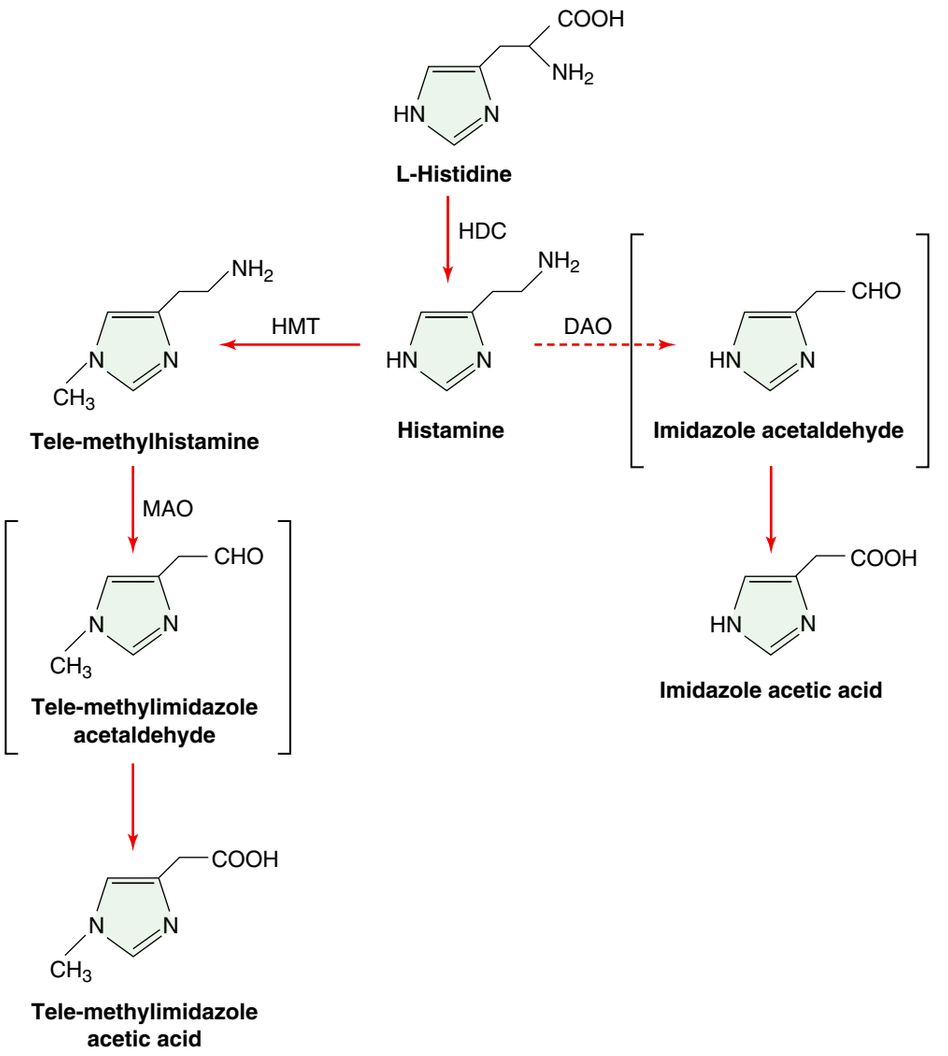

FIGURE 14-3 Synthesis and metabolism of histamine. *Solid lines* indicate the pathways for histamine formation and catabolism in brain. *Dashed lines* show additional pathways that can occur outside the nervous system. *HDC*, histidine decarboxylase; *HMT*, histamine methyltransferase; *DAO*, diamine oxidase; *MAO*, monoamine oxidase. Aldehyde intermediates, shown in brackets, have been hypothesized but not isolated.

and only small amounts of DAO are detectable. However, IAA, a GABA agonist, has been detected and can be formed in the rat brain in small amounts. Although IAA in the brain is probably normally formed by the transamination of histidine, it can also be formed by histamine oxidation under some circumstances. In some invertebrate nervous systems, such as Aplysia, histamine is metabolized to γ-glutamylhistamine.

Several forms of histidine decarboxylase may derive from a single gene. A single cDNA, cloned from rat [20], mouse and human cells, encodes a 74 kDa protein with functional HDC activity. Two species of HDC mRNA have been found in some cells, but the larger one, which contains an additional insert sequence, does not encode a functional enzyme and is not found in brain. Consistent with the immunohistochemical studies discussed above, HDC mRNA is localized to the caudal hypothalamus in rats. The human HDC gene is large, composed of 12 exons with a size of about 2.4 kb. The enzyme, which requires pyridoxal-5′-phosphate as a coenzyme, shares some homology with DOPA decarboxylase (see Ch. 12), another enzyme that requires this cofactor. Protein purification studies have shown HDC to be a dimer composed of two identical 55 kDa subunits. Post-translational modification of the enzyme occurs by an elastase-like enzyme, which converts the 74 kDa form to the smaller protein. Biochemical, biophysical and immunological studies show clear evidence for the existence of HDC isoenzymes [21]. Either post-translational modification of the protein or, possibly, allelic variants may contribute to the existence of these isoforms. The rat HDC gene has two potential *N*-glycosylation sites and two recognition sequences for phosphorylation by cAMP-dependent protein kinase (PKA). These potential modulatory sites could contribute to some of the heterogeneity in HDC.

Histamine synthesis in the brain is controlled by the availability of L-histidine and the activity of histidine decarboxylase. Although histamine is present in plasma, it does not penetrate the blood–brain barrier, such that histamine concentrations in the brain must be maintained by synthesis. With a K_m value of 0.1 mmol/l for L-histidine under physiological conditions, HDC is not saturated by histidine concentrations in the brain, an observation that explains the effectiveness of large systemic doses of this amino acid in raising the concentrations of histamine in the brain. The essential amino acid L-histidine is transported into the brain by a saturable, energy-dependent mechanism [5]. Subcellular fractionation studies show HDC to be localized in cytoplasmic fractions of isolated nerve terminals, i.e. synaptosomes.

HDC activity can be regulated by both hormonal and neuronal factors, most of which are poorly understood. Phosphorylation of the enzyme by PKA may be an important regulatory mechanism. Several regulatory sites have recently been found in the promoter region of the gene.

Unlike catecholamines and indoleamines, histamine itself is not a direct inhibitor of its biosynthetic enzyme, but it exerts feedback control through the H_3 autoreceptor. Perhaps the most powerful tool in the study of the histamine system is *S*-α-fluoromethylhistidine, a highly selective and potent 'suicide' inhibitor of HDC [22]. This compound has been used successfully to study many of the functions of histamine in brain.

Histamine is stored within and released from neurons but a neuronal transporter for histamine has not been found. Newly synthesized neuronal histamine is transported into TM neuronal vesicles by the vesicular monoamine transporter VMAT2 [16]. Both *in vivo* and *in vitro* studies show that depolarization of nerve terminals activates the exocytotic release of histamine by a voltage- and calcium-dependent mechanism. Once released, histamine activates both postsynaptic and presynaptic receptors. Unlike the nerve terminals from other amine transmitters, however, histaminergic nerve terminals do not exhibit a high-affinity uptake system for histamine [5, 9, 23]. Astrocytes may contain a histamine transport system.

In the vertebrate brain, histamine metabolism occurs predominantly by methylation. HMT, the histamine-methylating enzyme, uses the methyl donor *S*-adenosyl-L-methionine. The enzyme has a K_m of about 10 μmol/l for both histamine and the methyl cofactor, and has been localized to the soluble subcellular fraction. Antibodies raised against a highly purified kidney enzyme with a molecular weight of 33,000 co-precipitate the brain enzyme, showing strong similarities between the proteins. A 1.3 kb cDNA has been cloned and expressed in *Escherichia coli*; the encoded protein shows the characteristics of the natural enzyme [24]. Early studies suggested that isoforms of HMT might exist and, recently, it was shown that the HMT gene can be spliced to produce a shorter form (HMT-S, [25]). Although HMT-S mRNA is present in human brain and placenta, the protein does not methylate histamine and its biological significance remains unclear. HMT is subject to inhibition by both its product, t-MH, and, at higher concentrations, its substrate, histamine. Experimental inhibitors of HMT include metoprine and SKF91488. These agents have been used in metabolic studies as well as to probe functions for CNS histamine. As expected, they increase histamine concentrations in the brain and reduce the concentrations of t-MH and t-MIAA. Many other compounds can also inhibit HMT. For example, tacrine, a cholinesterase inhibitor used to treat Alzheimer's disease, also inhibits HMT at therapeutic doses.

Neuronal histamine can be methylated outside of histaminergic nerve terminals. In contrast to the striking regional distribution of histamine and HDC, HMT shows a more even distribution [14], suggesting a widespread HMT localization. In support of this, lesions that destroy

histaminergic fibers cause large reductions in HDC concentrations but with a lesser effect on brain HMT activity. The existence of glial cell lines containing HMT seemed to support an extraneuronal localization for histamine metabolism. However, immunochemical studies of brain HMT found a neuronal and vascular but not glial localization [26]. Because HMT does not follow the characteristic regional distribution of histamine and HDC, yet the HMT product t-MH does show this distribution, it is thought that the formation of t-MH is limited by the rate of histamine release from neurons. The rate at which histamine is formed and methylated (i.e. the histamine turnover rate) also follows this characteristic regional pattern and thus reflects the activity of histaminergic neurons. The hypothesis that histamine is methylated following its neuronal release is supported by recent work showing that extracellular histamine is methylated by isolated nerve terminal fractions to a much greater extent than it is transported [23]. The same study showed the existence of a membrane-bound form of HMT that could methylate newly released histamine in a manner analogous with that of acetylcholinesterase in the cholinergic system [23]. However, attempts to clone a unique membrane-bound form of this enzyme have not succeeded [25].

The product of histamine methylation, t-MH, is a substrate for MAO-B and is ultimately oxidized to t-MIAA, the end product of brain histamine metabolism. Thus, MAO inhibitors increase brain t-MH concentrations and lower t-MIAA concentrations, with little or no effect on histamine concentrations. Both t-MH and t-MIAA have been detected in brain and CSF. In the brain, t-MIAA concentrations are unaffected by probenecid, an inhibitor of the brain transport of other transmitter metabolites.

The activity of histaminergic neurons is regulated by H_3 autoreceptors and by other transmitter receptors. The observation that histamine can inhibit both its own synthesis and release from brain slices and synaptosomes led to the discovery of the histamine H_3 autoreceptor, a hypothesis that was confirmed by the development of unique agonists and antagonists of this receptor [27, 28] (Table 14-2). The prototype H_3 antagonist thioperamide enhances the firing rate of histaminergic neurons and increases neuronal histamine release, brain histamine turnover rates and t-MH concentrations in the brain. H_3 agonists, such as *R*-α-methylhistamine and immepip, produce the opposite effects. H_3 agonists and antagonists are important tools for understanding the brain histamine system, and several new agents are currently being developed for clinical uses. Receptors for several other transmitters have also been shown to regulate histaminergic dynamics (Table 14-1 and see section below).

The stimulatory effects of H_3 antagonists on brain histamine dynamics were initially attributed to the

TABLE 14-2 Characteristics of histamine receptors in the brain

Characteristics	H_1	H_2	H_3	H_4

Distribution†‡	Cerebellum, thalamus, hippocampus	Cerebral cortex, striatum, nucleus accumbens	Striatum, nucleus accumbens, cerebral cortex, substantia nigra	Hippocampus

The characteristics of the four major classes of histamine receptors are summarized. Question marks indicate suggestions from the literature that have not been confirmed. AA, arachidonic acid; DAG, diacylglycerol; $I_{kCa}{}^{2+}$, calcium-activated potassium current; IP_3, inositol 1,4,5-trisphosphate; NHE, sodium–proton exchange, PKC, protein kinase C; NO, nitric oxide; PI-PLC, phosphoinositide-specific phospholipase C; TXA_2, thromboxane A_2.

*Has brain-penetrating characteristics after systemic administration.
†All receptors may exist in non-neuronal brain tissue as well.
‡Distribution in guinea pig (H1 and H2) and rodent (H3, H4) brain. For the H1 receptor, distribution is very different across species.
§Contradictory findings have been reported.
¶Compounds show activities at both H3 and H4 receptors
‖see [1] for details, including abbreviations for conductance changes.

competitive antagonism of continuously-released neuronal histamine, which stimulates the H_3 autoreceptors. However, since there are known to be H_3 antagonists that do not increase brain histamine release, it is now thought that the inverse agonist activity of certain H_3 ligands accounts for their activation of the histaminergic system [29]. This explanation, consistent with *in vitro* studies on recombinant H_3 receptors (see below), would mean that ongoing, *in vivo* H_3 autoreceptor activity is constitutive and therefore does not depend on ongoing histamine-induced H_3 activation. This conclusion does not mean that spontaneous, neuronal histamine release is not occurring, only that it may not be continuously reaching and stimulating its autoreceptors.

MOLECULAR SITES OF HISTAMINE ACTION

Histamine acts on four G-protein-coupled receptors, three of which are clearly important in the brain. Table 14-2 summarizes the characteristics of known histamine receptors in mammals. These histamine receptors subtypes are all linked to G proteins, and all of them have been found inside and outside the brain. Within the brain, the H_1, H_2 and H_3 receptors all have unique regional distributions but none is localized exclusively to neurons. For the recently discovered H_4 receptor, only limited information on its brain localization is currently available. Selective agonists and antagonists are also available for each of the histamine receptors [30]. The judicious use of these compounds for receptor classification and discovery has been reviewed extensively [19, 31, 32].

H_1 receptors are intronless GPCRs linked to Gq and calcium mobilization. The H_1 receptor protein was successfully cloned from a cDNA library of bovine adrenal medulla [33]. This protein is encoded by a single exon and contains 486 (rat), 488 (guinea pig, mouse), 491 (bovine) or 487 (human) amino acids. The homology between the several receptor proteins is quite high in some intracellular domains (≈90%), but is significantly lower in other intracellular and extracellular regions. Features common to many of the G-protein-coupled receptors are present, including seven transmembrane domains, N-terminal glycosylation sites and phosphorylation sites for protein kinase A (PKA) and protein kinase C (PKC). The third cytoplasmic loop is large, characteristic of other phospholipase-C-linked receptors (see below).

H_1-linked intracellular messengers. Activated H_1 receptors are known to activate a pertussis-toxin-insensitive G protein, G_q, that stimulates phosphoinositide-specific phospholipase C (PI-PLC), with the subsequent generation of inositol 1,4,5-trisphosphate (IP_3) and diacylglycerol (DAG). These two mediators are known to elevate intracellular Ca^{2+} concentrations and to activate PKC, respectively [34], (see also Ch. 20). Both internal and external Ca^{2+} sources are required to initiate and maintain responses. The distribution of H_1-activated IP_3 concentrations in the brain corresponds well to the distribution of H_1-binding sites in the guinea pig [5].

H_1 receptors also can stimulate the activity of phospholipase A_2 (PLA_2), with the subsequent release of arachidonate and its metabolites. In platelets, this response does not require activation of the phosphoinositide cycle and is inhibited by pertussis toxin, suggesting a second, distinct $G_{i/o}$-protein-mediated transduction mechanism. In cells transfected with the H_1 receptor, PLA_2 activation is partially inhibited by pertussis toxin, also suggesting at least two transduction systems [30, 34].

H_1 receptors in brain slices can also stimulate glycogen metabolism [5] and can positively modulate receptor-linked stimulation of cAMP synthesis. The activation of brain cAMP synthesis by histamine is a well studied phenomenon that reveals a positive interaction between histamine receptors [35]. When studied in cell-free preparations, this response shows characteristics of H_2, but not H_1, receptors. When similar experiments are performed in brain slices, however, both receptors appear to participate in the response. Subsequent work showed that H_1 receptors do not directly stimulate adenylyl cyclase but enhance the H_2 stimulation, probably through the effects of calcium and PKC activation on sensitive adenylyl cyclase isoforms (see Ch. 21).

Activation of brain H_1 receptors also stimulates cGMP synthesis [19]. Outside the brain, histamine is known to relax vascular smooth muscle by activation of endothelial H_1 receptors, thereby increasing endothelial Ca^{2+} concentrations and stimulating the synthesis and release of nitric oxide. The latter, a diffusible agent, then activates the smooth muscle guanylyl cyclase [30]. Although less is known about these mechanisms in the CNS, there is evidence that brain H_1 receptor activation can produce effects that depend on guanylyl cyclase activity [19].

H_1 receptor activation induces depolarizing responses in many brain areas, notably hypothalamus, thalamus and cerebral cortex. In vertebrate brain, many of these effects are mediated by opening cation channels. H_1-induced excitation can also occur by blockade of K_{Leak} conductances [1]. In other cases, however, H_1 receptors can attenuate neuronal excitation by activating certain voltage-gated potassium channels. Most of the H_1 receptor-induced conductance changes are mediated by the IP_3–Ca^{2+} cascade.

H_2 receptors are intronless GPCRs linked to G_s proteins and cyclic AMP synthesis. The H_2 receptor cDNA has been cloned from several species, including dog, rat, guinea pig, mouse and human [28, 30]. Use of the polymerase chain reaction (PCR) with degenerate oligonucleotides and canine gastric parietal cDNA led to the cloning of the first H_2-receptor gene [36]. These intronless genes encode for receptor proteins having 358–359 amino acids

with a molecular weight of approximately 40,000 and show the typical features of G protein-coupled receptors. Like the H_1 receptor, the H_2 protein has sites for phosphorylation by PKC and for glycosylation. Unlike the former, the latter lacks a consensus site for PKA. The H_2 receptor shows only about a 40% homology with the H_1 receptor and shows some features that are often observed for receptors known to be positively coupled to adenylyl cyclase. Features include a short third cytoplasmic loop and a long C-terminal cytoplasmic tail [28]. The human H_2 receptor gene is located on chromosome 5. When expressed in cells, the cloned H_2 receptor shows binding profiles and biochemical characteristics that closely resemble the natural receptor. Both neuronal and non-neuronal cells of brain possess H_2 receptors [5]. H_2 receptors are abundant in the cerebral cortex, corpus striatum and nucleus accumbens of the guinea pig brain (Table 14-2). In the rat, characterization of brain H_2 receptors has been hampered by low concentrations of receptor; however, H_2 receptor mRNA has been observed in this species.

H_2-linked intracellular messengers. H_2 receptors are linked to increases in cAMP but also to other intracellular signals. It is well established that H_2 receptors lead to increases in cAMP concentrations in many tissues by stimulation of adenylyl cyclase [35]. Cells transfected with H_2 receptors demonstrate activation of adenylyl cyclase, confirming that cAMP is an important H_2 messenger. Since this effect is blocked by cholera toxin, a G_s-type protein is implicated in mediating these effects. Elevated cAMP concentrations then result in the activation of PKA, leading to numerous cellular changes (see Ch. 21). The second messenger cAMP is thought to be responsible for most of the effects of H_2 receptor stimulation. However, H_2 receptors activate adenylyl cyclase in homogenates from several regions of guinea pig brain, but the density of H_2-binding sites does not correlate with the magnitude of cyclase activation across regions. These and other experiments suggest that this receptor also uses additional transduction mechanisms, including activation of phospholipase C, increased intracellular Ca^{2+}, increased IP_3 concentrations, increased phospholipid methylation and decreased arachidonate release [28, 30, 35]. Both G_s and G_q proteins have been implicated in these responses, suggesting that the H_2 receptor can activate more than one type of G protein. Similar conclusions have been reached in studies of other G-protein-linked receptors. Further studies are needed to address the importance of the various signal transduction pathways for H_2 receptor function.

H_2 receptor stimulation in mammalian cerebral cortex and hippocampus produces excitation by inhibition of Ca^{2+}-activated K^+ conductances (Table 14-2). This effect resembles that produced by activation of β-adrenergic receptors in these areas and both are mediated by increases in the cAMP-PKA pathway [1]. H_2 receptor activation also facilitates depolarization by enhancing the 'I_H' current, a cation conductance change induced by hyperpolarization [1]. Although most of H_2 receptor signaling is therefore excitatory, H_2 receptors on interneurons of hippocampus also seem to be able to dampen maximum firing rates by inhibiting Kv3 channels [37].

H_3 receptors are a family of GPCRs produced by gene splicing and are linked to $G_{i/o}$. Although the genes encoding the H_1 and H_2 receptors were known since 1991, this information did not help to identify the gene encoding the third HA receptor. This new histamine receptor was already identified by pharmacological means in 1983 by Arrang and colleagues [38] and has for many years been regarded as an interesting drug target for CNS diseases. The molecular identity of the H3 receptor remained unknown until 1999, when, in a search for orphan GPCRs, a GPCR-related expressed sequence tag was identified *in silico* and used to clone a full-length human cDNA [39]. The cDNA contained an open reading frame of 445 amino acids with an aspartate residue in TM3 (Fig. 14-4). Such a residue is highly conserved in the family of biogenic amine receptors and was the first clue that the cDNA might encode for a new histamine receptor. The H_3 receptor protein shows very low homology with the H_1 and H_2 receptor (only to 22% and 20% respectively) or other GPCRs, explaining why the H_3 receptor gene was not cloned by homology screening with H_1- or H_2-receptor-specific probes. Currently, the rat, guinea-pig, mouse and monkey cDNAs have been cloned [40].

H_3 receptor gene splicing. The H_3 receptor gene from several species contains at least 3 introns (Fig. 14-5). Consequently, various isoforms have been identified for the human, rat and guinea pig H_3 receptor as a result of alternative splicing [40]. Alternative splicing of the third intron results in H_3 receptor isoforms, which contain different deletions in the third intracellular I3 loop. The I3 loop is known to be important for the GPCR signaling and indeed significant differences have in this respect been reported for the some of the isoforms (see below). Currently, at least 20 different human H_3 receptor isoform mRNAs have been identified as a result of various alternative splicing events [40]. However, functional characteristics and detailed information on their localization and relative abundance have been reported for only a small number of the isoforms [40].

H_3-linked intracellular messengers. Although the H_3 receptor was initially identified by pharmacological means, detailed information on this receptor's transduction mechanisms was only obtained after the cloning of its cDNA. A -pertussis-toxin-sensitive inhibition of cAMP accumulation in response to H_3 agonists has been observed in a variety of transfected cells, indicating that the H_3 receptor negatively regulates adenylate cyclase activity via $G_{i/o}$ proteins (Fig. 14-6). The H_3-mediated regulation of HDC activity is also controlled via the cAMP-adenylate

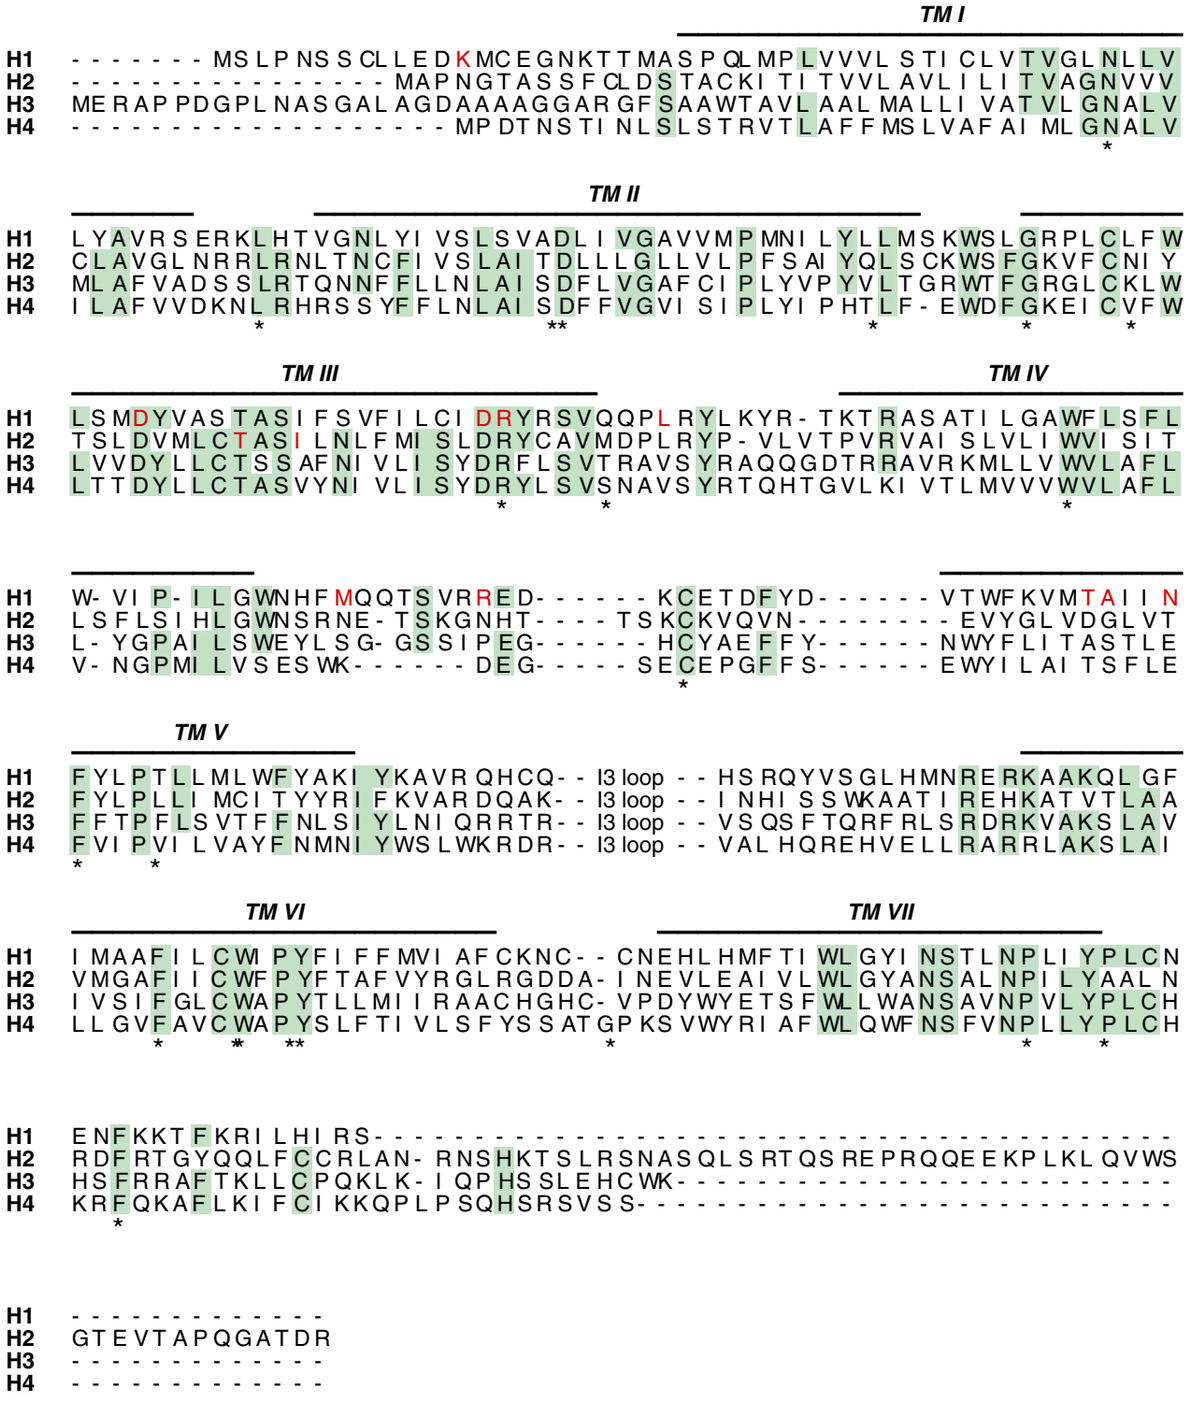

FIGURE 14-4 Amino acid sequence alignment of the four human HA receptors. The figure was produced using ClustalX [87] (see also ftp://ftp-igbmc.u-strasbg.fr/pub/ClustalX/). For ease of presentation, portions of the third intracellular loops (I3) have been omitted. The *green shaded areas* indicated at least 75% conservation between subtypes. The asterisks indicate amino acid conservation with the rhodopsin sequence. Residues in *red* have been mutated and studied for their functional role in receptor function (ligand binding, signaling, glycosylation, phosphorylation), as indicated in the tiny GRAP/GPCRDB database [88] (see also http://tinyGRAP.uit.no/). Above the sequences the putative transmembrane domains (*TM*) are indicated.

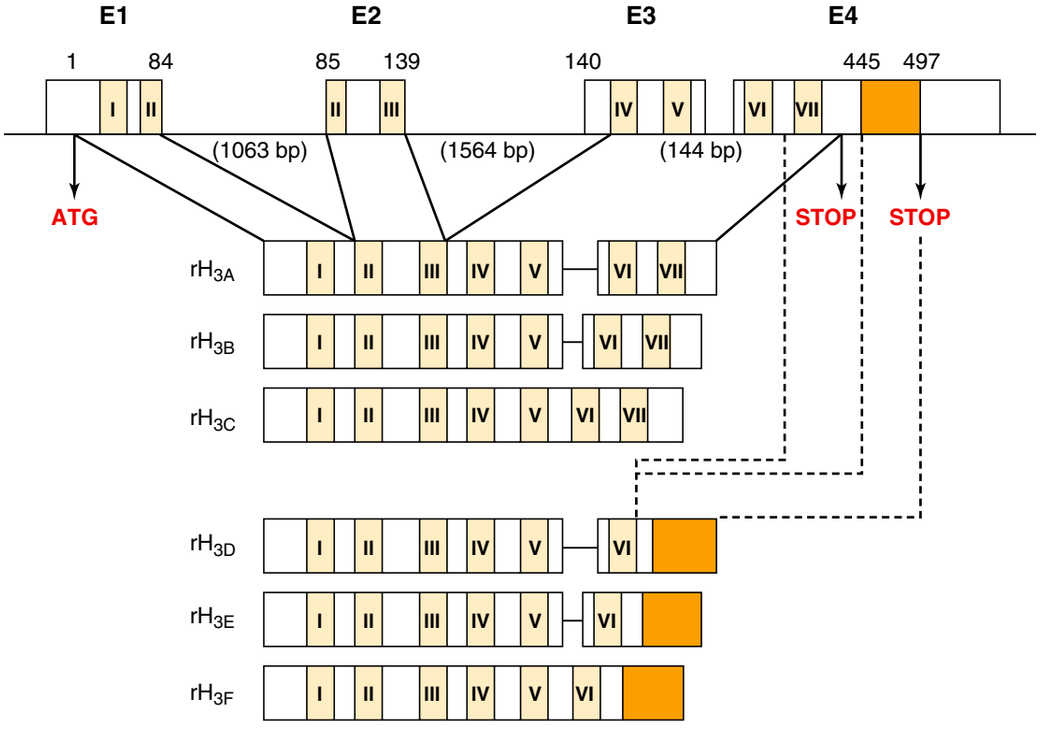

FIGURE 14-5 Isoforms of the rat H_3 receptor. The genomic structure of the receptor (**top**) shows four exons (*boxes*, E1–E4) and three introns (bp sizes are in parentheses). Peptide sequences that correspond to translated TM regions are labeled with roman numerals (I–VII). An alternatively spliced region (*orange box*) is depicted between the stop sequences. Six isoforms of the receptor (labels are on the left) result from alternative splicing. (Modified with permission from reference [2].)

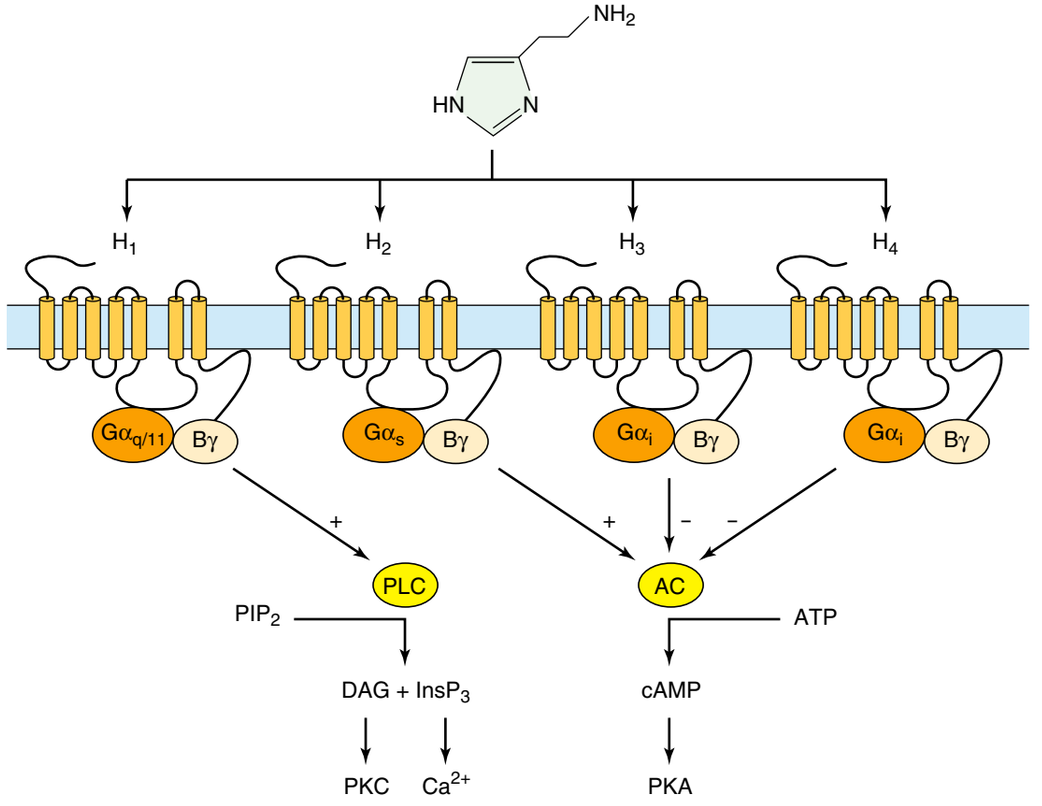

FIGURE 14-6 Main signaling pathways for histamine receptors. Histamine can couple to a variety of G-protein-linked signal transduction pathways via its four different receptors. The H_1 receptor activates the phosphatidylinositol turnover via Gq/11 proteins. The other receptors either positively (H_2 receptor) or negatively (H_3 and H_4 receptor) regulate adenylyl cyclase activity via Gs and $G_{i/o}$ protein activation respectively. Several additional signaling pathways have been described, which are not shown. Abbreviations: *PIP_2*, phosphatidylinositol 4,5-bisphosphate; *PLC*, phospholipase C; *AC*, adenylyl cyclase; *ATP*, adenosine triphosphate; *cAMP*, cyclic AMP; *PKC*, protein kinase C; *PKA*, protein kinase A.

cyclase-PKA pathway [41]. Recently, the H_3 receptor has also been reported to activate the MAPK pathway in both transfected cells and rat brain [42, 43]. Hippocampal administration of a MAPK inhibitor demonstrated that the MAPK activation in CA3 pyramidal cells is important for H_3 receptor-induced memory retention [43].

In transfected cells, H_3 receptor mediated activation of $G_{i/o}$ proteins has also been reported to modulate arachidonic acid release [29] and the Na^+/H^+ exchanger [44], and to inhibit Ca^{2+} influx and exocytosis of [^{3}H] noradrenaline from transfected SH-SY5Y-H_3 cells [45]. The inhibition of Ca^{2+} influx may be particularly relevant in view of the known physiological function of the brain H_3 receptor.

At present it is not known if all H_3 receptor isoforms similarly activate the wide array of signaling pathways. In transfected cells, the rat H_3(413) and H_3(397) isoforms both inhibit adenylate cyclase more efficiently than does the full length rat H_3 receptor isoform (445 amino acids), but the former are less efficient in activating the MAPK pathway. Much less information is available for the human H_3 receptor isoforms but shorter isoforms seem to couple more efficiently to $G_{i/o}$-proteins to inhibit cAMP production in transfected cells [40].

Constitutive H_3 receptor activity. In recent years it has become apparent that G-protein-coupled receptors can signal without the presence of the agonist, a phenomenon referred to as *constitutive activity*. Many GPCR antagonist ligands are able to reduce this agonist-independent signaling, an effect known as *inverse agonism*. All human HA receptors have now been reported to show constitutive activity [29, 46–48]. Moreover, well known therapeutics, such as cetirizine, loratadine, epinastine, cimetidine and ranitidine, act as inverse agonists *in vitro* at constitutively active H_1 or H_2 receptors.

The H_3 receptor is one of the few examples of a GPCR showing a high level of constitutive activity in a physiologically relevant system. Whereas almost all of the findings on constitutively active GPCRs have been obtained with transfected cells that express very high receptor densities, experiments performed *in vivo* have shown that the brain H_3 receptor spontaneously signals in the absence of endogenous histamine. Thus, constitutively active H_3 receptors inhibit histaminergic (and possibly other) neuronal activity and this activity can be inhibited by a structurally diverse set of inverse agonists, thereby increasing neuronal activity [29, 49]. H_3 receptor signaling (both agonist-activated and agonist-independent) occurs through Gi/o –linked inhibition of high voltage-activated calcium conductances (Table 14-2) [1].

H_4 receptors are very similar to H3 receptors in gene structure and signal transduction, but show limited expression in the brain. The H_4 receptor gene was identified in 2000 as a direct consequence of the human genome project. Use of the human H_3 receptor sequence led to the identification of a related orphan GPCR. Heterologous expression of the gene identified the orphan as a new member (H_4) of the histamine receptor family [32, 50]. The human H_4 receptor exhibits an exon/intron organization very similar to that of the H_3 receptor and the occurrence of isoforms can therefore be expected, but none so far have been reported. Within the brain, the H_4 receptor has been shown to be expressed only in the mouse hippocampus but outside the brain eosinophils, T-lymphocytes, neutrophils, mast cells, bone marrow, spleen, heart, lung and kidney show relatively high expression levels. This unique expression profile suggests that this new histamine receptor might be an interesting target for the regulation of immune function.

H_4-linked intracellular messengers. Like the H_3 receptor, the H_4 receptor couples primarily to pertussis toxin-sensitive $G_{i/o}$ proteins. In transfected cells, activation of the H_4 receptor leads to a $G_{i/o}$ protein-mediated inhibition of forskolin-stimulated adenylate cyclase activity, [^{35}S]GTPγS binding, and activation of MAP kinase. Moreover, in eosinophils and mast cells, a pertussis-toxin-sensitive calcium mobilization and chemotaxis has also been reported. The H_4 receptor can also couple to the relatively promiscuous G-proteins $G\alpha_{15}$ and $G\alpha_{16}$, leading to a stimulation of calcium mobilization. In view of the high expression of both the H_4 receptor and $G\alpha_{15}$ and $G\alpha_{16}$ proteins in cells of the immune system, this pathway could represent an important physiological second messenger system. At present no information is available on the signaling of the H_4 receptor in the CNS.

Histamine can modify ionotropic transmission at identified and unidentified sites. Although known receptors for histamine in mammals are all coupled to G proteins, two histamine-operated chloride channels (*hcl*A, *hcl*B, see [51] for discussion of nomenclature) were recently cloned from the fruit fly *D. melanogaster* [52, 53]. Both have the predicted four-transmembrane spanning regions and two cysteine bridges typical of all glycine and glutamate-operated chloride channels. These channels are most closely related in structure to human glycine receptors but also bear resemblance to GABA and glutamate ion channels. They are activated by micromolar concentrations of histamine and are blocked by high concentrations of some H_1 and H_2 antagonists. There is strong evidence that histamine activation of *hcl*A mediates the photoreceptor transmission in insect vision [51]. Although the mammalian homologs of these new histamine channels have not been found, there is substantial recent evidence for their existence in the mammalian brain [54, 55].

Histaminergic activation of ion channels may also occur through NMDA receptors [1]. This action occurs at the polyamine binding site on NR1/NR2B subunits and is sensitive to pH. Endogenous histamine may act at this site to facilitate the induction of long term potentiation, but this has not been established. Additional histamine receptors may still be discovered.

HISTAMINE ACTIONS ON THE NERVOUS SYSTEM

Histamine in the brain may act as both a neuromodulator and a classical transmitter. Histaminergic neurons appear to provide a variety of signaling mechanisms in the brain. A 'neuromodulator' role for histamine has received the most attention. Thus, activation of a small number of TM cells is thought to release histamine, which subsequently increases excitability in target cells distributed widely throughout the brain [56]. As mentioned, most of this histamine release is nonsynaptic, implying wide diffusion of the modulator. Such a system is consistent with the characteristics of known histamine receptors, which function through 'slow' transmission mechanisms requiring the production of intracellular second messengers (Table 14-2, see Ch. 10 for overview). However, as discussed above, neuronal histamine may also be capable of providing fast neurotransmission in the brain. For example, electrical stimulation of the TM cells has been shown to evoke fast excitatory postsynaptic potentials in phasically firing supraoptic neurons, effects which are mimicked by the application of histamine [54]. It was also recently shown that histamine increases chloride conductance in the thalamus by a mechanism that may be related to H_2 receptors, or to the putative mammalian histamine ion channel not yet characterized [55]. These findings imply that, like serotonin (see Ch. 13), histamine can activate both ligand-operated channels and receptors linked to second messengers.

Histaminergic neurons can regulate and be regulated by other neurotransmitter systems. A number of other transmitter systems can interact with histaminergic neurons (Table 14-1). As mentioned, the H_3 receptor is thought to function as an inhibitory heteroreceptor. Thus, activation of brain H_3 receptors decreases the release of acetylcholine, dopamine, norepinephrine, serotonin and certain peptides. However, histamine may also increase the activity of some of these systems through H_1 and/or H_2 receptors. Activation of NMDA, μ opioid, dopamine D_2 and some serotonin receptors can increase the release of neuronal histamine, whereas other transmitter receptors seem to decrease release. Different patterns of interactions may also be found in discrete brain regions.

Histamine in the nervous system may participate in a variety of brain functions. Several of the suspected physiological roles for histamine are related to its ability to increase the neuronal excitability [1, 2, 15]. For example, mutant mice lacking the H_1 receptor show defective locomotor and exploratory behaviors [57]. Neuronal histamine may increase attention and/or arousal by many mechanisms, including by enhancing sensory input [58]. All available evidence from several species shows that histaminergic neurons, when activated, increase wakefulness and induce electrographic arousal. For example, TM cell firing and neuronal histamine release is much higher during wakefulness, and pharmacological inhibition of TM activity induces sedation. H_1 receptors in the ventrolateral hypothalamus are one important site for the waking effect [59], but actions on the thalamus and cerebral cortex may also be significant. Of particular interest may be the role of the cholinergic system in histamine-activated arousal [60, 61]. The onset of sleep has been traced to cells in the ventral preoptic area of the hypothalamus, which, when activated, inhibit the histaminergic TM cells through GABAergic neurons. Thus, histamine is an important regulator of sleep–wake cycles and probably contributes to the diurnal changes in other brain functions as well. Experiments with mice lacking the HDC gene show that histaminergic neurons are essential for the waking needed to explore a novel environment [62].

Histamine also reduces seizure activity, another H_1-receptor-mediated effect. H_1 antagonists increase seizure onset and/or seizure duration in humans and animals, and H_1 receptor numbers are increased in some types of human epileptic foci [15]. H_3 antagonists increase seizure threshold in a variety of models, consistent with an elevation in neuronal histamine release. Centrally administered histamine agonists can also enhance learning and retention in laboratory animals [43, 61] but results with TM lesions suggest the opposite [63]. These apparently contradictory effects do not necessarily weaken the evidence for a histamine's role in learning but rather seem to suggest independent, opposing roles in various paradigms [64].

Histamine is a powerful regulator of many hypothalamic functions. Neuroendocrine responses, especially vasopressin release, are physiologically regulated by histaminergic neurons [54, 65]. Hypothalamic histamine may also participate in the physiological regulation of oxytocin, prolactin, adrenocorticotrophic hormone (ACTH) and β-endorphin release. Regulation of the latter two occurs by changes in release of both corticotropin-releasing hormone and vasopressin [66, 67]. Both H_1 and H_2 receptors seem to function in the histaminergic control of pituitary function.

Neuronal histamine is also an effective modulator of both food and water intake [15, 68]. Histamine and compounds that increase extracellular histamine concentrations are powerful suppressants of food intake. An action on the H_1 receptor in the ventromedial hypothalamus (VMH) seems to account for these effects [69]. Evidence that histamine contributes to the physiological control of appetite includes findings with genetically obese Zucker rats, which have very low concentrations of hypothalamic histamine. Furthermore, several studies suggest that leptin, a powerful physiological suppressant of appetite, signals through histaminergic activation of H_1 receptors. Histamine is also a powerful dipsogen (an agent that induces drinking), whether administered systemically or directly into the hypothalamus. Multiple hormonal and neuronal mechanisms may contribute to these effects [70]. Other suggested

roles for histamine in the regulation of vegetative functions include thermoregulation, regulation of glucose and lipid metabolism, and control of blood pressure [71, 72].

Histamine also induces antinociceptive (i.e. pain-relieving) responses in animals after microinjection into several brain regions [73, 74]. H_1 and H_2 mechanisms are significant and both neuronal and humoral mechanisms may be involved. Brain H_2 receptors appear to mediate some forms of endogenous analgesic responses, especially those elicited by exposure to stressors [75]. Many of the modulatory actions of histamine discussed above appear to be activated as part of stress responses. For reasons that remain unclear, histamine releasers, such as thioperamide, show only mild, biphasic antinociceptive actions, even though histamine is a potent and effective analgesic substance. Outside the brain, both H_1 and H_3 receptors exist on certain types of sensory nerves and activation of these receptors promotes and inhibits, respectively, peripheral nerve transmission related to pain and/or inflammation [76, 77].

Histamine may contribute to nervous system diseases or disorders. There are significant changes in the brain histamine system in several neurological diseases, such as multiple sclerosis, Alzheimer's disease, Down's syndrome and Wernicke's encephalopathy [1, 7, 15]. In some of these cases, there are clear changes in the number or morphology of histaminergic neurons. Whether from neurons or mast cells, histamine may participate in these processes by contributing to changes in vascular function, blood–brain barrier and/or immune activity. The ability of histamine to enhance excitatory transmission at NMDA receptors (discussed above) could explain its neurotoxic actions [7]. However, increases in neuronal histamine do not always enhance brain damage; histamine seems to exert a protective effect in some models of cerebral ischemia. Alterations in brain histamine content or dynamics may also be important for cognitive changes resulting from liver disease or histidinemia (an inborn error of histidine metabolism). In addition, histaminergic neurons are activated by vestibular disturbances, leading to the release of histamine in brainstem emetic centers. Thus, neuronal histamine may be one mediator of motion sickness [78].

Although histamine is not stored in neurons outside of the central nervous system, mast-cell-derived histamine can modify peripheral sensory nerve function. Both acute and chronic pain states can result from inflammation or peripheral nerve cell injury, and there is substantial evidence that mast cell histamine participates in these disorders.

SIGNIFICANCE OF BRAIN HISTAMINE FOR DRUG ACTION

Many clinically available drugs that modify sleep–wake cycles and appetite act through the histaminergic system. Blockade of brain H_1 receptors induces drowsiness and other signs of central nervous system depression in humans. For many years, these side effects limited the use of H_1 antagonists in allergic disorders such as hay fever. Newer, nonsedating, antihistamines (e.g. fexofenadine, loratidine) relieve peripheral allergic symptoms but have a low brain penetration, eliminating these sedative side effects. However, nearly all of the over-the-counter sleep aids are brain-penetrating H_1 antagonists (e.g. chlorpheniramine, diphenhydramine). There are also medications used to produce the opposite effect (i.e. increased wakefulness). One such drug, modafinil, was recently shown to increase the release of neuronal histamine [91].

Blocking H_1 receptors in the human brain has other important consequences. For example, brain-penetrating H_1 antagonists are effective for the treatment of motion sickness and Ménière's disease, a related disorder of the inner ear. Many other centrally acting drugs have a high affinity for H_1 receptors. Among tricyclic antidepressant drugs, those with the most pronounced sedative profile have the highest affinity for blocking H_1 receptors. H_1-receptor blockade also promotes appetite and weight gain. In fact, a recent study concluded that the weight-promoting effects of typical and atypical antipsychotic medications are directly related to the H_1-blocking properties of these drugs [79].

Drugs that modify pain perception act in part through the histaminergic system. Although pain-relieving opioid drugs such as morphine initiate many neurochemical changes, the activation of neuronal histamine release by these agents and the subsequent stimulation of brain H_2 receptors are critical for the mechanism of action of these compounds [80–82]. Stress responses also can contribute to opioid analgesia and histaminergic neurons appear to mediate the stress-induced potentiation of morphine antinociception. Although no pain-relieving drugs have been developed based on H_2 receptors, a family of novel analgesics has been discovered from drugs related to cimetidine (an H_2 antagonist) and burimamide (a drug with both H_2 and H_3 properties). Thus far, these drugs have been used only as research tools. Outside the brain, H_1 receptors on sensory nerve fibers are activated during some kinds of pain and inflammation, and H_1 antagonists are used for their anti-inflammatory and analgesic profiles [76]. By an opposing mechanism, H_3 agonists reduce pain transmission evoked by chemical and mechanical stimuli [77, 83]

Drugs that act on the H_3 receptor are being developed for the treatment of obesity, sleep disturbances, epilepsy and cognitive disorders. The ability of histamine to promote arousal, suppress appetite, elevate seizure threshold and stimulate cognitive processes implies that compounds able to enhance the release of neuronal histamine should mimic these effects. Several H_3 antagonists currently in development demonstrate such activity and show promise as effective and novel therapeutic agents [40, 84–86]. Because H_3 agonists suppress the release of

neuronal histamine, compounds that can activate brain H_3 receptors may become clinically useful sleep-promoting drugs.

ACKNOWLEDGMENTS

Several recently-published reviews were particularly helpful in preparation of this article [1–3]. Many important contributions to the subject of this chapter have not been cited due to space limitations, and we apologize to the authors of these papers for these omissions. We thank J. W. Nalwalk for careful proofreading. LBH is supported by grants (DA-03816, DA-015915).

THE AMINO ACID GLUTAMATE IS THE MAJOR EXCITATORY NEUROTRANSMITTER IN THE BRAIN

Glutamate mediates most of the fast excitatory neurotransmission in the CNS, and it excites virtually every neuron. Glutamate is the principal mediator of sensory information, motor coordination, emotions and cognition, including memory formation and memory retrieval. As many as 90% of the neurons of the brain use glutamate as their neurotransmitter, and approximately 80–90% of the synapses in the brain are glutamatergic [1]. Repolarization of membranes that are depolarized during glutamatergic activity may account for as much as 80% of the energy expenditure of the brain [2]. The very high consumption of glucose and oxygen by the brain (see Ch. 31) therefore largely fuels glutamatergic activity. The concentration of glutamate in brain gray matter structures varies between 10 and 15 µmol per gram of tissue, higher than in virtually all other tissues of the body. In white matter the glutamate concentration is 4–6 µmol/g. Glutamate takes part in many reactions in the brain (Fig. 15-1). Formation of glutamate is a step in the metabolism of glucose and amino acids; glutamate is a precursor for γ-aminobutyric acid (GABA) in GABAergic neurons and for glutamine in glial cells; it is a constituent of proteins and peptides, e.g. glutathione (γ-glutamyl-cysteinyl-glycine), which is a major defense against oxidative stress in cells. Therefore, all cells of the brain, neuronal and glial, contain glutamate, which is found in both the cytosol and mitochondria, in both the cell bodies and their processes. In glutamatergic neurons, glutamate is concentrated in synaptic vesicles in which compartment it represents 'transmitter glutamate'.

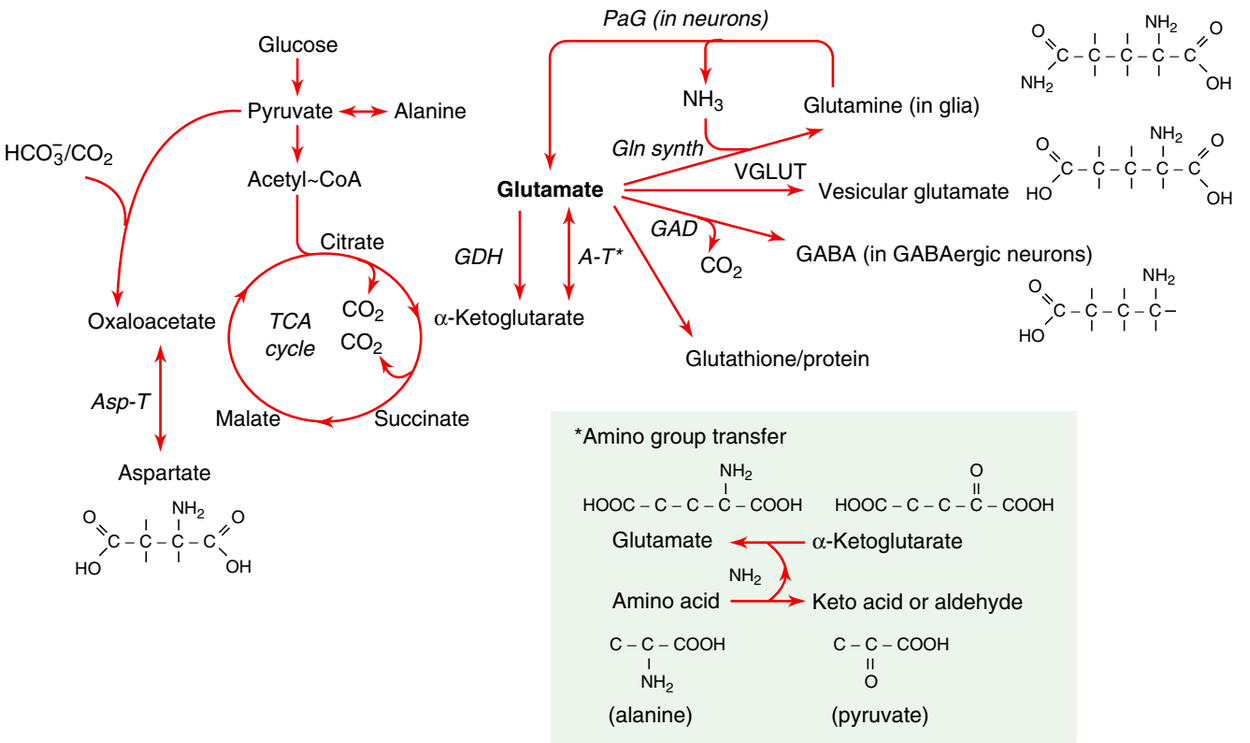

FIGURE 15-1 The formation of glutamate from α-ketoglutarate, a TCA cycle intermediate. α-Ketoglutarate, which is formed from glucose, constitutes the carbon backbone of glutamate. The amino group derives from another amino acid, which after donation of its amino group becomes a keto acid or an aldehyde (insert). This amino donor may be aspartate, GABA, alanine (shown in the insert) or some other amino acid. Glutamate takes part in many biochemical reactions: in glial cells it is converted to glutamine, in GABAergic neurons it is converted into GABA. Transmitter glutamate is defined by its accumulation into synaptic vesicles. In the **upper right corner** the glutamine cycle is shown, with conversion of glutamate into glutamine in glia and conversion of glutamine into glutamate in neurons. To **upper left** is shown pyruvate carboxylation (anaplerosis), which replenishes the TCA cycle (glial or neuronal) with malate or oxaloacetate to compensate for the loss of glutamate, glutamine, or (in GABAergic neurons) GABA. *Asp-T*, aspartate aminotransferase; *A-T*, aminotransferase reaction (Asp-T or other); *GABA*, γ-aminobutyric acid; *GAD*, glutamic acid decarboxylase; *GDH*, glutamate dehydrogenase; *Gln synth*, glutamine synthetase; *PaG*, phosphate-activated glutaminase; *TCA* cycle, tricarboxylic acid cycle; *VGLUT*, vesicular glutamate transporter. A more comprehensive scheme of glutamate metabolism can be found at http://www.genome.ad.jp/kegg/pathway/map/map00251.html.

BRAIN GLUTAMATE IS DERIVED FROM BLOOD-BORNE GLUCOSE AND AMINO ACIDS THAT CROSS THE BLOOD–BRAIN BARRIER

From a metabolic point of view, glutamate may be thought of as a carbon backbone (with hydrogens and hydroxyl groups attached) on the one hand and an amino group on the other. The carbon backbone derives from serum glucose, which, through glycolysis and the tricarboxylic acid (TCA) cycle (see Ch. 31), is converted to α-ketoglutarate. α-Ketoglutarate then receives an amino group from another amino acid through transamination and becomes converted into glutamate (Fig. 15-1). Glutamate is in equilibrium with – and continuously reconverted to – α-ketoglutarate and metabolized through the TCA cycle. The cerebral metabolic rate for glucose in human brain is approximately 0.4 μmol/min/g tissue, and the turnover of glutamate is approximately 0.8 μmol/min/g tissue [3]. This means that virtually all the glucose that enters the brain is metabolized through glutamate, since one molecule of glucose gives rise to two molecules of acetyl-CoA, which enter the TCA cycle to become α-ketoglutarate and hence glutamate (Fig. 15-1). In the rat brain the turnover of glutamate is approximately twice that of the human brain.

The amino group of glutamate derives from serum amino acids that cross the blood–brain barrier. Current evidence points to blood-borne branched-chain amino acids (leucine, isoleucine and valine) as important amino donors for glutamate synthesis. Because the uptake of amino acids into the brain is much less than the uptake of glucose, the amino group of glutamate must be recycled in the brain when the carbon backbone is broken down to CO_2 and water. Aspartate is one important amino group reservoir for glutamate synthesis. The highly active aspartate aminotransferase shuttles the amino group between α-ketoglutarate and another TCA cycle intermediate, oxaloacetate. These two intermediates are converted into glutamate and aspartate respectively when they accept an amino group. Other amino acids, such as alanine and GABA (in GABAergic neurons) are also important amino group reservoirs (Fig. 15-1). Theoretically, glutamate could be formed by reversal of the glutamate dehydrogenase (GDH) reaction: Glutamate + NAD(P) → α-ketoglutarate + NH_3 + NAD(P)H + H^+. This is unlikely, however, since the K_m for NH_3 and α-ketoglutarate in the reverse reaction, >12 mmol/l and 1 mmol/l, respectively, are far above normal brain concentrations (<300 μmol/l and 150 μmol/l, respectively). The specific role of glutamate dehydrogenase in the brain is not clear but it is an important enzyme in protein degradation: The metabolism of protein-derived amino acids involves transamination of the various amino acids into ketoacids; α-ketoglutarate accepts the NH_2 group in these transaminations and becomes converted into glutamate. Glutamate dehydrogenase removes the NH_2 group from glutamate as free NH_3 and shunts glutamate back into the TCA cycle as α-ketoglutarate.

GLUTAMINE IS AN IMPORTANT IMMEDIATE PRECURSOR FOR GLUTAMATE: THE GLUTAMINE CYCLE

Much of the glutamate that is released from nerve terminals is taken up from the extracellular fluid into astrocytic processes that surround synapses (Fig. 15-2). The mechanism of uptake is described later in this chapter. In astrocytes glutamate reacts with ammonia to form glutamine through the activity of glutamine synthetase, a cytosolic, ATP-dependent enzyme that astrocytes and oligodendrocytes express but neurons do not. This reaction is important even for the detoxification of free ammonia; accumulation of ammonia would interfere with synaptic function (see Ch. 34). Glutamine, which does not have neurotransmitter properties, is exported to the extracellular fluid and taken up by neurons (see below). In neurons glutamine is converted back to glutamate by phosphate-activated glutaminase, a mitochondrial and possibly neuron-specific enzyme in the brain. The trafficking of glutamate and glutamine between neurons and astrocytes is called the 'the glutamine cycle'. This cycle seems to be very active, its flux has been estimated at approximately 40% of the glutamate turnover rate [4], meaning that almost half the glutamate formed in neurons is transferred to glial cells. Whether all the neuronal glutamate taken up by glia is vesicular in origin is not known; reversal of glutamate transporters (see below) or exchange of intracellular glutamate for extracellular cystine may both be important mechanisms by which glutamate can leave neurons [5].

Several findings support the concept that glutamine is an important precursor for transmitter glutamate. When brain slices are incubated with radiolabeled glutamine, radiolabeled glutamate is formed that is releasable through a calcium-ion-dependent mechanism. The calcium dependence identifies the released glutamate as vesicular in origin (see Ch. 10). A way to study the fate of glutamine in the intact brain is to use isotopically labeled acetate to label glutamine. Carbon-13-labeled acetate does not enter neurons but it readily enters astrocytes, where it becomes metabolized to glutamine. After intravenous injection of ^{13}C-labeled acetate, magnetic resonance spectroscopy of the brain is consistent with the formation of ^{13}C-glutamine in astrocytes and the formation of ^{13}C-glutamate from that glutamine in neurons (magnetic resonance spectroscopy is discussed in Ch. 58).

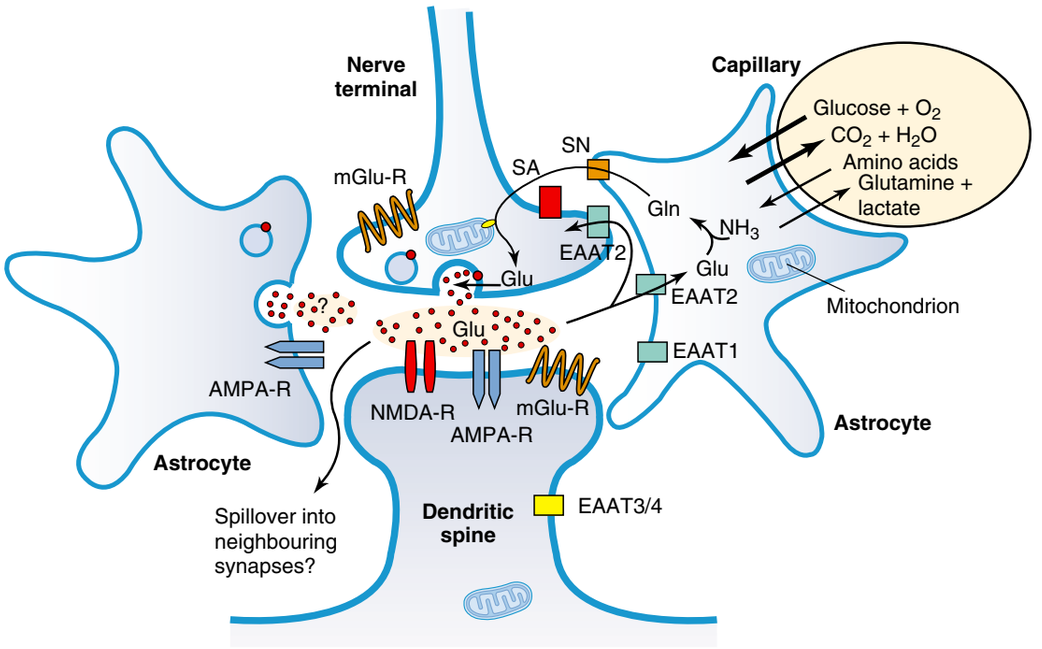

FIGURE 15-2 A glutamatergic, axodendritic synapse consisting of a presynaptic nerve terminal and a postsynaptic dendritic spine. The nerve terminal contains synaptic vesicles with glutamate transporters (*red dot*), mitochondria (*blue*) with glutaminase in nerve terminal (*yellow dot*), metabotropic glutamate receptors, and transporters for glutamate (EAAT2) and glutamine (SA transporters). The postsynaptic dendritic spine contains glutamate receptors, both ionotropic (AMPA and NMDA type) and metabotropic, and glutamate transporters (EAAT3 and EAAT4, the latter in cerebellar Purkinje cells). Surrounding the synapse are astrocytic processes with glutamate (EAAT1 and EAAT2) and glutamine transporters (SN transporters), glutamate receptors and even glutamate-filled vesicles. Green rectangles in plasma membrane of the axon terminal represent EAAT2 and of the astrocyte represent EAAT1/EAAT2 glu transporters. Glutamate that escapes out of the synapse without being cleared by transporters may spill over into neighboring synapses. *AMPA-R*, AMPA receptors; *EAAT1–4*, excitatory amino acid transporters 1–4; *Gln*, glutamine; *Glu*, glutamate; *mGlu-R*, metabotropic glutamate receptors; *SA* and *SN*, system A and system N transporters respectively (for glutamine).

Release of glutamate from nerve endings leads to loss of α-ketoglutarate from the tricarboxylic acid cycle. The glutamine cycle counteracts an important metabolic challenge inherent in glutamatergic neurotransmission: it helps prevent loss of α-ketoglutarate from the neuronal TCA cycle. When neurons release glutamate and astrocytes take it up, the neuronal TCA cycle loses α-ketoglutarate. If this loss of α-ketoglutarate from the TCA cycle is not countered, the downstream product oxaloacetate will not be available for the formation of citrate (Fig. 15-1; see Ch. 31), and the TCA cycle will eventually grind to a halt, with the consequence that energy metabolism stops. The return of glutamine for transmitter glutamate reduces the loss of neuronal α-ketoglutarate but probably does not prevent it completely, partly because astrocytes metabolize some transmitter glutamate through their own TCA cycle as an energy substrate. Two additional mechanisms exist that maintain the level of glutamate and TCA cycle intermediates in the nerve terminal: one is reuptake of glutamate from the extracellular fluid back into the nerve terminal, the other is the reaction of pyruvate (derived from glycolysis) with CO_2 to form TCA cycle intermediate malate, the precursor of oxaloacetate. This process is called pyruvate carboxylation. Pyruvate carboxylation in the nerve terminal may be catalyzed by malic enzyme, a reversible enzyme that utilizes CO_2 and NADPH to form malate from pyruvate [4]. Pyruvate carboxylation also takes place in astrocytes where it may be catalyzed by pyruvate carboxylase, an ATP-dependent, unidirectional enzyme that utilizes bicarbonate for the carboxylation of pyruvate to oxaloacetate. This reaction may support a net production and export of glutamine from astrocytes [4].

Because the carbon backbone of glutamate derives from serum glucose, the formation and further metabolism of glutamate (e.g. to glutamine or GABA) may be followed in the awake human brain or in animals with magnetic resonance spectroscopy after intravenous injection of ^{13}C-labeled glucose [3] (see MRS in Ch. 58). Glutamate and GABA become labeled with ^{13}C within a few minutes after injection of ^{13}C-labeled glucose. The labeling of glutamine lags somewhat behind that of glutamate, probably reflecting the time involved in release of glutamate from nerve endings, uptake by astrocytes, and conversion to glutamine (Fig. 15-2).

SYNAPTIC VESICLES ACCUMULATE TRANSMITTER GLUTAMATE BY VESICULAR GLUTAMATE TRANSPORTERS

One defining characteristic of transmitter glutamate is its accumulation in synaptic vesicles. The concentration of

glutamate in synaptic vesicles has been estimated at 60–250 mmol/l. The concentration of glutamate in the cytosol is only a few mmol/l, so glutamate is concentrated inside the vesicles. The inner radius of a glutamate-containing vesicle is on average about 17 nm, which gives a volume of 2×10^{-20} liters; a glutamate concentration of 100 mmol/l (or 6×10^{22} molecules/l) would therefore yield 1200 molecules of glutamate in each vesicle. Specialized proteins in the vesicular membrane, the vesicular glutamate transporters (VGLUTs), cause the accumulation of glutamate in synaptic vesicles. VGLUTs are multimeric protein complexes that are proton/glutamate antiporters (see Ch. 5). Vacuolar (V-type) H^+-dependent ATPase establishes a proton-based electric gradient across the vesicular membrane at the expense of ATP: protons accumulate in the lumen of the vesicle, which becomes positive relative to the cytosol. This gradient is the main driving force for the accumulation of glutamate, but the low pH of the vesicular lumen also contributes. However, if we consider the small volume of a vesicle, a vesicular pH in excess of 5 (a measured value) would imply less than 0.1 proton per vesicle. This probably means that a free proton is present in the vesicle less than 10% of the time, and that this is enough to attract glutamate. The VGLUTs have a K_m for glutamate of 1–2 mmol/l, are stimulated by chloride at a concentration of 4–10 mmol/l (which is the normal cytosolic concentration) and are sodium-independent. Three VGLUTs have been cloned. VGLUT 1 and 2 are localized to different populations of glutamatergic neurons. VGLUT3, on the other hand, is found in GABAergic, cholinergic and monoaminergic neurons, raising the possibility of novel roles for transmitter glutamate [6]. Even some astrocytes have glutamate-containing vesicles with VGLUT 1 and 2, and astrocytes have been shown to release glutamate in a calcium-ion-dependent manner that involves the participation of SNARE proteins (see Ch. 10) (Fig. 15-2).

The fraction of glutamate contained in vesicles in gray matter may be estimated from the density of glutamatergic synapses ($\approx1/\mu m^3$ or $1/10^{-15}$ liters), the number of vesicles per terminal (100–500), the volume of each vesicle ($\approx2\times10^{-20}$ liters) and the concentration of glutamate in the vesicles (60–250 mmol/l). With a total concentration of glutamate of 12 mmol/kg tissue (or 12 mmol/l), the above values mean that vesicular glutamate may account for 1–20% of the total level of glutamate, depending on the number of vesicles per synapse and the intravesicular concentration of glutamate. This value may seem small considering the high level of glutamate in the brain, but the high level of glutamate is mainly caused by the high metabolic activity of the brain rather than by vesicular glutamate. The higher the metabolic flux, the higher the level of metabolic intermediates, among them glutamate.

Zinc is present together with glutamate in some glutamatergic vesicles. Zinc colocalizes with glutamate in subpopulations of synaptic vesicles throughout the brain. Approximately 10% of the synaptic vesicles of glutamatergic terminals in the hippocampus contain a substantial amount of zinc, which is released together with glutamate. Vesicles accumulate zinc through the ZnT3 zinc transporter, which is located in the vesicular membrane. The importance of this colocalization lies in zinc's ability to modulate the activation of glutamate receptors, as described below.

IS ASPARTATE A NEUROTRANSMITTER?

Aspartate, like glutamate, can be released from brain slices in a calcium-dependent manner by depolarizing stimuli, and intriguingly the ratio of released aspartate to glutamate is not fixed. Aspartate, which is closely related to glutamate and which has excitatory properties, does not appear to be concentrated in synaptic vesicles and for this reason may not be a transmitter in the classic sense. Aspartate might, however, be released directly from the cytosol of nerve endings. Aspartate exclusively activates NMDA receptors, having no effect (agonist or antagonist) at AMPA receptors [7]. The role of aspartate in excitatory neurotransmission remains to be determined.

LONG-TERM POTENTIATION OR DEPRESSION OF GLUTAMATERGIC SYNAPSES MAY UNDERLIE LEARNING

Learning is a crucial aspect of our behavior. This is true for the motor, sensory, emotional and cognitive components of behavior (see also Ch. 53). Complex learning processes lie behind our ability to move our body in a purposeful manner, our ability to discern and understand the sensory information that we receive, the perception of stimuli as harmful or good, as well as memory formation, language acquisition and thought processes. Learning must have an anatomical substrate: the CNS must undergo some form of change that allows the storage of what is to be learnt. Our current understanding is that the changes that underlie such information storage occur at the synaptic level through processes collectively referred to as 'synaptic plasticity'. There is no general agreement as to whether these changes occur predominantly on the presynaptic or on the postsynaptic side of the synaptic cleft, but several molecular mechanisms that could be important for learning have been identified on both sides. Electrophysiologically, two phenomena can be seen that may be components of learning at the synaptic level. These are long-term potentiation (LTP) and long-term depression (LTD) of synaptic efficacy. A glutamatergic synapse that is briefly but strongly activated by high-frequency stimulation (e.g. 100 Hz) may relay impulses more efficiently thereafter and will do so for a long time,

for months or longer. This phenomenon, which was first described by Lømo in 1966, is termed LTP; the synapse has been 'potentiated' or strengthened (see also Hebb's postulate of learning, Ch. 53). However, prolonged low-frequency stimulation (1 Hz) of a glutamatergic synapse may cause it to relay impulses less efficiently on a long-term basis, a phenomenon termed LTD, reflecting that the synapse has been 'weakened'. Presynaptic mechanisms that may contribute to LTP include a greater success rate for the release of glutamate when an action potential arrives at the terminal and release of greater amounts of glutamate per action potential [8]. Postsynaptic mechanisms that mediate LTP and LTD are related to activation and trafficking of glutamate receptors, which is described below.

THE NEURONAL PATHWAYS OF THE HIPPOCAMPUS ARE ESSENTIAL STRUCTURES FOR MEMORY FORMATION

LTP has been shown in many parts of the brain but it has been most extensively studied in the hippocampus, a phylogenetically old part of the cerebral cortex that in humans is embedded in the temporal horn and in rats and rabbits lies beneath the parietal and temporal neocortex (Fig. 15-3A). The hippocampus is essential for (declarative) memory formation; in rats the role of hippocampus in acquisition of spatial information has been studied in

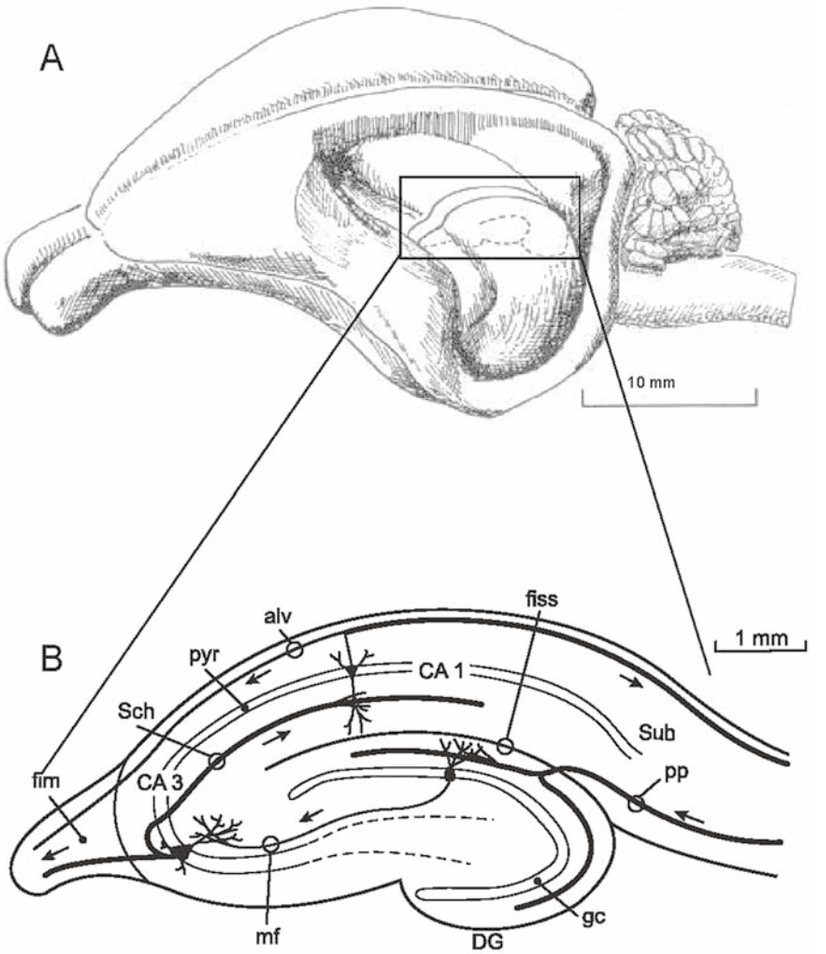

FIGURE 15-3 Hippocampus. (**A**) Its position beneath the parietal cortex in the rabbit brain (With permission from Andersen, P., Bliss, T. and Skrede, K. *Exp. Brain Res.* 13: 222–238, 1971; copyright Springer Verlag). (**B**) The main pathways of the hippocampus as seen in a hippocampal slice (With permission from Skrede, K. and Westgaard, R. H. *Brain Res.* 35: 589–593, 1971.). The main input to the hippocampus is the perforant path (*pp*), which originates in the entorhinal cortex and traverses the hippocampal fissure (*fiss*) to the granule cell layer (*gc*) of the dentate gyrus (*DG*). The perforant path axons traverse the middle part of the dendritic trees of the granule cells, making synapses with several granule cells as they pass through (synapses '*en passage*'). The axons of the granule cells make up the mossy fibres (*mf*) that make large synapses with pyramidal cells (*pyr*) of the CA3 region, also of the *en passage* type. The axons of the CA3 pyramidal cells have two branches: one exits the hippocampus and enters fimbria (*fim*) to reach septum; the other branch, the Schaffer collateral (*Sch*), makes synapses *en passage* with CA1 pyramidal cells. The CA1 pyramidal cells exit the hippocampus as the alveus and project mainly to the subiculum (*Sub*) and more sparsely through fimbria to the septum.

great detail. In the hippocampus the neuronal connections are highly ordered, so it is easy to identify specific populations of neurons and synapses. One may cut the hippocampus into transverse slices (Fig 15-3B) in which many of the neuronal connections are maintained. Such slices are excellent for electrophysiological recordings, a technique pioneered by Skrede and colleagues in the early 1970s. The anatomy of the hippocampus was described around 1900 by Santiago Ramón y Cajal. Axons from neurons in the entorhinal cortex enter the dentate gyrus as the perforant path (so called because it traverses the hippocampal fissure and 'perforates' the dentate gyrus). These axons form glutamatergic synapses with granule cells of the dentate gyrus. Axons of granule cells, the mossy fibers, form glutamatergic synapses with pyramidal cells of the CA3 region (CA stands for cornu ammonis–Ammon's horn). These neurons send axons to the septum through fimbria as well as collaterals (the Schaffer collaterals) to the CA1 region where they form glutamatergic synapses with pyramidal cells. In addition to this multisynaptic pathway from the entorhinal cortex to the CA1 region, there is a direct pathway from neurons in layer III of the entorhinal cortex to pyramidal neurons of the CA1 region. The axons of the CA1 pyramidal neurons exit the hippocampus as the alveus and project mainly to the subiculum, but some project to the septum through fimbria (Fig 15-3B). LTP can be induced at all these glutamatergic synapses.

IONOTROPIC AND METABOTROPIC GLUTAMATE RECEPTORS ARE PRINCIPAL PROTEINS AT THE POSTSYNAPTIC DENSITY

The classical glutamatergic synapse is a point of communication between a presynaptic nerve terminal and a postsynaptic dendritic spine (axo-dendritic synapses) or another nerve terminal (axo-axonal synapses). However, even astrocytes, oligodendrocytes and microglia express some types of glutamate receptor that may be stimulated by glutamate released from nerve terminals. Whereas glutamatergic terminals typically contact dendritic spines, GABAergic receptors are often located directly on dendritic shafts or on the soma. Glutamatergic synapses are easily recognized at high magnification as 'asymmetric': the postsynaptic membrane appears thicker than the presynaptic membrane (Fig. 15-4A). This postsynaptic density, or PSD, is on average 50 nm thick, and may contain as many as 100 different proteins, among them the glutamate receptors (Fig. 15-4B).

Glutamate receptors belong to one of two main categories: Ionotropic receptors are cation channels whose opening is enhanced when glutamate binds to the receptor. Metabotropic receptors do not conduct ion fluxes; instead they activate intracellular enzymes through G proteins when they bind glutamate (G proteins are discussed in Ch. 19).

THREE CLASSES OF IONOTROPIC GLUTAMATE RECEPTORS ARE IDENTIFIED

For ionotropic glutamate receptors, the agonist binding sites and associated ion channel are incorporated into the same macromolecular complex. Agonist binding forces a conformational change in the receptor that increases the probability of channel opening. The three classes of ionotropic receptor were originally named after reasonably selective agonists – *N*-methyl-D-aspartate (NMDA), α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) and kainate (KA). The affinity for glutamate is different for the different glutamate receptors. The EC50 for glutamate at NMDA receptors is approximately 1 μmol/l while at AMPA receptors it is approximately 400 μmol/l [7]. Several endogenous molecules may activate NMDA receptors, some of them are, just like glutamate itself, acidic amino acids, e.g. aspartate and homocysteate.

Six functional families of ionotropic glutamate receptor subunit can be defined by structural homologies. Since the cloning of the first glutamate receptor, GluR1, in 1989 [9], more than 16 mammalian genes that encode structurally related proteins have been identified. Currently, six families of ionotropic glutamate receptor subunit have been described. The subunits assemble into functional receptors shown in Figure 15-5. Within a given family, members show at least 80% identity at the amino acid level over the ≈400 amino acid stretch of membrane-spanning regions. Between families, however, a lower degree of identity exists (55% or less).

The ligand-gated ion channel receptors appear to be tetrameric assemblies of the individual subunits. A significant feature of the glutamate receptors is that different subunit combinations produce functionally different receptors as described below. *In situ* hybridization and immunohistochemistry have highlighted regional differences in expression of subunits encoding glutamate receptors. These differences illustrate the heterogeneity of glutamate receptors throughout the CNS. Together with differences in electrophysiological properties of different subunit combinations expressed in cell lines or oocytes, diverse patterns of subunit expression throughout the CNS support the existence of multiple subtypes of AMPA, kainate and NMDA receptors.

AMPA and kainate receptors are both blocked by quinoxalinediones but have different desensitization pharmacologies. AMPA receptors are widespread throughout the CNS; they serve as receptors for fast excitatory synaptic transmission mediated by glutamate. AMPA receptor subunits are GluR1-GluR4, kainate receptor

(**B**) Schematic representation of a dendritic spine of a glutamatergic synapse with some proteins of the postsynaptic density (*PSD*). Lipid rafts, scaffolding proteins (such as PSD95, GRIP, shank and homer) and cytoskeletal proteins (F-actin) help to concentrate and stabilize effector proteins at the spine. Effector proteins are glutamate receptors (AMPA-R, NMDA-R, mGlu-R), protein kinases and protein phosphatases, enzymes for the production of second messengers (nitric oxide, cAMP). *AdCyc,* adenylate cyclase; AKAP, (protein kinase) A-kinase anchoring protein; AMPA-R, AMPA receptor; CaMK II, Ca^{2+}/calmodulin-dependent kinase II; *CaN,* calcineurin (protein phosphatase 2B); *DAG,* diacylglycerol; *F-actin,* filamentous actin; *GRIP,* glutamate receptor-interacting protein; IP_3, inositol-1,4,5-triphosphate; *mGluR,* metabotropic glutamate receptor; *NMDA-R,* NMDA-receptor; *NOS,* nitric oxide synthase; *PKA* and *PKC,* protein kinase A and C respectively (activated by cAMP and Ca^{2+}/DAG respectively); *PLC,* phospholipase C; *PSD95,* postsynaptic density protein with a molecular weight of 95 kDa; *SER,* smooth endoplasmatic reticulum.

subunits are GluR5-GluR7 plus KA1 and KA2. GluRs are approximately 900 amino acids long, compared to about 480 amino acids for nicotinic, $GABA_A$ or glycine receptor subunits. The extra length of AMPA receptors is due to an unusually large N-terminal extracellular domain. GluR1–GluR4 subunits (also named GluRA–GluRD or, in mouse α1–α4) co-assemble with one another to form tetramers with the pharmacologic profile of AMPA receptors (Fig. 15-6). Thus, when *Xenopus* oocytes are injected with mixtures of GluR1–GluR4 mRNAs, receptors are formed that can be blocked specifically by certain quinoxalinediones, notably 6-nitro 7-sulphamobenzo[f] quinoxaline-2,3-dione (NBQX). NBQX is a potent and selective competitive antagonist of AMPA receptors but has a weak or no effect on other receptors.

Subunits of the GluR5–GluR7 family, on the other hand, coassemble with KA1 or KA2 into functional kainate receptors when studied in heterologous expression systems. Results of experiments with radioligands demonstrate that homomeric GluR5 and GluR7 receptors expressed in mammalian cell lines bind [^{3}H]kainate with low affinity (K_d 80–100 nmol/l). Such homomeric receptors may correspond to the 'low-affinity' kainate binding sites identified earlier in studies of plasma membranes from brain. Homomeric GluR6, KA1 and KA2 receptors, on the other hand, bind kainate with an affinity between 4 and 15 nmol/l respectively and may contribute to the 'high-affinity' kainate binding sites in brain. KA1 and KA2 are virtually inactive as ion channels when expressed alone and might therefore be thought of as modulatory subunits. Although none of the homomeric receptors is sensitive to AMPA, heteromeric complexes of GluR6 and KA1 do respond to AMPA with a desensitizing current.

AMPA receptors desensitize within milliseconds upon exposure to AMPA, and kainate receptors likewise upon exposure to kainate. AMPA and kainate receptors can be securely distinguished from one another by their response to two drugs, cyclothiazide and the lectin concanavalin A [10]. Cyclothiazide relieves AMPA receptor desensitization without affecting kainate receptors.

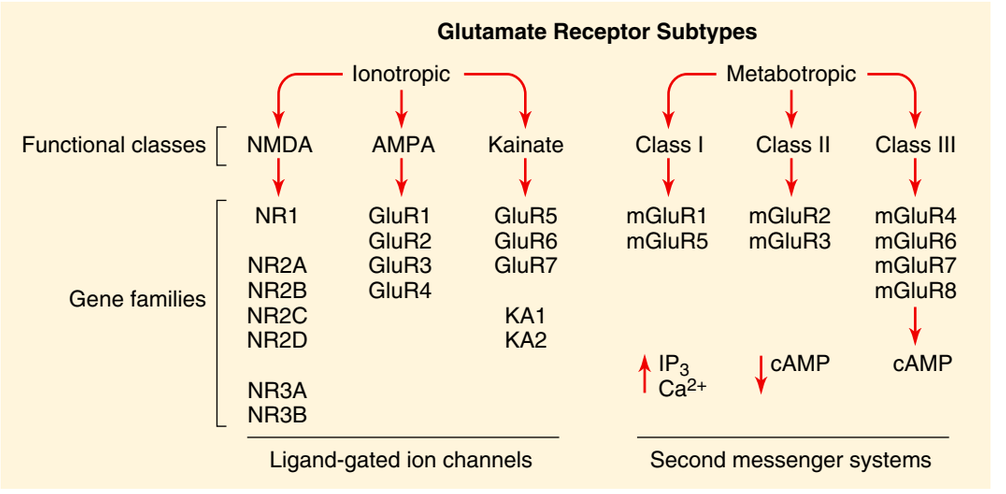

FIGURE 15-5 Molecular families of glutamate receptors. Each of the two main glutamate receptor divisions comprises three functionally defined groups (classes) of receptor. These are made up of numerous individual subunits, each encoded by a different gene.

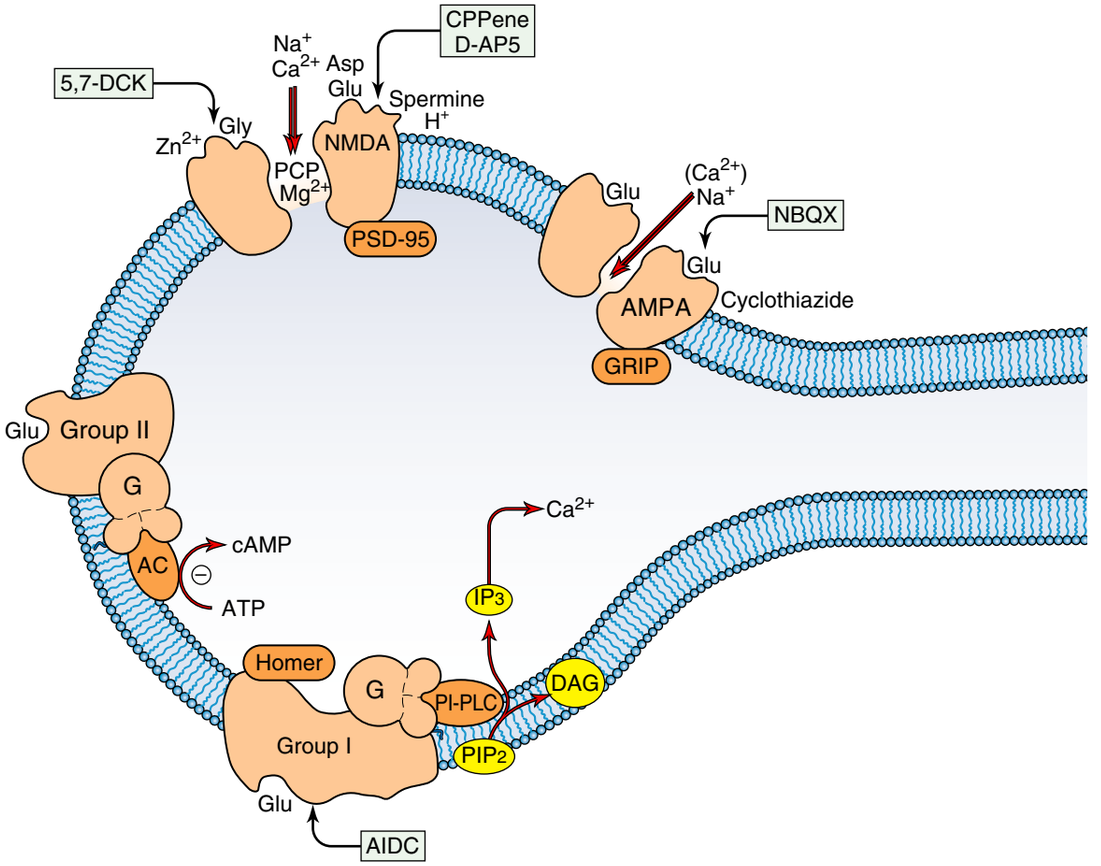

FIGURE 15-6 Schematic views of four types of glutamate receptor. Two heteromeric ionotropic receptors are shown, the NMDA and AMPA receptors, as well as group I and group II metabotropic receptors. Competitive antagonists of each receptor are boxed. The NMDA receptor channel is additionally blocked by Mg^{2+} and phencyclidine (*PCP*). Zn^{2+} is both a negative and a positive modulator. Protons suppress NMDA receptor activation, and polyamines, such as spermine, relieve the proton block. Cyclothiazide removes desensitization of AMPA receptors. Both classes of metabotropic receptor are coupled via G proteins (*G*) to intracellular enzymes, phosphoinositide-specific phospholipase C (*PI-PLC*) for group I receptors and adenylate cyclase (*AC*) for group II receptors. PI-PLC catalyzes the production of inositol-1,4,5-trisphosphate (IP_3) and diacylglycerol (*DAG*) from phosphatidylinositol-4,5-bisphosphate (*PIP2*). The resulting increase in cytoplasmic IP_3 triggers release of Ca^{2+} from intracellular stores. Activation of group II metabotropic glutamate receptors typically results in inhibition of AC. The cytoplasmic proteins PSD-95, GRIP and Homer anchor the receptors to the PSD complex. *AIDC*, 1-aminoindan-1,5-dicarboxylate; *5,7-DCK*, 5,7-dichlorokynurenic acid; *D-AP5*, D-2-amino-5-phosphonopentanoic acid; *CPPene*, 3-(2-carboxypiperazin-4-yl)1-propenyl-1-phosphoric acid; *NBQX*, 6-nitro 7-sulfamobenzo[f] quinoxaline-2,3-dione.

Conversely, concanavalin A relieves desensitization of kainate receptors, presumably via interaction with surface sugar chains, but has insignificant effects on AMPA receptors.

An important class of noncompetitive antagonists selective for AMPA receptors is represented by the 2,3-benzodiazepines such as GYKI 53655. These compounds act at sites different from those acted on by cyclothiazide and are useful tools for isolating synaptic responses mediated by kainate receptors. These compounds also show some promise as neuroprotective drugs for treating ischemic neuronal injury.

_N_-methyl-D-aspartate (NMDA) receptors have multiple regulatory sites. To date, three NMDA receptor subunit families have been identified, one represented by a single gene (NR1, encoding a protein of ≈900 amino acids), the second by four genes (NR2A–NR2D, ≈1450 amino acids) and the third by two known genes (NR3A–NR3B, about 1000 amino acids) (Fig. 15-5). Most if not all NMDA receptors in the brain are heteromeric receptors, as is likely to be the case with AMPA and kainate receptors. The mRNAs encoding most NMDA receptor subunits are differentially distributed, as are those of other glutamate receptors. Expression of NR1 mRNA is nearly ubiquitous in the CNS. In contrast, the four NR2 genes show differential patterns of expression (Fig. 15-7). NR2A is present throughout the forebrain and the cerebellum. NR2B and NR2C, however, have a more limited distribution. NR2B is expressed in highest levels in the forebrain and NR2C in the cerebellum where NR2B mRNA is not detected. NR2D expression seems virtually complementary to that of NR2A in being high in the midbrain and hindbrain but

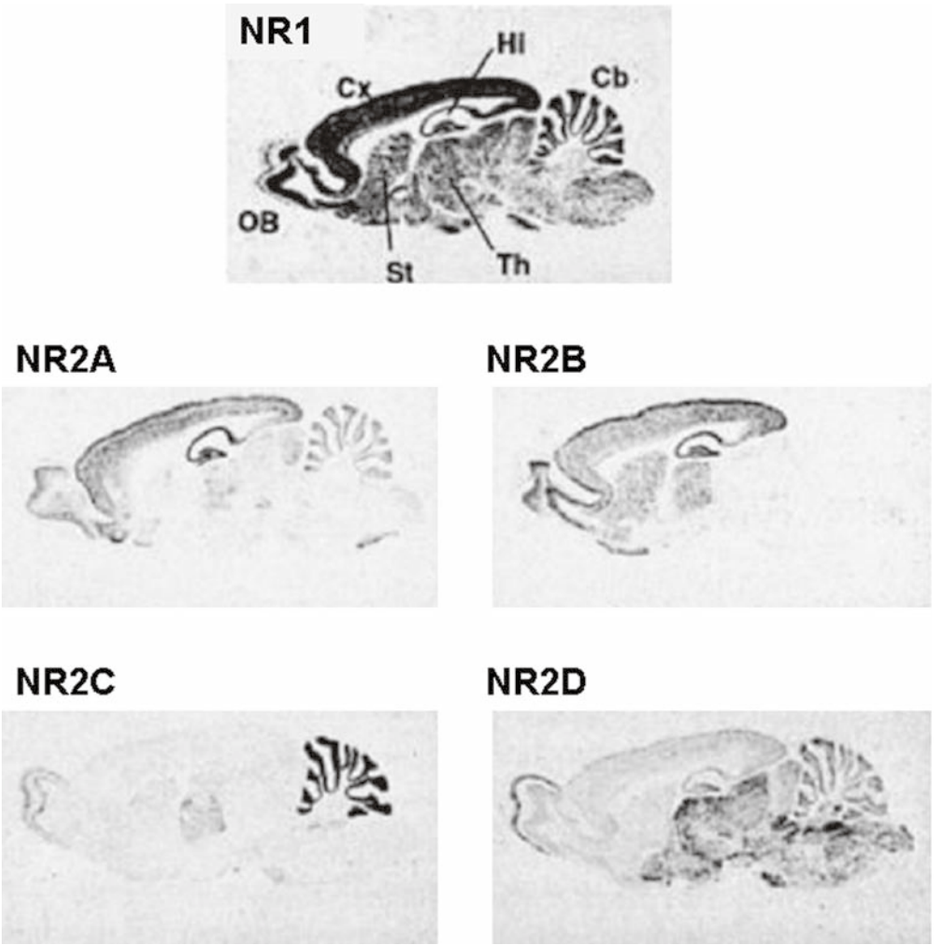

FIGURE 15-7 Regional distribution of mRNAs encoding the five NMDA receptor genes in adult rat brain, by *in situ* hybridization. *OB*, olfactory bulb; *Cx*, cortex; *Hi*, hippocampus; *Cb*, cerebellum; *Th*, thalamus; *St*, striatum. low in the forebrain. NR3A is expressed in the spinal cord and cortex, whereas NR3B is found mainly in motor neurons in the spinal cord, pons and medulla.

NMDA receptors are some of the most tightly regulated neurotransmitter receptors. There are no fewer than six distinct binding sites for endogenous ligands that influence the probability of ion channel opening (Fig. 15-6). These consist of recognition sites for two different agonists (glutamate and glycine) and a polyamine regulatory site, all of which promote receptor activation, and separate recognition sites for Mg^{2+}, Zn^{2+} and H^{+} that act to inhibit ion flux through receptors that have bound agonists. The redox state of the receptor also affects NMDA-receptor-mediated responses. One of the three pairs of cysteine residues may either be reduced (which enhances NMDA receptor-mediated currents) or oxidized and form disulfide bridges (which reduces currents).

NMDA receptor agonists are typically short-chain dicarboxylic amino acids such as glutamate, aspartate and NMDA. Acting at a site on the NR2 subunit, glutamate is the most potent endogenous agonist in the mammalian brain. NMDA itself, although a very selective agonist at these receptors, is 30 times less potent than glutamate in electrophysiological assays. Competitive antagonists of the glutamate recognition site are formed from the corresponding agonists by extending the carbon chain, sometimes in a ring structure and often including replacement of the ω-carboxyl group with a phosphonic acid group. Numerous competitive antagonists of this recognition site are available, notably D-2-amino-5-phosphonopentanoic acid (D-AP5) and 3-(2-carboxypiperazin-4-yl)1-propeny-1-phosphonic acid (2R-CPPene), the latter having a K_d of approximately 40 nmol/l in binding and functional studies. These compounds are polar and penetrate the blood–brain barrier only poorly, although recently several NMDA receptor blockers have been developed that have better access to the brain from the blood.

The NMDA receptor is unique among all known neurotransmitter receptors in its requirement for the simultaneous binding of two different agonists for activation. In addition to the conventional agonist-binding site typically occupied by glutamate, the binding of glycine to a

site on the NR1 subunit is required for receptor activation [7, 11]. Because neither glycine nor glutamate acting alone can open this ion channel, they are referred to as 'coagonists' of the NMDA receptor [11]. The glycine site on the NMDA receptor is pharmacologically distinct from the classical inhibitory glycine receptor (see Ch. 16) in that it is not blocked by strychnine and is not activated by β-alanine. Several small analogs of glycine, including serine and alanine, also act as agonists at this site. In both cases the D-isomer is 20–30-fold more potent than the L-isomer. D-serine, formed by serine racemase, is a potent endogenous agonist at the glycine site [12]. Bicyclic compounds and many derivatives of either kynurenic acid or quinoxalinedicarboxylic acid are competitive antagonists at the glycine site. Interestingly, most glycine site antagonists in these two series also block competitively the glutamate recognition site of AMPA receptors, suggesting possible structural similarities in the two ligand recognition sites. Halogenation of both ring structures typically induces a large increase in potency, with 5,7-dichlorokynurenic acid (5,7-DCK) being a potent (K_d = 60 nmol/l) and highly selective glycine-site antagonist.

Thus, glutamate and glycine act in concert to open NMDA receptor ion channels. In contrast, a very important brake on NMDA receptor activation is provided by extracellular Mg^{2+}, which exerts a voltage-dependent block of the open ion channel [13]. Other voltage-dependent blockers of NMDA receptor channels include MK-801, the anesthetic ketamine and the recreational drug of abuse phencyclidine (PCP). These blockers (and Mg^{2+}) exhibit varying degrees of voltage dependence and therefore probably recognize somewhat different domains in the channel of the NMDA receptor. Interestingly, the NR3A/NR3B subunits also possess a glycine binding site. Incorporation of an NR3 subunit into NMDA receptors reduces Ca^{2+} permeability of the receptor channel.

Another important endogenous allosteric inhibitor of NMDA receptor activation is H^+. Protons reduce the frequency of channel opening at NR2B-containing receptors over the physiological pH range, with a midpoint at pH 7.4. At pH 6.0, receptor activation is nearly completely suppressed [14]. This suggests that an ionizable histidine or cysteine may play a key role in receptor activation. One or more modulatory sites that bind polyamines such as spermine and spermidine are also found on NMDA receptors. Occupancy of one of the polyamine sites relieves tonic proton block and thus potentiates NMDA receptor activation in a pH-dependent manner [14]. At higher concentrations, however, polyamines produce a voltage-dependent block of the ion channel and thus inhibit ion flux through activated receptors.

In addition to the regulatory mechanisms discussed above, an interesting form of Ca^{2+}-dependent inactivation of NMDA receptors is brought about by calmodulin. Activated by Ca^{2+} entry, calmodulin interacts with the C-terminal domain of the NR1 subunit (Fig 15-4B); this interaction causes inactivation of the receptor manifested by reduced channel opening frequency and reduced channel open time [15]. The Ca^{2+}/calmodulin-dependent phosphatase calcineurin was also shown to inactivate NMDA receptors [16], suggesting a two-step process for modulation involving dephosphorylation of the NMDA receptor followed by binding of Ca^{2+}-calmodulin.

The transmembrane topology of glutamate receptors differs from that of nicotinic receptors. Knowledge about which segments of a receptor are intracellular, extracellular and transmembrane is necessary for identifying the ligand recognition sites, for understanding the mechanism by which ligand binding leads to channel opening, for interpreting mutagenesis data and for identifying potential targets for drug development. A variety of experimental approaches indicate that nicotinic receptor subunits have four transmembrane domains, with both N- and C-termini facing the extracellular fluid (Ch. 11). However, analysis of the AMPA receptor subunit GluR3 indicated only three transmembrane domains [7, 17]. Most interestingly, the channel-lining M2 domain, which harbors the Q/R site (see below), was found to be a re-entrant pore loop, with both ends facing the cytoplasm (Fig. 15-8A). Subsequent studies of NMDA receptor subunits provided evidence for a similar transmembrane topology [7,18], suggesting that the glutamate receptor family has a different topology from that of other ligand-gated ion channels typified by the nicotinic acetylcholine receptors.

Structure of the agonist binding site has been analyzed. Homology mapping of the glutamate receptors on to the crystal structure of bacterial amino-acid-binding proteins and functional evaluation of GluR3–GluR6 chimeras suggested that agonist binding requires portions of both the large N-terminus and a short region between M3 and M4. An important step forward was provided by Gouaux and collaborators, who crystallized a soluble fusion protein consisting of these two binding domains of the GluR2 subunit connected by a short amino acid linker [19]. The agonist binding pocket lies at the hinge region of a clamshell-like gorge (Fig 15-8B). Much has been learned about the mechanism of receptor activation by studying the structure of these two binding domains crystallized with different agonists and antagonists. Agonists contact residues on both upper and lower lobes of the clamshell (Figs 15-8C,D) and binding causes partial closure of the clamshell. The resulting torque on the receptor is thought to be transmitted mechanically to the pore region, flipping the channel into the open conformation (reviewed in [20]). Interestingly, partial agonists appear to cause less domain closure than full agonists and competitive antagonists work by binding in the pocket and preventing domain closure by a foot-in-the-door mechanism. The structure of the glycine binding site of the NR1 subunit has also been solved and, like the GluR2 binding pocket, the glycine binding site lies at the base of

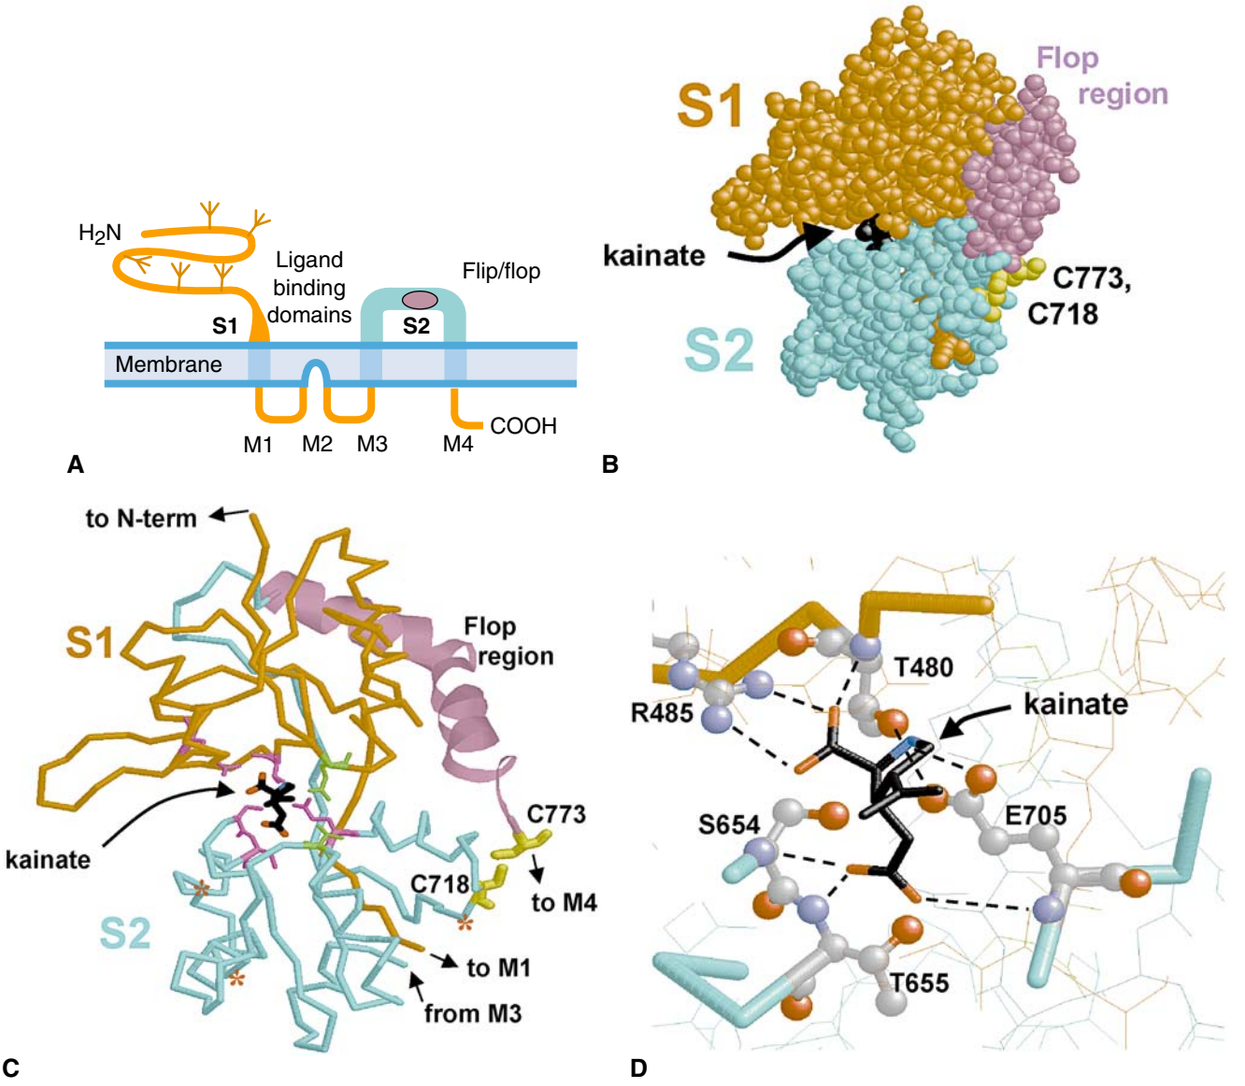

FIGURE 15-8 Transmembrane topology and binding pocket of glutamate receptors. The flip/flop region is indicated in *violet*. (**B**) Space-filled representation of the kainate-bound S1 and S2 domains of GluR2 joined by an 11-residue linker peptide, with coloration the same as in (**A**) The flop domain is helical and located on a solvent-exposed face of the protein. The position of a single-kainate agonist molecule (*black*) within a deep gorge of the protein is indicated; the two disulfide-bonded cysteines (C718 and C773) are shown in *yellow*. (**C**) Backbone representation of the subunit, with kainate (*black*) docked into its binding site. The kainate-binding residues are shown as stick figures in *magenta*, the two cysteines in *yellow* and the flop helix structure in *violet*. The two *green* residues (E402 and T686) do not directly bind to kainate but instead interact with each other, helping to hold the clamshell in the closed conformation.(**D**) Close-up view of the ligand-binding pocket. The binding residues are in space-filled representation, with atoms colored conventionally (*gray* carbon, *light blue* nitrogen, *red* oxygen), (Courtesy of E. Gouaux; from reference [7]).

a cleft between the two large extracellular lobes. A comparison of the GluR2 and NR1 binding pockets explains clearly the basis of agonist and antagonist selectivity.

Genetic regulation via splice variants and RNA editing further increases receptor heterogeneity: the flip/flop versions and the Q/R site. Splice variants that impart functional differences and/or different cellular expression patterns have been found for most of the glutamate receptor subunits. The first splice variants to be described were the so-called 'flip' and 'flop' versions of the AMPA receptor subunits GluR1–GluR4 [21]. The messenger RNA (mRNA) encoding each of these subunits exists in two versions differing by a 115 bp segment. Within this encoded cassette of 38 amino acids that lie in the extracellular loop between the M3 and M4 segments (Fig. 15-8), the two alternative versions differ by only 9–11 amino acids, mostly conservative substitutions. The flip and flop splice variants give rise to receptors that differ in desensitization rate and in their regional distribution in the brain. C-terminal splice isoforms of many glutamate receptor subunits also exist and control the

linkage to cytoskeletal proteins and their anchoring in the subsynaptic membrane. Alternative exon selection within the large N-terminal extracellular domain of NR1 influences many modulatory sites, including those sensitive to pH, Zn^{2+} and polyamines (e.g. spermine). Thus, alternative exon selection is used by neurons to fine-tune the properties of all three classes of ionotropic glutamate receptor.

An important form of regulation is achieved by editing of the primary RNA transcripts of the AMPA and kainate receptor subunits. AMPA receptors that contain the GluR2 subunit are much less permeable to Ca^{2+} than those assembled without GluR2. This important feature of GluR2 was traced by site-directed mutagenesis techniques to a single amino acid within the second membrane-associated domain [22]. A glutamine (Q) resides in this position in GluR1, GluR3 and GluR4, but an arginine (R) is present in GluR2 (Fig. 15-9); this site has thus been named the 'Q/R site'. In addition to Ca^{2+} permeability, the Q/R site influences single channel conductance and the sensitivity of the activated receptor to block by polyamine spider toxins and cytoplasmic polyamines. Voltage-dependent block by cytosolic polyamines gives rise to inward rectification of AMPA receptors with low GluR2 abundance. Interestingly, the genomic DNA sequence has a glutamine codon in the Q/R position, even for the GluR2 subunit in which the mature mRNA has an arginine codon in this site. A small family of double-stranded RNA adenosine deaminases are employed as 'editors' to control the amino acid encoded by this critical codon [23]. RNA editing of the Q/R and other sites, with associated changes in ionic permeability, have also been demonstrated for some kainate receptor subunits. The conditions under which neurons utilize RNA editing to regulate the permeability properties of their glutamate receptors remain to be demonstrated.

Given this combination of internal and C-terminus splice variants and site-specific RNA editing, it appears that four to eight or more mature RNAs can be made from each of the 16 known genes encoding mammalian ionotropic receptor subunits. Thus, neurons have a massive degree of flexibility in constructing a potentially huge number of receptors. The actual degree of glutamate receptor heterogeneity utilized by neurons remains a major unanswered question.

The permeation pathways of all ionotropic glutamate receptors are similar, but *vive la difference*. AMPA, kainate and NMDA receptors contain ion channels that conduct fluxes of Na^+ and Ca^{2+}, but ion selectivity depends on the subunit composition of the receptor. Current flow through AMPA receptors containing GluR2 is normally largely carried by the movement of Na^+ from the extracellular face to the intracellular compartment; these receptors have very low Ca^{2+} permeability. However, receptors that lack GluR2 are three to five times more permeable to Ca^{2+} than to Na^+, because of the absence of an arginine in the Q/R site, as mentioned above. An asparagine residing in the homologous site of all NMDA receptor subunits confers high Ca^{2+} permeability on these receptors [24]. Replacement by site-directed mutagenesis of this asparagine with an arginine produces NMDA receptors with very low Ca^{2+} permeability, similar to that of GluR2-containing AMPA receptors. An arginine or glutamine residing in the Q/R site of all known kainate receptor subunits also reduces the degree of Ca^{2+} permeability. Thus it is likely that the critical portion of the pore that forms the cation selectivity filter is similar among all glutamate receptors.

The permeation pathway of NMDA receptors has a property that sets them apart from other conventional ligand-gated receptors. At membrane potentials more negative (hyperpolarized) than about −50 mV, the concentration of Mg^{2+} in the extracellular fluid of the brain is sufficient to virtually abolish ion flux through NMDA receptor channels even in the presence of the coagonists glutamate and glycine [13] (Fig. 15-10C). Thus, although glutamate and glycine are bound to their receptive sites and the channel is 'activated', the entry of Mg^{2+} into the channel pore blocks the movement of ions through

the channel. In the presence of Mg^{2+} ions NMDA receptor channels exhibit a characteristic J-shaped current–voltage relationship. As the membrane potential is made less negative or even positive, the affinity of Mg^{2+} for its binding site decreases and the block becomes ineffective. Depolarization-induced relief from voltage-dependent channel block by Mg^{2+} is at the root of several of the most interesting aspects of NMDA receptor function (see below).

GLUTAMATE PRODUCES EXCITATORY POSTSYNAPTIC POTENTIALS

Both NMDA and AMPA receptor components of excitatory postsynaptic potentials (EPSPs) are produced by the brief (1 ms) appearance of free transmitter in the synaptic cleft (Fig 15-10A). Synaptically released glutamate thus

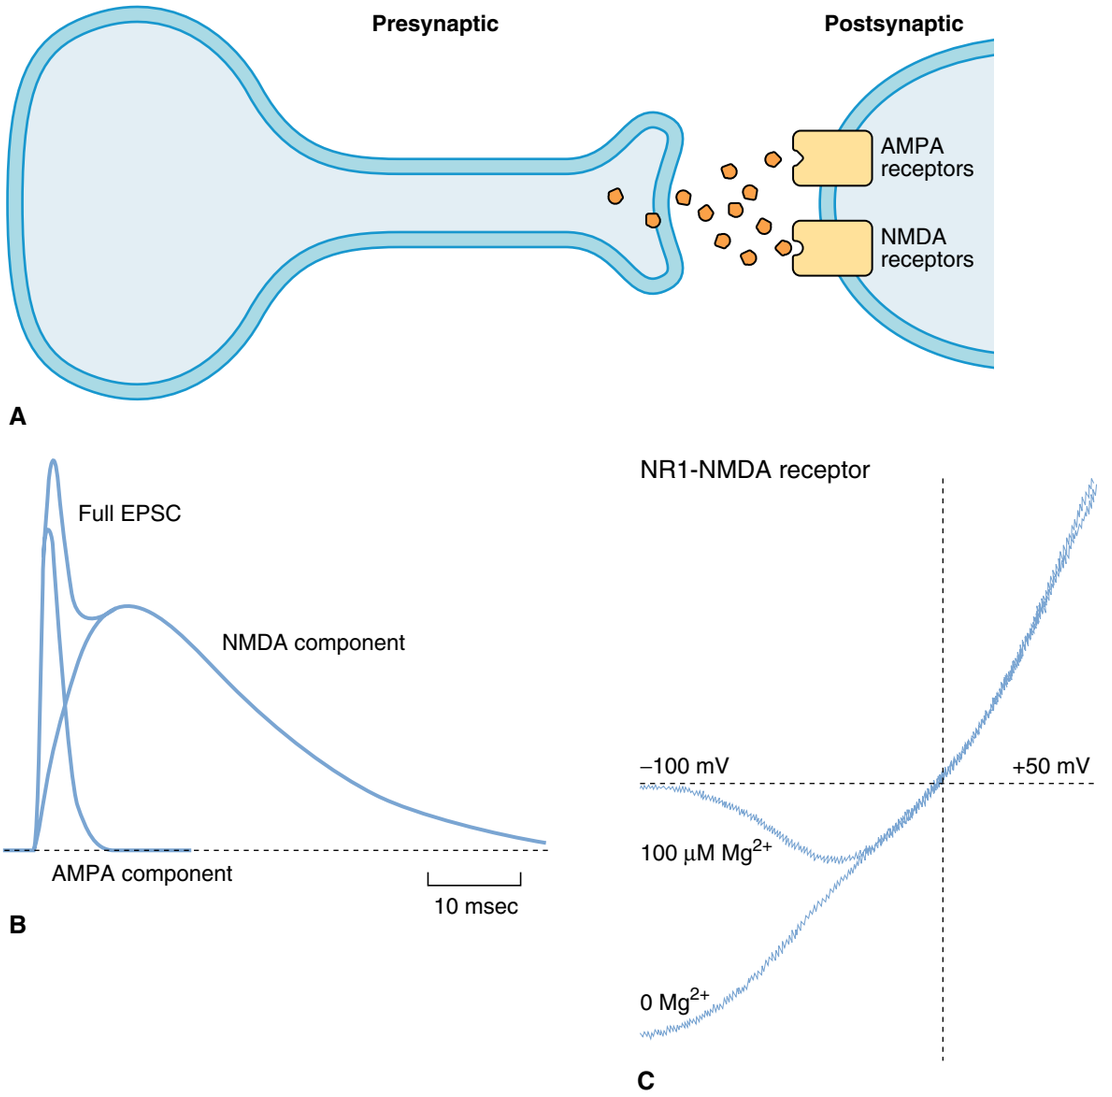

FIGURE 15-10 Biophysical properties of synaptic AMPA and NMDA receptors. (**A**) Diagram showing a postsynaptic cluster of NMDA and AMPA receptors and release of glutamate into the synaptic cleft. (**B**) Excitatory postsynaptic currents (EPSCs) of hippocampal neurons comprise both AMPA- and NMDA-receptor components. EPSCs are upward-going at positive membrane potentials. Treatment with the NMDA receptor blocker D-2-amino-5-phosphonopentanoic acid (D-AP5) or the AMPA receptor antagonist 6-nitro 7-sulfamobenzo[f] quinoxaline-2,3-dione (NBQX) reveals the other component in isolation, as shown. The EPSC is composed of a brief AMPA receptor component and a more prolonged NMDA component. (**C**) Current voltage relationships for NMDA receptors. Receptors can be expressed in *Xenopus* oocytes by microinjection of *in vitro* transcribed RNA encoding various glutamate-receptor subunits. Oocytes were voltage-clamped to permit measurement of ionic currents flowing across the plasma membrane following exposure to agonists. In the presence of an agonist, the membrane potential was slowly ramped from –100 to 50 mV and the membrane current recorded. The *horizontal dashed line* shows zero membrane current. Receptors formed from homomeric NRIA subunits exhibit a roughly linear current–voltage relationship in the absence of Mg^{2+} but, in the presence of Mg^{2+}, current flux through NMDA receptor channels becomes progressively smaller as the membrane potential is made more negative. At –100 mV, the NMDA-induced current is virtually abolished by Mg^{2+}.

results in a two-component excitatory postsynaptic current (EPSC) upon binding to AMPA and NMDA receptors at most central synapses (Fig. 15-10B). Activation of AMPA receptors mediates a component that has rapid onset and decay, whereas the component mediated by NMDA receptor activation has a slower rise time and a decay lasting up to several hundred milliseconds. Rapid desensitization of AMPA receptors may control the time course of EPSPs at many synapses. The long time course of NMDA receptor activation, by contrast, provides more opportunity for temporal and spatial summation of multiple inputs. The resulting summed depolarization may allow other synaptic inputs or nonsynaptic membrane channels to initiate action potential firing. The decay time of the NMDA receptor component is approximately 100 times longer than the mean open time of the channel, so before the bound ligands dissociate, the receptor cycles through the open and closed states many times. The more prolonged activation of NMDA receptors is thought to be due to the higher affinity of glutamate for NMDA than AMPA receptors; high affinity often results from a slow dissociation of the agonist from its receptor.

Genetic knockouts provide clues to ionotropic receptor functions. In most neurons, full editing of the GluR2 subunit mRNA ensures that synaptic AMPA receptors will permit only insignificant Ca^{2+} influx. However, mice engineered to harbor a GluR2 gene that cannot be edited at the mRNA level expressed AMPA receptors with increased calcium permeability [25]. These mice develop seizures and die by 3 weeks of age, demonstrating that GluR2 editing is essential for normal brain development. Moreover, deletion of the GluR2 editing enzyme, RAD1, by gene targeting is also lethal, and this phenotype can be rescued by expression of a GluR2 subunit that has arginine hard-coded into the Q/R site. These results indicate that GluR2 mRNA itself is the most important target of the RAD1 editor. Surprisingly, complete deletion of the GluR2 allele, which also increases Ca^{2+} permeability of AMPA receptors in the targeted mouse neurons, neither induced seizures nor proved lethal in homozygous mice. Rather, Ca^{2+} entry through GluR2-lacking synaptic AMPA receptors could produce a form of LTP [26]. These two genetic manipulations might have had such different outcomes because of different genetic backgrounds of the mice in the two studies. Alternatively, it is possible that a complete absence of GluR2 impairs AMPA receptor assembly, because the density of synaptic AMPA receptors appeared to be low in the latter study.

Conventional gene targeting of the NMDA receptor NR1 subunit interferes with breathing and is lethal within a few hours of birth. However, mouse strains in which the NR1 gene knockout is restricted to the CA1 region of the hippocampus survive and grow normally [27]. Remarkably, LTP is impaired in the CA1 but not in other hippocampal regions, and these mice exhibit impaired spatial memory in a water maze task. These findings demonstrate the essential role of NMDA receptors in LTP in the CA1 region, and also strongly suggest that LTP in the CA1 region is necessary for the acquisition of spatial memory.

METABOTROPIC GLUTAMATE RECEPTORS MODULATE SYNAPTIC TRANSMISSION

Eight metabotropic glutamate receptors (mGluRs) have been identified that embody three functional classes. Metabotropic glutamate receptors are so named because they are linked by trimeric G proteins to cytoplasmic enzymes [28]. To date eight mGluRs have been cloned and named mGluR1–mGluR8. The corresponding genes encode proteins that are thought to span the plasma membrane seven times and, like the ionotropic receptors, they possess an unusually large N-terminal extracellular domain preceding the membrane-spanning segments. mGluRs have been grouped into three functional classes based on amino-acid sequence homology, agonist pharmacology and the signal transduction pathways to which they are coupled (Fig 15-5). Members of each class share ≈70% sequence homology, with about 45% homology between classes. Alternatively spliced variants have been described for mGluR1, mGluR4, mGluR5 and mGluR7.

Glutamate itself activates all of the recombinant mGluR, but with widely varying potencies ranging from 2 nmol/l (mGluR8) to 1 mmol/l (mGluR7). Highly selective agonists for each of the three groups have been identified. 3,5-dihydroxyphenylglycine (DHPG) appears to be a selective group I agonist, 2R,4R-4-aminopyrrolidine-2–4-dicarboxylate (APDC) is highly selective and reasonably potent (400 nmol/l) agonist for group II, whereas L-amino-4-phosphonobutyrate (L-AP4) is a selective agonist of group III mGluR. Some phenylglycine derivatives are mGluR antagonists but highly group-selective antagonists remain to be identified.

mGluRs are linked to diverse cytoplasmic signaling enzymes. The classification of mGluR into three groups is further supported by a consideration of their signal transduction mechanisms. Group I mGluRs stimulate phospholipase C activity and the release of Ca^{2+} from cytoplasmic stores (Fig. 15-6). The ability to increase intracellular Ca^{2+} levels differs between the members of this class and their splice variants, a property probably attributable to the different affinities each receptor has for the G protein. Activation of phospholipase C leads not only to the formation of IP_3 but also diacylglycerol, which in turn activates protein kinase C (see Ch. 20). Activation of group II and group III mGluRs results in the inhibition of adenylate cyclase (Fig. 15-6). This response is blocked by pertussis toxin, which suggests that a G protein of the G_i family is involved (Chs 19 and 21).

Postsynaptic mGluR activation modulates ion channel activity. mGluR located on the postsynaptic membrane modulate a wide variety of ligand- and voltage-gated ion channels expressed on central neurons, as would be expected if receptor activation is coupled to multiple effector enzymes (ion channels are discussed in Ch. 6). Activation of all three classes of mGluR has been shown to inhibit L-type voltage-dependent Ca^{2+} channels, and both group I and II mGluR inhibit N-type Ca^{2+} channels. mGluR activation also decreases a high-threshold Ca^{2+} current in spiking neurons of *Xenopus* retina. Activation of mGluR closes voltage-dependent, Ca^{2+}-dependent K^+ channels in hippocampal and other cortical neurons, leading to slow depolarization and consequent neuronal excitation. The exact mechanism of mGluR modulation of K^+ currents is at present unclear but could occur through activation of CaMKII. In cerebellar granule cells, mGluR activation increases the activity of Ca^{2+}-dependent and inwardly rectifying K^+ channels, leading to a reduction in excitability.

A large number of ligand-gated channels are also modulated by mGluR activation including NMDA and kainate receptors as well as dopamine, $GABA_A$ and norepinephrine receptors. Whether activation of mGluR acts to inhibit or potentiate an ionotropic receptor depends on what component of the signal transduction mechanism is affected and this is often tissue-specific. For example, in hippocampal pyramidal cells group I, mGluR activation potentiates currents through NMDA receptors. This effect is reduced by inhibitors of either protein kinase C or src kinase, and may proceed through dual signaling pathways. In contrast, in cerebellar granule cells, mGluR activation inhibits NMDA-receptor-induced elevations of intracellular calcium also by a mechanism thought to involve PKC.

Presynaptic mGluR activation can lead to presynaptic inhibition. Immunohistochemical studies at both the light and electron microscopic level have firmly placed a number of mGluRs on the presynaptic terminals of central neurons. Activation of presynaptic mGluR blocks both excitatory glutamatergic and inhibitory GABAergic synaptic transmission in a variety of central structures. For example, activation of mGluR2 located on presynaptic granule cell terminals blocks EPSPs evoked in CA3 hippocampal pyramidal neurons by mossy fiber stimulation. In contrast, transmission at synapses between Schaffer collaterals and CA1 pyramidal cells is resistant to presynaptic mGluR2 activation but is blocked by activation of mGluR4 or 7, as suggested by the effect of L-AP4, an agonist of all group III mGluRs. The actual mechanism of how mGluR activation regulates synaptic transmission is unclear. However, because all three mGluR groups are known to inhibit voltage-dependent Ca^{2+} channels it seems probable that presynaptic Ca^{2+} channels are targets for mGluR modulation. A direct demonstration of this has been shown in presynaptic terminals of the calyx of Held in the brain stem, where mGluR agonists suppress a high-voltage-activated P/Q-type Ca^{2+} conductance, thereby inhibiting transmitter release at this glutamatergic synapse [29].

Genetic knockouts provide clues to mGluR functions. The ability to ascertain the precise physiological functions of mGluR has been hampered, in part, by the lack of sufficiently potent and selective pharmacological agents. The use of alternative strategies for the study of mGluR is therefore clearly warranted. To address this problem, several research groups have used gene targeting to produce 'knockout' mice that are devoid of the mGluR subtype of interest. These experiments point directly to a physiological role for a number of mGluRs. Establishment of specific neuronal connections in the mature nervous system occurs by a process in which redundant connections formed during development are eliminated. In the adult cerebellum, each Purkinje cell (PC) is innervated by a single climbing fiber (CF) that originates from the inferior olive of the medulla. This one-to-one relationship is preceded by a developmental stage in which each PC is innervated by multiple CFs. Massive elimination of synapses formed by CFs occurs postnatally, and a monosynaptic relationship is established at around postnatal day 20 in the mouse. Mice that lack the *mGluR1* gene show symptoms of cerebellar dysfunction such as ataxic gait, intention tremor and dysmetria, and they are impaired in motor coordination and motor learning [30]. These mutant mice are deficient in long-term depression (LTD) at CF-PC synapses; LTD in the cerebellum is thought to be a cellular basis for motor learning. In these *mGluR1* mutant mice, innervation of multiple CFs onto a PC persists into adulthood, suggesting that the precise sculpting of these synaptic connections requires activation of mGluR1 during development.

The strong expression of mGluR2 in dentate gyrus granule cells has suggested a role for this receptor in presynaptic regulation of transmission at the mossy fiber–CA3 pyramidal neuron synapses as described above. In mice lacking the *mGluR2* gene, basal synaptic transmission was indistinguishable from wild-type responses. In contrast, presynaptic inhibition at mossy fiber synapses induced by the mGluR2 agonist DCG-IV was markedly reduced in the mutant mice, confirming a role for mGluR2 receptors in the presynaptic regulation of neurotransmission. Interestingly, this mGluR2 deficiency was without effect on the magnitude of LTP induced at these synapses, but LTD was significantly impaired [31]. In a variety of CNS structures including the hippocampus, olfactory tract, spinal cord and thalamus, activation of presynaptically located Group III mGluRs by L-AP4 inhibits synaptic transmission. One member of this group, mGluR4, is preferentially expressed in the cerebellum and has a role in the presynaptic regulation of synaptic transmission. Targeted elimination of the *mGluR4* gene reveals that mGluR4 is essential in providing a presynaptic mechanism for maintaining synaptic efficacy during repetitive

activation, and suggests that the presence of mGluR4 at the parallel fiber–PC synapse is required for maintaining normal motor function [32]. Likewise, mGluR8 seems to be the exclusive mediator of presynaptic inhibition at the lateral perforant path in the mouse.

GLUTAMATE RECEPTORS DIFFER IN THEIR POSTSYNAPTIC DISTRIBUTION

NMDA and AMPA receptors are spread across the postsynaptic density (PSD), whereas metabotropic glutamate receptors (except mGluR7) are located along the periphery of the PSD (Fig. 15-2). NMDA receptors appear to be present at most or all glutamatergic synapses whereas the content of AMPA receptors is variable – from zero to about 50 receptors per PSD [33]. Some synapses are 'silent', meaning that activation of them does not elicit AMPA receptor currents when the plasma membrane is hyperpolarized and Mg^{2+} blocks NMDA receptors. Such silent synapses contain only NMDA receptors. However, AMPA receptors are recruited from the cytosol to the PSD to activate such silent synapses in LTP.

PROTEINS OF THE POSTSYNAPTIC DENSITY MEDIATE INTRACELLULAR EFFECTS OF GLUTAMATE RECEPTOR ACTIVATION

The PSD is a multiprotein complex with many functions (Fig. 15-4B). From the perspective of glutamatergic neurotransmission it may be viewed as a signal transduction machine that converts the extracellular glutamate signal into various intracellular signals. Apart from glutamate receptors, the PSD contains ion channels, glycolytic enzymes, transporters (e.g. a lactate transporter), proteins of intracellular signaling pathways, cell adhesion molecules and scaffolding proteins that link the proteins of the PSD together. Some of the proteins of the PSD are made lipophilic by the binding of two palmitic acid residues. Therefore they have an affinity for so-called lipid rafts, small areas of the plasma membrane that are rich in cholesterol and sphingomyelin [34]. Such rafts are present in dendritic spines and help to concentrate proteins of the PSD at the spines (Fig. 15-4B).

A major scaffolding protein of the PSD is PSD95. Two N-terminal cysteines of this protein bind palmitic acid residues, which anchor PSD95 to lipid rafts [30]. PSD95 contains several domains that bind other proteins: three so-called PDZ domains (short for PSD95/disc large/zona occludens-1), a src homology (SH3) domain, and a guanylate kinase (GK) domain. This family of proteins are called MAGUKs (membrane-associated guanylate kinases, although the guanylate kinase domain is catalytically inactive). PDZ domains are stretches of about 90 amino acids that bind C-termini of other proteins.

Neuroligin is a protein that binds to the PDZs of PSD95. Neuroligin reaches into the synaptic cleft and interacts with β-neurexin, a protein that reaches into the synaptic cleft from the presynaptic side; β-neurexin is anchored presynaptically to the PDZ domain of another MAGUK, CASK. This arrangement connects the pre- and postsynaptic elements and stabilizes the synapse mechanically.

The NR2 subunit of the NMDA receptor binds to PDZ domains of PSD95 with its cytoplasmic C-terminus. PSD95 also binds α-actinin, which again binds to filamentous actin (F-actin), a main cytoskeletal protein in dendritic spines. In this manner PSD95 anchors the NMDA receptor to the cytoskeleton of the dendritic spine.

PSD95 also couples the NMDA receptor to intracellular signaling systems that mediate intracellular effects of NMDA receptor activation. Calcium ions that enter the postsynaptic cell through the NMDA receptor bind to calmodulin probably at all glutamatergic synapses. Calmodulin with bound Ca^{2+} activates a protein kinase, Ca^{2+}/calmodulin-dependent kinase II (CaM kinase II). CaM kinase II is one of the most abundant proteins at the PSD; it connects to α-actinin via the scaffolding protein densin. Activated CaM kinase II can phosphorylate a host of other proteins. One such protein is the GluR1 subunit of the AMPA receptor, which is phosphorylated on a serine residue (ser 831). Phosphorylation of GluR1 by CaM kinase II increases the conductance of the AMPA receptor, which is one mechanism that contributes to potentiation of glutamatergic synapses.

The Ca^{2+}–calmodulin complex may also activate nitric oxide synthase (NOS), which binds to a PDZ domain of PSD-95. Activated NOS produces NO from arginine; NO, in turn, activates guanylate cyclase, the enzyme that catalyzes the conversion of GTP to the intracellular messenger cGMP, which activates protein kinase G (PKG).

AKAP (A-kinase anchor protein) is another scaffolding protein of the PSD. AKAP binds PKA (protein kinase A), PKC (protein kinase C), and the protein phosphatase calcineurin (PP2B) as well as the SH3 and GK domains of PSD95. This arrangement ensures a close proximity of NMDA receptors to PKA. Calcium influx through the NMDA receptor causes Ca^{2+}/calmodulin activation of adenylate cyclase and formation of cAMP. cAMP activates PKA, which, among other things, phosphorylates GluR1 on serine 845; this phosphorylation is necessary for recruitment of AMPA receptors to the plasma membrane of the dendritic spine. In fact, AMPA receptors are to a variable degree located intracellularly, whence they may be recruited to the postsynaptic membrane to strengthen the synapse during induction of LTP. Long-term depression of glutamatergic synapses, which is also mediated by NMDA

receptor activation, involves Ca^{2+}-dependent activation of the phosphatase calcineurin, which causes the dephosphorylation of GluR1 on serine 845 [35]. The result of this dephosphorylation is the relocation of AMPA receptors from the plasma membrane to the cytosol.

AMPA receptors do not appear to bind directly to PSD95, but may do so indirectly through other proteins, such as TARPs (*trans*-membrane AMPA-R regulatory proteins), and this interaction appears necessary for the recruitment of AMPA receptors from the intracellular pool to the PSD. The C termini of AMPA receptors bind directly to other PSD proteins with PDZ domains: GRIP (glutamate receptor-interacting protein), PICK1 (protein interacting with C kinase 1), ABP (AMPA receptor-binding protein) and SAP97 (synapse-associated protein of 97 kDa). GRIP is another protein that is palmitoylated and therefore has an affinity for lipid rafts [34].

GRIP, PICK1 and PSD95 also interact with kainate receptor subunits GluR5 and 6. PKC, which binds to PICK1, may phosphorylate these subunits, thereby causing them to anchor more stably at the synapse, a mechanism that could strengthen kainate receptor-mediated transmission.

Metabotropic glutamate receptors are anchored to the periphery of the PSD by the scaffolding proteins homer and shank (Fig. 15-4). Homer is a cytoplasmic protein that may multimerize and link proteins that have homer-binding motifs, such as mGluRs and shank. Shank binds to the GK domain of PSD95 and thus links mGluRs to PSD95. Through homer, mGluRs also connect to the IP_3 receptor (1,4,5-trisphosphate receptors) [36]; the activation of the IP_3 receptor by IP_3 causes the release of Ca^{2+} from the smooth endoplasmic reticulum (Ch. 20). The proximity of mGluRs and IP_3 receptors ensures that the IP_3 that is formed upon stimulation of type I mGluRs reaches the IP_3 receptor. Similar arrangements occur presynaptically, where mGluR7a binds to the PDZ domain of PICK1.

SMALL GTP-BINDING PROTEINS (GTPases) MEDIATE CHANGES IN GENE EXPRESSION UPON NMDA RECEPTOR ACTIVATION

Synaptic plasticity manifesting as LTP or LTD depends in part on formation of new proteins, which requires transcription of specific genes. Activation of NMDA receptors during LTP may cause more than a hundred genes to be transcribed, resulting in the formation of mRNAs. Some genes are turned on immediately upon NMDA receptor activation, others are activated later. The genes encode transcription factors, AMPA receptor subunits, cytoskeletal proteins, intracellular signaling molecules, ion pumps, and enzymes of energy metabolism [37] (see also Ch. 26).

The intracellular mechanisms that relay glutamate receptor activation to transcription constitute a much-studied field. Small, monomeric GTPases are important activators or silencers of signaling pathways that lead to changes in gene transcription. A final step in these pathways is the activation of transcription factors that cause initiation of transcription.

Ras is a small GTPase that is central in mediating alteration of gene transcription upon NMDA receptor activation. Ras stimulates several intracellular signaling pathways, including the Raf–MEK–ERK pathway and the PI3 kinase (phosphoinositide 3-OH kinase) pathway, the latter leading to activation of protein kinase B (Akt/PKB) as well as the MEKK–JNKK–JNK pathway. Phosphorylated (activated) ERK translocates from the cytosol to the nucleus, where it activates the transcription factors Elk and CREB. Akt/PKB activation leads to the activation and nuclear translocation of transcription factors NFκB and CREB. Activation and nuclear translocation of JNK lead to the activation of the transcription factors c-Jun, c-Fos and ATF2.

Small GTPases, such as Ras, cycle between an active GTP-bound state and an inactive GDP-bound state (Ch. 19). They are regulated by activating GEFs (guanyl exchange factors) and inhibitory GAPs (GTPase activating proteins). GEFs stimulate the exchange of GDP for GTP, which enables the GTPases to bind to their effector proteins. GAPs stimulate the GTPases to hydrolyze their bound GTP to GDP, which causes them to lose signaling activity. GEFs and GAPs may become activated through binding of calcium ions, Ca^{2+}/calmodulin and/or diacylglycerol. A Ras-specific GAP, synGAP (synaptic GAP), binds to PSD95. A Ras GEF has been identified that associates with NMDA receptor subunit NR2B [38]. Thus, glutamate receptor activation may activate both GAPs and GEFs to modulate the activity of Ras and its downstream effectors. Recent evidence suggests that NMDA receptor-triggered activation of Ras and Raf kinases mediates LTP and LTD, respectively, by facilitating the insertion or removal of AMPA receptors in the postsynaptic membrane ([39] for review).

An enigma of LTP research has been how the neuron comes to strengthen just the activated synapse and not all its synapses, since the mRNA made in the cell body will tend to become distributed throughout the cell. An answer seems to be that the LTP-inducing stimulus, in addition to activating genes in the cell body, marks the synapse where the mRNAs are to be translated into protein. The 'mark' may be the activation of cytoplasmic polyadenylation element binding protein (CPEB) by phosphorylation [40]. CPEB, a component of the PSD that binds to the 3′ end of translationally dormant mRNAs, is phosphorylated upon NMDA receptor activation and initiates a process that causes elongation of the mRNA poly (A) tail. This polyadenylation of the mRNAs triggers their translation into protein only at the potentiated synapse.

DENDRITIC SPINES ARE MOTILE, CHANGING THEIR SHAPE AND SIZE IN RESPONSE TO SYNAPTIC ACTIVITY WITHIN MINUTES

Intense synaptic activity leads to enlargement of the dendritic spine and the PSD. Although the pathways that regulate spine morphology in response to synaptic activity are not fully known, influx of calcium ions through the NMDA receptor is an important first signal and modulation of actin is a final result. Interestingly, overexpression of the GluR2 AMPA receptor subunit increases the number and size of spines in cortical neurons, whereas GluR2 depletion causes spine retraction [41]. This effect was traced to a region in the GluR2 N-terminus, which probably interacts with another extracellular protein. The spines are highly motile structures. Most of the actin of the dendritic spine is broken down and rebuilt within a minute. Small GTPases of the Rho family regulate actin morphology [42]. Among them, Rac and Cdc42 promote outgrowth of the actin cytoskeleton to create or enlarge spines, whereas activation of Rho itself has been shown to cause a loss of spines. The balance between Rac and Cdc42 on the one hand and Rho on the other is therefore important in controlling spine morphology in response to NMDA receptor activation. Rho GEFs have been identified that bind to PSD-95. Citron, a downstream effector of Rho, also binds to PSD95. In addition, both Rac and Cdc42 may be activated through Ras-dependent pathways.

SODIUM-DEPENDENT SYMPORTERS IN THE PLASMA MEMBRANES CLEAR GLUTAMATE FROM THE EXTRACELLULAR SPACE

The area of the synaptic cleft is approximately $0.1\,\mu m^2$ and the width is ≈20 nm, which gives a volume of approximately 2×10^{-18} liter, 100 times greater than that of a synaptic vesicle. Therefore, the concentration of glutamate in the cleft when a vesicle has emptied its content will be in the low millimolar range. Rapid removal of glutamate from the extracellular space is important for the synapse to function properly on a millisecond time scale and to avoid overexcitation of the postsynaptic cell. This is accomplished by diffusion of glutamate out of the synaptic cleft; however, to maintain a gradient for diffusion glutamate must be actively removed from the extracellular fluid.

Removal of glutamate occurs by both high-affinity transporters (with K_ms in the low micromolar range) and low-affinity transporters (with K_ms around 0.5 mmol/l). Only the former have been characterized on a molecular level. Glutamate removal has two components: binding of glutamate to the transporters and translocation to the interior of the cell. Binding is an important component, as the following calculation will show: The density of glutamatergic synapses in gray matter is roughly $1/\mu m^3$. A bouton may release the content of about 2–5 vesicles per second. With a content of ≈1,200 molecules of glutamate per vesicle, the amount of glutamate released per second would be 2,500–6,000. In the same volume 15,000–20,000 glutamate transporters may be present [43]. Therefore, binding of glutamate to transporters is a rapid form of inactivation. The translocation of glutamate to the interior of the cell may take only a few additional milliseconds.

The high density of glutamate transporters and the tendency for astrocytic processes to cover the synaptic cleft (Fig. 15-2) controls the degree of spillover of glutamate into neighboring synapses. Spillover of glutamate from one synapse to another does occur, however, and has been shown to modulate transmission at nearby synapses, both glutamatergic, GABAergic and monoaminergic. Modulation of GABAergic and monoaminergic neurotransmission through spillover of glutamate occurs through activation of presynaptic metabotropic glutamate receptors on nerve terminals.

Five high-affinity glutamate transporters have been identified. They are termed EAAT 1–5 (for excitatory amino acid transporter). EAAT2 is the principal transporter in the forebrain; it is present in both astrocytes and nerve terminals (Fig. 15-2). EAAT1 is only present in astrocytes; it is abundant in cerebellum but is also expressed in the forebrain. EAAT3 is expressed in neurons in the whole brain and is found presynaptically on GABAergic nerve terminals, whereas EAAT4 is largely expressed on dendrites of cerebellar Purkinje cells. EAAT5 is expressed in retina. In the rat EAAT1–3 are termed GLAST, GLT and EAAC1, respectively; EAAT4 and 5 have the same names in man and rat.

The high density of glutamate transporters means that they may compete with glutamate receptors for binding of transmitter glutamate and thus modulate the glutamate signal. The density of glutamate transporters at the cell membrane as well as their affinity for glutamate are probably subject to regulation. Activation of PKC leads to a loss of EAAT2 from the cell membrane but causes an increase of EAAT3 in the cell membrane. Glutamate transporter-associated proteins (GTRAPs) have been identified that bind to and regulate the affinity of transporters for glutamate.

Electron microscopic studies with immunocytochemical detection of glutamate transporters show that the majority of the transporters are localized in astrocytic cell membranes, and it is generally assumed that most transmitter glutamate gets taken up by astrocytes as a part of the glutamine cycle (see above). However, when brain slices are exposed to the glutamate analog D-aspartate, this compound is found in nerve terminals, not primarily in astrocytes. Therefore, there is some uncertainty regarding

the quantitative importance of astrocytes versus neurons for uptake of transmitter glutamate.

The uptake of glutamate occurs against its concentration gradient and so needs a driving force, which is provided primarily by the sodium electrochemical gradient across the plasma membrane. Glutamate enters cells together with three sodium ions and one proton; one potassium ion is counter-transported [43]. Uptake of glutamate is therefore electrogenic, resulting in a net movement of positive charge across the plasma membrane. The glutamate transporters also act as chloride channels, but the chloride conductance is not coupled to the transport of glutamate.

Because glutamate uptake is driven by cation gradients it is a secondarily active process that relies on the activity of the sodium-potassium ATPase (Ch. 5). For each molecule of glutamate that is taken up, one molecule of ATP is spent on the extrusion of the three sodium ions in exchange for two potassium ions. In addition, one molecule of ATP is spent if glutamate is converted into glutamine in astrocytes by the ATP-dependent glutamine synthetase. Several studies suggest that this energy expenditure is covered by increased glycolysis. Glycolysis gives two molecules of ATP per molecule of glucose that is converted to lactate. Excess lactate exits the astrocytes to the extracellular fluid and enters neurons where it is used as an energy source [44] (see also Ch. 31).

SODIUM-DEPENDENT GLUTAMINE TRANSPORTERS IN PLASMA MEMBRANES MEDIATE THE TRANSFER OF GLUTAMINE FROM ASTROCYTES TO NEURONS

Astrocytes convert much of transmitter glutamate into glutamine, and glutamine is exported to the extracellular space from which neurons accumulate it. Both astrocytes and neurons have transporters that are sodium-driven and that concentrate glutamine inside the cells. The astrocytic and neuronal transporters are called system N transporters (SN) and system A transporters (SA), respectively (Fig. 15-2). They are closely related, but the astrocytic SN transporter exchanges a proton for sodium and does therefore not carry a net charge into the cell. It therefore depends entirely on the chemical component of the sodium gradient. This feature allows for transporter reversal when the sodium gradient becomes reduced, as would occur when astrocytes depolarize, so that some glutamine may leak out of the astrocytes into the extracellular fluid. An increase in intracellular glutamine or pH (reduction in $[H^+]$) would contribute in the same direction. System A transporters do not exchange a proton for sodium and therefore carry a net charge into the neuron. Therefore system A transporters are driven by both the sodium gradient and the membrane potential, which makes them less likely to leak glutamine to the extracellular fluid [45]. The net effect of SN being more leaky than SA is a flux of glutamine from astrocytes to neurons.

EXCESSIVE GLUTAMATE RECEPTOR ACTIVATION MAY MEDIATE CERTAIN NEUROLOGICAL DISORDERS

Glutamate and its analogs can be neurotoxins and cause excitotoxicity. Glutamate and structurally related ligands, such as NMDA and kainate, in addition to their powerful excitatory effects at glutamate receptors, are potent neurotoxins (see also Ch. 32). The toxic effect of glutamate and its analogs is related to their excitatory properties at glutamate receptors, and this type of toxicity is therefore called excitotoxicity. That glutamate and other amino acids act as neurotoxins was first realized in the 1970s when these agents were given orally to immature animals. Acute neurodegeneration was observed in those areas not well protected by the blood–brain barrier, notably the arcuate nucleus of the hypothalamus. The mechanisms of neurodegeneration are divergent, and activation of all classes of ionotropic glutamate receptor has been implicated.

Intracerebroventricular injection of kainic acid has been shown to result in a well-characterized pattern of neuronal cell damage. In the hippocampus, kainic acid causes a selective lesion of the CA3 pyramidal neurons, an area rich in KA1 and GluR6 receptors. The lesion does not compromise passing axons, which is why this type of (excitotoxic) lesion is often referred to as 'axon-sparing'. Kainic acid injection into the hippocampus also leads to epileptiform discharges in cells normally innervated by the damaged pyramidal neurons.

Some dietary neurotoxins may cause excessive glutamate receptor activation and cell death. Some rare food contaminants are glutamate analogs and cause excessive glutamate receptor activation leading to neuronal cell death. Domoic acid is a shellfish poison that potently activates kainate receptors and produces seizures and death or, if the patient survives, chronic memory impairment because of damage to the hippocampus. Amyotrophic lateral sclerosis (ALS) is a disorder that entails degeneration of upper and lower motor neurons (in the motor cortex and spinal cord/medulla oblongata respectively). While 90% of cases are sporadic, 10% are hereditary. The high incidence of ALS in the Pacific island of Guam was determined to be due to the dietary ingestion of the cycad *Cycas circinalis*. This seed contains an amino acid, β-*N*-methylamino-L-alanine (BMAA). In the presence of bicarbonate, BMAA becomes excitotoxic through a mechanism that involves the activation of AMPA and NMDA receptors. The action of BMAA can be blocked

by the NMDA receptor antagonist D-AP5. Another disorder that also primarily affects upper and lower motor neurons is neurolathyrism, a disorder occurring in East Africa and India. It is associated with the dietary consumption of the chick pea *Lathyrus sativus*. The glutamate-like excitant β-*N*-oxalylamino-L-alanine (BOAA) has been identified as the toxin in this plant. The action of BOAA at AMPA receptors may be responsible for the observed degeneration of motor neurons (see Motor Neuron Diseases, Ch. 44).

A mold that has been reported to contaminate sugar cane in China produces nitropropionic acid, a toxin that causes destruction mainly of the basal ganglia if ingested. Nitropropionic acid is not a glutamate analog, but an inhibitor of succinate dehydrogenase of the TCA cycle. The toxin causes ATP depletion and secondary loss of ion gradients that drive the glutamate transporters; the result is extracellular accumulation of glutamate and excessive stimulation of glutamate receptors, which leads to neuronal death. Such over-stimulation of glutamate receptors caused by energy failure is typical even in hypoxia and ischemia, as discussed below.

Glutamate-mediated excitotoxicity contributes to ischemic neuronal death. Glutamate-mediated toxicity is a central event in several acute brain disorders. In stroke, cardiac arrest, drowning and pre- or perinatal hypoxia/ischemia the delivery of oxygen and glucose to the brain is impaired. As a result, ATP production and energy-dependent processes are inhibited and, most importantly, the maintenance of ion gradients across plasma, vesicular, mitochondrial and endoplasmatic membranes are dissipated. With respect to glutamate this situation means that the transporters of the plasma membrane, which are driven by the sodium gradient, reverse and let glutamate out into the extracellular space (Fig. 15-11; see Ch. 32). Transporter reversal occurs rapidly after inhibition of ATP formation, since the half-life of ATP in the brain is only a few seconds. Because of the lack of ATP, vesicular release of glutamate (an ATP-dependent process) probably does not contribute much to the high extracellular levels of glutamate during energy deficiency. Massive activation of glutamate receptors with influx of sodium and calcium ions follows from the high extracellular levels of glutamate. The influx of sodium, which secondarily causes influx of chloride and water, leads to intracellular edema, which may cause rupture of the cell membrane and lysis of the cell.

The influx of calcium causes a multitude of effects, although the many phosphorylation-dependent processes that are normally triggered by calcium influx must be inhibited during energy failure because of the rapid depletion of ATP and GTP. Calcium influx may cause formation of reactive oxygen species, such as NO through the activation of NO synthase and superoxide through the activation of xanthine oxidase or through the derangement of the electron transport chain of the mitochondria.

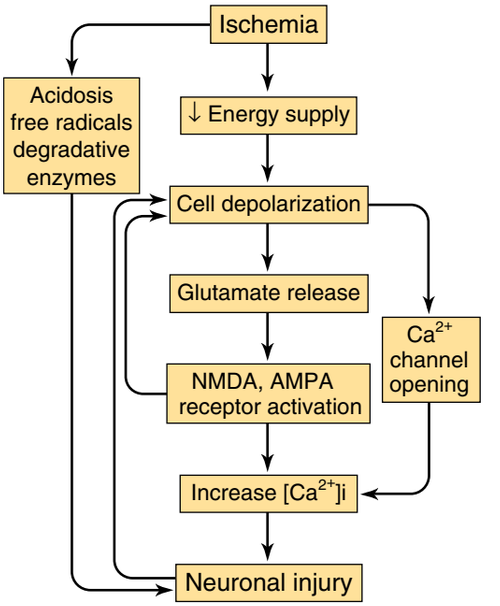

FIGURE 15-11 Potential paths leading to neuronal injury resulting from an episode of ischemic insult. An ischemic episode initiates a complex pathway involving the depletion of cellular energy stores and the release of free radicals. The energy depletion permits sustained activation of glutamate receptors and the consequent entry of Ca^{2+} via NMDA receptors, (GluR2-lacking) AMPA receptors and voltage-gated Ca^{2+} channels. Elevation of intracellular Ca^{2+} causes excessive activation of a variety of Ca^{2+}-dependent enzymes. Excessive neuronal depolarization results in neuronal injury and often cell death.

NO may react with superoxide to yield the highly reactive peroxynitrite, $ONOO^-$. Superoxide may also be converted into H_2O_2 and the reactive hydroxyl radical, •OH. In this way excessive activation of glutamate receptors leads to oxidative damage. The calcium influx has a major effect on mitochondria and causes them to depolarize and swell. This leads to a pore being formed in the outer mitochondrial membrane, which allows the escape of cytochrome c and procaspases from the mitochondria into the cytosol. Cytochrome c activates the caspase cascade, which leads to apoptotic cell death (Ch. 35).

Inhibition of glutamate receptors may ameliorate excitotoxicity. The important role of glutamate in ischemic and hypoxic brain damage is illustrated by the protective effect that antagonists of glutamate receptors have. In animal models of stroke antagonists of NMDA receptors or AMPA receptors reduce the volume of the infarct by approximately 50% and may be effective even when given several hours after the initial insult. Unfortunately, such antagonists have not yet proved useful in humans, partly because the infarct volumes tend to be greater and more variable in humans and the antagonists do not penetrate readily into the ischemic tissue, partly because some glutamate antagonists cause side effects, such as hypotension, ataxia and cognitive disturbances, that have sidelined their clinical development.

Ischemic tissue is acidotic because of accumulation of lactate and other acidic metabolites. A low pH is generally detrimental for brain tissue but should shut down certain splice variants of NMDA receptors, as described above. Interestingly, neuroprotective drugs in the ifenprodil class inhibit NMDA receptors by shifting the pK for the proton-accepting group in an alkaline direction, such that at physiological pH protons occupy a larger fraction of the proton sites and thus render a larger fraction of NMDA receptors unavailable for activation.

Epileptiform activity involves glutamate receptor activation. Involvement of excitatory amino acids in epilepsy is well documented. A large number of animal models of epilepsy have clearly implicated a central role for the glutamate receptor family (see Ch. 37). Excessive stimulation of glutamatergic pathways, block of glutamate transporters or pharmacological manipulation resulting in glutamate receptor activation can precipitate seizures. Epileptiform activity usually begins with excessive AMPA receptor activation; as seizure activity intensifies, an increased involvement of NMDA receptors is observed. Results of studies with a variety of animal models have shown that NMDA receptor antagonists can reduce the intensity and duration of seizure activity. Antagonism of AMPA receptor activation usually prevents initiation of the seizure. This suggests that epileptiform activity depends on the interplay between synaptic AMPA and NMDA receptors. Evidence from human tissue supports the role of glutamate receptors in epilepsy. For example, in patients with refractory complex partial seizure, epileptic hippocampal tissue shows an upregulation of AMPA and NMDA receptors. Moreover, prolonged opening of GluRs by an anti-Glu receptor antibody in Rasmussen's encephalitis produces uncontrollable seizures (see Ch. 37).

GABA SYNTHESIS, UPTAKE AND RELEASE 291
GABA is formed *in vivo* by a metabolic pathway referred to as the GABA shunt 291

GABA RECEPTOR PHYSIOLOGY AND PHARMACOLOGY 293
GABA receptors have been identified electrophysiologically and pharmacologically in all regions of the brain 293

STRUCTURE AND FUNCTION OF GABA RECEPTORS 293
$GABA_B$ receptors are coupled to G proteins and a variety of effectors 293
$GABA_B$ receptors are heterodimers 293
$GABA_A$ receptors are chloride channels and members of a superfamily of ligand-gated ion channel receptors 293
A family of pentameric $GABA_A$-receptor protein subtypes exists 294
The $GABA_A$ receptor is the major molecular target for the action of many drugs in the brain 296
Neurosteroids, which may be physiological modulators of brain activity, enhance $GABA_A$ receptor function 297
The three-dimensional structures of ligand-gated ion channel receptors are being modeled successfully 297
Mouse genetics reveal important functions for $GABA_A$ receptor subtypes 297

GLYCINE AS A CENTRAL NEUROTRANSMITTER: GLYCINE SYNTHESIS, UPTAKE AND DEGRADATION 298

GLYCINE RECEPTOR PHYSIOLOGY AND PHARMACOLOGY 298
A number of amino acids can activate, to varying degrees, the inhibitory glycine receptor 298
Glycine is inhibitory on ligand-gated, strychnine-sensitive Cl^- channel receptors but excitatory on *N*-methyl-D-aspartate receptors 298

GLYCINE RECEPTORS: STRUCTURE, PATHOLOGY AND LOCALIZATION 299
Glycine receptors belong to the same gene superfamily as does the $GABA_A$ receptor 299
Glycine receptors are mutated in hyperekplexia and may co-localize with $GABA_A$ receptors 299

GABA AND GLYCINE ARE THE MAJOR RAPIDLY ACTING INHIBITORY NEUROTRANSMITTERS IN BRAIN 300

γ-Aminobutyric acid (GABA) is the major inhibitory neurotransmitter in the mammalian CNS. It was discovered in 1950 by Roberts and Awapara. Electrophysiological studies between 1950 and 1965 suggested a role for GABA as a neurotransmitter in the mammalian CNS. Since then, GABA has met the five classical criteria for assignment as a neurotransmitter: it is present in the nerve terminal; it is released from electrically stimulated neurons; there is a mechanism for terminating the action of the released neurotransmitter; its application to target neurons mimics the action of inhibitory nerve stimulation; and specific receptors exist [1, 2].

In view of the ubiquitous nature of GABA in the CNS, it is perhaps not too surprising that its functional significance should be far-reaching. A growing body of evidence suggests a role for altered GABAergic function in neurological and psychiatric disorders of humans, primarily related to hyperexcitability. These include developmental malfunctions, mental retardation and epilepsy; sleep disorders; drug dependence, especially alcoholism; sensorimotor processing, including various types of learning, as well as schizophrenia; and motor coordination disorders such as tardive dyskinesia, Huntington's disease and Parkinson's disease. Pharmacological manipulation of GABAergic transmission is an effective approach for the treatment of anxiety [3–6]. In addition, it has been demonstrated that the nervous-system-depressant actions of the major clinical general anesthetics result from an enhancement of inhibitory synaptic transmission mediated by $GABA_A$ receptors [7, 8].

GABA SYNTHESIS, UPTAKE AND RELEASE

GABA is formed *in vivo* by a metabolic pathway referred to as the GABA shunt. The GABA shunt is a closed-loop process with the dual purpose of producing and conserving the supply of GABA. GABA is present in high

Basic Neurochemistry: Molecular, Cellular and Medical Aspects
0-12-088397-X

concentrations (millimolar) in many brain regions. These concentrations are about 1,000 times higher than concentrations of the classical monoamine neurotransmitters in the same regions. This is in accord with the powerful, abundant, and specific actions of GABAergic neurons in these regions. Glucose is the principal precursor for GABA production *in vivo*, although pyruvate and other amino acids also can act as precursors. The first step in the GABA shunt is the transamination of α-ketoglutarate, formed from glucose metabolism in the Krebs cycle, by GABA: α-ketoglutarate transaminase (GABA-T, also known as. α-oxoglutarate-T) into L-glutamic acid [1, 2] (Fig. 16-1). Glutamic acid decarboxylase (GAD) catalyzes the decarboxylation of glutamic acid to form GABA. GAD appears to be expressed only in cells that use GABA as a neurotransmitter. GAD, localized with antibodies or mRNA hybridization probes, serves as an excellent marker for GABAergic neurons in the CNS. Two related but different genes for GAD have been cloned, suggesting independent regulation and properties for the two forms of GAD: GAD_{65} and GAD_{67} [2]. GAD_{65} is localized to nerve endings where it synthesizes GABA for secretory synaptic vesicles; mouse knockouts for this isozyme show seizure susceptibility and impaired experience-modulated plasticity [9]. GAD_{67} appears to be associated with synthesis of nonvesicular GABA; GABA in this pool can be released from cells by reversal of the plasma membrane transport process [2]. Furthermore, expression of GAD and some GABA receptor subunits has been demonstrated in some non-neural tissues, indicating the likely function of GABA outside of the CNS. A mouse knockout of GAD_{67} shows normal brain activity but cleft palate [2].

GABA is metabolized by GABA-T to form succinic semialdehyde. To conserve the available supply of GABA, this transamination generally occurs when the initial parent compound, α-ketoglutarate, is present to accept the amino group removed from GABA, reforming glutamic acid (see also Ch. 15). Therefore, a molecule of GABA can be metabolized only if a molecule of precursor is formed. Succinic semialdehyde can be oxidized by succinic semialdehyde dehydrogenase (SSADH) into succinic acid and can then re-enter the Krebs cycle, completing the loop [1] (Fig. 16-1).

GABA release into the synaptic cleft is stimulated by depolarization of presynaptic neurons. GABA diffuses across the cleft to the target receptors on the postsynaptic surface. The action of GABA at the synapse is terminated by reuptake into both presynaptic nerve terminals and surrounding glial cells. The plasmalemma transport system mediating reuptake of GABA is both temperature- and ion-dependent. These transporter molecules are capable of bidirectional neurotransmitter transport. They have an absolute requirement for extracellular Na^+ ions with an additional dependence on Cl^- ions (see also Ch. 5). The ability of the reuptake system to transport GABA against a concentration gradient has been demonstrated using synaptosomes. Under normal physiological conditions, the ratio of internal to external GABA is about 200. The driving force for this reuptake process is supplied by the movement of Na^+ down its concentration gradient [2, 10] (see Ch. 5). GABA taken back up into nerve terminals is available for reutilization, but GABA in glia is metabolized to succinic semialdehyde by GABA:T and cannot be resynthesized from glutamate in this compartment, since glia lack GAD. Ultimately, GABA can be recovered from this source by a circuitous route involving the Krebs cycle [1]; GABA in glia is converted to glutamine, which is transferred back to the neuron, where

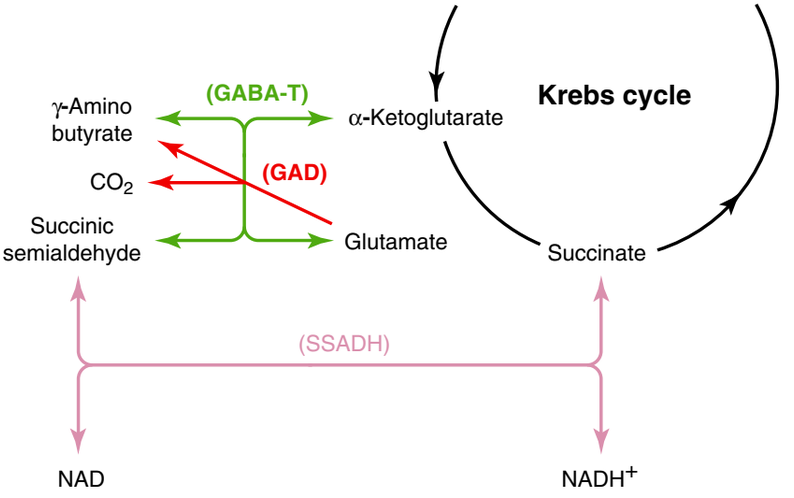

FIGURE 16-1 GABA shunt. These reactions, which participate in the synthesis and metabolism of GABA, are called the 'GABA shunt' because the amount of α-ketoglutarate that is metabolized via these reactions to succinate is shunted around the succinic dehydrogenase step of the TCA cycle and thus decreases the formation of succinyl-CoA. GAD produces GABA and CO_2 from glutamate (*red arrows*). GABA-T removes GABA by converting it to succinic semialdehyde (*SSA*) via transamination with α-ketoglutarate which re-forms glutamate (*green arrows*). SSA is oxidized by NAD and SSA dehydrogenase (*lavender arrows*) to $NADH^+$ and succinate, which re-enters the tricarboxylic cycle.

glutamine is converted by glutaminase to glutamate. The latter re-enters the GABA shunt (see further details in Chs 15 and 31).

The family of GABA plasmalemma transporters is a set of 80 kDa glycoproteins with 12 transmembrane regions; they have no sequence homology with GABA receptors but helped to establish the superfamily of sodium-dependent neurotransmitter transporters. Pharmacological and kinetic studies have suggested a variety of subtypes, and four separate but related entities have been demonstrated by molecular cloning [10]. This has led to rapid developments in understanding the localization, pharmacological specificity, structure-function and mechanism of GABA transport across the cell membrane [10, 11]. Separate proteins with 10 membrane-spanning regions are involved in active transport of GABA from the cytosol into secretory vesicles inside the cell, a mechanism energized by an ATP-dependent proton electrochemical gradient, independent of Na^+ [2, 12] (see also Ch. 5).

GABA RECEPTOR PHYSIOLOGY AND PHARMACOLOGY

GABA receptors have been identified electrophysiologically and pharmacologically in all regions of the brain. Because GABA is widely distributed and utilized throughout the CNS, early GABAergic drugs had very generalized effects on CNS function. The development of more selective agents has led to the identification of at least two distinct classes of GABA receptor, $GABA_A$ and $GABA_B$. They differ in their pharmacological, electrophysiological and biochemical properties. Like the receptors for acetylcholine and glutamate, receptors for GABA employ both ligand-gated ion channels and G-protein-coupled receptors (discussed in Ch. 19). Electrophysiological studies of the $GABA_A$-receptor complex indicate that it mediates an increase in membrane conductance with an equilibrium potential near the resting level of −70 mV. This conductance increase often is accompanied by a membrane hyperpolarization, resulting in an increase in the firing threshold and, consequently, a reduction in the probability of action potential initiation, causing neuronal inhibition. This reduction in membrane resistance is accomplished by the GABA-dependent facilitation of Cl^- ion influx through a receptor-associated channel. On the other hand, increased Cl^- permeability can depolarize the target cell under some conditions of high intracellular Cl^-. This in turn potentially can excite the cell to fire or to activate Ca^{2+} entry via voltage-gated channels and has been proposed as a physiologically relevant event, especially in embryonic neurons [3] (see also Ch. 6).

Electrophysiological data suggest that there are two GABA-recognition sites per $GABA_A$-receptor complex [13]. An increase in the concentration of GABA results in an increase in the mean channel open time because of opening of doubly liganded receptor forms, which exhibit open states of long duration. It has been demonstrated that the increase in the ionic permeability of the $GABA_A$ receptor complex is transient in the continuing presence of agonist [13]. This phenomenon is known as desensitization and is rapidly reversible. The molecular mechanism of desensitization is not understood, and various hypotheses remain under investigation.

STRUCTURE AND FUNCTION OF GABA RECEPTORS

$GABA_B$ receptors are coupled to G proteins and a variety of effectors. $GABA_B$ receptors were identified by their insensitivity to the $GABA_A$ antagonist bicuculline and certain $GABA_A$-specific agonists [2–4, 13]. The GABA analog (−) baclofen (β-(4-chloro-phenyl)-γ-aminobutyric acid) was found to be a potent and selective $GABA_B$ agonist. $GABA_B$ receptors [14] are members of the group III G-protein-coupled receptors (Ch. 19), with structural similarity to the metabotropic glutamate receptors.

$GABA_B$ receptors can mediate both postsynaptic and presynaptic inhibition, through coupling to a variety of effector systems [14]. Some $GABA_B$ receptors are coupled to activation of certain K^+ channels, producing slow inhibitory synaptic currents. Other $GABA_B$ receptors can decrease Ca^{2+} conductance, regulate inositol trisphosphate production (Ch. 20) and/or inhibit cAMP production (Ch. 21). Presynaptic inhibition may occur as a result of $GABA_B$ receptors on nerve terminals causing a decrease in the influx of Ca^{2+}, and thereby reducing the release of neurotransmitters (Chs10 and 22). These responses may have a net excitatory effect when inhibiting GABA nerve ending release (autoreceptors) or may inhibit the release of other neurotransmitters including glutamate, having a net inhibitory effect.

$GABA_B$ receptors are heterodimers. Two $GABA_B$ receptor subunits have been cloned, R1 and R2. Neither of these appears to express functional receptors on their own, but they are active when coexpressed, suggesting that a dimer is trafficked to the cell surface and forms an active complex. Evidence shows that the R1 subunit contains the GABA binding site while the R2 subunit interacts with the G protein [14].

$GABA_A$ receptors are chloride channels and members of a superfamily of ligand-gated ion channel receptors. The $GABA_A$ receptor is a pseudo-symmetric pentamer spanning the membrane and forming a chloride ion channel (Figs 16-2, 16-3). The binding of GABA or of structural analogs with agonist activity opens the chloride ion channel [3, 4, 13]. $GABA_A$ receptors have structural and functional homology with certain other

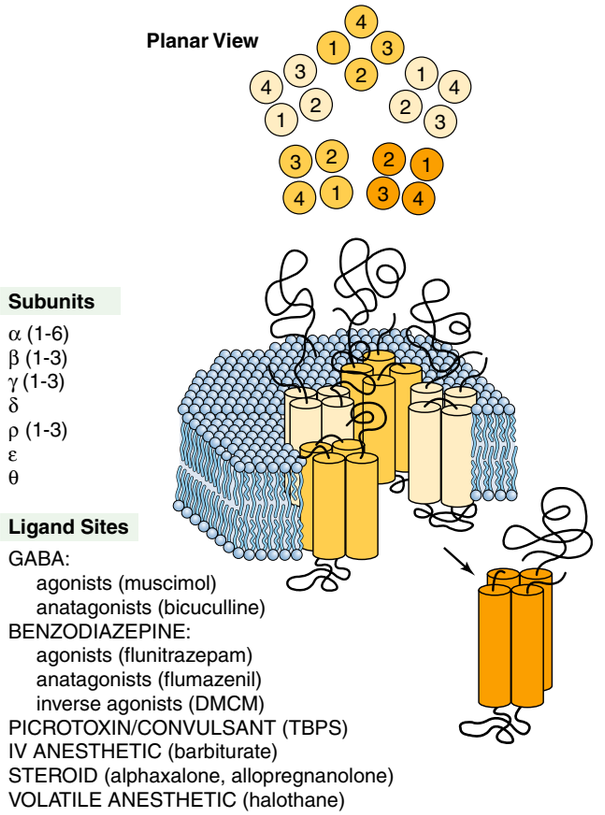

FIGURE 16-2 Schematic of $GABA_A$ receptors. (**Lower panel**) The protein is shown as a pseudosymmetrical membrane-spanning ion channel protein made of five homologous subunits, each of which has four membrane-spanning regions (MSRs, numbered 1–4) as shown in one of the subunits that is pulled out. (**Upper panel**) The view from outside the cell (plan view) shows the arrangement of the five subunits (each with four MSRs) around the central core, the chloride ion channel. Also listed are the subunit families that can be utilized in composing each receptor, and the ligands that have binding sites on the receptor (see also Fig. 16-3).

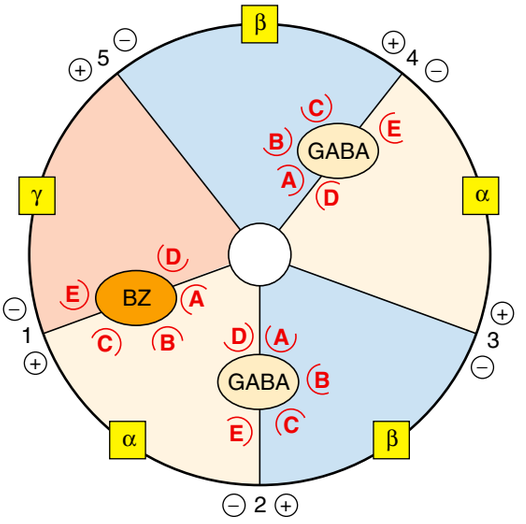

FIGURE 16-3 Donut model of $GABA_A$ receptor heteropentamer showing ligand binding and subunit interaction domains. The five subunits (*–β–γ–α–β–α–*) and five subunit interfaces (*1–5*) are shown, indicating the two different subunit interfaces for each subunit ((–) and (+)), the ligand binding pockets for GABA and benzodiazepines (*BZ*), and the various peptide loops (*A–E*) involved in ligand binding and subunit interfaces. These loops are homologous in other members of the ligand-gated ion channel superfamily, including the glycine receptor. The pore in the center represents the chloride channel.

Cys-loop-containing ligand-gated ion channel receptors, and their subunits have sequence homology, thus defining a gene superfamily. This family includes the nicotinic acetylcholine receptor (Ch. 11), the strychnine-sensitive glycine receptor (see below), and the serotonergic 5-HT_3 receptor (Ch. 13). The superfamily is also sometimes called the Cys-loop family, to distinguish it from the ionotropic excitatory amino acid receptors [4].

Each $GABA_A$ receptor subunit contains four putative α-helical membrane-spanning domains (M1–M4) with a predominantly hydrophobic character. One or more membrane-spanning regions from each subunit, principally M2, form the walls of the channel pore (see also Ch. 11). The sequences of these transmembrane segments are highly conserved between the subunits of the $GABA_A$ receptor as well as between members of the gene superfamily. The region between M3 and M4 contains a long, variable, intracellular domain. This contributes to the subtype specificity and may participate in intracellular regulatory mechanisms such as phosphorylation and interaction with other cellular constituents [2–4].

A family of pentameric $GABA_A$-receptor protein subtypes exists. The $GABA_A$ receptor was first cloned using partial protein sequence, and verification of these cDNAs as GABA-receptor subunits was made by expression in *Xenopus* oocytes of GABA-activated channels [2–4, 13]. According to current understanding of the molecular structure of the $GABA_A$ receptor-ionophore complex, it is a heteropentameric glycoprotein of about 275 kDa composed of combinations of at least 19 different but closely related polypeptides. The subunits are 50–60 kDa and have 20–30% sequence identity between classes and about 70% identity within a class: α1–6, β1–3, γ1–3, δ, ε, θ, π and ρ1–3 (Fig. 16-2). The mammalian ε and θ subunits probably correspond to γ4 and β4 identified in birds. This suggests that the genes probably evolved from a common ancestral sequence; the evolutionary relationships are shown in the dendrogram of Figure 16-4 [4, 5, 15]. In addition, splice variants exist for several of the subunits.

Differential distribution of $GABA_A$-receptor-subunit mRNAs and polypeptides in brain is consistent with data indicating regional variations in physiological function, pharmacology and biochemistry. It seems clear that different combinations with differing pharmacologic properties and conductances are expressed in different neuronal populations, and even different membrane locations in a given cell. The subunit composition of native isoforms

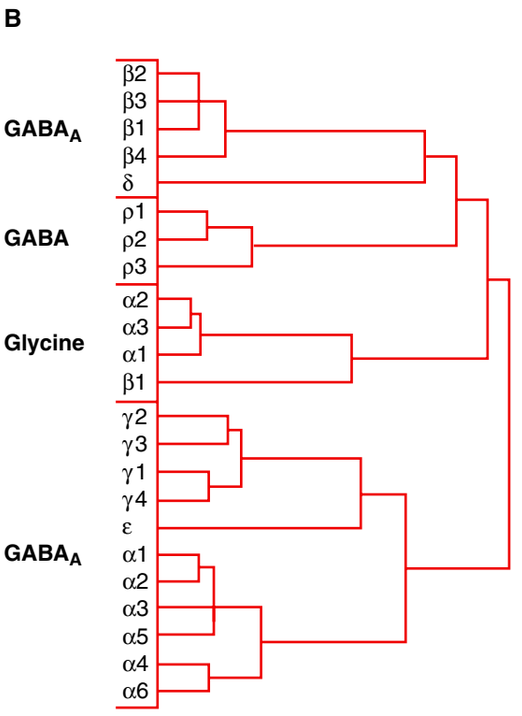

FIGURE 16-4 Evolutionary relationships between DNA sequences of $GABA_A$ receptors and glycine receptors. The dendrogram is based on literature data for human cDNAs, provided by Tim Hales and Ewen Kirkness, analyzed by Ziwei Chen, Kui Yang and Richard Olsen.

has been deduced by a combination of techniques: determining which polypeptides are present in a given cell, finding which ones can be isolated together as an oligomer by using subunit-specific antibodies, and analyzing which pharmacological properties can be reconstituted from recombinant subunits of known combinations. Table 16-1 summarizes data on the most abundant isoforms identified, their localization and their unique pharmacological properties [2–5, 13, 15]. The ρ subunits are expressed primarily, if not exclusively, in the retina, where they appear to form Cl^- channels, possibly homomers, with novel pharmacology. Pharmacological responses to GABA that are insensitive to both bicuculline and baclofen (non-A, non-B) are attributed by some authors to receptors termed $GABA_C$ [16]. Some, but not all, of these responses are produced by the ρ subunit, which is also insensitive to the usual $GABA_A$ modulatory drugs such as benzodiazepines and anesthetics [2, 4, 16].

Proteins associated with the intracellular loop of $GABA_A$ receptor subunits participate in the trafficking of receptors from Golgi membranes to the plasmalemma, the concentrating of receptors at synaptic sites, and the production of changes in subcellular localization and density associated with plasticity. Such changes in plasticity include endocytotic removal of receptors from the plasmalemma following long-term ligand exposure [17–19] (see details of relevant topics of trafficking, endocytosis and plasticity in Chs 9, 30 and 53). Proper direction of receptors to specific cell surface loci and specific synapses requires the γ2 subunit and the microtubule linker-protein, GABARAP, which is, however, not a synaptic anchoring protein. The protein gephyrin, isolated with glycine receptors (see below), colocalizes with synaptic $GABA_A$ receptors and appears to have an anchoring function. The construction of synapses and remodeling during experience is currently an intensive area of research. Other subunits may substitute for γ2 in pentamers; for example, the δ subunit forms receptors that are excluded from synapses. Extrasynaptic receptors appear to play a functional role in mediating tonic inhibition, responding to spillover of synaptically released transmitter or even to ambient extracellular levels, depending on the location. They also appear to be the major target of action of certain modulatory drugs (see below).

Phosphorylation sites for one or more kinases are present on virtually all of the subunits. Phosphorylation of the β subunits by cAMP-dependent protein kinase (PKA) and phosphorylation of β and γ subunits by protein kinase C and tyrosine kinase have been reported [2, 17]. Current studies are directed toward an understanding of the functional consequences of phosphorylation of

TABLE 16-1 Summary of native $GABA_A$ receptor subtypes

Subunit composition	Location	Function	Comments
α1β2γ2	Widespread, esp. GABA neurons	Sedation, anticonvulsant	Adult, BZ-sensitive Reduced in drug tolerance?
α2β3γ2	Forebrain, spinal cord	Anxiety, muscle relaxant	Axon hillock in some cells, BZ-sensitive Embryonic and adult, BZ-sensitive
α2β1γ1	Glia		
α3β3γ2	Cortex	Anticonvulsant	Embryonic and adult, BZ-sensitive
α4β2γ2	Thalamus		Insensitive to agonist BZ
α4β2/3γ2	Dentate gyrus		Elevated in drug withdrawal?
α4β2δ	Thalamus	Tonic inhibition	Extrasynaptic, BZ- insensitive, adult
α4β2/3δ	Dentate gyrus		
α5β3γ2	Hippocampus CA1 Sensory ganglia	Tonic inhibition	Extrasynaptic, BZ-sensitive
α6β2/3γ2	Cerebellar granule cells		Insensitive to agonist BZ
α6β2/3δ	Cerebellar granule cells	Tonic inhibition	Extrasynaptic, BZ-insensitive, adult
γ3, θ, ε	Little information		

$GABA_A$ receptors for both acute and more prolonged time frames (see also Chs 21 and 24).

The $GABA_A$ receptor is the major molecular target for the action of many drugs in the brain. The $GABA_A$ receptor-chloride ion channel complex includes five major types of ligand-binding domain. Two copies of the GABA-binding site are present at α/β subunit interfaces (Fig. 16–3). One of the most useful agonists is the compound muscimol, a naturally occurring GABA analog isolated from the psychoactive mushroom *Amanita muscaria*. It is a potent and specific agonist at $GABA_A$ receptors and has been a valuable tool for pharmacological and radioligand-binding studies (Fig. 16–2). Other GABA agonists include isoguvacine, 4,5,6,7-tetrahydroisoxazolo-[5,4-*c*]pyridin-3-ol (THIP), 3-aminopropane-sulfonate and imidazoleacetic acid. The classical $GABA_A$-receptor antagonist is the convulsant bicuculline, which reduces current by decreasing the opening frequency and mean open time of the channel [2, 13]. It is likely that bicuculline produces its antagonistic effects on $GABA_A$ receptor currents by competing with GABA for its binding sites. On the other hand, the convulsant picrotoxin binds to separate sites that block the chloride channel.

The GABA-gated chloride ion channel is modulated by several classes of drugs that bind to allosteric sites on the receptor complex: the benzodiazepines, barbiturates and related intravenous general anesthetics such as etomidate and propofol, as well as anesthetic steroids and endogenous neurosteroids. It appears that some types of $GABA_A$ receptor are directly enhanced by ethanol and volatile general anesthetics (Fig. 16-2) [7, 8, 20].

Benzodiazepine receptor-binding sites copurify with the GABA-binding sites, including co-immunoprecipitation with antibodies that were developed to recognize the protein containing the GABA-binding site [2, 3, 13, 15]. This indicates that the benzodiazepine receptor is an integral part of the $GABA_A$ receptor–Cl^- channel complex (Fig. 16-3). Benzodiazepine agonists represent the currently most useful group of agents in the general class of depressant drugs, which also includes barbiturates, that show anticonvulsant, anxiolytic and sedative-hypnotic activity (Chs 37 and 55). Well-known examples include diazepam and chlordiazepoxide, which often are prescribed for their antianxiety effects [3–5]. The mechanism of action of benzodiazepine agonists is to enhance GABAergic transmission. From electrophysiological studies, it is known that these benzodiazepines increase the frequency of channel opening in response to GABA, thus accounting for their pharmacological and therapeutic actions [2, 6, 13]. In addition, the benzodiazepine site is coupled allosterically to the binding sites for the other modulatory ligands, such as barbiturate, steroid, anesthetic and picrotoxin [2]. $GABA_A$ receptors show heterogeneity with respect to certain benzodiazepine-site ligands [4–6]. A wide variety of nonbenzodiazepines, such as the β-carbolines, cyclopyrrolones and imidazopyridines, also bind to the benzodiazepine site.

Barbiturates comprise another class of drugs commonly used therapeutically for anesthesia and control of epilepsy (Ch. 37). Phenobarbital and pentobarbital are two of the most commonly used barbiturates. Phenobarbital has been used to treat patients with epilepsy since 1912. Pentobarbital is also an anticonvulsant but is sedative at the effective concentration. Barbiturates at pharmacological concentrations allosterically increase binding of benzodiazepines and GABA to their respective binding sites [2]. Measurements of mean channel open times show that barbiturates act by increasing the proportion of channels opening to the longest open state (9 ms) while reducing the proportion opening to the shorter open states (1 and 3 ms), resulting in an overall increase in mean channel open time and Cl^- flux [13].

Channel blockers, such as the convulsant compound picrotoxin, cause a decrease in mean channel open time. Picrotoxin works by preferentially shifting opening channels to the briefest open state (1 ms). Thus, both picrotoxin and barbiturates appear to act on the gating process of the $GABA_A$ receptor channel, but their effects on the open states are opposite to each other. Experimental convulsants such as pentylenetetrazol and the cage convulsant t-butyl bicyclophosphorothionate (TBPS) act in a manner similar to picrotoxin, preventing Cl^- channel permeability. The antibiotic penicillin is a channel blocker with a net negative charge. It blocks the channel by interacting with the positively charged amino acid residues within the channel pore, consequently occluding Cl^- passage through the channel [2, 13].

There have been numerous studies on the role of $GABA_A$ receptors in anesthesia. A considerable amount of evidence has been compiled to suggest that general anesthetics, including barbiturates, volatile gases, steroids and alcohols, enhance GABA-mediated Cl^- conductance. A proper assessment of this phenomenon requires not only a behavioral assay of anesthesia but also *in vitro* models for the study of receptor function. In this regard, not only electrophysiological methods but also neurochemical measurements of Cl^- flux and ligand binding have been useful. For example, a strong positive correlation exists between anesthetic potencies and the stimulation of GABA-mediated Cl^- uptake. This is seen with barbiturates and anesthetics in other chemical classes [21].

Comparison of ligand-gated ion channels that vary in sensitivity to anesthetic modulation, using the chimera and site-directed mutagenesis approach, has identified amino acids in the membrane-spanning domains that are critical for anesthetic sensitivity [8]. Direct evidence of ethanol augmentation of $GABA_A$ receptor function, measured either by electrophysiological techniques or agonist-mediated Cl^- flux, has been reported [8, 20]. The similarity between the actions of ethanol and sedative drugs such as benzodiazepines and barbiturates that enhance GABA action suggests that ethanol may exert some of its effects by enhancing the function of $GABA_A$ receptors. Ethanol potentiation of $GABA_A$ receptor function appears to be dependent upon the cell type tested and

the method of assay. This suggests that the ethanol interaction may be an indirect action, or specific for certain receptor subtypes [2, 8, 20].

Neurosteroids, which may be physiological modulators of brain activity, enhance $GABA_A$ receptor function. This enhancement by steroids involves direct action on the membrane receptor protein rather than through the classical genomic mechanism mediated by soluble high-affinity cytoplasmic steroid hormone receptors (see Ch. 52). Chemically reduced analogs of the hormones progesterone and corticosterone derivatives administered to animals and humans exert sedative–hypnotic and anti-anxiety effects. This led to the development of a synthetic steroid anesthetic, alphaxalone. These neuroactive steroids are potent modulators of $GABA_A$-receptor function *in vitro* [8, 13, 22]. Neurosteroids can be produced in the brain endogenously and may influence CNS function under certain physiological or pathological conditions. Numerous observations suggest that neurosteroids physiologically affect the CNS: these include the rapid behavioral effects of administered steroids; diurnal and estrous cycle effects on behavior; sex-specific pharmacology, especially of GABAergic drugs; and the development of withdrawal symptoms following cessation of chronically administered steroids. Neuroactive steroids have effects similar to those of barbiturates in that they enhance agonist binding to the GABA site and allosterically modulate benzodiazepine and TBPS binding [2, 3, 13, 22]. Also, like barbiturates, high concentrations of neurosteroids directly activate the $GABA_A$ receptor Cl^- channel. These observations led to the hypothesis that the neurosteroid-binding site may be similar to the barbiturate site but the sites of action for the two classes of drugs are clearly not identical [2].

The three-dimensional structures of ligand-gated ion channel receptors are being modeled successfully. Recent remarkable progress in structural definition of the nicotinic acetylcholine receptor, both the extracellular domain and the membrane-spanning domains (see Ch. 11), are beginning, in turn, to allow modeling of the $GABA_A$ receptor. This will be helpful in suggesting mechanisms whereby GABA binding can gate the chloride ion channel, and the action of modulatory ligands. Photoaffinity-labeling and site-directed mutagenesis of the $GABA_A$ receptors suggest that the binding sites for benzodiazepines are localized at the interface of the α and γ subunits and that those for GABA ligands are located at the interface between the α and β subunits [13, 15]. The binding pockets for each class of ligand appear to be formed from several loops of amino acids (Fig. 16-3). These models are consistent with studies on recombinant $GABA_A$ receptors expressed in heterologous cells. Such studies show that the nature of the α and β subunits determines the pharmacological specificity at the GABA and benzodiazepine sites and that the γ subunits are necessary for sensitivity to benzodiazepines and insensitivity to Zn^{2+} inhibition [3–5, 13, 15]. $GABA_A$ receptors come in five flavors with respect to benzodiazepines: combinations including the α1 subunit have a high affinity for certain 'type 1-selective' benzodiazepine site ligands, while those with the α2, α3 and α5 subunits have moderate affinity. The α5 subunit has a unique specificity to bind most benzodiazepine ligands but not the sedative drug zolpidem [4–6]. Some $GABA_A$ receptors apparently lack benzodiazepine-binding sites altogether or have a novel pharmacological profile at this site. Subunit combinations containing the α4 or α6 subunit with a γ subunit bind benzodiazepine inverse agonists but not agonists and are moderately sensitive to Zn^{2+} and neurosteroids. Combinations containing α4 or α6 with a δ subunit instead of a γ subunit do not bind benzodiazepine-site ligands, are highly sensitive to Zn^{2+} and are relatively more sensitive to neurosteroids and possibly other modulators such as ethanol [5, 6, 8, 20, 22]. This implicates the extrasynaptic $GABA_A$ receptors in the action of endogenous neurosteroids, general anesthetics and alcohol, and suggests a role for these receptors in tonic inhibition.

Mouse genetics reveal important functions for $GABA_A$ receptor subtypes. The use of mouse genetics has given tremendous insights into the functions of various subtypes of $GABA_A$ receptors. Gene targeting (knockouts) for several subunits reveal important phenotypic traits resulting from the loss of the receptor isoform. Most striking has been the relatively benign nature of phenotypes in mice lacking major $GABA_A$ receptor subunits, including α1 and β2, as well as α6. The γ2 and β3 knockouts are neonatally lethal, indicating important functions. The α5 and δ knockout phenotypes are more subtle. Mice lacking δ become insensitive to neurosteroids, while mice lacking α5 show improved performance in hippocampus-dependent spatial memory acquisition [2, 5, 6] (see also Ch. 53).

Further, the removal of benzodiazepine sensitivity in a selective α subunit in a mouse using the gene knockin technique has established that the α1 subunit plays a major role in the sedative and amnesiac effects of benzodiazepines, part of the anticonvulsant effect and little of the anxiolytic effect; the latter effects are more importantly mediated by the α2 subunit [5, 6]. The β subunit selectivity for the drugs loreclezole (an anxiolytic) and etomidate (an anesthetic) allowed determination that a single residue in the M2 domain could account for this selectivity (β2 = β3 >β1). When a mouse knockin selectively removed the etomidate sensitivity of the β2 subunit, the animals showed reduced sensitivity to sedative effects of etomidate but no reduction of the true anesthetic effects. In contrast, mutation of the β3 subunit to negate etomidate sensitivity of that subunit alone resulted in a mouse with no sensitivity to the anesthesia produced by etomidate. This proved that the GABA receptor is the target of at least this one anesthetic (etomidate) and, furthermore, that the specific locations in the brain of β3 subunits are important for anesthetic action, while the

corresponding β2 subunits, even when insensitive to this drug, did not produce a loss of anesthetic action in the organism [5–7].

GLYCINE AS A CENTRAL NEUROTRANSMITTER: GLYCINE SYNTHESIS, UPTAKE AND DEGRADATION

It was first proposed in 1965 that glycine acts as a neurotransmitter in mammalian spinal cord, and since then glycine has been demonstrated to meet all of the criteria for that designation. Glycine is widely recognized as a major inhibitory neurotransmitter in the vertebrate CNS, especially the spinal cord and brainstem, where it is crucial for the regulation of motoneuron activity [1]. In addition, glycinergic interneurons are found in the retina, the auditory system and other areas involved in the processing of sensory information. Like GABA, glycine inhibits neuronal firing by gating Cl^- channels but with a characteristically different pharmacology.

The immediate precursor of glycine is serine, which is converted to glycine by the activity of the enzyme serine hydroxymethyltransferase (SHMT) (see Fig. 40-3). Glycine is packaged into synaptic vesicles by the H^+-dependent vesicular inhibitory amino acid transporter (VIAAT or vGAT), which also transports GABA [12] (see Ch. 5). As for GABA, Ca^{2+}-dependent release of glycine and specific postsynaptic glycine receptors have been rigorously demonstrated. The postsynaptic action of glycine is terminated by its reuptake via high-affinity plasmalemma transporter systems located in glycinergic nerve terminals and glial cells. Molecular cloning has identified two glycine transporter genes, *glyT1* and *glyT2*, which are members of the Na^+/Cl^--dependent transporter superfamily [10, 23]. GlyT1 is abundantly expressed in astrocytes throughout the CNS, whereas GlyT2 is highly localized in glycine-releasing nerve terminals of spinal cord and brain stem. Both glycine transporters differ in their transport stoichiometries and substrate affinities [24] and appear to have different roles at glycinergic synapses. GlyT1 catalyzes the removal of glycine from postsynaptic glycine receptors, whereas GlyT2 is essential for replenishing the presynaptic pool of glycine from which synaptic vesicles are reloaded with neurotransmitter [23]. GlyT1 may in addition regulate glycine levels at excitatory NMDA receptors (see below), and selective GlyT1 inhibitors may therefore prove useful in the treatment of diseases associated with impaired glutamatergic transmission, such as schizophrenia [23]. Glycine is degraded intracellularly by the glycine cleavage system (see Fig. 40-3), a multienzyme complex composed of four different proteins, which, in the CNS, appears to be primarily localized in astrocytes [25]. Mutations in the glycine cleavage system cause nonketotic hyperglycinemia, a disease characterized by severe mental retardation ('glycine encephalopathy') (discussed in Ch. 40).

GLYCINE RECEPTOR PHYSIOLOGY AND PHARMACOLOGY

A number of amino acids can activate, to varying degrees, the inhibitory glycine receptor. The amino acids that can activate the glycine receptor include β-alanine, taurine, L-alanine, l-serine and proline. GABA is largely inactive at this receptor [1, 26]. There are only few known high-affinity antagonists of the inhibitory glycine receptors. They include the plant alkaloid strychnine, which is highly selective for the glycine receptor, and the amidine steroid RU 5135, which is less selective. Both compounds bind to the glycine receptor with nanomolar affinities. In addition, different low-affinity antagonists exist [27]. The binding sites for glycine and competitive antagonists like strychnine are overlapping but not identical. Current findings indicate that up to three molecules of glycine are required to activate the glycine receptor. This high cooperativity may reflect the low binding energy of a ligand as small as glycine.

As for the $GABA_A$ receptor, positive modulators that enhance glycine receptor activity have been identified. These include alcohols, neurosteroids, tropeines and the divalent metal ion Zn^{2+}, which is highly enriched in some types of excitatory neuron [27]. Zn^{2+} release from such neurons may potentiate glycine receptors at neighboring inhibitory synapses and thus facilitate inhibition following strong excitation.

Glycine is inhibitory on ligand-gated, strychnine-sensitive Cl^- channel receptors but excitatory on *N*-methyl-D-aspartate receptors. Although acting as a classical neurotransmitter at inhibitory ion channel receptors, glycine is also an activating ligand at a class of excitatory ion channel receptors, the *N*-methyl-D-aspartate (NMDA) receptors (see Ch. 15). Different investigators have shown that glycine is an essential coagonist of the NMDA receptor that is required for channel activation in addition to glutamate, and that glycine is normally present in the extracellular space at the required concentrations. Regulation of NMDA receptor activity via the release and/or reuptake of glycine may be important for allowing cross-talk between inhibitory and excitatory synapses in different regions of the CNS [28]. It appears curious that common amino acids like glycine and glutamate, which have other roles in metabolism, are employed as signaling molecules in the nervous system and that glycine is utilized as both an inhibitory and an excitatory neurotransmitter. However, sequence analysis indicates that receptors for signaling molecules evolved from prokaryotic proteins utilized for binding and recognition of nutrients in the environment, including glycine, glutamate and GABA. GABA, a carbon- and nitrogen-storage

molecule in plants and algae, appears to act as a colony-stimulating factor for abalone, an invertebrate mollusk. Thus, amino acids may have been used as informational molecules already early in evolution.

GLYCINE RECEPTORS: STRUCTURE, PATHOLOGY AND LOCALIZATION

Glycine receptors belong to the same gene superfamily as the $GABA_A$ receptor. The native glycine receptor is a macromolecular complex of about 250 kDa composed of a combination of homologous polypeptides identified as α (48 kDa) and β (58 kDa), which form a quasisymmetrical pentameric arrangement around a central ion pore [26, 27]. There is approximately 50% amino acid sequence identity between the α and β subunits; a comparatively high homology to $GABA_A$ receptor proteins is also evident (Fig. 16-4). In addition, a 93 kDa polypeptide named gephyrin copurifies with the glycine receptor. Photoaffinity labeling of the glycine receptor has indicated that binding sites for glycine and strychnine are found on the α subunit. The α and β subunits span the postsynaptic membrane and are glycosylated. Like the $GABA_A$ receptor and nicotinic acetylcholine receptor subunits, glycine receptor subunits have four hydrophobic segments, M1–M4, which may span the lipid bilayer as α-helices (Fig. 16-2) [27].

Unlike the α and β subunits, the glycine receptor associated protein gephyrin is a highly hydrophilic polypeptide that is cytoplasmically localized at postsynaptic membranes. Gephyrin anchors the glycine receptor in the postsynaptic membrane by attaching it to cytoskeletal elements [18] (Fig. 16-5). Such a role appears analogous to that of the ankyrin family of proteins, which restrict lateral mobility of many membrane proteins, including transporters and channels. The 43 kDa protein rapsyn appears to play this cytoskeleton-linking role with acetylcholine receptors (see Ch. 11); gephyrin or related proteins are also associated with $GABA_A$ receptors. Antisense treatment and gene knockout indicate that gephyrin is essential for the clustering of glycine receptors and certain $GABA_A$ receptor subtypes at developing inhibitory synapses. In addition, in peripheral organs, gephyrin has an enzymatic function in the biosynthesis of the molybdenum cofactor, a coenzyme of oxidoreductases.

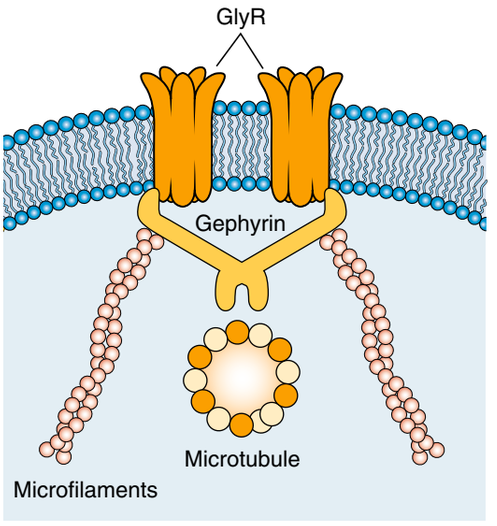

FIGURE 16-5 Model of gephyrin-dependent glycine receptor (GlyR). Trafficking/anchoring. Gephyrin (*light orange*) links the GlyR in the membrane to the intracellular cytoskeleton (microtubules and microfilaments) for trafficking to the surface, clustering at synapses and dispersion of clusters during plasticity.

Site-directed mutagenesis studies of glycine receptor subunits have led to a greater understanding of domains within the ligand-gated ion channel polypeptides that participate in pentamer assembly and interaction with the cytoskeleton, as well as the agonist-binding pocket and ion channel domains [26, 27]. For example, α subunits can produce functional homopentameric channels in recombinant expression systems, while β subunits cannot. The α homomeric glycine receptors are sensitive to the $GABA_A$ antagonist picrotoxin and may represent extrasynaptically located receptors. Heteromeric αβ GlyRs are insensitive to picrotoxin and are clustered at synaptic sites. Mutagenesis of certain amino acid residues in the extracellular domain of β subunits, making them similar to α subunits, confers the ability to assemble into homomeric channels. Mutagenesis of other amino acid residues that differ between α and β subunits has identified domains involved in binding glycine and Zn^{2+}, a metal ion that modulates glycine receptor function [27].

Glycine receptors are mutated in hyperekplexia and may co-localize with $GABA_A$ receptors. Currently, four α subunit genes, but only one β gene, have been identified in vertebrates [27]. The α2 (and α4) subunits are primarily expressed neonatally, whereas α1 and α3 are found primarily postnatally. Functional expression of the α_1–α_4 transcripts in frog oocytes generates glycine-gated Cl^- channels that are blocked by nanomolar concentrations of strychnine. Mutations of the α_1 and β subunits, in particular, substitutions by leucine or glutamine of an arginine residue located at position 271 of the α1 polypeptide, have been associated with hyperekplexia, a rare neurological disease characterized by an exaggerated startle response. Mutations in both α and β subunits have also been implicated in single-gene mutations in mice that show neurologically distinct phenotypes [26, 27, 29].

Immunocytochemical mapping with monoclonal antibodies specific for the α subunits reveals glycine receptor immunoreactivity in regions that also bind [^{3}H]strychnine in autoradiographic studies. Although most glycine receptors are found in spinal cord and brainstem, a small but significant population is located in more rostral brain regions. Interestingly, β subunit mRNA is abundant in many brain structures and even non-neural tissues, where neither [^{3}H]strychnine binding nor known α subunit

mRNAs are found. Thus, glycine receptor proteins may have yet unknown functions.

Ultrastructural and electrophysiological studies indicate that glycine and GABA may be co-utilized as neurotransmitters at distinct subsets of inhibitory synapses. Immunoelectron microscopy revealed glycine receptor antigen apposed to nerve terminals that contain the GABA synthesizing enzyme GAD, which constitutes a highly reliable marker for GABAergic neurons [21]. Furthermore, co-release of GABA and glycine at single postsynaptic sites has been demonstrated by electrophysiological recording in slice preparations from spinal cord and has been shown to result in the simultaneous activation of both $GABA_A$ and glycine receptors [30]. As glycine and $GABA_A$ receptors differ in their elementary channel conductances and kinetic response properties, glycine and GABA co-release may allow the formation of postsynaptic response properties that are distinct from those of purely glycinergic or GABAergic synapses, respectively.

GABA AND GLYCINE ARE THE MAJOR RAPIDLY ACTING INHIBITORY NEUROTRANSMITTERS IN BRAIN

The roles of these two neurotransmitters are very similar: both use ionotropic ligand-gated chloride channels with structural homology, although the receptors are clearly distinct entities and with totally different regional localization. Diversity of subunit isoforms has been exhibited in both $GABA_A$ and glycine receptors. The data suggest a varied pharmacology and physiology associated with differing isoform combinations. An understanding of the nature of these combinations should assist in the development of a new series of therapeutic agents that interact with $GABA_A$ or glycine receptors in a more specific manner than currently available drugs. Furthermore, a detailed understanding of the functional domains of the proteins may aid in rational drug design. Gene-targeting studies and analyses of existing mutant mice have revealed important roles for GABA and glycine receptors in nervous system function and development. Finally, plastic changes in subunit composition have been documented as a result of environmental experiences, giving new clues to understanding mechanisms of learning, disease states and drug dependence [2, 17, 19, 26, 27].

NOMENCLATURE OF PURINES AND PYRIMIDINES 303

PURINE RELEASE AND METABOLISM 303
Interstitial nucleotides are derived from intracellular sources 303
Extracellular nucleotides are regulated by ectoenzymes 304
There are several sources of extracellular adenosine 305

PURINERGIC RECEPTORS 306
The P-site of adenylyl cyclase inhibits cyclic AMP accumulation 308
There are four adenosine receptor subtypes 308
Xanthines block P_1 but not P_2 receptors 309
P_2 receptors are subdivided into ionotropic P_{2X} receptors and metabotropic P_{2Y} receptors 309

EFFECTS OF PURINES IN THE NERVOUS SYSTEM: ADENOSINE RECEPTORS 312
A_1 adenosine receptors are inhibitory in the central nervous system 313
A_{2A} adenosine receptors are highly expressed in the basal ganglia 314
A_{2B} adenosine receptors regulate vascular permeability 314
A_3 adenosine receptors are few in the central nervous system 314

EFFECTS OF PURINES IN THE NERVOUS SYSTEM: ATP RECEPTORS 314
P_{2X} subunits form trimeric ion-gated channels 314
P_{2Y} receptors are activated by adenine and uridine nucleotides 315

NOMENCLATURE OF PURINES AND PYRIMIDINES

Purines such as ATP and adenosine play a central role in the energy metabolism of all life forms. This fact probably delayed recognition of other roles for purines as autocrine and paracrine substances and neurotransmitters. Today it is recognized that purines are released from neurons and other cells and that they produce widespread effects on multiple organ systems by binding to purinergic receptors located on the cell surface. The principal ligands for purinergic receptors are adenosine, ATP and UTP. Primordial voltage-gated ion channels may have evolved at an early stage to respond to ATP, an early chemical signal. Such a possibility is suggested by the high homology between cloned P_{2X} receptors and epithelial Na^+ channels.

A nucleoside consists of a purine or pyrimidine base linked to a pentose, either D-ribose to form a ribonucleoside or 2-deoxy-D-ribose to form a deoxyribonucleoside. Three major purine bases and their corresponding ribonucleosides are adenine/adenosine, guanine/guanosine and hypoxanthine/inosine. The three major pyrimidines and their corresponding ribonucleosides are cytosine/cytodine, uracil/uradine and thymine/thymidine. A nucleotide such as ATP (Fig. 17-1) is a phosphate or polyphosphate ester of a nucleoside.

PURINE RELEASE AND METABOLISM

Interstitial nucleotides are derived from intracellular sources. In addition to its central role in cellular energy metabolism, ATP is a classical neurotransmitter that is packaged into secretory granules of neurons and adrenal chromafin cells and released in quanta in response to

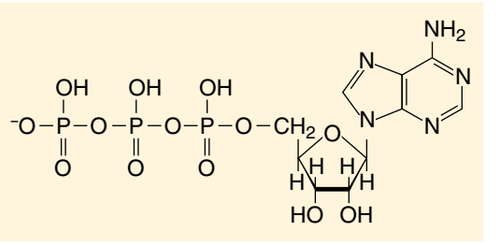

FIGURE 17-1 Adenosine 5′-triphosphate. A purine nucleotide consisting of adenine, ribose and triphosphate.

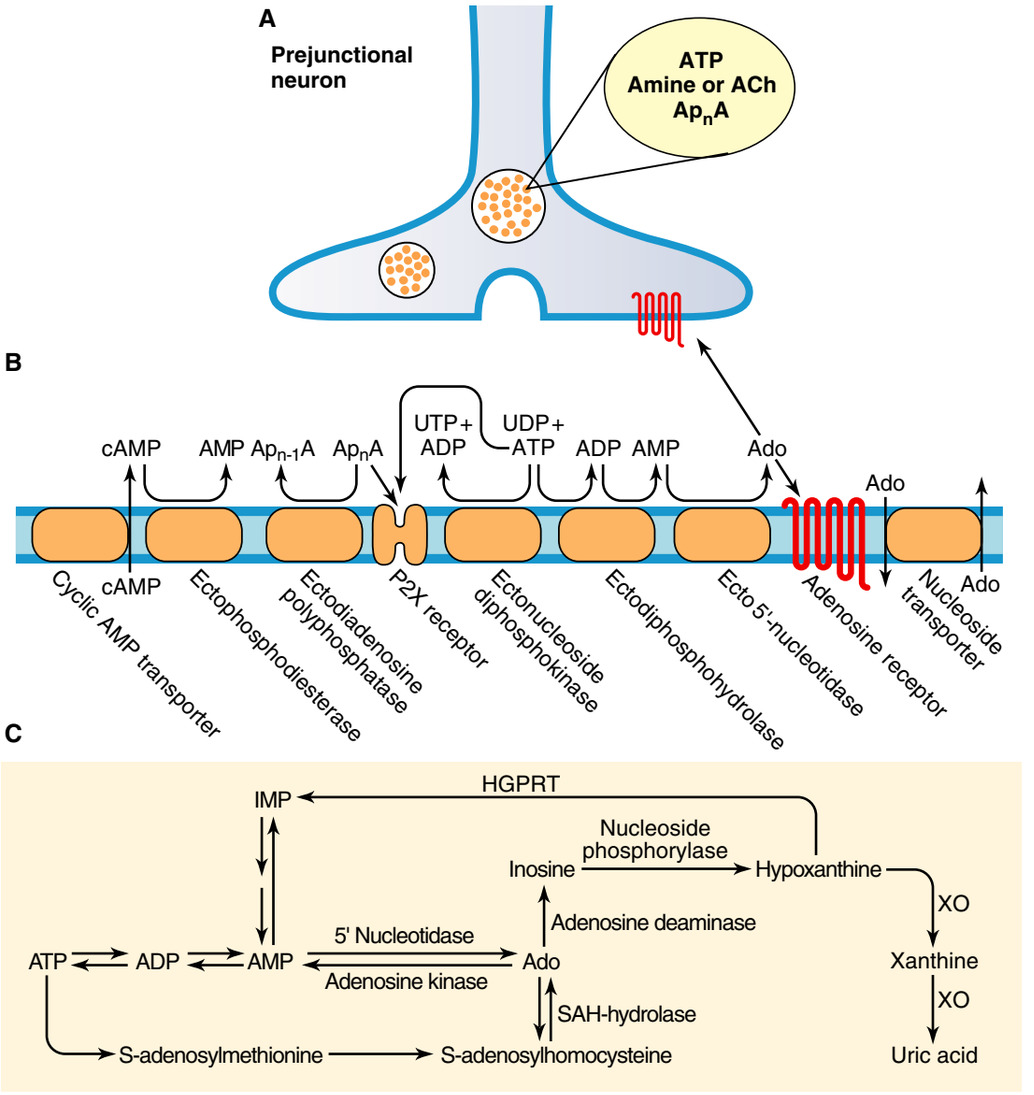

FIGURE 17-2 Purine release and metabolism. (**A**) Prejunctional neuron. Adenine nucleotides are schematically depicted as being stored as cotransmitters in synaptic granules (*see enlargement*). *Amine*, aminergic neurotransmitter; *Ach*, acetylcholine; Ap_nA, diadenosine polyphosphate. (**B**) Postjunctional membrane. Adenine nucleotides (ANs) and uridine nucleotides, diadenosine polyphosphates and cyclic AMP are degraded by ectoenzymes. Adenosine (*Ado*) and inosine accumulate in hypoxic, ischemic or metabolically active cells. Cyclic AMP accumulates as a second messenger in response to various neurotransmitters (see Ch. 21). These purines can be transported to the interstitial space by membrane-associated transport proteins. Both prejunctional (**A**) and postjunctional (**B**) adenosine receptors are depicted as traversing the plasma membrane seven times, as is typical of receptors that interact with GTP-binding proteins, including P_1 and P_{2Y} (not shown) receptors. A P_{2X} postjunctional ATP receptor is depicted as a ligand-gated channel. (**C**) Cytosol. The major pathways of intracellular adenosine metabolism are shown. *HGPRT*, hypoxanthine-guanine phosphoribosyl transferase; *IMP*, inosine monophosphate; *SAH*, *S*-adenosylhomocysteine; *XO*, xanthine oxidase.

action potentials, as illustrated in Figure 17-2A. Thus, ATP is released from synaptosomal preparations of cortex, hypothalamus and medulla. In cortical synaptosomes, a portion of the ATP that is released is co-released with acetylcholine or norepinephrine, but the majority is released from neurons that are neither adrenergic nor cholinergic. In affinity-purified cholinergic nerve terminals, ATP and acetylcholine are co-released in a ratio of 1:10. ATP is also released through channels or transporters from endothelial, epithelial and other cell types in response to hypoxia, mechanical stress or other stimuli to become available to cell-surface receptors and enzymes [1].

Extracellular nucleotides are regulated by ectoenzymes. Ectoenzymes are involved in the rapid metabolism of ATP and other nucleotides in the extracellular space [2]. ATP applied to rat brain hippocampal slices is mostly converted to adenosine in less than a second. Some of the enzymes involved in ATP, UTP and nucleoside metabolism are depicted in Figure 17-2B. Inhibitors of these

TABLE 17-1 Substrates and inhibitors of enzymes that are involved in nucleotide and nucleoside metabolism

Enzyme	Substrate	Inhibitor
ATP diphosphohydrolase	ATP, ADP	ARL67156
Diadenosine polyphosphatase	APnA	Suramin*
5′ nucleotidase	AMP	AOPCP
Nucleoside transporter	Adenosine	Dipyridamole, NBTI, mioflazine
Adenosine deaminase	Adenosine	EHNA, 2-deoxycoformycin
Adenosine kinase	Adenosine	5′-iodotubercidin, 5′-deoxy-5′-amino-adenosine
Xanthine oxidase	Hypoxanthine, xanthine	Allopurinol, CMTA
Nucleoside phosphorylase	Inosine	8-aminoguanosine

* Suramin also is an inhibitor of P_2 receptors.

AOPCP, α, β-methylene-adenosine diphosphate; AP_nA, diadenosine polyphosphate (n=3–6); ARL 67156, 6-*N*,*N*-diethyl-D-β,γ-dibromomethylene ATP; CMTA, 2-(3-cyano-4-isobutoxyphenyl)-4-methyl-5-thiazolecarboxylic acid; EHNA, erythro-9-(2-hydroxy-3-nonyl)adenine; NBTI, nitrobenzylthioinosine.

enzymes that are useful as experimental tools are listed in Table 17-1.

Ecto-ATP diphosphohydrolase (ADPase or apyrase) is a plasmalemma-bound enzyme that dephosphorylates extracellular ATP and ADP to produce AMP. This enzyme is identical to CD39, an activation marker found on B lymphocytes. A selective inhibitor of ecto-ATPase is ARL67156 (Table 17-1). This compound potentiates the effect of endogenously released as well as endogenously added ATP. Extracellular AMP is converted to adenosine by ecto-5′-nucleotidase, an enzyme that is attached to the cell surface by a glycosyl phosphatidylinositol linker. 5′-Nucleotidases catalyze the conversion of purine and pyrimidine nucleoside monophosphates to the corresponding nucleosides. CD73 is a 5′-nucleotidase that is found on T and B lymphocytes [3]. Ecto-5′-nucleotidase can be blocked by α,β-methylene-adenosine diphosphate (AOPCP). In histochemical studies, ecto-5′-nucleotidase has been found to be associated with plasma membranes of glial cells and astrocytes, particularly near synaptic terminals. Soluble cytosolic 5′-nucleotidases also exist and are involved in the formation of adenosine during increased metabolic activity. Even a small decrease in ATP concentration within cells can lead to a large fractional increase in AMP, because under normal conditions the concentration of ATP inside cells is about 50 times higher than that of AMP. The differentiation of neural cells is dependent on 5′-nucleotidase activity, suggesting that adenosine formation from continuously released nucleotides is essential for neuron survival. 5′-Nucleotidase is phosphorylated and activated by protein kinase C. In rat brain, ischemia results in an upregulation of 5′-nucleotidase on activated astrocytes. This is thought to increase the capacity of damaged tissue to form neuroprotective adenosine. Extracellular adenosine also can be derived from the metabolism of extracellular cyclic AMP by an ectocyclic AMP phosphodiesterase. Stimulation of receptors that stimulate cyclic AMP accumulation (β-adrenergic or VIP receptors) in cultured rat cortical neurons causes the accumulation of extracellular adenosine, which can be blocked by inhibition of cyclic AMP transport, cyclic nucleotide phosphodiesterase, or 5′-nucleotidase, indicating that extracellular cyclic AMP is a source of the adenosine.

Diadenosine polyphosphates are found in the synaptic granules of some nerves, can activate some P_2 receptors and are degraded in the extracellular space. In neural tissues the activity of ectodiadenosine polyphosphatases is lower than ecto-ATP-diphosphohydrolase. Hence, the diadenosine polyphosphates have a longer half-life in the extracellular space than does ATP.

UDP and UTP are selective agonists of certain of the P_{2Y} receptors. It is not yet clear what factors control the release of uridine nucleotides into the extracellular space. UTP can be formed from UDP in the extracellular space by the action of the enzyme nucleoside diphosphokinase, which catalyzes the transfer of the γ-phosphate of nucleoside triphosphates to nucleoside diphosphates, e.g., ATP + UDP → ADP + UTP.

There are several sources of extracellular adenosine. Adenosine is not a classical neurotransmitter because it is not stored in neuronal synaptic granules or released in quanta. It is generally thought of as a neuromodulator that gains access to the extracellular space in part from the breakdown of extracellular adenine nucleotides and in part by translocation from the cytoplasm of cells by nucleoside transport proteins, particularly in stressed or ischemic tissues (Fig. 17-2C). Extracellular adenosine is rapidly removed in part by reuptake into cells and conversion to AMP by adenosine kinase and in part by degradation to inosine by adenosine deaminases. Adenosine deaminase is mainly cytosolic but it also occurs as a cell surface ectoenzyme.

Adenosine and homocysteine are formed from the hydrolysis of *S*-adenosylhomocysteine (SAH) by the enzyme SAH hydrolase (Fig. 17-2C). Attempts to measure intracellular adenosine are complicated by the fact that

over 90% of intracellular adenosine may be weakly bound to this enzyme. SAH is formed from *S*-adenosylmethionine (SAM), which is a cofactor in transmethylation reactions. SAH is the precursor of a sizable fraction of adenosine under resting conditions, but most adenosine is derived from the 5′-nucleotidase pathway during conditions of hypoxia, ischemia or metabolic stress. The accumulation of high concentrations of adenosine under these conditions also leads to a large increase in inosine resulting from adenosine deamination. Intracellular adenosine can be reincorporated into the nucleotide pool upon phosphorylation by the cytosolic enzyme adenosine kinase. In normoxic resting tissues, most adenosine is rephosphorylated since the K_m of adenosine kinase is 10–100 times lower than the K_m of adenosine deaminase. Deamination, which leads to a large accumulation of inosine, becomes the major pathway of adenosine metabolism when adenosine levels are elevated, because maximal adenosine kinase activity is much less than maximal adenosine deaminase activity. Inhibitors of adenosine kinase or adenosine deaminase, by elevating adenosine, have been found to produce adenosine-like actions in laboratory animals. The concentrations of adenosine and inosine in the interstitial fluid of brain and other tissues are increased when oxygen demand exceeds oxygen supply. The effect of adenosine is to increase oxygen delivery by dilating most vascular beds and generally to decrease oxygen demand by reducing cellular energy utilization. In the brain this is usually manifested as a decrease in neuronal firing and decreased release of excitatory neurotransmitters.

Adenosine and inosine can be transported across cell membranes in either direction, facilitated by a membrane-associated nucleoside transport protein. Concentrative transporters have also been identified. Messenger RNA for a pyrimidine-selective Na^+-nucleoside cotransporter (rCNT1) and a purine-selective Na^+-nucleoside cotransporter (rCNT2) are found throughout the rat brain. Most degradation of adenosine is intracellular, as evidenced by the fact that inhibitors of adenosine transport, such as dipyridamole, increase interstitial levels of adenosine. Dipyridamole is used clinically to elevate adenosine in coronary arteries and produce coronary vasodilation. In high doses, dipyridamole can accentuate adenosine-receptor-mediated actions in the CNS, resulting in sedation and sleep, anticonvulsant effects, decreased locomotor activity and decreased neuronal activity.

Hypoxanthine is derived from inosine by the enzyme nucleoside phosphorylase. Hypoxanthine can be converted to IMP by hypoxanthine-guanine phosphoribosyl transferase (HGPRT), one of the enzymes of the purine salvage pathway. Lesch–Nyhan syndrome is a severe neurological disorder caused by a deficiency of HGPRT (Box 17-1). AMP can be formed from IMP by insertion of an amino group at C-6 in place of the carbonyl oxygen. This is a two-step reaction involving the formation of adenylosuccinate as an intermediate. Unsalvaged hypoxanthine is oxidized to xanthine, which is further oxidized to uric acid by xanthine oxidase (Fig. 17-2C, 17-3). Molecular oxygen, the oxidant in both reactions, is reduced to H_2O_2 and other reactive oxygen species. In man, uric acid is the final product of purine degradation and is excreted in the urine.

PURINERGIC RECEPTORS

Receptors for both ATP and adenosine are widely distributed in the nervous system, as well as in other tissues. The notion that there are purinergic receptors, i.e. proteins on the surface of cells that bind and respond to purines, was slow to evolve. The first evidence was the observation of cardiovascular effects of purines. Drury and Szent-Gyorgyi [4] first noted effects of adenine nucleotides on cardiac and vascular tissues in 1929. Then, 34 years later, Berne identified a physiological role for adenosine as a mediator of coronary vasodilation in response to myocardial hypoxia [5]. In the 1970s adenosine was found to stimulate cyclic AMP formation in brain slices. Since then, physiological effects of adenosine on almost all tissues have been described. Based on the responses of various tissues to purines, Burnstock proposed that there are distinct receptors that bind adenosine or ATP, designated P_1 and P_2 receptors respectively [6]. The existence of adenosine receptors was not widely accepted until the 1980s, when saturable binding sites for radioactive adenosine analogs were demonstrated in brain. The existence of adenosine receptors was proved unequivocally when the first adenosine receptors were cloned in 1990 [7]. Originally, the 'P' in P_1 and P_2 was meant to designate 'purinergic' receptors. However, it has now been discovered that some of the P_2 receptors bind pyrimidines (UTP or UDP) preferentially over the purine, ATP. Hence, the 'P' in P_2 is now used to designate purine or pyrimidine. Despite these exceptions, P_1 and P_2 receptors collectively are still generally referred to as purinergic receptors.

In addition to adenosine, various synthetic adenosine analogs activate P_1 but not P_2 receptors and synthetic ATP analogs or UTP analogs activate P_2 receptors but not adenosine receptors. However, not all purines activate P_1 or P_2 receptors. For example, adenine, guanosine and uric acid do not activate P_1 receptors. Inosine, the purine nucleoside product of adenosine deamination, generally has weak activity at P_1 receptors, but inosine binds to adenosine A_3 receptors, interferes with adenosine metabolism, modulates immune function and has neuroprotective effects. Its biological potency at A_3 adenosine receptors is greater in rodent species than in human. These actions of inosine may be physiologically significant because inosine accumulates to very high levels (>1 mmol/l) in ischemic tissues. Inosine stimulates mast-cell degranulation by binding to A_3 receptors but also produces anti-inflammatory effects by blocking the activation of macrophages, lymphocytes and neutrophils. In brain, inosine decreases

BOX 17-1

Inherited diseases of purine metabolism

George J. Siegel

Lesch–Nyhan syndrome (LNS) is an X-linked recessive inherited disorder usually evident at 6–10 months of age with choreiform movements, compulsive self-mutilation, spasticity, mental retardation, hyperuricemia and gout. LNS is associated with many types of mutations in the gene for the purine salvage enzyme hypoxanthine-guanine phosphoribosyltransferase (HGPRT) [1, 2]. This enzyme normally catalyzes the recycling of purines from degraded DNA and RNA. There is an almost complete deficiency of this enzyme in patients with the full syndrome. However, individuals with a partial deficiency in HGPRT generally have hyperuricemia and gout but not the full neurologic manifestations [3]. Treatment with allopurinol, which inhibits xanthine oxidase, reduces the levels of uric acid and the attendant symptoms of hyperuricemia but does not ameliorate the neurologic phenomena. Transgenic mouse models made to be genetically deficient in HGPRT or doubly deficient in HGPRT and in another purine salvage enzyme, adenine phosphoribosyltransferase (APRT), and thus devoid of any purine salvage pathways, do not show behavioral abnormalities reflective of the LNS phenotype [4]. However, administration of an inhibitor of APRT to HGPRT-deficient mice did produce self-injurious behavior [5]. Mice, in contrast to humans, exhibit uricase activity that might alter the consequences of high uric acid [6]. Other diseases associated with hyperuricemia, as in gout or phosphoribosylpyrophosphate synthetase deficiency, are not associated with the neurologic phenotype of LNS. Administration of dopamine agonists to rats with 6-*OH*-dopamine-induced lesions of catecholamine pathways or to primates with surgical lesions of the nigrostriatal pathway demonstrate stereotypical and self-injurious behaviors. These patterns appear related to supersensitivity of dopamine D1 receptors (see Ch. 12). Positron emission tomography with [^{18}F]-fluorodopa (see Ch. 58) has demonstrated abnormally few dopaminergic nerve terminals and cell bodies in the basal ganglia and frontal cortex of LNS patients, suggesting pervasive developmental abnormalities in dopaminergic systems [7]. Developmental dopaminergic neuronal system abnormalities may be related to the genetic alteration that occurs in the context of a multigene regulation pattern specific for the species [8, 9].

Mutations in the gene for adenylosuccinate lyase (ASL), inherited as an autosomal recessive disorder in purine metabolism, are associated with severe mental retardation and autistic behavior, but apparently not self-mutilation [10, 11]. This enzyme catalyzes two distinct reactions in the *de novo* biosynthesis of purines: the cleavages of adenylosuccinate (S-Ado) and succinylaminoimidazole carboxamide ribotide (SAICAR), both of which accumulate in plasma, urine and cerebrospinal fluid of affected individuals [12]. Measurements of these metabolites in urine is useful in screening neonates for this metabolic error [13]. **Deficiency of the muscle-specific myoadenylate deaminase (MADA)** is a frequent cause of exercise-related myopathy and is thought to be the most common cause of metabolic myopathy. MADA catalyzes the deamination of AMP to IMP in skeletal muscle and is critical in the purine nucleotide cycle. It is estimated that about 1–2% of all muscle biopsies submitted to medical centers for pathologic examination are deficient in AMP deaminase enzyme activity. MADA is 10 times higher in skeletal muscle than in any other tissue. Increase in plasma ammonia (relative to lactate) after ischemic exercise of the forearm may be low in this disorder, which is a useful clinical diagnostic test in patients with exercise-induced myalgia [14]. Genetta *et al.* [15] stated that AMPD deficiency is the most prevalent genetic disease in humans, the number of people heterozygous approaching 10% of Caucasians and individuals of African descent [16]. A small percentage of homozygous-deficient individuals, approximately 1.8% of the population, display symptoms of chronic fatigue and lost productivity as well as a predisposition to stress-related ailments, including heart disease and stroke [15, 16].

ischemia-reperfusion injury, perhaps by suppressing inflammation, preserves glial viability and promotes axon regeneration after injury.

The development of synthetic compounds that activate P_1 or P_2 receptors has been important for elucidating how these receptors function, because some of these compounds are more potent and selective than the parent purines, and most are more stable than the short-lived endogenous compounds adenosine and ATP.

The P-site of adenylyl cyclase inhibits cyclic AMP accumulation. Since P_1 and P_2 receptors are located on the cell surface, they bind purines or pyrimidines in the extracellular space. There also is an adenosine binding site located intracellularly on the enzyme adenylyl cyclase (see Ch. 21). This is referred to as the 'P-site' of adenylyl cyclase. Binding of adenosine and other purines, notably 3′AMP, 2′deoxy-3′-ATP and 2′,5′-dideoxyadenosine to this site, inhibits adenylyl cyclase activity [8]. The P-site of adenylyl cyclase and other intracellular purine binding sites are not classified as purinergic receptors.

There are four adenosine receptor subtypes. There are four subtypes of adenosine (P_1) receptor that have been cloned. These are referred to as A_1, A_{2A}, A_{2B} and A_3 (Fig. 17-4). All four of these belong to the superfamily of receptors that signal via guanosine triphosphate (GTP)-binding proteins (G proteins) and contain seven hydrophobic membrane-spanning segments, as illustrated in the case of the A_1 adenosine receptor in Figure 17-5 (see also Ch. 19). The receptors consist of a single subunit of molecular masses 35–46 kDa and have one or two consensus sequences for N-linked glycosylation (NXS/T) in their second extracellular loops. The human A_3 adenosine receptors also have two sites of N-linked glycosylation near the amino terminus. It is thought that these glycosylation sites may be involved in targeting receptors for expression on the cell surface. Adenosine receptors also contain multiple serine and threonine residues on the third intracellular loop or near the carboxyl terminus. In some cases, these may become phosphorylated and lead to receptor desensitization during prolonged exposure to adenosine. The greatest similarities in the structure of the adenosine receptor subtypes are found in the transmembrane segments, particularly in segments 2, 3 and 7. This suggests that these segments may be aligned next to each other in the plane of the membrane bilayer to form a ligand binding pocket. Three of the adenosine

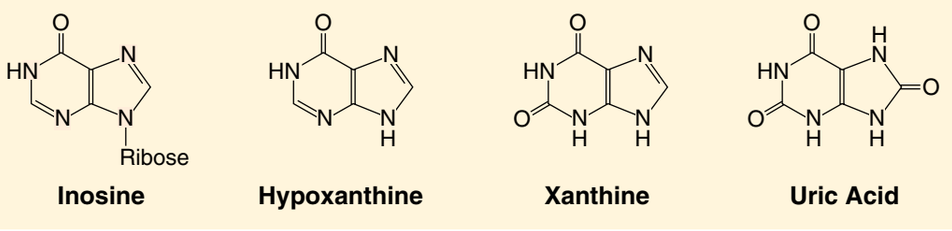

FIGURE 17-3 Adenosine metabolites. Adenosine is converted to inosine by adenosine deaminase. Removal of the ribose by nucleoside phosphorylase produces hypoxanthine, which is sequentially oxidized to xanthine and uric acid by xanthine oxidase.

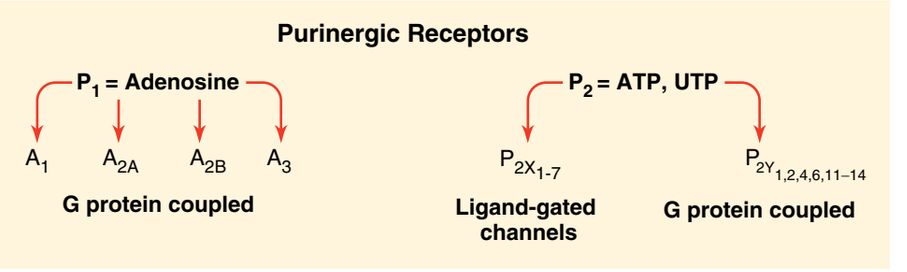

FIGURE 17-4 The purinergic receptor family. The purinergic receptors are divided into two major families, the P_1 or adenosine receptors and P2 receptors, which principally bind ATP, ADP, UTP or UDP. The P_{2Y14} receptor binds UTP-sugars. P_1 and P_{2Y} receptors are coupled to GTP binding proteins. P_{2X} subunits form trimeric ligand-gated ion channels.

receptors, A_1, A_{2B} and A_3, have a cysteine residue, thought to be palmitoylated, within 25 amino acids from the carboxyl terminus. The addition of this fatty acid may anchor the carboxyl terminal region of the receptor to the plasma membrane. As illustrated in Figure 17-6, the structure of the G-protein-coupled purinergic receptors varies little between species, and there is somewhat greater variability between subtypes, even within a single species. The adenosine receptor subtypes, their effectors and the identity of some selective agonists and antagonists are listed in Table 17-2.

Xanthines block P_1 but not P_2 receptors. One of the criteria initially used to distinguish between adenosine and ATP receptors was selective blockade of the former by xanthines (Fig. 17-7) such as caffeine (1,3,7-trimethylxanthine) and theophylline (1,3-dimethylxanthine). These xanthines occur naturally in coffee, tea and chocolate, and their well known stimulant action has been attributed to blockade of adenosine receptors in the CNS. Recently, 8-phenylxanthines, 8-cycloalkylxanthines and nonxanthine synthetic antagonists have been synthesized and characterized as adenosine receptor antagonists that are thousands of times more potent and, in some cases, more selective for individual adenosine receptor subtypes than are caffeine and theophylline.

P_2 receptors are subdivided into ionotropic P_{2X} receptors and metabotropic P_{2Y} receptors. P_{2X} receptors are ionotropic ligand-gated ion channels ($P_{2X1–7}$). There are

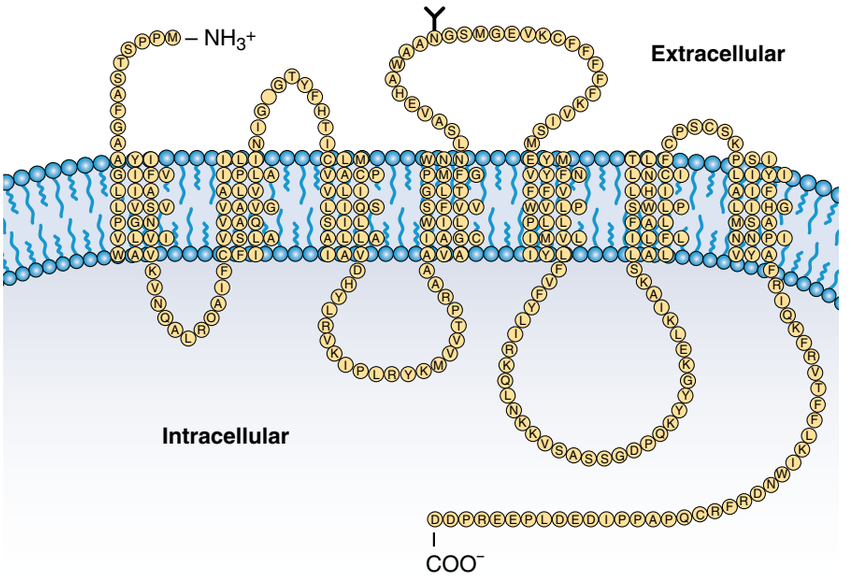

FIGURE 17-5 Deduced amino acid sequence and structure of the human A_1 adenosine receptor. This typical adenosine receptor is a member of the large family of guanine nucleotide-binding protein-coupled receptors that span the plasma membrane seven times. An unusual feature of adenosine receptors is the short amino terminus lacking N-linked glycosylation sites. These are found instead on extracellular loop 2 (as pictured). The ligand-binding pocket is thought to be formed by amino acids in transmembrane segments 2, 3, and 7. GTP-binding proteins are thought to interact with juxtamembranous regions of intracellular loops 2 and 3 and the carboxyl terminus.

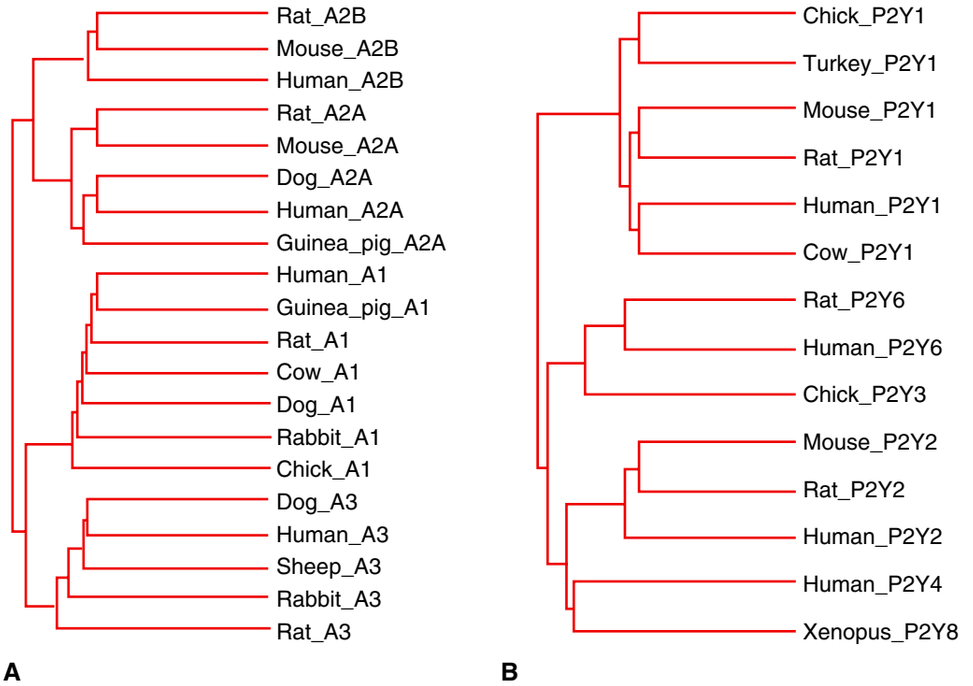

FIGURE 17-6 Dendrograms illustrating structural similarities among G-protein-coupled purinergic receptor subtypes. Distance along the horizontal axes is proportional to differences between species. (**A**) Adenosine receptor subtypes; the rat and rabbit A_3 receptors are 73.2% similar. (**B**) P_{2Y} receptor subtypes; the *Xenopus* P_{2Y8} and human P_{2Y4} receptors are 71.1% similar. P_{2Y3} is an avian receptor ortholog of human P_{2Y6}.

CGS21680, 2-[4-(2-carboxyethyl)phenethylamino]-5′-*N*-ethylcarboxamidoadenosine; CPA, N^6-cyclopenthyladenosine; CPX, 1,3-dipropyl-8-cyclopentylxanthine; MRE3008F20, 5N-(4-methoxyphenylcarbamoyl)amino-8-propyl-2-(2-furyl)pyrazolo[4,3-e]-1,2,4-triazolo[1,5-c]pyrimidine (human only); NECA, 5′-*N*-ethylcarboxamidoadenosine; SPT, *p*-sulfophenyltheophylline; SCH58261, 5-amino-7-(2-phenylethyl)-2-(2-furyl)-pyrazolo-[4,3-ε]-1,2,4-triazolo[1,5-c)pyrimidine; IB-MECA; N^6-(2-iodo)benzyl-5′-N-methylcarboxamidodiadenosine; ZM241385, 4-(2-[7-amino-2-[2-furyl][1,2,4]triazolo[2,3-α][1,3,5]triazin-5-yl-amino]ethyl)phenol.

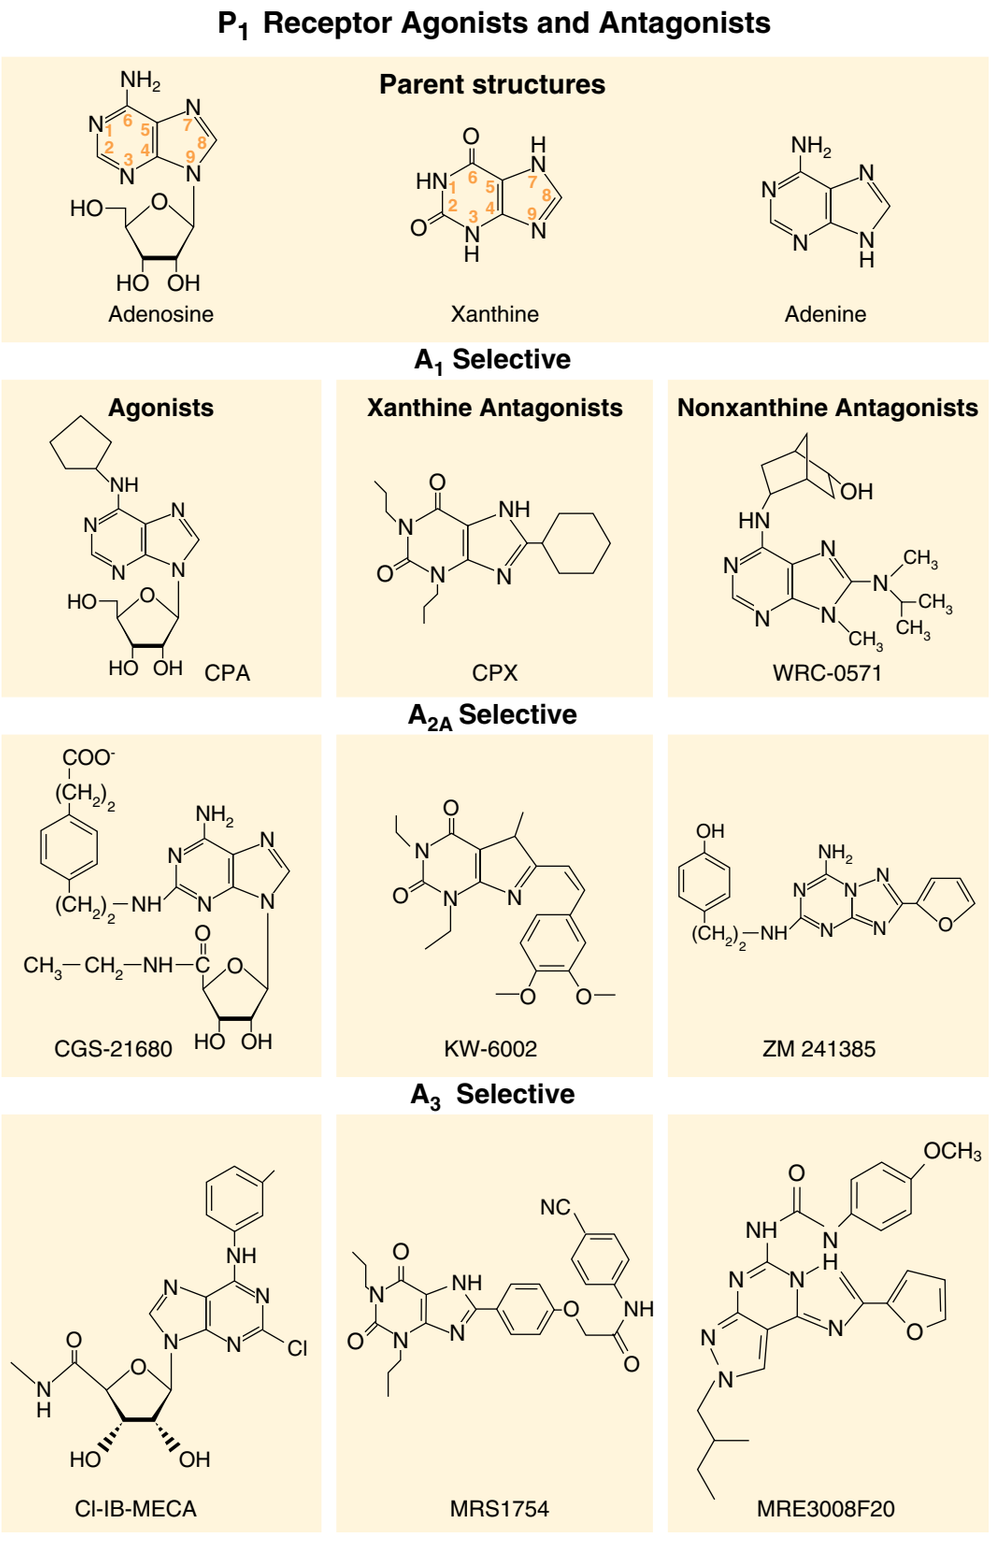

FIGURE 17-7 The structures of selective agonists and antagonists of adenosine receptors.

eight subtypes of metabotropic G-protein-coupled P_{2Y} receptors. The subtypes that have been cloned and identified to date as P_{2Y} receptors are P_{2Y1}, P_{2Y2}, P_{2Y4}, P_{2Y6} and $P_{2Y11–14}$. A putative receptor designated P_{Y15} was subsequently shown not be a purinergic receptor. The nomenclature is not sequential because of receptors that were either cloned from nonmammalian vertebrates or misidentified as purinergic receptors. It is likely that the number of P_{2Y} receptors will increase as the natural ligands for a group of cloned orphan receptors with highly similar sequence homology are identified. The P_{2Y} receptors can be subdivided into four categories based on their pharmacology: (a) P_{2Y1} and $P_{2Y11–13}$ receptors bind adenine-nucleotides, preferentially ATP and ADP; (b) P_{2Y6} receptors bind uracil-nucleotides, preferentially UTP and UDP; (c) P_{2Y4} and P_{2Y6} receptors bind ligands from both categories; and (d) P_{2Y14} receptors bind UDP-glucose, UDP-galactose or UDP-*N*-acetylglucosamine. They can also be grouped according to their G protein coupling, either to G_q (P_{2Y1}, P_{2Y2}, P_{2Y4}, P_{2Y6}, P_{2Y11}) with activation of phospholipase C and an inositol trisphosphate [IP_3]-dependent mobilization of intracellular Ca^{2+} (see Ch. 20) or to G_i ($P_{2Y12–14}$) with inhibition of adenylyl cyclase (see Ch. 21) [9]. The subset of receptors that respond to UTP was previously referred to as P2U receptors. The P_{2Y1} receptor is selectively activated by ADP and has the unusual feature of being blocked by ATP. This ADP receptor is found in platelets and was previously called $P2_T$ and P_{2YADP}. The P_{2Y2} receptor is activated by UTP and ATP with similar potency and is not activated by nucleoside diphosphates. Diadenosine tetraphosphate is a potent agonist at this receptor. The P_{2Y4} receptor is highly selective for UTP over ATP and is not activated by nucleoside diphosphates. The P_{2Y6} receptor is activated most potently by UDP and weakly or not at all by UTP, ADP and ATP.

The P_{2X} receptors are structurally unrelated to P_{2Y} receptors. They have two transmembrane domains with intracellular N and C termini separated by a large extracellular loop. P_{2X} receptors are heteromultimeric proteins that combine several subunits to form homomeric or heteromeric functional ion channels [10]. In general the P_{2X} receptors are activated by ATP and 2-methio-ATP. [^{35}S]ATPγS has been used as a radioligand for the direct labeling of cloned P_{2X} receptors. α,β-methylene-ATP is an agonist of P_{2X1} and P_{2X3} receptors but does not activate the other P_{2X} subtypes. ADP is a selective agonist of P_{2X5} and P_{2X6} receptors, and benzoyl-ATP is an agonist of the P_{2X7} receptor, an unusual receptor, previously called P2Z, that can cause cell lysis by promoting the formation of large pores. A problem that continues to hamper the study of P_2 receptors is the absence of receptor-subtype-selective antagonists (Table 17-3). The compounds that are used as P_2 receptor antagonists have low affinity for the receptors. These include reactive blue 2 (P_{2Y} receptors), suramin ($P_{2Y1} > P_{2Y2} > P_{2Y4}$), NF023 ($P_{2X}$ receptors) and pyridoxal phosphate-6-azophenyl-2′,4′-disulfonic acid (PPADS; $P_{2X} > P_{2Y}$). ATP and ARL-66,096 are antagonists of P_{2Y1} receptors.

TABLE 17-3 Antagonists for P_{2X} receptors

Receptor	Antagonist (rat pIC_{50}, M)
P_{2X1}	NF 449 (9.5)
P_{2X2}	NF 279 (6.4)
P_{2X3}	TNP-ATP (9.5)
P_{2X4}	Protons (6.8)
P_{2X5}	PPADS (6.7)
P_{2X6}	None
P_{2X7}	Brilliant Blue G (8.0)

NF 279, 88′-(carbonylbis(imino-4,1-phenylenecarbonylimino-4,1-phenylenecarbonylimino)) bis(1,3,5-naphthalenetrisulphonic acid); NF 449, 4,4′,4″,4‴-(carbonylbis(imino-5,1,3-benzenetriylbis(carbonyl imino)))tetra kis-benzene-1,3-disulfonic acid; PPADS, pyridoxalphosphate-6-azophenyl-2′,4′-disulfonic acid tetrasodium salt; TNP-ATP, 2′- (or 3′)-*O*-(trinitrophenyl)adenosine 5′-triphosphate

The distribution of mRNAs for P_2 receptors in the nervous system of the adult rat is summarized in Table 17-4.

EFFECTS OF PURINES IN THE NERVOUS SYSTEM: ADENOSINE RECEPTORS

The adenosine that activates receptors in the nervous system is derived in part from adenine nucleotides packaged in the synaptic granules of nerves and in part from ATP and adenosine derived from sources other than synaptic granules. Adenosine release evoked by electrical stimulation is completely dependent on propagated electrical activity, is blocked by tetrodotoxin (TTX) and is largely Ca^{2+}-dependent. Adenosine release by anoxia is Ca^{2+}-independent and largely insensitive to TTX. Many of the central actions of adenosine can be attributed to inhibition of Ca^{2+}-dependent excitatory neurotransmitter release. Most of these effects appear to be presynaptic and are mediated by G proteins coupled to inhibition of N-type Ca^{2+} channels or to stimulation of K^+ channels. However, in some instances, adenosine produces excitatory effects in the CNS. For example, in the nucleus tractus solitarius (NTS), adenosine increases glutamate release and elicits excitatory cardiovascular effects [11]. Both excitatory and inhibitory effects of adenosine have been noted in hippocampal slices. In spinal cord, adenosine can be derived from capsaicin-sensitive, small-diameter primary afferent neurons and potentiates the antinociceptive action of norepinephrine [12]. Opiates have been shown to induce release of adenosine from brain slices, synaptosomes and the spinal cord, and adenosine receptor antagonists block some of the effects of opiates. It has also been suggested that some of the behavioral effects of alcoholic beverages may be mediated by adenosine because intoxicating concentrations of ethanol can block adenosine transport.

TABLE 17-4 Distribution of P_2 receptor mRNAs in the central nervous system

Receptor	Accession no.	Transcript location
P_{2X1}	NM_002558	Large motor neurons of the spinal cord; important for neurotransmission to smooth muscle
P_{2X2}	NM_174873	Sensory and autonomic ganglia, dorsal and ventral horn of the spinal cord, thalamus, hypothalamus, preoptic area, red nucleus, oculomotor nucleus, locus coeruleus and dorsal motor nucleus of the vagus
P_{2X3}	NM_002559	Dorsal root ganglion, superficial dorsal horn of spinal cord, a subset of small-diameter sensory neurons, nucleus of the solitary tract, spinal trigeminal nucleus (important for peripheral pain)
P_{2X4}	NM_175568	Widespread in brain and spinal cord
P_{2X5}	NM_175080	Proprioceptive neurons of mesencephalic trigeminal nucleus, sensory ganglia
P_{2X6}	NM_005446	Widespread in brain, spinal cord and sensory ganglia, predominantly found in skeletal muscle
P_{2X7}	NM_177427	Found in cells of the immune system but not in CNS
P_{2Y1}	NM_002563	Telencephalon, diencephalon, mesencephalon, cerebellum
P_{2Y2}	NM_176072	Found in pituitary
P_{2Y4}	X91852	Not detected in human brain
P_{2Y6}	NM_176796	Not found in neuronal tissue
P_{2Y12}	AF313449	Brain (glia), spinal cord
P_{2Y13}	AF406692	
P_{2Y14}	NM 133577	Brain (glia), peripheral immune cells

A_1 adenosine receptors are inhibitory in the central nervous system. A_1 receptors were originally characterized on the basis of their ability to inhibit adenylyl cyclase in adipose tissue. A number of other G-protein-mediated effectors of A_1 receptors have subsequently been discovered; these include activation of K^+ channels, extensively characterized in striatal neurons [13], and inhibition of Ca^{2+} channels, extensively characterized in dorsal root ganglion cells [14]. Activation of A_1 receptors has been shown to produce a species-dependent stimulation or inhibition of the phosphatidylinositol pathway in cerebral cortex. In other tissues, activation of A_1 receptors results in synergistic activation of the phosphatidylinositol pathway in concert with Ca^{2+}-mobilizing hormones or neurotransmitters [15]. The effectors of A_1 adenosine receptors and other purinergic receptor subtypes are summarized in Table 17-2.

A_1 adenosine receptors are widely distributed in the central nervous system (Fig. 17-8). These receptors have been extensively characterized in brain because they are expressed in high density (0.5–1.0 pmol/mg membrane protein) and because of the development of several high-affinity radioligands, including [^{3}H]CPX. In the periphery, adenosine A_1 receptors are found in the heart, where they produce negative inotropic, chronotropic and dromotropic responses; in adipose tissue where they inhibit lipolysis and enhance insulin-stimulated glucose transport; and in kidney where they constrict preglomerular arterioles and produce antidiuresis. At the neuromuscular junction, adenosine inhibits acetylcholine release by a prejunctional effect on A_1 adenosine receptors.

Effects of adenosine that have been attributed to activation of central A_1 receptors include sedation, anticonvulsant activity, analgesia and neuroprotection. Adenosine

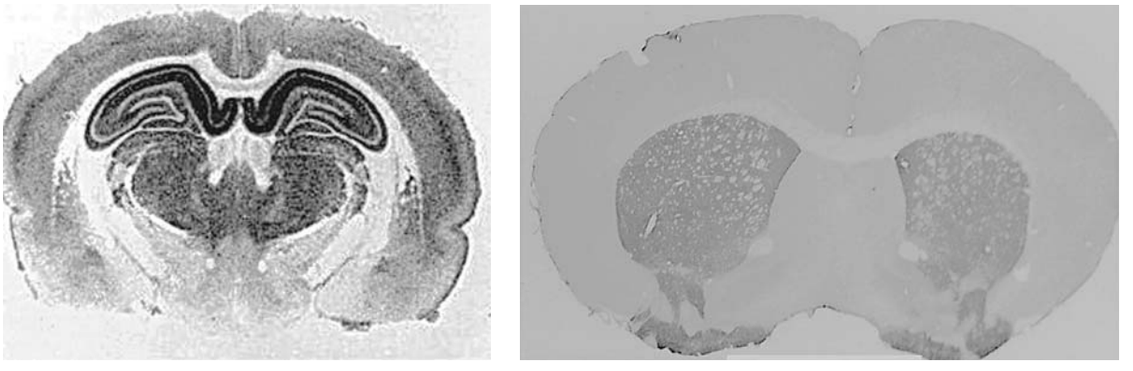

FIGURE 17-8 Distribution of A_1 and A_{2A} receptors in rat brain. (**A**) Autoradiograph of the binding of the A_1-selective radioligand [^{3}H]cyclohexyladenosine to a slice of rat brain. (Courtesy of Dr Kevin Lee, University of Virginia.) Note the widespread distribution of A_1 receptors and the particularly high density of receptors in the hippocampus. (**B**) Immunohistochemistry of A_{2A} adenosine in the mouse brain. Note the restricted striatal distribution.

modulates synaptic plasticity associated with distinct stimulation frequency patterns. Presynaptic A_1 adenosine receptors inhibit neurotransmitter release, especially at high neuronal stimulation frequency. Activation of A_1 receptors reduces long-term changes in synaptic efficiency (long-term potentiation) in various brain regions; e.g., activation of A_1 receptors reduces long-term potentiation of the population spikes evoked in the hippocampal CA1 area by stimulation of the Schaffer fibers. Release of glutamate and aspartate from nerve terminals in the CA1 region of the hippocampus is highly sensitive to inhibition by adenosine. Adenosine-induced antinociception is mediated in part by central A_1 receptors and by presynaptic A_1 receptor-induced inhibition of substance P- and CGRP-mediated release from terminals of sensory afferents, but mostly by activation of dorsal horn postsynaptic A_1 receptors located in lamina II of the spinal cord.

A_{2A} adenosine receptors are highly expressed in the basal ganglia. A_2 receptors were originally classified on the basis of their ability to stimulate cyclic AMP accumulation in neuronal tissues. Based on substantial differences in binding affinity for adenosine, these were divided into A_{2A} and A_{2B} subtypes, a subdivision that has subsequently been confirmed by molecular cloning. Adenosine analogs substituted on the 2-position, such as ATL146e and CGS21680, are agonists that bind with higher affinity to A_{2A} than to A_{2B} receptors. Caffeine, the most widely used psychoactive drug, has some selectivity as an antagonist of A_{2A} receptors. In transgenic mice that lack the A_{2A} receptors, caffeine reduces exploratory activity, an effect opposite to its usual one of stimulating exploratory activity. Potent and selective antagonists of A_{2A} receptors have been developed, including caffeine-like xanthines, such as CSC and KW-6002 and nonxanthine antagonists ZM241385 and SCH58261.

In the CNS, high-density expression of A_{2A} receptors is restricted to the striatum, nucleus accumbens and olfactory tubercle (Fig. 17-8B). In striatum, A_{2A} receptors are coexpressed in striatopallidal neurons with enkephalin and dopamine D_2 receptors. Blockade of A_{2A} receptors mimics the action of dopamine D_2 receptor agonists. Activation of A_{2A} adenosine receptors enhances cyclic AMP formation, whereas activation of D_2 dopamine receptors inhibits cyclic AMP formation. The administration of drugs that stimulate dopamine receptors, such as apomorphine and L-DOPA, to rodents with a unilateral lesion of the nigrostriatal pathway induces a turning behavior contralateral to the lesioned side, an effect due to the development of supersensitivity of dopamine receptors in the denervated striatum. Compounds that block adenosine receptors also produce such turning behavior and potentiate the effects of dopamine agonists. On the other hand, adenosine A_{2A} agonists inhibit D_2-mediated behaviors. Modulation by adenosine of striatal dopaminergic systems may contribute to the psychomotor depressant effects of adenosine agonists and to the psychomotor stimulatory effects of methylxanthines. The progressive degeneration of nigrostriatal neurons that occurs in Parkinson's disease results in a loss of dopaminergic input to striatal output neurons, enhanced striatopallidal GABAergic signaling and, hence, the motor disturbances that are characteristic of the disease (see Ch. 46). Replacement of dopaminergic input by administration of exogenous L-DOPA has been the primary therapeutic strategy for the treatment of Parkinson's disease for decades, but the complications associated with long-term L-DOPA treatment, particularly the 'wearing off' effects and the development of severe motor disturbances known as dyskinesias, have driven the search for alternative treatments. Adenosine A_{2A} receptors have become a target of therapeutic interest for a number of diseases, including Parkinson's disease [16, 17], mostly because of their discrete anatomical localization and their antagonistic interaction with dopamine D_2 receptors [18].

A_{2A}-selective adenosine receptor antagonists reverse the motor deficits in animal models of Parkinson's disease and potentiate the therapeutic effects of L-DOPA without producing dyskinesias. As such, they may have potential as adjunctive antiparkinsonian drugs. In addition, A_{2A} -receptor antagonists may also be useful in slowing the progression of neurodegeneration due to their neuroprotective effects in Parkinson's disease and other models of neurodegenerative disorders.

A_{2A} receptors that are present on sensory nerves in the carotid body, aortic body and elsewhere in the periphery produce excitatory sensory input. These receptors have been implicated in the production of pain associated with angina pectoris, ulcer and the human blister base preparation.

A_{2B} adenosine receptors regulate vascular permeability. A_{2B} receptors are found on endothelial cells, where they regulate vascular permeability, and on epithelial cells, where they regulate water secretion. These receptors are upregulated in the hippocampus following cerebral ischemic preconditioning and are thought to play a protective role. Both A_{2A} and A_{2B} receptors contribute to dilation of cerebral microvessels in response to adenosine.

A_3 adenosine receptors are few in the central nervous system. In the rat, abundant A_3 transcript is found exclusively in testes. However, the transcript for similar sheep and human receptors is modestly expressed throughout the brain and heavily expressed in pineal gland, lung and spleen.

EFFECTS OF PURINES IN THE NERVOUS SYSTEM: ATP RECEPTORS

P_{2X} subunits form trimeric ion-gated channels. As noted in Figure 17-4, there are seven genes encoding P_{2X}

channel subunits. Functional channels form when these receptors form homo- or heterotrimers [19]. The pharmacology of these channels is complex and may depend on the subunit composition of channel complexes.

P_{2X}-receptor-mediated responses in central and peripheral neurons indicate that ATP is a fast neurotransmitter that acts by opening ligand-gated ion channels [20]. P_2 receptors have a very wide tissue distribution. Excitatory effects of ATP on neurons in the CNS have been noted in the cuneate nucleus, cerebellar Purkinje cells, the cerebral cortex and cells in the sensory vestibular and trigeminal nuclei.. Effects of P_{2X} antagonists on excitatory postsynaptic currents in CA1 and CA3 pyramidal neurons suggest that P_2 receptors facilitate glutamate release. P_{2X} receptors may be important in central regulation of cardiorespiratory function; they have a critical role in peripheral chemoreceptor function and in modulating respiratory responses to hypoxia and hypercapnia. These receptors are also found in the gastrointestinal tract, veins and arteries, urinary bladder, vas deferens, nictitating membrane, cardiac muscle and pheochromocytoma (PC12) cells. In many instances, ATP has been noted to have biphasic or inhibitory effects, attributed in part to its breakdown to adenosine.

The release of ATP from a variety of cell types and its activation of P_{2X} receptors on sensory afferents is important in the initiation of pain that results from tissue trauma, inflammation or nerve injury. Adenosine, which may result from the rapid ectonucleotidase-mediated degradation of extracellular ATP, also modulates the pain pathways both centrally and peripherally. The P_{2X3} and heteromeric $P_{2X2/3}$ receptors in particular are present on a variety of nociceptive primary afferent neurons and may be involved in pain transmission. In addition, ATP can be released from spinal interneurons or by terminals of primary afferents in the spinal cord, where it modulates spinal nociceptive transmission by acting either on presynaptic P_{2X} receptors (1–3) to facilitate the release of glutamate or on postsynaptic P_{2X} receptors (homomeric P_{2X2}, P_{2X4}, and P_{2X6} and heteromeric $P_{2X4/6}$) on second-order neurons to stimulate fast excitatory transmission. If developed, potent and selective P_{2X} receptor antagonists, especially for P_{2X3} and $P_{2X2/3}$ receptors, could provide useful antinociceptive agents for the treatment of inflammatory, neuropathic and visceral pain.

P_{2Y} receptors are activated by adenine and uridine nucleotides. Most of the known P_{2Y} receptors have been detected in the nervous system [21]. The majority of P_{2Y} receptors inhibit neuronal N-type Ca^{2+} channels and M-type K^+ channels. P_{2Y1} receptors are found exclusively on platelets, on their precursor megakaryocyte cells and on certain other cultured hematopoietic cells, such as K562 leukemia cells. They can be distinguished from other P_2 receptors in that ADP is the most potent natural agonist and ATP is a competitive antagonist. ADP acts via a G protein to inhibit cyclic AMP accumulation, mobilize intracellular Ca^{2+} and stimulate granule secretion. ADP activates $P_{2Y}1$ and $P_{2Y}12$ receptors found on platelets and promotes platelet activity. Clopidogrel is metabolized in the liver to form a $P_{2Y}12$ antagonist that is used clinically to inhibit clotting.

Stable and potent P_{2Y2} receptor agonists are being administered by inhalation as a potential treatment for cystic fibrosis. P_{2Y14} receptors are unusual in that they are activated by UDP-glucose, UDP galactose and UDP-*N*-acetylglucosamine [22].

P_{2Y} receptors that are found on endothelial cells elicit a Ca^{2+}-dependent release of endothelium-dependent relaxing factor (EDRF) and vasodilation. A secondary activation of a Ca^{2+}-sensitive phospholipase A2 increases the synthesis of endothelial prostacyclin, which limits the extent of intravascular platelet aggregation following vascular damage and platelet stimulation. The P_{2Y}-mediated vasodilation opposes a vasoconstriction evoked by P_{2X} receptors located on vascular smooth muscle cells. The latter elicit an endothelial-independent excitation (i.e. constriction). P_{2Y} receptors are also found on adrenal chromaffin cells and platelets, where they modulate catecholamine release and aggregation respectively.

In the brain, P_{2Y} receptors may mediate the ability of ATP to enhance the postsynaptic actions of glutamate. Cotransmitter synergistic actions of ATP on the functional effects of glutamate may play an important role in learning and memory [23] (see also Ch. 53). Upregulation of P_{2Y14} receptors occurs in specific brain regions, including increased expression in astrocytes after immunological challenge, and suggests a mechanism for nervous system response to inflammation.

NEUROPEPTIDES 317
Many neuropeptides were originally identified as pituitary or gastrointestinal hormones 317
Peptides can be grouped by structural and functional similarity 317
The function of peptides as first messengers is evolutionarily very old 318
Various techniques are used to identify additional neuropeptides 319
The neuropeptides exhibit a few key differences from the classical neurotransmitters 319
Neuropeptides are often found in neurons with conventional neurotransmitters 320
The biosynthesis of neuropeptides is fundamentally different from that of conventional neurotransmitters 321
Many of the enzymes involved in peptide biogenesis have been identified 321
Neuropeptides are packaged into large, dense-core vesicles 325
Diversity is generated by families of propeptides, alternative splicing, proteolytic processing and post-translational modifications 326

NEUROPEPTIDE RECEPTORS 326
Most neuropeptide receptors are seven-transmembrane-domain, G-protein-coupled receptors 326
Neuropeptide receptors are not confined to synaptic regions 327
Expressions of peptide receptors and the corresponding peptides are not well matched 327
The amiloride-sensitive FMRF-amide-gated sodium ion channel is among the few peptide-gated ion channels identified 328
Neuropeptide receptors are becoming molecular targets for therapeutic drugs 328

NEUROPEPTIDE FUNCTIONS AND REGULATION 328
The study of peptidergic neurons requires a number of special tools 328
Peptides play a role in the plurichemical coding of neuronal signals 329
Neuropeptides make a unique contribution to signaling 329
Regulation of neuropeptide expression is exerted at several levels 329

PEPTIDERGIC SYSTEMS IN DISEASE 330
Diabetes insipidus occurs with a loss of vasopressin production in the Brattleboro rat model 330
Mutations and knockouts of peptide-processing enzyme genes cause a myriad of physiological problems 330
Neuropeptides play key roles in appetite regulation and obesity 330
Enkephalin knockout mice reach adulthood and are healthy 331
Neuropeptides are crucial to pain perception 331

Basic Neurochemistry: Molecular, Cellular and Medical Aspects

NEUROPEPTIDES

Many neuropeptides were originally identified as pituitary or gastrointestinal hormones. Probably the first neuropeptide to be identified was vasopressin, a nine-amino-acid peptide secreted by the nerve endings in the neural lobe of the pituitary. The source of the vasopressin is the magnocellular neurons of the hypothalamus, which send axons to the neurohypophysis, which is the site of release into the blood, in classic neurosecretory fashion. Like vasopressin, a number of gastrointestinal peptides, such as cholecystokinin (CCK), are also found at high concentrations in the nervous system. In the gastrointestinal system, CCK is secreted into the blood by the duodenum and governs the delivery of digestive enzymes and bile acids into the intestine. In contrast to vasopressin and CCK, the hypothalamic releasing factors are peptides released into a special portal blood system that bathes the anterior pituitary, controlling the secretion of pituitary hormones (see Ch. 52). In this system, 'portal' means two successive capillary beds, one in the hypothalamus and one in the anterior pituitary. Substance P was first purified as a 'sialogogic peptide', causing salivation in a bioassay. Now substance P is recognized as a major bioactive peptide in many neuronal pathways, including pain signaling. Since there are so many peptides, this chapter focuses on the principles of how neuropeptides are synthesized, stored and released and how they act on the cells they regulate. Comparisons among peptides and smaller, 'fast-acting', 'classical' or 'conventional' neurotransmitters will be emphasized. It is significant to note that the number of known neuropeptides far exceeds the number of fast-acting conventional neurotransmitters.

Peptides can be grouped by structural and functional similarity. Although the list of neuropeptides is already quite long, as seen in the partial listing in Figure 18-1,

Selected Bioactive Peptides

Hypothalamic releasing factors

CRH: corticotropin releasing hormone
GHRH: growth hormone releasing hormone
GnRH: gonadotropin releasing hormone
Somatostatin
TRH: thyrotropin releasing hormone

Pituitary hormones

ACTH: adrenocorticotropic hormone
αMSH: α-melanocyte stimulating hormone
β-endorphin
GH: growth hormone
PRL: prolactin
FSH: follicle stimulating hormone
LH: luteinizing hormone
TSH: thyrotropin [thyroid stimulating hormone]

GI and brain peptides

CCK: cholecystokinin
Gastrin
GRP: gastrin releasing peptide
Motilin

PYY: peptide YY

Endocrine only?

Calcitonin
Insulin
Secretin
Parathyroid hormone

FIGURE 18-1 Selected bioactive peptides are grouped by structural similarity or by tissue source.

additional neuropeptides are still being identified. Like GABA and glutamate or dopamine and norepinephrine, which differ by only a single carboxyl or hydroxyl group, yet have very different functions, many neuropeptides with similar structures have very different functions. Vasopressin and oxytocin are the two major neurohypophyseal peptides, and each consists of nine amino acids. These two peptides are identical at seven of those residues and are thought to be the result of gene duplication early in evolution. The actions of the two peptides are distinct: oxytocin causes milk letdown and uterine contraction, while vasopressin causes water retention in the kidney and blood vessel contraction. Likewise, the opiate peptides share a common Tyr–Gly–Gly–Phe–Met/Leu sequence at their NH_2-terminus and are potent endogenous opiates with distinct patterns of selectivity at the various classes of opiate receptor (see Ch. 56). The three glycoprotein hormones from the anterior pituitary, thyroid stimulating hormone (TSH), luteinizing hormone (LH) and follicle-stimulating hormone (FSH), share a common α subunit but have distinct β subunits, and only the αβ dimer is biologically active. The tachykinin group includes substance P and various frog skin peptides, all with similar core sequences and –Phe–X–Gly–Leu–Met–NH_2 at the COOH-terminus. The gastrointestinal peptides CCK and gastrin share a common COOH-terminal sequence (Trp–Met–Asp–Phe–NH_2) and are among the few peptides that undergo tyrosine sulfation. The sites of action of CCK and gastrin are distinct: gastrin stimulates gastric acid secretion, while CCK stimulates enzyme and bile acid delivery to the small intestine. Interestingly, the common COOH-terminal tetrapeptide, while inactive in the gastrointestinal tract, is abundant in the cerebral cortex and has important behavioral actions.

The function of peptides as first messengers is evolutionarily very old. In phylogenetic terms, neuropeptides were established very early as molecules effecting intercellular communication. In coelenterates, such as *Hydra*, there are many peptides used in neurotransmission, but many of the 'conventional' neurotransmitter systems, such as acetylcholine (ACh), catecholamines and serotonin,

covered in previous chapters, are not found [1]. The nerve net is strongly peptidergic in the lowest animal group with a nervous system, the cnidarians, which includes sea anemones, corals, jellyfishes and *Hydra*. Yeasts use bioactive peptides such as a- and α-mating factors to communicate.

Various techniques are used to identify additional neuropeptides. Bioassays are the oldest and surest way to identify biologically active peptides; more recently, with the advent of receptor-based assays, peptides have been identified by their ability to bind to a known receptor and thus to displace a ligand or to produce a biological response. The use of a relatively homogeneous tissue source, such as adrenal chromaffin granules, enabled identification of peptides derived from chromogranin A. Mass spectrometry, with its great sensitivity, is being used to characterize peptides from many sources. As noted above, peptides important in the nervous system were often identified first in some peripheral source, such as CCK in the gut, or even in unusual places, such as frog skin. Since α-amidation of the COOH-terminus of peptides has proven to be a signature of bioactive peptides, assays specific for COOH-terminal α-amides were developed and used to discover neuropeptide Y and several other peptides. Molecular biological approaches have also been used to discover many new peptides. Subtractive hybridization and differential display have been used to identify both the cocaine- and amphetamine-regulated transcript (CART) and RESP18, a dopamine-regulated transcript. Finally, screens using orphan receptors, which have no known ligand, were used to find natural ligands, such as orphanin FQ/nociceptin and orexin/hypocretin. Systematic scans of sequence databases can identify additional family members and potential peptide precursors, by taking into account key features of precursor structures.

The neuropeptides exhibit a few key differences from the classical neurotransmitters. First, neuropeptides are present in tissues at much lower concentrations than classical neurotransmitters. Consistent with this, neuropeptides are also active at receptors at correspondingly lower concentrations. For example, the concentration of ACh and NE in synaptic vesicles is in the 100–500 mmol/l range, while the concentration of neuropeptide in a large dense core vesicle is 3–10 mmol/l at most. Correspondingly, the affinity of ACh for its receptors is in the micromolar to millimolar range, while peptides typically bind to their receptors with affinities in the nanomolar to micromolar range.

Probably the most striking difference between neuropeptides and conventional neurotransmitters is in their biosynthesis (Fig. 18-2). Neuropeptides are derived from larger, inactive precursors that are generally at least 90 amino acid residues in length [2–4]. The simplest example is prolactin, a pituitary product. The signal sequence for

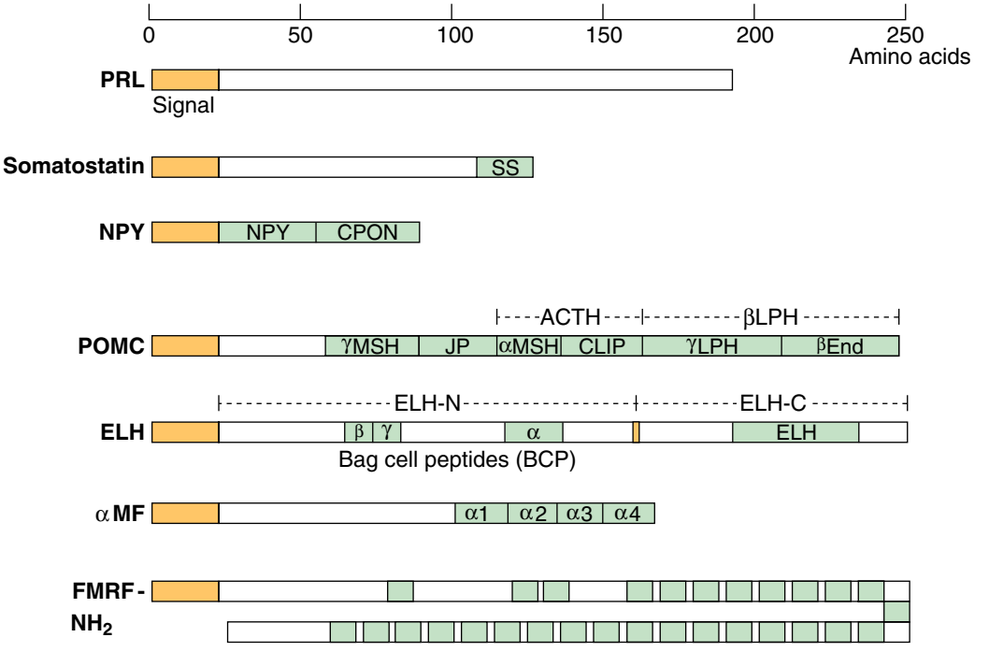

FIGURE 18-2 Structures of selected bioactive peptide precursors are diagrammed. The structures of prolactin (*PRL*), somatostatin, neuropeptide Y (*NPY*), pro-opiomelanocortin (*POMC*), egg-laying hormone (*ELH*), yeast α-mating factor (*αMF*) and FMRF-amide precursors (*FMRF-NH$_2$*) are indicated. Signal sequences are shaded and on the left of each precursor. *βEnd*, β-endorphin; *ACTH*, adrenocorticotropic hormone; *CLIP*, corticotropin-like intermediate lobe peptide; *CPON*, C-terminal flanking peptide of NPY; *JP*, joining peptide; *LPH*, lipotropin; *MSH*, melanocyte-stimulating hormone; *SS*, somatostatin.

prolactin must be removed and disulfide linkages must form, but no further enzymatic steps are necessary. The next simplest case is somatostatin, in which a single cleavage after signal peptide removal produces the bioactive peptide. Neuropeptide Y (NPY) is derived from proneuropeptide Y after signal peptide removal, cleavage between NPY and the C-terminal flanking peptide of NPY (CPON) and additional modifications, which are discussed below. The pro-opiomelanocortin (POMC) precursor includes several different bioactive peptides, as does the egg-laying hormone (ELH) precursor [2]. One interesting attribute common to peptide precursors in evolutionarily older species is the existence of multiple copies of the same bioactive peptide in one precursor; this is exemplified by the FMRF-NH_2 (Phe–Met–Arg–Phe–amide) precursor, with 29 copies of the active peptide [5]. Even in yeast, a similar process is used, so that four copies of α-mating factor are produced from the α-mating factor precursor. Precursors with multiple copies of bioactive peptide are much less common in evolutionarily more advanced species, although the rat TRH precursor contains five copies of the TRH tripeptide.

The supply of conventional neurotransmitters in small synaptic vesicles is replenished in nerve terminals by local synthesis, and many conventional neurotransmitters are recaptured after secretion. In striking contrast, neuropeptides are initially synthesized in the cell soma, sequestered within the lumen of the secretory pathway and transported down the axon while undergoing cleavages and other processing events, after which the peptide-containing, large dense-core vesicle (LDCV) is used once. After exocytosis, the membrane components of the LDCV must be reinternalized and either destroyed or transported back to the cell body for reuse. Thus, no re-use of either the neuropeptides or their immediate precursors occurs at the synapse.

Release is another area of difference: conventional neurotransmitters are secreted from small synaptic vesicles (SSVs) after cytosolic [Ca^{2+}] transiently reaches concentrations of 50–100 µmol/l, while peptides are released from LDCVs at lower concentrations of cytosolic [Ca^{2+}] (Fig. 18-3). Conventional neurotransmitter release is thought to occur very close to the site of Ca^{2+} entry (see Chs 9, 10), while neuropeptides are typically released at a distance from the site of Ca^{2+} entry (Fig. 18-4). Furthermore the Ca^{2+} that stimulates exocytosis from LDCVs may come from either internal stores or the extracellular fluid. Thus, the location of LDCVs relative to the site of Ca^{2+} influx has a very crucial impact on the intensity of stimulation necessary for secretion to occur.

Neuropeptides are often found in neurons with conventional neurotransmitters. As illustrated in Figure 18-3, both conventional neurotransmitters and neuropeptides are found at a majority of the synapses in the nervous system. Neuropeptide expression is extremely plastic, even in the adult. For example, the hypothalamic neurons that express vasopressin and those that synthesize

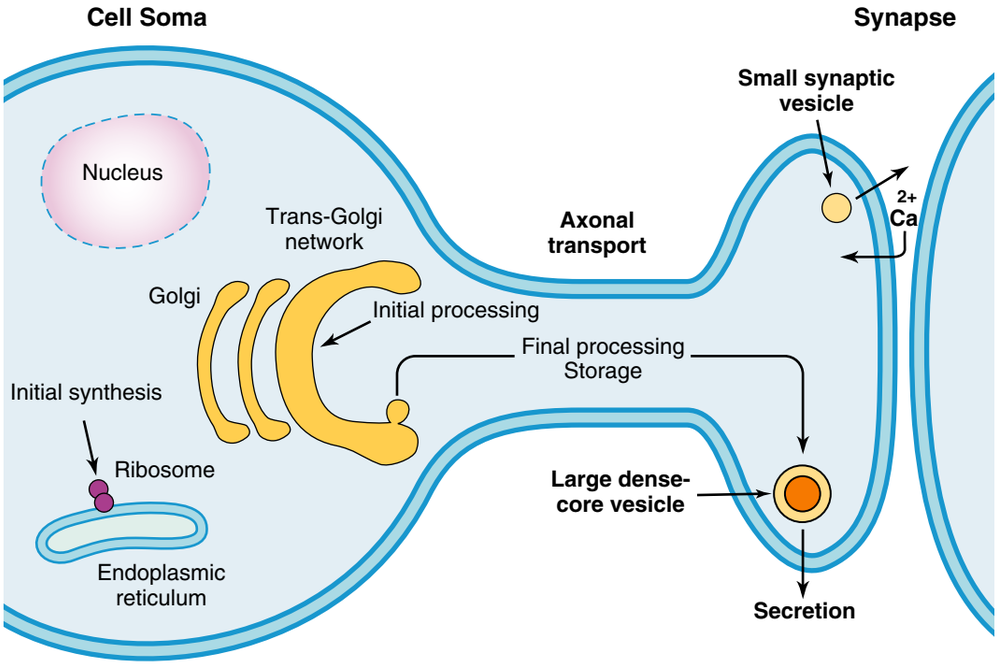

FIGURE 18-3 Intracellular pathway of bioactive peptide biosynthesis, processing and storage. Neuropeptide precursors are synthesized on ribosomes at the endoplasmic reticulum and processed through the Golgi. Axonal transport of the large dense-core vesicle to the synaptic site of release precedes the actual secretion.

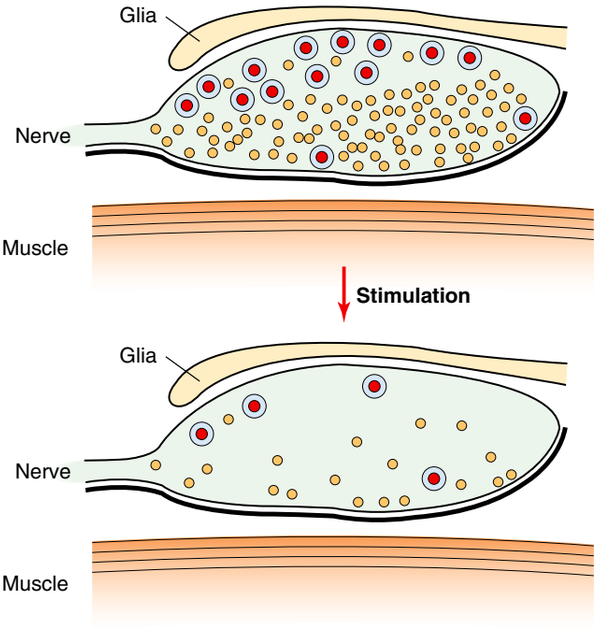

FIGURE 18-4 Neuropeptides and conventional neurotransmitters are released from different parts of the nerve terminal. A neuromuscular junction containing both large dense-core vesicles (containing the neuropeptide SCP) and also small synaptic vesicles (containing acetylcholine) was stimulated for 30 min at 12 Hz (3.5 s every 7 s). Depletion of the small clear vesicles at the muscle face and of the peptide granules at the nonmuscle face of the nerve terminal was observed. After stimulation, there was an increase in the number of large dense-core vesicles within one vesicle diameter of the membrane. (Adapted from reference [37].)

corticotropin-releasing hormone (CRH) are situated close to each other but constitute separate and virtually nonoverlapping populations of neurons in the normal animal. However, after glucocorticoid concentrations are lowered by blockade of adrenal cortical function or removal of the adrenal glands, vasopressin neurons begin to express CRH and CRH neurons begin to synthesize vasopressin. This adaptive response can be understood from a teleological point of view by knowing that CRH normally stimulates the adrenocorticotropic-hormone (ACTH)-producing cells of the anterior pituitary to secrete ACTH and that ACTH stimulates glucocorticoid production in the adrenal cortex. Vasopressin acts synergistically to increase ACTH secretion in times of need, such as following adrenalectomy. In addition to neuropeptides, many LDCVs contain ATP, just as many conventional neurotransmitter vesicles do, so that ATP is released along with neuropeptides. ATP and adenosine can have potent synaptic actions in their own right (see Ch. 17 for purinergic systems).

The biosynthesis of neuropeptides is fundamentally different from that of conventional neurotransmitters. To add to the complexity discussed above, the metabolism of neuropeptide precursors is tissue-specific, with a general rule that most precursors are expressed in more than one tissue and that the processing is not identical in different tissues (Fig. 18-5) [2–4]. For example, anterior pituitary corticotropes cleave POMC to ACTH(1–39), a molecule that stimulates adrenal glucocorticoid production. Neurons in the arcuate nucleus cleave ACTH and α-amidate, the smaller peptide to create ACTH(1–13)NH_2, which cannot stimulate the adrenal cortex but does have potent behavioral effects in the CNS. Intermediate pituitary melanotropes go one step further and α-*N*-acetylate the amidated peptide to produce α-melanocyte-stimulating hormone (αMSH). The skin-darkening activity of αMSH is especially important in lower vertebrates for which background color adaptation is protective. Similarly, corticotropes produce β-lipotropin (βLPH), which has no activity as an opiate peptide, while melanotropes and CNS neurons cleave βLPH to produce the potent opiate peptide β-endorphin(1–31). In some tissues, the β-endorphin may be shortened at the COOH-terminus, which decreases its opiate activity, or α-*N*-acetylated at its NH_2-terminus, which abolishes opiate activity. The cellular control of these different patterns of processing is beginning to be understood, with the identification of some of the enzymes that mediate these steps.

Other examples of tissue-specific processing include proenkephalin, proglucagon, procholecystokinin and prosomatostatin. Somatostatin neurons in the hypothalamus primarily produce a 14-residue form of the peptide, while somatostatin endocrine cells of the pancreas and intestine produce a 28-residue form derived from the same precursor. Proenkephalin is processed in the adrenal medulla to a set of opiate peptides of 15–35 residues, while proenkephalin in the brain is cleaved primarily to the pentapeptides met-enkephalin and leu-enkephalin. Procholecystokinin in the gut is processed to peptides of approximately 30 residues, which act on the pancreas and gallbladder, while smaller CCK-related peptides with behavioral effects are found in the brain. These smaller CCK-related peptides have no effects when applied to the pancreas or gallbladder. Understanding peptide biosynthesis and peptide structures is important, since many smaller peptide fragments are active, frequently exhibiting biological activities distinct from that of the larger parent peptide [6].

Many of the enzymes involved in peptide biogenesis have been identified. The most common steps in precursor processing and the enzymes involved are shown in Figure 18-6. The endoproteases involved are prohormone convertases 1 and 2 (PC1 and PC2), the exopeptidase is carboxypeptidase E (CPE) and the α-amidating enzyme is peptidylglycine α-amidating monooxygenase (PAM). The nomenclature for PCs is very confusing and is summarized in Table 18-1; this chapter uses the original names for the PCs. Many steps in their biosynthesis, such as signal peptide cleavage, disulfide bond formation, the addition and subsequent modification of N-linked and O-linked oligosaccharides, phosphorylation and sulfation,

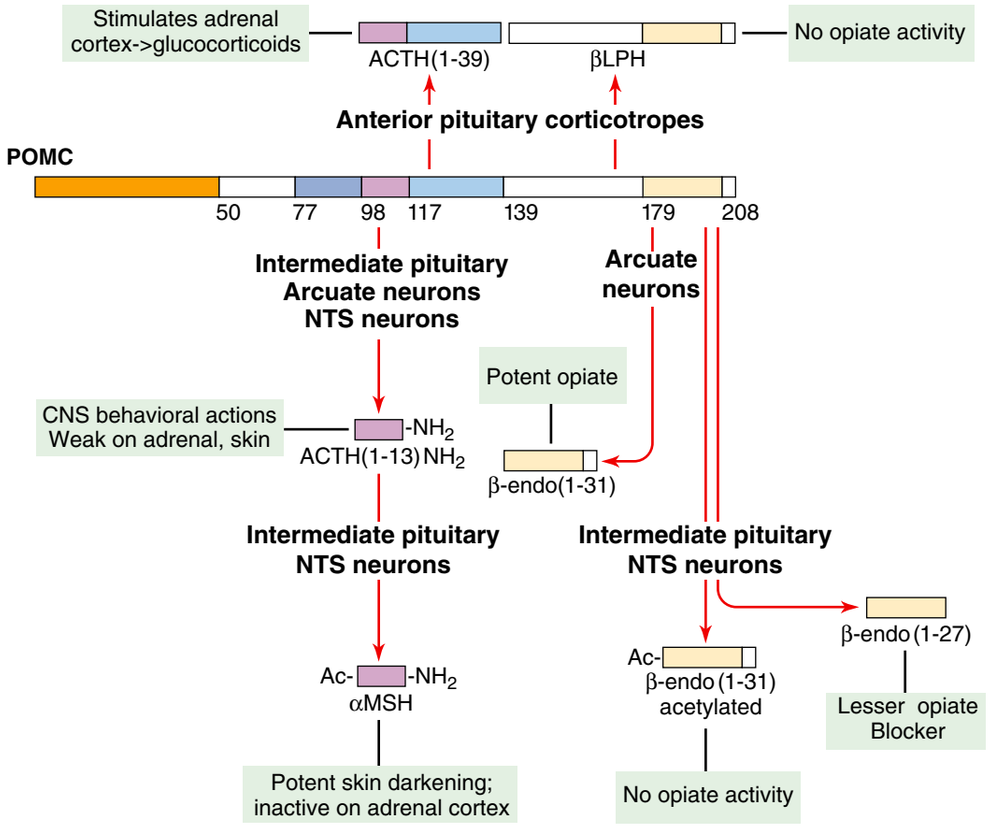

FIGURE 18-5 Tissue-specific processing of the pro-opiomelanocortin (*POMC*) precursor yields a wide array of bioactive peptide products. Processing of the POMC precursor varies in various tissues. In anterior pituitary, adrenocorticotropic hormone (*ACTH (1–39)*) and β-lipotropin (β-*LPH*) are the primary products of post-translational processing. Arcuate neurons produce the potent opiate β-endorphin (β-*endo (1–31)*) as well as ACTH(1–13)NH_2. Intermediate pituitary produces α-melanocyte-stimulating hormone (α*MSH*), acetylated β-endo(1–31) and β-endo(1–27). *NTS*, nucleus tractus solitarius.

are not unique to neuropeptides. As shown in Figure 18-3, many of the post-translational steps occur as the maturing neuropeptides travel down the axon toward the synapse in LDCVs. The later steps in neuropeptide biosynthesis (Fig. 18-6) are unique to neurons and endocrine cells.

Key enzymes in neuropeptide biosynthesis include endoproteases, exoproteases and enzymes modifying the ends of the peptides. The discovery and characterization of Kex2p, the endoprotease that cleaves yeast pro-α-mating factor to produce four copies of the pheromone α-mating factor (Fig. 18-2), were key to the discovery of the mammalian prohormone convertases, including furin, PC1, PC2, PC4, PC5, PC8 and PACE4 [3, 4, 7]. The prohormone convertases share homology with bacterial subtilisins at their NH_2-termini, and have an Asp–His–Ser catalytic triad, which consists of the three key amino acids involved in catalysis (denoted D, H and S in Fig. 18-6). Eukaryotic enzymes in this family all have an essential 'P' domain COOH-terminal to the subtilisin-related enzymatic domain, followed by a variable region [3]. The proregion of each enzyme (Fig. 18-6) must be present during biosynthesis for the protease to fold correctly but must be removed to yield an activated protease. For PC1 and furin, removal of the proregion occurs within a few minutes of biosynthesis while the enzyme is in the endoplasmic reticulum and is most probably an autocatalytic event. For the other prohormone convertases, removal of the proregion occurs much more slowly. Expression of active PC2 is thought to require coexpression of the peptide 7B2 (Fig. 18-6), which appears to perform a chaperone function and may also prevent expression of PC2 endoproteolytic activity until PC2 has been deposited into secretory granules [8]. Pro-SAAS may be a corresponding chaperone/inhibitor peptide for PC1.

The mammalian endoproteases most clearly involved in neuropeptide processing are PC1 and PC2, Ca^{2+}-dependent proteases found in secretory granules whose expression is limited to neurons and endocrine cells (Fig. 18-6). Several other members of this endoprotease family are more widely expressed, while still others are expressed in restricted locations distinct from neurons and endocrine cells. For example, furin is found in virtually all cells and is localized primarily to the *trans*-Golgi network; furin catalyzes cleavages important in peptide function, such as the initial cleavage of the precursors to ELH, nerve growth factor and parathyroid hormone, as well as cleavage within the insulin receptor precursor to produce the active αβ dimer form of that receptor. Furin may also be instrumental in the activation of some of the other processing enzymes, such as PC2 and CPE.

PC1 and PC2 cleave at selected pairs of basic amino acids in peptide precursors: Lys–Arg, Arg–Arg, Lys–Lys and Arg–Lys. PC1 may also catalyze cleavages at selected single Arg sites present in some precursors, such as prosomatostatin and procholecystokinin. Cleavages in LDCVs by PCs are tightly controlled, often occurring in a very orderly fashion (Fig. 18-7). The initial cleavages of POMC

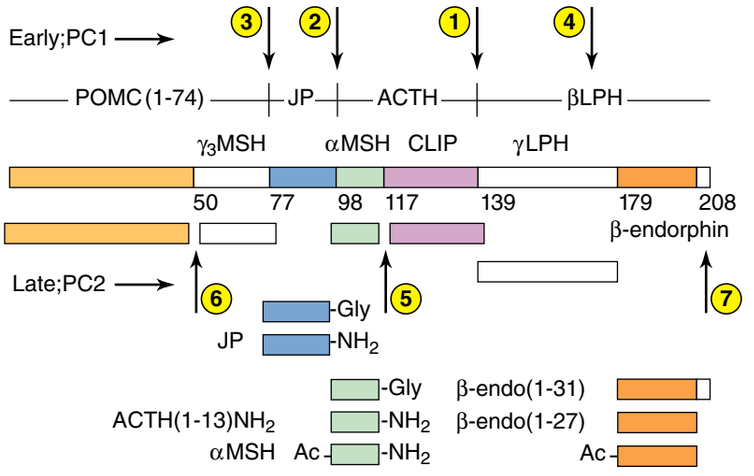

FIGURE 18-7 Processing of the pro-opiomelanocortin (*POMC*) precursor proceeds in an ordered, stepwise fashion. Cleavage of the POMC precursor occurs at seven sites, with some of the reactions being tissue-specific. The circled numbers indicate the temporal order of cleavage in tissues where these proteolytic events occur. *ACTH*, adrenocorticotropic hormone; *CLIP*, corticotropin-like intermediate lobe peptide; *JP*, joining peptide; *LPH*, lipotropin; *MSH*, melanocyte-stimulating hormone; *PC*, prohormone convertase.

occur in less than 1 hour (Fig. 18-7, steps 1 and 2, performed by PC1), while other cleavages occur only after several hours (Fig. 18-7, steps 6 and 7, performed by PC2). The endoproteolytic cleavage of propeptides is often the rate-limiting reaction in peptide biosynthetic processing.

The pattern of cleavages catalyzed by PC1, PC2 and furin when expressed in neurons and endocrine cells is much more selective than the pattern of cleavages seen in test tube assays with purified enzymes. For example, although prohormone convertases usually cleave at the COOH-terminus of a pair of basic residues in model peptide substrates, the cleavages in cells can be in the middle of the pairs of basic residues, as in the case of POMC cleavage (cleavage 6; Fig. 18-7), where the basic residues are separated and remain with the two resulting mature peptides [2]. It is likely that the Ca^{2+} concentration and internal pH of LDCVs are two variables used by neurons and endocrine cells to regulate endoproteolytic activity in LDCVs.

Additional endoproteases may be shown to play a role in neuropeptide biosynthesis. Leading candidates are the mammalian homolog of the yeast aspartyl protease-3 (YAP-3) and a thiol protease. The processing of proANF, which involves cleavage after a single Arg residue in proANF, cannot involve PC1 or PC2 since there are negligible amounts of these PCs in the heart.

CPE is a soluble protein found in virtually all LDCVs in neurons and endocrine cells (Fig. 18-6) [9]. It removes basic residues, Lys or Arg, from the COOH termini of peptide intermediates produced by the prohormone convertases, and has a pH optimum of 5.0–5.5, similar to the pH inside LDCVs. It was originally identified by its tissue distribution and substrate specificity, along with its specific inhibition by guanidinoethylmercaptosuccinic acid (GEMSA). CPE is a Co^{2+}- and Zn^{2+}-activated enzyme with a short proregion that is normally removed during maturation of the enzyme; unlike the prohormone convertases, CPE is active with the proregion attached. The carboxypeptidase function of peptide processing is not normally rate-limiting since peptide intermediates with COOH-terminal basic residues are detected only at extremely low concentrations in tissue or LDCV extracts. The structure of CPE has been modeled, based on the crystal structure of duck carboxypeptidase D domain II [10, 11]. The carboxypeptidase catalytic core has two domains, one of 300 residues with the one catalytic Zn^{2+} ion, and one with 80 residues. Additional carboxypeptidases were identified in mice lacking CPE, notably CPD, an integral membrane enzyme with two active and one inactive carboxypeptidase domains. The relative importance of CPE and these additional carboxypeptidases to neuropeptide processing *in vivo* is unclear. Given that cleavage at a pair of basic residues can be in the middle of the pair, there is good reason to think that an aminopeptidase will eventually be found in LDCVs.

PAM is a bifunctional enzyme found in nearly all LDCVs (Fig. 18-6) [12]. PAM acts on peptide substrates after endoproteolytic cleavage and exopeptidase action, when a COOH-terminal Gly residue is exposed, and converts the peptidyl-Gly into the corresponding peptide-NH_2. About half the known bioactive peptides are α-amidated, and α-amidation is generally crucial to biological potency. The peptidyl-Gly and peptide-COOH forms are usually inactive at physiological concentrations. The first step of the α-amidation reaction is performed by peptidylglycine α-hydroxylating monooxygenase (PHM), which is the NH_2-terminal portion of the bifunctional PAM protein; as with CPE, the pH optima for both enzymatic domains of PAM are around 5.5. PHM binds two Cu^{2+} atoms, which participate in catalysis by undergoing cycles of reduction and oxidation. PHM uses ascorbic acid as the reductant, with one atom of oxygen from O_2 incorporated into the peptide during the hydroxylation step. Thus, PHM is enzymatically very similar to dopamine β-hydroxylase (DBH), which converts dopamine to norepinephrine (see Ch. 12).

The crystal structure of the 315 residue catalytic core of PHM has been solved, revealing two domains of roughly equal size, each with one Cu^{2+} ion. The two copper ions are about 11 Å apart, with the peptide substrate relatively close to one of the two copper ions [12]. The second step of the α-amidation reaction is performed by a second enzymatic domain of PAM, peptidyl-α-hydroxyglycine α-amidating lyase (PAL). The PAL domain constitutes a novel, divalent metal ion-dependent enzyme. Neurons primarily express an integral membrane form of the bifunctional PAM protein (Fig. 18-6), while an additional mRNA-splicing event enables some endocrine cells to express soluble versions of the protein, lacking the transmembrane domain. In the integral membrane forms of PAM, the short COOH-terminal domain extends into the cytoplasm and participates in the routing of PAM into LDCVs and its recovery from the cell surface. The supply of reduced ascorbate in LDCVs is maintained by cytochrome b_{561}, a heme-containing protein that has six transmembrane domains and shuttles electrons from cytosolic ascorbate to ascorbate in the lumen of the LDCVs [13]. Cytochrome b_{561} is also found in catecholamine-containing vesicles, where it performs a similar function for DBH (see Ch. 12). Nervous and endocrine tissues have a high-affinity plasma membrane ascorbate uptake system to maintain concentrations of reduced ascorbate about 100-fold above the blood concentration of ascorbate, while many other tissues do not concentrate ascorbate significantly [14].

Several peptides have NH_2-terminal pyroglutamic acid residues, also termed cyclic glutamic acid (<Glu), which are essential to bioactivity. Prime examples are thyrotropin-releasing hormone (TRH) and gonadotropin-releasing hormone (GnRH). The enzyme responsible for this modification is glutaminyl cyclase, which converts the original NH_2-terminal Gln into Glu. Glutaminyl cyclase is a soluble, secretory pathway protein of 41 kDa, and requires divalent metal ion for full activity [15].

Another important but infrequent modification of peptides is α-*N*-acetylation (Figs 18-5, 18-7). During POMC processing, α-*N*-acetylation greatly increases the skin-darkening potency of ACTH(1–13)NH_2 while abolishing both the adrenal steroidogenic potency of ACTH and the opiate activity of β-endorphin [2]. The enzyme(s) responsible for this modification has not yet been purified or cloned.

As an example, Figure 18-7 shows the pattern of processing steps in the POMC system [2]. The initial endoproteolytic steps (Fig. 18-7, steps 1–4) are mediated by PC1 and occur in all POMC-producing neurons and endocrine cells, usually in the numerical order shown. It is clear that steps 1 and 2 are initiated in the *trans*-Golgi network and continue in LDCVs, while step 4 occurs only in LDCVs. Steps 5–7 occur only in LDCVs and seem to require PC2. In the adult anterior pituitary, corticotropes contain PC1 but not PC2 and perform only cleavages 1–4. However, during early postnatal development, corticotropes also express PC2 and cleavages 5–7 are transiently seen. In the rat, expression of PC2 and cleavage within ACTH (cleavage 5) decline simultaneously a few weeks after birth, at about the time that the adult pattern of ACTH control over adrenal steroidogenesis appears.

Melanotropes and CNS neurons making POMC express both PC1 and PC2 and, thus, the smaller peptide products are seen in these cells. PAM is expressed in all POMC-producing cells, so the α-amidation of joining peptide (JP), a small peptide with no clear biological function, occurs rapidly in all POMC cells (Fig. 18-7). In the melanotropes of the intermediate pituitary and the POMC neurons of the nucleus of the solitary tract, α-*N*-acetylation of ACTH(1–13)NH_2 and β-endorphin occurs. In melanotropes, α-*N*-acetylation of ACTH can occur before cleavage 5. As indicated in Figure 18-5, the particular cleavages made and the modifications made to the NH_2- and COOH-termini of the peptide products determine the mixture of bioactive peptides released.

Neuropeptides are packaged into large, dense-core vesicles. In many cases, the peptide products from the processing of a propeptide are packaged together in an equimolar fashion in LDCVs and the peptides and the soluble processing enzymes (PC1, PHM, CPE) are all released together in response to stimuli (Fig. 18-8) [2, 3]. By comparison, there are also examples where the products of propeptide processing are sorted into different LDCVs or are subject to degradation. In *Aplysia* bag cell neurons, ELH is formed from the COOH terminus of the ELH precursor (Fig. 18-2), while α, β and γ bag cell peptides (BCPs) are formed from the NH_2-terminal portion (Fig. 18-8). The initial cleavage of the pro-ELH precursor

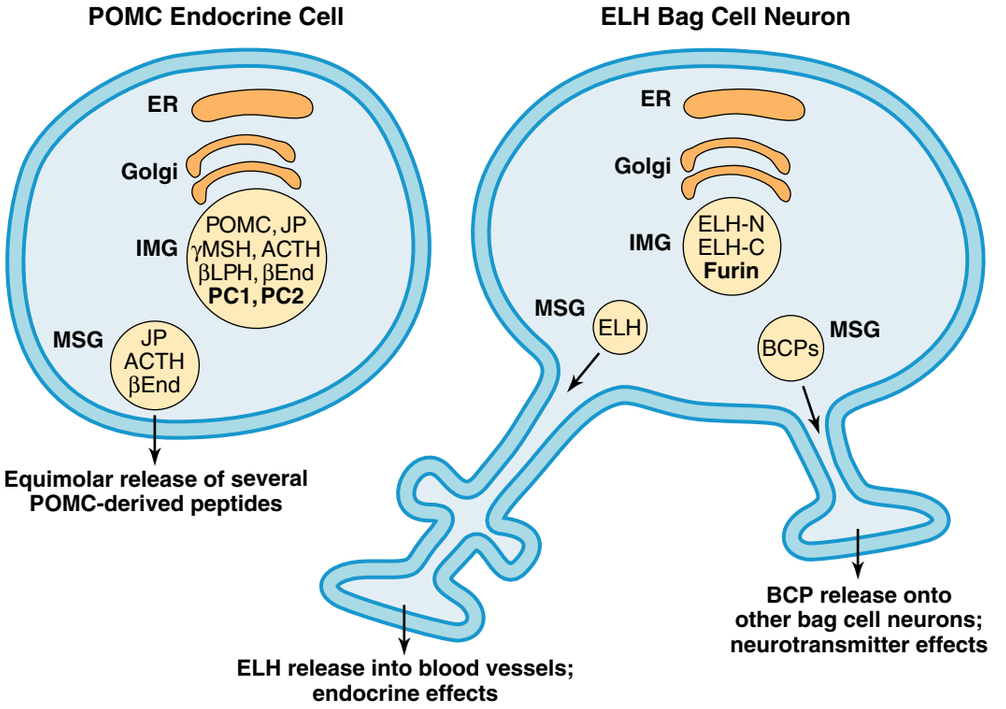

FIGURE 18-8 Cell-specific packaging of peptides into large dense-core vesicles can lead to very different patterns of peptide secretion. Sorting of neuropeptides into distinct mature secretory granules (*MSG*) is shown for bag cell neurons but does not occur for endocrine cells. *βEnd*, β-endorphin; *ACTH*, adrenocorticotropic hormone; *BCP*, bag cell peptide; *ELH*, egg-laying hormone, *POMC*, pro-opiomelanocortin; *ER*, endoplasmic reticulum; *IMG*, immature granules; *JP*, joining peptide; *LPH*, lipotropin; *MSH*, melanocyte-stimulating hormone; *PC*, prohormone convertase.

occurs in the *trans*-Golgi network and the peptides are then separated into two distinct types of LDCV, which are sent to different parts of the cell (Fig. 18-8). These two sets of peptides mediate a coordinated set of behaviors involved in egg laying. Similarly, in TRH neurons, the NH_2- and COOH-terminal domains of the pro-TRH precursor are separated from each other and stored in distinct LDCVs.

Diversity is generated by families of propeptides, alternative splicing, proteolytic processing and post-translational modifications. The huge number of biologically active peptides is the result of many factors. First, there are several families of genes which clearly evolved from a common ancestor (Fig. 18-1): examples include the three precursors to β-endorphin, dynorphin and the enkephalins; the precursors to gastrin and CCK; and the precursors to oxytocin and vasopressin. Second, there are several peptide precursors that yield multiple copies of bioactive peptide: examples include the ELH precursor, the α-mating factor precursor, the FMRF-NH_2 precursor and the enkephalin precursor. Likewise, several distinct biological activities are found within the POMC and ELH precursors. Third, there is alternative splicing of mRNAs encoding preprohormones, first discovered in the calcitonin and calcitonin gene-related peptide precursors but also seen in the case of the preprotachykinin precursor, which yields substance P, substance K and several other peptides, depending on the splicing pattern (Fig. 18-9) [16]. Finally, RNA editing can be involved, as in the case of the amphibian bombesin-like peptides, where nucleotides in the mRNA are changed and the final protein is not a direct reflection of the sequence encoded in the gene. RNA editing is also seen in the glutamate (Ch. 15) and serotonin receptors (Ch. 13 and Ch. 15) and probably will be found elsewhere as detection methods become more sophisticated.

NEUROPEPTIDE RECEPTORS

Most neuropeptide receptors are seven-transmembrane-domain, G-protein-coupled receptors. The first neuropeptide receptors characterized were those for substance P and neurotensin, and most have the general architecture shown in Figure 18-10. The basic rules for the function of these seven-transmembrane-domain receptors are the same as the rules established for similar serpentine receptors for conventional small molecule neurotransmitters, such as muscarinic, adrenergic and metabotropic glutamatergic receptors (Chs 10–16). In general, there are more receptors than peptides, and in mammals there are over 100 neuropeptides known; in *Drosophila*, current analyses recognize 22 neuropeptide prohormone precursors and 44 peptide receptor genes [17]. For many peptides, the extracellular domain plays a major role in ligand binding (Fig. 18-10) [18]. In addition, the key components of the

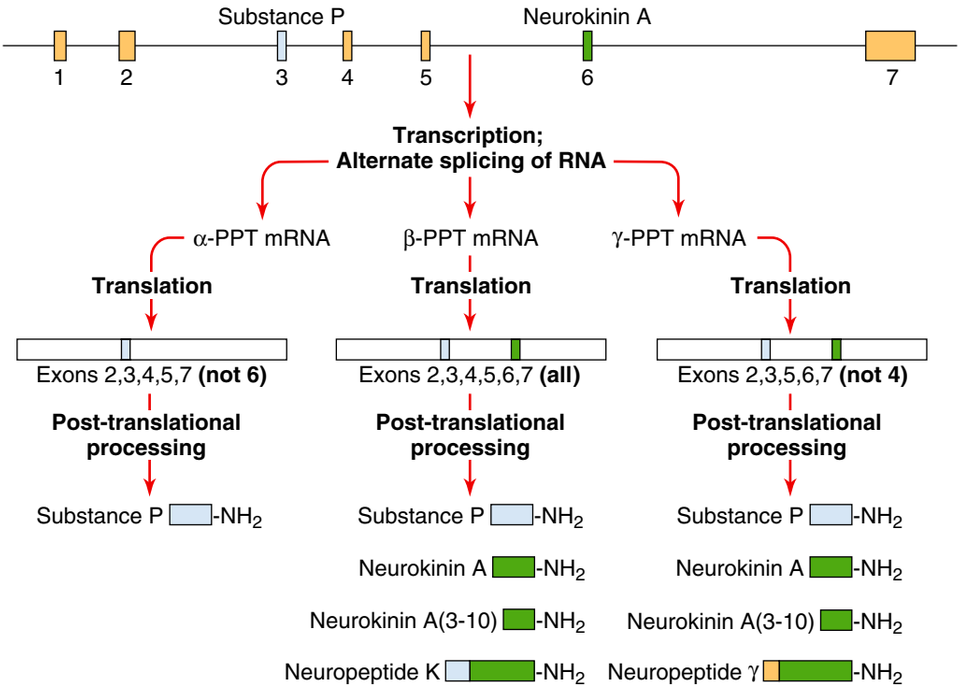

FIGURE 18-9 Several mechanisms through which the substance P gene gives rise to different bioactive peptides in different neurons. Alternative splicing of mRNA leads to translation of distinct precursors, and subsequent processing leads to unique mature peptides. *PPT*, pre-protachykinin. (Adapted from reference [16].)

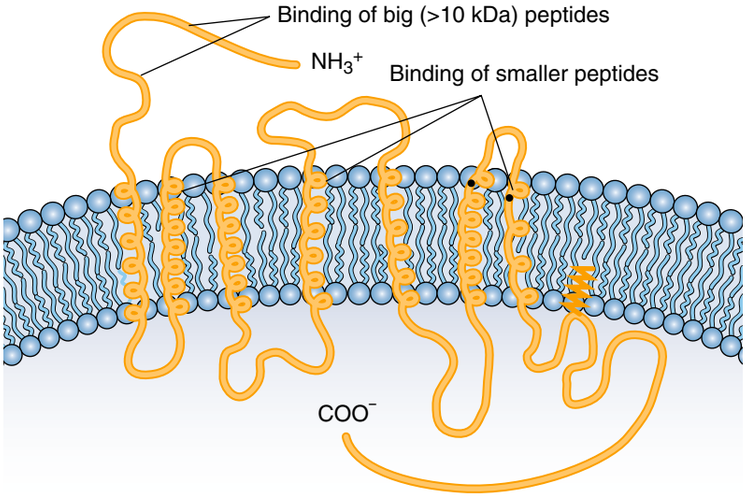

FIGURE 18-10 Serpentine (seven-transmembrane-domain) receptors for peptides have binding for their peptide ligands within the membrane and in the NH_2-terminal loop.

binding sites for many peptides also include the analogous residues important for binding small nonpeptide ligands to their receptors, within the transmembrane domains and in the extracellular loops [18].

The binding specificity of neuropeptide receptors for a given neuropeptide may vary considerably. Five somatostatin receptors have been identified; they bind somatostatin similarly and all inhibit adenylyl cyclase. However, these receptors differ substantially with regard to their interaction with various somatostatin analogs used for therapeutic purposes. For example, the receptor called SSTR2 binds a small peptide analog, octreotide, much more tightly than the other somatostatin receptors. This differential sensitivity is being used for therapeutic drug targeting [19]. Changing a few amino acids in transmembrane domains VI and VII of SSTR1 to the residues found in SSTR2 (Fig. 18-10) allows the mutant SSTR1 to bind the peptide analog as well as SSTR2. Similar changes in specificity are seen with several other peptide receptor families [16, 18, 20].

Neuropeptide receptors are not confined to synaptic regions. Peptidergic neurotransmission often operates on a slower time scale than conventional neurotransmitters, so it is not surprising that peptide receptors are often localized at a distance from the synapse. For example, although some substance P terminals contact membranes loaded with substance P receptor, only a small fraction of the substance P receptor-laden membrane is apposed to synaptic terminals. Substance P may diffuse a considerable distance from its release site and still find a receptor with which it can interact [21].

Expressions of peptide receptors and the corresponding peptides are not well matched. Neuropeptides can act at many sites. They may act directly on a postsynaptic target at the synapse; presynaptically on the terminal that released the peptide (autocrine effects); on an immediately adjacent cell (juxtacrine effects); or on a cell a few cell diameters away from the site of release (paracrine effects). In addition, peptides can exert their actions after traveling through the circulation to reach their target (endocrine effects), as in the case of hypothalamic releasing factors and neurohypophyseal hormones.

There is some correspondence of the peptide families and the families of peptide receptors, but it is certainly not simple. For example, there are three related opiate peptide precursors, POMC, proenkephalin and prodynorphin, and three major types of opiate receptor, μ, κ and δ. The best endogenous ligands for the μ receptor are β-endorphin and endomorphins-1 and -2 (Tyr–Pro–Phe/Trp–Phe–NH_2); enkephalins are the best ligands for δ receptors and dynorphins are best for κ receptors. However, the sites at which opiate peptides and opiate receptors are expressed in the brain do not show a simple 1:1 correspondence. Recently, an orphan receptor resembling the opiate receptors was expressed and used to identify its endogenous ligand, which was called orphanin FQ or nociceptin. This preprohormone is most similar to the dynorphin precursor and defines a fourth type of opiate-like peptide containing the sequence Phe–Gly–Gly–Phe instead of the Tyr–Gly–Gly–Phe sequence that originally defined the opiate peptide family. The orphanin FQ peptide is hyperalgesic in that it increases pain sensitivity, which is the opposite action to the opiate peptides. Reduction of the level of the orphanin FQ receptor in brain using antisense oligonucleotides leads to analgesia. In addition, endomorphins-1 and -2 show tighter binding and much greater selectivity for μ opiate receptors than other natural peptides [22, 23].

Similarly, five closely related melanocortin receptors that respond to various peptides derived from the POMC precursor have been identified (Fig. 18-7) [24]. As expected, the receptor on adrenal cortical cells responds best to ACTH, which normally stimulates adrenal steroidogenesis, and the receptor on melano cytes responds best to αMSH, which causes skin darkening. However, the pattern of melanocortin receptor expression in the brain is not simply explained by the known patterns of peptide expression in the brain or by the known effects of POMC-derived peptides when applied to various brain regions. With this number of peptide receptors, it is obvious that production of final peptide products must be precisely controlled and that different biosynthetic processing pathways can dramatically affect the biological activity observed (Figs 18-5, 18-7).

The amiloride-sensitive FMRF-amide-gated sodium ion channel is among the few peptide-gated ion channels identified. FMRF-amide induces a fast excitatory depolarizing response in selected neurons due to direct activation of an amiloride-sensitive sodium channel. Using cDNA from the snail *Helix aspersa* and a *Xenopus* oocyte expression system, an amiloride-sensitive, FMRF-amide-activated sodium channel was identified. The acid-sensing ion channels found in sensory neurons are also modulated by FMRF-NH_2 and by neuropeptide FF [25]. These channels have only two transmembrane domains and as such are similar in structure to the directly gated ion channels activated by some purinergic ligands (Ch. 17) and by hydrogen ions.

Neuropeptide receptors are becoming molecular targets for therapeutic drugs. The large number of neuropeptides and even larger number of neuropeptide receptors have raised the hope that neuropeptide receptors could become useful drug targets [26]. Radiolabeled peptides are being used to localize tumors and metastases [20]. Nonpeptidic antagonists acting at specific substance P receptors are being tested as antidepressants [27, 28]. Another major target is CRH, for a number of stress-related psychiatric disorders [28].

Many creatures use peptides to control their environments. Cone snails produce over a thousand different peptide toxins, which are exquisitely targeted to ion channels [29]. Similarly, insects produce peptide toxins to kill each other, with spiders being the champions at this endeavor. The ion channels affected by these toxins are becoming medically and agriculturally useful – for example, there are distinct calcium channels expressed in different tissues at various developmental times. The natural toxins, which are highly selective among closely related subtypes of ion channel, are being exploited for therapeutic purposes. Similarly, spider toxins are being adapted as insecticides.

NEUROPEPTIDE FUNCTIONS AND REGULATION

The study of peptidergic neurons requires a number of special tools. These tools include methods to detect the neuropeptides both in cells and after release, the enzymes specific to their biosynthesis and their cognate receptors. Since the actions of peptides require secretion, measurements of cell content (e.g. immunostaining) can be deceptive, with a decrease in content reflecting increased release.

Antibody-based detection methods include immunocytochemistry, which gives qualitative data but has very good spatial resolution. Radioimmunoassays provide a quantitative measure of release or content. One of the major limitations of all antibody-based methods is the potential for cross-reactivity among the many peptides. For example, some of the most sensitive 'gastrin' antisera also detect CCK, since the peptides share a common COOH-terminal tetrapeptide sequence. Methods for detection of the mRNAs encoding neuropeptides include Northern blots, which provide quantitative data and information on splice variants, but lack fine anatomical resolution. The more commonly used polymerase chain reaction, which can be quantitative but often is used in a more qualitative manner, provides great sensitivity. Alternatively, *in situ* hybridization preserves anatomical relationships and can be used to obtain both qualitative and quantitative data.

Direct methods for detection of neuropeptides include metabolic labeling with an appropriate radioactive amino acid and chemical isolation of peptides. Direct methods are difficult to apply to peptides or their receptors in the CNS, where the cells expressing the peptide are part of a large population of other neurons or endocrine cells. Reversed-phase high-pressure liquid chromatography or two-dimensional polyacrylamide gel electrophoresis, coupled with mass spectrometric identification, has revolutionized the identification of tiny amounts of peptides and receptors in tissue extracts. Similarly, the ability to mark living neurons producing a specific neuropeptide precursor with a fluorescent tag (e.g. green fluorescent protein expression driven by the promoter for the peptide precursor) has revolutionized the ability to study the functions of specific peptidergic neurons [30].

Peptide agonists and antagonists are becoming available for many peptides, and these are essential to a successful dissection of the function of peptidergic synapses, as they have been for conventional neurotransmitters (discussed in Chs 11–16). These approaches have the advantage that a physiologically important trait, binding of the ligand to the receptor, is being observed, and they can reveal binding to several related receptors, which are then distinguished by antisera, *in situ* hybridization, or drugs specific for receptor subtypes.

Peptides play a role in the plurichemical coding of neuronal signals. Many sets of neurons are chemically coded, giving rise to the concept of plurichemical transmission. For example, from the human lumbar paravertebral ganglion, adrenergic neurons efferent to blood vessels in skin and muscle usually contain NPY along with norepinephrine, while adrenergic neurons innervating hair follicles express primarily norepinephrine. The dual transmission on to blood vessels is important since the catecholamine effects undergo rapid tachyphylaxis, while sustained contraction of the blood vessels is mediated by NPY. It is likely that a similar but more complex mixture of phenotypes occurs in the CNS; for example, some CCK-containing neurons also secrete dopamine while others release glutamate [31]. Peptides are generally released by the same neurons that release fast-acting classical neurotransmitters, and each transmitter has its own unique effects on target tissues.

Neuropeptides make a unique contribution to signaling. The release of neuropeptides generally requires a more intense stimulus than that required for release of fast-acting classical neurotransmitters. The more intense stimulus presumably results in more entry of Ca^{2+} into the presynaptic terminal, allowing Ca^{2+} to diffuse from its entry site to the LDCVs (Figs 18-3, 18-4). As a result, the contribution of peptides vs. fast-acting conventional neurotransmitters to signaling can vary with the pattern of stimulation. For example, in *Aplysia*, several identified motor neurons devote about 10% of their total protein synthesis to their respective peptide neurotransmitters. Peptide release in each case has been shown to require extracellular Ca^{2+}, and release increases with the frequency of action potentials, in the range of frequencies seen in behaving animals. In addition to the peptides, several of the motor neurons secrete ACh. In these motor neurons, peptide release increases more strongly with action potential frequency than does release of ACh, so the ratio of peptide to ACh is dependent on frequency. In addition, there are unique postsynaptic responses, such as elevation of cAMP concentrations in muscles, which can be mimicked only by application of the peptides and not by the conventional neurotransmitters.

In other examples, the amount of peptide available for release can be depleted by repeated firing of a terminal since new peptide must arrive by axonal transport, while new conventional neurotransmitters are synthesized or recaptured locally and transported into small synaptic vesicles.

Regulation of neuropeptide expression is exerted at several levels. Control of neuropeptide function is mediated by factors controlling rates of prepropeptide gene transcription, translation, peptide degradation and secretion (Fig. 18-11). On the scale of seconds to minutes, peptide secretion is not always coupled lock-step with classical transmitter release (example above). Peptides are inactivated by diffusion and by proteolysis, so it would be expected that inhibition of specific extracellular proteases

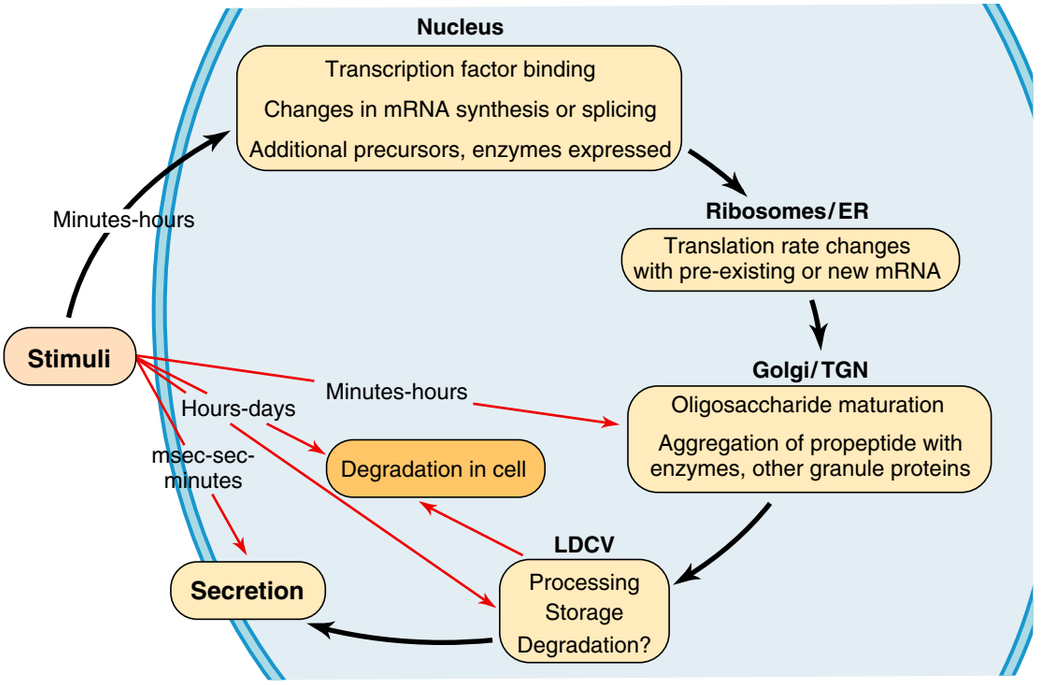

FIGURE 18-11 Regulation of neuropeptide expression is exerted at several levels. *ER*, endoplasmic reticulum; *LDCV*, large dense-core vesicle; *TGN*, *trans*-Golgi network.

could lead to increased effectiveness of their neuropeptide substrates, as has been shown in the cases of CCK and the enkephalins.

On a time scale of minutes to hours, the transcription of prepropeptide mRNA is regulated. Peptide mRNAs are often immediate early genes, showing extremely rapid responses to stimuli that are not blocked by inhibitors of protein translation. The rate of translation of existing prepropeptide mRNAs can also change dramatically within a few minutes of stimulation. Since processing enzymes must also be synthesized and inserted into the same LDCVs as the peptide precursors, the rate of production of these enzymes might be expected to show changes under physiological conditions. They do show such changes but usually more slowly than the peptide precursors. As seen above (Figs 18-5–18-8), the peptide products produced are crucially dependent on the mixture of processing enzymes in the LDCVs.

On a scale of hours to days, dramatic changes can be seen in cells producing peptides that are subjected to chronic stimulation or inhibition. POMC production by intermediate pituitary melanotropes is inhibited by treatment of rats with dopaminergic agonists or exposure of frogs to a light background; POMC production is stimulated by treatment of rats with dopaminergic antagonists or exposure of frogs to a dark background. The expression of processing enzymes, the number of LDCVs and the rate of cell division are also responsive to these treatments. Similarly, the processing of different regions of the pro-TRH precursor responds to thyroid hormone status, and it is possible that the routing of ELH and the BCPs is regulated (Fig. 18-8). In response to the changes in steroid hormone concentrations that occur during the estrous cycle in female rats, the concentration of CCK mRNA varies more than twofold in a subset of CCK-producing CNS neurons.

PEPTIDERGIC SYSTEMS IN DISEASE

Diabetes insipidus occurs with a loss of vasopressin production in the Brattleboro rat model. In the Brattleboro rat, a single-base deletion in the vasopressin gene alters the COOH terminus of preprovasopressin so that it cannot leave the endoplasmic reticulum; as a result, no neurons make vasopressin. Intriguingly, a frameshift mutation occurs in postmitotic neurons, most often an additional deletion of two nucleotides, so that the neurons somewhat regain the ability to produce vasopressin. In the *hpg* mouse, a spontaneous mutation in the gonadotropin-hormone-releasing hormone gene results in loss of gonadal function in homozygous animals. For both vasopressin and growth hormone, dominant negative mutations occur which block successful expression of the normal gene – these dominant negative phenotypes are presumably due to defects in folding in the endoplasmic reticulum or packaging into large dense-core granules.

Mutations and knockouts of peptide-processing enzyme genes cause a myriad of physiological problems. A single-base change in the CPE gene changes Ser^{202} to Pro, yielding a CPE molecule that is malfolded, inactive and incapable of exiting from the endoplasmic reticulum [9]. The phenotype observed in these *fat*/*fat* mice, which includes obesity and late-onset diabetes mellitus, is caused in part by high concentrations of inactive proinsulin in the blood, with very little mature, functional insulin (Fig. 18-12). In the brains of these *fat*/*fat* mice, there is an excess of immature, biologically inactive neuropeptide fragments, such as neurotensin–Lys–Arg and thyrotropin-releasing hormone intermediates. It is still unclear how the loss of CPE function causes all the biochemical effects observed, with selective loss of processing of several peptides, while other peptide systems remain relatively quite normal.

The fact that the naturally occurring CPE knockout (*fa*/*fa*) is viable might be taken as a surprise, but this has led to the search for additional CPE-like enzymes, which were indeed found [9]. Mouse knockouts for furin die at about embryonic day 11, while knockouts for PACE4 and PAM die at or before embryonic day 15 [32]. The surprising result is that knockouts for PC1, PC2 and the PC2 chaperone-inhibitor 7B2 are viable, although not normal. The PC1 knockout mouse has symptoms due to hyperproinsulinemia, the excessive secretion of uncleaved and inactive proinsulin, while human PC1 nulls exhibit early-onset severe obesity, perhaps due to the loss of MSH in the hypothalamus [32]. The PC2 knockout has deficits with glucagon and MSH biosynthesis, but is fairly normal. Surprisingly, the 7B2 knockout has far more severe problems than the PC2 knockout, exhibiting very high ACTH levels and a lethal form of Cushing's disease [33]. As expected, the 7B2 knockout mice have little or no detectable PC2 activity in any tissues.

Neuropeptides play key roles in appetite regulation and obesity. Many genes for neuropeptides and neuropeptide receptors have been implicated in obesity and cachexia, anorexia and bulimia [34]. For example, NPY administration into the CNS causes overeating and obesity. A second peptide involved in obesity is leptin, a product of adipocytes and the stomach. The leptin gene is defective in the *ob*/*ob* mouse but in normal mice leptin binds to its receptor in the hypothalamus, causing a decrease in the synthesis and release of hypothalamic NPY.

Control of feeding behavior involves peripheral peptides (insulin, ghrelin, leptin) plus several peptides in the CNS (orexins/hypocretins, CCK, galanin, MSH, neuropeptide Y, CRH, cocaine-and-amphetamine-regulated transcript (CART)) [35, 36]. Some of the same peptides are involved in reward systems crucial to drug addiction. Specific receptor blockers are being tested for many of these peptide-receptor systems, with the hope of very selective actins with minimal side effects [35]. For example, there are two CCK receptor subtypes, CCK-A and

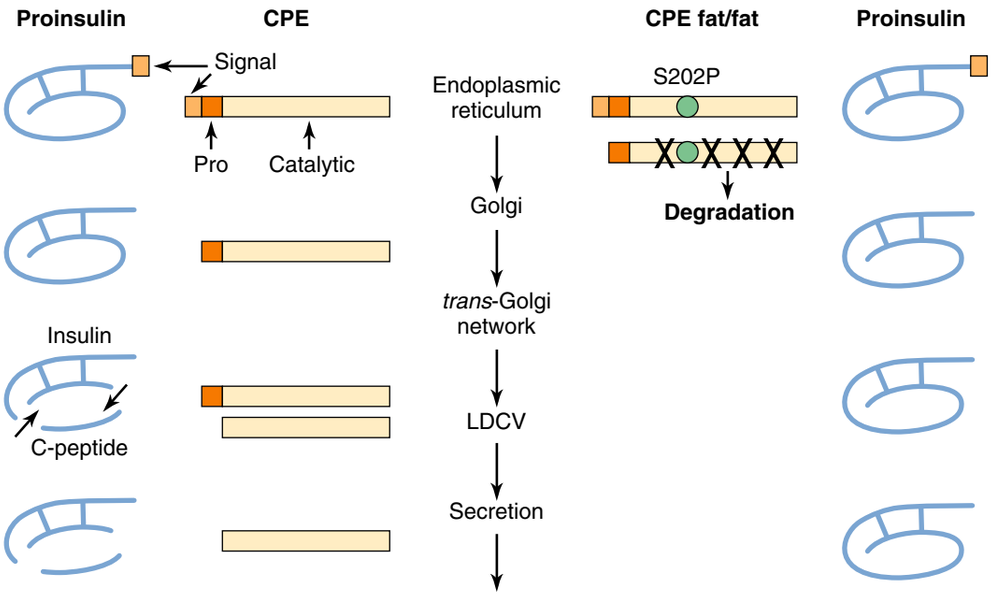

FIGURE 18-12 The *fat/fat* mutation in carboxypeptidase E (*CPE*) leads to secretion of proinsulin, not mature insulin, and results in diabetes. The S202P mutation within CPE results in degradation of the enzyme and defective insulin processing in the *fat/fat* heterozygous mouse. *LDCV*, large dense-core vesicle.

CCK-B. Protease inhibitors that slow the degradation and inactivation of endogenous CCK promote satiety via CCK-A receptor. By contrast, the CCK-B receptor is important in mediating anxiety and panic attacks, and CCK antagonists are in clinical use to treat these symptoms.

Enkephalin knockout mice reach adulthood and are healthy. When the proenkephalin gene, one of the three endogenous opiate peptide precursor genes, was eliminated from the mouse genome by genetic engineering, the knockout mice exhibited a normal hotplate/tail-flick responses; in normal mice, the tail-flick response (moving the tail away from a hot light) is diminished by prior exposure to another noxious stimulus, an unavoidable electrical foot-shock. This indicates that enkephalin plays no role in the normal tail-flick response but does play a role in centrally mediated analgesia. Similarly, β-endorphin knockout mice also show a loss in centrally mediated analgesia. Behavioral abnormalities in the enkephalin knockout mice include reduced exploratory activity in an unfamiliar environment and increased aggressiveness in the resident–intruder test. In both enkephalin and β-endorphin knockout mice, there are no compensatory increases in the concentrations of the remaining endogenous opiate peptides.

Neuropeptides are crucial to pain perception. Substance P is released in the spinal cord by a subset of dorsal root ganglion neurons; Substance P is crucial to the sensation of noxious stimuli. Substance P binds to the neurokinin-1 receptor, which gets rapidly internalized and recycled to the plasma membrane of the neurons [21]. When substance P receptors are partially ablated, the sensitivity to noxious stimuli decreases. In conditions of chronic pain, the pattern of peptide expression can also change. For example, there is a dramatic increase in the expression of the opiate peptide dynorphin in the spinal cord, while dynorphin is undetectable in the normal animal.

HETEROTRIMERIC G PROTEINS 335
The family of heterotrimeric G proteins is involved in transmembrane signaling in the nervous system, with certain exceptions 335
Multiple forms of heterotrimeric G proteins exist in the nervous system 336
Each G protein is a heterotrimer composed of single α, β and γ subunits 336
The functional activity of G proteins involves their dissociation and reassociation in response to extracellular signals 337
G proteins couple some neurotransmitter receptors directly to ion channels 338
G proteins regulate intracellular concentrations of second messengers 338
G proteins have been implicated in membrane trafficking 338
G protein βγ subunits subserve numerous functions in the cell 339
The functioning of heterotrimeric G proteins is modulated by other proteins 340
G proteins are modified covalently by the addition of long-chain fatty acids 341
The functioning of G proteins may be influenced by phosphorylation 342

SMALL G PROTEINS 342
The best characterized small G protein is the Ras family, a series of related proteins of ≈21 kDa 342
Rab is a family of small G proteins involved in membrane vesicle trafficking 343

OTHER FEATURES OF G PROTEINS 343
G proteins can be modified by ADP-ribosylation catalyzed by certain bacterial toxins 343
G proteins are implicated in the pathophysiology and treatment of disease 344

G proteins comprise several families of diverse cellular proteins that subserve an equally diverse array of cellular functions. These proteins derive their name from the fact that they bind the guanine nucleotides guanosine triphosphate (GTP) and guanosine diphosphate (GDP) and possess intrinsic GTPase activity. G proteins play a central role in signal transduction as well as in a myriad of cellular processes, including membrane vesicle transport, cytoskeletal assembly, cell growth and protein synthesis (see Chs 5, 8 and 9).

Mammalian G proteins can be divided into two major categories: heterotrimeric G proteins and small G proteins. This chapter reviews the types of G protein that exist in the nervous system and the ways in which they regulate signal transduction and other processes essential for brain function.

HETEROTRIMERIC G PROTEINS

The family of heterotrimeric G proteins is involved in transmembrane signaling in the nervous system, with certain exceptions. The exceptions are instances of synaptic transmission mediated via receptors that contain intrinsic enzymatic activity, such as tyrosine kinase or guanylyl cyclase, or via receptors that form ion channels (see Ch. 10). Heterotrimeric G proteins were first identified, named and characterized by Alfred Gilman, Martin Rodbell and others close to 20 years ago. They consist of three distinct subunits, α, β and γ. These proteins couple the activation of diverse types of plasmalemma receptor to a variety of intracellular processes. In fact, most types of neurotransmitter and peptide hormone receptor, as well as many cytokine and chemokine receptors, fall into a superfamily of structurally related molecules, termed G-protein-coupled receptors. These receptors are named for the role of G proteins in mediating the varied biological effects of the receptors (see Ch. 10). Consequently, numerous effector proteins are influenced by these heterotrimeric G proteins: ion channels; adenylyl cyclase; phosphodiesterase (PDE); phosphoinositide-specific phospholipase C (PI-PLC), which catalyzes the hydrolysis of phosphatidylinositol 4,5-bisphosphate (PIP_2); and phospholipase A_2 (PLA_2), which catalyzes the hydrolysis of membrane phospholipids to yield arachidonic acid. In addition, these G proteins have been implicated in

Basic Neurochemistry: Molecular, Cellular and Medical Aspects
0-12-088397-X

several other intracellular processes, such as vesicular transport (Ch. 9) and cytoskeletal assembly (Chs 8 and 28).

Multiple forms of heterotrimeric G proteins exist in the nervous system. Three types of heterotrimeric G protein were identified in early studies. G_t, termed transducin, was identified as the G protein that couples rhodopsin to regulation of photoreceptor cell function (see Ch. 49), and G_s and G_i were identified as the G proteins that couple plasma membrane receptors to the stimulation and inhibition, respectively, of adenylyl cyclase, the enzyme that catalyzes the synthesis of cAMP (see Ch. 21).

Since that time, over 35 heterotrimeric G protein subunits have been identified by a combination of biochemical and molecular cloning techniques [1–4]. In addition to G_t, G_s and G_i, the other types of G protein in brain are designated G_o, G_{olf}, G_{gust}, G_z, G_q and $G_{11–16}$. Moreover, for most of these G proteins, multiple subtypes show unique distributions in the brain and peripheral tissues. G proteins are now divided into four main categories (Table 19-1): the G_s family stimulates adenylyl cyclase; the G_i family (which includes G_o, G_{gust}, G_z) can inhibit adenylyl cyclase, activate a certain type of K^+ channel, inhibit voltage-gated Ca^{2+} channels, activate the MAP-kinase pathway or activate phosphodiesterase; the G_q family activates PI-PLC; and the G_{12} family activates a group of proteins termed Rho-GEFs (guanine nucleotide exchange factors, which are described in greater detail below).

Each G protein is a heterotrimer composed of single α, β and γ subunits. The different types of G protein contain distinct α subunits, which confer part of the specificity of functional activity. G protein α subunits, listed in Table 19-1, are categorized on the basis of their structural and functional homologies. Current nomenclature identifies several subfamilies of G protein α subunit: $G_{\alpha s}$, $G_{\alpha i}$, $G_{\alpha q}$ and $G_{\alpha 12}$. The M_r of these proteins varies between 38,000 and 52,000. As a first approximation, these distinct types of α subunits share common β and γ subunits. However, multiple subtypes of β and γ subunit are known: five β subunits of M_r 35,000–36,000 and 11 γ subunits of M_r 6,000–9,000. These proteins show distinct cellular distributions, and differences in their functional properties are becoming increasingly apparent [1–4].

TABLE 19-1 Heterotrimeric G protein α-subunits in brain

Family	M_r*	Toxin-mediated ADP-ribosylation	Effector protein(s)†
G_s			
$G_{\alpha s1}$	52,000	Cholera	Adenylyl cyclase (activation)
$G_{\alpha s2}$	52,000		
$G_{\alpha s3}$	45,000		
$G_{\alpha s4}$	45,000		
$G_{\alpha olf}$	45,000		
G_i			
$G_{\alpha i1}$	41,000	Pertussis	Adenylyl cyclase (inhibition)
$G_{\alpha i2}$	40,000		K^+ channel (activation)
$G_{\alpha i3}$	41,000		Ca^{2+} channel (inhibition)
			?PI-Phospholipase C (activation)
			?Phospholipase A_2
$G_{\alpha o1}$	39,000	Pertussis	K^+ channel (activation)
$G_{\alpha o2}$	39,000		Ca^{2+} channel (inhibition)
$G_{\alpha t1}$	39,000	Cholera and pertussis	Phosphodiesterase (activation) in rods and cones
$G_{\alpha t2}$	40,000		
$G_{\alpha gust}$	41,000	Unknown	Phosphodiesterase (activation) in taste epithelium
$G_{\alpha z}$	41,000	None	?Adenylyl cyclase (inhibition)
G_q	41,000–43,000		
$G_{\alpha q}$		None	PI-Phospholipase C (activation)
$G_{\alpha 11}$		Unknown	
$G_{\alpha 14}$			
$G_{\alpha 15}$			
$G_{\alpha 16}$			
G_{12}	44,000	None	Rho-GEFs (activation)
$G_{\alpha 12}$			
$G_{\alpha 13}$			

Question marks indicate that the association between the particular G proteins and effector proteins shown in the table remains tentative.

*Values shown reflect apparent M_r by gel electrophoresis in most cases. Values shown for $G_{\alpha gust}$, $G_{\alpha z}$ and $G_{\alpha 11–16}$ reflect calculated M_r based on amino acid sequence.

†For several of the effector proteins listed, the functional regulation of the effector is mediated, in part or in full, by the βγ subunits associated with the indicated α subunit.

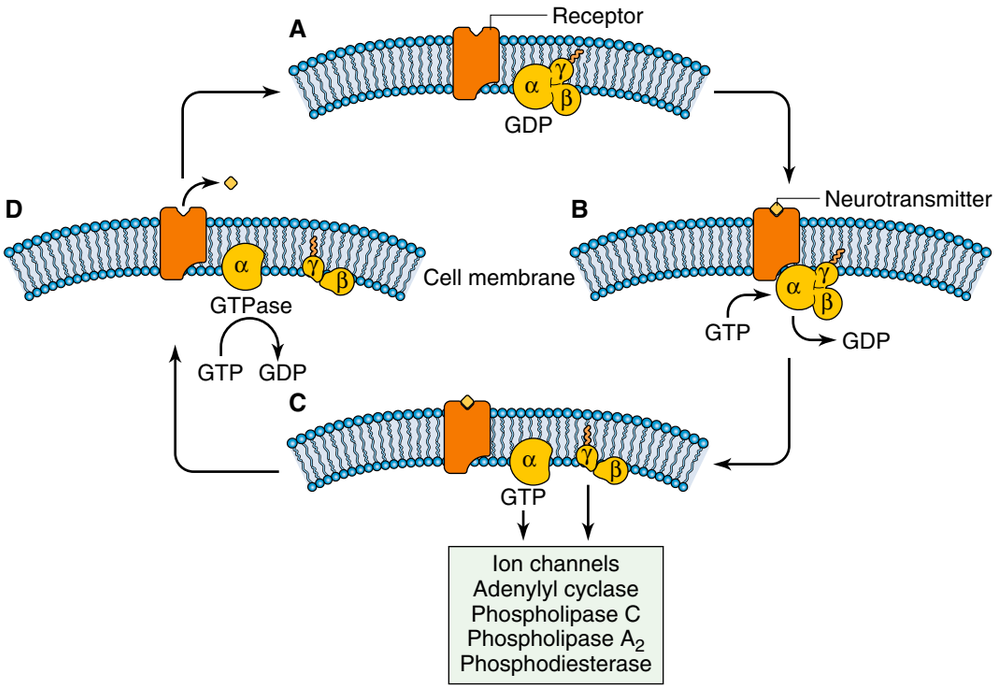

FIGURE 19-1 Functional cycle of heterotrimeric G proteins. (**A**) Under basal conditions, G proteins exist in cell membranes as heterotrimers composed of single α, β and γ subunits and are associated only loosely with neurotransmitter receptors. In this situation, GDP is bound to the α subunit. (**B**) Upon activation of the receptor by its ligand, such as a neurotransmitter, the receptor physically associates with the α subunit, which leads to the dissociation of GDP from the subunit and the binding of GTP instead. (**C**) GTP binding induces the generation of free α subunit by causing the dissociation of the α subunit from its β and γ subunits and the receptor. Free α subunits (bound to GTP) and free βγ subunit dimers are functionally active and directly regulate a number of effector proteins, which, depending on the type of subunit and cell involved, can include ion channels, adenylyl cyclase, phospholipase C, phospholipase A_2 and phosphodiesterase. (**D**) GTPase activity intrinsic to the α subunit degrades GTP to GDP. This leads to the reassociation of the α and βγ subunits, which, along with the dissociation of ligand from receptor, leads to restoration of the basal state. (With permission from Hyman and Nestler [36].)

The functional activity of G proteins involves their dissociation and reassociation in response to extracellular signals. This G protein cycle is shown schematically in Figure 19-1. In the resting state, G proteins exist as heterotrimers that bind GDP and are associated with extracellular receptors (Fig. 19-1A). When a ligand binds to and activates the receptor, it produces a conformational change in the receptor, which in turn triggers a dramatic conformational change in the α subunit of the G protein (Fig. 19-1B). This conformational change leads to (a) a decrease in the affinity of the α subunit for GDP, which results in the dissociation of GDP from the α subunit and the subsequent binding of GTP because the cellular concentration of GTP is much higher than that of GDP; (b) dissociation of a βγ subunit dimer from the α subunit; and (c) release of the receptor from the G protein (Fig. 19-1B,C). This process generates a free α subunit bound to GTP as well as a free βγ subunit dimer, both of which are biologically active and regulate the functional activity of effector proteins within the cell. The GTP-bound α subunit is also capable of interacting with the receptor and reducing its affinity for ligand. The system returns to its resting state when the ligand is released from the receptor and the GTPase activity that resides in the α subunit hydrolyzes GTP to GDP (Fig. 19-1D). The latter action leads to reassociation of the free α subunit with the βγ subunit complex to restore the original heterotrimers.

The structural basis of the interactions among the α, β, and γ subunits of G proteins and between the subunits and the associated receptor has become increasingly understood as the three-dimensional structure of these proteins has been determined [5, 6]. Each α subunit has two identifiable domains. One contains the GTPase activity and the GTP-binding site. This domain also appears to be most important in binding βγ subunits as well as various effector proteins. The function of the other domain remains unknown, but it may be involved in the dramatic conformational shift that occurs in the protein upon exchanging GTP for GDP. The ability of the heterotrimeric G protein to bind to a receptor is thought to depend on sites located within all three G protein subunits. Thus, the different α subunits, as well as subtypes of β and γ subunits, seem to be responsible for targeting a particular type of G protein to a particular type of receptor.

G proteins couple some neurotransmitter receptors directly to ion channels. It is now clearly established that G protein subunits, when released from their G protein-receptor interactions, can directly gate (i.e. open or close) specific ion channels [2, 7–9]. One of the best examples of this mechanism in brain is the coupling of many types of receptor to the activation of an inward-rectifying K^+ channel (GIRK) via pertussis-toxin-sensitive G proteins, i.e. subtypes of G_i, in many types of neurons. The coupled receptors include opioid, α_2-adrenergic, D_2-dopaminergic, muscarinic cholinergic, 5-HT_{1A}-serotonergic and $GABA_B$. In initial studies, it was controversial as to whether the free α subunit or the free $\beta\gamma$ dimer was responsible for this action. Based on the results of elegant studies in which cloned channel and G protein subunits have been expressed in a variety of cell types, the general consensus is now that the $\beta\gamma$ complex is the more important mechanism [7, 8]. The region of the GIRK that binds to the $\beta\gamma$ complex has been identified. Moreover, it seems that particular combinations of β and γ subtypes are more effective at opening this channel than others. In addition, some subtypes of α_i can open the channel, although not to the same extent as the $\beta\gamma$ subunits.

These same neurotransmitter receptors also are coupled via pertussis-toxin-sensitive G proteins to voltage-gated Ca^{2+} channels. In this case the channels are inhibited by the interaction. Available evidence supports a primary role for $\beta\gamma$ in mediating this effect, although there is some evidence that α_i (including α_o) subunits also can be involved [9]. Binding of the G protein subunits to the Ca^{2+} channels reduces their probability of opening in response to membrane depolarization. This mechanism is best established for L-type Ca^{2+} channels, which are also inhibited by dihydropyridine antihypertensive drugs, such as verapamil, but may also operate for other types of voltage-gated Ca^{2+} channel (see also Chs 6 and 22).

G proteins regulate intracellular concentrations of second messengers. G proteins control intracellular cAMP concentrations by mediating the ability of neurotransmitters to activate or inhibit adenylyl cyclase. The mechanism by which neurotransmitters stimulate adenylyl cyclase is well known. Activation of those neurotransmitter receptors that couple to G_s results in the generation of free $G_{\alpha s}$ subunits, which bind to and thus directly activate adenylyl cyclase. In addition, free $\beta\gamma$-subunit complexes activate certain subtypes of adenylyl cyclase (see Ch. 21). A similar mechanism appears to be the case for $G_{\alpha olf}$, a type of G protein structurally related to $G_{\alpha s}$ that is enriched in olfactory epithelium and striatum (Ch. 50).

The mechanism by which neurotransmitters inhibit adenylyl cyclase and decrease neuronal levels of cAMP has been more difficult to delineate. By analogy with the action of G_s, it was proposed originally that activation of neurotransmitter receptors that couple to G_i results in the generation of free $G_{\alpha i}$ subunits, which bind to and, thereby, directly inhibit adenylyl cyclase. Initially, such direct inhibition of adenylyl cyclase by $G_{\alpha i}$ was difficult to demonstrate in some cell-free reconstitution experiments. Nevertheless, there is now strong evidence, including insight coming from the crystalline structures of these proteins, that certain subtypes of adenylyl cyclase are directly inhibited by $G_{\alpha i}$. For other adenylyl cyclase isoforms, free $\beta\gamma$-subunit complexes, generated by the release of $G_{\alpha i}$, appear to mediate inhibition of the enzyme (Ch. 21). In addition to G_i, there is evidence that $G_{\alpha z}$, which is considered a subtype of the G_i family on the basis of sequence homologies, also can mediate neurotransmitter inhibition of adenylyl cyclase.

The transducin family of G proteins mediate signal transduction in the visual system (Ch. 49) by regulating specific forms of phosphodiesterase that catalyze the metabolism of cyclic nucleotides (Ch. 21). $G_{\alpha t}$ activates PDE via direct binding to the enzyme. Gustducin ($G_{\alpha gust}$) shares a high degree of homology with $G_{\alpha t}$. It is enriched in taste epithelium and is believed to mediate signal transduction in this tissue via the activation of a distinct form of phosphodiesterase.

The ability of many neurotransmitters and their G-protein-coupled receptors to stimulate the phosphoinositide second-messenger pathway is mediated by the activation of PI-PLC, which, as mentioned above, catalyzes the hydrolysis of PIP_2 to form the second messengers inositol triphosphate (IP_3) and diacylglycerol (DAG) (Ch. 20). Such receptor-induced activation of PI-PLC is mediated via G proteins and involves the regulation specifically of the β isoform of PI-PLC [10, 11]. (By contrast, it is the γ isoform of PI-PLC that is regulated by growth factors (Ch. 27) and their tyrosine kinase receptors (Ch. 24).) In most cases, G_q mediates neurotransmitter regulation of PI-PLC_β, and it is thought that $G_{\alpha q}$ and related α subunits bind to and directly activate the enzyme. In some cell types, $\beta\gamma$ subunits released from G_i proteins directly bind and activate PI-PLC_β. The mechanism by which G proteins mediate neurotransmitter regulation of arachidonic acid metabolism (see Ch. 33), via the activation or inhibition of PLA_2, is less well established but also may involve $\beta\gamma$ dimers released from subtypes of G_i [1].

G proteins have been implicated in membrane trafficking. In addition to mediating signal transduction at the plasma membrane, certain heterotrimeric G proteins have been implicated in several processes that involve the trafficking of cell membranes, although the precise mechanisms involved remain incompletely understood. For example, the $G_{\alpha i}$ subunit has been detected at relatively high concentrations in intracellular membranes, including the Golgi complex, *trans*-Golgi network and endoplasmic reticulum [12, 13]. Experiments that involve activation or inhibition of this subunit with various guanine nucleotides suggest that $G_{\alpha i}$ may regulate the budding of membrane vesicles through these organelles. It also has been suggested that $G_{\alpha i}$ could be involved in the process by

which portions of the plasma membrane are vesicularized into the cytoplasm via endocytosis. Synaptic vesicle trafficking is discussed in detail in Chapter 9.

G protein βγ subunits subserve numerous functions in the cell. In early studies, G protein βγ subunits were thought to be inactive proteins that merely sequestered active α subunits or anchored them to the plasma membrane. However, it has become clear that βγ subunits, acting as dimers, are highly active biological molecules that play important roles in several cellular functions.

As mentioned above, βγ subunits directly bind to and activate a class of K^+ channels called GIRKs and bind to and modulate the activity of PI-PLC_β and certain classes of adenylyl cyclase. The βγ subunits also bind to several other proteins, including certain protein kinases as well as phosducin and Ras-GEFs (see below). The ability of such diverse cellular proteins to bind βγ subunits has led to a search for a common structural motif in these various target proteins that is responsible for binding to the βγ subunits. One possibility is that the target proteins contain, within their primary structures, a specific amino acid sequence termed the pleckstrin homology (PH) domain, which binds βγ with high affinity.

One class of protein kinase that binds βγ subunits is called G -protein-receptor kinases (GRKs). These kinases phosphorylate G-protein-coupled receptors that are occupied by ligand and thereby mediate one form of receptor desensitization (Ch. 23). It now appears that βγ subunits play a key role in this process [14]. As shown in Figure 19-2, the GRK is normally a cytoplasmic protein that does not come into appreciable contact with the plasma membrane receptor under basal conditions. Ligand binding to the receptor activates the associated G protein, which results in the generation of free α and βγ subunits. The βγ subunits, which remain membrane-bound (as will be described below), are now free to bind to the C-terminal domain of the GRK. This draws the GRK into close physical proximity with the receptor and enables receptor phosphorylation. In this way, the βγ subunits direct GRKs, which have constitutive catalytic activity, to those receptors that are ligand-bound.

Another important role for βγ subunits is regulation of the mitogen-activated protein kinase (MAP-kinase) pathway [15]. MAP-kinases are the major effector pathway for growth factor receptors (see Chs 10, 23 and 27). However, signals that act through G-protein-coupled receptors, particularly those coupled to G_i, can modulate growth factor activation of the MAP-kinase pathway. This is mediated via βγ subunits. Activation of the receptors leads to the generation of free βγ subunits, which then activate the MAP-kinase pathway at some early step in the cascade. Some possibilities include direct action of the βγ subunits on Ras (see below) or on one of several 'linker' proteins between the growth factor receptor itself and activation of Ras.

Recent research has implicated $G_{\beta\gamma}$ subunits in mediating G-protein signaling in the absence of activation of the G protein's associated receptor. This mechanism involves a newly discovered modulatory protein, called GoLoco, which triggers the release of free βγ dimers from G-protein–receptor complexes without receptor activation and leads to βγ regulation of its several effector proteins. This GoLoco mechanism is described further in the next section of this chapter.

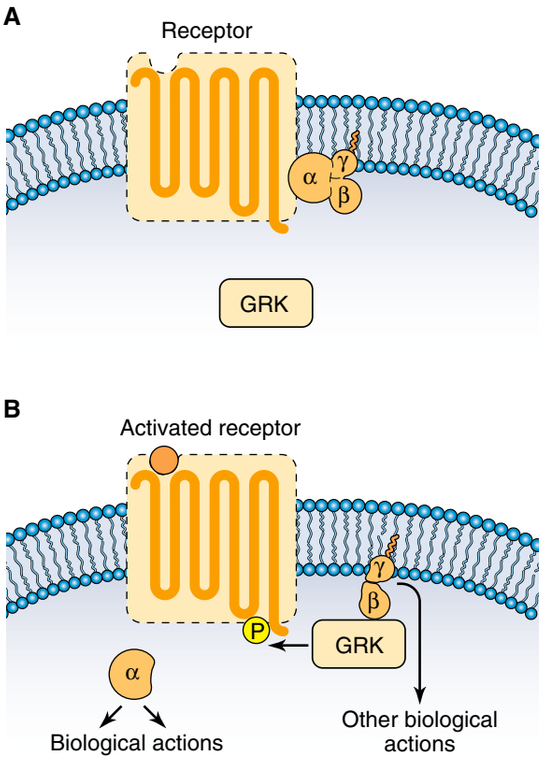

FIGURE 19-2 Schematic illustration of the role of G protein βγ subunits in intracellular targeting of proteins. (**A**) Under resting conditions, the receptor is associated loosely with a heterotrimeric G protein and G protein-receptor kinases (*GRK*) are cytoplasmic and therefore unable to phosphorylate the receptor. (**B**) Upon activation of the receptor and G protein, free α subunit is generated, which can lead to a variety of physiological effects. In addition, a free βγ subunit dimer is generated, which can bind to the GRK and draw it toward the membrane, where it can phosphorylate the ligand-occupied receptor. In this way, βγ subunits can direct GRKs specifically to the targets, which are those receptor molecules occupied by ligand. Free βγ also produces other physiological effects by interacting with other cellular proteins. The βγ complex is tethered to the membrane by an isoprenyl group on the γ subunit, as depicted.

The activity of G protein βγ subunits is modulated by another protein termed phosducin [16]. Phosducin is a cytosolic protein enriched in retina and pineal gland but also expressed in brain and other tissues. Phosducin binds to G protein βγ subunits with high affinity. The result is prevention of βγ subunit reassociation with the α subunit. In this way, phosducin may sequester βγ subunits, which initially may prolong the biological activity of the α subunit. However, eventually this sequestration may inhibit G protein activity by preventing the direct biological

effects of the βγ subunits as well as preventing regeneration of the functional G protein heterotrimer. How phosducin functions in intact cells remains incompletely understood, although the ability of phosducin to bind to βγ subunits is altered upon its phosphorylation by cAMP- or Ca^{2+}-dependent protein kinases (see Ch. 23). This raises the possibility that phosducin may be an important physiological modulator of G protein function.

The molecular specificity of subtypes of β and γ subunits is an area of intense research [4, 17]. The five known forms of G protein β subunit, whose structures are highly similar, are divided into two families comprising $G_{Aβ1–4}$ and $G_{β5}$. $G_{β5}$ appears unique in its selective association with a particular type of G protein modulatory protein known as RGS proteins (see 'Regulators of G protein signaling', below) [18]. The 11 forms of γ subunit are more divergent structurally. Some show striking regional distributions in the brain: for example, $G_{Aγ7}$ is highly enriched in striatum [19]. Different forms of β and γ subunit interact with each other with widely varying abilities in *in vitro* expression systems. Identifying which forms of βγ subunit complexes occur *in vivo* and the specificity of these complexes for various target proteins, such as adenylyl cyclases, K^+ channels, GRKs and others, remains an important area of investigation.

The functioning of heterotrimeric G proteins is modulated by other proteins. It has been known for years that the activity of small G proteins is modulated by proteins that bind to the G proteins and stimulate their intrinsic GTPase activity (see below). These are termed *GTPase-activating proteins* (GAPs; Fig. 19-3). Now, analogous proteins have been identified also for heterotrimeric G proteins [20]. These GAPs, first identified in yeast but subsequently found in mammalian tissues, are termed *RGS proteins*. RGS proteins bind to G protein α subunits and stimulate their GTPase activity. This action hastens the hydrolysis of GTP to GDP and more rapidly restores the inactive heterotrimer; thus, RGS proteins inhibit the biological activity of G proteins. In addition, RGS proteins impart important scaffolding properties that alter the function of multiprotein signaling complexes at the plasma membrane.

Some 20 forms of mammalian RGS protein are now known, and most are expressed in brain with highly specific regional patterns [21]. All RGS proteins act on the G_i and G_q family of G proteins, with varying degrees of specificity. Figure 19-4 shows the categorization of mammalian RGS proteins based on their structural properties [20]. All RGS proteins contain a core RGS domain, which is responsible for regulating G protein α subunit GTPase activity. However, several other domains contained within the RGS protein subtypes differ and confer other diverse functions on these proteins, in addition to the proteins' GAP activity. One example is provided by the R7 subfamily of RGS proteins. This subfamily, which uniquely associates with $G_{β5}$, contains a GGL ($G_γ$-like) domain

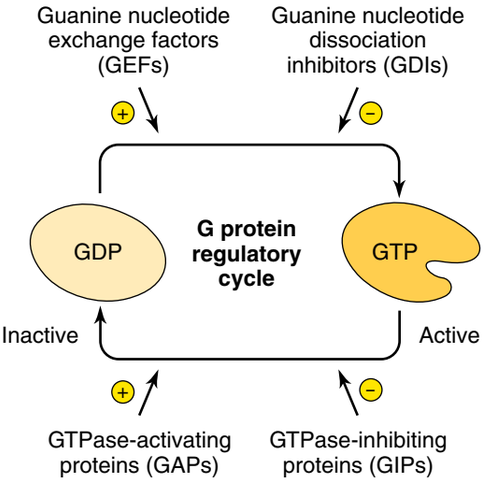

FIGURE 19-3 Schematic illustration of proteins that modulate the functioning of G proteins. The functional activity of G proteins is controlled by cycles of binding GDP versus GTP. This is associated with a major conformational change in the protein, as depicted. There are several proteins that regulate this cycle and thereby regulate the functional activity of G proteins. Analogous modulator proteins exist for heterotrimeric G protein α subunits and for small G proteins. There are proteins that facilitate the release of GDP from the G protein and thereby enhance G protein function. Examples of such guanine nucleotide exchange factors (*GEFs*) are receptors for heterotrimeric G proteins or a large number of GEFs specific for various small G proteins. There are proteins, GTPase-activating proteins (*GAPs*), that activate the GTPase activity intrinsic for the G proteins and thereby inhibit G protein function. Examples are the regulators of G protein-signaling (RGS) proteins for heterotrimeric G proteins and a series of GAPs specific for various small G proteins. There also may be GTPase-inhibitory proteins (GIPs) that exert the opposite effects. Heterotrimeric βγ subunits can be viewed as such; analogous proteins have been proposed for the small G proteins. Phosducin, by binding to βγ subunits, would represent yet another regulatory protein that modulates G protein function.

that may enable these RGS subtypes to substitute for $G_γ$ subunits in regulation of G-protein-coupled receptor function.

Another example is provided by the R12 subfamily of RGS proteins [22]. These subtypes contain the GoLoco motif described earlier. The name of the motif comes from the fact that it interacts with G proteins and the fact that the *Drosophila* homolog of RGS12 is called Loco. GoLoco binds directly to $G_{αi}$ and stabilizes it in its GDP-bound form. At the same time, it leads to the dissociation of $G_{βγ}$ subunit dimers, which then activate numerous effectors. This occurs independent of ligand activation of the associated G-protein-coupled receptor. In this way, RGS12 proteins can stimulate receptor-independent G protein signaling. Several other types of protein contain Go-Loco motifs and similarly regulate G protein signaling. Examples are the AGS (activators of G protein signaling) proteins [23].

These are just some examples of the diverse functions of RGS proteins in mammalian cells. Given the number and diversity of RGS proteins, and their region-specific expression in brain, there is considerable interest in

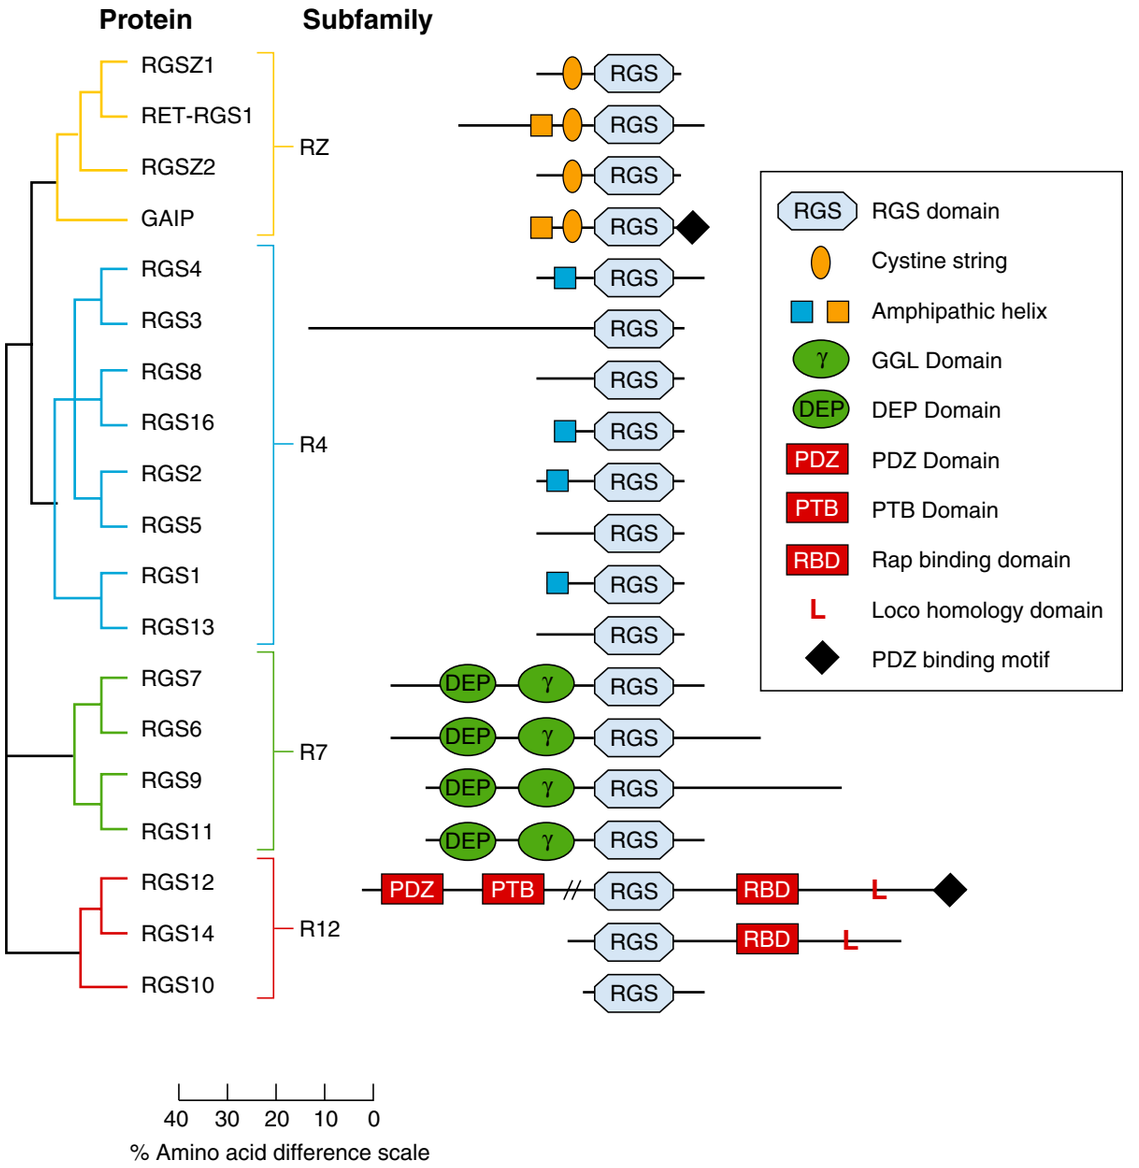

FIGURE 19-4 Schematic illustration of the structure and classification of mammalian RGS proteins. All the proteins contain a highly conserved RGS domain that has GAP activity. Most of the proteins contain additional domains that mediate other functions. The figure does not include several other types of homologous proteins, which lack the RGS domain but nevertheless are considered members of the RGS superfamily.

targeting them in the development of new pharmacotherapeutic agents for neuropsychiatric disorders. There is also growing evidence that alterations in the activity of specific RGS proteins, for example via changes in their expression or phosphorylation, modulate the activity of specific G proteins and, consequently, the sensitivity of specific G-protein-coupled receptors. Such mechanisms have been implicated, for example, in disorders as diverse as drug addiction (Ch. 56) and schizophrenia (see also Ch.54) [24, 25].

G proteins are modified covalently by the addition of long-chain fatty acids. Addition of these lipid groups appears to modify the ability of the G proteins to interact with other proteins or with the plasma membrane. Several fatty acid modifications have been demonstrated: myristoyl groups, which consist of 14 carbon chains (C_{14}); farnesyl groups (C_{15}); palmitoyl groups (C_{16}); and geranylgeranyl, or isoprenyl, groups (C_{20}) [26, 27]. Myristoyl groups are added via amide links to N-terminal glycine residues present in certain proteins. Farnesyl and isoprenyl groups are added to cysteine residues of specific C-terminal motifs. Farnesyl and isoprenyl groups are reduced and, therefore, the addition of these groups to G proteins is also reduced in the presence of inhibitors of cholesterol synthesis in *in vitro* models. Palmitoyl groups also are added to cysteine groups within specific consensus amino acid sequences.

All G protein α subunits are modified in their N-terminal domains by palmitoylation or myristoylation. These modifications may regulate the affinity of the α subunit for its βγ subunits and, thereby, the likelihood of dissociation or reassociation of the heterotrimer. The modifications also may help determine whether the α subunit, released upon ligand-receptor interaction, remains associated with the plasma membrane or diffuses into the cytoplasm. This could have important consequences on the types of effector protein regulated. It is also possible that palmitoylation, but not myristoylation, is regulated dynamically. There is evidence that palmitoylation can be regulated by ligand binding, which makes this a potentially important control point. However, very little is known about palmitoyl transferases and depalmitoylases, the enzymes responsible for palmitoylation. In contrast, myristoylation appears to be a one-time event in the life cycle of an α subunit.

G protein γ subunits are modified on their C-terminal cysteine residues by isoprenylation [26, 27]. There is now strong evidence that this modification plays a key role in anchoring the γ subunit and its associated β subunit to the plasmalemma. The importance of this anchoring is illustrated in Figure 19-2, which shows that the ability of βγ subunits to direct GRKs to ligand-bound receptors depends on this membrane localization.

The functioning of G proteins may be influenced by phosphorylation. G proteins, as well as their associated receptors and RGS proteins, have been reported to undergo phosphorylation by a host of protein serine/threonine kinases and protein tyrosine kinases. While the ramifications of receptor phosphorylation are becoming increasingly well understood (see Chs 23 and 24), the effect of phosphorylation of G proteins and RGS proteins, and its role in the regulation of physiological processes, have been more difficult to establish with certainty. This remains an important area of future investigation.

SMALL G PROTEINS

In addition to the heterotrimeric G proteins, other forms of G protein play important roles in cell function. These proteins belong to a large superfamily often referred to as 'small G proteins' because of their low M_r (20,000–35,000) [28]. The small G proteins, like the heterotrimeric G proteins, bind guanine nucleotides, possess intrinsic GTPase activity and cycle through GDP- and GTP-bound forms (as shown in Fig. 19-1). One unifying feature of the various classes of G protein is that the binding of GTP versus GDP dramatically alters the affinity of the protein for some target molecule, apparently by inducing a large conformational change. Small G proteins appear to function as molecular switches that control several cellular processes. Examples of small G proteins and their possible functional roles are given in Table 19-2.

TABLE 19-2 Examples of small G proteins

Class	Proposed cellular function
Ras	Signal transduction (control of growth factor and MAP-kinase pathways)
Rac, CDC42	Signal transduction (control of cellular stress responses and MAP-kinase pathways)
Rab	Localized to synaptic vesicles, where it regulates vesicle trafficking and exocytosis
Rho	Assembly of cytoskeletal structures (e.g. actin microfilaments)
ARF	ADP-ribosylation of $G_{\alpha s}$; assembly and function of Golgi complex
EFTU	Associated with ribosomes, where it regulates protein synthesis
Ran	Nuclear-cytoplasmic trafficking of RNA and protein

ARF, ADP-ribosylation factor; EFTU, eukaryotic elongation factor.

The best characterized small G protein is the Ras family, a series of related proteins of ≈21 kDa proteins. Ras proteins were identified originally as the oncogene products of Harvey and Kirsten rat sarcoma viruses. Subsequently, normal cellular homologs, also known as proto-oncogenes, of viral Ras were identified. Mammalian Ras proteins are encoded by three homologous genes: the photo-oncogene for Harvey Ras virus (H-*ras*), the proto-oncogene for Kirsten Ras virus (K-*ras*) and neural Ras (N-*ras*), although all three forms of Ras are found in diverse mammalian tissues, including brain. All three forms of Ras are membrane-associated proteins [28].

The activity of Ras is highly regulated by a variety of associated proteins, as shown in Figure 19-3 [28]. Guanine nucleotide exchange factors (GEFs) stimulate the release of GDP from inactive Ras, which facilitates the binding of GTP. Thus, GEFs increase the activity of Ras. Multiple forms of GEFs have been identified, some specific for Ras and others for different small G proteins. In contrast, GAPs bind to Ras and activate its intrinsic GTPase activity, thereby reducing the functional activity of Ras. There also may be GTPase-inhibitory proteins (GIPs) that bind Ras and inhibit this GTPase activity, although these remain poorly described. In addition, small G proteins are modified by guanine nucleotide dissociation inhibitors (GDIs), which reduce the rate of exchange of GDP for GTP.

The analogy between Ras and its related proteins, on the one hand, and heterotrimeric G proteins and their related proteins, on the other, is striking (Fig. 19-3). G-protein-coupled receptors, in their ligand-bound form, essentially function as GEFs for the heterotrimeric G proteins, whereas RGS proteins function as GTPase-activating proteins and βγ subunits as GDIs. One major difference between the systems is that the intrinsic GTPase activity of Ras is far lower than that of heterotrimeric G protein α subunits. As a result, GAPs exert a much more profound effect on the functioning of Ras, essentially turning it on and off.

Upon binding GTP, a major conformational change occurs in Ras, which is thought to be responsible for its functional activation. Ras has long been known to be a major control point for cell growth and some of the effector molecules through which Ras produces its myriad effects have been identified. Numerous types of cell signal, including many and perhaps most growth factors, converge on Ras to regulate MAP-kinase pathways and, thereby, to produce their diverse effects on cell function (see Chs 27 and 24) [28, 29]. Briefly, it appears that activation of growth factor receptors results in the activation of a GEF, termed Sos, which in turn activates Ras. Activated Ras then binds to the N-terminal domain of a protein kinase called Raf, the first protein kinase in the MAP-kinase pathway. Ras appears to activate Raf via an indirect mechanism. Ras, which is membrane-bound, draws Raf to the plasmalemma, where it (Raf) is activated through other means that are not yet completely understood. Anchoring of Ras in the plasmalemma may be mediated by isoprenylation, another point of analogy between Ras and heterotrimeric G proteins (Fig. 19-2).

Although the major mechanism governing Ras activation is through growth factors, as outlined above, Ras function can also be modulated by heterotrimeric G protein and second-messenger pathways [28, 29]. The ability of free βγ subunits, particularly those released from G_i, to activate Ras, was mentioned earlier. In addition, the cAMP cascade inhibits Ras activity in several systems, although it is unknown whether this occurs via direct phosphorylation by cAMP-dependent protein kinase of Ras or a closely associated protein. 'Cross-talk' such as this among these various intracellular cascades emphasizes that the multitude of intracellular messengers are highly integrated to coordinate the response of a cell to a myriad of extracellular signals.

Rab is a family of small G proteins involved in membrane vesicle trafficking. Mammalian tissues contain around 30 forms of Rab, which specifically associate with the various types of membrane vesicles and organelles that exist in cells [30, 31]. Rab proteins, named originally as *ras*-related proteins in brain, are isoprenylated and associate with membranes, as do isoprenylated Ras and G protein γ subunits. However, unlike these other G proteins, the GTP and GDP binding to Rab appears to regulate its association with membrane compartments.

Subtypes of Rab, particularly Rab3, have been implicated in the regulation of exocytosis and neurotransmitter release at nerve terminals (see also Chs 9 and 10) [30, 31]. One possible scheme by which this might occur is shown in Figure 19-5. In its GTP-bound form, Rab associates with synaptic vesicles and interacts with other membrane proteins to create a complex unfavorable for vesicle docking and perhaps fusion. Upon depolarization of the nerve terminal, a Rab GAP is activated, which results in dissociation of the GDP form of Rab from the vesicle membrane. This enables the synaptic vesicle to proceed with docking and fusion. The mechanism by which depolarization leads to activation of a Rab GAP and subsequently to release of Rab from the vesicle remains unknown, but Ca^{2+} is believed to be involved. To complicate matters further, several other proteins are involved in this Rab-synaptic vesicle cycle, including a Rab GDP dissociation inhibitor, which regulates the ability of Rab to bind to synaptic vesicles, and rabphilin, one of several synaptic vesicle proteins that can bind Rab (see Ch. 9).

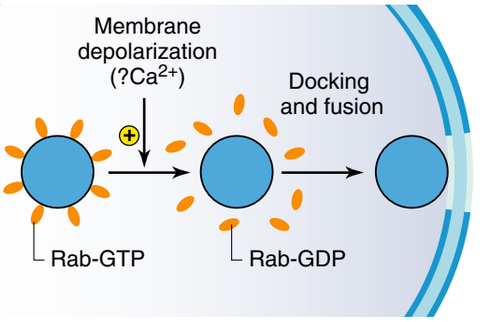

FIGURE 19-5 Schematic illustration of the proposed role of Rab in neurotransmitter release. Under basal conditions, GTP is bound to Rab3, which allows Rab3 to associate with other proteins on synaptic vesicles. This creates conditions unfavorable for the docking and fusion of vesicles at the nerve terminal plasma membrane. Membrane depolarization results in hydrolysis of the GTP bound to Rab, possibly via a Ca^{2+}-induced activation of Rab-GTPase activity. Rab then dissociates from the vesicle, creating a condition more favorable for docking and fusion. A large number of other synaptic vesicle proteins contribute to this process.

OTHER FEATURES OF G PROTEINS

G proteins can be modified by ADP-ribosylation catalyzed by certain bacterial toxins. Among the tools that facilitated the discovery and characterization of G proteins were the bacterial toxins cholera and pertussis, which were known to influence adenylyl cyclase activity. Subsequently, it was shown that the actions of these toxins are achieved by their ability to catalyze the addition of an ADP-ribose group donated from nicotinamide adenine dinucleotide (NAD) to specific amino acid residues in certain heterotrimeric G protein α subunits [1].

Cholera toxin catalyzes the ADP-ribosylation of a specific arginine residue in $G_{\alpha s}$ and $G_{\alpha t}$. This covalent modification inhibits the intrinsic GTPase activity of these α subunits and thereby 'freezes' them in their activated, or free, state (Fig. 19-1C). By this mechanism, cholera toxin stimulates adenylyl cyclase activity and photoreceptor transduction mechanisms. The ability of cholera toxin to ADP-ribosylate $G_{\alpha s}$ may require the presence of a distinct protein, ADP-ribosylation factor (ARF). ARF, which is itself a small G protein (Table 19-2), also is ADP-ribosylated by cholera toxin. ARF is implicated in controlling membrane vesicle trafficking (see Ch. 9).

In contrast, pertussis toxin catalyzes the ADP-ribosylation of a specific cysteine residue in $G_{\alpha i}$, $G_{\alpha o}$ and $G_{\alpha t}$ [1]. Only α subunits bound to their βγ subunits can undergo this modification. Pertussis-toxin-mediated ADP-ribosylation inactivates these α subunits such that they cannot exchange GTP for GDP in response to receptor activation (Fig. 19-1B). By this mechanism, pertussis toxin blocks the ability of neurotransmitters to inhibit adenylyl cyclase or to influence the gating of K^+ and Ca^{2+} channels in target neurons. However, since $G_{\alpha z}$ is not a substrate for pertussis toxin, the toxin may not be able to block neurotransmitter-mediated inhibition of adenylyl cyclase in all cases. The G_q and G_{11-16} types of G protein α subunit are not known to undergo ADP-ribosylation.

A third type of bacterial toxin, diphtheria toxin, catalyzes the ADP-ribosylation of eukaryotic elongation factor (EFTU), a type of small G protein involved in protein synthesis (Table 19-2). The functional activity of the elongation factor is inhibited by this reaction. Finally, a botulinum toxin ADP-ribosylates and disrupts the function of the small G protein Rho, which appears to be involved in assembly and rearrangement of the actin cytoskeleton (Table 19-2). These toxins may be involved in neuropathy (see Ch. 36) and membrane trafficking (see Ch. 9).

G proteins are implicated in the pathophysiology and treatment of disease. The best characterized examples of G protein abnormalities involved in a disease state are endocrinopathies caused by mutations in $G_{\alpha s}$ [32, 33]. There are both 'gain of function' and 'loss of function' mutations. Examples of gain of function mutations, which result in increased or constitutive activity of $G_{\alpha s}$, include forms of acromegaly, which involves hypersecretion of growth hormone, and McCune–Albright syndrome, which involves hyperossification of bone, *café-au-lait* skin hyperpigmentation and mixed endocrine hyperfunction. Examples of loss of function mutations include Albright's hereditary osteodystrophy, characterized by abnormal bone formation, as well as forms of pseudohypoparathyroidism, a rare hereditary disease in which target tissues are resistant to the physiological actions of parathyroid hormone despite the existence of a normal number of functionally active hormone receptors. In addition, mutations in $G_{\alpha i}$ have been implicated in certain forms of ovarian and adrenal cortical tumor.

Neurofibromatosis type 1, a familial disorder characterized by multiple benign tumors of certain glial cells, is due to a mutation in the gene that codes for one form of GAP that regulates Ras [34]. The mutation in GAP that leads to neurofibromatosis renders GAP unable to activate GTPase activity of Ras. This means that the GTP-bound form of Ras remains active for abnormally long periods of time, which leads to abnormal cellular growth.

Of course, the critical importance of Ras and most other small G proteins in cell growth and differentiation is highlighted by the consideration, stated above, that several forms of these proteins are proto-oncogenes (see also Ch. 25). This means that mutations in these proteins that result in alterations in their regulatory properties can lead to oncogenesis. Ras in particular has been implicated in several human cancers [32]. It has been estimated that as many as 30% of all human cancers contain mutations in one of the three Ras genes. While the frequency of Ras mutations in some types of human cancer is very low, its frequency in certain cancers, such as squamous cell carcinoma, lymphatic cancers and colorectal adenocarcinoma, is very high.

In addition to their involvement in specific disease states, concentrations of heterotrimeric G protein subunits, as well as of particular RGS protein subtypes, are altered in specific regions of the central nervous system in response to chronic exposure to many types of psychoactive drugs. This has been shown for the antidepressant drugs lithium, which is used in the treatment of mania and depression (Ch. 55), and for several drugs of abuse [24, 25, 35] (see also Ch. 56). Evidence has been presented to suggest that drug-induced alterations in G protein and RGS protein levels influence signal transduction pathways in the brain and, thereby, contribute to the therapeutic or addictive actions of these drugs.

An increasing number of G proteins and RGS proteins have been deleted or overexpressed in genetic mutant mice. Not surprisingly, some of these mice exhibit complex behavioral abnormalities and in some cases abnormal responses to psychotropic drugs. These data further highlight the importance of G protein signaling in the brain in health and disease and open new paths for investigation in the years ahead.

THE INOSITOL LIPIDS 347
The three quantitatively major phosphoinositides are structurally and metabolically related 347
The quantitatively minor 3′-phosphoinositides are synthesized by phosphatidylinositol 3-kinase. 348
Phosphoinositides are cleaved by a family of phosphoinositide-specific phospholipase C isozymes 350

THE INOSITOL PHOSPHATES 354
D-myo-inositol 1,4,5-trisphosphate ($I(1,4,5)P_3$) is a second messenger that liberates Ca^{2+} from the endoplasmic reticulum via intracellular receptors 354
The metabolism of inositol phosphates leads to regeneration of free inositol 354
Highly phosphorylated forms of myo-inositol are present in cells 355

DIACYLGLYCEROL 356
Protein kinase C is activated by the second messenger diacylglycerol 356

PHOSPHOINOSITIDES AND CELL REGULATION 358
Inositol lipids can serve as mediators of other cell functions, independent of their role as precursors of second messengers 358

A large variety of ligands, including neurotransmitters, neuromodulators and hormones, exert their physiological action via an intracellular second-messenger system in which the activated receptor–ligand complex stimulates the turnover of inositol-containing phospholipids, resulting in the formation of the second messengers inositol trisphosphate and diacylglycerol. The original demonstration that phosphoinositide turnover was under neurohumoral control dates back to the pioneering studies of the Hokins in the early 1950s [1]. Although it was recognized for many years that alterations in Ca^{2+} homeostasis and protein phosphorylation accompanied these changes in inositol lipid turnover, it was not until some 30 years later that inositol 1,4,5-trisphosphate and diacylglycerol were identified as second messenger molecules capable of mobilizing intracellular Ca^{2+} and activating protein kinase C, respectively. For a historical perspective, the reader is referred to a review by Irvine [2]. In this chapter, the biochemical and cellular bases of this ubiquitous pathway, as well as its pharmacological significance, are examined in the context of the nervous system. To better understand the events leading to the enhanced inositol lipid turnover, it is necessary first to review the underlying structural chemistry.

THE INOSITOL LIPIDS

The three quantitatively major phosphoinositides are structurally and metabolically related. These consist of phosphatidylinositol (PI) and the two polyphosphoinositides, namely phosphatidylinositol 4-phosphate (PI4P) and phosphatidylinositol 4,5-bisphosphate ($PI(4,5)P_2$)* (Fig. 20-1). PI consists of a diacylglycerol (DAG) moiety, which is phosphodiesterified to myo-inositol, a 6-carbon polycyclic alcohol (Fig. 20-1). myo-inositol, one of nine possible isomers of hexahydroxycyclohexane, has one axial and five equatorial hydroxyls and is by far the most prevalent isomer in nature. myo-inositol is particularly enriched in neural tissues (5–20 mmol/l), where it serves not only as a precursor molecule for inositol lipid synthesis but also as a physiologically important osmolyte [3]. The distinctive configuration of myo-inositol can be more readily understood by making use of Agranoff's turtle, in

*The 'Chilton Conference' nomenclature for inositol lipids is used throughout this chapter, e.g. PI, PI4P, $PI(4,5)P_2$ for phosphatidylinositol, phosphatidylinositol 4-phosphate and phosphatidylinositol 4,5-bisphosphate respectively. Note that the IUB-recommended nomenclature for these lipids is PtdIns, PtdIns4P and $PtdIns(4,5)P_2$ (see Ch. 3).

Basic Neurochemistry: Molecular, Cellular and Medical Aspects

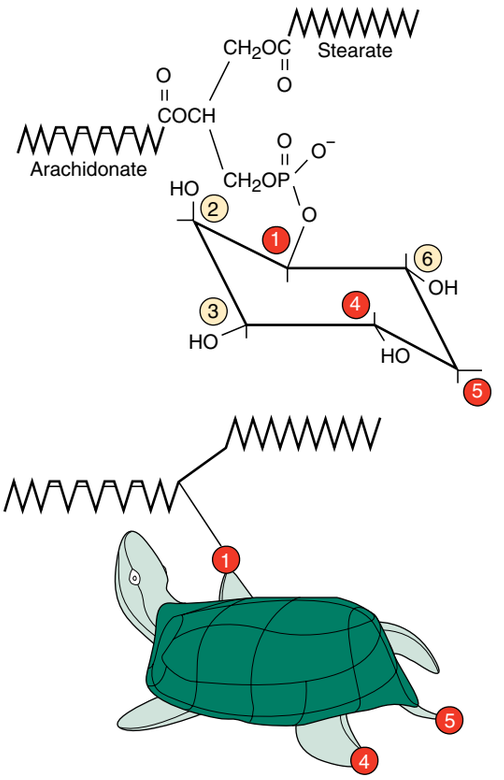

FIGURE 20-1 Stereochemistry of the quantitatively major inositol lipids. Inositol lipids characteristically contain stearic acid (18:0) and arachidonic acid (20:4 ω6) esterified to the 1 and 2 position of sn-glycerolphosphate, respectively. The phosphate (colored circle) is diesterified to the 1 position of D-myo-inositol. myo-inositol in its favored chair conformation has five equatorial hydroxyls and one axial hydroxyl. Looking at the chair from above and counting counterclockwise, the axial hydroxyl is then in position 2. As indicated by the drawing, the inositol molecule can be conveniently viewed as a turtle [4], in which the diacylglycerol phosphate moiety is attached to the right front leg (position 1), next to the raised head (the axial hydroxyl in position 2). The other equatorial hydroxyls are represented by the remaining limbs and the tail. Phosphatidylinositol (PI) can be phosphorylated at position 4 (the rear left leg), or the rear left leg as well as the tail (positions 4 and 5 as shown), to yield phosphatidylinositol 4-phosphate (PI4P) and phosphatidylinositol 4,5-bisphosphate ($PI(4,5)P_2$) respectively.

which the cyclohexane chair configuration is viewed as a turtle with the axial hydroxyl as the head, and hydroxyls in the five equatorial positions serving as the four limbs and tail (Fig. 20-1; [4]). At present, there are no known brain phosphoinositides containing cyclitols other than myo-inositol, nor are there as yet examples of inositol lipids in which the inositol is diesterified to DAG at a position other than D-1.

There exists an unusual uniformity in the fatty acid composition of the inositol lipids. All three of the major phosphoinositides are enriched in the 1-stearoyl, 2-arachidonoyl ('ST/AR') sn-glycerol species (≈80% in brain). The polyphosphoinositides (PI4P and $PI(4,5)P_2$) are present in much lower amounts than PI. $PI(4,5)P_2$ has been shown to be predominantly, although not exclusively, localized to the plasmalemma [5]. Because of its high complement of plasmalemmas, the brain is one of the most enriched sources of the polyphosphoinositides.

The phosphoinositides are synthesized from the glycerolipid precursor phosphatidic acid (PA) via the formation of the liponucleotide intermediate cytidine diphosphate diacylglycerol (CDP-DAG; Fig. 20-2B; see also Ch. 3). This reaction is catalyzed by CDP-DAG synthase, a 51 kDa protein localized to both mitochondrial and endoplasmic reticulum membranes. Subsequently, PI synthase, an extremely hydrophobic 24 kDa protein primarily localized to the endoplasmic reticulum and Golgi, catalyzes the formation of PI. The latter is then phosphorylated to PI4P in a reaction requiring ATP and catalyzed by PI 4-kinase (PI4K; Fig. 20-2A).

Cloning studies have revealed the presence of three distinct isoforms of PI4K of 97, 110 and 230 kDa. The 97 kDa enzyme is inhibited by adenosine and by the monoclonal antibody 4C5G. In contrast, neither the 110 kDa nor the 230 kDa isoform is markedly inhibited by these agents. Also in contrast to the 97 kDa isozyme, both are sensitive to the fungal metabolite wortmannin, albeit at relatively high concentrations. The ability of wortmannin to block the sustained agonist-induced turnover of inositol lipids has led to the suggestion that wortmannin-inhibitable isoforms of PI4K are involved in the regulation of hormone-sensitive pools of phosphoinositides [6].

PI4P is further phosphorylated via PIP kinase to $PI(4,5)P_2$ (Fig. 20-2A). This enzyme is found both in brain membranes and cytosol and does not phosphorylate PI. Two distinct classes of PIP kinase can be identified, types I and II, each with three distinct subfamilies (α, β and γ) [7]. Although the type I enzyme preferentially phosphorylates PI(4)P to $PI(4,5)P_2$, it can also phosphorylate PI3P (a 3′-phosphoinositide, see below) at either the 4′ or 5′ positions of the inositol ring to yield $PI(3,4)P_2$ and $PI(3,5)P_2$. There is also a PI 5-kinase, further adding to the complexity of phosphoinositide metabolism. The type II PIP kinase exhibits a preference for PI(5)P over PI(4)P and will phosphorylate at the 4-position of the inositol ring to yield $PI(4,5)P_2$. As with the type I enzyme, type II PIP-kinases will also phosphorylate 3′-phosphoinositides. Both $PI(4,5)P_2$ and PI4P can be dephosphorylated by phosphatases, with most information available regarding the 5-phosphatases. Of these, the major members are synaptojanins and the product of the oculocerebrorenal syndrome gene. These are discussed in more detail in the following section.

The quantitatively minor 3′-phosphoinositides are synthesized by phosphatidylinositol 3-kinase. These lipids (principally, PI3P, $PI(3,4)P_2$, $PI(3,5)P_2$ and $PI(3,4,5)P_3$), documented by Cantley and colleagues in the mid-1980s, are present in both neural and non-neural tissues at concentrations well below those found for either PI4P or $PI(4,5)P_2$ (for review, see [8]). In resting cells, the concentration of PI3P exceeds, by an order of magnitude, that of

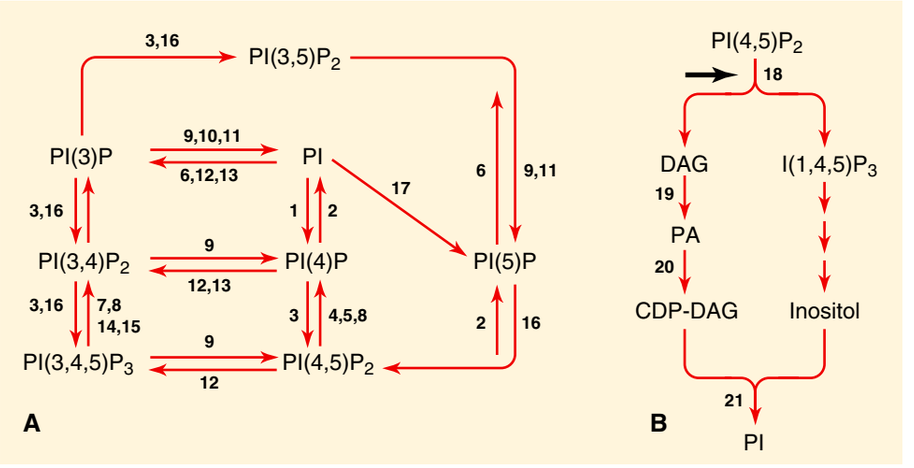

FIGURE 20-2 Pathways of inositol lipid metabolism. (**A**) Interrelationship between routes of synthesis and degradation of the 'canonical' inositol lipids (PI, PI(4)P and PI(4,5)P_2) and the 3-phosphoinositides. Numbers refer to the following enzymes (for explanation of abbreviations, see text): 1, PI 4-kinase; 2, PI 4-phosphatase; 3, PIP kinase I; 4, OCRL gene product; 5, synaptojanin; 6, PI 3-kinase (III); 7, pharbin. 8, PIPP; 9, PTEN; 10, myotubularin; 11, sac1p phosphatase; 12, PI 3-kinase (I); 13, PI 3-kinase (II); 14, GIP; 15, SHIP; 16, PIP kinase II; 17, PI 5-kinase. (**B**) Regenerative cycle of phosphoinositide resynthesis following receptor–ligand-mediated breakdown of PI(4,5)P_2 (bold arrow) and generation of the second messengers DAG and I(1,4,5)P_3. Numbers refer to the following enzymes: 18, phosphoinositide-specific phospholipase C; 19, DAG kinase; 20, CDP-DAG synthase; 21, PI synthase.

the other 3-phosphoinositides. However, whereas the concentration of PI3P is relatively stable in cells, the mass of PI(3,4)P_2 and PI(3,4,5)P_3 can increase dramatically upon receptor activation [8]. The metabolic interrelationships of the 3-phosphoinositides are shown in Figure 20-2A.

The key enzyme involved in the synthesis of the 3-phosphoinositides is PI 3-kinase (PI3K). Three major classes of PI3K have been described, based upon lipid substrate specificity and regulation. Class I PI3Ks are able to phosphorylate PI, PI4P and PI(4,5)P_2 in vitro to form PI3P, PI(3,4)P_2 and PI(3,4,5)P_3 respectively, although their preferred substrate in vivo is PI(4,5)P_2. The catalytic subunits of this class of PI3K form heterodimeric complexes with adaptor or regulatory proteins that link the enzyme to upstream signaling events.

Class I PI3K catalytic subunits can be further subdivided. Class I A catalytic subunits (110–130 kDa) interact with PI3K regulatory proteins (p85) that contain two SH2 domains. The presence of the latter enables the enzyme to more readily associate with phosphorylated tyrosine residues present on upstream proteins, such as receptors with intrinsic tyrosine kinase activity or, alternatively, nonreceptor tyrosine kinases, such as src- or JAK kinases, thereby linking PI3K to tyrosine kinase signaling pathways (see Ch. 24). Phosphotyrosine binding to the regulatory domain of PI3K is thought to permit the translocation of the enzyme from cytosol to plasmalemma.

Class I B catalytic subunits (110 kDa) are stimulated by βγ subunits derived from G proteins (see Ch. 19). A regulatory protein (p101) that associates tightly with the catalytic subunit has been isolated. Both type A and type B catalytic subunits of class I PI3K interact with a small GTP-binding protein, Ras, although the significance of this interaction remains uncertain. Class I PI3Ks can be potently inhibited by either wortmannin, a fungal metabolite, or by LY294002, a quercetin analog. Both inhibitors bind to the catalytic subunit of PI3K and inhibit kinase activity. Class II and class III PI3Ks have a more restricted substrate specificity; both exhibit a strong preference for PI as a substrate but class II enzymes can also phosphorylate PI(4)P, at least in vitro. Unlike class I PI3Ks, neither class II nor class III PI3Ks appear to be regulated by extracellular stimuli.

The 3-phosphoinositides can be degraded via the action of three structurally distinct families of enzymes: 3′-or 4′-phosphatases from the CX5R families, which share a limited consensus sequence, CXXXXXR, in their catalytic core domain; and the 5′-phosphatases. Of the 3′-phosphatases, myotubularin, Sac1p phosphatase and PTEN (phosphatase and TENsin homolog) are major examples. Myotubularin was originally thought to be a tyrosine phosphatase responsible for myotubular myopathy, but was subsequently demonstrated to be a lipid phosphatase, whose substrate specificity is restricted to PI3P. Sac1p phosphatase, originally identified in yeast as a suppressor of actin mutations, also demonstrates a restricted substrate specificity in that it will not hydrolyze 3-phosphoinositides that possess vicinal phosphates, e.g. PI(3,4)P_2 or PI(3,4,5)P_3. However, it will hydrolyze PI3P or PI(3,5)P_2, with PI3P being preferred. Like myotubularin, PTEN was originally described as a tyrosine phosphatase that exhibited tumor suppressive properties, but it was subsequently recognized that the enzyme was primarily a lipid phosphatase, the latter activity being

essential for its ability to regulate cell proliferation. PTEN will dephosphorylate all 3-phosphoinositides and $I(1,3,4,5)P_4$ in vitro, and $PI(3,4)P_2$ and $PI(3,4,5)P_3$ in vivo.

Although relatively little is known about the 4-phosphatases, two such enzymes have been cloned and sequenced. These enzymes can also dephosphorylate inositol phosphates. Degradation of $PI(3,5)P_2$ and $PI(3,4,5)P_3$ can also be accomplished via the action of type II 5-phosphatases. The type II enzyme hydrolyzes both lipids and inositol phosphates, while type I 5′-phosphatases hydrolyze only the water-soluble inositol phosphates. At least four members of the type II 5-phosphatase family can be identified: the GAP-containing inositol 5-phosphatases (GIPs), Sac1p-containing inositol 5-phosphatases (SCIPs), SH2-domain-containing inositol 5-phosphatases (SHIPs) and proline-rich-domain-containing inositol 5-phosphatases (PIPs). The GIPs will dephosphorylate both $PI(4,5)P_2$ and $PI(3,4,5)P_3$, as well as the corresponding inositol phosphates. A type II 5-phosphatase gene, which is disrupted in the human X-chromosome-linked developmental disorder Lowe's oculocerebrorenal (OCRL) syndrome, has been identified as a GIP homolog. The wild type gene product is reportedly enriched in the Golgi or lysosomal fractions and preferentially hydrolyzes $PI(4,5)P_2$, but also has activity toward $PI(3,4,5)P_3$, $I(1,4,5)P_3$ and $I(1,3,4,5)P_4$. Lowe's syndrome, which results in mental retardation, congenital cataracts and renal tubular acidosis, is the only known inborn error of phosphoinositide metabolism.

Two synaptojanins are members of the SCIP family: synaptojanin 1 is restricted in distribution to neurons and plays a role in synaptic vesicle recycling, whereas synaptojanin 2 is ubiquitously expressed (see Ch. 9). Both synaptojanins are phosphoinositide 5-phosphatases capable of hydrolyzing $PI(4,5)P_2$ and $PI(3,4,5)P_3$. Thus, they could conceivably metabolize one bioactive lipid, namely $PI(3,4,5)P_3$, to yield an alternate, i.e. $PI(3,4)P_2$, a phosphoinositide implicated in the regulation of Akt (see 'Phosphoinositides and cell regulation', below). Two members of the SHIP family have been identified (SHIP1 and SHIP2), as well as two splice variants of SHIP1. These enzymes are characterized by an N-terminal SH2 domain and a C-terminal proline-rich domain. The preferred substrate of both SHIP1 and SHIP2 is $PI(3,4,5)P_3$, but both will also hydrolyze $I(1,3,4,5)P_4$. The PIPs are characterized by an N-terminal proline-rich domain, and examples include pharbin and PIPP (proline-rich inositol polyphosphate 5-phosphatase). Both enzymes will hydrolyze $PI(3,4,5)P_3$, as well as $PI(4,5)P_2$, $PI(3,5)P_2$ and corresponding soluble inositol phosphates.

In contrast to their more highly expressed counterparts, the 3-phosphoinositides do not serve as substrates for phospholipase C (PLC), the enzyme known to be activated in stimulated phosphoinositide turnover. This observation indicates that the 3-phosphoinositides themselves, rather than their breakdown products, are likely to be the intracellular mediators of biological activity. PI3P, $PI(3,4)P_2$ and $PI(3,4,5)P_3$ can bind to specific domains within proteins, thereby facilitating protein–protein interactions. As will be detailed below ('Phosphoinositides and cell regulation'), roles for 3-phosphoinositides in the regulation of membrane trafficking, cell survival and maintenance of the cytoskeleton have been proposed.

Phosphoinositides are cleaved by a family of phosphoinositide-specific phospholipase C isozymes. PLC catalyzes the phosphodiesteratic breakdown of $PI(4,5)P_2$, a reaction activated by a large number of pharmacologically distinct CNS receptors [9] (Table 20-1). The breakdown of $PI(4,5)P_2$ generates two second messenger molecules: (a) diacylglycerol, which is released into the plane of the plasmalemma and can then activate protein kinase C, and (b) inositol 1,4,5-trisphosphate ($I(1,4,5)P_3$), which is released into the cytosol and mobilizes the release of intracellular Ca^{2+} following the activation of $I(1,4,5)P_3$ receptors (see below and Ch. 22). The metabolism of these second messengers occurs in either membrane (DAG) or cytosolic ($I(1,4,5)P_3$) compartments of the cell (Fig. 20-2B). Thus DAG is phosphorylated by DAG kinase to form PA, the precursor molecule for PI and polyphosphoinositide synthesis, these events occurring in plasmalemma and other intracellular sites. In contrast, $I(1,4,5)P_3$ undergoes a series of sequential dephosphorylations, catalyzed by cytosolic or membrane-bound phosphatases, which ultimately yield free myo-inositol. The latter is then available for the resynthesis of PI, in the presence of CDP-DAG and PI synthase.

Four isoforms of PLC (β, γ, δ and ε; Fig. 20-3) have been identified in the brain, with the nomenclature based upon the chronology of their discovery. The α isoform was subsequently identified as a proteolytic fragment of PLCδ (for reviews, see [10, 11]). Because the lower eukaryotes such as yeast and slime molds possess only the δ isoform, it has been suggested that the other isoforms evolved

TABLE 20-1 Examples of ligand-activated phosphoinositide hydrolysis in neural tissues

Muscarinic	Neuropeptide Y
Adrenergic	Neurotensin
Histaminergic	Gastrin-releasing peptide
Serotonergic	Bombesin
Glutamatergic	Substance P
Endothelin	Oxytocin
Purinergic	Eledoisin
Thromboxane	Neurokinin
Prostaglandin	Vasointestinal peptide
Bradykinin	Angiotensin
Vasopressin	Gonadotropin-releasing hormone
Nerve growth factor	Platelet-activating factor
Cholecystokinin	Thyrotropin-releasing hormone

For the identities of the individual receptor subtypes that couple to phosphoinositide hydrolysis, the reader is referred to the individual chapters on neurotransmitters in this volume.

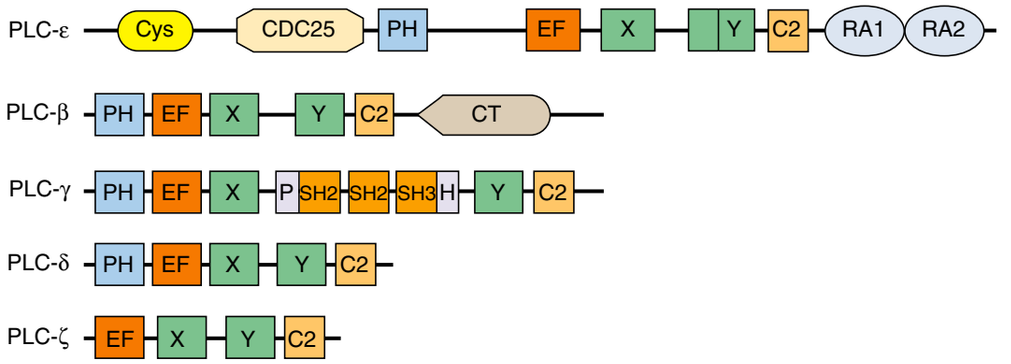

FIGURE 20-3 Linear representation of the five classes of PLC isoforms that can be distinguished by the presence of different domains. (Modified with permission from reference [11].)

from an archetypal PLCδ. The β, γ and δ isoforms of PLC have molecular weights of approximately 130–155, 145 and 85 kDa respectively. Each has been extensively purified, their complementary DNA (cDNA) sequences elucidated and antibodies have been raised to the recombinant proteins. PLCε has been identified in the brain and is of larger size (210 kDa). One additional isoform of PLC found only in sperm has been described – PLC_ζ. A number of isozymes of each subtype of PLC have been identified such that at least 12 distinct isozymes are thought to exist. Isozymes of PLC require the presence of Ca^{2+} for full activation and will hydrolyze the inositol lipids with a selectively for $PI(4,5)P_2$ over PI.

Despite the similar functions of each isozyme, only two regions of amino acid homology exist (X and Y), one of 150 and a second of 120 amino acid residues, which are 54% and 42% identical among the isozymes but are differentially localized within each enzyme (Fig. 20-3). The X and Y domains form the catalytic core of the enzyme. A characteristic of the β and δ isoforms is that relatively few amino acids (40–110) separate the X and Y entities, whereas a much larger separation is observed for the PLCγ isoform (approx. 400). In addition, in PLCγ, the region between X and Y contains amino acid sequences that are found in nonreceptor tyrosine kinases (SH_2 and SH_3 domains). All four isoforms possess pleckstrin homology (PH) domains. The latter are considered to enable the enzyme to become tethered to the plasmalemma via an interaction with $PI(4,5)P_2$. In addition, all PLC isoforms possess an E-F hand domain, which is located between PH and X domains, and a C2 domain, which is located close to the Y domain.

The γ and δ forms of PLC can be distinguished from PLCβ by the virtual absence of a 400–500 amino acid consensus sequence present in the C-terminal region of PLCβ. Consistent with the absence of putative transmembrane spanning domains, most PLC activity is localized to the cytoplasm, although a significant amount of activity is associated with membrane fractions.

Four distinct mechanisms of activation of PLC have been identified. As shown in Figure 20-4, agonist occupancy of receptors that possess intrinsic tyrosine kinase activation (e.g. platelet derived growth factor) can result in receptor dimerization and autophosphorylation of the cytoplasmic tails on tyrosine residues (mechanism I) (see Ch. 24). The presence of these phosphorylated tyrosine residues serves to 'recruit' proteins (such as PLCγ) that possess SH2 domains. In doing so, the cytosolic effector enzyme PLCγ is brought into close proximity to the plasmalemma, the site of its substrate, $PI(4,5)P_2$, and of its activation by phosphorylation. Other receptors activate PLC via intervening guanine-nucleotide-binding (G) proteins. The interaction of a ligand with a receptor (e.g. muscarinic cholinergic) results in the activation and dissociation of G_q, a pertussis- toxin-insensitive G protein, to liberate α_q (see Ch. 19) (mechanism II). The latter then may activate $PLC\beta_1$ and/or $PLC\beta_3$. In a third mechanism, the ligand–receptor interaction results in the activation and dissociation of a pertussis-toxin-sensitive G protein (G_i or G_o), which in turn liberates α_i or α_o and βγ subunits (Ch. 19). In this case, it is the βγ subunits, but not the α subunit, that can then activate $PLC\beta_3$ (or, in the case of hematopoietic cells, $PLC\beta_2$). Different regions of the PLC molecule appear to be required for α_q or βγ activation. Thus, whereas cleavage of the carboxyl terminal portion of $PLC\beta_1$ renders it refractory to α_q regulation, the amino terminal region of the molecule is required for βγ activation.

The discovery of PLCε reveals a fourth mechanism whereby the enzyme can be activated (Fig. 20-5). PLCε possesses two Ras-binding (RA) domains in its carboxyl terminal region, and occupancy of these by Ras-GTP results in activation of the enzyme. In addition, the enzyme possesses a CDC-25 domain at its N-terminus, which serves as a guanine nucleotide exchange factor (GEF) for small GTP-binding proteins such as Ras or Rap1A. Thus PLCε can not only activate the GDP-bound forms of these small GTP-binding proteins but can also be

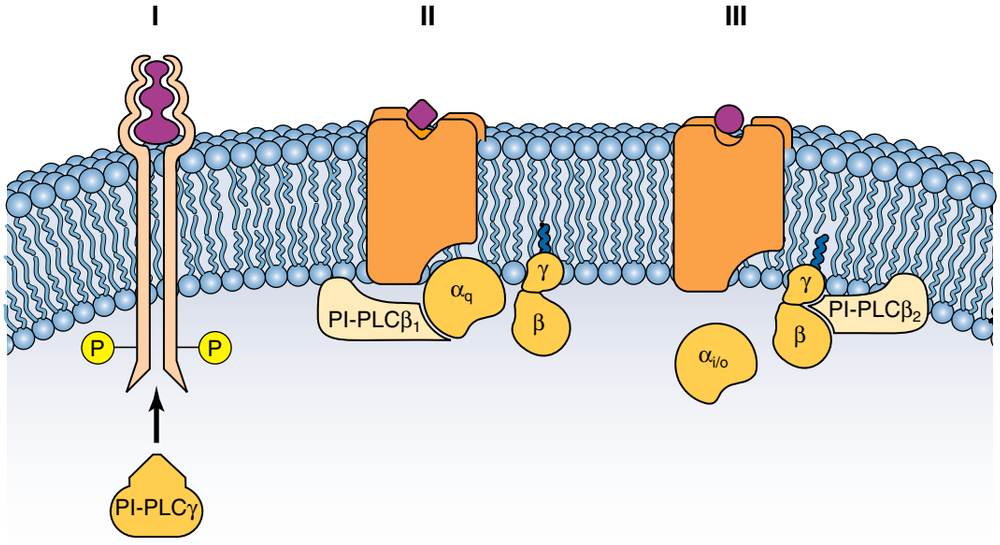

FIGURE 20-4 Three of four distinct mechanisms for the activation of phosphoinositide-specific phospholipase C (PI-PLC). In mechanism I, the ligand activates a receptor that possesses an intrinsic tyrosine kinase. Following dimerization of the receptor, it becomes autophosphorylated on tyrosine residues present in the cytoplasmic domain of the receptor. PI-PLCγ is then recruited to the plasmalemma, via interaction of its SH2 domains with the phosphorylated tyrosine residues on the receptor, and is activated by phosphorylation. In mechanism II, the ligand-receptor interaction results in the dissociation of a pertussis-toxin-insensitive G-protein (G_q), to liberate α_q. The latter then activates either PI-PLCβ_1 or PI-PLCβ_3. In mechanism III, the ligand–receptor interaction results in the dissociation of a pertussis-toxin-sensitive G-protein (e.g. G_i or G_o), which in turn liberates α_i/α_o and $\beta\gamma$ subunits. The latter can then activate either PI-PLCβ_2 or PI-PLCβ_3. Note that, although $\beta\gamma$ subunits derived from G_q could also theoretically activate this pathway, this possibility is less likely, given the abundance of G_i/G_o relative to G_q.

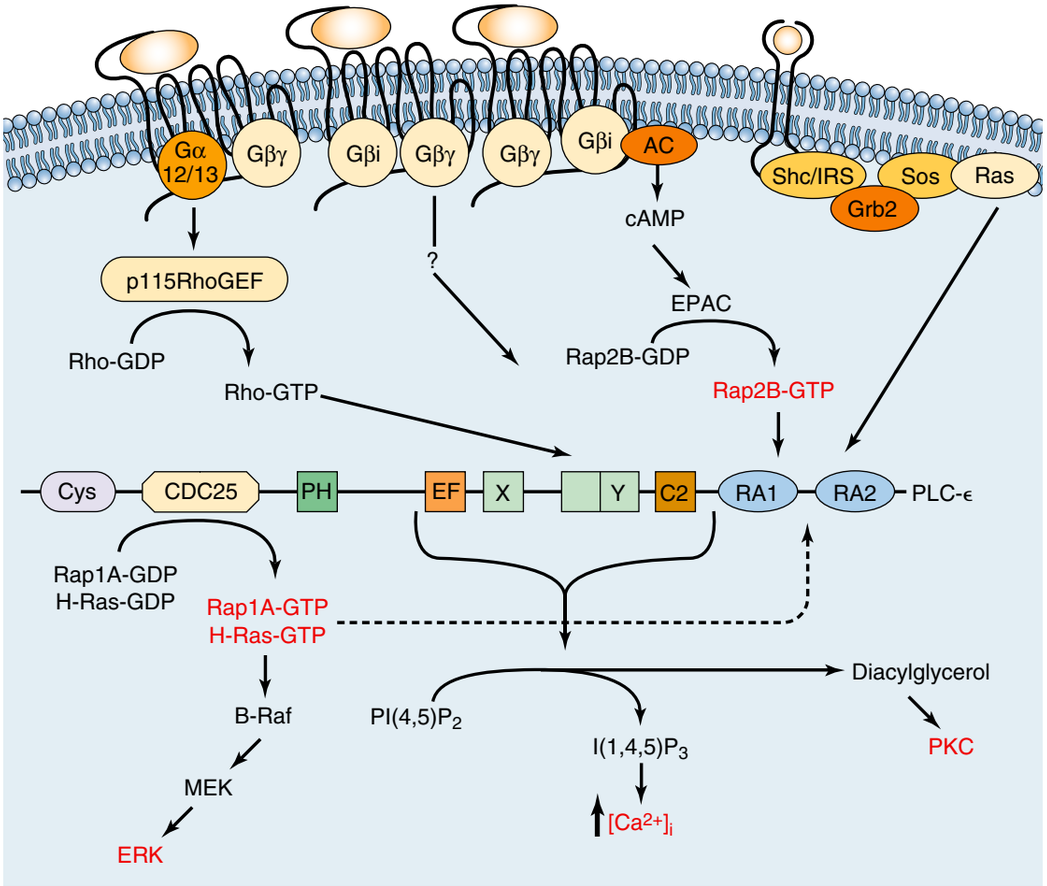

FIGURE 20-5 Activation of PLC-ε by heterotrimeric ($G_{\alpha 12/13}$, $G_{\beta\gamma}$, $G_{\alpha s}$) and small G protein (Ras, Rho and Rap) signaling pathways (see text for details). (Modified with permission from reference [11].) Note that Ras, activated via the mitogen-activated protein kinase (MAPK) pathway, may also activate PLCε. For details of the MAPK pathways and abbreviations, see Chapter 24.

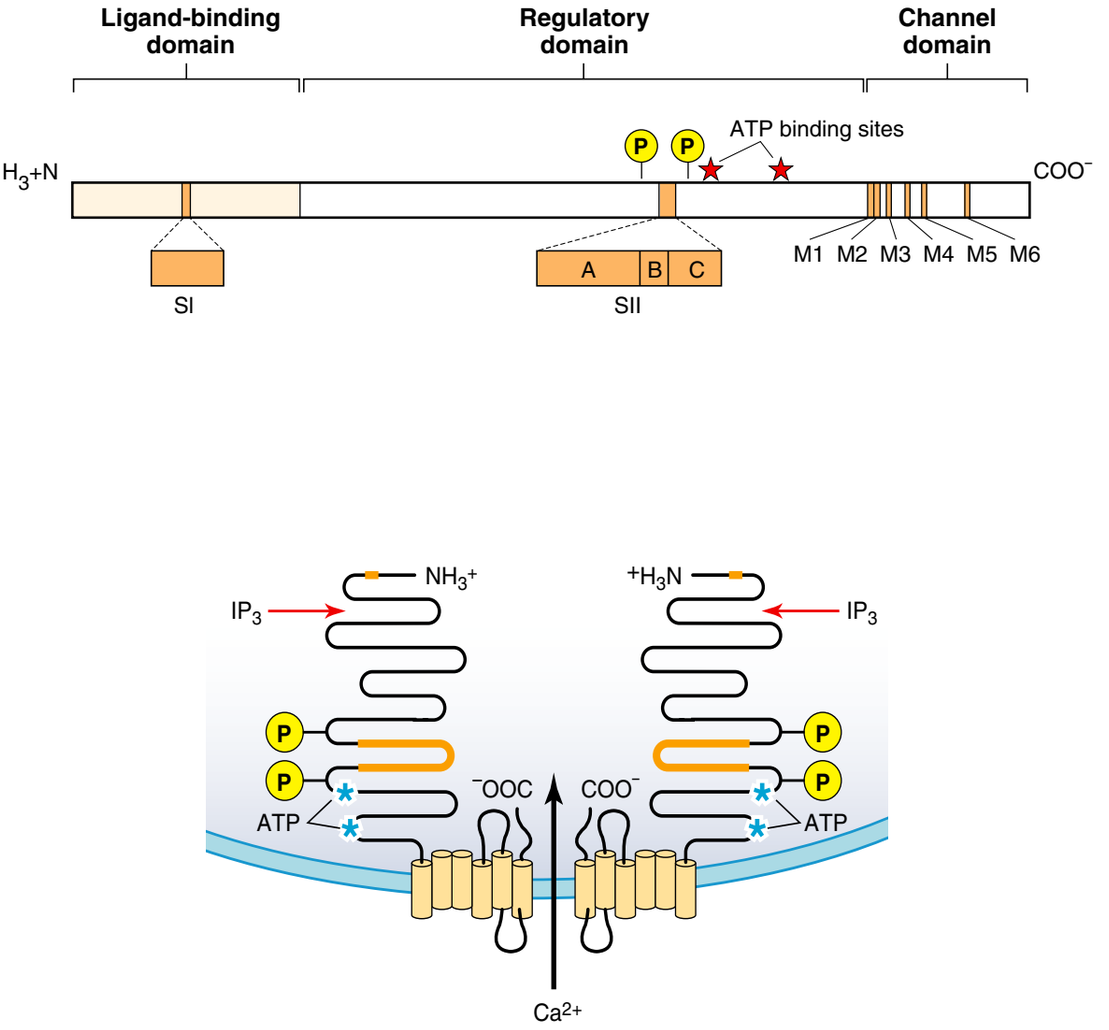

FIGURE 20-6 (**A**) Linear representation of the IP_3 receptor showing the three functional domains. P, phosphorylation sites; SI and SII isoforms produced by alternative RNA splicing; MI–M6, membrane-spanning regions. (**B**) Model of IP_3 receptor showing transmembrane topology. activated by the GTP-bound forms of either Ras or Rap1A. An additional small GTP-binding protein, Rho, can also directly activate PLCε, although via interaction with a site distinct from the Ras binding domains. Rho may become active following ligand occupancy of receptors coupled to $G_{\alpha 12/13}$ and the subsequent activation of a Rho GEF. βγ subunits derived from G_i are also able to activate PLCε, and thus this highly versatile enzyme may serve as a 'nexus' for both heterotrimeric and small G protein signaling pathways [11]. In addition, it appears that cyclic AMP can indirectly activate PLCε, via the cyclic nucleotide's ability to activate EPAC (a GEF), which in turn will activate Rap2B. The latter (like Ras and Rap1A) can then bind to the Ras domain and activate PLCε.

It should be noted that the process whereby $PI(4,5)P_2$ is cleaved by PLC and subsequently resynthesized is metabolically expensive. Thus, for each mole of $PI(4,5)P_2$ hydrolyzed and resynthesized, 3 moles of ATP and 1 mole of CTP are consumed. ATP is consumed at the DAG kinase, PI4-kinase and PIP-kinase steps, whereas CTP is utilized by CDP-DAG synthase. Consequently, it is likely that, under physiological conditions, $PI(4,5)P_2$ breakdown is kept to a minimum. Since $PI(4,5)P_2$ represents only a minor fraction of the total inositol lipid pool, its resynthesis would be a prerequisite for both acute and sustained signaling. Despite the obvious physiological importance, mechanisms that regulate the resynthesis of $PI(4,5)P_2$ have not been well-defined. However, some evidence has

been presented in favor of the regulation of PI4-kinase and PI(4)P5-kinase by a diverse array of agents, including PA, GTP and protein kinase C [12].

THE INOSITOL PHOSPHATES

D-*myo*-inositol 1,4,5-trisphosphate ($I(1,4,5)P_3$) is a second messenger that liberates Ca^{2+} from the endoplasmic reticulum via intracellular receptors. The unique ability of $I(1,4,5)P_3$ to mobilize intracellular Ca^{2+} was first demonstrated by Berridge and colleagues in the early 1980s [13]. When directly injected into cells, or added to permeabilized cells or membrane fractions, $I(1,4,5)P_3$ elicits increased release of Ca^{2+} from a store that has been associated with the endoplasmic reticulum (Ch. 22). That specific receptor sites mediate the action of $I(1,4,5)P_3$ was first inferred from the presence of binding sites in membrane fractions obtained from selected brain regions, notably the cerebellum, the brain region most enriched in these receptors. The purified receptor is a glycoprotein with a molecular weight of 260–313 kDa and it is highly selective for $I(1,4,5)P_3$ (for reviews, see [14, 15]). The IP_3-receptor (IP_3-R) consists of three distinct regions (Fig. 20-6A). A ligand-binding domain is located at the amino terminal region of the molecule. A regulatory (coupling) domain contains potential phosphorylation sites for protein kinase A and protein kinase C, an immunophilin binding site, a Ca^{2+}-sensor binding site and two ATP-binding sites, which regulate the affinity with which IP_3 binds to the receptor. The receptor channel domain through which Ca^{2+} is released consists of six transmembrane spanning segments.

The native IP_3-R exists as a homotetramer with both amino and carboxyl termini facing the cytoplasm. Upon binding of an IP_3 molecule to each of the four subunits, a conformational change in the receptor is presumed to occur that results in the opening of the intrinsic Ca^{2+} channel (Fig. 20-6B). A critical feature of IP_3-Rs is that their opening is regulated by cytosolic Ca^{2+}, the latter acting as a 'coagonist' at the IP_3-R. Thus, paradoxically, the ability of $I(1,4,5)P_3$ to mobilize intracellular Ca^{2+} is itself regulated by Ca^{2+}, with nanomolar concentrations of Ca^{2+} being a prerequisite for Ca^{2+} channel opening. This sensitivity to Ca^{2+} allows IP_3-Rs to act as Ca^{2+}-induced Ca^{2+} release (CICR) channels that promote the amplification of smaller triggering events (see further details in Ch. 22). Activation of PLC-linked receptors frequently results in oscillations of the intracellular Ca^{2+} signal. The relationship between IP_3 production and signal oscillations is discussed in Chapter 22.

It has been observed that the IP_3-R can be activated in the absence of its ligand, $I(1,4,5)P_3$, by a group of proteins termed Ca^{2+}-binding proteins (CaBPs), a subfamily of E-F hand-containing proteins known as neuronal Ca^{2+} sensors [17]. These proteins are exclusively expressed in neurons and are particularly enriched in synaptic/dendritic fields. The addition of CaBPs can directly activate the IP_3-R in a Ca^{2+}-dependent manner, via interaction with the N-terminus region of the receptor. This raises the possibility that CaBPs can act on IP_3-Rs to potentiate the Ca^{2+} signals that arise from other sources, e.g. ligand-gated ion channels.

At least three distinct forms of the IP_3-R have been identified, and these share an overall amino acid homology of 60–80%. Type I predominates in the cerebellum and has been most extensively studied. It is the largest of the 3 forms of the receptor and, unlike type II and III receptors, the gene possesses a 120 nucleotide insert. Type II IP_3-Rs are found mainly in non-neural tissues, whereas type III receptors occur in both neural and non-neural tissues. In response to chronic activation, IP_3-Rs are degraded via the ubiquitin–proteasome pathway [14] (see also Ch. 2).

The metabolism of inositol phosphates leads to regeneration of free inositol. $I(1,4,5)P_3$ can be metabolized either by a membrane-bound enzyme, 5-phosphatase, to yield inositol 1,4-bisphosphate ($I(1,4)P_2$) or by a cytosolic 3-kinase to form inositol 1,3,4,5-tetrakisphosphate ($I(1,3,4,5)P_4$) (Fig. 20-7; see [18] for review). Both of these activities may be regarded as 'off signals', terminating the action of $I(1,4,5)P_3$. The $I(1,4)P_2$ that results from 5-phosphatase action is dephosphorylated further by an inositol bisphosphatase to inositol 4-monophosphate (I(4)P)] and then by the action of inositol monophosphatase to free inositol. $I(1,3,4,5)P_4$, which itself has been suggested to possess a second-messenger function in facilitating the entry of Ca^{2+} into cells, also serves as a substrate for the same 5-phosphatase that acts on $I(1,4,5)P_3$, with the resultant formation, in this instance, of inositol 1,3,4-trisphosphate ($I(1,3,4)P_3$). Unlike the 1,4,5-trisphosphate isomer, $I(1,3,4)P_3$ is ineffective at mobilizing intracellular Ca^{2+}. $I(1,3,4)P_3$ can be further metabolized to inositol 1,3-bisphosphate ($I(1,3)P_2$) or inositol 3,4-bisphosphate ($I(3,4)P_2$) (Fig. 20-7). These compounds are then dephosphorylated by 4- or 3-phosphatases to yield inositol 3- or 1-monophosphates respectively.

The inositol polyphosphate 5-phosphatases belong to a family of enzymes that terminate the signals generated by inositol lipid kinases and PLC. To date, two major types of 5-phosphatase have been identified, both of which share a common '5-phosphatase' domain of approximately 300 amino acids, with several highly conserved motifs. Type-I enzymes are 43–65 kDa and preferentially hydrolyze $I(1,4,5)P_3$ and $I(1,3,4,5)P_4$, with the attendant formation of $I(1,4)P_2$ and $I(1,3,4)P_3$, but have little or no activity towards membrane-bound phosphoinositides. The prototypic form of a type-I 5-phosphatase is a 43 kDa protein that is post-translationally modified by farnesylation of the carboxyl terminus CAAX motif; this modification juxtaposes the enzyme with the membrane. Type-II enzymes are larger (75–160 kDa) and will hydrolyze both water-soluble inositol phosphates and lipids that

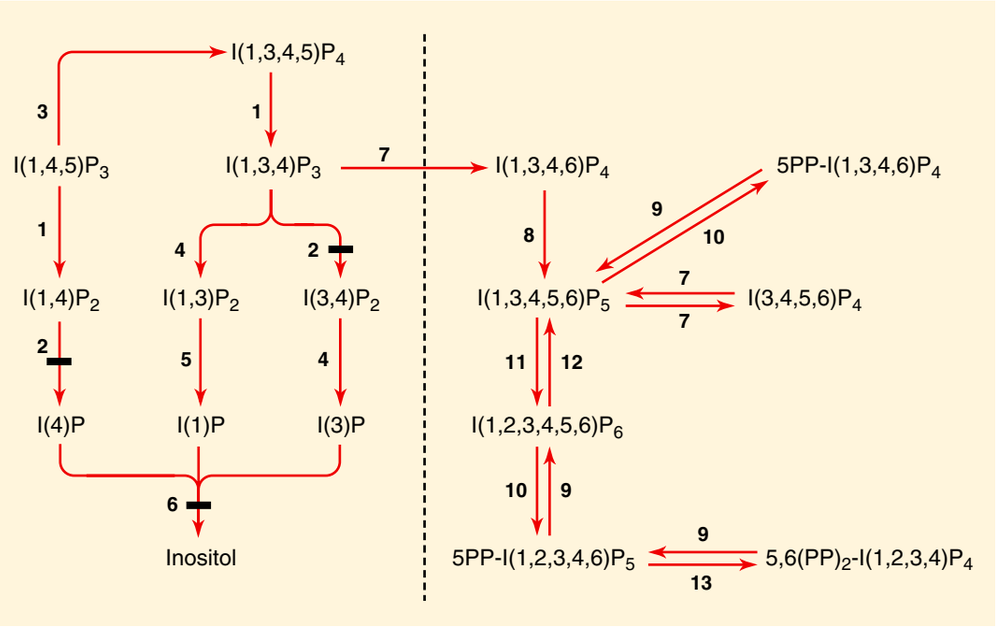

FIGURE 20-7 Pathways of inositol phosphate metabolism. Note that the metabolism of the second messenger $I(1,4,5)P_3$ is shown to the left of the dashed line, while the interconversions of the higher inositol phosphates are shown to the right of the dashed line. Only the quantitatively major established pathways are depicted. Li^+ is known to block the dephosphorylation reactions indicated by the (*black*) bars. Numbers refer to the following enzymes: 1, inositol polyphosphate 5-phosphatase (I); *2*, inositol polyphosphate 1-phosphatase; *3*, $I(1,4,5)P_3$ 3-kinase; *4*, inositol polyphosphate 4-phosphatase; *5*, inositol polyphosphate 3-phosphatase; *6*, inositol monophosphate phosphatase; *7*, $I(1,3,4)P_3$ 6-kinase/$I(3,4,5,6)P_4$ 1-kinase; *8*, Ipmk; *9*, DIPP; *10*, IP_6 kinase; *11*, Ipk 1; *12*, MIPP; *13*, PP-IP_5 kinase.

possess a phosphate group at the 5-position of the inositol ring. For further details regarding these type II phosphatases, see the section on the metabolism of the 3-phosphoinositides.

A single enzyme, inositol monophosphatase, leads to loss of the remaining phosphate and the regeneration of free inositol. This enzyme exhibits similar affinities for all five of the equatorial inositol monophosphate hydroxyls. Inositol 2-phosphate, which is not produced in this degradative pathway, is a poor substrate, a property that is probably attributable to its axial configuration. The enzyme is inhibited by Li^+ in an uncompetitive manner; i.e. the degree of inhibition is a function of substrate concentration. The putative link between the ability of Li^+ to interfere with phosphoinositide turnover and its therapeutic efficacy in the treatment of bipolar disorders is discussed in Box 20-1 and Chapter 55. It should be noted that unlike most other tissues, brain can synthesize inositol de novo by the action of inositol monophosphate synthase, which cyclizes glucose 6-phosphate to form I(3)P. The enzyme has been localized immunohistochemically to the brain vasculature.

The action of Li^+ on inositol monophosphatase has greatly facilitated the use of [^{3}H]inositol in the study of stimulated phosphoinositide turnover [19]. Berridge and colleagues demonstrated that in the presence of both Li^+ and a phosphoinositide-linked ligand, the amount of labeled intracellular inositol phosphates that accumulates following a preincubation with [^{3}H]inositol can be stimulated as much as 50-fold. In contrast, the presence of either Li^+ or ligand alone has very little effect on [^{3}H]inositol monophosphate accumulation. Although ligand-activated turnover is initiated by $PI(4,5)_2$ breakdown and the generation of $I(1,4,5)P_3$, this product is quickly degraded. As an index of receptor activation, it is thus more convenient to use an indirect measurement, the accumulation of labeled inositol monophosphates in the presence of Li^+, than to attempt to measure the transient appearance of labeled $I(1,4,5)P_3$ within a few seconds of ligand addition.

Highly phosphorylated forms of *myo*-inositol are present in cells. $I(1,2,3,4,5,6)P_6$ (phytic acid) is the most abundant species [3]. IP_6 had long been known as the principal phosphate storage molecule in plants; it has also been found ubiquitously expressed in animal cells at concentrations of 10–60 µmol/l. Biosynthesis of IP_6 occurs by a complex series of reactions (Fig. 20-7; for review, see [20]), starting with the phosphorylation of $I(1,4,5)P_3$ by IP_3 3-kinase and subsequent dephosphorylation of IP_4 to $I(1,3,4)P_3$. The latter serves as a substrate for $I(1,3,4)P_3$ 6-kinase, a 46 kDa enzyme that also phosphorylates $I(3,4,5,6)P_4$ at the 1-position to form IP_5. This versatile enzyme can also act on $I(1,3,4,5,6)P_5$ as a 1-phosphatase, an activity that may be of physiological significance, since there is evidence that the product, $I(3,4,5,6)P_4$, is an intracellular signaling molecule, modulating the activity of chloride channels in

BOX 20-1

Does the Action of Li^+ on the Phosphoinositide Labeling Cycle Explain the Therapeutic Action of Li^+ in Manic Depressive Psychosis?

Given the striking effect of Li^+ on the metabolism of the inositol phosphates (see above) and the clinical effectiveness of Li^+ in bipolar mental illness (see Ch. 55), it is tempting to speculate that the therapeutic effects of Li^+ are mediated via a regulation of inositol lipid turnover. It has been suggested that the uncompetitive inhibition of inositol monophosphatase by Li^+ mediates its therapeutic action in affective disorders [1, 2]. The inositol depletion hypothesis proposes that monophosphatase inhibition in vivo lowers inositol levels in cells that are most actively producing inositol monophosphate, i.e. have maximally activated their phosphoinositide-linked receptors. This selectivity is the result of the uncompetitive nature of the Li^+ inhibition, since the degree of inhibition is proportional to the amount of substrate, i.e. inositol monophosphate. PI synthase is then proposed to be slowed by lack of inositol substrate. Thus, overactive cells are thought to be selectively inhibited. Although clinically therapeutic doses of Li^+ do achieve sufficiently high levels of Li^+ in the brain (about 1 mmol/l) to inhibit the monophosphatase, experiments in rats with even higher doses show only a 25% lowering of brain inositol. This degree of lowering of brain inositol would not appear to be sufficiently near the K_m of PI synthase to slow PI synthesis. It has also been observed that Li^+ must be administered for many days before a therapeutic effect is seen. This suggests that delayed effects of Li^+, such as regulation of enzymes, might better correlate with the clinical effect. While the inositol depletion hypothesis appears attractive in many respects, its validity remains to be demonstrated. A number of other biochemical sites of Li^+ action have been reported [3,4], and it may be that multiple actions of Li^+ are necessary for its clinical effectiveness.

epithelial cells. $I(1,3,4,6)P_4$ is converted to IP_5 following phosphorylation at the 5-position by inositol phosphate multikinase (Ipmk), an enzyme capable of phosphorylating inositol at multiple positions in vitro, although not all of these activities may be relevant in vivo. IP_5 may play a role in cell proliferation. The phosphorylation of IP_5 at the 2-position to yield IP_6 is carried out by a homolog of the yeast 2-kinase (Ipk1), which is enriched in brain.

An additional layer of complexity was introduced upon the discovery of the existence of diphosphorylated inositol phosphates, which contain energy-rich pyrophosphoryl (PP) residues (see [3] for review). These include $PP\text{-}IP_4$ ($5PP\text{-}I(1,3,4,6)P_4$), IP_7 ($5PP\text{-}I(1,2,3,4,6)P_5$) and IP_8 ($5,6(PP)_2\text{-}I(1,2,3,4)P_4$). The formation of the latter is catalyzed by IP_7 kinase, which has not yet been cloned. Formation of the other two pyrophosphoryl derivatives is catalyzed by IP_6 kinase, for which three isoforms (46–49 kDa) have been cloned from animals. The activity of both IP_6 and IP_7 kinases is reversible in vitro, thereby acting as ATP synthases. This property led to the suggestion that IP_7 and IP_8 might function as high energy phosphate donors, although the physiological significance of this reverse reaction has yet to be demonstrated. In addition to this reverse kinase route for dephosphorylation of the diphosphoinositol polyphosphates, two other activities have been described: a multiple inositol polyphosphate phosphatase (MIPP), which is enriched in brain, and a group of enzymes known as diphosphoinositol polyphosphate phosphatase (DIPP).

Multiple physiological roles for IP_6 and the diphosphoinositol polyphosphates have been proposed, including effects on endocytosis and mRNA transport [3]; however, definitive evidence for many of these functions is lacking. Such studies are complicated by possible nonspecific effects of this highly negatively charged molecule. Of note is the report of an IP_6/IP_7-dependent protein kinase activity that phosphorylates pacsin/syndapin I, a protein involved in synaptic vesicle recycling [21].

DIACYLGLYCEROL

Protein kinase C is activated by the second messenger diacylglycerol. This unique family of protein kinases was originally identified in the late 1970s by Nishizuka and colleagues [22]. At least 14 isoforms of protein kinase C (PKC) (70–80 kDa) may exist in mammalian tissues. Four conserved (C) and five variable (V) regions can be discerned (Fig. 20-8). PKC isoforms can be distinguished by the presence or absence of motifs that dictate the cofactor requirements for maximal catalytic activity. The C1 region contains two cysteine-rich repeats and represents the site at which DAG regulates the enzyme. A 'pseudosubstrate' sequence is also present in this region of the molecule and blocks kinase activity until the enzyme becomes activated by DAG. The C2 region confers the Ca^{2+} sensitivity of PKC, whereas the C3 and C4 domains are, respectively, the ATP- and substrate binding sites. The 'conventional'

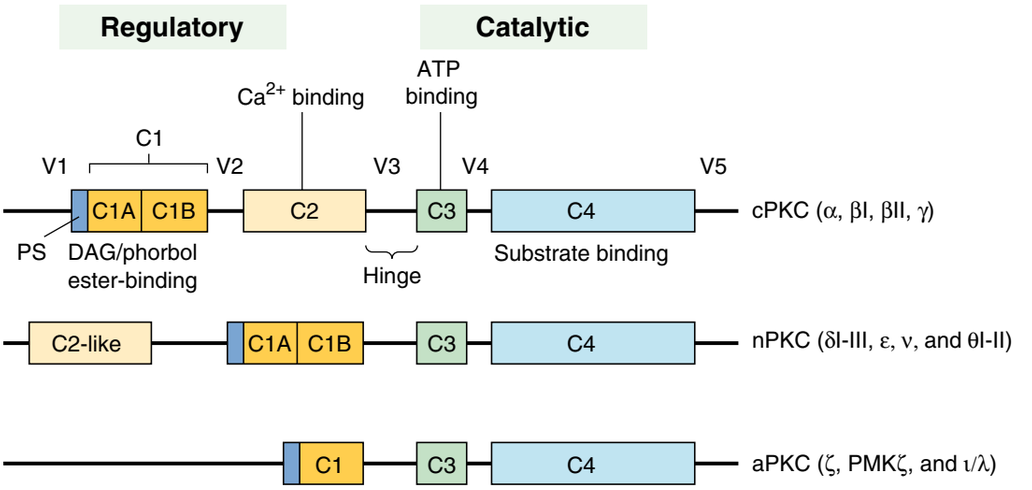

FIGURE 20-8 Linear representation of PKC isozymes. See text for details. Reproduced with permission from Tan, S. L. and Parker, P. J. Biochemical Journal 376: 545–552, 2003 [23] © The Biochemical Society.

isoforms of PKC (cPKC: α, β and γ) are Ca^{2+} sensitive, whereas the 'novel' isoforms (nPKC: δ, ε, η and σ) lack the conventional C2 region and are accordingly Ca^{2+}-insensitive. An additional variation in PKC structures is observed for the ζ and ι/λ isoforms, which possess only one cysteine-rich repeat. These isoforms are not regulated by DAG, are constitutively active and are termed 'atypical' (aPKC). The V3 'hinge' region of the molecule is susceptible to proteolysis following persistent activation of PKC.

All isoforms of PKC are predominantly localized to the cytosol and, upon activation, undergo translocation to either plasma or nuclear membranes. However, newly synthesized PKCs are localized to the plasmalemma and are in an 'open' conformation in which the autoinhibitory pseudosubstrate sequence is removed from the substrate binding domain. The 'maturation' of PKC isoforms is effected by phosphoinositide-dependent kinase-I (PDK-I), which phosphorylates a conserved threonine residue in the activation loop of the catalytic (C4) domain [24]. This in turn permits the autophosphorylation of C-terminus threonine and serine residues in PKC, a step which is a prerequisite for catalytic activity (see also Chs 22 and 23). The phosphorylated enzyme is then released into the cytosol, where it is maintained in an inactive conformation by the bound pseudosubstrate. It was originally thought that 3-phosphoinositides such as $PI(3,4)P_2$ and $PI(3,4,5)P_3$ could directly activate PKCs. However, it now seems more likely that these lipids serve to activate PDK-1 (a frequent contaminant of PKC preparations).

Although many cellular proteins are potential targets for phosphorylation by PKC, the myristoylated alanine-rich protein kinase C substrate (MARCKS) appears to be a major in vivo substrate. MARCKS is an acidic filamentous actin cross-linking protein that is found in high concentrations at presynaptic junctions and that is directed to the plasmalemma via a myristoylated amino-terminal membrane binding domain. This interaction keeps MARCKS in close proximity to PKC, thereby facilitating efficient phosphorylation. Upon phosphorylation MARCKS undergoes a translocation from the membrane to the cytoplasm, and its ability to cross-link actin filaments is lost. Other PKC substrates include vinculin, talin, adducins and annexins. Since each of these proteins is involved in linking plasma or intracellular membranes to cytoskeletal structures, an important aspect of PKC signaling appears to be the regulation of membrane cytoskeleton interactions.

From overexpression studies, it can be inferred that individual isoforms of PKC are precisely directed to distinct subcellular locations (e.g. PKCα to the endoplasmic reticulum and PKCδ to the Golgi). Directing PKC isozymes to specific subcellular loci appears to occur via interaction of the enzyme with localized intracellular binding proteins. Such proteins may or may not be substrates for PKC. An example of the latter category would be RACK (receptors for activated C kinase) 1. RACKs are thought to interact only with activated PKCs and to direct translocated PKCs to specific loci.

The phorbol esters are useful for studying the function of PKC since they mimic the stimulatory effects of DAG on the enzyme. These tumor-promoting plant products and their synthetic derivatives are able to penetrate intact cells. Many inferences regarding the intracellular actions of PKC are based on results of studies on whole-cell preparations with the phorbol esters. These substances, like DAG, may produce feedback inhibition of signal transduction at a number of metabolic levels. Results of experiments using phorbol esters in whole cells are thus often complex and must be interpreted cautiously. Notwithstanding this consideration, based upon

experiments with phorbol esters there is ample evidence to implicate PKC in a number of complex processes, including long-term potentiation (see Ch. 53).

Since I(1,4,5)P_3 production leads to increased intracellular Ca^{2+}, which in turn can stimulate PKC action, the two messengers DAG and I(1,4,5)P_3 often act in concert. DAG can, however, arise in cells from sources other than the phosphoinositides. For example, DAG can be generated from the action of a phosphatidylcholine (PC)-specific phospholipase C or from the transfer of phosphorylcholine from PC to ceramide in the synthesis of sphingomyelin (see Ch. 3). If the DAG released from stimulated phosphoinositide turnover specifically activates cellular PKC, one might expect ST/AR DAG to be a particularly effective activator of the enzyme. It turns out to be only marginally better than other long-chain fatty acyl DAGs; however, chemical analysis indicates that brain DAG is enriched in the ST/AR species. It would therefore seem that ST/AR DAG is de facto the principal activator of PKC in vivo, even though the enzyme shows little specificity for it.

As a second messenger, DAG is rapidly metabolized under normal conditions, and the predominant route is via phosphorylation to PA, a reaction catalyzed by DAG kinase, for which multiple forms of 64–140 kDa have been identified and characterized. All possess a C-terminal catalytic domain and two or three cysteine-rich repeat sequences. The α, β and γ forms possess E-F hands and are thus likely to be regulated by changes in the concentration of cytosolic Ca^{2+}. Expression of the mRNA for the α, β, γ, ζ and θ forms of DAG kinase appears to be highest in the brain. Once DAG is phosphorylated to PA, this in turn can be converted into PI via CDP-DAG (Fig. 20-2B).

PHOSPHOINOSITIDES AND CELL REGULATION

Inositol lipids can serve as mediators of other cell functions, independent of their role as precursors of second messengers. Although the major focus of studies of the phosphoinositides has centered on the role played by these lipids in transmembrane signaling events, in particular the generation of second messengers linked to Ca^{2+} homeostasis and protein phosphorylation, it is now abundantly clear that inositol lipids are important mediators of a diverse array of cell functions. This, in large part at least, can be attributed to the fact that the D-3 phosphoinositides and polyphosphoinositides (in particular PI(4,5)P_2) can interact with protein modules that direct them to specific targets. Many proteins have evolved lipid-binding domains that exhibit some degree of specificity for different classes of phosphoinositides [25] (Table 20-2). Through interaction of these particular high-affinity lipid domains (and others that have yet to be fully characterized), phosphoinositides can recruit specific proteins and regulate multiple cell functions both in the CNS and in non-neural cells. Putative functions for phosphoinositides in membrane trafficking, maintenance of the cytoskeleton, cell death/survival and regulation of ion channels are discussed below. The role of phosphoinositides in anchoring certain cell surface proteins via a PI-glycan linkage is discussed in Chapter 3.

TABLE 20-2 Examples of domains within proteins that specifically interact with inositol lipids

Domain	Lipid
PH	PI(4,5)P_2 or PI(3,4)P_2 or PI(3,4,5)P_3
FYVE	PI(3)P
C2	Anionic phospholipids
ENTH	PI(4,5)P_2 or PI(3,4,5)P_3
FERM	PI(4,5)P_2
MARCKS	PI(4,5)P_2 or PI(3,4)P_2

C2, protein kinase C domain; ENTH, epsin N-terminal homology; FERM, band 4.1, exrin, radixin, moesin; FYVE, Fab1, YOTB, Vac1, EEA1; MARCKS, myristoylated alanine-rich protein kinase C substrate; PH, pleckstrin homology.

Membrane trafficking. A direct role for the quantitatively major phosphoinositides, i.e. PI4P and PI(4,5)P_2, in the exocytosis of neurosecretory granules was first proposed by Eberhard et al., who observed that the ATP requirement for Ca^{2+}-regulated exocytosis in chromaffin cells could be attributed to the generation of PI(4,5)P_2 (see details of exocytosis in Ch. 9). Subsequently, studies in PC12 cells revealed that three cytosolic proteins (termed 'priming of exocytosis proteins' (PEPs)) were demonstrated to be prerequisites for exocytosis. PEP1 and PEP3 were identified as PI4P 5-kinase and the PI-transfer protein respectively, while PEP2 represents PI 4-kinase. It was subsequently observed that the introduction of antibodies to PI(4,5)P_2 into permeabilized PC12 cells blocked the secretion of catecholamines. Thus, for catecholamine exocytosis to occur, a series of reactions culminating in the synthesis of PI4P and PI(4,5)P_2 is required.

The requirement for PIP_2 in these membrane trafficking events reflects the ability of the lipid, which is localized in the plasmalemma, to recruit synaptotagmin, a putative Ca^{2+} sensor for exocytosis. The latter protein is located in the membrane of the secretory organelle and interacts with PI(4,5)P_2 via its C2 domains. It is thought that the synaptotagmin-PI(4,5)P_2 interactions facilitate the close apposition of the vesicle and target membranes [27]. PI(4,5)P_2 also regulates the clathrin-dependent endocytosis of synaptic vesicles by binding to key endocytic proteins, including the clathrin adaptor AP-180, dynamin and epsin (via PH or ENTH domains; Table 20-2).

The interaction of PI(4,5)P_2 (or PI(3,4,5)P_3)) with these cytosolic proteins facilitates their recruitment to the plasmalemma and, in the case of dynamin, also stimulates the GTPase activity [28]. Synaptic PI(4,5)P_2 (and PI(3,4,5)P_3))

is dephosphorylated by synaptojanin. A loss of synaptojanin function results in an increase in $PI(4,5)P_2$ content and an accumulation of clathrin-coated vesicles – which suggests that $PI(4,5)P_2$ may also be required for efficient uncoating. The 3-phosphoinositides also appear to play a role in late endocytic events, since inhibition of PI 3-kinase (PI3K) with wortmannin prevents the postendosomal sorting of platelet-derived growth factor receptor (PDGF-R). Moreover, mutations of the PDGF-R that prevent its association with PI3K result in receptors that fail to undergo trafficking from the Golgi to lysosomes. Through its interaction with the FYVE domain (Table 20-2) of the clathrin adapter protein-2 (AP-2), PI3P may also play a role in the assembly of clathrin-coated pits at the plasmalemma. A much lower affinity binding occurs between AP-2 and either $PI(3,4)P_2$ or $PI(3,4,5)P_3$.

Maintenance of the cytoskeleton. $PI(3,4)P_2$, $PI(3,4,5)P_3$, PI4P and $PI(4,5)P_2$ all avidly bind to a group of 'capping' proteins that regulate actin assembly, e.g. gelsolin and profilin(see also Ch. 9). Upon the binding of inositol lipids to these proteins, the barbed ends of the actin filaments become uncapped and the addition of actin monomers is permitted, resulting in the production of filamentous (F-) actin. Because the 3-phosphoinositides are present at relatively low concentrations, it is probable that PI4P and $PI(4,5)P_2$ play the major role in regulation of actin assembly. Direct evidence for phosphoinositide regulation of the actin cytoskeleton has been obtained from experiments with permeabilized platelets [29]. The addition of $PI(4,5)P_2$ (or PI4P, $PI(3,4)P_2$ or $PI(3,4,5)P_3$)) to these preparations results in an increase in the number of barbed ends and in the proportion of F-actin. Moreover, the time-course of increases in $PI(4,5)P_2$ concentration in stimulated platelets parallels the appearance of F-actin. Remodeling of the actin cytoskeleton also occurs in parallel with membrane rearrangements during endocytosis. $PI(4,5)P_2$ appears to play a role since disruption of synaptojanin function leads not only to deficits in endocytosis but also to abnormalities in the presynaptic cytoskeleton.

$PI(4,5)P_2$ also plays a role in the formation of membrane adhesion complexes – sites where the actin cytoskeleton is linked to the extracellular matrix (focal adhesions) or to cell-cell contacts through interactions with integrins or cell adhesion molecules (CAMs) (see Chs 2 and 7). Many proteins in these adhesion complexes bind $PI(4,5)P_2$ and, by doing so, have increased binding to each other. For example, when vinculin binds to $PI(4,5)P_2$, there is a conformational change in the molecule, which then allows the binding of talin, actin and VASP, thereby allowing newly synthesized actin filaments to be linked to integrins. Similarly, members of the ERM family of proteins (ezrin, radixin and moesin) display enhanced binding to CAMs in the presence of $PI(4,5)P_2$, following the interaction of the lipid with the FERM domain (Table 20-2).

Cell death and cell survival. The 3-phosphoinositides play a key role in the control of cell death (apoptosis) or survival, via their ability to regulate the activity of a kinase that is pivotal in these processes – Akt (PKB), a serine-threonine kinase (Chs 23 and 35). Following PI3K activation, $PI(3,4,5)P_3$ (or $PI(3,4)P_2$)) recruits Akt to the plasmalemma via its PH domain [30]. Phosphoinositide-dependent kinase-1 (PDK-1), which also possesses a PH domain with high affinity for $PI(3,4,5)P_3$, is directed to the same region of the membrane and phosphorylates ^{308}Threonine on Akt. Additional phosphorylation of Akt on ^{473}Serine by a PDK-2 kinase allows for full activation of Akt. When the concentrations of 3-phosphoinositides decline, the activated Akt is released from the membrane and is able to phosphorylate multiple target proteins.

The ability of 3-phosphoinositides to stimulate cell proliferation/survival via activation of Akt is countered by the 3-phosphatase PTEN, which hydrolyzes $PI(3,4)P_2$ and $PI(3,4,5)P_3$. A link between PTEN activity and 3-phosphoinositide content in cells is evident from the observations that: (a) overexpression of PTEN results in a dramatic reduction in the cellular content of these lipids, and (b) 3-phosphoinositide concentrations are greatly elevated in mammalian PTEN-null cell lines [28]. Cells in which PTEN activity is reduced have increased tumorigenic properties, since Akt inhibits apoptosis and promotes cell survival. Conversely, PTEN activity programs the fate of the cell toward apoptosis. Mutations of PTEN have been shown to occur in a wide range of tumor types, but with a particularly high frequency in glioblastomas.

Regulation of ion channel activity. Evidence that $PI(4,5)P_2$ can regulate ion channel activity has been obtained from experiments in which the lipid was reconstituted into artificial membranes or, alternatively, by the addition of $PI(4,5)P_2$ to excised membrane patches [31] (see also Ch. 6). The addition of $PI(4,5)P_2$ can either facilitate the opening of some channels, e.g. plasmalemmal Ca^{2+} pump, P/Q- and N-type Ca^{2+} channels, inwardly rectifying K^+ channels, ryanodine-sensitive Ca^{2+} release channels and Na^+/H^+ exchanger or, conversely, inhibit the activity of other channels, e.g. cyclic-nucleotide ion gated channels in rods and $I(1,4,5)P_3$-gated calcium release channel. Other systems, probably the majority, appear to be completely insensitive to $PI(4,5)P_2$, e.g. voltage-gated Na^+ and K^+ channels and Na^+/K^+ pump. Little is known of the mechanism whereby $PI(4,5)P_2$ regulates ion channel activity, except that the lipid is presumed to bind directly to cationic sites on the channels, and that these are distinct from the phosphoinositide binding domains listed in Table 20-2.

ACKNOWLEDGMENTS

The authors wish to thank Dion Frischer for her invaluable assistance in all aspects of the preparation of this

chapter. The work was supported in part by NIH Grant NS23831 (SKF).

INTRODUCTION: THE SECOND MESSENGER HYPOTHESIS 361

ADENYLYL CYCLASES 362
Regulation of cAMP formation is determined by the activity of adenylyl cyclase 362
Multiple forms of adenylyl cyclase exist in the nervous system 362
The membrane forms of adenylyl cyclase are similar in their amino acid sequence and putative topographical structure 363
Adenylyl cyclases have multiple modes of regulation 364
Adenylyl cyclases are regulated by $G_{\alpha s}$ and $G_{\alpha i}$ 364
Adenylyl cyclase subtypes are also regulated by $\beta\gamma$ subunits 365
Adenylyl cyclases show differential regulation by Ca^{2+} 365
Adenylyl cyclases are regulated upon phosphorylation 366
Diversity of adenylyl cyclases leads to dramatic cell-to-cell differences in regulation of the cAMP pathway 366
Adenylyl cyclase in learning and memory 367
Adenylyl cyclase is subject to long-term regulation in the nervous system 368

GUANYLYL CYCLASE 368
Membrane-bound forms of guanylyl cyclase act as plasma membrane receptors 368
Soluble forms of guanylyl cyclase are activated by nitric oxide 370
Nitric oxide functions as an intracellular second messenger 370

PHOSPHODIESTERASES 370
There are multiple forms of phosphodiesterases in brain 370
Ca^{2+}/calmodulin-stimulated phosphodiesterases (PDE1) 371
cGMP-regulated phosphodiesterases (PDE2 and PDE3) 371
cAMP-specific phosphodiesterases (PDE4, PDE7 and PDE8) 372
cGMP-specific phosphodiesterases (PDE5, PDE6 and PDE9) 372
PDE10 and PDE11 373
Phosphodiesterase enzymes show a distinctive molecular structure 373
One of the primary mechanisms for regulation of phosphodiesterase enzyme activity is phosphorylation 374
Phosphodiesterase inhibitors show promise as pharmacotherapeutic agents 374

FUNCTIONAL ROLES FOR CYCLIC cAMP AND CYCLIC cGMP 375
Cyclic AMP can be viewed as subserving two major functions in the nervous system 375
Most of the effects of cyclic AMP on cell function are mediated via protein phosphorylation 375
The mechanisms by which cyclic GMP produces its physiological effects are more varied 375

FUTURE PERSPECTIVES 376

INTRODUCTION: THE SECOND MESSENGER HYPOTHESIS

The mechanisms by which extracellular molecules, such as neurotransmitters and circulating hormones that act on plasmalemma receptors, alter intracellular processes have been intensively investigated for several decades. One of the seminal advances in this field came in the late 1950s when Earl Sutherland and his colleagues demonstrated that epinephrine induces glycogenolysis in the liver by stimulating the synthesis of an intracellular second messenger, adenosine 3′-5′-cyclic monophosphate (cyclic AMP or cAMP). Since that time, cAMP and other small molecules (e.g. cGMP, Ca^{2+}, nitric oxide and the metabolites of phosphatidylinositol (Ch. 20) and of arachidonic acid (Ch. 33)) have been shown to serve a myriad of second messenger roles in the nervous system. These messengers mediate many of the actions of most types of extracellular signal on diverse aspects of neuronal function (Fig. 21-1). This chapter reviews the proteins involved in the synthesis and metabolism of the cyclic

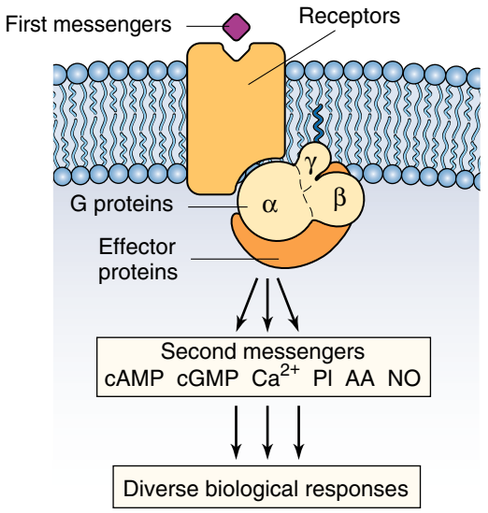

FIGURE 21-1 Schematic illustration of the second messenger hypothesis. This hypothesis, supported by decades of research, states that many types of first messengers in the brain, through the activation of specific plasma membrane receptors and G proteins, stimulate the formation of intracellular second messengers, which mediate many of the biological responses of the first messengers in target neurons. Prominent second messengers in the brain include cAMP, cGMP, Ca^{2+}, the metabolites of phosphatidylinositol (*PI*) (e.g. inositol triphosphate and diacylglycerol) and of arachidonic acid (*AA*) (e.g. prostaglandins, prostacyclins, thromboxanes, leukotrienes), and nitric oxide (*NO*).

nucleotide second messengers, cAMP and cGMP, in the nervous system.

ADENYLYL CYCLASES

Regulation of cAMP formation is determined by the activity of adenylyl cyclase. This enzyme activity is itself regulated by the action of neurotransmitter receptors mediated via intracellular messengers. Adenylyl cyclase can also be activated directly by forskolin, a plant diterpene that has been useful in studies of enzyme regulation and purification. The substrate for adenylyl cyclase is a complex of Mg^{2+} and ATP. In addition, free divalent cation (e.g. free Mg^{2+}), in excess of ATP, is a requisite cofactor for enzyme activity. As shown in Figure 21-2, adenylyl cyclase forms cAMP by creating a cyclic phosphodiester bond with the α-phosphate group of ATP, and the concomitant release of pyrophosphate provides energy for the reaction.

Biochemical and molecular cloning studies indicate the existence of nine separate and unique forms of adenylyl cyclase (AC), which comprise a distinct enzyme family, referred to as AC1–AC9 [1, 2]. These members of the adenylyl cyclase superfamily are all membrane-bound. There is also an additional soluble form, sAC, that has catalytic activity similar to the others but is genetically the most divergent member of the family. All the membrane-bound forms of adenylyl cyclase are activated by the stimulatory G protein $G_{\alpha s}$ (see Ch. 19), and all with the exception of AC9 are stimulated by forskolin. The soluble form sAC is not stimulated by either $G_{\alpha s}$ or forskolin but is sensitive to bicarbonate levels. All known forms of adenylyl cyclase are inhibited by P-site inhibitors, which are adenosine analogs that act at the catalytic site of the enzyme. The different forms of adenylyl cyclase exhibit distinct patterns of expression in brain and peripheral tissues and are differentially regulated by Ca^{2+}/calmodulin (see Ch. 23), by the G protein subunits $G_{\alpha i}$ and $G_{\beta\gamma}$ (see Ch. 19) and by phosphorylation.

Multiple forms of adenylyl cyclase exist in the nervous system. AC1 is expressed exclusively in brain, adrenal and retina, and is the only neural-specific adenylyl cyclase [3–5]. In brain, AC1 is expressed at high levels in the hippocampus, cerebral cortex, cerebellum, olfactory system and pineal gland. AC8 is expressed in brain, as well as in lung and parotid gland. In brain, AC8 is enriched in the olfactory bulb, thalamus, habenula, cerebral cortex and hypothalamic nuclei. The catalytic activity of AC1 and AC8 is stimulated by Ca^{2+}/calmodulin and thereby could be regulated through activation of NMDA glutamate receptors that permit Ca^{2+} entry into neurons and through voltage-sensitive Ca^{2+} channels (see Chs 6, 15). This type of regulation has been implicated in several forms of neural plasticity. Further evidence for a role of AC1 and AC8 in synaptic plasticity is the finding that mice lacking these forms of adenylyl cyclase have deficits in spatial memory as well as in long-term potentiation, which is a cellular electrophysiologic model of learning and memory that can be measured in the hippocampus and other brain regions [6, 7] (see Ch. 53).

AC2 is expressed at high levels in many brain regions but it is also found at lower levels in skeletal muscle, lung and heart [4, 5]. The highest levels are found in

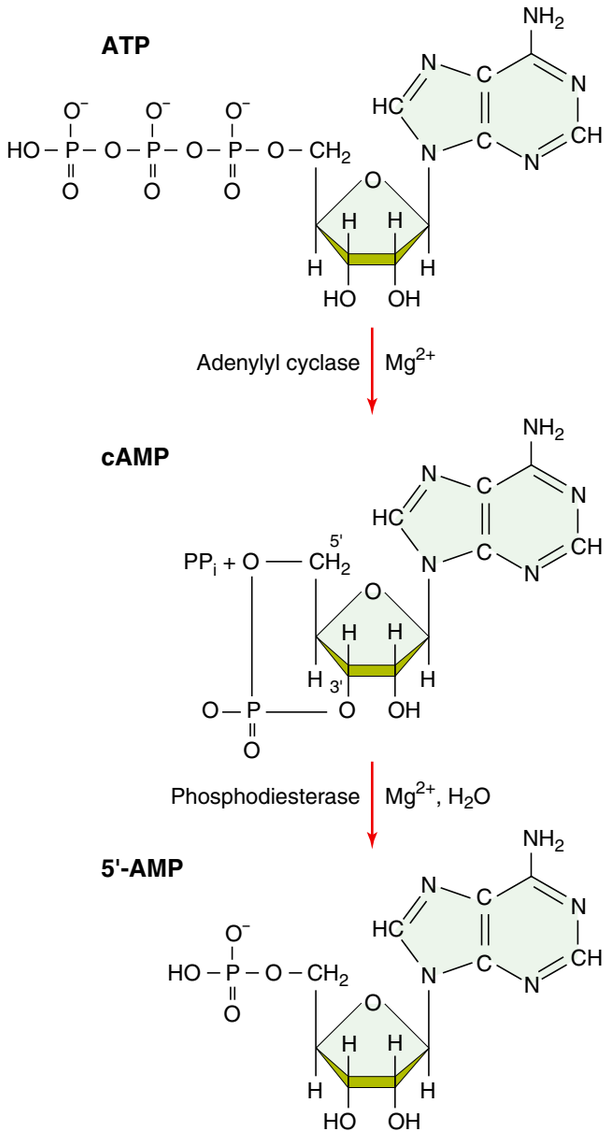

FIGURE 21-2 Chemical pathways for the synthesis and degradation of cAMP. cAMP is synthesized from ATP by the enzyme adenylyl cyclase with the release of pyrophosphate, and is hydrolyzed into 5′-AMP by the enzyme phosphodiesterase. Both reactions require Mg^{2+}. Analogous reactions underlie the synthesis and degradation of cGMP (not shown). PP_i, inorganic pyrophosphate.

hippocampus, hypothalamus and cerebellum, while moderate levels are found in neocortex, piriform cortex and amygdala. AC3 is highly enriched in olfactory epithelium and is expressed at lower levels in other brain regions, as well as in male germ cells, pancreas, brown adipose tissue, uterus, lung and heart [8]. AC4 is widely distributed in brain and has been identified in most peripheral tissues tested to date [9].

AC5 is enriched in the brain and is especially localized to the striatum and related structures (e.g. nucleus accumbens, olfactory tubercle) that are innervated by dopaminergic fibers (see Ch. 46). As a result, it is often referred to as 'striatal adenylyl cyclase' [10, 11]. AC5 is also expressed in heart and kidney (where it is associated with blood vessels), the anterior lobe of the pituitary and the retina. These tissues share the common feature of having dopamine innervation and it has been suggested that AC5 is associated uniquely with dopamine actions [10]. AC6 is structurally similar to the AC5 and both are inhibited by free Ca^{2+} at physiological concentrations (0.1–1.0 mmol/l) [12]. AC6 is enriched in brain and heart but is ubiquitous with low levels of expression seen in other tissues (e.g. testes, muscle, kidney and lung).

AC7 is found in several tissues, with highest levels in lung and spleen, moderate levels in heart, and low levels in brain, kidney and skeletal muscle [13, 14]. In brain, the highest levels are found in cerebellar granule cells, while lower levels are seen in hippocampus, neocortex and striatum. AC9 is expressed in brain and skeletal muscle but also displays widespread distribution in other tissues. The soluble isoform sAC is enriched in testes but is also found in other tissues.

The membrane forms of adenylyl cyclase are similar in their amino acid sequence and putative topographical structure. Their structure is illustrated in Figure 21-3 [1, 2]. Hydropathicity profiles of their amino acid sequences indicate that the adenylyl cyclases contain two regions (M1 and M2), each of which consists of six putative membrane-spanning hydrophobic domains. At the N-terminus, there is a short variable amino terminus preceding the membrane-spanning domain. In addition, there are two large cytoplasmic domains (C1 and C2), one between the two hydrophobic regions and the other at the carboxy terminus of the protein. These cytoplasmic domains also contain the ATP binding/catalytic domains. The predicted molecular weight of AC1 is 124 kDa [15], although other types of analysis indicate a native molecular mass of more than 200 kDa. This suggests that adenylyl cyclases may exist *in situ* as a dimer or as a complex with other regulatory proteins.

The two cytoplasmic domains are the most highly conserved portions of the known forms of adenylyl cyclase and share approximately 40% sequence homology across all membrane-bound forms of adenylyl cyclase. In addition, C1 and C2 within a given enzyme share an even greater degree of homology. C1 is larger (360–390 amino acids) than C2 (255–330 amino acids). These cytoplasmic regions have been subdivided into a and b domains (Fig. 21-3). C1a and C2a are similar to each other and to certain sequences of both membrane-bound and soluble guanylyl cyclases (the enzyme that catalyzes the synthesis of cGMP – see below). These contain the nucleotide-binding sites and are thought to be the catalytic domains of the enzyme. Both C1 and C2 appear to be necessary for catalytic activity: there is no enzymatic activity when only one of the domains is expressed, but activity is reinstated when the two halves are co-expressed [9].

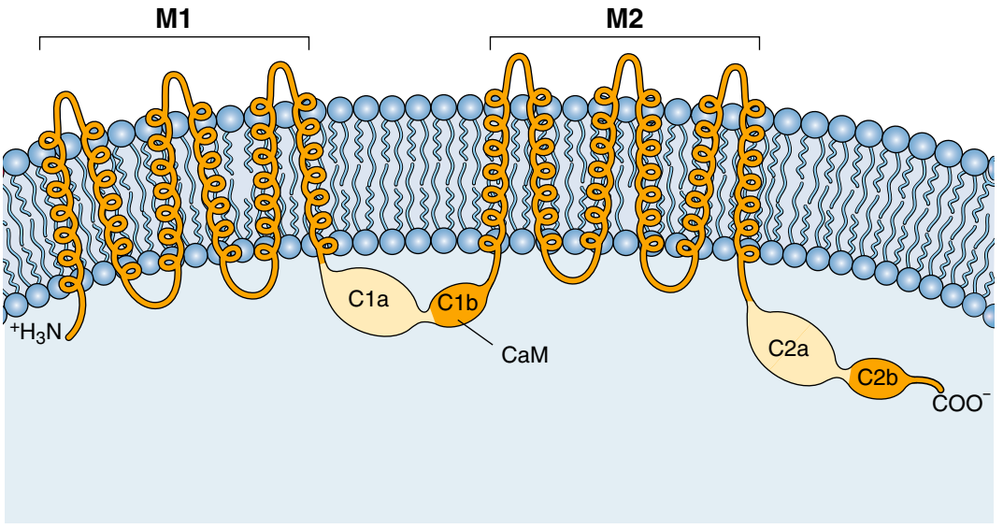

FIGURE 21-3 Schematic illustration of the proposed topographical structure of adenylyl cyclase (AC). Hydropathicity profiles predict that different forms of AC contain two hydrophobic regions (M1 and M2), each of which contain six membrane spanning regions, and two relatively less hydrophobic regions (C1 and C2), which are thought to be located in the cytoplasm. The catalytic domains may be located within C1 and C2, and both are necessary for functional activity of the enzyme. The carboxy (COO^-) portion of the C1 and C2 domains determines whether βγ subunit complexes inhibit AC1 or stimulate AC2 and AC4. The C1b domain contains a calmodulin-binding site and is thought to mediate Ca^{2+}/calmodulin activation of certain forms of the enzyme.

Studies of the crystalline structure of adenylyl cyclase, together with functional mutation studies, indicate that the C1 and C2 domains form the catalytic core of adenylyl cyclases [16, 17]. The forskolin-binding site is located in a hydrophobic pocket created by the interface of C1 and C2. Likewise, $G_{\alpha s}$ interacts with both domains, the majority of the contact being made with C2, and the binding results in rotation of the C1 domain around the C2 region, presumably to position the active site for catalysis [16, 17]. This site is probably also the site for binding of the other G protein subunits, such as the inhibitory $G_{\alpha i}$, which could act to stabilize the C1 domain of certain isoforms (e.g. AC5 and AC6) and thereby block rotation of C1 around C2 and block formation of the active catalytic site. Substitution or mutation studies demonstrate that the amino acid residues contacting the substrate are conserved in all types of adenylyl cyclase. The substrate specificity can be switched from ATP to GTP, the substrate for guanylyl cyclases, by substituting specific amino acids in this region of the catalytic domains.

The 12-transmembrane-spanning domain topology of the adenylyl cyclase enzymes is similar to that found in the ABC family of transporters (see Ch. 5), which includes the cystic fibrosis transmembrane rectifier and the P-glycoprotein. However, there is currently no convincing evidence of a transporter or channel function for mammalian adenylyl cyclases. The structural similarity may indicate that these functionally divergent protein families are derived in an evolutionary sense from related proteins.

Adenylyl cyclases have multiple modes of regulation. Adenylyl cyclases and the cAMP second messenger system have been implicated in diverse cellular functions in brain, including learning, memory, cognition and mood to name just a few (see Chs 53 and 55). The involvement of adenylyl cyclases in these essential and complex functions dictates that the control of cAMP formation should be finely controlled. Experimental evidence supports this conclusion, demonstrating that the adenylyl cyclase isoforms are differentially regulated by multiple forms of $G_{\alpha s}$, $G_{\alpha i}$ and $G_{\beta\gamma}$, free Ca^{2+} and Ca^{2+}/calmodulin, as well as by covalent modifications (e.g. protein phosphorylation and glycosylation).

In general, the 10 different forms of adenylyl cyclase can be divided into three major and two minor groups based on their functional attributes as well as on their sequence homology. The three major families are: (1) the Ca^{2+}/calmodulin-stimulated isoforms, which include AC1, AC3, and AC8; certain of these enzymes are inhibited by $G_{\beta\gamma}$; (2) the $G_{\beta\gamma}$-stimulated isoforms, which include AC2, AC4, and AC7; and (3) the Ca^{2+} and $G_{\alpha i}$ inhibited isoforms, which are AC5 and AC6. The other two categories each have a single member: (4) AC9, which is the most divergent of the membrane-bound isoforms, is stimulated by $G_{\alpha s}$, inhibited by calcineurin (a protein phosphatase), and is insensitive to forskolin; (5) sAC, the only soluble isoform, is the most divergent and is most similar to the adenylyl cyclase found in Cyanobacteria.

Adenylyl cyclases are regulated by $G_{\alpha s}$ and $G_{\alpha l}$. Each of the different forms of adenylyl cyclase can be stimulated by activated $G_{\alpha s}$ (i.e. $G_{\alpha s}$ bound to GTP). In this way $G_{\alpha s}$ couples endocrine and neurotransmitter receptors that stimulate cAMP formation to adenylyl cyclases

in many cellular systems. As described in Chapter 19, activation by G-protein-coupled receptors occurs when a neurotransmitter or hormone binds to the receptor and catalyzes the exchange of GDP for GTP at the G protein α subunit. This promotes the dissociation of the α and βγ subunits, which allows for activated $G_{\alpha s}$ to interact with and stimulate adenylyl cyclase. The GTP-bound form has 10-fold higher affinity than the GDP-bound form of $G_{\alpha s}$ for adenylyl cyclase. GTPase activity contained within the α subunit hydrolyzes GTP to GDP and thereby leads to the reassociation with βγ. This intrinsic GTPase activity provides a time dependent switch for turning off the active form of $G_{\alpha s}$ and adenylyl cyclase activity, as well as $G_{\beta\gamma}$ that is deactivated by its reassociation with $G_{\alpha s}$. The GTPase activity can be accelerated by a specific RGS/GAP (regulator of G protein signaling/GTPase activator protein), PX1-RGS, which speeds up the termination of $G_{\alpha s}$-stimulated adenylyl cyclase activity.

It is also notable that AC1 and AC8 are activated synergistically by $G_{\alpha s}$ and Ca^{2+}/calmodulin. This finding suggests that these forms of the enzyme are capable of responding to receptors coupled to $G_{\alpha s}$ as well as to those that increase intracellular Ca^{2+} levels. This may be of particular importance to the function of these proteins in integrating the consequences of multiple extracellular stimuli as well as in synaptic plasticity, as mentioned earlier.

There are also many neurotransmitter and hormone receptors that contribute to the fine control of cAMP formation by inhibition of adenylyl cyclase. The action of inhibitory receptors is mediated by several different forms of the $G_{\alpha i}$ family, specifically the $G_{\alpha i1}$, $G_{\alpha i2}$, $G_{\alpha i3}$, $G_{\alpha o}$ and $G_{\alpha z}$ subtypes. The G_{α} subunits of these isoforms can inhibit the catalytic activity of adenylyl cyclase when the enzyme is activated by either $G_{\alpha s}$ or forskolin. The inhibition of catalytic activity does not occur via competition with $G_{\alpha s}$ but appears to occur by an interaction at a symmetric site on the AC molecule. $G_{\alpha i}$-mediated inhibition of adenylyl cyclase is most dramatic for AC5 and AC6. A few other forms of adenylyl cyclase, most notably AC1, can be inhibited by $G_{\alpha o}$ but this effect is not as potent as the inhibition of AC5 and AC6 by $G_{\alpha i}$ isoforms. The GTPase activity of $G_{\alpha i}$ family members can be accelerated by a large family of RGS proteins (see Chapter 19).

Adenylyl cyclase subtypes are also regulated by βγ subunits. The regulation by $G_{\beta\gamma}$ varies dramatically with the different forms of adenylyl cyclase [1, 2, 18]. In the presence of $G_{\alpha s}$, the addition of $G_{\beta\gamma}$ complexes inhibits AC1 and AC8 but stimulates AC2, AC4, and AC7. The concentration of $G_{\beta\gamma}$ required for its inhibitory effect on AC1 is higher than the concentration of free $G_{\alpha s}$ required to activate this enzyme. This indicates that dissociation of $G_{\beta}\gamma$ from other, more abundant G proteins (e.g. $G_{\alpha i}$ and $G_{\alpha o}$) would be the primary source of $G_{\beta\gamma}$ for this type of inhibition to occur in brain that expresses relatively high levels of these G protein subtypes. The effect of $G_{\beta\gamma}$ on AC1 and AC8 is notable in that the inhibition is more potent than either $G_{\alpha i}$ or $G_{\alpha o}$. There is evidence that AC5 and AC6 are also inhibited by $G_{\beta\gamma}$, but this may be via indirect mechanisms and not direct interactions with enzyme molecules.

Stimulation of AC2, AC4, and AC7 by $G_{\beta\gamma}$ complexes is not only dependent on the presence of $G_{\alpha s}$ but leads to synergistic activation of these AC enzymes. As is the case for inhibition of AC1, the concentration of $G_{\beta\gamma}$ required for activation of AC2, AC4, and AC7 is higher than for $G_{\alpha s}$. This implies that activation of neurotransmitter receptors coupled to $G_{\alpha s}$ or $G_{\alpha i}/G_{\alpha o}$ may be able to activate adenylyl cyclase subtypes, and these responses could be synergistic under certain conditions. AC2, AC4 and AC7 are not directly influenced by $G_{\alpha i}$ or $G_{\alpha o}$.

Studies with chimeras of the different enzymes indicate that the stimulatory effect of $G_{\beta\gamma}$ depends on the carboxy half of the adenylyl cyclase molecule [9]. These studies have utilized 'noncovalent' chimeras, where the amino half of AC1 (containing the first membrane-spanning and cytoplasmic domains) is co-expressed in cultured cells with the carboxy half of either AC1 or AC2 (containing the second membrane-spanning and cytoplasmic domains). Depending on whether the carboxy portion is from AC1 or AC2, the coexpressed chimera is either inhibited or stimulated, respectively, by $G_{\beta\gamma}$ complexes. The binding site in the AC enzymes that are stimulated by $G_{\beta\gamma}$ corresponds to amino acid residues 956–982 of AC2, which sequence is located near the middle of the second catalytic domain. This sequence also contains a putative consensus $G_{\beta\gamma}$-binding site that is found in other enzymes known to be regulated by $G_{\beta\gamma}$, including G-protein-coupled receptor kinase, inward-rectifying K^+ channels and phospholipase C_{β}. These data highlight the key role of $G_{\beta\gamma}$ in the regulation of multiple signaling molecules important for neuronal function.

In addition to the selective responses of adenylyl cyclases to $G_{\beta\gamma}$ subunits, it is likely that different forms of G_{β} and G_{γ} subunits influence the various forms of adenylyl cyclase in different ways [19]. There are five known forms of G_{β} subunits and 11 known forms of G_{γ} subunits (see Ch. 19). Differential expression and regulation of these subunits could provide still additional mechanisms for selectively controlling adenylyl cyclase catalytic activity in specific neuronal cell types.

Adenylyl cyclases show differential regulation by Ca^{2+}. The regulation of the various forms of adenylyl cyclase by Ca^{2+} provides an important mechanism by which receptors that influence ligand- or voltage-stimulated Ca^{2+} channels, or receptors that influence intracellular Ca^{2+} levels via coupling to $G_{\alpha q}$, exert control over the cAMP signaling cascade (see Ch. 22) [1, 2]. AC1 and AC8, and possibly AC3, are activated by Ca^{2+}/calmodulin. This effect is synergistic with $G_{\alpha s}$, while AC2, AC4, AC5, and AC6 are insensitive to Ca^{2+}/calmodulin. AC1 and AC8 are activated by voltage-stimulated Ca^{2+} channels but not by receptors that couple to $G_{\alpha q}$ and release of intracellular Ca^{2+}.

The concentration of Ca^{2+} required for half-maximal activation of AC1 is approximately 150 mmol/l, while AC8 is five times less sensitive. The C1b domain of adenylyl cyclase appears to mediate the activation of the enzyme by Ca^{2+}/calmodulin (see Fig. 21-3). Activation of AC1 by Ca^{2+}/calmodulin can be blocked by a peptide fragment of the C1b portion of this enzyme. This peptide is also capable of binding Ca^{2+}/calmodulin itself.

Although AC5 and AC6 are not influenced by Ca^{2+}/calmodulin, these two forms of the enzymes are inhibited by free Ca^{2+}. The concentrations of Ca^{2+} required for this inhibition are in the physiological range (0.1–1.0 mmol/l) that would be observed upon activation of voltage-sensitive Ca^{2+} channels in neurons [1]. The localization of AC5 and AC6 in the brain indicates that this form of Ca^{2+} influx is the primary means of Ca^{2+} regulation of these enzymes.

Adenylyl cyclase are regulated upon phosphorylation. In addition to direct regulation by binding G protein subunits and Ca^{2+}, certain forms of adenylyl cyclase are regulated upon their phosphorylation by second-messenger-dependent protein kinases (see Ch. 23). The protein kinases that have been most extensively studied are cAMP-dependent protein kinase (protein kinase A), protein kinase C, and Ca^{2+}/calmodulin-dependent protein kinase. Activation of protein kinase A inhibits AC5 and AC6 [20],while activation of protein kinase C inhibits AC4 and AC6. In contrast, AC1, AC2, AC3 and AC5 are phosphorylated and activated by the activation of protein kinase C. Although AC1, AC3 and AC8 are directly activated by Ca^{2+}/calmodulin, AC1 and AC3 are inhibited by activation of Ca^{2+}/calmodulin-dependent protein kinase. This counter regulation most likely represents a negative feedback inhibition of these AC isoforms by Ca^{2+} signaling (see also Ch. 22). Although these initial observations are exciting, much further work is needed to define the physiological role of adenylyl cyclase phosphorylation by second-messenger-dependent protein kinases and perhaps by other protein kinases.

Diversity of adenylyl cyclases leads to dramatic cell-to-cell differences in regulation of the cAMP pathway. The differential sensitivity of AC1–AC8 to G protein α and $\beta\gamma$ subunits and to Ca2+ provides potentially complex mechanisms for the regulation of cAMP formation. The three major categories of adenylyl cyclases, based on their regulatory properties discussed above are illustrated in Figure 21-4.

While the schemes for regulation are hypothetical, certain features do suggest different patterns of regulation of cAMP formation in cells that are consistent with the different forms of adenylyl cyclase expressed in the cell, or their phenotype. For example, in cells that contain AC1, AC3 or AC8 (Fig. 21-4A), cAMP formation would be stimulated by extracellular signals that activate receptors coupled to $G_{\alpha s}$ as well as by those signals that increase Ca^{2+} entry into the cells. Neurons expressing AC1 may have inherently high levels of cAMP formation due to basal stimulation by Ca^{2+}/calmodulin. In fact, the high levels of adenylyl cyclase enzymatic activity known to be present in brain, relative to other tissues, may be partly explained in this way. This high level of enzyme activity could also underlie the requirement for additional mechanisms by which this type of adenylyl cyclase is inhibited: cAMP formation would be inhibited in these cells not only by signals that activate receptors coupled to $G_{\alpha i}$ but also by additional signals that activate receptors coupled to other G proteins (e.g. $G_{\alpha o}$ and $G_{\alpha q}$) via the release of $G_{\beta\gamma}$ subunits. This could provide a mechanism for keeping 'in check' the high cAMP synthetic capacity present in brain, as well as providing multiple mechanisms for the regulation of cAMP formation through a variety of extracellular signals.

A very different situation would exist in cells that primarily express AC2, AC4 and AC7 (Fig. 21-4B). In these cells, enzyme activity would not be stimulated by Ca^{2+}/calmodulin but would be increased by signals that activate receptors coupled to $G_{\alpha s}$, as well as by additional signals that activate receptors coupled to other G proteins through the generation of $G_{\beta\gamma}$ subunit complexes. This would provide a mechanism by which cAMP formation is regulated in an integrated manner by multiple extracellular stimuli. In fact, there are several examples in brain of interactions between receptors coupled to $G_{\alpha s}$ and those coupled to other G proteins. For example, stimulation of adenylyl cyclase activity in cerebral cortex by activation of β-adrenergic receptors (which are coupled to $G_{\alpha s}$) can be potentiated by activation of α_1-adrenergic or $GABA_B$ receptors (which coupled to other G proteins), which alone have little or no effect on cAMP formation [21]. This potentiation could result from the release of free $\beta\gamma$ complexes from the G proteins coupled to the α_1-adrenergic or $GABA_B$ receptors (e.g. $G_{\alpha o}$ and/or $G_{\alpha q}$). However, these potentiating effects are dependent on extracellular Ca^{2+} and could also, therefore, be mediated by activation of Ca^{2+}-dependent intracellular pathways (see Ch. 22).

The third situation would be cells that express AC5 and AC6. In these cells, adenylyl cyclase would be activated potently by $G_{\alpha s}$ (Fig. 21-4C). However, this activation would be tightly controlled, since the same signals would lead to activation of protein kinase A, which would phosphorylate and inhibit these adenylyl cyclases and thereby inhibit further cAMP formation. Activation of AC5 and AC6 would be further controlled by receptors coupled to $G_{\alpha i}$ and those that increase levels of free Ca^{2+}, both of which exert an inhibitory effect on these enzymes. In addition, receptors coupled to $G_{\alpha q}$, which would lead to activation of protein kinase C, would also be expected to inhibit AC5 and AC6. These types of mechanism may be of particular relevance to psychotropic drugs that act on dopamine-rich brain regions (i.e. neostriatum and nucleus accumbens), including drugs of abuse and antipsychotic drugs, since AC5 is highly enriched in these brain areas as mentioned above (see Chs 12, 46 and 56).

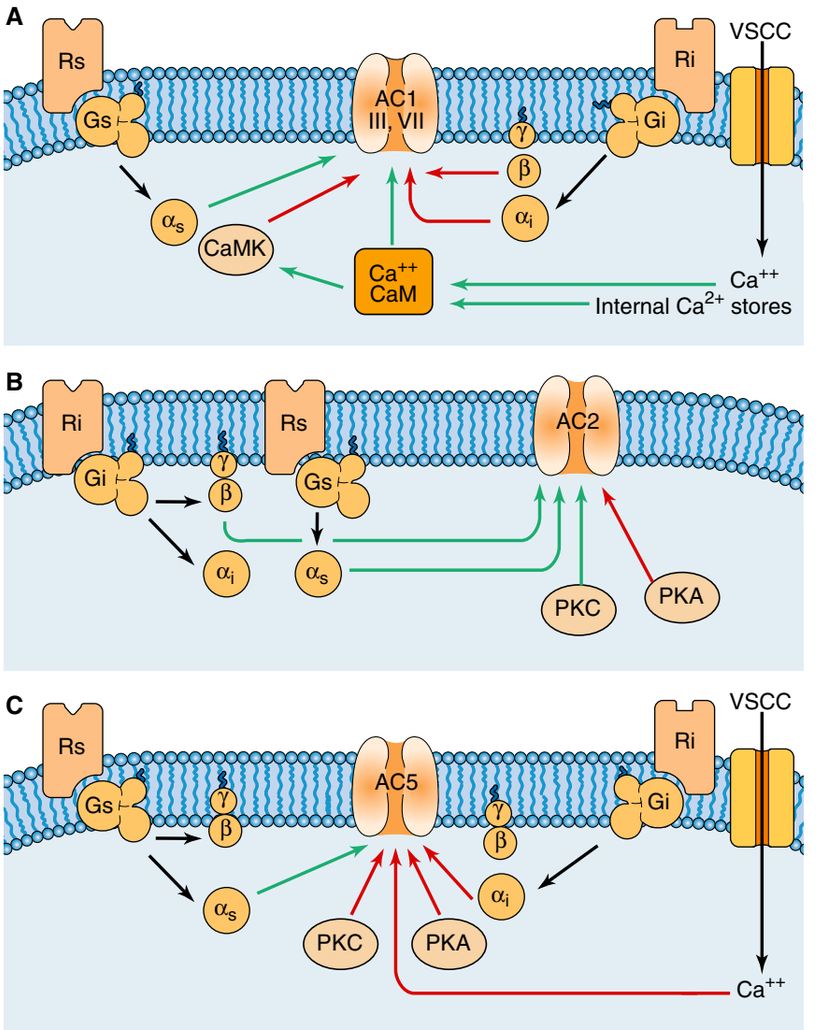

FIGURE 21-4 Schematic illustration of the mechanisms by which the activity of different types of adenylyl cyclase (*AC*) may be regulated. Whereas all types of AC are activated by $G_{\alpha s}$ (αs) and forskolin, different types of the enzyme can be distinguished by their regulation by Ca^{2+} and G protein subunits. Activation and inhibition are indicated by green and red arrows, respectively. (**A**) Since AC1, AC3, and AC8 are stimulated by Ca^{2+}/calmodulin (Ca^{2+}/CaM), an increase in cellular Ca^{2+} levels, which can result from increased entry of Ca^{2+} into the cell either via voltage sensitive Ca^{2+} channels (VSCC) or via NMDA receptor channels, would be expected to activate these enzymes. The actions of Ca^{2+}/CaM are synergistic with $G_{\alpha s}$. In addition, in the presence of activated $G_{\alpha s}$, AC1 is inhibited by $\beta\gamma$ subunits. The potency of $G_{\alpha s}$ to activate the enzyme is some 10- to 20-fold higher than that of $\beta\gamma$ complexes to inhibit it, so that activation of enzyme activity is the predominant effect when only stimulatory receptors and Gs are activated. $G_{\alpha i}$ mediates neurotransmitter inhibition of these AC, and enzyme activity is decreased by Ca^{2+}/CaM-stimulated kinase (CaMK). (**B**) AC2, AC4 and AC7AC4 are stimulated by $\beta\gamma$ complexes, but only in the presence of activated $G_{\alpha s}$. The receptors (*Rx*) and G protein α subunits that provide the $\beta\gamma$ subunits for this type of regulation could conceivably involve receptors coupled to several types of G protein (e.g. G_i, G_o, G_q, etc.). The activation by $\beta\gamma$ is synergistic with $G_{\alpha s}$. Note: while the same $\beta\gamma$ complexes are shown for all the G proteins listed, there are several known subtypes of β and γ subunits, which may well influence the various types of AC in different ways. These enzymes can also be regulated by protein kinase A (PKA) or protein kinase C (PKC) as indicated. (**C**) AC5 and AC6 are inhibited by free Ca^{2+}. In addition, these enzymes are inhibited upon phosphorylation by protein kinase A (PKA) or protein kinase C (PKC). AC5 and AC6 are also inhibited by $G_{\alpha i}$, but are not influenced by $\beta\gamma$ subunits.

Adenylyl cyclase in learning and memory. The cAMP-signal transduction cascade has been demonstrated to play a role critical to the formation of long-term memory in both cellular models and in animals. The specific adenylyl cyclases involved are being identified by current research. In AC1 mutant mice there is a partial disruption of long-term potentiation (LTP), a cellular model of learning and memory [22]. This effect is specific to the mossy fiber pathway of the hippocampus, indicating that LTP in other pathways such as the Schaffer collaterals may involve other types of adenylyl cyclase. Complete elimination of LTP in the mossy fiber pathway was observed in AC1 and AC8 double knockout mice, demonstrating a role for both Ca^{2+}/calmodulin-sensitive forms of adenylyl

cyclase [23]. The AC1 and AC8 double mutant mice also display loss of contextual and passive avoidance long-term memory in models of fear-associated learning as well as spatial memory [23]. In these models the double knockout mice are able to learn a task but the memory only lasts 5–10 minutes, unlike the long-term memory displayed by wild type mice.

Adenylyl cyclase is subject to long-term regulation in the nervous system. It has been known for many years that prolonged exposure of cells to a receptor agonist typically leads to desensitization of receptor function, whereas prolonged exposure to an antagonist can lead to sensitization of receptor function. Increasing evidence indicates that such desensitization and sensitization can be achieved, depending on the receptor and cell type involved, through alterations in the receptors themselves as well as through alterations in the series of proteins that are distal to the receptor and that mediate receptor function, including adenylyl cyclase [24]. Possible mechanisms underlying adaptations in adenylyl cyclase involved in desensitization and sensitization of receptor function could conceivably include phosphorylation of the enzyme as well as alterations in its expression at transcriptional, translational, and post-translational levels. Investigations into these mechanisms have just begun.

Processes of receptor desensitization and sensitization are best established for G-protein-coupled receptors coupled (positively or negatively) to the cAMP system. Agonist- and antagonist-dependent changes in these receptors themselves are discussed elsewhere in this text (Chs 12 and 13). However, adaptations in postreceptor signaling proteins also play an important role in controlling receptor sensitivity under a variety of physiological and pathological conditions. One example in which adaptations in adenylyl cyclase have been related to long-term adaptations in receptor function is opiate tolerance and dependence (see also Ch. 56). In this case, chronic exposure to opiates leads to coordinate upregulation in the activity of the cAMP cascade (including higher levels of adenylyl cyclase and protein kinase A and in some cases lower levels of inhibitory G proteins) in specific opiate-responsive brain regions [24, 25]. Upregulation of the cAMP cascade contributes to opiate tolerance and dependence by opposing the acute actions of opiates (which stimulate receptors coupled to $G_{\alpha i}$). Increased expression of adenylyl cyclase, which in some brain regions is seen selectively for the AC1 and AC8, may be achieved at the level of gene expression, since higher levels of enzyme mRNA are observed as well [26, 27]. More specifically, there is increasing evidence that opiate induction of AC8 in these regions is mediated by the transcription factor CREB (cAMP response element binding protein; see Ch. 26).

In addition to drug regulation of adenylyl cyclase mediated through agonist or antagonist effects on receptors, some drugs produce direct effects on the adenylyl cyclase protein. One example is forskolin, which, as stated earlier, directly stimulates the catalytic activity of all known forms of the enzyme. Another example is lithium, the drug of choice in the treatment of bipolar disorder. The lithium ion inhibits adenylyl cyclase acutely, by interfering with the Mg^{2+} binding sites on the enzyme. This action accounts for some of lithium's side-effects, such as inhibition of thyroid hormone production, which is dependent on the cAMP cascade. However, chronic lithium administration, which is required for its beneficial clinical effects, leads to increases in adenylyl cyclase expression in brain [28], which may represent a compensatory response to acute inhibition of the enzyme. Whether this upregulation of adenylyl cyclase contributes to lithium's clinical effects remains unknown (see Ch. 55).

GUANYLYL CYCLASE

Guanylyl cyclase (GC) catalyzes the synthesis of cGMP from GTP in a reaction analogous to that shown in Figure 21-2 for adenylyl cyclase. Like cAMP, cGMP is known to regulate many cellular proteins, such as protein kinases, ion channels and phosphodiesterases. Two major classes of GC are known to exist, identified originally on the basis of their subcellular distribution: membrane-bound and soluble [29–32]. The general types of mechanism by which these GC types are thought to be regulated by extracellular signals are shown in Figure 21-5.

Membrane-bound forms of guanylyl cyclase act as plasma membrane receptors. The transmembrane forms of GC proteins possess extracellular surface domains that function as neuropeptide receptors, a single transmembrane domain, an intracellular kinase homology domain and a catalytic domain. The activation of membrane-bound GC requires a complex series of steps involving oligomerization of the receptor, ligand binding and modulation of intracellular domains. Activation of enzyme activity requires phosphorylation of the kinase homology domain, which also contains an ATP-binding site that is required for GC activity. Indeed, the binding of ATP to the site may play a role in transducing the binding of ligand at the receptor domain to the activation of enzyme activity in the catalytic domain. This would be functionally homologous to the role of GTP-binding to G proteins in transducing the binding of ligand to G-protein-coupled receptors in the regulation of adenylyl cyclase.

There are seven membrane forms of GC, designated GC-A to GC-G [33]. Two forms, GC-A and GC-B (M_r ≈120 kDa), serve as receptors for atrial natriuretic peptide (ANP) and related peptides. ANP is a 28-amino-acid peptide isolated originally from cardiac atria as an important factor in the regulation of sodium excretion and blood pressure. GC-A binds ANP, as well as brain natriuretic peptide (BNP), and is located in vascular tissue and kidney.

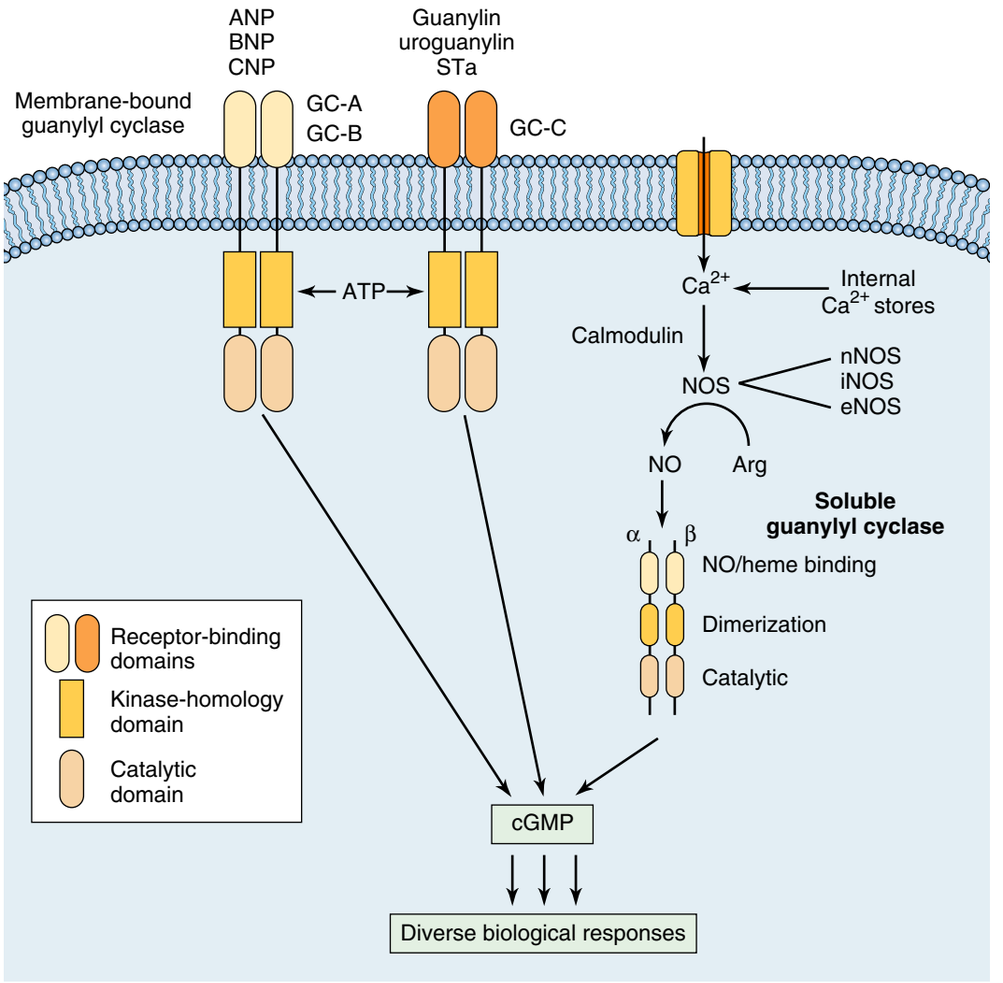

FIGURE 21-5 Schematic illustration of the mechanisms by which first messengers stimulate guanylyl cyclase. Two major classes of guanylyl cyclase are known: membrane-bound and soluble. The membrane-bound forms (*GC-A*, *GC-B* and *GC-C*) contain extracellular receptor domains that recognize specific peptide ligands (atrial natriuretic peptide and related peptides): GC-A binds atrial natriuretic peptide (*ANP*) and brain natriuretic peptide (*BNP*) and GC-B binds C-type natriuretic peptide (*CNP*). GC-C binds the endogenous peptides guanylin and uroguanylin, as well as a heat stable bacterial enterotoxin (*STa*). The membrane-bound receptors contain an intracellular kinase-like domain that binds ATP and a catalytic domain that synthesizes cGMP from GTP. The soluble forms contain the catalytic domains only (α and β subunits), and are activated by nitric oxide (*NO*). Catalytic activity of soluble guanylyl cyclase is dependent on the presence of both α and β subunits. First messengers lead to activation of NO synthesis by increasing cellular levels of Ca^{2+}, which in conjunction with calmodulin activates NO synthase (*NOS*). First messengers increase cellular Ca^{2+} levels in most cases by depolarizing neuronal membranes and thereby activating voltage-dependent Ca^{2+} channels and increasing the flux of Ca^{2+} into the cell (e.g. nerve impulses, glutamate, acetylcholine, substance P). In some cases, Ca^{2+} can enter the cell directly via ligand-gated ion channels (e.g. as with NMDA glutamate receptors). First messengers can also regulate cellular Ca^{2+} levels by stimulating Ca^{2+} release from intracellular stores. There are three forms of NOS: neuronal (*nNOS*), inducible (*iNOS*) and endothelial (*eNOS*).

GC-B is expressed in neuronal tissue and binds the C-type natriuretic peptide (CNP). There is also a truncated form of GC-B that lacks the intracellular kinase and catalytic domains. The truncated form may act to bind and clear the peptide ligands. Increasing evidence suggests that these peptides play important roles as extracellular signals in diverse tissues including brain. Activation of GC and the consequent increased levels in cellular cGMP mediate some of the cellular actions of these peptides on target tissues. A third and related GC type, GC-C, is localized to the intestine and binds the endogenous peptides guanylin and uroguanylin. GC-C can also be activated by a bacterial enterotoxin.

It is worth mentioning that membrane-bound forms of GC, which can be considered 'signal transducing enzymes', are structurally homologous to other signal transducing enzymes, such as certain protein tyrosine kinases and phosphatases, which also possess receptor moieties in their extracellular (amino terminus) domain and enzyme catalytic activity in their intracellular domain (see Ch. 24). Activation of many of these receptors occurs upon ligand-induced dimerization of the receptors, and a similar

mechanism may occur for the membrane-bound forms of guanylyl cyclase.

The ligands for the other forms of membrane-bound GC are less well characterized. In some cases the functions of these GC forms have not been identified. GC-D is expressed in olfactory sensory neurons but its function has not been determined. GC-E and GC-F are expressed in photoreceptor cells in the retina and play a role in phototransduction. GC-G is widely expressed in peripheral tissues and brain but its ligand binding domain is similar to that for GC-A/GC-B, suggesting that it may be regulated by an ANP/BNP-like ligand [34].

Soluble forms of guanylyl cyclase are activated by nitric oxide. These enzymes are homologous to the catalytic domains of the membrane-bound forms of GC. They are considered heterodimers because they appear to exist, under physiological conditions, as complexes of α and β subunits, each with M_r of 70–80 kDa. Both types of soluble GC contain three primary domains: an amino-terminus heme domain responsible for binding nitric oxide (NO), a dimerization domain and a carboxy terminus catalytic domain. The αβ heterodimer is required for enzyme activity [35]. This can be seen as similar to the situation for AC, which contains two catalytic entities within a single polypeptide chain (Fig. 21-5).

There are multiple isoforms of the α and β subunits of soluble GC that exhibit distinct tissue and cellular distributions. Most of the isoforms are expressed in brain, including α_{1-3} and β_1 and β_3. The β_2 subunit is found primarily in lung. This isoform also contains a consensus sequence at its carboxy terminus for isoprenylation or carboxymethylation, which could serve to anchor the protein to the plasma membrane. It has been proposed that specific isoforms of the α and β subunits of GC may form heterodimers with distinct functional and regulatory properties, although this remains to be established with certainty.

A major advance in our understanding of the regulation of soluble guanylyl cyclase was the demonstration that the activity of these enzymes is potently activated by NO [36, 37]. NO activates these enzymes via interactions with the heme prosthetic groups located in the amino-terminus. This conclusion is supported by the finding that removal of the heme group results in an enzyme that cannot be activated by NO. However, there are additional sites that are known to be regulated by NO (i.e. vicinal thiols) that could also contribute to the actions of NO. The synthesis of NO is controlled by NO synthase (NOS), which in turn is regulated by Ca^{2+}/calmodulin as described below. Thus, the generation of NO and activation of sGC is stimulated by numerous types of neurotransmitters that lead to increased intracellular Ca^{2+} levels, including glutamate, acetylcholine, substance P, histamine and bradykinin. Similarly, all organic nitrate drugs (e.g. nitroglycerin, nitroprusside), which are used in the treatment of ischemic heart disease, induce vasodilatation via the activation of soluble GC and increased levels of cGMP.

Nitric oxide functions as an intracellular second messenger. NOS converts L-arginine into free NO and citrulline in a reaction that requires a tetrahydrobiopterin cofactor and NADPH [36, 37]. Three types of NOS have been identified by molecular cloning [30, 38]. Type I NOS, also referred to as neuronal NOS (nNOS), is found at high concentrations in nervous tissue, as well as other tissues. Ca^{2+}/calmodulin binds to nNOS and increases its catalytic activity (Fig. 21-5). Neurotransmitters that increase cellular Ca^{2+} levels would thereby be expected to stimulate sGC activity in those neurons that contain this form of NO synthase. Type II NOS is referred to as macrophage NOS or inducible NOS (iNOS). It is expressed at low levels under basal conditions but is induced in response to immunologic or other challenges. Type III NOS is referred to as endothelial NOS (eNOS), and it is also activated by Ca^{2+}/calmodulin. In addition, this form of NOS is associated with the plasmalemma and is associated with the production of endothelium-derived relaxing factor (EDRF). Despite this nomenclature, Type II and type III NOS, in addition to type I, contribute to signal transduction in the brain.

Free NO also acts as an intercellular messenger. According to this scheme, NO, generated in response to an increase in intracellular Ca^{2+} levels in one neuronal cell type, can diffuse out of the cell and into a second neuron, where it would stimulate guanylyl cyclase activity and produce specific physiological effects. Such a role for NO has been proposed as contributing to the mechanisms underlying long-term potentiation [39].

It is important to note that, in addition to guanylyl cyclase, NO may directly regulate other types of cellular protein. Further work is needed to identify these NO substrates.

PHOSPHODIESTERASES

Given the significant role of cyclic nucleotides in signal transduction pathways, it is not surprising that the metabolism, like the synthesis, of these second messengers is highly regulated. Such metabolism is achieved by a large family of enzymes, the phosphodiesterases (PDEs), which catalyze the conversion of cAMP and cGMP into 5′-AMP and 5′-GMP, respectively, via hydrolysis of the 3′-phosphoester bonds. PDEs usually act as homodimers.

There are multiple forms of phosphodiesterases in brain. Eleven major subfamilies/types of PDE, listed in Table 21-1, have been delineated, based primarily on three criteria: (1) the amino acid sequence homology; (2) the kinetic properties of each enzyme for hydrolyzing cAMP and cGMP; and (3) the mechanisms for regulation of PDE activity [40, 41]. The kinetic properties are characterized according to the affinity of each enzyme for cAMP or cGMP. The affinity is derived from the K_m values: a low K_m signifies that the enzyme has a high affinity for

TABLE 21-1 Classification and selected properties of cyclic nucleotide phosphodiesterases

	Family regulatory/kinetic characteristics	Genes described	Inhibitors*
1	Ca^{2+}/calmodulin-stimulated PDEs PDE1A/1B, low affinity, cAMP/cGMP PDE1C, high affinity for cAMP	PDE1A PDE1B PDE1C	Trifluoperazine Vinpocetine SCH51866† (0.1 µmol/l)
2	cGMP-stimulated PDEs Regulated by cGMP Low affinity for cAMP and cGMP	PDE2 (soluble, particulate)	EHNA, erytho-9-(2-hydroxy-3-nonyl) adenine
3	cGMP-inhibited PDEs Regulated by phosphorylation and cGMP High affinity, cGMP > cAMP	PDE3A PDE3B	Milrinone Enoximone Amrinome‡
4	cAMP-specific PDEs Regulated by phosphorylation and cAMP High affinity, cAMP >>> cGMP	PDE4A PDE4B PDE4C PDE4D	Rolipram Ro20–1724
5	cGMP-binding, cGMP-specific PDEs Regulated by phosphorylation, cGMP High affinity, cGMP >>> cAMP	PDE5A	Sildenafil Zaprinast Dipyridamole SCH51866† (0.1 µmol/l)
6	Retina cGMP specific PDEs Regulated by transducin High affinity, cGMP >>> cAMP	PDE6A PDE6B PDE6C	Zaprinast Zaprinast Zaprinast
7	cAMP-specific PDE Rolipram-insensitive	PDE7A PDE7B	–
8	cAMP-specific PDEs IBMX- and rolipram-insensitive	PDE8A PDE8B	–
9	cGMP-specific PDE IBMX-insensitive	PDE9	SCH51866† (1.5 µmol/l)
10	Dual substrate, cAMP-inhibited PDE High affinity, cAMP >>> cGMP	PDE10	SCH51866† (1.0 µmol/l) Dipyridamole
11	Dual substrate PDE cGMP>cAMP	PDE11A	Dipyridamole

*In addition to the relatively specific inhibitors listed in this table, there are a number of compounds, particularly the methylxanthines (e.g. theophylline, isobutylmethylxanthine (IBMX), papaverine, caffeine), that inhibit most major forms of PDE except the newer forms).
†SCH51866 is not selective and inhibits PDE1, PDE5, PDE9, and PDE10 with IC50 values shown.
‡The compounds listed here are among a large number that have been developed as specific inhibitors of PDE3.

substrate. For example, a low K_m PDE typically has a K_m of <5 µmol/l.

Ca^{2+}/calmodulin-stimulated phosphodiesterases (PDE1). The PDE1 family is stimulated by Ca^{2+}/calmodulin and consists of several soluble subtypes in brain and peripheral tissues. Two isozymes of PDE1,of 61 kDa and 63 kDa, account for more than 90% of total brain PDE activity. Separate genes for each of these isozymes have been identified and are referred to as PDE1A (61 kDa) and PDE1B (63 kDa). Both enzymes exhibit relatively low affinity for cGMP and for cAMP and are referred to as dual substrate PDEs. PDE1A is expressed at highest levels in cerebral cortex and hippocampus and at moderate levels in amygdala [42]. Expression of PDE1B is high in brain regions innervated by dopaminergic fibers (e.g. striatum, nucleus accumbens, olfactory tubercle), with moderate levels of expression found in hippocampus and cerebral cortex [42]. An additional isozyme, PDE1C (73 kDa), also encoded by a distinct gene, has been identified in brain and testes. Interestingly, PDE1C has a high affinity for cAMP, in contrast to the low affinity that PDE1A and PDE1B exhibit for cyclic nucleotides.

The activity of PDE1 isozymes can be regulated under physiological conditions by those extracellular signals that influence intracellular Ca^{2+} levels. This may be particularly relevant, in a physiological sense, for PDE1C, given its high affinity for cAMP. There is also evidence that these enzymes are regulated by protein phosphorylation [16, 43]. The 61 and 63 kDa isozymes are good substrates for protein kinase A and Ca^{2+}/calmodulin-dependent protein kinase, respectively. Such phosphorylation decreases the functional capacity of the enzymes by decreasing their affinity for Ca^{2+}/calmodulin complexes.

cGMP-regulated phosphodiesterases (PDE2 and PDE3). There are two PDE families that are regulated by cGMP, one that is stimulated (PDE2) and one that is inhibited (PDE3). Both these PDEs are found in soluble and membrane-associated forms. cGMP-stimulated PDE2 has low affinity for cAMP and cGMP and, like PDE1, is a dual substrate PDE. There are at least two cyclic nucleotide binding sites on PDE2: one is the catalytic site, the other is a high affinity site that allosterically regulates the catalytic activity of the enzyme. This second site has homology with an evolutionarily conserved sequence known as a

GAF domain, named after different classes of proteins that contain this site, including cGMP-specific and cGMP-regulated PDEs, adenylyl cyclase (cyanobacterial) and *Escherichia coli* transcription factor FhlA [44]. Similar sites are found in PDE5, PDE6, PDE9, PDE10 and PDE11. PDE2 can be activated 10–50-fold by concentrations of cGMP that are found in cells. However, stimulation is transient since cGMP is also a substrate for the enzyme and is therefore metabolized rapidly. Localization studies demonstrate that PDE2 expression is largely restricted to brain and adrenal gland [45]. Within brain, the highest levels of the enzyme are seen in cerebral cortex, striatum, and hippocampus. PDE2 may be a primary effector for the physiological actions of cGMP in cells that do not express appreciable levels of cGMP-dependent protein kinase. In contrast to PDE2, there is currently no evidence for the presence of cGMP-inhibited PDE3 in brain. In contrast to PDE2, PDE3 is inhibited by cGMP and has a low K_m for cAMP. PDE3 is enriched in heart and vascular tissues, where it regulates cardiac and smooth muscle contraction.

cAMP-specific phosphodiesterases (PDE4, PDE7 and PDE8). There are three different PDEs that show a high affinity specifically for cAMP: PDE4, PDE7 and PDE8. Members of the PDE4 family are found in many tissues, in both soluble and membrane-associated forms, and are abundant in the central nervous system. There are four members of the PDE4 family, PDE4A, PDE4B, PDE4C and PDE4D, each encoded by a separate gene and each with multiple splice variants. PDE4A and PDE4B are expressed at relatively high levels in hippocampus, cerebral cortex and striatum and represent the majority of the membrane-bound form of PDE4 in these brain regions [46]. PDE4D represents the majority of the soluble PDE4 in brain. Expression of PDE4C is relatively low in nervous tissue. The four PDE4 genes are highly conserved across several mammalian species [41]. The PDE4 isozymes are regulated by phosphorylation and by binding cAMP. In addition, the expression of certain PDE4 genes is significantly regulated by activation of the cAMP intracellular pathway. Indeed, this is considered a primary mechanism for enhancing the function of these isozymes in some cell types.

PDE7 and PDE8 are two relatively new families of high affinity cAMP-specific PDEs. There are known two members of each family, PDE7A and PDE7B, and PDE8A and PDE8B [47, 48]. Unlike PDE4, PDE7 and PDE8 are not inhibited by rolipram, a well-characterized and specific inhibitor of PDE4. PDE7A is expressed at high levels in the immune system but is also expressed throughout the brain, with highest levels seen in hippocampus, olfactory system, thalamus and certain brainstem nuclei [49]. PDE7B is expressed in several peripheral tissues, including pancreas, heart, thyroid, skeletal muscle and liver, but is also expressed at relatively high levels in certain brain regions, including hippocampus.

A unique feature of PDE8 and of PDE9 (see below) is that they are insensitive to isobutylmethylxanthine (IBMX), which inhibits most other forms of PDE. The amino terminus of PDE8 also contains a PAS domain, named for the proteins first discovered to contain this moiety (Per, Arnt and Sim proteins). PAS domains have been shown to mediate homomeric or heteromeric protein-protein interactions and can influence the subcellular distribution of proteins [50]. The two forms of PDE8 display unique expression patterns in peripheral tissues and in brain. PDE8A is expressed at highest levels in liver and testes but at very low levels in brain, where it is undetectable by in situ hybridization analysis. PDE8B is expressed primarily in the brain with highest levels in the hippocampus and cerebral cortex. Expression of PDE8B has also been observed in thyroid gland of human, but not rat.

cGMP-specific phosphodiesterases (PDE5, PDE6 and PDE9). PDE5, PDE6 and PDE9 are soluble PDE isozymes with high affinity for cGMP that hydrolyze this substrate to the monoester. The PDE5, PDE6 and PDE9 isozymes are also referred to as the cGMP-specific PDEs since they display a 50-fold selectivity for cGMP relative to cAMP. Although PDE5 and PDE6 both have high affinity for cGMP, they are structurally distinct. PDE5 and PDE6 also contain GAF domains in the N-terminus that influence phosphorylation and interaction of the catalytic subunits respectively. PDE5 is enriched in smooth muscle, including lung and erectile tissue, but is also expressed in brain at lower levels and has been implicated in learning and memory [51]. PDE5 inhibitors, such as sildenafil, have proved to be effective for the treatment of erectile dysfunction.

There are several members of the PDE6 family, all of which are light-activated photoreceptor isozymes. Activation of photoreceptor PDE6 in rod and cone outer segments is mediated by transducin, a G protein specific to retina (see Ch. 49). PDE6 is a multimeric enzyme complex, composed of α, β, γ and δ subunits. The functional complex is a heterodimer comprised of α and β subunits and the inhibitory γ subunit (two copies). The δ subunit aids in solubilizing PDE6. PDE6 is inactive in the dark; light results in its activation via a complex biochemical cascade analogous to mechanisms for activation of G-protein-coupled receptors (see Ch. 49 for complete description).

PDE9 has the highest affinity/lowest K_m of the cGMP-specific PDEs. Because of its high affinity for cGMP, it is thought that PDE9 may be a key regulator for levels of this cyclic nucleotide. It is widespread in brain with highest levels of expression in the cerebellar Purkinje cells, striatum, nucleus accumbens, cerebral cortex and hippocampus [51]. The pattern of PDE9 is similar to that of soluble GC, suggesting a functional coupling of PDE9 and sGC for regulation of cGMP levels. PDE9 has five splice variants (PDE9A1–5), and some of these are expressed at high levels in the immune system, as well as intestine and prostate.

PDE10 and PDE11. PDE10 and PDE11 are relatively new members of the PDE family. Both are dual substrate PDEs although they differ in their selectivity for cAMP and cGMP. PDE10 has a higher affinity for cAMP than cGMP (K_m values are 0.05 and 3.0 µmol/l respectively) [48] while PDE11A has higher affinity for cGMP than cAMP (K_m values are 0.5 and 1.0 µmol/l respectively) [52]. Although PDE10A has higher affinity for cAMP, it has a fivefold greater V_{max} for cGMP, suggesting that cAMP, by occupying the catalytic site, may act as an inhibitor of cGMP hydrolysis. Both PDE10A and PDE11A have sequence homology in the N-terminus with PDE2, PDE5 and PDE6 that encode GAF domains. The GAF domains could serve as noncatalytic cGMP binding sites for allosteric modulation of enzyme activity. PDE10A is expressed in testis and brain, where it is enriched in striatum. PDE11A is expressed in skeletal muscle, prostate, liver, kidney, pituitary and salivary gland, with relatively low levels in brain.

Phosphodiesterase enzymes show a distinctive molecular structure. Members of each of the seven PDE families have been characterized by molecular cloning techniques [40, 41]. All the enzymes thus far identified in mammalian tissues contain a highly conserved region of approximately 300 amino acids at the carboxy terminus. Deletion studies have confirmed that this region represents the catalytic domain. Within this region there are a number of conserved histidine residues that appear to play a role in folding of the proteins and are required for their catalytic activity. It has also been suggested that the histidine residues may bind zinc, given the structural similarities of the PDEs with zinc hydrolases.

The regions outside the catalytic domain, particularly the amino terminus, are much more variable across the different PDE families. These regions contain many of the regulatory sites that control PDE activity (Fig. 21-6). For example, this region contains the Ca^{2+}/calmodulin

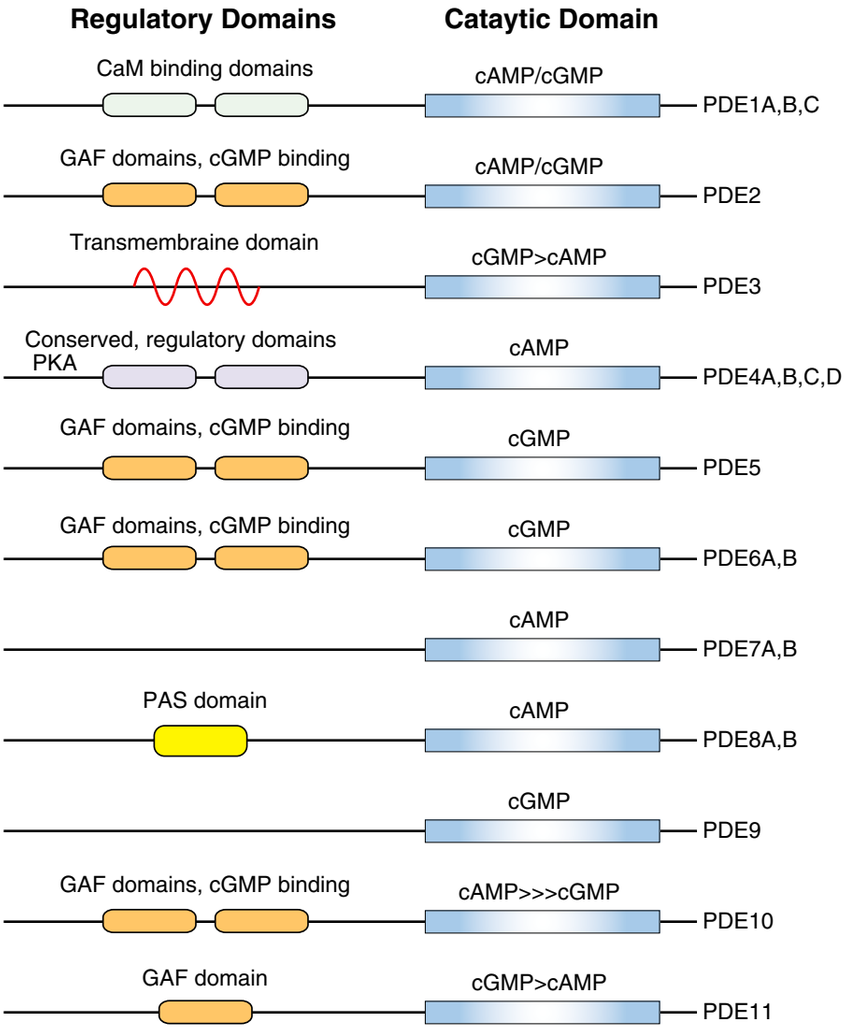

FIGURE 21-6 Schematic illustration of the overall structure and regulatory sites of eleven different phosphodiesterase subtypes. The catalytic domain of the phosphodiesterases are relatively conserved, and the preferred substrate(s) for each type is shown. The regulatory domains are more variable and contain the sites for binding of Ca^{2+}/calmodulin (*CaM*) and cGMP, as well as GAF and PAS domains. The regulatory domains also contain sites of phosphorylation by cAMP-dependent protein kinase (*PKA*).

binding site on PDE1. Similarly, those PDEs that possess high affinity cGMP-binding sites that apparently serve an allosteric function (i.e. PDE2, PDE5, PDE6, PDE10 and PDE11) share a GAF domain. There are also several phosphorylation sites within this region in PDE1, PDE3, PDE4 and PDE6. There is evidence for an additional phosphorylation site in the carboxy terminus of certain PDE4 isozymes that is a substrate for the extracellularly regulated protein kinase (ERK).

The association of PDE isozymes with the cell membrane is mediated by a conserved, hydrophobic sequence in the amino terminus of the proteins. This has been most convincingly demonstrated for PDE4A: when the amino terminus is removed PDE4A is no longer localized to the membrane fraction. A similar amino terminus sequence is found in the membrane-bound forms of PDE2, and may also mediate the membrane-association of certain PDE3 isozymes.

In addition to the numbers of distinct genes that encode the 11 described families of PDEs, there is evidence that multiple protein products can be derived from individual genes. This has been established for the PDE1, PDE2, PDE4, PDE8 and PDE9 genes. These multiple forms provide yet another mechanism to increase the diversity of PDEs expressed in different tissues or under various biological conditions. For example, the four PDE4 genes give rise to at least 17 variants as a result of alternative splicing or the presence of multiple promoter start sites within the genes [41]. Many of these variants are conserved across species, which suggests that they may have functional importance.

While the physiological significance of most of these PDE4 variants has not been fully appreciated, certain variants have been shown to differ dramatically with respect to their regulatory properties. Short and long forms of PDE4D are generated by alternative splicing. Expression of the short forms (D1 and D2, 67–72 kDa) results from activation of an intronic promoter, whereas expression of the long form (D3, 93 kDa) results from activation of another promoter located further upstream. The long form, but not the short forms, contains a site for phosphorylation and is regulated by protein kinase A [53]. Although the short forms are not regulated by phosphorylation, their expression is increased at the transcriptional level by cAMP [54]. The PDE4A-C genes also have splice variants that give rise to short and long forms that may be regulated in a similar manner. The activity of the long, but not the short, form is enhanced by phosphatidic acid and phosphatidylserine.

One of the primary mechanisms for regulation of phosphodiesterase enzyme activity is phosphorylation. PDE1 is phosphorylated by Ca^{2+}/calmodulin-dependent protein kinase II (CaM-kinase II), which results in decreased affinity of this enzyme for Ca^{2+}/calmodulin and an increase in the concentration of Ca^{2+} needed for its activation. PDE1 is also phosphorylated by protein kinase A, which likewise decreases its binding to Ca^{2+}/calmodulin. The inhibition of PDE1 by protein kinase A could serve to sustain intracellular cAMP levels under certain physiological conditions.

Protein kinase A also phosphorylates PDE2, PDE3 and PDE4, although the function of these enzymes is thereby influenced in different ways. Only the particulate form of PDE2 is phosphorylated by the protein kinase, but this is not known to influence enzyme activity. Phosphorylation of PDE3 by protein kinase A in rat adipocytes stimulates the catalytic activity of the enzyme. PDE3 in these cells is also phosphorylated and activated by an insulin-activated kinase, which has not yet been identified with certainty.

PDE4 is similarly activated upon phosphorylation by protein kinase A. As discussed above, only the long form of PDE4 is phosphorylated; the short forms lack the amino terminus that contains the phosphorylation site. This provides a mechanism for rapid and readily reversible activation of PDE4 (by phosphorylation) as well as more long-term and sustained regulation of PDE4 (by gene expression). Certain PDE4 isozymes are reported to be phosphorylated by protein kinase C and MAP-kinases, and in response to insulin, although these phosphorylation reactions are incompletely characterized and the functional consequences are not yet well-established.

Phosphodiesterase inhibitors show promise as pharmacotherapeutic agents. This may not be surprising given the widespread role of cyclic nucleotides in the regulation of cell function [40, 41]. The best examples of drugs that influence PDEs are the methylxanthines; these drugs are used therapeutically in the treatment of obstructive pulmonary disease and are the mild stimulants present in coffee, tea and related substances. Inhibition of PDE contributes to some of the clinical effects of these drugs. The widespread use of PDE5 inhibitors in the treatment of erectile dysfunction was mentioned earlier.

Other examples of PDE inhibitors with possible clinical usefulness are inhibitors of PDE3 or PDE4 (Table 21-1). Based on the localization of PDE3 to heart and vascular tissue and the role of cAMP in regulating heart muscle contraction and smooth muscle relaxation, a large number of PDE3 inhibitors have been developed for possible clinical applications in cardiovascular medicine.

Inhibitors of PDE4 have been developed as cognitive-memory enhancing agents and as possible antidepressants. As discussed for adenylyl cyclases, experimental evidence *in vitro* and *in vivo* demonstrates a role for the cAMP cascade in learning and memory, and inhibition of PDE4 has proved to be an effective approach to enhancing learning and memory in these models [55] (see Ch. 53). Further evidence for the importance of PDE4 isozymes in neuronal function comes from the *dunce* mutation in *Drosophila*. This mutation, which results in learning and memory deficits, involves loss of function of a cAMP-specific PDE that is functionally homologous to PDE4.

The rationale for the use of PDE4 inhibitors for the treatment of depression comes from the observations that

many types of antidepressant treatments appear to increase cAMP function in brain (see also Ch. 55). It is speculated that persistent increases in cAMP function may lead to some of the long-term adaptive changes in the brain thought to underlie the antidepressant effects of these agents [56]. Although early clinical trials demonstrated that PDE4-specific inhibitors have antidepressant efficacy, these drugs also produce unwanted side-effects that have limited their use. The presence of multiple PDE4 subtypes in brain raises the possibility that there may be developed more selective inhibitors that retain antidepressant actions and avoid unwanted side-effects.

FUNCTIONAL ROLES FOR CYCLIC cAMP AND CYCLIC cGMP

Over the last four decades, cAMP has been shown to serve as an intracellular second messenger for numerous extracellular signals in the nervous system. In fact, the number of functional processes regulated by cAMP is too large to enumerate here in detail. It is important, however, to review the general types of effects that cAMP exerts in neurons.

Cyclic AMP can be viewed as subserving two major functions in the nervous system. First, cAMP mediates some short-term aspects of synaptic transmission: some rapid actions of certain neurotransmitters on ion channels that do not involve ligand-gated channels are mediated through cAMP.

Second, cAMP, along with other intracellular messengers, plays a central role in mediating other aspects of synaptic transmission: virtually all other effects of neurotransmitters on target neuron functioning, both short-term and long-term, are achieved through intracellular messengers. This includes regulation of the general metabolic state of the target neurons, as well as modulatory effects on their neurotransmitter synthesis, storage and release, neurotransmitter receptor sensitivity, cytoskeletal organization and structure, and neuronal growth and differentiation. This also includes those long-term actions of neurotransmitters that are mediated through alterations in neuronal gene expression.

It is important to emphasize that such a role for cAMP and other intracellular messengers is not limited to actions of neurotransmitters mediated via G-protein-coupled receptors. Thus, although activation of ligand-gated ion channels leads to initial changes in membrane potential independent of intracellular messengers, activation of ligand-gated ion channels also leads to numerous additional (albeit slower) effects that are mediated via intracellular messengers. For example, activation of certain glutamate receptors (which are ligand-gated ion channels) leads rapidly to membrane depolarization and more slowly to increases in cellular levels of cAMP (e.g. by activation of Ca^{2+}/calmodulin-sensitive forms of adenylyl cyclase). cAMP then mediates several other effects of glutamate on the neurons. By virtue of numerous interactions between cAMP and other intracellular messenger cascades, these pathways play the central role in coordinating a myriad of neuronal processes and adjusting neuronal function to environmental cues [57].

Most of the effects of cyclic AMP on cell function are mediated via protein phosphorylation. By far the most important mechanism by which cAMP exerts its myriad physiological effects is through the specific activation of protein kinase A. This was first demonstrated by Edwin Krebs and his co-workers for cAMP regulation of glycogenolysis and shortly thereafter shown to be a widespread mechanism in nervous system by Paul Greengard and his colleagues. Indeed, cAMP-dependent protein kinase is now known to phosphorylate virtually every major class of neural protein; this accounts for the ability of cAMP to influence so many diverse aspects of neuronal function. The ability of cAMP to activate protein kinases, and the role of protein phosphorylation in the regulation of neuronal function, is covered in greater detail in Chapter 23.

How do a wide variety of neurotransmitters and hormones produce tissue- and cell-specific biological responses, if many such responses are mediated by the same intracellular messengers, cAMP and cAMP-dependent protein kinase? Specificity is achieved at two levels: at the level of tissue-specific receptors for the neurotransmitter or hormone and at the level of tissue-specific substrate proteins for the protein kinase. Only tissues that possess specific receptors will respond to a certain neurotransmitter or hormone. Moreover, since all cells contain very similar catalytic subunits of protein kinase A (see Ch. 23), the nature of the proteins that are phosphorylated in a given tissue depends on the types and amounts of proteins expressed in that tissue and on their accessibility to the protein kinase.

There are important exceptions to the rule that the physiological effects of cAMP in mammals are achieved via the activation of protein kinase A. The most prominent is a class of ion channels, referred to as HCN (hyperpolarization cyclic nucleotide gated) channels, that directly bind, and are thereby gated by, cAMP. Several forms of HCN channel are widely expressed in brain and peripheral tissues and have been implicated in the regulation of many facets of cell function.

The mechanisms by which cyclic GMP produces its physiological effects are more varied. It has been more difficult to identify second messenger actions of cGMP compared to cAMP. This probably reflects the lower concentrations of cGMP in most tissues and the likelihood that cGMP plays a less widespread role in cell function.

Nevertheless, physiological actions of cGMP are being identified. The best studied action is in the retina (see above), where cGMP mediates the effects of light on cation channels in rod outer segments by directly binding

to and gating the channels. In addition, cGMP has been shown to activate and inhibit specific forms of PDE, as discussed earlier in this chapter, also through direct binding to the enzymes.

In addition to such direct actions of cGMP on effector proteins, many physiological effects of cGMP are probably mediated via the activation of cGMP-dependent protein kinase (protein kinase G) and the subsequent phosphorylation of specific substrate proteins (see Ch. 23). For example, the ability of neurotransmitters to influence certain ion channels in target neurons is mediated through increased cellular levels of cGMP, the activation of protein kinase G and the subsequent phosphorylation of the channels (or some associated protein) by the protein kinase. As another example, in certain neuronal cell types, neurotransmitters that increase cGMP levels, through the activation of protein kinase G and the phosphorylation and activation of dopamine-and cAMP-regulated phosphoprotein of 32 kDa (DARPP-32, an inhibitor of protein phosphatase1 discussed in Ch. 23), would alter the phosphorylation state of the numerous proteins dephosphorylated by this protein phosphatase.

FUTURE PERSPECTIVES

Although tremendous progress has been made in characterizing the enzymes that control the synthesis and metabolism of cyclic nucleotides in the nervous system, our understanding of the regulation and interaction of these systems is far from complete. Work is now needed to definitively characterize, for each of these enzyme subtypes, its unique distribution pattern in the brain as well as its distinct functional and regulatory properties.

Future studies of cyclic nucleotide-mediated and other signal transduction pathways in the brain will utilize recent advances in molecular and cellular neurobiology to determine the role of these pathways in coordinating the functions of individual neurons and of synaptic connections among neurons. These approaches will be combined with gene mutation technology to more fully probe the function of specific signal transduction proteins in neuronal function and complex behavior. Characterization of these signal transduction pathways will ultimately elucidate how dysfunction of these systems contributes to psychiatric and neurological disorders.

THE CONCEPT OF Ca^{2+} AS A CELLULAR SIGNAL 379

MEASUREMENT OF CELLULAR Ca^{2+} CONCENTRATIONS AND MOVEMENTS 379

Ca^{2+} REGULATION AT THE PLASMA MEMBRANE 380
Two distinct mechanisms for controlling $[Ca^{2+}]_i$ at the plasma membrane are provided by a Ca^{2+}-ATPase pump and a Na^+/Ca^{2+} exchanger 380

Ca^{2+} STORES AND Ca^{2+} POOLS 381
The only known mechanism for Ca^{2+} accumulation by the endoplasmic reticulum is by means of sarcoendoplasmic reticulum Ca^{2+}-ATPase (SERCA) pumps 381
Mitochondria may accumulate Ca^{2+} by an energy-dependent process 381
Calcium is stored at other significant sites in the cell 382

Ca^{2+} SIGNALING 382
Release of intracellular Ca^{2+} is mediated primarily via inositol 1,4,5-trisphosphate receptors and ryanodine receptors 382
Ca^{2+} can enter cells via voltage- or ligand-dependent channels and by capacitative entry 383
Periodic temporal and spatial patterns of Ca^{2+} signaling give rise to calcium oscillations and waves 384
Release of intracellular Ca^{2+} may occur from 'calciosomes', a subfraction of the endoplasmic reticulum 386
Ca^{2+}-signaling events in excitable and nonexcitable cells, although distinct, share some common characteristics 387

Ca^{2+}-REGULATED PROCESSES 388
Ca^{2+} is required for acute cellular responses such as contraction or secretion 388
Ca^{2+} also plays a role in more prolonged cellular events such as mitogenesis and apoptosis 389

THE CONCEPT OF Ca^{2+} AS A CELLULAR SIGNAL

In most eukaryotic cells, a large electrochemical gradient for Ca^{2+} exists across the plasma membrane. The −70 to −90 mV potential across the membrane favors the accumulation of cations, yet the cytoplasmic concentration of free ionized calcium ($[Ca^{2+}]_i$) is less than one-10,000th of that in the extracellular milieu. There are also intracellular organelles, such as the endoplasmic reticulum (ER) and secretory granules, that contain 1,000–10,000-fold greater concentrations of Ca^{2+} than the cytoplasm. It is likely that these gradients for Ca^{2+} evolved partly because of the incompatibility of a phosphate-based energy economy with the high Ca^{2+} concentrations in seawater. The system that has evolved permits rapid changes in $[Ca^{2+}]_i$ as a cellular signaling mechanism. This chapter focuses on the mechanisms of Ca^{2+} storage and compartmentation in cells and the mechanisms by which cellular Ca^{2+} signaling occurs in neurons and other cell types.

MEASUREMENT OF CELLULAR Ca^{2+} CONCENTRATIONS AND MOVEMENTS

From the earliest measurements of tissue calcium, it was clear that total calcium is largely a measure of stored calcium. Through the years, scientists have used a variety of indirect measures of $[Ca^{2+}]_i$. These include shortening of or tension in muscles; secretion from secretory cells; the activity of Ca^{2+}-dependent enzymes, most notably glycogen phosphorylase; and flux of K^+, or K^+ currents, as a reflection of Ca^{2+}-activated K^+ channels. In addition, investigators often use the radioactive calcium ion [$^{45}Ca^{2+}$] as an indirect indicator of Ca^{2+} concentrations and Ca^{2+} movements.

The development of fluorescent Ca^{2+} indicators that can be introduced easily into almost any vertebrate cell revolutionized calcium signaling research in the 1980s (Fig. 22-1) [1]. The majority of these compounds are

Basic Neurochemistry: Molecular, Cellular and Medical Aspects

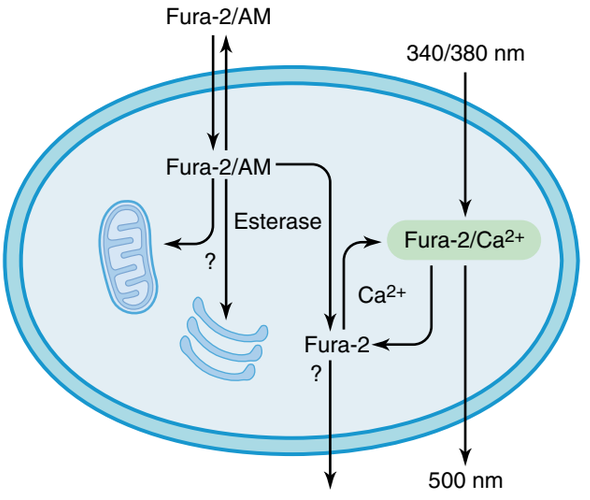

FIGURE 22-1 Introduction of esterified fluorescent Ca^{2+} indicators into cells. The fluorescent indicator, in this example fura-2, is presented to cells as the acetoxymethyl ester (*fura-2/AM*). This relatively lipid-soluble chemical permeates into the cytoplasm of cells, where esterases cleave the acetoxymethyl ester groups, liberating the Ca^{2+} binding moiety (*fura-2*). Fura-2 then reversibly combines with Ca^{2+} and, when excited alternatively with light of wavelengths 340 and 380 nm, gives rise to fluorescence at 500 nm, which can be used for quantitation of $[Ca^{2+}]_i$. Potential complications with the use of these fluorescent dyes, indicated in this figure by ?, are uptake into intracellular organelles and leak of dye from the cells. (Redrawn and modified from reference [4] with permission of Landes Bioscience.)

derivatives of the calcium ion chelator 'BAPTA', 1,2-bis (*o*-aminophenoxy)ethane-*N*,*N*,*N*′,*N*′-tetraacetic acid. A major advantage is that the wavelengths of their fluorescence maxima shift upon binding of calcium ions. This allows one to utilize these indicators in fluorescence microscope systems to obtain reasonably accurate quantitation of intracellular calcium ion concentrations.

Prior to the introduction of these synthetic Ca^{2+} indicators, a few laboratories in the 1970s employed the Ca^{2+}-activated photoproteins aequorin and obelin to study calcium dynamics. At the time, methodology restricted the broad use of this technique as a research tool. In particular it was challenging or impossible to introduce these photoproteins into the cytoplasm of most cells. However, these studies laid the groundwork for developing genetically engineered fluorescent proteins that overcome these obstacles. The introduction of green fluorescent protein (GFP) and its derivatives as genetically encoded proteins has again revolutionized the study of intracellular calcium [2]. Fluorescent proteins have been designed to incorporate many of the properties of the organic fluorescent indicators, including families with different calcium sensitivities. The same fluorescent microscope systems can be used to detect them. However, unlike the organic fluorophors, the fluorescent proteins can be introduced into cells with specific promoters and coupled to specific targeting signals, so that optical imaging using these calcium-sensitive proteins can be studied not just in single cells but also in intact tissues or organisms. The level of control in targeting these fluorescent proteins is exquisite, where expression can be restricted to a specific tissue within an organism and further restricted to a selected compartment within a cell. These genetically encoded proteins provide an important experimental approach to define intricate spatiotemporal calcium signaling processes that may often only be fully appreciated in an intact multicellular system.

Yet another method of assessing calcium ion movements in cells is by direct measurement of the current that such movement generates. Originally such currents were detected by impaling cells with microelectrodes, but most of the understanding of Ca^{2+} channel function has come from more recent work utilizing the powerful patch-clamp technique (see Ch. 6). In the whole-cell configuration, the investigator is afforded the opportunity of measuring calcium currents while manipulating both the intracellular and extracellular milieus. With excised patches, the behavior of single calcium channels can be investigated in similarly controlled environments. This approach, described in Chapter 6, has been very useful for describing voltage-activated Ca^{2+} channels [3].

Ca^{2+} REGULATION AT THE PLASMA MEMBRANE

Although there are a number of mechanisms in cells for buffering or sequestering Ca^{2+} to prevent untoward or inappropriate rises in $[Ca^{2+}]_i$, in the long term, it is the activity of plasma membrane transport processes that determines the steady-state $[Ca^{2+}]_i$. This is because the plasma membrane acts as a Ca^{2+} buffer of essentially infinite capacity. This results from *in vivo* clamping of the extracellular concentration of Ca^{2+} by dietary and endocrine mechanisms. In *in vitro* experiments, this results from incubation volumes very much larger than the cell volume.

Two distinct mechanisms for controlling $[Ca^{2+}]_i$ at the plasma membrane are provided by a Ca^{2+}-ATPase pump and a Na^+/Ca^{2+} exchanger. The basic properties of both the pump and the exchanger are discussed in Chapter 5. Of the two mechanisms, the plasma membrane Ca^{2+} pump is ubiquitous in eukaryotic cells. Na^+/Ca^{2+} exchanger expression is more restricted: it is found in excitable cells, such as nerve and muscle. As its name implies, the exchanger can, at least in theory, drive extrusion of Ca^{2+} from the cell by a process coupled to the inward movement of Na^+ down its concentration gradient. However, because in resting cells the outward electrochemical gradient is so very large, there is debate as to the extent to which the exchanger actually contributes to the lowering of $[Ca^{2+}]_i$, at least under resting conditions. This debate hinges on assumptions about the stoichiometry and

driving forces for the exchanger in intact cells. It is clear that turnover of Ca^{2+} through the exchanger can be substantial, and this may be important in the rapid control of $[Ca^{2+}]_i$ during activity. The exchanger is of pharmacological interest because of the possibility that digitalis glycosides, which disturb the normal transmembrane Na^+ gradient, augment cardiac contraction by facilitating Ca^{2+} entry or delaying Ca^{2+} exit via the exchanger (see Ch. 5). It also has been suggested that the exchanger provides a rapidly responding buffer that can allow an inward movement of Ca^{2+} under conditions requiring restoration of Ca^{2+} to intracellular storage organelles [4].

The plasma membrane Ca^{2+}-ATPase pump effects outward transport of Ca^{2+} against a large electrochemical gradient for Ca^{2+}. The mechanism of the pump involves its phosphorylation by ATP and the formation of a high-energy intermediate. This basic mechanism is similar for both the plasma membrane and ER pumps; however, the structures of these distinct gene products are substantially different. As discussed below, the ER pump, sometimes called a sarcoendoplasmic reticulum Ca^{2+}-ATPase (SERCA) pump, is inhibited potently by certain natural and synthetic toxins that do not affect the plasma membrane pump. The plasma membrane pump, but not the SERCA pump, is controlled in part by Ca^{2+} calmodulin, allowing for rapid activation when cytoplasmic Ca^{2+} rises.

Ca^{2+} STORES AND Ca^{2+} POOLS

Within cells, the major calcium storing, buffering and signaling organelle appears to be the ER or, as discussed below, a specialized compartment of it. Other specialized structures that may be involved in calcium storage include the mitochondria and the nucleus. There was, for a time, a rather widely held belief that mitochondria represented the major source of signaling calcium that was released by hormone or neurotransmitter receptor activation. Perhaps the most convincing demonstration that mitochondria were not involved primarily in hormonal responses came with the discovery of inositol 1,4,5-trisphosphate (IP_3, or, to distinguish it from other positional isomers, $I(1,4,5)P_3$), as the mediator of intracellular release of Ca^{2+} (reviewed in [5, 6] and discussed below; see also Ch. 20). IP_3 was clearly shown to act only on nonmitochondrial stores. As endoplasmic reticulum is the principal nonmitochondrial calcium storage compartment, this was taken as evidence that ER is the critical storage site for signaling calcium. Whether this is a property of generic ER or of a specialized ER component is still a matter of some debate and is discussed in more detail in a subsequent section.

The only known mechanism for Ca^{2+} accumulation by the endoplasmic reticulum is by means of sarcoendoplasmic reticulum Ca^{2+}-ATPase SERCA pumps. Inside the lumen of the ER, the Ca^{2+} storage capacity is enhanced substantially by one or more low-affinity calcium binding proteins. In muscle, this protein is calsequestrin, while in most other cells the major protein is calreticulin. Each molecule of calreticulin has multiple Ca^{2+}-binding sites with an affinity in the high micromolar range and one site with an affinity in the nanomolar range. The significance of this high-affinity site is not known.

The functions of the calcium-storage capacity of the ER are at least threefold: the association of Ca^{2+} with Ca^{2+}-binding proteins in the ER is part of a chaperone function that is essential for normal protein synthesis; the rapid rate of Ca^{2+} uptake by endoplasmic pumps provides short-term cytoplasmic Ca^{2+} buffering that resists untoward and transient changes in $[Ca^{2+}]_i$; and, finally, many signaling pathways employ elevated $[Ca^{2+}]_i$ to activate physiological processes. Extensive Ca^{2+} release from ER is coupled to activation of Ca^{2+} entry across the plasma membrane, a process known as capacitative calcium entry, which is discussed below.

Mitochondria may accumulate Ca^{2+} by an energy-dependent process. Unlike the ER, mitochondria do not employ a specific Ca^{2+} transporter, but rather Ca^{2+} is accumulated via an electrogenic Ca^{2+} channel. The energy for driving accumulation of Ca^{2+} comes from the substantial mitochondrial membrane potential generated by the proton gradient established by the electron transport chain that also couples respiration to ATP synthesis. Experimentally, Ca^{2+} accumulation can be driven either by mitochondrial substrate oxidation or by ATP hydrolysis. In the latter case, H^+ accumulation and membrane potential generation occurs through reversal of the ATP synthetase. Drugs that interfere with electron transport, such as antimycin, or that collapse the proton gradient, such as protonophors, also block mitochondrial Ca^{2+} uptake. Experiments employing either subcellular fractions, permeable cells or *in situ* imaging of sequestered Ca^{2+} have all demonstrated that the kinetics of Ca^{2+} uptake do not permit significant accumulation of Ca^{2+} by mitochondria under resting conditions (Fig. 22-2). However, once the threshold for uptake is reached, the driving force for Ca^{2+} accumulation is substantial, and if $[Ca^{2+}]_i$ is elevated for a prolonged period of time, mitochondria can accumulate Ca^{2+} to remarkable concentrations. In recent years, Ca^{2+}-sensitive proteins, based on aequorin and GFP, have been specifically directed to mitochondria. These studies have revealed that mitochondria can accumulate Ca^{2+} rapidly and efficiently without any apparent prolonged period of $[Ca^{2+}]_i$ elevation. In reconciling these observations with the physiology of the mitochondrial Ca^{2+} uptake mechanism, it is suggested that there can be close apposition of mitochondria to ER Ca^{2+} release channels [7]. In these cases the local $[Ca^{2+}]_i$ is higher than that measured in the bulk of the cytoplasm and is above the threshold for uptake into the mitochondria. Such a spatial relationship may also exist between mitochondria and the plasma membrane. These latter observations suggest

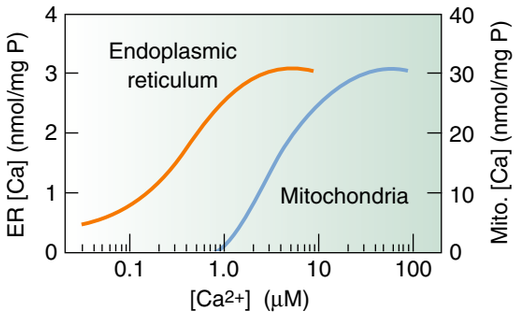

FIGURE 22-2 ATP-dependent uptake of calcium into endoplasmic reticulum and mitochondria as a function of extraorganellar Ca^{2+} concentration. As $[Ca^{2+}]_i$ was raised, ATP-dependent Ca^{2+} uptake into the endoplasmic reticulum (ER) and mitochondrial pools increased. Data for ER uptake were determined as the amount of Ca^{2+} [$^{45}Ca^{2+}$] taken up by saponin-permeabilized hepatocytes after addition of ATP and in the presence of mitochondrial inhibitors. The curve for mitochondrial uptake was obtained by subtracting the ATP-dependent uptake in the presence of these inhibitors from that in the absence of inhibitors. For additional details consult Burgess *et al.* [31]. Stylized data taken from results originally reported in Burgess *et al.* [31]. (Redrawn and modified from reference [4] with permission of Landes Bioscience.)

potential physiological roles of mitochondrial Ca^{2+} uptake, such as protecting the cell from deleterious effects of prolonged $[Ca^{2+}]_i$ elevation, or shaping spatiotemporal Ca^{2+} responses during receptor activation. Although Ca^{2+} uptake by mitochondria is electrogenic, Ca^{2+} efflux is neutral, an exchange for either $2H^+$ or $2Na^+$, and proceeds more slowly than cytoplasmic and plasma membrane buffering. Thus, Ca^{2+} accumulated during periods of prolonged stress is released to the cytoplasm at a sufficiently slow rate that the excess can be removed from the cell without significantly elevating $[Ca^{2+}]_i$.

Calcium is stored at other significant sites in the cell. These include secretory granules, lysosomes and the nucleus. The Ca^{2+} in secretory granules generally has been considered to be relatively inert and to function largely in a structural capacity. However, evidence exists that this Ca^{2+} can be released during cell stimulation and can participate in the control of Ca^{2+} signaling (see NAADP discussion below) and in secretion. The nuclear pores generally prevent the development of substantial gradients of Ca^{2+} between the nucleoplasm and cytoplasm. Nonetheless, calcium does signal to the nucleus, having effects on gene transcription and cell growth, with elevations of nuclear Ca^{2+}. Although originally thought to occur by diffusion through nuclear pores from the bulk cytoplasm, it is now recognized that extensions of endoplasmic reticulum, complete with Ca^{2+} release sites, occur in the nuclear envelope. A reticular network of nuclear calcium stores has been identified in an epithelial cell line [8]. The locality of such Ca^{2+} stores in and around the nucleus suggests that cell stimulation can lead to discharge of Ca^{2+} directly into the nucleoplasm, allowing local control of calcium signals and nuclear function independent of changes in cytoplasmic $[Ca^{2+}]_i$.

Ca^{2+} SIGNALING

The processes of calcium signaling consist of the molecular and biophysical events that link external stimuli to the expression of appropriate intracellular responses by means of increases in cytoplasmic Ca^{2+}. The external signal is most commonly a neurotransmitter, hormone or growth factor but, in the case of excitable cells, the initial chemical stimuli may bring about membrane excitation, which in turn activates a calcium-signaling pathway.

Release of intracellular Ca^{2+} is mediated primarily via inositol 1,4,5-trisphosphate receptors and ryanodine receptors. The calcium ions that give rise to a $[Ca^{2+}]_i$ signal can come either from intracellular stores or from external Ca^{2+} entering across the plasma membrane. Typically, both sources are utilized. The most ubiquitous of the intracellular Ca^{2+} release mechanisms involves the phosphoinositide specific phospholipase C (PI-PLC)-derived second messenger IP_3, which acts by binding to a specific receptor on the ER or a specialized component of the ER. The IP_3 receptor/channel appears to be a homotetramer containing four binding sites for IP_3. Distinct subtypes of the receptor exist, representing products of at least three distinct genes, and additional forms arise as a result of alternative splicing. The origin of IP_3 and the characteristics of IP_3 are discussed in Chapter 20.

The interaction of IP_3 with its receptor involves complex and poorly understood regulatory interactions among the receptor, IP_3 and Ca^{2+} – the latter apparently exerting influence from both the cytoplasmic and luminal aspects of the receptor. Ca^{2+} in the lumen of the ER appears to sensitize the receptor to IP_3. On the cytoplasmic surface, low concentrations of Ca^{2+} sensitize while higher concentrations are inhibitory. These actions may contribute to the 'all-or-none' oscillatory behavior of $[Ca^{2+}]_i$ signals seen in some cell types. This phenomenon will be discussed in more detail below.

The other major type of intracellular Ca^{2+}-mobilizing receptor is the ryanodine receptor. The ryanodine receptor is named for a toxin that binds to the molecule with high affinity and was employed in its purification and characterization. Like the IP_3 receptor, it is a homotetramer, and these receptors share considerable structural homology [9]. In its most specialized setting, in skeletal muscle, the ryanodine receptor is gated by a direct conformational interaction with a dihydropyridine receptor in the *t*-tubule membrane (see Ch. 43). This coupling permits rapid release of stored Ca^{2+} when an action potential invades the *t*-tubule system. However, the physiological ligand for the ryanodine receptor is usually Ca^{2+} itself; i.e. it is considered to be a calcium-induced calcium release (CICR) Ca^{2+} channel (see also Ch. 20). Because Ca^{2+} can

sensitize the IP_3 receptor to IP_3, the IP_3 receptor also can exhibit CICR behavior. However, some IP_3 is always required for its action, whereas the ryanodine receptor can function as a 'pure' CICR receptor. Although the ryanodine receptor is thought to be regulated primarily by CICR, a small water-soluble molecule, cyclic adenosine diphosphate ribose (cADPr), functions as a regulatory ligand for at least some forms of the ryanodine receptor [10]. cADPr functions in a manner somewhat similar to IP_3: its principal site of action is the ER and it appears to increase the opening probability of the ryanodine receptor channel by increasing its sensitivity to Ca^{2+}. Another water-soluble molecule, synthesized by the same family of enzymes that generate cADPr, is nicotinic acid-adenine dinucleotide phosphate (NAADP). NAADP can also mobilize intracellular Ca^{2+} but, unlike cADPr, it does not appear to modulate CICR channels. The principal locations of the NAADP receptor appear to be secretory granules and/or lysozymes. While the NAADP receptor does not exhibit CICR activity itself, the Ca^{2+} released from this Ca^{2+} pool may promote a CICR response by interacting with calcium release channels on the ER. It is tempting to speculate that Ca^{2+} signaling in neurons may be regulated by changing concentrations of cADPr and NAADP, and there is limited evidence for this suggestion [11]. In at least one cell type, the IP_3 receptor, cADPr-sensitive ryanodine receptor and NAADP receptor seem to function in a cooperative manner to promote neurosecretion at the frog neuromuscular junction [12].

Ca^{2+} can enter cells via voltage- or ligand-dependent channels and by capacitative entry. These three fundamental mechanisms of regulated calcium ion entry across the plasma membrane involve, respectively, voltage-dependent Ca^{2+} channels, ligand-gated Ca^{2+} channels and capacitative Ca^{2+} entry associated with phospholipase C-coupled receptors.

Voltage-dependent Ca^{2+} channels are found in a variety of excitable cell types, including neurons, myocytes, endocrine cells and neuroendocrine, such as chromaffin, cells [3] but they are almost never found in classical 'nonexcitable' cells, such as epithelial cells, leukocytes and fibroblasts. By definition, voltage-dependent channels can be activated by membrane depolarization. In addition, they are subject to complex combinations of voltage-dependent activation and voltage-dependent or calcium-mediated inactivation mechanisms similar to the voltage-dependent regulation of Na^+ channels described by Hodgkin and Huxley (see Ch. 6). These are the Ca^{2+} channels that provide the activator Ca^{2+} for cardiac contractility, for contraction of some smooth muscle types and, generally, for discharge of neurotransmitters by Ca^{2+}-dependent exocytosis (see Ch. 9) and synaptic transmission (see Ch. 10). In most instances, their activation is initiated by membrane depolarization, whether by propagated action potential or by the opening of other ligand-gated channels. However, in some cases, the channels are activated by removing an inhibitory influence, such as a decrease in a hyperpolarizing K^+ conductance, or by sensitizing the channels to activation at resting membrane potential through their phosphorylation.

There are at least five different types of voltage-dependent Ca^{2+} channel molecules, differing in their gating kinetics, modes of Ca^{2+}-inactivation and Ca^{2+}-iregulation, and sensitivity to specific marine toxins [13] (see Ch. 6). The distinctions between the types of channel are of considerable interest because the different subtypes are believed to subserve different cellular functions. For example, the control of neurotransmitter release in peripheral sympathetic neurons appears to be under the predominant control of N-type calcium channels.

Ligand-gated ion channels are numerous, and some permit sufficient entry of Ca^{2+} for cellular activation. Here, ligand-gated channels denote channels that are gated directly by agonist binding rather than through the generation of second messengers. Generally the ligand-binding sites are located on the channel proteins, which are invariably nonspecific cation channels; as yet no receptor-gated channels specific for Ca^{2+} have been clearly identified. Ligand-gated ion channels are discussed in detail in Chapters 10, 11, 13, 15–17.

Capacitative Ca^{2+} entry is the predominant mode of regulated Ca^{2+} entry in nonexcitable cells but it also occurs in a number of excitable cell types. This pathway of Ca^{2+} entry is usually associated with the activation of phospholipase C, which mediates the formation of IP_3 (see Ch. 20). Intracellular application of IP_3 mimics the ability of hormones and neurotransmitters to activate calcium ion entry, and activation of calcium ion entry by hormones and neurotransmitters can be blocked by intracellular application of low-molecular-weight heparin, which potently antagonizes IP_3 binding to its receptor. There is considerable evidence for the presence of an IP_3 receptor in the plasma membrane of some cells types. $I(1,3,4,5)P_4$, a product of IP_3 phosphorylation, has been shown in some cells to augment this action of IP_3 in activating PM calcium ion entry, but in others IP_3 alone is clearly sufficient.

However, the current view of the regulation of calcium ion entry into the cytoplasm by PLC-linked stimuli holds that activation occurs not as a direct result of the action of IP_3 on the plasma membrane but indirectly, as a result of depletion of calcium ions from an intracellular store by IP_3 [14]. In the context of this 'capacitative model', the actions of intracellularly applied IP_3 and heparin reflect the effects of these maneuvers on intracellular release process from ER into cytosol, rather than via the plasma membrane. The reported actions of $I(1,3,4,5)P_4$, if in fact they do represent physiological control mechanisms, may reflect an ability of $I(1,3,4,5)P_4$ to augment the calcium-releasing ability of IP_3, rather than a distinct and

specific action at the plasma membrane. Originally the capacitative model for calcium ion entry was proposed on the basis of circumstantial evidence about the relative rates of emptying and refilling of intracellular stores of calcium. More direct tests of the model have arisen from the discovery of reagents, such as thapsigargin and cyclopiazonic acid, that selectively inhibit the ATP-dependent Ca^{2+} pumps that maintain the stores of intracellular calcium in the IP_3-sensitive pool (Fig. 22-3). These reagents can deplete this pool of Ca^{2+} without stimulating the formation of inositol phosphates. Numerous reports have demonstrated that Ca^{2+} entry across the plasma membrane is activated in cells treated with such agents[15]. Importantly, this Ca^{2+} entry is not affected by concomitant stimulation of inositol phosphate production.

Two general mechanisms have been considered by which a depleted intracellular Ca^{2+} pool might communicate with the plasma membrane [4]. There is evidence that the IP_3 receptor is associated with the cytoskeleton, and this association may tether the IP_3 receptor to the plasma membrane. Depletion of intracellular calcium stores might cause a conformational change in the IP_3 receptor, which could be conveyed to the plasma membrane via the cytoskeleton or by a more direct protein–protein interaction. Alternatively, signaling could occur through the action of a diffusible messenger released by the depleted intracellular calcium store and acting on calcium channels in the plasma membrane.

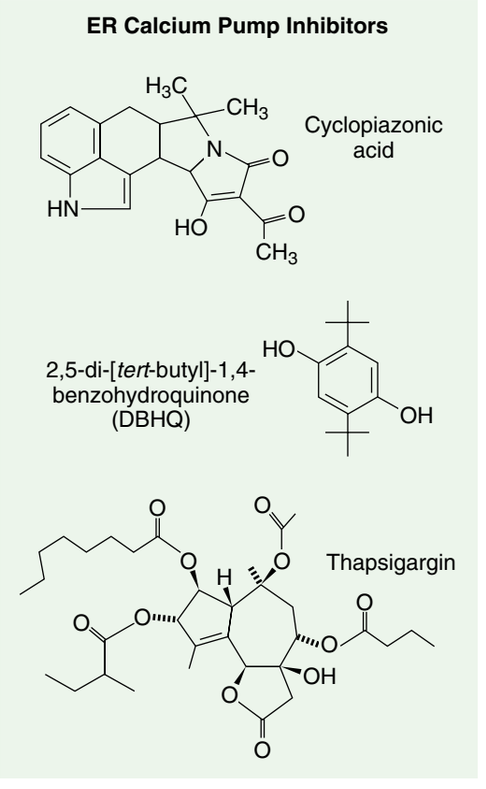

FIGURE 22-3 Structures of compounds that inhibit sarcoendoplasmic reticulum Ca^{2+}-ATPase (SERCA) calcium pumps.

Channels associated with capacitative calcium ion entry have been characterized electrophysiologically. In leukocytes, the current associated with the depletion of intracellular Ca^{2+} stores is highly Ca^{2+}-selective and, on the basis of noise analysis, is believed to involve minute single channels [16] (see Ch. 6). This is the calcium release-activated calcium current (I_{CRAC}). In other cell types, currents with significantly different properties have been identified, including in some instances store-operated nonselective cation channels. These marked electrophysiological distinctions may be indicative of distinct channel types mediating capacitative calcium ion entry in different cell types.

While the molecular identity of the capacitative Ca^{2+} entry channel is not known, a candidate is a homolog of the *Drosophila* mutant *trp*. This photoreceptor mutant is incapable of maintaining a sustained photoreceptor potential. This phenotype could be mimicked by the calcium entry blocker lanthanum, and it was suggested that the related defect is a failure of Ca^{2+} entry.

Now described as a *trp* superfamily, more than 20 vertebrate *trp* homologs have been identified and these can be divided phylogenetically into three subfamilies: *trpC* (termed 'canonical' as they are most closely related to *Drosophila trp*), *trpV* and *trpM*. Some of these proteins are potential contenders for the capacitative calcium ion entry channel. In particular, expression of members of the TRPC and TRPV families in mammalian cells has been shown to augment capacitative calcium ion entry, but their role is still a matter for debate [17].

A major function of capacitative calcium ion entry is to provide for sustained Ca^{2+} signaling. However, it also importantly provides a means for rapid replenishment of intracellular stores following their release by IP_3 and the cessation of agonist activation. How is this accomplished in those excitable cells that do not express capacitative calcium ion entry? The answer may be that excitable cells generally do, while nonexcitable cells generally do not, express a rapidly turning over sodium–calcium exchange transporter (see Ch. 5). This transporter could provide an energy-efficient route for rapidly adjusting cytoplasmic Ca^{2+} in response to rapid uptake demands of a depleted intracellular Ca^{2+} store. Because the resting turnover of this exchanger is relatively fast, it may be that such a pathway provides kinetic continuity of Ca^{2+} stores with extracellular Ca^{2+}, and thus serves to replenish intracellular stores in the absence of any store-dependent regulation. The relation of plasmalemma Na/Ca exchange transporter to local cytosolic Ca^{2+} concentrations and Ca^{2+} stores is discussed in Chapter 5.

Periodic temporal and spatial patterns of Ca^{2+} signaling give rise to calcium oscillations and waves. As discussed above, the IP_3 receptor is subject to complex and only

partially understood regulation by both IP_3 and calcium ion. The complicated kinetic behavior of the IP_3 receptor is believed to underlie calcium oscillations and waves. In excitable cells, oscillations in $[Ca^{2+}]_i$, reflecting periodic fluctuations in membrane electrical activity, have been known for some time. The clearest example results from the rhythmic cardiac action potentials that drive bursts of Ca^{2+} release, entry and extrusion and thereby maintain the pumping activity of the heart. However, $[Ca^{2+}]_i$ often will oscillate in cells through mechanisms that have nothing to do with surface membrane excitability. Calcium oscillations have been shown to be important regulators of cell function, including specific gene regulation. Thus, much effort has been devoted to understanding the control mechanisms giving rise to $[Ca^{2+}]_i$ waves and oscillations [18].

Intracellular calcium oscillations generally fall into one of two categories involving different mechanisms: baseline transients, or spikes, and sinusoidal oscillations. Figure 22-4 illustrates these two oscillatory patterns.

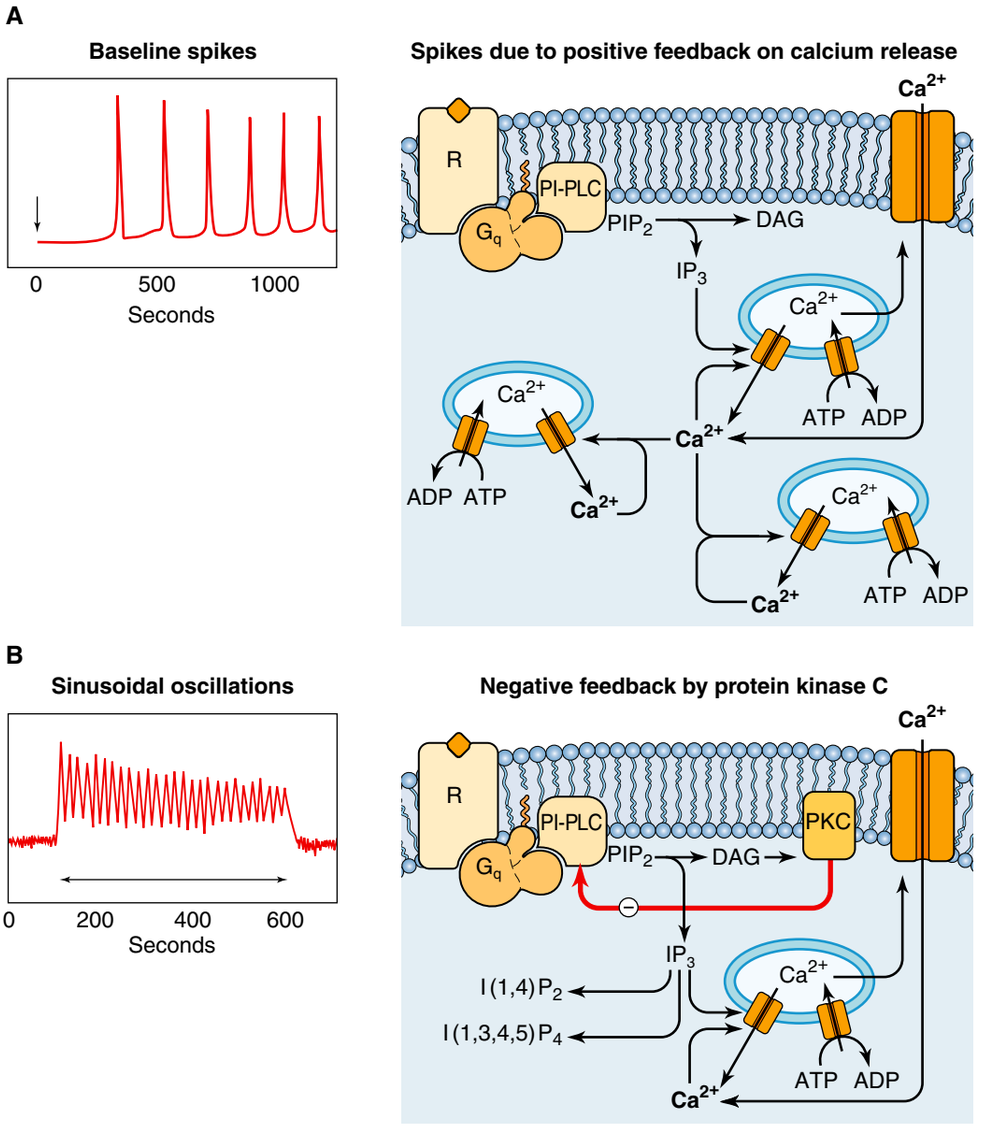

FIGURE 22-4 Patterns and mechanisms for major types of $[Ca^{2+}]_i$ oscillation. (**A**) **Left.** A single rat hepatocyte treated with vasopressin exhibits low-frequency baseline spikes of $[Ca^{2+}]_i$. **Right.** The mechanism for baseline $[Ca^{2+}]_i$ spiking is seen as being initiated by a small release of Ca^{2+} from a 'calciosome' by IP_3, and then, in the presence of a sensitizing concentration of IP_3, Ca^{2+} regeneratively activates release at neighboring release sites, leading to an all-or-none $[Ca^{2+}]_i$ wave propagating through the cell. (**B**) **Left.** A single mouse lacrimal acinar cell treated with methacholine exhibits higher frequency sinusoidal oscillations superimposed on an elevated baseline. **Right.** The mechanism underlying sinusoidal oscillations is suggested to occur as follows: phosphoinositide-specific phospholipase C (*PI-PLC*) activation leads to production of IP_3 and mobilization of Ca^{2+}, but also to protein kinase C (*PKC*) activation. With some delay, the latter inhibits PI-PLC, causing a fall in IP_3 and an attenuation of the $[Ca^{2+}]_i$ signal. The inhibition of PI-PLC also attenuates the PKC signal, leading to a cyclical increase in $[Ca^{2+}]_i$. Continuing cycling of this feedback loop gives rise to sinusoidal oscillations. *DAG*, diacylglycerol; *R*, receptor. (Redrawn and modified from reference [4] with permission of Landes Bioscience.)

Baseline spikes are characterized by rapidly-rising transient increases in $[Ca^{2+}]_i$ from a baseline of $[Ca^{2+}]_i$ that is generally quite close to the resting concentration. In contrast, sinusoidal oscillations more closely resemble true sine-wave oscillations and they are generally of a higher frequency than baseline spikes, >1/min as opposed to frequencies of <1/min for baseline spikes. They also generally appear as symmetrical oscillations superimposed on a sustained concentration of $[Ca^{2+}]_i$ that is somewhat above the prestimulus baseline. Another notable difference between the two types of oscillations is that baseline spikes may, at least in some instances, continue throughout prolonged periods of stimulation, while sinusoidal oscillations tend to diminish with time, generally lasting for only a few minutes. However, the most significant and characteristic distinction between the two types of oscillation is the relationship of the oscillation amplitude and frequency to stimulus strength, or agonist concentration. For baseline spikes, increasing the agonist concentration increases the frequency with little effect on the amplitude, while, for sinusoidal oscillations, increasing the agonist concentration increases the average $[Ca^{2+}]_i$ without affecting the frequency of the oscillations. Furthermore, for baseline spikes, but not for sinusoidal oscillations, the latency before the first $[Ca^{2+}]_i$ spike is inversely related to the agonist concentration. The mechanism underlying the varying frequency of spiking may also be responsible for the varying latency of the first spike, but this is not necessarily so. The persistent, constant amplitude baseline spikes require a *positive feedback* mechanism, sometimes called *feed-forward*, to accelerate the reaction and generate the spikes, followed by either a negative feedback or some capacity limitation, such as full depletion of an intracellular pool, to terminate each spike. However, negative feedback alone is sufficient to explain the behavior of constant-frequency sinusoidal oscillations.

In most instances, baseline spiking will continue for at least a few cycles in the absence of extracellular Ca^{2+} and therefore it is generally agreed that they represent cycles of discharge and reuptake of Ca^{2+} by intracellular stores. Although other models have been proposed, the currently favored mechanism of baseline $[Ca^{2+}]_i$ spiking involves fluctuations in $[Ca^{2+}]_i$ while cellular concentrations of IP_3 are constant (Fig. 22-4). Models along this theme require that Ca^{2+} itself provide both positive and negative regulation of the $[Ca^{2+}]_i$ signal. Important evidence for such regulation would be the demonstration of $[Ca^{2+}]_i$ spiking induced by direct intracellular application of IP_3. This has been demonstrated in oocytes and, in a few cases, in small, mammalian cells by intracellular introduction of IP_3 through whole-cell patch pipette perfusion. These findings suggest that a mechanism operates distally to the production of IP_3 to generate $[Ca^{2+}]_i$ spikes.

As discussed above, biphasic regulation of IP_3-induced Ca^{2+} release by Ca^{2+} is reminiscent of the behavior of the CICR channel from skeletal muscle. In addition, the inhibitory action of Ca^{2+} on IP_3-induced Ca^{2+} release develops more slowly than the activation, with a time constant of about 0.5 seconds. There is obvious similarity between this scheme, which involves a rapid Ca^{2+} activation of release followed by a more slowly developing Ca^{2+} inhibition, and the feed-forward and feedback regulation of action potentials by depolarization. Also as discussed above, changes in ER luminal $[Ca^{2+}]$ may regulate the sensitivity of the IP_3 receptor. Thus, these kinetically distinct modes of regulation of the IP_3 receptor by both cytoplasmic and luminal Ca^{2+} may provide the ingredients for production of regenerative spikes and waves of $[Ca^{2+}]_i$.

Much less attention has been paid to sinusoidal oscillations of intracellular Ca^{2+}, although, strictly speaking, they may represent the only instance in which the term 'oscillations' is applied correctly. These are roughly symmetrical fluctuations usually superimposed on a raised basal level of $[Ca^{2+}]_i$. The most significant characteristic of these oscillations is their constant frequency at different agonist concentrations. These sinusoidal oscillations are considerably simpler than the baseline spike type of $[Ca^{2+}]_i$ oscillation and can be explained simply by a single negative feedback on the $[Ca^{2+}]_i$-signaling mechanism. Although this may not apply in all cases, it appears that the negative feedback responsible for the sinusoidal oscillations is often due to protein kinase C (PKC). The site of negative inhibition appears to be on or proximal to PI-PLC. Activation of PI-PLC increases diacylglycerol (DAG), which in turn activates PKC. The latter feeds back and inhibits PI-PLC (see Ch. 20). This leads to a diminution in DAG production, diminished PKC activity and relief of the inhibition of PI-PLC. Continuous cycling of this delayed feedback loop generates oscillations in PI-PLC activity, which, in the absence of some feed-forward input, gradually damp down to a sustained level under tonic control by the opposing forces of receptor activation and PKC inhibition. It is important to point out that in this particular scheme $[Ca^{2+}]_i$ is simply a passive follower of the oscillating IP_3 production and plays no obvious active role in generating or modulating the oscillations. Thus, this particular type might more appropriately be called 'DAG oscillations' or 'PI-PLC/PKC oscillations' (Fig. 22-4).

Release of intracellular Ca^{2+} may occur from 'calciosomes', a subfraction of the endoplasmic reticulum. Considerable evidence suggests that the major site of calcium sequestration and the source of intracellular calcium for signaling is the ER. In addition to the points already made, subcellular fractionation studies have demonstrated positive correlations of ATP-dependent Ca^{2+} accumulation and of IP_3-mediated Ca^{2+} release with classical enzymatic markers for ER. Calcium uptake into the IP_3-sensitive store is augmented by oxalate; this augmentation is a property generally associated with the ER.

However, there are some inconsistencies with the idea that the IP_3-sensitive calcium store and the ER are entirely coincident. For one, there is really no correlation between

the quantity of ER present in a given cell type and its sensitivity to calcium signaling through IP_3. In contrast to the studies cited above, there are at least an equal number of subcellular fractionation studies in which a separation of IP_3-induced Ca^{2+} release or IP_3 binding from enzymatic markers for the ER has been observed. Perhaps the sarcoplasmic reticulum of muscle presents the best characterized paradigm for an organelle distinct from generic ER and specialized for storing and releasing calcium (see Ch. 43). A biochemical characteristic of sarcoplasmic reticulum that distinguishes it from ER is the presence of high concentrations of a high-capacity, low-affinity calcium-binding protein, calsequestrin. A similar protein, calreticulin, found in nonmuscle cells, is structurally and functionally homologous to calsequestrin. On the basis of such findings, it has been proposed that an organelle specialized for storing and releasing calcium exists and that this organelle is distinct from generic ER. It has been proposed that this organelle be designated 'calciosome' [19].

With the exception of skeletal muscle, perhaps the Purkinje cell of the cerebellum has been most extensively characterized with respect to its Ca^{2+}-releasing and -sequestering organelles. The Purkinje cells of birds are especially amenable to immunocytochemical studies because they contain much higher concentrations of IP_3 receptors than any other cell type and unusually high concentrations of SERCA pumps and ryanodine receptors. In birds, the major calcium-storage protein, calsequestrin, is almost identical to the mammalian molecule. High-affinity antibodies, which facilitate immunocytochemistry, are available. In these bird Purkinje cells, IP_3 receptor distribution in membranes is not linked tightly to SERCA pumps or even to calsequestrin. However, a population of vacuoles positive for calsequestrin as well as for either the IP_3 receptor or the ryanodine receptor was found. These structures may qualify as calciosomes since presumably they are involved in storing as well as releasing calcium ion [20]. It has been suggested that specialized stacks of ER, rich in IP_3 receptor but without substantial quantities of SERCA pumps or calsequestrin, may act as either reservoirs of receptor or buffer of cytoplasmic IP_3. Interestingly, overexpression of IP_3 receptors in fibroblasts leads to the formation of structures similar to the IP_3 receptor-containing ER stacks found in Purkinje cells.

Although the existence of a specialized subcompartment of the ER is widely accepted [20], the term 'calciosome' has not gained universal acceptance. This may be due to the fact that in many systems the distinction between the calciosome and the ER is still not clearly established [21].

Ca^{2+}-signaling events in excitable and nonexcitable cells, although distinct, share some common characteristics. Traditionally, calcium-signaling studies have been divided into two separate categories: studies focusing on excitable cells, such as nerve and muscle, and studies focusing on electrically nonexcitable cells, such as epithelial or blood cells. Although both cell types utilize the release of intracellular Ca^{2+} as one means of generating cytoplasmic calcium signals, excitable cells often accomplish this by CICR while the predominant mechanism for nonexcitable cells involves IP_3 [22] (see also Ch. 20). Also, signaling in both cell types depends to a large degree on plasma membrane Ca^{2+} channels, but the Ca^{2+} channels in the plasma membrane of nonexcitable cells do not appear to be regulated by membrane potential, and their pharmacology is quite distinct from that of the channels in excitable cells. Even so, calcium-signaling mechanisms in excitable and nonexcitable cells may be much more alike than is generally appreciated. A shared paradigm involves coordinated regulation of intracellular calcium ion release and calcium ion entry across plasma membranes [22]. For reasons probably having to do with their distinct functions, interesting distinctions as well as similarities in basic mechanisms have evolved in these two general cell types.

In electrically nonexcitable cells, Ca^{2+} signaling is typically a biphasic process. Neurotransmitters and hormones cause a release of calcium ions to the cytoplasm from an intracellular organelle, and this is followed by entry of calcium ions into the cytoplasm across the plasma membrane. The intracellular-release phase of the calcium signal is attributable to IP_3, while the second phase of the response is attributed to capacitative calcium ion entry, a process of retrograde signaling such that the empty calcium-storage organelle produces a signal for calcium ion entry across the plasma membrane.

In many instances, neurons and other electrically excitable cells also utilize the IP_3-signaling system. For example, there are smooth muscle types which function in the IP_3 mode, the voltage-dependent calcium channel and CICR mode or even combinations of the two. In some instances, when intracellular calcium ions are released by IP_3 in excitable cells, this may be coupled to capacitative calcium ion entry, but there are clear examples where this is not the case. Rather, virtually all excitable cells have plasma membrane Ca^{2+} channels that are activated by membrane depolarization. In addition, excitable cells frequently express another intracellular Ca^{2+} release channel, the ryanodine receptor (discussed above). The physiological activator of the ryanodine receptor is believed to be Ca^{2+} itself: the channel opens when the Ca^{2+} concentration in its vicinity increases rapidly, generating CICR, and this can give rise to the regenerative 'all-or-none' calcium ion release behavior for which muscle and nerve cells are noted. In heart cells, for example, Ca^{2+} signaling is initiated by membrane depolarization, which activates surface membrane voltage-gated Ca^{2+} channels. A rapid entry of calcium ions serves as a 'trigger' for activating the ryanodine receptor and, subsequently, a much larger release of intracellular calcium ions [22].

The common conceptual feature of these two calcium-signaling motifs (Fig. 22-5) is that they provide a tight coordination of calcium ion entry and intracellular

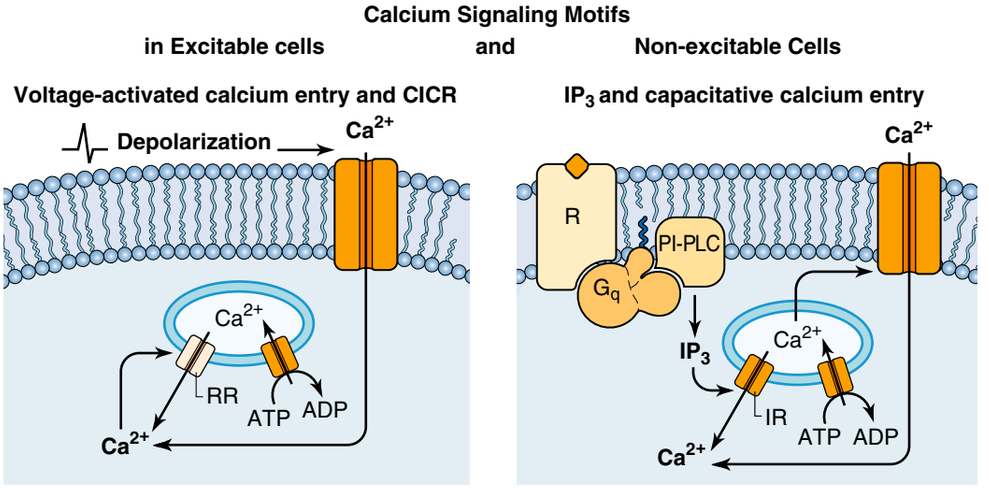

FIGURE 22-5 Motifs of $[Ca^{2+}]_i$ signaling. In electrically excitable cells (**left**), Ca^{2+} may enter when voltage-dependent Ca^{2+} channels are activated by the depolarization associated with action potentials. This Ca^{2+} can cause further release of intracellularly stored Ca^{2+} by activating a Ca^{2+}-induced Ca^{2+} release (*CICR*) mechanism associated with the ryanodine receptor (*RR*) Ca^{2+} channels. In electrically nonexcitable cells (**right**), signaling generally is initiated when an agonist activates a surface membrane receptor (*R*), which, usually, through a G-protein (G_q or G_i), activates phosphoinositide-specific phospholipase C (*PI-PLC*), which degrades phosphatidylinositol 4,5-bisphosphate, releasing the soluble messenger, inositol 1,4,5-trisphosphate (*IP_3*). IP_3 activates an IP_3 receptor (*IR*) and, thus, releases Ca^{2+} from an intracellular organelle to the cytoplasm. The release of Ca^{2+} from the organelle causes a signal to be generated, which activates a plasma membrane Ca^{2+} entry pathway, capacitative Ca^{2+} entry. (Modified with permission from reference [22].)

calcium ion release. They also provide amplification for the calcium signal but in functionally distinct ways. In excitable cells, the process of CICR amplifies the *magnitude* and *spatial distribution* of the momentary calcium signal, assuring, in the case of the heart for example, sufficient Ca^{2+} for catalyzing rapid cross-bridge formation and force development. In nonexcitable cells, the retrograde signaling provided by capacitative calcium ion entry amplifies the duration of the calcium signal, providing sustained, tonic responses of, for example, exocrine gland cells.

These characteristics of excitable and nonexcitable cells are not as distinct as once believed. For example, capacitative calcium ion entry contributes to calcium signaling in a number of excitable cells types [15]. Also, as discussed in the preceding section, the all-or-none regenerative calcium signals that occur in nerves and muscles now are known to occur in nonexcitable cells. Thus, it is interesting that while the term nonexcitable appropriately describes the electrophysiological behavior of their surface membranes, the regenerative intracellular Ca^{2+} spikes that often are exhibited by so-called nonexcitable cells constitute a clear example of excitable behavior of their intracellular milieu. This occurs because the IP_3 receptor functions as a CICR receptor whose sensitivity to Ca^{2+} is regulated by the binding of IP_3 and *vice versa*. Perhaps this is not so surprising, given the considerable homology between the amino acid sequences of the IP_3 and ryanodine receptors. Electrically nonexcitable cells generally contain a single, relatively homogeneous intracellular pool of calcium, which is sensitive to IP_3, while electrically excitable cells may have a more complex arrangement of several intracellular calcium pools, each regulated by a distinct mechanism.

Thus, there may be substantial similarity between Ca^{2+}-signaling systems in excitable and nonexcitable cells. It may be useful for neuroscientists and others traditionally focusing on excitable cells to take note of developments in the rapidly evolving field of calcium signaling and calcium channels in nonexcitable cells [22]. It is especially important to take cognizance of variations in calcium-signaling motifs in studies of the relationship between patterns of gene expression and specific calcium-signaling pathways.

Ca^{2+}-REGULATED PROCESSES

Ca^{2+} is required for acute cellular responses such as contraction or secretion. Sydney Ringer is credited with the first appreciation of the role of calcium as a regulator of cell function. He discovered that frog hearts beat longer *in vitro* if the saline solutions are made from 'hard' water rather than from distilled water, and with this observation the role of Ca^{2+} in excitation-contraction coupling was discovered [23] (see Ch. 43). Subsequently, Ca^{2+} was found to act as a signal for myriad cellular responses. It is a major component of the epithelial cell secretion signaling pathways, including both discharge of proteins and transepithelial secretion of salts and water. In the liver, Ca^{2+} regulates carbohydrate metabolism, including both glycogenolysis and gluconeogenesis (see Chs 31 and 42). In blood cells, various functions including secretion and chemotaxis are subtended by PI-PLC-dependent $[Ca^{2+}]_i$ signaling. Muscle contraction involves interaction of Ca^{2+} with calcium-binding proteins specific to the muscle type: in fast skeletal muscle, this protein is troponin and its binding of Ca^{2+} leads to disinhibition of myosin ATPase

(see Ch. 43). In other muscle types, regulation of the phosphorylation of myosin light chain is mediated by calcium.

In virtually all cases, the initial target of calcium is a specific calcium-binding protein. The most extensively characterized of these, calmodulin [24], was discovered as a regulator of cyclic nucleotide phosphodiesterase [24] (see Ch. 21) and it is now recognized as the most ubiquitous Ca^{2+}-sensing protein, found in all eukaryotic organisms including yeasts. Calmodulin has four binding sites for Ca^{2+} with dissociation constants in the 1–10 µmol/l range. Ca^{2+} binding induces a conformational change that imparts signaling information to a number of different molecules, including protein kinases and phosphatases.

Ca^{2+} also plays a role in more prolonged cellular events such as mitogenesis and apoptosis. Following mitosis, a cell must either commit to re-enter the cell cycle or exit into the quiescent state, G_0, in which a differentiated function is maintained (see Ch. 25). At a later time and with appropriate stimuli, many, but not all, cell types may re-enter the cell cycle to divide further. In circumstances in which a particular cell function is no longer needed, as in the case of the thymus, systemic signals may initiate the complex process of self-digestion and packaging, termed apoptosis [25] (apoptosis is discussed in Ch. 35). Mutations of key genes, the proto-oncogenes that control mitogenesis, can lead to inappropriate cell division or cancers. The mutated genes responsible for these transformations are called oncogenes. It is noteworthy, although perhaps not unexpected, that the vast majority of proto-oncogenes code for proteins involved in signal transduction pathways. One proto-oncogene, *bcl-2*, acts as a suppressor of apoptosis. Consequently, if it is expressed in excess, cancerous growth can result.

Ca^{2+} signaling is believed to play an important role in the regulation of cell growth and differentiation [26] as well as in apoptosis [25] (discussed below). Ca^{2+} is generally required for the activation of mitogenesis and, in many instances, increases in $[Ca^{2+}]_i$ have been associated with the actions of mitogenic agents: calcium ionophores or thapsigargin can stimulate DNA synthesis, especially if combined with a PKC activator such as an active phorbol ester. Although not proven, this action of phorbol esters may explain their well-known tumor-promoting activity.

In addition to being regulated by cytoplasmic Ca^{2+}, there is evidence that mitogenesis may be regulated by intracellular Ca^{2+} stores, perhaps via capacitative calcium ion entry. Interestingly, depletion of intracellular stores by thapsigargin can induce either mitogenesis, a quiescent G_0 state, or apoptosis, depending on the cell lines studied. These differential effects could result from thapsigargin-induced Ca^{2+} signals or from inhibition of protein synthesis due to diminished concentrations of stored Ca^{2+}. The concentration of ER Ca^{2+} plays an important role at several steps in protein synthesis. In instances in which prolonged treatment with thapsigargin induces apoptosis, inhibition of protein synthesis may contribute to this process.

Sustained increases in intracellular Ca^{2+} have various toxic effects on cells [27]. However, in the case of thapsigargin toxicity, it appears that the cells are killed by the specific, genetically programmed process known as apoptosis. When cells die as a result of toxic insult, the process is often one of necrosis. This is a relatively nonspecific process involving cell lysis, the release of cellular contents, which subsequently must be 'cleaned up' by the immune system, involving an inflammatory reaction. However, complex organisms also have the need for cells to die at appropriate times in development and in maintenance of normal organ function. In such instances, a more orderly, noninflammatory process of programmed cell death, or apoptosis, occurs. This involves degradation of nuclear DNA by specific endonucleases, resulting in the characteristic DNA ladders that are diagnostic of apoptosis; cellular shrinkage; and ultimately the packaging of cellular constituents in membrane-delimited structures, known as apoptotic bodies, for disposition by leukocytes [25] (see also Ch. 35).

There is considerable evidence for a role of Ca^{2+} signaling in apoptosis [28], and it is interesting to note that the above mentioned Bcl-2, which acts as a suppressor of apoptosis, has been located in mitochondria and ER, organelles involved in Ca^{2+} homeostasis. In one form of apoptosis, induced by glucocorticosteroids, studies have identified a Ca^{2+} influx associated with lymphoid cell death. In addition, the action of glucocorticoids to induce apoptosis could be mimicked by Ca^{2+} ionophores. Similarly, thapsigargin triggers a full apoptotic response. Chelation of Ca^{2+} by intracellular chelators, extracellular ethyleneglycotetraacetic acid (EGTA) or overexpression of the Ca^{2+}-binding protein calbindin inhibits apoptosis due to glucocorticoids and other agents. Finally, calmodulin antagonists have been reported to disrupt apoptosis in a variety of systems. Together, these data suggest a central role for Ca^{2+} in apoptosis in response to glucocorticoids and other agents [29]. However, there is also evidence that, in addition to changes in cytoplasmic calcium ion serving as a signal or modulator for apoptosis, a fall in the concentration of Ca^{2+} in the ER can signal a full apoptotic response, independently of the associated rise in cytoplasmic Ca^{2+} [30]. It is not clear at this time whether this response proceeds through the same signaling pathway involved in capacitative calcium ion entry.

PROTEIN PHOSPHORYLATION IS OF FUNDAMENTAL IMPORTANCE IN BIOLOGICAL REGULATION

Protein phosphorylation is the major molecular mechanism through which protein function is regulated in response to extracellular stimuli both inside and outside the nervous system. Virtually all types of extracellular signal, including neurotransmitters, hormones, light, neurotrophic factors and cytokines, produce most of their diverse physiological effects by regulating phosphorylation of specific phosphoproteins in their target cells. Roughly one third of all proteins in eukaryotes are phosphorylated and virtually every class of neuronal protein is regulated by phosphorylation. The process is reversible, enabling cells to respond dynamically to a myriad of signals in the environment. Although proteins are covalently modified in many other ways, including ADP-ribosylation, acylation (acetylation, myristoylation, isoprenylation), carboxymethylation, tyrosine sulfation and glycosylation, none of these mechanisms is nearly as widespread and readily subject to regulation by physiological stimuli as is phosphorylation. Thus, protein phosphorylation is by far the most prominent mechanism of neural plasticity, an idea first proposed by Paul Greengard more than 30 years ago. In this chapter, we present an overview of the vital role played by protein phosphorylation in the regulation of neuronal function.

Regulation of protein phosphorylation involves a protein kinase, a protein phosphatase and a substrate protein. These components interact according to the scheme shown in Figure 23-1. A substrate protein is converted from the dephospho form to the phospho form by a protein kinase, and the phospho form is converted back to the dephospho form by a protein phosphatase [1].

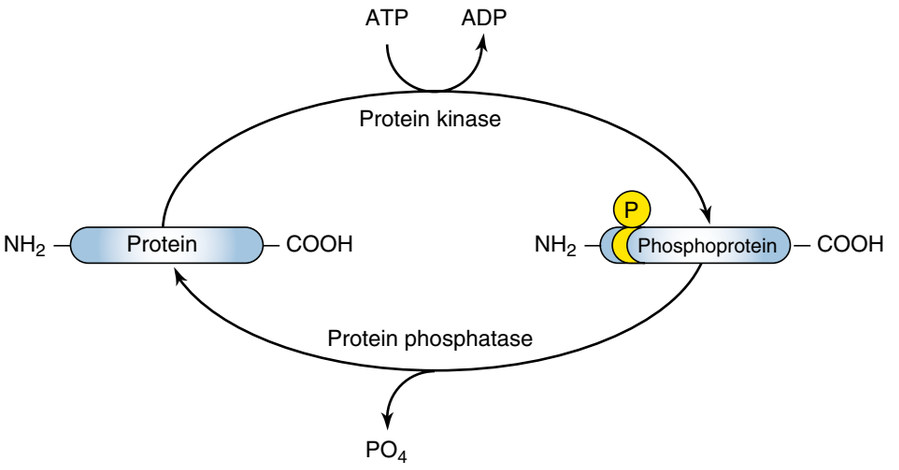

FIGURE 23-1 Schematic diagram of the conversion of a dephosphoprotein to a phosphoprotein by a protein kinase and the reversal of this reaction by a protein phosphatase.

Protein kinases constitute one of the largest single enzyme families and account for 1.7% of all human genes. The protein kinase complement of the human genome, 'the kinome', is made up of 518 protein kinase genes [2]. Figure 23-2 shows a dendrogram constructed by comparisons of the genomic sequences of model organism kinomes, which illustrates the complexity of this diverse family of enzymes. Protein kinases are classified as protein serine–threonine kinases, which phosphorylate substrate proteins on serine or threonine residues, or as protein tyrosine kinases, which phosphorylate substrate proteins on tyrosine residues (discussed in Ch. 24). A small number of protein kinases, as will be seen below, are referred to as 'dual-function' kinases because they phosphorylate substrate proteins on serine, threonine and tyrosine residues. Over 95% of protein phosphorylation occurs on serine residues, 3–4% on threonine residues, and less than 1% on tyrosine residues. In all cases, the kinases catalyze the transfer of the terminal (γ) phosphate group of ATP to the hydroxyl moiety in the respective amino acid residue; Mg^{2+} is required for this reaction. Protein phosphatases catalyze the cleavage of these phosphoester bonds through hydrolysis.

Because phosphate groups are negatively charged, phosphorylation of a protein alters its charge, which can then alter the conformation of the protein and ultimately its functional activity. A change in the state of protein phosphorylation can be achieved physiologically through increases or decreases in the activity of either protein kinases or protein phosphatases. Examples of each of these mechanisms occur in the nervous system, often in concert with one another, to elicit complex temporal patterns of protein phosphorylation.

A general scheme of the diverse pathways through which extracellular signals regulate neuronal function through protein phosphorylation is illustrated in Figure 23-3. Two major mechanisms are involved. In one, extracellular signals, or first messengers, regulate protein kinases or protein phosphatases indirectly by acting on plasmalemma receptors, thereby regulating the intracellular concentration of a second messenger in target neurons [1]. This is the case for first messengers that act through G-protein-coupled receptors, including receptors for many neurotransmitters, hormones, cytokines and sensory stimuli such as visible light and odorants (Ch. 19). It also holds for first messengers that act through receptors containing intrinsic ion channels, such as some glutamate, GABA and acetylcholine receptors (see Ch. 10). Prominent second messengers in the nervous system that directly activate protein kinases include cAMP, cGMP (Ch. 21), Ca^{2+} and diacylglycerol (DAG; see Ch. 20). The next steps in these pathways are the activation of specific classes of protein serine–threonine kinases or protein phosphatases by these second messengers and the subsequent phosphorylation or dephosphorylation of specific substrate proteins, leading, through one or more steps, to specific biological responses.

In the other major mechanism, first messengers directly regulate protein kinase and phosphatase activities by acting on plasma membrane receptors that possess the enzyme activity within their cytoplasmic domains. This is the case for most types of neurotrophic factors as well as many cytokines (Ch. 27). The intrinsic protein kinase and phosphatase activities are stimulated upon ligand binding, which leads to changes in the phosphorylation state of specific substrate proteins and to the generation of specific biological responses.

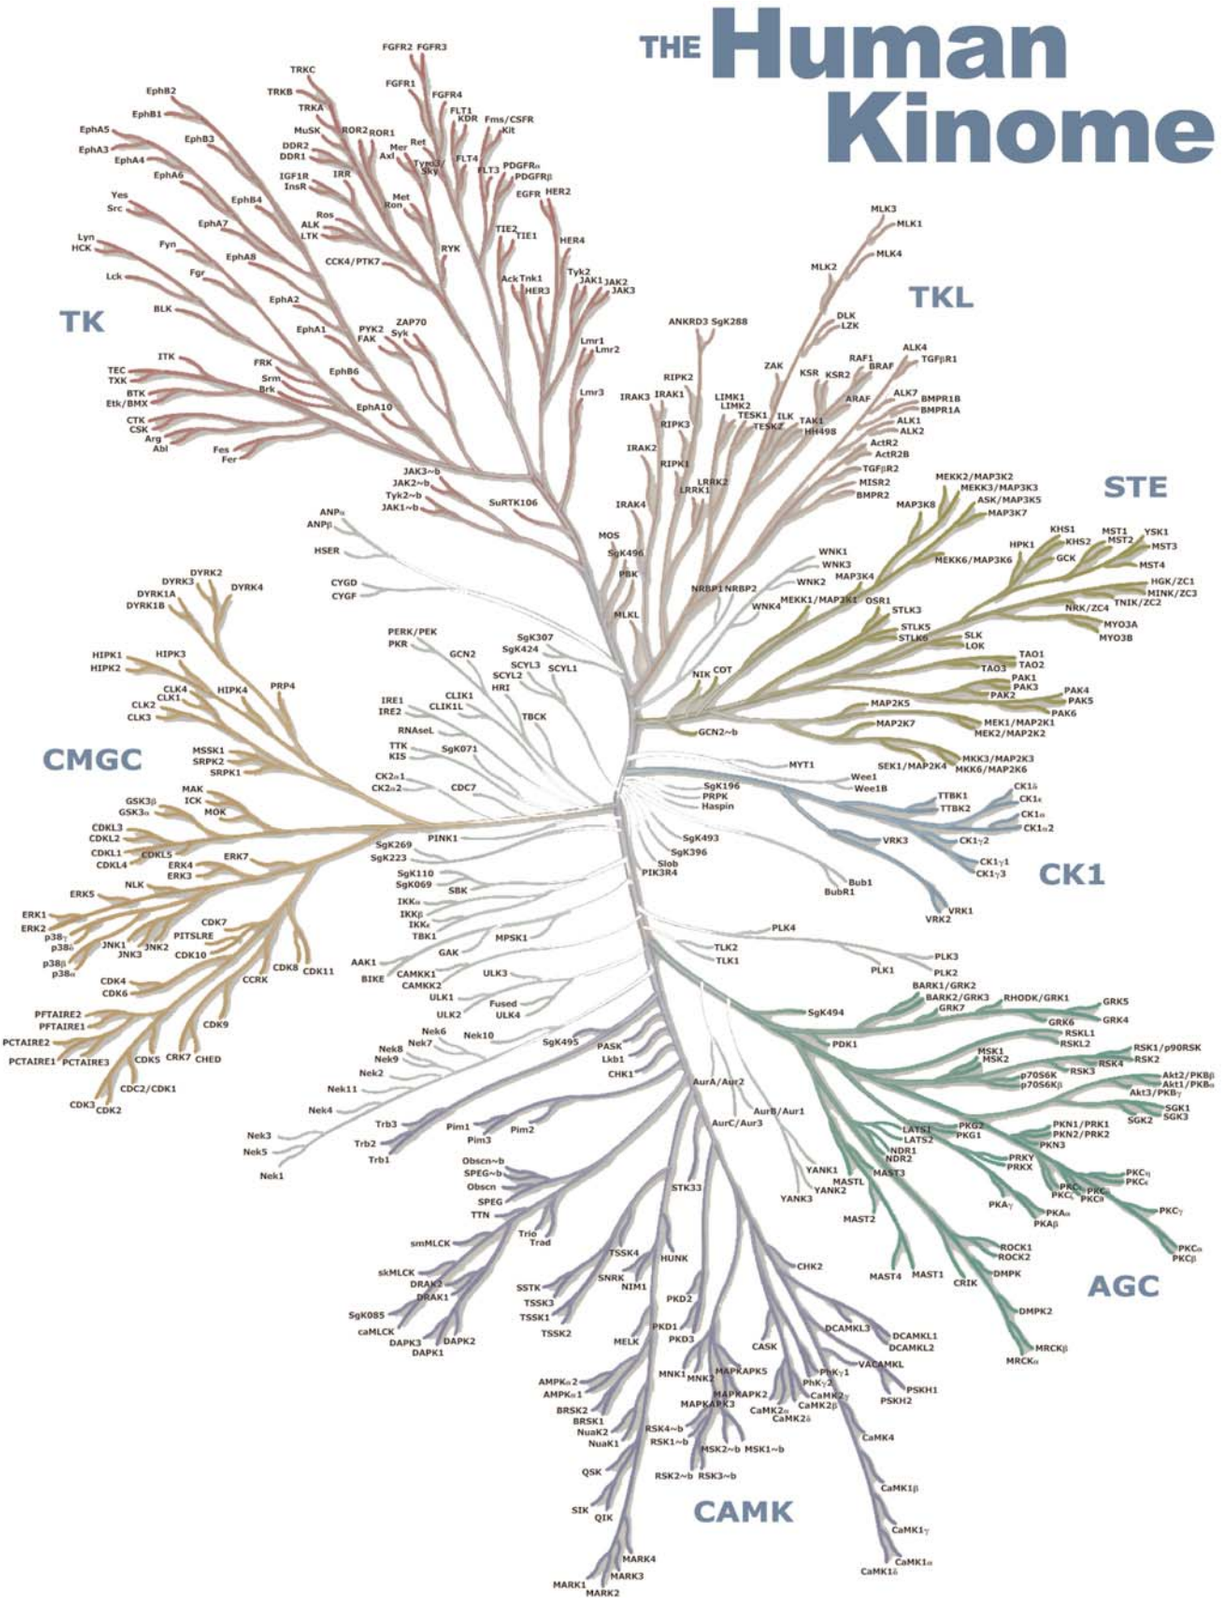

FIGURE 23-2 The human kinome. This dendrogram or phylogenetic tree demonstrating the complexity of the protein kinase superfamily shows the relationships between different protein kinase groups. Group names: AGC includes PKA, PKG, and PKC families; CAMK, Ca^{2+}/calmodulin-dependent protein kinase; CKI, cell kinase1; CMGC includes CDK, MAPK, GSK3, CLK families; TK, tyrosine kinase; TKL, tyrosine-kinase-like; STE are members of the MAPK cascade and include homologs of yeast Sterile 7, Sterile 11, Sterile 20 kinases. Related information can be found at www.kinase.com. (Adapted from the original article [2] with permission from *Science* and Michael Melnick of Cell Signaling Technologies – www.cellsignal.com.)

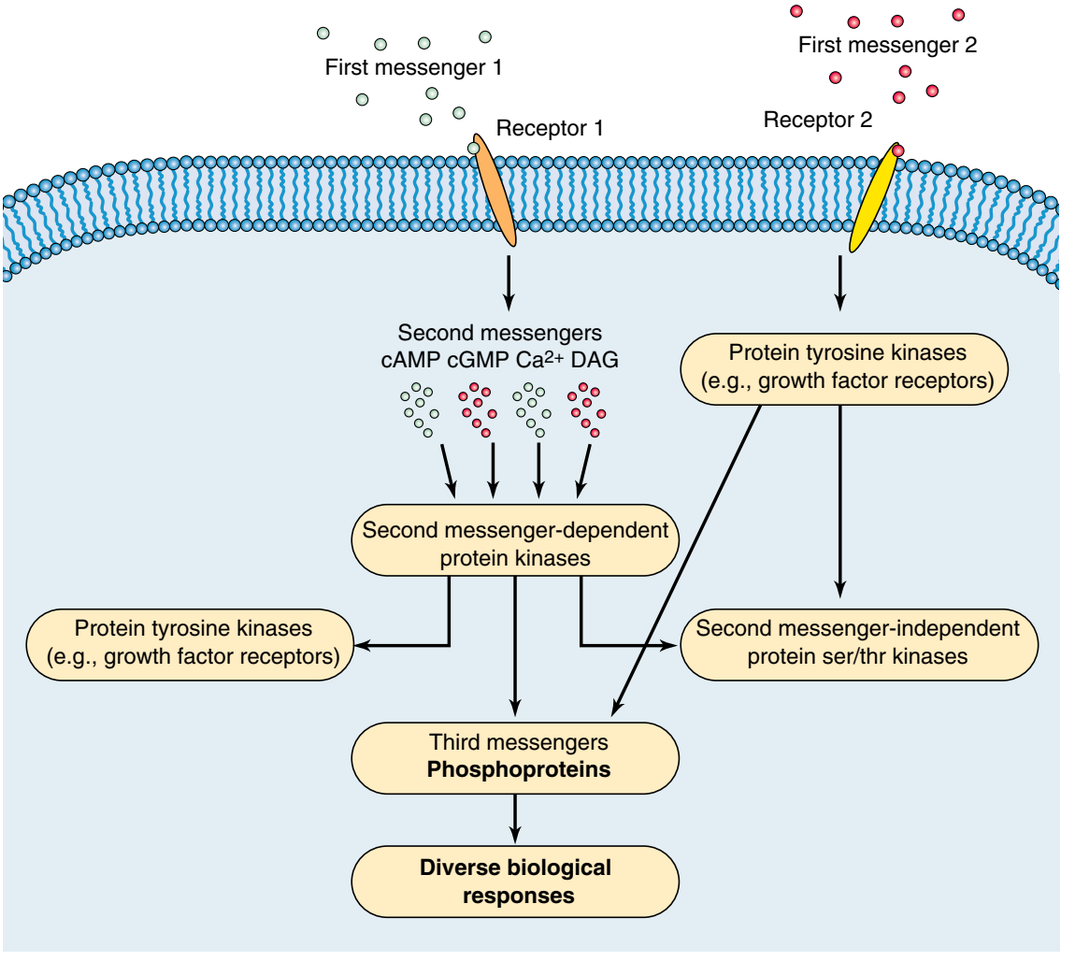

FIGURE 23-3 Signals in the brain. Extracellular signals, termed first messengers, produce specific biological responses in target neurons via a series of intracellular signals, termed second or third messengers. Second messengers in the brain include cAMP, cGMP, Ca^{2+} and diacylglycerol (*DAG*). cAMP and cGMP produce most of their second-messenger actions through the activation of cAMP-dependent and cGMP-dependent protein kinases, respectively. Ca^{2+} exerts many of its second-messenger actions through the activation of Ca^{2+}-dependent protein kinases, as well as through a variety of physiological effectors other than protein kinases. Not illustrated in the figure is the fact that some protein phosphatases can also be regulated directly by second messengers, for example calcineurin, which is activated by Ca^{2+}. The brain also contains a large number of other protein serine–threonine kinases (Table 23-1) that are not activated directly by second-messenger pathways or by protein tyrosine kinases. The brain and other tissues contain two major classes of protein tyrosine kinases. Some of these enzymes are physically associated with plasmalemma receptors, such as most growth factor receptors, and become activated upon ligand binding to the receptors. Others, such as src, are not physically associated with receptors but are influenced indirectly by both second-messenger pathways and receptor protein tyrosine kinases.

PROTEIN SERINE–THREONINE KINASES

Protein kinases differ in their cellular and subcellular distribution, substrate specificity and regulation. These properties determine the functional roles played by the very large number of protein kinases that have been found in mammalian tissues, most of which are known to be expressed in neurons [3]. The major classes of protein serine–threonine kinase in the brain, listed in Table 23-1, are covered in this chapter. The major classes of protein tyrosine kinases in the brain are discussed in Chapter 24. Among the best studied protein kinases in the brain are those activated by the second messengers cAMP, cGMP, Ca^{2+} and DAG [4, 5].

cAMP-dependent protein kinase (protein kinase A; PKA) was first discovered by Edwin Krebs, Edmond Fisher and colleagues and is composed of catalytic and regulatory subunits. The holoenzyme of the kinase, which consists of a tetramer of two catalytic (C) and two regulatory (R) subunits, is inactive. cAMP activates the holoenzyme by binding to the regulatory subunits, thereby causing dissociation of the holoenzyme into a free regulatory subunit dimer and free active catalytic subunits [6].

TABLE 23-1 Major classes of protein serine–threonine kinases

Second-messenger-dependent protein kinases	Protein kinase A (cAMP kinase)
	Protein kinase G (cGMP kinase)
	Ca^{2+}/calmodulin kinases (CaM kinases)
	Protein kinase C
MAP kinases	ERKs
	JNKs or SAPKs
MAP kinase-regulating kinases	MEKs
	SEKs
	Raf
	MEK kinases
Cdks	Cdk1
	Cdk5
CDK-regulating kinases	CAK
	CAK kinase
GRKs	
Others	RSKs
	Cell kinases (CK1)
	IκB kinase (IKK)
	GSK3β

This list is not intended to be comprehensive. The protein kinases listed are present in many cell types in addition to neurons and are included here because of their multiple functions in the nervous system, including regulation of neuron-specific phenomena. Not included are other protein kinases present in diverse tissues, including brain, that play a role in generalized cellular processes, such as intermediary metabolism, and that may not play a role in neuron-specific phenomena. CAK, CDK-activating kinase; CDK, cyclin-dependent kinase; ERK, extracellular signal-regulated kinase; GRK, G protein receptor kinase; JNK, Jun kinase; MAP kinase, mitogen activated protein kinase; MEK, MAP kinase and ERK kinases; RSK, ribosomal S6 kinase, GSK, glycogen synthase kinase; SAPK, stress-activated protein kinase; SEK, SAPK kinase.

Neurotransmitter receptors that are coupled to G protein complexes that stimulate or inhibit cAMP synthesis have as their target PKA, which is the most important effector for this cyclic nucleotide (see Ch. 21). cAMP phosphodiesterases which hydrolyze this second messenger represent a second mechanism controlling PKA activity. Three isoforms of the C subunit, each of about 40 kDa, and four isoforms of the R subunit, each of 50–55 kDa, have been cloned from mammalian tissues. The three C subunits, designated Cα, Cβ and Cγ, exhibit a very similar and broad substrate specificity, i.e. they phosphorylate a large number of physiological substrate proteins, and can generally be considered isoforms of one another. The four R subunits consist of two forms each of type I and type II proteins. RIIα and RIIβ, but not RIα and RIβ, undergo autophosphorylation, as described below. Most of these R and C subunits of the protein kinase show a wide cellular distribution in the brain.

PKA activity is present throughout the cell, associated with the plasma membrane as well as cytoplasmic and nuclear fractions. The kinase is highly compartmentalized within the cell, in large part via a series of anchoring proteins, termed A kinase anchor proteins (AKAPs) [7]. Several forms of AKAP are known, many of about 75–79 kDa. AKAPs bind specifically with the RIIα and RIIβ subunits of the protein kinase and thereby tether these regulatory subunits and their bound catalytic subunits to specific subcellular sites, for example postsynaptic densities. Postsynaptic densities are specializations in distal dendrites that appose presynaptic nerve terminals and contain some of the neurotransmitter receptors and other proteins required for synaptic transmission. In this way, AKAPs keep the protein kinase in close proximity to the cascade of signal transduction proteins it phosphorylates to regulate synaptic transmission. The important role played by AKAPs under physiological conditions is indicated by experiments in which synthetic polypeptides that disrupt AKAP–RII interactions have been shown to disrupt specific physiological effects of PKA [7].

cGMP-dependent protein kinase (PKG) is a dimer of two identical subunits. Each subunit, with an M_r of ≈75 kDa, contains a regulatory domain, which binds cGMP, and a catalytic domain [8]. As with the cAMP-dependent enzyme, cGMP activates the inactive holoenzyme by binding to the regulatory domain of the molecule; however, unlike the cAMP-dependent enzyme, activation of the cGMP-dependent holoenzyme is not accompanied by dissociation of the subunits. PKG shows a much more limited cellular distribution and substrate specificity than PKA. This reflects the smaller number of second-messenger actions of cGMP in the regulation of cell function. The first messenger, nitric oxide, stimulates cGMP production by directly activating guanylyl cyclases (see Ch. 21). cGMP phosphodiesterases hydrolyze cGMP and are the pharmacological targets of therapeutic agents such as sildenafil used to treat erectile dysfunction [9].

Calcium/calmodulin-dependent protein kinases (CaM kinases; CaMKs) are one of two major classes of calcium-dependent kinases in the nervous system. The brain contains at least six major types of CaMK, each with very different properties. CaMKII is abundant in the CNS and, like PKA, exhibits a broad cellular distribution and substrate specificity and can be considered a 'multifunctional protein kinase' in that it probably mediates many of the second-messenger actions of Ca^{2+} in many types of neuron [10] (Ch. 22). CaMKII contains a regulatory domain that, in the resting state, binds to and inhibits a catalytic domain; this inhibition is relieved when Ca^{2+}/calmodulin binds to the regulatory domain. The enzyme exists under physiological conditions as large multimeric complexes of identical or distinct subunit isoforms of 50–60 kDa. In response to intense stimulation of glutamate receptors, CAMKII is autophoshorylated and becomes active in a Ca^{2+}/calmodulin-independent manner [11] (see Ch. 15). Because of this stimulation-sensor capability, CaMKII, more than any other protein kinase, has been implicated in the synaptic plasticity underlying learning and memory [11] (see Ch. 53).

CaMKs I and IV also appear to play important roles in mediating many of the second-messenger actions of Ca^{2+} in the nervous system, although their substrate specificity remains only partially known. One interesting feature of CaMKs I and IV is that both appear to be activated not only by Ca^{2+}/calmodulin-binding but also upon their phosphorylation by other protein kinases, which have been termed CaMKI kinase and CaMKIV kinase respectively. These CaMK kinases may also be Ca^{2+}/calmodulin-dependent enzymes. CaMKIV kinase has been cloned. Interestingly, this kinase is itself phosphorylated and inhibited by PKA, thereby providing a prominent mechanism by which the cAMP and Ca^{2+} cascades interact, as will be covered in greater detail below.

The remaining three types of CaMK are phosphorylase kinase, myosin light-chain kinase and CaMKIII. These each appear to phosphorylate fewer substrate proteins, and in some cases only one protein, under physiological conditions, and each may therefore mediate relatively fewer actions of Ca^{2+} in the nervous system.

Protein kinase C (PKC) comprises the other major class of Ca^{2+}-dependent protein kinases and is activated by Ca^{2+} in conjunction with DAG and phosphatidylserine (discussed in Ch. 20). Multiple forms of PKC have been cloned, and the brain is known to contain at least seven species of the enzyme. The variant forms of PKC exhibit different cellular distributions in the brain and different regulatory properties. For example, they differ in the relative ability of Ca^{2+} and DAG to activate them: some require both Ca^{2+} and DAG, whereas others can be activated by DAG alone, apparently without an increase in cellular Ca^{2+} concentrations. However, these enzymes show similar substrate specificities and, as a result, are often considered isoforms.

PKC exists under physiological conditions as single polypeptide chains of about 80 kDa. Each polypeptide contains a regulatory domain, which, in the resting state, binds to and inhibits a catalytic domain. This inhibition is relieved when Ca^{2+} and/or DAG binds to the regulatory domain. PKC exhibits a broad substrate specificity and mediates numerous second-messenger functions of Ca^{2+} in target neurons.

Under basal conditions, PKC is predominantly a cytoplasmic protein. Upon activation by Ca^{2+} or DAG, the enzyme associates with the plasma membrane, the site of many of its known physiological substrates, including receptors and ion channels. In fact, the translocation of PKC from the cytoplasm to the membrane has long been used as an experimental measure of enzyme activation. Such translocation has often been assayed by phorbol ester binding; phorbol esters are tumor-promoting agents that selectively bind to and activate PKC. The molecular basis of the translocation of PKC from the cytoplasm to the plasma membrane has been solved. Subsequent to activation, PKC binds with high affinity to a series of membrane-associated proteins, termed receptors for activated C kinase (RACK) [12]. RACKs thereby function by analogy with the AKAPs for PKA to direct or recruit these widely expressed enzymes to subcellular sites where their activity is required.

Diverse actions of extracellular signals are mediated by second-messenger-dependent protein kinases. The intracellular application, by microinjection or transfection of PKA, PKG, CaMKII or PKC into particular types of neuron has been shown to mimic specific physiological responses (regulation of ion channels, neurotransmitter release and gene transcription) to specific first messengers (neurotransmitters or nerve impulses) for those neurons. Where specific inhibitors of the kinases are available, their application has been shown to block the ability of the neurotransmitters to elicit those responses. Taken together, these findings demonstrate that activation of these second-messenger-dependent protein kinases is both a necessary and sufficient step in the sequence of events by which certain first messengers produce some of their physiological effects.

Transgenic methodologies have provided further evidence for the importance of second-messenger-dependent protein kinases in the regulation of brain signal transduction. The best example to date is provided by mice lacking subunits of CaMKII. These animals show deficiencies in a form of synaptic plasticity, long-term potentiation, in the hippocampus as well as abnormal spatial learning, a form of learning dependent on hippocampal function (see also Ch. 53).

The mitogen-activated protein kinase cascade is second-messenger-independent. Although the second-messenger-dependent protein kinases were identified first as playing an important role in neuronal function, we now know that many other types of protein serine–threonine kinase are also essential (Table 23-1). Indeed, one of the most critical discoveries of the 1990s was the delineation of the mitogen-activated protein kinase (MAP kinase or MAPK) cascades.

MAPKs were first described as mitogen-activated protein-kinases and shown to play an important role in cell growth. The same enzymes were described in brain as 'microtubule-associated protein kinases' for their phosphorylation of microtubule-associated proteins and other neuronal cytoskeletal proteins (see Ch. 8). However, the mechanisms by which the activity of the enzymes were controlled by extracellular signals remained a mystery until these mechanisms were elucidated largely through advances in yeast signal transduction and the subsequent identification of homologous signaling proteins in mammalian cells.

The basic scheme for MAPK cascades is shown in Figure 23-4. MAPK is part of a 'phosphorelay' system composed of three sequentially activated kinases [13]. MAPK, inactive under basal conditions, is activated by phosphorylation by another protein kinase, termed

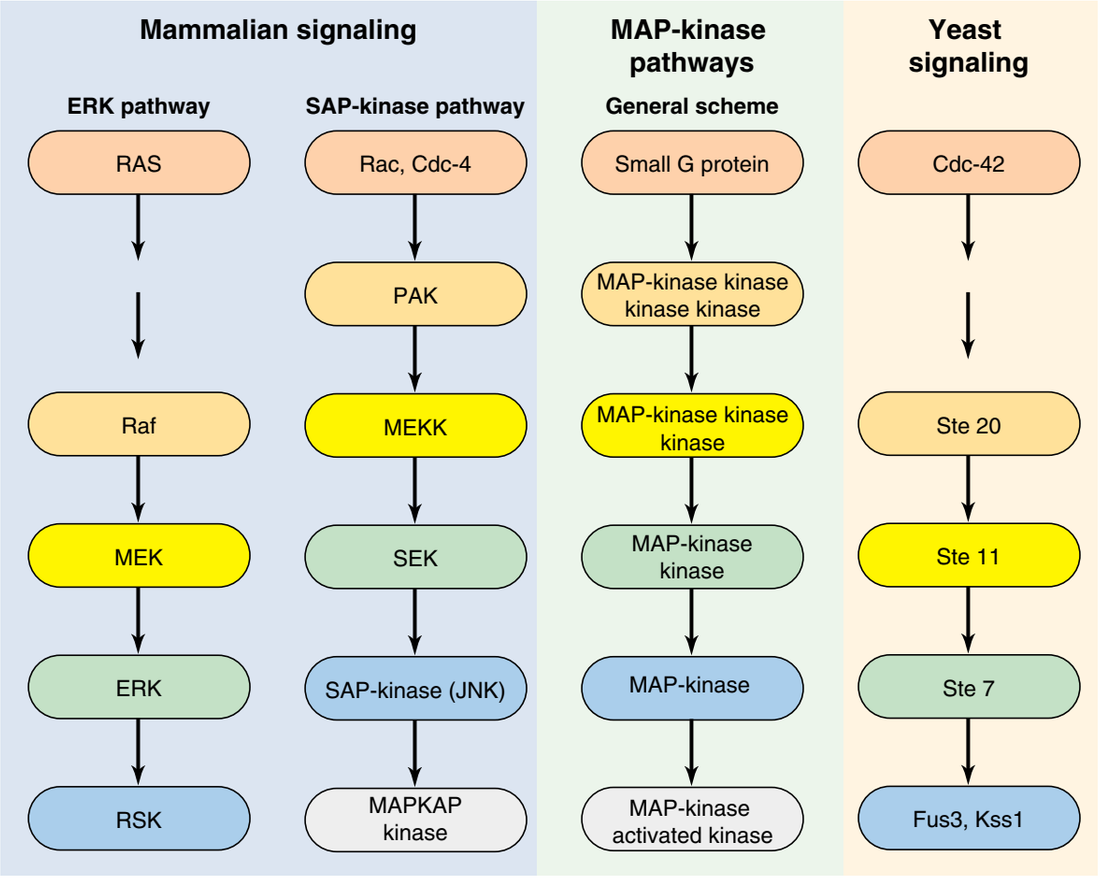

FIGURE 23-4 Schematic diagram of mitogen-activated protein kinase (*MAP-kinase*) pathways. To the **right** is shown the original pathway delineated in yeast. To the **left** are shown the homologous pathways more recently identified in mammalian cells, including brain. *ERK*, extracellular signal-regulated kinase; *JNK*, Jun kinase; *MAPKAP kinase*, MAP-kinase-activated protein kinase; *MEK*, MAPK and ERK kinase; *MEKK*, MEK kinase; *PAK*, p21-activated kinase; *RSK*, ribosomal S6 kinase; *SAP-kinase*, stress-activated protein kinase; *SEK*, SAP-kinase kinase.

MAPK kinase (MAPKK). MAPK kinase itself is activated by phosphorylation by still another protein kinase, termed MAPK kinase kinase (MAPKKK). MAPK kinase kinase is activated upon interaction with a member of the Ras superfamily of small G proteins, which are bound to the plasma membrane (see Ch. 19). The exact mechanism of activation remains unknown, but it is believed that Ras and related proteins, in the activated GTP-bound form, can bind MAPK kinase kinase and thereby draw the kinase to the plasmalemma, where it is activated by as yet unknown factors, perhaps even an additional kinase, MAPK kinase kinase kinase (MAPKKKK). The mechanism governing the activation of Ras and related proteins by extracellular signals is quite complex and involves numerous 'linker' proteins, for example Shc, Grb and Sos, that couple Ras to a variety of plasmalemma-associated growth factor–protein tyrosine kinase receptors (see Chs 20, 24 and 27).

The best characterized family of MAPKs in the brain are the *extracellular signal-regulated protein kinases* (ERKs) that are activated by the neurotrophins and related growth factors (Fig. 23-4) [14, 15]. The MAPK kinases responsible for phosphorylation and activation of the ERKs are referred to as *MAPK and ERK kinases* or MEKs. MEK phosphorylates ERK on a threonine and tyrosine residue, both of which are required for ERK activation. MEK is, therefore, an example of a dual-function protein kinase that can phosphorylate a substrate protein on these two types of residue. The phosphorylated threonine and tyrosine residues in all known forms of ERK are separated by a single amino acid, giving rise to the conserved threonine–amino-acid–tyrosine sequence (T–X–Y). The MAPK kinase kinases responsible for MEK activation include a group of protein serine–threonine kinases termed Raf. Raf, in turn, is activated in part by one of three known forms of Ras, which is activated in response to the binding of many types of growth factors to their receptors. Thus, the neurotrophins, such as nerve growth factor (NGF), brain-derived neurotrophic factor (BDNF) and related growth factors, such as epidermal growth factor and insulin, bind to plasma membrane receptors that possess intrinsic protein tyrosine kinase activity in their cytoplasmic domains. Activation of this

activity upon growth factor binding leads to Ras activation via a cascade of linker proteins, as mentioned above (see Ch. 27).

The brain contains numerous forms of ERK, MEK and Raf (designated ERK1, 2, 3; MEK1, 2; Raf 1, 2, 3; and so on), which are expressed in distinct populations of neurons. Given that the major activators of the ERK cascade are growth factors, it is not surprising that these enzymes have been implicated in neuronal growth, differentiation and survival. Moreover, it has become apparent that these enzymes also are likely to play a role in synaptic transmission in the adult nervous system.

A second family of MAPKs is referred to as *stress-activated protein kinases* (SAPKs) [3, 14, 15]. This includes JNKs, or Jun kinases, named originally for their phosphorylation of the transcription factor c-Jun. SAPKs were first identified in peripheral tissues on the basis of their activation in response to cellular forms of stress, which include X-ray irradiation and osmotic stress. More recently, they have been demonstrated to be activated in brain by several cytokines as well as by synaptic activity [16]. As shown in Figure 23-3, SAPKs are activated by SAPK kinases (SEKs), which are in turn activated by SEK kinases. The Ras-like small G proteins implicated in SEK kinase activation are Rac and Cdc-42. In this case, it appears that Rac/Cdc-42 triggers activation of SEK kinase by stimulating its phosphorylation by still another protein kinase termed p21-activated kinase (PAK). Thus, PAK can be considered a MAPK kinase kinase kinase, which is analogous to the cascade of protein kinases found in yeast (Fig. 23-4).

A dramatic feature of MAPK cascades is the series of successive protein kinases involved. While the evolutionary basis of such cascades remains unknown, they clearly evolved very early and could provide the basis for explosive amplification of an initiating extracellular signal that acts on very rare plasmalemma receptors. A major challenge in current research is to define the precise mechanisms for the myriad effects of MAPKs by identifying their physiological substrate proteins. Among their best-characterized substrate proteins are transcription factors [3, 14, 15] (see Ch. 26). Phosphorylation of c-Jun by JNK is thought to increase transcriptional activity of c-Jun. Elk-1, also a transcription factor, is phosphorylated and activated by ERK. Upon phosphorylation, Elk-1 complexes with other proteins to form serum response factor, which binds to the serum response element present in the promoters of numerous genes, including c-Fos, another transcription factor (details of transcription are found in Ch. 26).

A third group of MAPKs are p38 kinases, of which there are four subtypes: α, β, γ, and δ. P38 MAPKs are activated by many stimuli including hormones, ligands for G-protein-coupled receptors and stresses [13, 17]. P38 MAPK has been implicated in the pathological changes accompanying inflammatory and apoptotic processes of various cell types, including neurons [17] (see Ch. 35 for discussion of apoptosis). More recently, several additional MAPKs such as ERK5 [18], ERK7 [19] and ERK8 [20] have been identified, which may constitute additional MAPK groups.

Other classes of proteins are also known to be physiological substrates for the MAPKs. Tyrosine hydroxylase, the rate-limiting enzyme in the synthesis of catecholamine neurotransmitters, is phosphorylated by ERK, which appears to increase the activity of the enzyme in response to other activating stimuli (see below and Ch. 12). Phospholipase A_2, the first enzyme in the generation of prostaglandin and related metabolites of arachidonic acid, is phosphorylated and activated by ERK (Ch. 33). Cytoskeletal proteins, such as microtubule-associated proteins and tau (see below), are also prominent substrates, although the precise effect phosphorylation has on the physiological activity of these proteins remains poorly understood. Finally, among the substrates for the MAPK are still other protein kinases. Thus, one important effector mechanism for ERK is phosphorylation and activation of ribosomal S6 kinases (RSKs), protein serine–threonine kinases first identified for their phosphorylation and regulation of ribosomal proteins but now known to phosphorylate other types of substrate, including the transcription factor cAMP response element binding protein (CREB) (Ch. 26). An analogous motif is seen for the SAPKs, which also appear to produce some of their biological effects via the phosphorylation and activation of other serine–threonine kinases, such as MAPK-activated protein kinase (MAPKAP).

The brain contains many other types of second-messenger-independent protein kinases. Examples of other second-messenger-independent protein kinases are listed in Table 23-1. Many of these include enzymes that were identified originally in association with a particular substrate protein but shown later to play a more widespread role in brain signal transduction. The functional role of one of these, β-adrenergic receptor kinase (βARK), a type of G protein receptor kinase (GRK), is discussed further below.

Other examples of protein serine–threonine kinases are the cyclin-dependent kinases (CDKs), identified originally for their role in the control of the cell cycle. Such kinases, again identified originally in yeast, are among a large number of proteins termed cell division cycle (Cdc) proteins. Most CDKs are activated through association with cofactors called cyclins and phosphorylation by upstream protein kinases termed CDK-activating kinases (CAKs). An atypical member of the CDK family is CDK5 [21]. CDK5 is highly enriched in neurons and functions during CNS development as well as in fully differentiated adult neurons. Its activity is dependent upon association with the neuron-specific cofactors p35 or p39. CDK5 has been implicated in a broad number of CNS functions, including cortical layer formation, learning and memory, cytoskeletal dynamics, synaptic vesicle recycling, and

regulation of dopamine neurotransmission [22]. It has also been implicated in several neurological and neuropsychiatric disorders such as drug addiction [23, 24], Alzheimer's and Parkinson's disease and amyotrophic lateral sclerosis, and is further discussed in the relevant chapters. The list of physiological substrates for CDK5 is growing and includes activators of protein kinases such as MEK1 and inhibitors of protein phosphatases such as inhibitor-1 and DARPP-32 (discussed below).

Another example of a second-messenger-independent serine–threonine kinase is Iκ-kinase (IKK), which regulates the NFκB (nuclear factor κB) transcription factor. This system is classically known to be involved in inflammatory responses and carcinogenesis but in recent years has been implicated in signal transduction mechanisms in the nervous system [25]. Briefly, in response to cytokines or other first messengers, IKK becomes activated and phosphorylates IκB subunits that are bound to NFκB in the cytoplasm. Phosphorylation of IκB triggers its ubiquitination and degradation in proteasomes. This results in the generation of free NFκB, which translocates to the nucleus to regulate gene expression.

Most protein serine–threonine kinases undergo autophosphorylation. The autophosphorylation of most protein kinases is associated with an increase in kinase activity [4, 10]. In some instances, such as with the RII subunit of PKA, autophosphorylation represents a positive feedback mechanism for kinase activation, in this case by enhancing the rate of dissociation of the RII and C subunits. In the case of CaMKII, autophosphorylation causes the catalytic activity of the enzyme to become independent of Ca^{2+} and calmodulin. This means that the enzyme, activated originally in response to elevated cellular Ca^{2+}, remains active after Ca^{2+} concentrations have returned to baseline. By this mechanism, neurotransmitters that activate CaMKII can produce relatively long-lived alterations in neuronal function. In other instances, such as with the receptor-associated protein tyrosine kinases (discussed in Ch. 24), autophosphorylation is an obligatory step in the sequence of molecular events through which those kinases are activated and produce physiological effects.

PROTEIN SERINE–THREONINE PHOSPHATASES

Protein dephosphorylation is catalyzed by phosphohydrolases called protein phosphatases. While the number of protein tyrosine kinases is roughly comparable to the number of protein tyrosine phosphatases, protein serine–threonine kinases vastly outnumber the protein serine–threonine phosphatases, of which about 25 different species are known to exist. This relative under-representation may be accounted for by the alternative diversification of independent regulatory proteins that can control and target a given protein phosphatase [26]. Many first messengers elicit physiological responses in the brain through the specific regulation of protein phosphatases.

The brain contains multiple forms of protein serine–threonine phosphatases. These differ in their regional distribution, substrate specificity and regulation by cellular messengers. The original classification of protein serine–threonine phosphatases as protein phosphatase 1 or 2 (PP1 or PP2) was based on their preferred dephosphorylation of, respectively, the β or α subunit of phosphorylase kinase. PP2 was later subdivided into three subtypes, termed PP2A, PP2B and PP2C, based on differential biochemical and regulatory properties. Each of these enzymes, including several subtypes, has now been cloned along with several additional protein serine–threonine phosphatases [3, 27, 28]. The current classification of these various enzymes, listed in Table 23-2, has retained their historical nomenclature, despite the fact that we now know that such a classification does not follow particular structural or functional properties. For example, PP1 and PP2A are closely related structurally and functionally, whereas PP2C is more distantly related, based on amino acid homology. More recently, newly identified members of the phosphatase family, PP4, PP5 and PP6 have been reported, but little information is yet available regarding their functions or targeting [29, 30].

Protein phosphatase 1. Four subtypes of PP1, derived from three genes, are known. These enzymes, listed in Table 23-2, are highly homologous and exhibit similar substrate specificities; therefore, they can be considered isoforms. However, the proteins exhibit very distinct patterns of distribution in the brain. PP1 dephosphorylates a wide array of substrate proteins. Its catalytic subunit can form complexes with over 50 regulatory subunits in a

TABLE 23-2 Classes of protein serine–threonine phosphatases

Protein phosphatases	Inhibitor proteins
PP1 (α, β, γ_1, γ_2)	Inhibitor 1, inhibitor 2 DARPP-32, NIPP1
PP2A	Inhibitor 1^{2A}, inhibitor 2^{2A}
PP2B (calcineurin)	Immunophilins Cyclosporin A-cyclophilin, FK06-FK506-binding protein
PP2C	
PP4	
PP5	
Others?	
Dual-function phosphatases (VH1 family)	

Cdc, cell division cycle; DARPP-32, dopamine and cAMP-regulated phosphoprotein of 32 kDa; MAPK, mitogen-activated protein kinase; NIPP1, nuclear inhibitor of PP1; PP, protein phosphatase; VH1, vaccinia virus.

mutually exclusive manner [31]. As a result, numerous PP1-dependent cellular functions are controlled by independent mechanisms. Regulation of PP1 by some inhibitor proteins will be discussed below. The molecular structure of PP1 has been solved at the atomic level and has revealed molecular mechanisms for some of these inhibitors [32].

The subcellular localization of PP1 appears to be determined by a series of other proteins, which are now considered to be integral subunits of the enzyme [31]. For example, the M subunit directs PP1 to myofibrils in smooth muscle. In addition, the several known isoforms of PP1 show region-specific expression in the brain. Certain forms, PP1α and PP1γ1, are highly enriched in dendritic spines of certain neurons, which presumably reflects the important role played by the enzyme in synaptic transmission. The subunit responsible for this dendritic localization may be a protein called spinophilin [33, 34]. The cell nucleus also contains high concentrations of PP1, where it is believed to play an important role in the dephosphorylation of transcription factors critical to the control of gene transcription. One PP1 regulatory protein responsible for directing signals to the nucleus ('nuclear targeting'), which was identified by the yeast two-hybrid approach, is called PNUTS (phosphatase 1 nuclear targeting subunit) [35, 36].

Protein phosphatase 2A accounts for as much as 1% of total cellular protein and for the major portion of serine–threonine phosphatase activity in most tissues and cells [37]. It is a multisubunit enzyme composed of three subunits: a catalytic, or C, subunit; a scaffold A subunit, which provides structural support to the C subunit; and a regulatory B subunit, which is in part responsible for PP2A functional specificity. There are two known forms of the C subunit but these are very similar functionally and are considered to be isoforms of each other. In contrast, multiple forms of the B subunit occur, which are expressed differentially in mammalian tissues. Distinct classes of B subunits, termed B, B′, and B″, can bind to the AC complex to form a large array of heterotrimeric complexes. The interactions of the various regulatory B subunits with the AC complex are competitive, and these B subunits can differentially exchange, so that PP2A specificity and location may be controlled through their relative abundance and expression [38]. Some regulatory B subunits are expressed specifically in the brain and are highly enriched in specific regions of the CNS. There is substantial evidence that PP2A activity is regulated by extracellular signals through phosphorylation and other post-translational modifications of PP2A complexes. The relative importance of PP2A in the nervous system and elsewhere may be suggested by the panoply of naturally occurring small molecule inhibitors, some of which will be discussed below.

Protein phosphatase 2B, also called calcineurin, is a Ca^{2+}/calmodulin-activated enzyme composed of two major subunits: the A subunit contains the catalytic activity and is highly homologous to PP1, and the B subunit contains two calmodulin-like domains responsible for binding Ca^{2+}/calmodulin [39]. PP2B is expressed in a region-specific manner in the brain and enriched particularly in striatum. PP2B, like PP1, exhibits broad substrate specificity. Moreover, based on its regulation by Ca^{2+}, it is believed to mediate many physiological responses to neurotransmitters and nerve impulses. PP2B binds with high affinity to AKAPs, which localize the enzyme to subcellular sites also enriched in PKA, such as postsynaptic densities. As will be seen below, this is presumably one molecular basis for the complex interactions found between PP2B, the protein kinase and other regulatory proteins.

The activity of PP2B is regulated by a series of proteins termed immunophilins [28, 40]. These proteins, the prototypical example of which is cyclophilin, were first identified as the targets of potent immunosuppressive drugs such as cyclosporin and FK-506. It is now known that immunophilins bind to PP2B and inhibit its catalytic activity, and immunosuppressive drugs promote this inhibitory action. Both the A and B subunits of PP2B are involved in the binding of immunophilins. The immunosuppressive/immunophilin-mediated reduction in PP2B activity results in loss of the ability of Ca^{2+} to activate T lymphocytes, which mediates the immunosuppressive effects of the drugs. Although first described in the immune system, immunophilins are expressed in the brain in a region-specific manner and have been implicated in the regulation of synaptic transmission [41]. It will be interesting in future studies to further elaborate the functional importance of PP2B–immunophilin interactions in the regulation of neuronal function.

Protein phosphatase 2C, unlike the other serine threonine phosphatases, is a monomeric enzyme for which few targeting proteins have yet been identified. Furthermore, to date, there are no inhibitors of PP2C available. As a result it has been difficult to examine the role of PP2C in intact cells. Although it is encoded by seven different mammalian genes and is expressed in the brain, relatively few neural substrates have been identified. Likely substrates include the autophosphorylation site of CaMKII, the casein kinase I site on DARPP-32 (Ser137) and the PKA site on tyrosine hydroxylase (Ser40) (see discussion of these proteins below). Recently, a role for PP2C in the nervous system has been implicated by the observation that it binds and dephosphorylates one of the metabotrophic glutamate receptors (mGluR3) [42]. PP2C has been found to interact with the cystic fibrosis transmembrane conductance regulator chloride channel as well as the AKT potassium channel in *Arabidopsis*. Clearly more information is needed on the function and regulation of PP2C and its role in the regulation of receptors and channels in the CNS.

Protein serine–threonine phosphatases play a critical role in the control of cell function. This is demonstrated by several naturally occurring toxins that inhibit cellular

protein phosphatase activity. Some of these are potent tumor-promoting agents. Examples of such toxins are okadaic acid and microcystin, which are potent inhibitors of PP1 and PP2A. In addition to demonstrating the critical balance maintained in cells between protein phosphorylation and dephosphorylation, these protein phosphatase inhibitors have been used as tools to elaborate the specific role of protein phosphatases in the nervous system.

Protein phosphatase 1 is regulated by protein phosphatase inhibitor proteins. PP1 is inhibited by at least four such proteins: inhibitor 1, inhibitor 2, dopamine- and cAMP-regulated phosphoprotein of 32 kDa (DARPP-32) and nuclear inhibitor of PP1 (NIPP1) (Table 23-2). Inhibitor 1 is a substrate for PKA; inhibitor 2 is a substrate for glycogen synthase kinase-3; DARPP-32 and NIPP1 are substrates for PKA and casein kinases. DARPP-32 is phosphorylated by additional kinases as well (see below). PKA phosphorylation of inhibitor 1 and DARPP-32 leads to activation of their phosphatase-inhibitory activity, whereas phosphorylation of inhibitor 2 and NIPP1 leads to inactivation of their phosphatase-inhibitory activity. All four inhibitors are low-molecular-weight, acid-soluble, heat-stable proteins and exhibit some homology in their amino acid composition.

Whereas inhibitors 1 and 2 and NIPP1 appear to be widely distributed in mammalian tissues, including brain, DARPP-32 shows a much more restricted distribution. The protein is enriched in discrete populations of neurons in the brain, most prominently those that express D1-dopamine receptors (see Chs 12, 46 and 54). Some neuronal cell types thus appear to contain unique species of phosphatase inhibitor proteins. The critical role played by these proteins in neuronal function is illustrated below.

In contrast to inhibitor 1, DARPP-32 and NIPP1, which regulate signal transduction, the function of inhibitor 2 appears to be different. There is evidence that inhibitor 2 associates with PP1, as the phosphatase is newly synthesized and contributes to the proper folding of the enzyme [40]. Inhibitor 2 can thus be considered a chaperone protein. The inactive PP1–inhibitor 2 complex can then be activated upon phosphorylation of inhibitor 2 by glycogen synthase kinase-3. Whether this process is regulated in neurons in association with synaptic activity remains unknown.

Mitogen-activated protein kinase phosphatases are dual-function protein phosphatases. Just as the MAPK kinases (e.g. MEKs) are unique as dual-functioning kinases in that they phosphorylate MAPKs on threonine and tyrosine residues, there are unique dual-function ing protein phosphatases that reverse the phosphorylation and activation of MAPKs [43]. Such MAPK phosphatases (MKPs) were first identified as a product of vaccinia virus (VH1) and later found in all eukaryotic cells. There are now numerous members of this VH1 family of dual-functioning protein phosphatases. These enzymes are more closely related, in terms of their amino acid sequences, to protein tyrosine phosphatases than to protein serine–threonine phosphatases.

Some members of this family have been shown to mediate the dephosphorylation of MAPKs under physiological conditions. Others dephosphorylate Cdc-2 and related CDKs. However, relatively little is known to date about the regional distribution of these dual-functioning phosphatases in the brain and the specific function these enzymes serve in the regulation of neuronal signal transduction. Considerable interest has focused on one particular MAPK phosphatase, which can be induced very rapidly, at the level of gene transcription, in target cells in response to cellular activation [44].

NEURONAL PHOSPHOPROTEINS

Virtually all types of neuronal protein are regulated by phosphorylation. Examples of neuronal phosphoproteins are given in Table 23-3. Regulation of these proteins by phosphorylation is reviewed in detail elsewhere [4, 10, 45–49]. Phosphorylation of these many types of protein is involved in carrying out or regulating virtually every process in the nervous system. Indeed, it is difficult to identify a neural process, including an example of neural

TABLE 23-3 Examples of proteins regulated by phosphorylation

Enzymes involved in neurotransmitter biosynthesis
Tyrosine hydroxylase
Tryptophan hydroxylase
Neurotransmitter receptors
Adrenergic receptors
Dopamine receptors
Opioid receptors
Glutamate receptors
Many others
Monoamine-reuptake plasma membrane transporters
Monoamine vesicle transporters (VAT)
Ion channels
Voltage-dependent Na^+, K^+, Ca^{2+} channels
Ca^{2+}-dependent potassium channels
Enzymes and other proteins involved in the regulation of second messengers
G proteins
Phospholipases
Adenylyl cyclases
Guanylyl cyclases
Phosphodiesterases
IP_3 receptor
Protein kinases
Autophosphorylated protein kinases (protein kinases phosphorylating themselves)
Protein kinases phosphorylated by other protein kinases (many examples)
Protein phosphatase inhibitors
DARPP-32
Inhibitors 1 and 2

TABLE 23-3 Examples of proteins regulated by phosphorylation—cont'd

Cytoskeletal protein involved in neuronal shape and motility
- Actin
- Tubulin
- Neurofilaments (and other intermediate filament proteins)
- Myosin
- Microtubule-associated proteins
- Actin-binding proteins

Synaptic vesicle proteins involved in neurotransmission
- Synapsins
- SNAP25
- Syntaxin
- Synaptobrevin (VAMP)
- rabphilin
- RIM1
- SNAP
- Synaptotagmin
- Amphihysin
- Dynamin
- Synaptophysin
- Synaptojanin
- Others

Transcription factors
- CREB family members
- Fos and Jun family members
- STATs
- Steroid and thyroid hormone receptors
- NFκB-IKB family
- Serum response factors

Other proteins involved in DNA transcription or mRNA translation
- RNA polymerase
- Topoisomerase
- Histones and nonhistone nuclear proteins
- Ribosomal protein S6
- eIF (eukaryotic initiation factor)
- eEF (eukaryotic elongation factor)
- Other ribosomal proteins

Proteins implicated in neurodegeneration
- APP
- Tau

Miscellaneous
- 14–3-3
- Rhodopsin
- Neural cell adhesion proteins
- MARCKS
- GAP-43

This list is not intended to be comprehensive but to indicate the wide array of neuronal proteins regulated by phosphorylation. Some of the proteins are specific to neurons but most are present in many cell types in addition to neurons and are included because their multiple functions in the nervous system include the regulation of neuron-specific phenomena. Not included are the many phosphoproteins present in diverse tissues, including brain, that play a role in generalized cellular processes, such as intermediary metabolism, and that do not appear to play a role in neuron-specific phenomena. *NMDA,* *N*-methyl-D-aspartate; *CREB,* cAMP response element-binding proteins; *STAT,* signal-transducing activators of transcription; *IP_3,* inositol trisphosphate; *DARPP-32,* dopamine and cAMP-regulated phosphoprotein of 32 kDa; *RIM,* Rab3a interacting molecule; *NFκB,* nuclear factor κB; *BAPP,* amyloid precursor protein; *GAP-43,* growth-associated protein of 43 kDa; *MARCKS,* myristoylated alanine-rich C kinase substrate.

plasticity, in which phosphorylation of specific phosphoproteins is not integrally involved.

In the presynaptic compartment, phosphorylation of enzymes that synthesize neurotransmitters regulates the capacity of a neuron for synaptic transmission. Phosphorylation of ion channels regulates the ability of these channels to open or close in response to the propagation of an action potential, thereby mediating synaptic release of neurotransmitters as well as more general changes in neuronal excitability. Phosphorylation of synaptic-vesicle-associated proteins regulates neurotransmitter release in response to subsequent stimuli. In the postsynaptic compartment, phosphorylation of ion channels controls the membrane potential and excitability of neurons. Phosphorylation of receptors and other signaling proteins regulates the ability of neurotransmitters and other first messengers to produce their physiological effects. Phosphorylation of neuronal cytoskeletal and related proteins regulates axoplasmic transport as well as neuronal growth, shape, survival and elaboration, and retraction of dendritic and axonal processes. Phosphorylation of transcription factors and ribosomal proteins regulates the expression of specific genes in target neurons, the ultimate form of signal transduction and neural plasticity.

Protein phosphorylation is an important mechanism of memory. Phosphorylation of any of the aforementioned types of protein can be viewed as 'molecular memory': a change in the structure and function of a protein that reflects perturbation of a specific signal-transduction pathway in a specific neuronal cell type. Presumably, learning and memory manifested at a behavioral level are established through the accumulation of many types of phosphorylation event that alter the functioning of individual neurons and the neural circuits in which they operate. Short-term memory may involve the phosphorylation of presynaptic or postsynaptic proteins in response to synaptic activity, which would result in transient facilitation or inhibition of synaptic transmission. Long-term memory may involve the phosphorylation of proteins that play a part in the regulation of gene expression, which would result in more permanent modifications of synaptic transmission. For example, long-term potentiation (LTP), one of the most extensively studied models of memory at the cellular level, seems to be initiated through short-term changes in Ca^{2+}-dependent protein phosphorylation and maintained by longer-term changes in gene expression (see Ch. 53 for further discussion of memory).

Neuronal phosphoproteins differ considerably in the number and types of amino acid residues phosphorylated. The complexity of intracellular regulation is underscored by the now numerous and well-established observations of numerous proteins that are phosphorylated on more than one amino acid residue by more than

one type of protein kinase. Depending on the protein, phosphorylation of different residues can lead to similar or opposite changes in the function of that protein. It may take, for example, phosphorylation of multiple nearby residues to produce a change in the charge of the protein sufficient to result in some critical change in function. This appears to be the case for MAPKs, activation of which requires the phosphorylation of nearby threonine and tyrosine residues. In contrast, phosphorylation of one residue may activate a protein, whereas phosphorylation of another might inhibit it; this is the case for CREB, as will be described below. In still other cases, interactions among the sites of phosphorylation of a protein can be more complex: phosphorylation of one residue can influence the ability of the other residues to undergo phosphorylation. Phosphorylation of neuronal proteins by more than one protein kinase can integrate the activities of multiple intracellular pathways to achieve coordinated regulation of cell function.

Phosphorylation of a protein can influence its functional activity in several ways. For many proteins, a change in charge and conformation, due to the addition of phosphate groups to the primary structure, results in alterations in their intrinsic functional activity. For example, the catalytic activity of an enzyme can be switched on or off, or an ion channel can open or close, upon such a change in charge and conformation. For many other proteins, phosphorylation-induced changes in charge and conformation result in alterations in the affinity of the proteins for other molecules. For example, phosphorylation alters the affinity of numerous enzymes for their cofactors and end-product inhibitors, phosphorylation of receptors can alter their affinity for G proteins and phosphorylation of some transcription factors alters their DNA-binding properties.

To illustrate some of the roles played by protein phosphorylation in the regulation of nervous system function, some well characterized neuronal phosphoproteins and some aspects of neurotransmission regulated by phosphorylation in the pre- and postsynaptic compartments are discussed in detail.

Regulation of neurotransmitter synthesis: tyrosine hydroxylase. This protein is the rate-limiting enzyme in the biosynthesis of the catecholamine neurotransmitters dopamine, norepinephrine and epinephrine. Diverse extracellular signals have been shown to stimulate catecholamine biosynthesis *in vivo*, effects mediated at least in part through increases in the catalytic activity of tyrosine hydroxylase (see also Ch. 12). Such changes in the catalytic activity of tyrosine hydroxylase are achieved largely through cAMP-dependent and Ca^{2+}-dependent phosphorylation of the enzyme [50, 51].

Tyrosine hydroxylase is a tetramer of identical 60 kDa subunits. The enzyme is an effective substrate for at least nine different protein kinases (Fig. 23-5). One site, serine 40, of tyrosine hydroxylase is phosphorylated by PKA, PKC, PKG, CaMKII, and MAPKAP kinases 1 and 2. CaMKII and MAPKAP kinases 1 and 2 also phosphorylate a second site, serine 19. Phosphorylation of either site by CaMKII is reported to require the presence of an 'activator' protein, termed 14-3-3. Phosphorylation of tyrosine hydroxylase increases the catalytic activity of the enzyme by increasing its V_{max} and its affinity for its biopterin cofactor and by decreasing the affinity of the enzyme for its end-product inhibitors. Tyrosine hydroxylase also contains additional serine residues that are phosphorylated by other protein kinases. For example, the enzyme is phosphorylated on Ser31 by ERK 1 and 2, which is also thought to increase the catalytic activity of the enzyme. This site has also recently been reported to serve as a substrate for CDK5 [52]. While CDK5 may directly phosphorylate Ser31 of tyrosine hydroxylase, it may also block phosphorylation of this site by ERK1/2 by phosphorylating and inhibiting the ERK-activating kinase MEK. Additionally, phosphorylation of Ser31 of tyrosine hydroxylase in humans may be affected through alternative splicing that results in the expression of isoforms of tyrosine hydroxylase with different amino acid sequences adjacent to Ser31, which alters its ability to undergo phosphorylation. In some cell culture preparations, tyrosine hydroxylase has been observed to be phosphorylated at a fourth site, serine 8, by Cdc2. This is an astounding degree of complex regulation converging on a single enzyme, and efforts are still under way to understand its full physiological significance.

Tyrosine hydroxylase is present in neurons in the CNS and PNS that synthesize catecholamines. The enzyme is also present at high concentrations in cells that are developmentally related to catecholaminergic neurons, such as

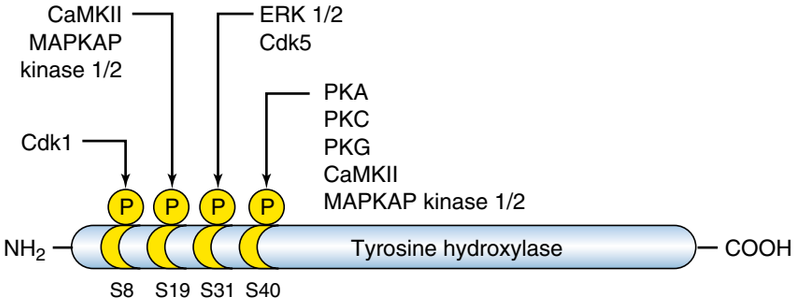

FIGURE 23-5 Schematic diagram of tyrosine hydroxylase with sites of phosphorylation indicated (*yellow*) along with the protein kinases.

adrenal chromaffin cells and pheochromocytoma cells. Tyrosine hydroxylase is predominantly a cytosolic protein and is present in high concentrations in catecholaminergic nerve terminals.

The regulation of phosphorylation of tyrosine hydroxylase is affected by stimuli that increase Ca^{2+} or cAMP concentrations in neurons, including nerve impulse conduction and certain neurotransmitters in well-defined regions of the nervous system, in the adrenal medulla and in cultured pheochromocytoma cells. In addition, tyrosine hydroxylase phosphorylation is stimulated by nerve growth factor in certain cell types, possibly via the activation of ERKs. These changes in the phosphorylation of tyrosine hydroxylase have been shown to correlate with changes in the catalytic activity of the enzyme and in the rate of catecholamine biosynthesis.

Several key questions remain with regard to the regulation of tyrosine hydroxylase by phosphorylation. What is the precise effect of the phosphorylation of each of these serine residues on the catalytic activity of the enzyme? How does the phosphorylation of multiple residues affect enzyme activity? Does the phosphorylation of one residue affect the ability of the others to be phosphorylated? Tyrosine hydroxylase provides a striking example as to how multiple intracellular messengers and protein kinases converge functionally through the phosphorylation of a single substrate protein. Phosphorylation of tyrosine hydroxylase by cAMP-dependent and Ca^{2+}-dependent protein kinases and by MAPK cascades enables a catecholaminergic cell to adjust its rate of neurotransmitter biosynthesis to a host of external stimuli and to changing physiological needs.

Regulation of neurotransmitter receptors: the β-adrenergic receptor. This receptor, of which three subtypes have been cloned, mediates many of the effects of norepinephrine and epinephrine in the brain and peripheral tissues. One of the dramatic features of β-adrenergic receptor function is its rapid desensitization in response to agonist stimulation. It is now known that one important mechanism for this desensitization is phosphorylation of the receptor both by PKA and by a receptor-associated protein kinase, βARK (also called GRK2; Fig. 23-6).

Activation of the β-adrenergic receptor leads, via coupling with G_s, to activation of adenylyl cyclase and increased concentrations of cAMP and of activated PKA. The activated kinase then leads to the many physiological effects of β-adrenergic receptor stimulation via the phosphorylation of numerous substrate proteins. However, among those proteins phosphorylated by the kinase is the receptor itself, which is phosphorylated on several serine residues in its cytoplasmic domains. This phosphorylation reduces subsequent activation of the receptor, and the precise mechanisms underlying this desensitization are becoming increasingly understood. It is now believed that phosphorylation of the receptor triggers its internalization via a dynamin-dependent process from the plasma membrane, rendering it inaccessible to further agonist stimulation.

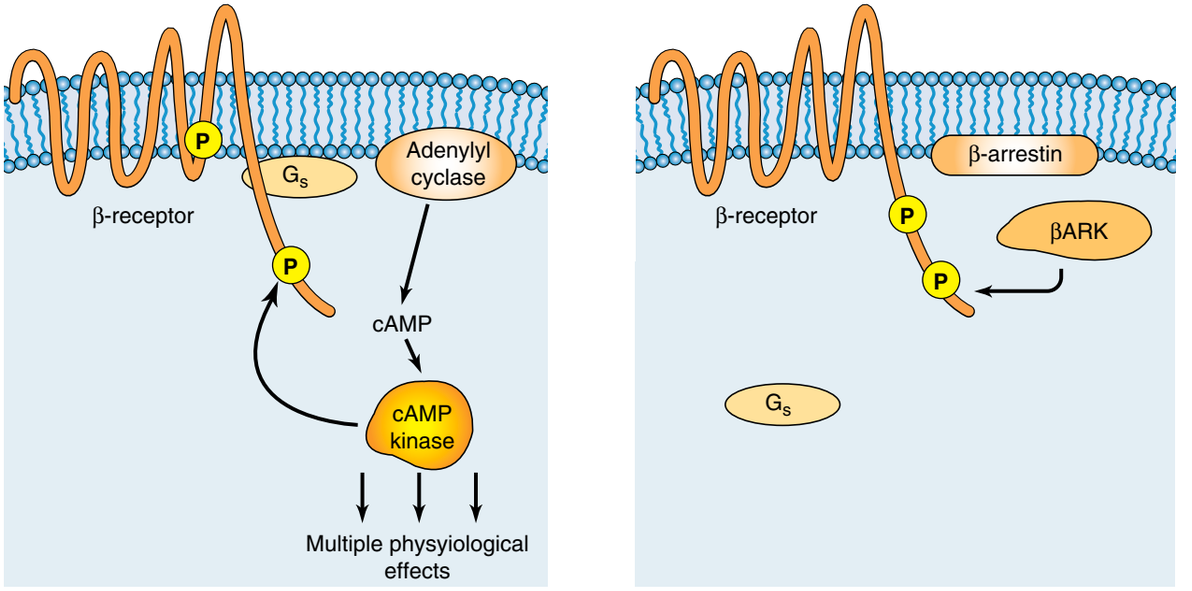

FIGURE 23-6 Schematic diagram illustrating desensitization of the β-adrenergic receptor mediated by receptor phosphorylation. (**A**) Activation of the β-adrenergic receptor by its ligand results, via coupling with G_s, in stimulation of adenylyl cyclase, increased concentrations of cAMP and stimulation of cAMP-dependent protein kinase, which mediates the physiological effects of β-receptor activation through the phosphorylation of numerous cellular proteins. The protein kinase also phosphorylates several serine residues in cytoplasmic domains of the receptor, which results in receptor desensitization. (**B**) Activation of the β-adrenergic receptor also results in a conformational change in the receptor, which renders it an effective substrate for β-adrenergic receptor kinase (β*ARK*). βARK phosphorylates the receptor at distinct serine residues, which leads to the functional 'uncoupling' of the receptor from G_s, thereby resulting in receptor desensitization. This uncoupling requires the action of an additional protein, termed β-arrestin, which interacts preferentially with the phosphorylated receptor to prevent its activation of G_s

Internalized receptor can either be returned to the plasma membrane upon its dephosphorylation or undergo proteolysis during periods of prolonged agonist exposure.

Phosphorylation of the β-adrenergic receptor by PKA can be viewed as a classical example of negative feedback: activation of the receptor stimulates intracellular cascades that feed back to reduce further receptor activation. Phosphorylation of the receptor by PKA could also mediate heterologous desensitization of the receptor: any neurotransmitter–receptor system that works through cAMP would be expected to stimulate β-adrenergic receptor phosphorylation via PKA and lead to receptor desensitization. This is one mechanism by which one neurotransmitter–receptor system can affect another.

The β-adrenergic receptor is also phosphorylated on several distinct serine residues by βARK, a protein serine–threonine kinase that is constitutively active and not regulated by second messengers (Fig. 23-6). Rather, this kinase can phosphorylate the receptor only when the receptor is bound to ligand; i.e. the binding of ligand to the receptor alters the conformation of the receptor such that it is rendered a good substrate for the receptor kinase. Upon phosphorylation by βARK, the receptor is then able to bind an additional protein, called β-arrestin, which in a sense sequesters the receptor and renders it unable to interact further with ligand or G protein. Studies (described in Ch. 19) have shown that the βγ subunits of G proteins are required to bring βARK, predominantly a cytosolic enzyme, into close association with those plasma membrane-associated receptors that are occupied by ligand.

Phosphorylation of the β-adrenergic receptor by βARK, like its phosphorylation by the cAMP-dependent enzyme, represents an example of negative feedback. However, unlike phosphorylation by cAMP-dependent protein kinase, phosphorylation by βARK represents an example of homologous desensitization: only the β-adrenergic receptor would be affected in this process and, moreover, only those receptor molecules occupied by ligand would be affected.

This model of receptor desensitization appears to be a general mechanism by which many G-protein-coupled receptors are desensitized upon persistent ligand binding [53]. Thus, there are at least six forms of βARK-like kinases cloned to date, which are referred to as GRKs. The GRKs are differentially expressed in the nervous system, and each GRK appears to phosphorylate a distinct subset of G-protein-coupled receptors. To date, GRKs have been shown to phosphorylate and desensitize several G-protein-coupled receptors, which, in addition to the β-adrenergic receptor, include α_2-adrenergic receptors and the opioid receptors. In addition, several forms of arrestin are known which are believed to contribute to the specific desensitization of G-protein-coupled receptor function by the various GRKs.

Neurotransmitter release and the synaptic vesicle cycle. Many of the proteins involved in the regulation of neurotransmitter release are regulated by phosphorylation [54, 55]. Neurotransmitter-filled synaptic vesicles congregate in the presynaptic nerve terminal. These vesicles undergo exocytosis when an action potential invades the terminal and triggers the influx of Ca^{2+} via voltage-gated Ca^{2+} channels. The Ca^{2+} signal then triggers the fusion of synaptic vesicles with the plasmalemma and results in neurotransmitter release. Subsequently, the vesicles are recovered by endocytosis and are recycled for subsequent release events (Fig. 23-7). Not surprisingly, mechanisms controlling these processes dramatically affect synaptic plasticity. Also, many of the same processes are involved in synaptogenesis. A large number of protein families have been implicated in the docking, priming and fusion of synaptic vesicles to the nerve terminal plasma membrane, and the molecular details of this complex process are now well established [56]. While most of the proteins involved in this process are phosphorylated by diverse types of protein kinases, the precise physiological role played by each phosphorylation event remains the subject of ongoing research.

For example, the membrane proteins SNAP25 (15 kDa synaptosomal associated protein), syntaxin 1 and synaptobrevin (also known as VAMP) are key mediators of the release process through the formation of a 7S complex. These proteins serve as substrates for various Ca^{2+}-sensitive and -insensitive kinases such as CAMKII (syntaxin 1A, synaptobrevin, SNAP25), PKC (SNAP25) and casein kinase II (syntaxin 1A), but the functions of the individual phosphorylation events await further elucidation. It seems likely that the phosphorylation of these proteins and their interactions with two other soluble phosphoproteins, NSF (N-ethylmaleimide-sensitive fusion protein) and SNAP (soluble NSF attachment protein), contribute to the regulation of vesicle priming and subsequent docking or fusion. Synaptotagmins are Ca^{2+}- and phospholipid-binding synaptic-vesicle phosphoproteins, which interact with SNAP25, synaptobrevin and syntaxin 1A to mediate synaptic vesicle exocytosis. It is probably phosphorylated by casein kinase II and CaMKII. Other synaptic vesicle phosphoproteins include Munc18 (nsec1), RAB3A, rabphilin and synaptophysin, to name a few.

It has recently become evident that some forms of LTP are thought to be expressed by lasting changes in neurotransmitter release, which requires PKA activation. LTP is lost when the genes for the Ca^{2+}/calmodulin-sensitive adenylyl cyclase, as well as regulatory and catalytic subunits of PKA, are knocked out. One synaptic vesicle protein, RIM1, is known to be a PKA substrate and is thought to be a mediator of this process. LTP cannot be detected in hippocampal circuits from RIM1 knockout mice. Loss of RIM1 also leads to the specific loss of presynaptic LTP in cerebellar neuron primary cultures [57]. This latter defect can be rescued by presynaptic expression of wild-type RIM1, but not by a site-directed mutant form of RIM1 in which the PKA site had been changed to alanine so that it could no longer serve as a PKA substrate. The question remains as to whether RIM phosphorylation by PKA is

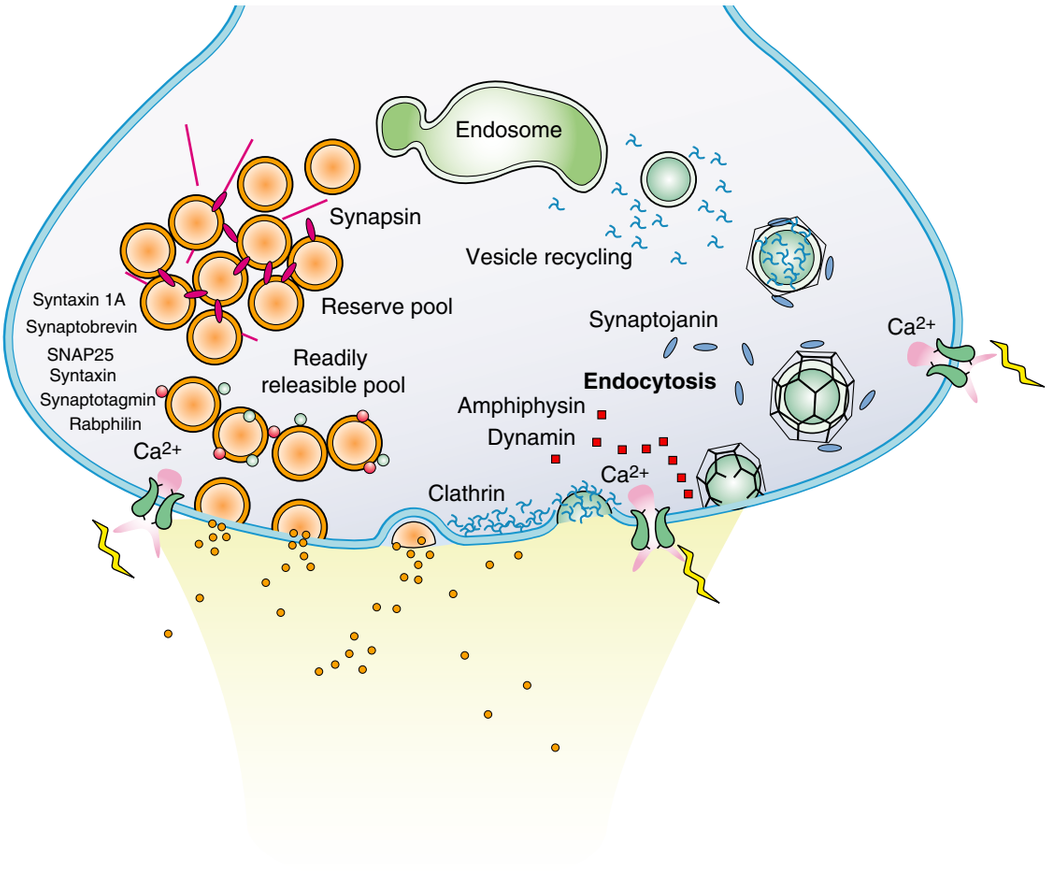

FIGURE 23-7 Schematic diagram of the synaptic vesicle cycle. Neurotransmitter-filled vesicles held in the reserve pool are trafficked to a readily releasable pool where they are docked, primed and fused with the plasmalemma at the synaptic cleft. Also depicted is the clathrin-mediated endocytosis of the fused vesicles, which is followed by their uncoating and recycling via early endosomal fusion and budding of vesicles. This returns the vesicles to the reserve pool. Some of the phosphoproteins which regulate these steps are shown. For a more detailed description of this process and the phosphoproteins involved the reader is directed to the excellent text by Cowen *et al.* [67].

sufficient to induce this LTP, or whether there may be other PKA substrates that cause LTP. In agreement with the role, of RIM1 in synaptic plasticity, knockout mice are also severely deficient in learning and memory [58].

One of the best-characterized phosphoproteins involved in the synaptic vesicle cycle is the peripheral membrane protein synapsin. The synapsin family includes three isoforms, synapsin I, II and III. The precise function subserved by synapsins is unknown, although their phosphorylation by CaMKII may release vesicles from a reserve pool, where they are thought to be anchored to the cytoskeleton via synapsin, allowing them to move to a readily releasable pool poised for membrane fusion and neurotransmitter release. Synapsins also serve as substrates for PKA, MAPK and CDK5. Of course, the voltage-gated Ca^{2+} channels that mediate Ca^{2+} entry into the nerve terminal are substrates for PKA and other kinases, phosphorylation events that robustly regulate the physiological activity of these channels.

In order to maintain sustained responsiveness to repetitive firing and the structural integrity of the synapse, neurotransmitter release (exocytosis) must be tightly coupled to vesicle recovery (endocytosis) [59]. Synaptic vesicle endocytosis is mediated by the structurally unrelated dephosphoin family of phosphoproteins, which includes amphiphysin I, dynamin, synaptojanin, epsin, eps15 and AP180 [60]. These proteins are involved in the clathrin-mediated endocytosis and subsequent uncoating prior to vesicle fusion with synaptic endosomes. All these proteins are coordinately dephosphorylated by calcineurin. Rephosphorylation of the various dephosphins is essential for the maintenance of subsequent cycles of endocytosis. Characterizing the phosphorylation events involving dephosphins is the subject of active study. Amphiphysin, dynamin, eps15, epsin and synaptojanin have each been shown to be substrates for CDK5, and dynamin is also a substrate for PKC.

Postsynaptic signaling pathways and synaptic plasticity. Postsynaptic forms of synaptic plasticity are also heavily regulated by protein phosphorylation. For example, control of protein dephosphorylation catalyzed by PP1 has

been demonstrated to be a key aspect of the signaling pathways underlying LTP and LTD (long-term depression). PP1 activity contributes to the induction of LTD, and inhibition of PP1 has been shown to promote LTP. Numerous studies implicate the regulation of PP1 by inhibitor-1 in the hippocampus and DARPP-32 in the striatum as key mediators of synaptic strength.

In one model of LTP (Fig. 23-8) first suggested by John Lisman [61] involving inhibitor-1, high frequency stimulation causes intense NMDA receptor activation and increased intracellular Ca^{2+} concentrations, which activates Ca^{2+}/calmodulin-dependent forms of adenylyl cyclases (see Ch. 21). Increased cAMP levels activates PKA, which phosphorylates inhibitor-1 at Thr35. As a result, inhibitor-1 is converted into a potent inactivator of PP1. Inhibitor-1-mediated blockade of PP1 activity allows CaMKII to achieve a Ca^{2+}-independent state of activity through its autophosphorylation, as mentioned earlier.

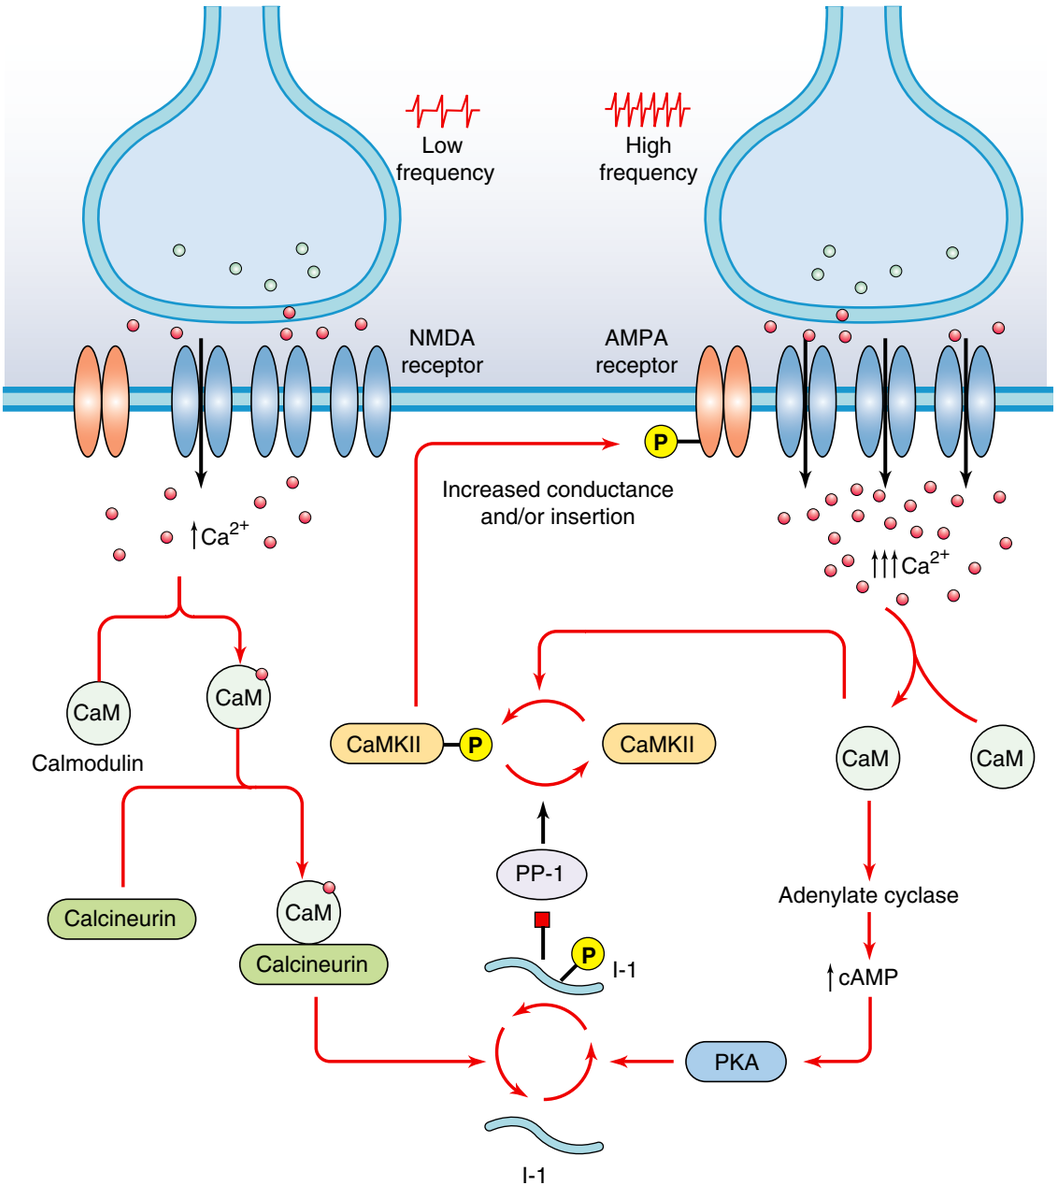

FIGURE 23-8 Schematic diagram of postsynaptic mechanisms of synaptic plasticity. In this model, low-frequency stimulation of postsynaptic neurons results in a mild increase in intracellular Ca^{2+} levels and activation of relatively lower amounts of calmodulin (CaM), which binds with higher affinity to and activates calcineurin, maintaining inhibitor-1 in the dephosphorylated state (**left**). High-frequency activation leads to adequate amounts of activated CaM to activate Ca^{2+}/CaM-dependent adenylyl cyclase and PKA-dependent phosphorylation of inhibitor-1 at Thr35 (**right**). This pathway, in combination with Ca^{2+}/CaM-dependent activation of CaMKII, causes autophosphorylation of CaMKII at Ser286, thereby allowing the kinase to become CaM-independent and contribute to strengthening of the synapse by a number of pathways [24]. (Redrawn with permission from Winder, D. G. and Sweatt, J. D. Roles of serine/threonine phosphatases in hippocampal synaptic plasticity. *Nat. Rev. Neurosci.* 2: 461–474, 2001.)

This, in turn, results in increased levels of phosphorylation of several CaMKII substrates that contribute to increased synaptic strength. These include AMPA glutamate receptors and the transcription factor CREB.

In contrast to LTP, LTD is induced by low-frequency stimulation. This causes the selective activation of PP2B (calcineurin), which maintains inhibitor-1 in its dephosphorylated state. Several studies, including those using inhibitor-1 knockout mice and transgenic mice expressing a constitutively active form of inhibitor-1, demonstrate that the control of PP1 activity by inhibitor-1 in the hippocampus affects neuronal plasticity and learning and memory.

In the dopaminoceptive neurons of the striatum, the inhibitor-1 homolog, DARPP-32, similarly is converted into a PP1 inhibitor when phosphorylated at Thr34 by PKA. However, in the medium spiny neurons of the striatum different neurotransmitter receptors and signaling pathways come into play. In these neurons, activation of D_1 dopamine receptors invokes the G_s-adenylyl cyclase-cAMP-PKA pathway, which causes DARPP-32 to be converted to a PP1 inhibitor. DARPP-32 can also be converted into a PP1 inhibitor through phosphorylation of the same residue by PKG. The numerous pathways that result in increased PKA- or PKG-dependent phosphorylation of DARPP-32 and inhibition of PP1 are opposed by other pathways, such as activation of glutamate receptor channels, which results in increased intracellular Ca^{2+} levels. Under these latter circumstances, increased Ca^{2+} levels activate PP2B, which dephosphorylates Thr34 site on DARPP-32, which converts it back to its PP1-noninhibiting form.

Changes in the phosphorylation state of DARPP-32, through activation of its phosphatase-inhibitory activity, indirectly influence the phosphorylation state of many other proteins and thereby mediate some of the effects of dopamine and of these other first messengers on cell function. The full spectrum of proteins regulated in this way by DARPP-32 phosphorylation has not yet been identified, although voltage-gated Ca^{2+}, Na^+ and K^+ channels, the Na^+,K^+-ATPase, and AMPA and NMDA glutamate receptors represent examples of well characterized target proteins [33]. Regulation of these proteins by DARPP-32 provides a mechanism by which alterations in DARPP-32 phosphorylation lead, under physiological conditions, to changes in the electrical excitability of neurons and to important forms of behavioral plasticity mediated by these cells.

The ability of DARPP-32 and inhibitor-1 to be phosphorylated at their PKA site is affected by phosphorylation at numerous other sites. DARPP-32 is phosphorylated by CDK5 and casein kinases I and II, all of which affect the phosphorylation state at Thr34. Inhibitor-1 also serves as a substrate of CDK5, at a site that is not homologous to the CDK5 site on DARPP-32. Further work is needed to understand the physiological significance of these other phosphorylation reactions.

Regulation of gene transcription: CREB. CREB is a prototypical example of a transcription factor whose physiological activity is regulated by phosphorylation. It is one of a family of proteins that mediates some of the effects of cAMP on gene expression [62]. CREB binds to a specific sequence of DNA, termed a cAMP response element (CRE), in the promoter (regulatory) regions of genes and thereby increases or decreases the rate at which those genes are transcribed (see Ch. 26).

The details of the mechanism by which CREB influences gene expression are becoming increasingly understood (Fig. 23-9) [62, 63]. In the basal, or unstimulated, state, CREB is bound to its CREs but does not alter transcriptional rates under most circumstances. Stimulation of a cell by a variety of first messengers leads to the phosphorylation and activation of CREB, which then leads to the regulation of gene transcription. Such phosphorylation of CREB occurs on a single serine residue, serine 133, and can be mediated by one of several protein kinases.

The detailed mechanisms involved in CREB phosphorylation were first established for the cAMP pathway. A first messenger that increases cAMP concentrations leads to activation of PKA and to translocation of the free catalytic subunit of the protein kinase into the nucleus, where it phosphorylates CREB on serine 133. Such phosphorylation then promotes the binding of CREB to a CREB-binding protein (CBP). CBP, upon binding CREB, interacts directly with the RNA polymerase II complex, which mediates the initiation of transcription. In most cases, such interactions lead to the activation of transcription, although it is possible that the expression of some genes may be repressed.

Stimulation of a cell by first messengers that increase cellular Ca^{2+} concentrations similarly activates CREB (Fig. 23-9). This appears to occur via the phosphorylation of CREB on serine 133 by a CaMK, probably CaMKIV as well as, possibly, CaMKI. It remains to be established whether the activated kinase translocates to the nucleus, by analogy with the catalytic subunit of the cAMP kinase, or whether elevated Ca^{2+} signals enter the nucleus and activate the kinase already there. Interestingly, phosphorylation of CREB on a distinct serine residue, serine 142, by CaMKII appears to inhibit the transcriptional activity of CREB *in vitro*, although whether this inhibitory effect occurs *in vivo* is unknown.

CREB is also phosphorylated on serine 133 by stimulation of growth factor signaling cascades [63]. This occurs via a complex pathway involving MAPK cascades (Fig. 23-9). Thus, as outlined earlier, nerve growth factor and related neurotrophins that act on receptor tyrosine kinases lead to the successive activation of Ras, Raf, MEK and ERK. Activated ERK then phosphorylates and activates a serine–threonine kinase, RSK, particular subtypes of which directly activate CREB via the phosphorylation of serine 133.

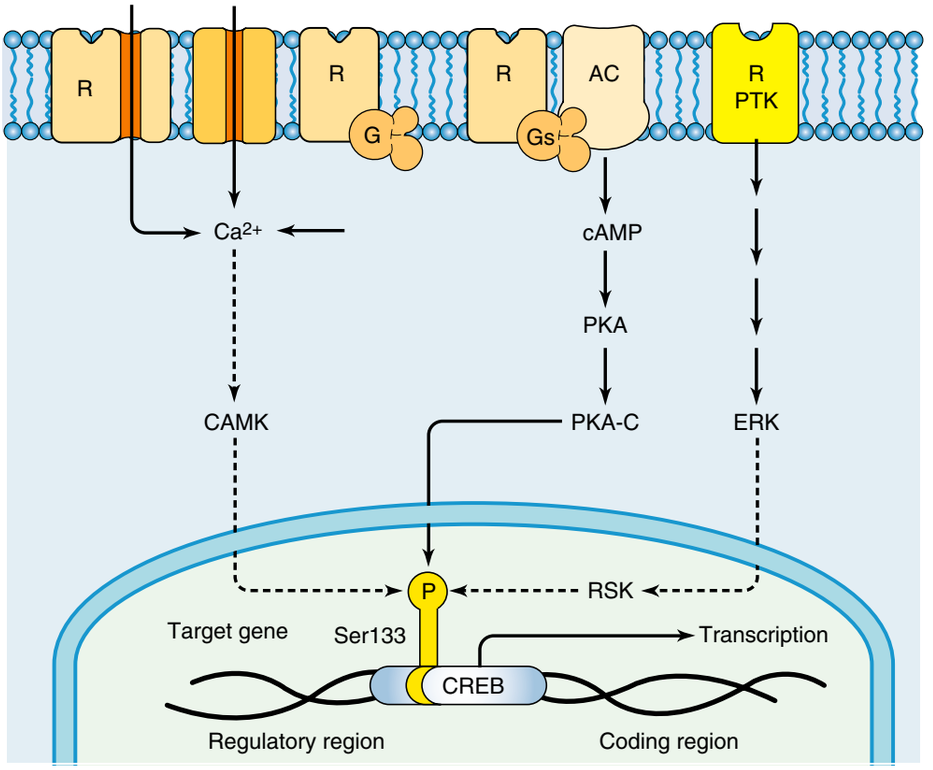

FIGURE 23-9 Schematic diagram of the mechanisms by which diverse types of first messengers converge on the phosphorylation of serine 133 of cAMP response element-binding protein (*CREB*). Some first messengers do this by increasing cAMP concentrations by activation of G-protein-coupled receptors (*R*), G_s, adenylyl cyclase (*AC*) and cAMP-dependent protein kinase (*PKA*), which then phosphorylates CREB on ser 133. Others do so by increasing Ca^{2+} concentrations by activation of ionotropic receptors (*R*) that flux Ca^{2+}, by activation of voltage-gated Ca^{2+} channels through membrane depolarization or by activation of G-protein-coupled receptors that elevate intracellular Ca^{2+} concentrations, for example via the phospholipase C pathway. Increased concentrations of Ca^{2+} then lead to activation of Ca^{2+}/calmodulin-dependent protein kinases (type IV and, possibly, I) (*CaM-K*), which also phosphorylate CREB on ser 133. Still others do so by activating ERK: by activation of receptor-associated protein tyrosine kinases (*R-PTK*) and the mitogen-activated protein kinase cascade (Figs 23-3, 23-4). Activation of extracellular signal-regulated kinase (*ERK*) then phosphorylates and activates ribosomal S6 kinase (*RSK*), which also phosphorylates CREB on ser 133. The step at which the cytoplasmic signal is transduced to the nucleus is well established for PKA: activation of the kinase leads to its dissociation and generation of the free catalytic subunit (*PKA-C*), which then translocates to the nucleus and phosphorylates CREB. The process is less well established for the CaMKs and ERK, as indicated by the *dashed lines*. Phosphorylation of CREB on ser 133 activates its transcriptional activity and leads to changes in the rate of transcription of target genes.

There is evidence that the dephosphorylation of CREB is catalyzed by PP1 and, perhaps, PP2A [28, 40]. Phosphorylation of NIPP-1 (a protein phosphatase inhibitor protein described above) may contribute to the tightly timed pulse of phospho-CREB induced in the nucleus following cell stimulation. According to this scheme, the catalytic subunit of PKA, for example, would rapidly phosphorylate CREB, resulting in a change in transcription and, with a slightly slower time course, phosphorylate and reduce the phosphatase-inhibitory activity of NIPP1. This would release PP1 from its tonic inhibition and result in CREB dephosphorylation.

The number of neural genes known to contain CREs is growing as more and more genes are cloned. Prominent examples are tyrosine hydroxylase, c-*fos*, proenkephalin, prodynorphin, somatostatin and vasoactive intestinal polypeptide (*VIP*). Expression of these genes has been shown to be regulated at their CREs by the phosphorylation of CREB or a CREB-like protein. In fact, for some genes, for example, tyrosine hydroxylase, activation of CREB appears to be the critical transcriptional mechanism controlling both the basal level of gene expression and the induction of expression seen in response to cellular stimulation.

Consideration of CREB highlights the view, mentioned earlier in this chapter, that among the many cellular processes regulated by protein phosphorylation is gene transcription. This view is further underscored by the knowledge that virtually all classes of transcription factor undergo phosphorylation by numerous types of protein kinases. Even transcription factors that are regulated primarily through alterations in their own transcription, such as c-Fos and other immediate early gene transcription factors, are influenced by phosphorylation.

For example, c-Fos is heavily phosphorylated on a series of serine residues in the C-terminal domain of the protein by several types of protein kinases. The likely functional importance of these phosphorylation sites is indicated by the fact that the difference between c-Fos (the normal cellular form of the protein) and v-Fos (the viral oncogene product) is a frameshift mutation in the v-Fos protein, which obliterates the phosphorylated serine residues. It is speculated that the loss of these phosphorylation sites removes one mechanism by which the cell can regulate the protein, thereby leading to cellular transformation.

Cellular signals converge at the level of protein phosphorylation pathways. Individual intracellular messenger pathways, such as cAMP, Ca^{2+} and MAPK pathways, are often drawn as distinct biochemical cascades that operate in parallel in the control of cell function. While this is useful for didactic purposes, it is now well established that these various pathways function as complex webs, with virtually every conceivable type of interaction seen among them.

This can be illustrated by known interactions between the cAMP and Ca^{2+} pathways. A first messenger that initially activates the cAMP pathway would be expected to exert secondary effects on the Ca^{2+} pathway at many levels via phosphorylation by PKA. First, Ca^{2+} channels and the inositol trisphosphate (IP_3) receptor will be phosphorylated by PKA to modulate intracellular concentrations of Ca^{2+}. Second, phospholipase C (PLC) is a substrate for PKA, and its phosphorylation modulates intracellular calcium concentrations, via the generation of IP_3, as well as the activity of PKC, via the generation of DAG, and several types of CAMK. Similarly, the Ca^{2+} pathway exerts potent effects on the cAMP pathway, for example, by activating or inhibiting the various forms of adenylyl cyclase expressed in mammalian tissues (see Ch. 21).

The cAMP and Ca^{2+} pathways also interact at the level of protein kinases and protein phosphatases. This is illustrated by inhibitor-1 and DARPP-32, which are phosphorylated and activated by PKA and then inhibit PP1, which can dephosphorylate numerous substrates for Ca^{2+}-dependent protein kinases. Another example is the physical association between PKA and PP2B (a Ca^{2+}/calmodulin-activated enzyme) via the AKAP-anchoring proteins.

Multiple interactions are also being demonstrated between the traditional second-messenger pathways and the MAPK cascades. Free βγ G protein subunits, generated upon activation of receptors coupled to the G_i family, lead to activation of the ERK pathway. The mechanism by which this occurs, which may involve an interaction between the βγ subunits and Ras or Raf, is a subject of intensive research (see Ch. 19). In addition, increases in cellular Ca^{2+} concentrations lead to stimulation of the ERK pathway, apparently via phosphorylation by CaMKs of proteins, for example Shc and Grb, that link growth factor receptor tyrosine kinases to Ras. Activation of the cAMP pathway exerts the opposite effect in most cells: it results in inhibition of the ERK pathway, possibly via the phosphorylation and inhibition of Raf by PKA.

Another major way by which intracellular messenger pathways interact is via phosphorylation of the same substrate proteins. There are numerous examples of this, some discussed earlier in this chapter. One striking example is provided by CREB, which is phosphorylated on the same single serine residue by PKA, CaMK and RSK, activated by the MAPK cascade.

The above discussion suggests that a single extracellular signal may elicit changes in numerous intracellular signaling cascade, which would raise questions as to how specific biological responses are achieved in a cell. In reality, such specificity is achieved because not all the aforementioned interactions occur in every cell type. Specific interactions depend on the strength and persistence of the original extracellular signal, the subcellular location where the signal acts and the specific subtypes of individual signaling proteins that are expressed in a cell at the relevant subcellular sites. In addition, regulation of intracellular messenger pathways does not depend on the actions of a single extracellular signal but rather on the integration of multiple signals that impinge on cells at any given point in time.

Nevertheless, rather than being generated through a single molecular pathway, most physiological responses should be viewed as the complex product of the coordinated actions of multiple cellular messengers involving multiple molecular pathways. This extraordinary complexity underscores the difficulty in determining the precise molecular basis of a given physiological process. The central role of protein phosphorylation as a regulatory mechanism that mediates the actions of many individual cellular messengers and the interactions among them imbues the study of protein phosphorylation with a unique potential: to provide an experimental framework within which the layers of molecular steps that underlie and regulate cell function may be unraveled.

PROTEIN PHOSPHORYLATION MECHANISMS IN DISEASE

The study of protein phosphorylation has helped to clarify the mechanisms involved in the causes and manifestation of disorders of the nervous system. Two illustrative examples are given here: Alzheimer's disease and opiate addiction.

Abnormal phosphorylation of specific neural proteins may contribute to the development of Alzheimer's disease. Alzheimer's disease is a serious dementing illness of enormous medical and societal importance (see Ch. 47). It involves the degeneration of specific types of neuron in the brain. An invariable feature of Alzheimer's disease is the appearance of amyloid plaques. These plaques contain the Aβ amyloid protein, and there is some

evidence to suggest that the accumulation of Aβ contributes to neuronal degeneration and that mutations in the gene that codes for this protein are involved in a small number of cases of familial Alzheimer's disease.

Aβ is derived from amyloid precursor protein (APP) through proteolytic processing. In normal cells, APP is processed into fragments that are not associated with disease states. It is not yet known why APP is cleaved anomalously to yield Aβ to a greater extent in Alzheimer's disease. However, increasing evidence indicates that signal-transduction pathways involving protein phosphorylation are potent regulators of APP cleavage and can alter the rates of cleavage both at normal sites and at sites yielding putative amyloidogenic fragments [64]. The role of PKC in this process has received the most attention. Activators of PKC, or inhibitors of PP1, such as okadaic acid, dramatically stimulate APP proteolysis, whereas PKC inhibitors diminish cleavage of the protein. The finding that PKC regulates APP processing raises the possibility that agents that regulate this protein kinase, or specific protein phosphatases, might prove to be useful in the clinical management of Alzheimer's disease.

Further support for the potential clinical utility of drugs that influence protein kinases or protein phosphatases in Alzheimer's disease is the increasing evidence that aberrant phosphorylation mechanisms, i.e. excessive phosphorylation of the microtubule-associated protein called tau, contributes to the formation of neurofibrillary tangles, another component of the structural pathology of Alzheimer's disease and the related frontotemporal dementias [64, 65]. Under normal conditions, the most important kinases that phosphorylate tau are CDK5 and GSK3β (glycogen synthase kinase-3 β), both serine–threonine kinases. There is some evidence that other kinases (e.g. MAP kinases) may play a role in the hyperphosphorylation of tau associated with the development of neurofibrillary tangles, although this remains a subject of controversy. Intense research is under way to test whether inhibition of these various kinases may be clinically useful in the treatment of these dementing illnesses.

Upregulation of the cyclic AMP pathway is one mechanism underlying opiate addiction. The mechanisms by which opiates induce tolerance, dependence and withdrawal in specific target neurons has been a major focus of research for many years. The inability to account for prominent aspects of opiate addiction solely on the basis of alterations in endogenous opioid peptides or in opiate receptors has shifted attention to postreceptor mechanisms [66].

The noradrenergic neurons of the locus ceruleus have provided a useful model system for the study of opiate addiction (see Ch. 56). Acutely, opiates inhibit these neurons, in part by inhibiting the cAMP pathway via inhibition of adenylyl cyclase. Chronically, these neurons become tolerant to opiates; that is, their firing rates recover toward normal levels with continued exposure to the drug. Furthermore, they become dependent on opiates; that is, their firing rates increase far above control levels upon removal of the drug. These changes in the electrical excitability of locus ceruleus neurons mediate many of the physical signs and symptoms associated with opiate-withdrawal syndromes.

Increasing evidence indicates that a chronic opiate-induced upregulation of the cAMP pathway, manifested by increased concentrations of adenylyl cyclase, PKA and several phosphoprotein substrates for the protein kinase, contributes to opiate tolerance, dependence and withdrawal exhibited by locus ceruleus neurons [66]. This upregulated cAMP pathway can be viewed as a homeostatic response of the neurons to persistent opiate inhibition of the cells. In the chronic opiate-treated state, the upregulated cAMP pathway helps return neuronal firing rates to control levels, i.e. tolerance. Upon abrupt removal of the opiate via the administration of an opiate receptor antagonist, the upregulated cAMP accounts for part of the withdrawal activation of the cells.

Chronic opiate-induced upregulation of the cAMP pathway appears to be mediated in part by CREB: chronic opiate administration increases CREB expression; mice deficient in CREB show attenuated physical opiate dependence and withdrawal; and selective reductions of CREB in the locus ceruleus prevent upregulation of specific components of the cAMP pathway in response to chronic opiate administration [66]. This latter action is associated with attenuation of the electrical excitability of locus ceruleus neurons and of physical opiate dependence and withdrawal.

Upregulation of the cAMP pathway may be a common mechanism by which a number of neuronal cell types respond to chronic opiates and develop tolerance and dependence (see Ch. 56). There is also evidence that similar mechanisms involving alterations in the cAMP second-messenger and protein phosphorylation pathway may mediate aspects of addiction to other types of drugs of abuse, for example, cocaine and alcohol [66].

ACKNOWLEDGMENT

We thank Dr Craig Powell for helpful discussions in the preparation of this revised chapter.

ROLE OF TYROSINE PHOSPHORYLATION IN THE NERVOUS SYSTEM 426

Tyrosine phosphorylation is involved in every stage of neuronal development 426

Tyrosine phosphorylation has a role in the formation of the neuromuscular synapse 428

Tyrosine phosphorylation contributes to the formation of synapses in the central nervous system 429

Tyrosine phosphorylation plays an important role in synaptic transmission and plasticity 430

TYROSINE PHOSPHORYLATION IN THE NERVOUS SYSTEM

Protein phosphorylation is one of the most important mechanisms in the regulation of cellular function. Proteins can be phosphorylated on serine, threonine or tyrosine residues. Most phosphorylation occurs on serine and threonine, with less than 1% on tyrosine (see Ch. 23). This perhaps accounts for the late discovery of tyrosine phosphorylation, which was found first on polyoma virus middle T antigen in 1979 by Hunter and colleagues [1, 2]. Since then, a plethora of tyrosine-phosphorylated proteins has been discovered. Originally, tyrosine phosphorylation was believed to be involved primarily in regulating cell proliferation, since many oncogene products and growth factor receptors are protein tyrosine kinases (PTKs). However, it has become clear that tyrosine phosphorylation is involved in regulating a variety of cellular processes. In fact, the nervous system contains a large variety of PTKs and protein tyrosine phosphatases (PTPs), and some of these are exclusively expressed in neuronal tissues. Figure 24-1 shows the

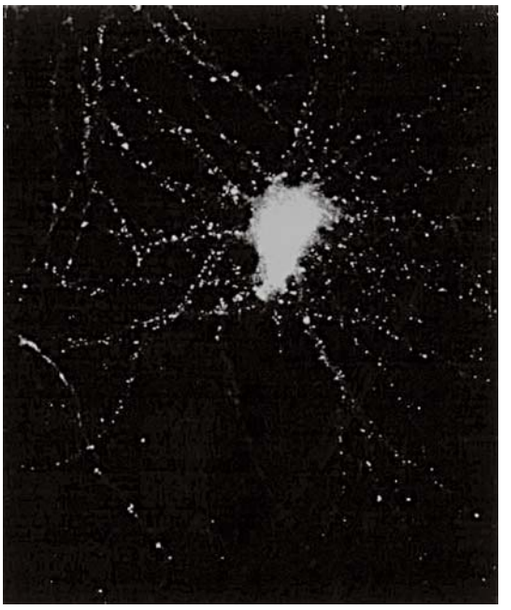

FIGURE 24-1 Phosphotyrosine staining of a hippocampal neuron. A cultured rat hippocampal pyramidal neuron is stained with an antiphosphotyrosine antibody and detected by a secondary antibody conjugated to rhodamine. The staining reflects the presence of tyrosine-phosphorylated proteins throughout the neuron, including the cell body and synaptic regions.

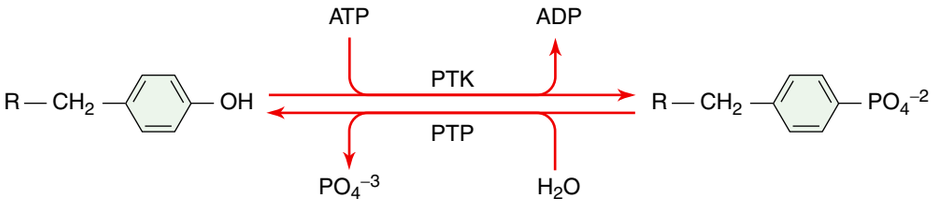

FIGURE 24-2 Tyrosine phosphorylation and dephosphorylation. Protein tyrosine kinases (*PTK*) catalyze the transfer of the γ-phosphate group from ATP to the hydroxyl group of tyrosine residues, whereas protein tyrosine phosphatases (*PTP*) remove the phosphate group from phosphotyrosine. *R*, protein.

immunocytochemical staining of a cultured hippocampal neuron with a phosphotyrosine antibody [3]. It reveals the presence of tyrosine-phosphorylated proteins in the cell body as well as in synapses, suggesting that tyrosine phosphorylation may play a role in neuronal function. Furthermore, many neuronal processes are modulated by inhibitors of PTK or PTP, or by modification of the genes encoding these enzymes.

Tyrosine phosphorylation is regulated by the balance between the activities of PTKs and PTPs (Fig. 24-2). Phosphorylation of a tyrosine residue adds negative charges to its side chain and increases its size. These alterations may consequently trigger structural changes and potential functional modifications in the tyrosine-phosphorylated protein. In addition, the phosphorylated tyrosine and its surrounding amino acids may become a molecular adhesive that interacts with phosphotyrosine binding proteins, thereby changing its subcellular localization and functions.

PROTEIN TYROSINE KINASES

Upon completion of the Human Genome Project, 90 unique genes are identified to encode PTKs [4]. Among these, 58 encode receptor protein tyrosine kinases (RPTKs), which can be categorized into 20 subfamilies (see Fig. 24-6) [5]; and 32 encode nonreceptor protein tyrosine kinases (NRPTKs), which belong to 10 subfamilies (Fig. 24-3) [5]. RPTKs are integral membrane proteins while NRPTKs are intracellular. The catalytic activity of each type of kinase is subject to regulation by extracellular stimuli.

Nonreceptor protein tyrosine kinases contain a catalytic domain, as well as various regulatory domains important for proper functioning of the enzyme. NRPTKs are found in the inner leaflet of the plasma membrane, cytosol, endosomal membranes and nucleus. These include the Src, Jak, Abl, Tec, Ack, Csk, Fak, Fes, Frk and Syk subfamilies (Fig. 24-3). Since a great deal is known about the structure and regulation of the Src family tyrosine kinase, we will use it to illustrate the principles in NRPTK signaling; unique features in other subfamilies will be indicated when appropriate. The catalytic domain of PTKs is about 250 amino acids in length and is by itself a functional enzyme. However, most, if not all, PTKs are larger and contain regulatory domains in addition to the catalytic domain. The regulatory domains restrain the catalytic domain and minimize basal kinase activity in the absence of stimulation. When stimulated, the regulatory domains relieve their restraints on the catalytic domain and allow kinase activation. The regulatory domains also direct the protein to specific subcellular targets or compartments, interact with potential substrates and assemble with other signaling molecules. The structural domains of the Src kinase family are, in order from the N-terminus: the SH4 (Src homology 4), SH3, SH2 and SH1 domains. SH1 is the catalytic domain; SH2 and SH3 are both molecular adhesives important for protein–protein interaction; whereas the SH4 domain, residing at the very N-terminus, is important for membrane attachment. Between the SH4 and the SH3 domains lies a region whose sequence varies considerably among different members of the Src family.

The SH4 domain, at the very N-terminus of the Src family kinases, contains a myristoylation site critical for membrane localization of Src. *N*-myristoylation is catalyzed cotranslationally by *N*-myristoyl transferase. Following removal of the N-terminal methionine, myristate is transferred from myristoyl coenzyme A to the glycine residue at the second position. Although myristoylation is necessary for anchoring Src to membrane, it is insufficient. The basic residues in the SH4 domain in Src and Blk interact with the negatively charged head groups of phospholipids and help to attach these kinases to the membrane. In other Src family members palmitoylation of a cysteine residue in the SH4 domain secures their interaction with membrane. While myristoylation is irreversible, electrostatic interaction and palmitoylation are reversible. For example, Ser17 in Src can be phosphorylated by protein kinase A (PKA). Phosphorylation decreases the local positive charge and consequently dissociates Src from the negatively charged membrane. Similarly, palmitate can be removed from the cysteine residue to release Src family kinases from the membrane to the cytosol. An N-terminal pleckstrin homology (PH) domain in the Tec family tyrosine kinases anchors these kinases to membrane by binding specifically to

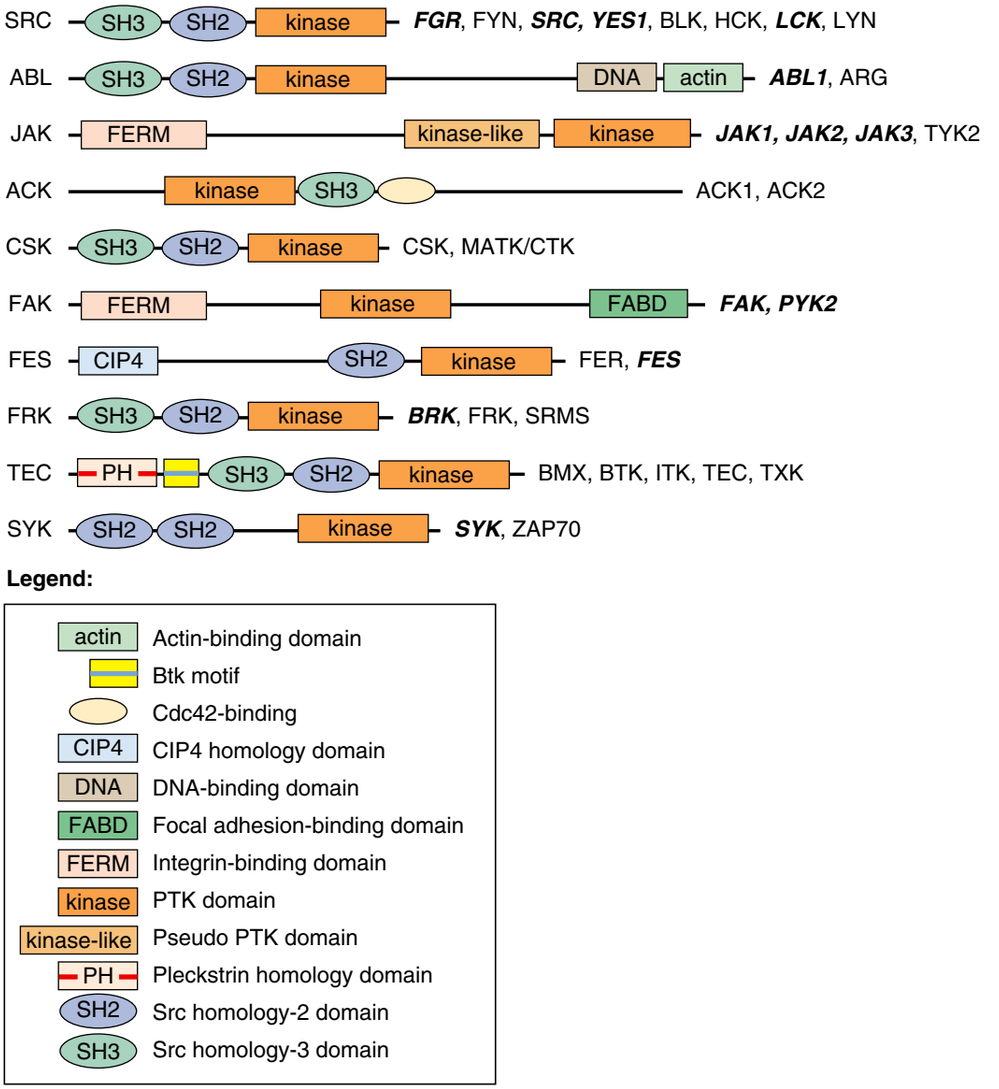

FIGURE 24-3 Nonreceptor protein tyrosine kinase (NRPTK) families. The family members are shown to the right and family name to the left of each NRPTK. Inset indicates the PTK catalytic domain and other domains for the regulation of localization and function. (From reference [5], with permission of *Nature*. © *Nature* 2001.)

phosphatidylinositol-3,4,5-trisphosphate (PI-3,4,5-P3) in membrane (see Ch. 20).

The unique domain following the SH4 domain from the N-terminus is a region with considerable variation in the amino acid sequences among different Src family members. This unique domain may be involved in protein–protein interactions. For example, the unique region of Lck is linked to CD4 and CD8, while those of Fyn and Lyn may be associated with the T- and B-cell antigen receptors.

The SH3 domain consists of approximately 60 amino acid residues and is C-terminal to the unique domain. Its five β strands form a globular structure whose N- and C-termini are in proximity to each other. SH3 domains mediate both intermolecular and intramolecular interactions, targeting short amino acid sequences that consist of specific proline-rich motifs in a left-handed helix – polyproline type II helix. A typical SH3 domain ligand is composed of two prolines separated by scaffolding residues (XP–X–XP) (reviewed in [6, 7]). It can bind to SH3 domain in either one of two opposite orientations, depending on the position of an additional positively charged residue in the peptide sequence. Type I ligands have a consensus sequence of RPLPPLP. Type II ligands adopt an inverted orientation and have a consensus sequence of ∅PPLPXR, where ∅ represents a hydrophobic amino acid. Small peptide ligands have a low affinity for the SH3 domain (5–50 μmol/l) and low sequence specificity. Interaction between SH3 domains and proline-rich sequences within proteins confers higher affinity and specificity. Despite the presence of consensus SH3 binding sequences, variations from this central theme do exist for SH3 domains from different members of the Src family tyrosine kinases. The neuronal form of Src

contains a six-amino-acid insert within the SH3 domain. This insertion appears to decrease the affinity of the SH3 domain for known ligands since most of the SH3 ligands fail to interact with the neuronal form of Src. This insertion may change the specificity of the Src SH3 domain for neuronal targets and increase its activity by reducing intramolecular interaction.

The SH2 domain is about 100 amino acid residues in length and lies between the SH3 and SH1 domains. This domain interacts with phosphorylated tyrosine residue in a sequence-specific manner; thus this type of protein–protein interaction is directly regulated by tyrosine phosphorylation (reviewed in [8]). SH2 domains contain two binding pockets for their ligands. One of these pockets contains a positively charged arginine residue, which interacts with the negatively charged phosphotyrosine residue. The other pocket interacts with three to five amino acids C-terminal to the phosphotyrosine and plays a major role in determining substrate specificity. However, amino acid residues N-terminal to the phosphotyrosine have also been shown to contribute to SH2 domain binding. The affinity of an SH2 domain for its interacting phosphotyrosine peptide is in the nanomolar range. Removal of the phosphate group from the peptide reduces the affinity for the peptide by about three orders of magnitude. Like the SH3 domain, the N- and C-termini of the SH2 domain are proximal to each other; this juxtaposition allows the formation of a protruding globular structure without significant disruption of the structure of the parent molecule and, importantly, exposes the ligand-binding surface. Compared to SH3 domain ligands, there is less of a consensus peptide sequence among SH2 ligands (Table 24-1). SH3 and SH2 domains are found in a variety of signaling molecules depicted in Figure 24-4.

The SH1 domain is the catalytic domain. The crystal structures of Src-family tyrosine kinases have been solved [9,10]. In general, the catalytic (SH1) domain has an overall bilobal structure, with a small N-terminal lobe and a large C-terminal lobe. The N-lobe contains a glycine-rich sequence, GXGXXGXV, and an invariable downstream lysine for ATP binding. Mutation of this lysine often leads to loss of catalytic activity. The C-lobe contains a glutamate residue that catalyzes transfer of the phosphate group from ATP to tyrosine. ATP fits in the cleft between the two lobes with its γ-phosphate pointing outward while the substrate peptide interacts at the cleft opening. There is considerable flexibility in the relative orientation of these two lobes. The active conformation of the kinase allows the proper alignment of the ATP terminal phosphate with the substrate tyrosine residue. However, the two lobes of an inactive kinase are swung apart so that the ATP terminal phosphate is not aligned with the substrate. Figure 24-5A shows the X-ray crystallographic analysis of hck.

Under physiological conditions, NRPTKs are highly specific in directing tyrosine phosphorylation toward appropriate substrates. This specificity relies on the intrinsic predilection of the catalytic domain towards specific amino acid sequences within protein substrates. In addition, noncatalytic domains, e.g., SH2, SH3 and PH domains of NRPTKs, distribute these kinases to the subcellular region where appropriate substrates are in proximity or abundance, thus favoring phosphorylation of these proteins rather than other substrates.

The regulatory domain is the region C-terminal of the SH1 domain. It contains a tyrosine residue (Y527 in Src; see Glossary for single letter code for amino acids) critical for modulating kinase activity (reviewed in [11]). Under basal conditions, Y527 is phosphorylated by another NRPTK, C-terminal Src kinase (Csk). The phosphorylated Y527 interacts with SH2 domain from the same molecule. This intramolecular interaction favors and is further stabilized by association of Src SH3 domain with the polyproline helix in the linker region between SH1 and SH2 domains. As a result of these interactions, a critical acidic residue is pushed away from the active site, resulting in inhibition of Src kinase activity. Src can be activated by relieving these intramolecular constraints. One of these mechanisms is by dephosphorylation of Y527 and subsequent disruption of the two intramolecular interactions mentioned above. The initial Src kinase activity allows autophosphorylation of Y416 in the activation loop, additional conformational change and maximal enzyme activity subsequently. This model nicely accounts for some earlier observations. For example, v-Src, the tumorigenic form of Src that lacks the negative regulatory domain containing Y527, has very high basal activity. Mutation of Y527 to phenylalanine can increase Src activity. In light of the opposing effects of phosphorylation of Y527 and Y416 on Src kinase activity, different PTPs differentially regulate its enzyme activity. Dephosphorylation of Y527 catalyzed by the leukocyte common antigen (CD45) or an SH2 domain-containing PTP (SHP-2) activates Src while dephosphorylation of Y416 by another phosphatase (SHP-1) inactivates it. Figure 24-5B shows the regulatory mechanisms for Src family tyrosine kinases.

The key in activation of Src family kinases is the disruption of intramolecular interactions and relief of autoinhibition. In addition to dephosphorylation of Y527 by PTPs, the SH2-phosphoY527 bond can be disrupted by competition with a high affinity phosphotyrosine ligand.

TABLE 24–1 Specificity and affinity of SH2, phosphotyrosine binding (PTB) and SH3 domains

Domains	Consensus sequence of ligands	K_D
SH2	$pYR_1R_2R_3$	1–10 nmol/l
PTB	∅ NP*X*pY	25–100 nmol/l
SH3	RPLPPLP, ∅ PPLP*X*R	5–50 μmol/l

The consensus sequences of the ligands interacting with SH2, PTB and SH3 domains are listed with their dissociation constants. Both SH2 and PTB domains bind to phosphotyrosine in a sequence-specific manner. Tyrosine dephosphorylation can reduce the affinity of the SH2 domain to its ligand by 1,000-fold. R_1, R_2 and R_3 represent variable amino acids depending on the specific SH2 domain involved. *X* represents any amino acid. ∅ represents a hydrophobic amino acid; pY, phosphotyrosine.

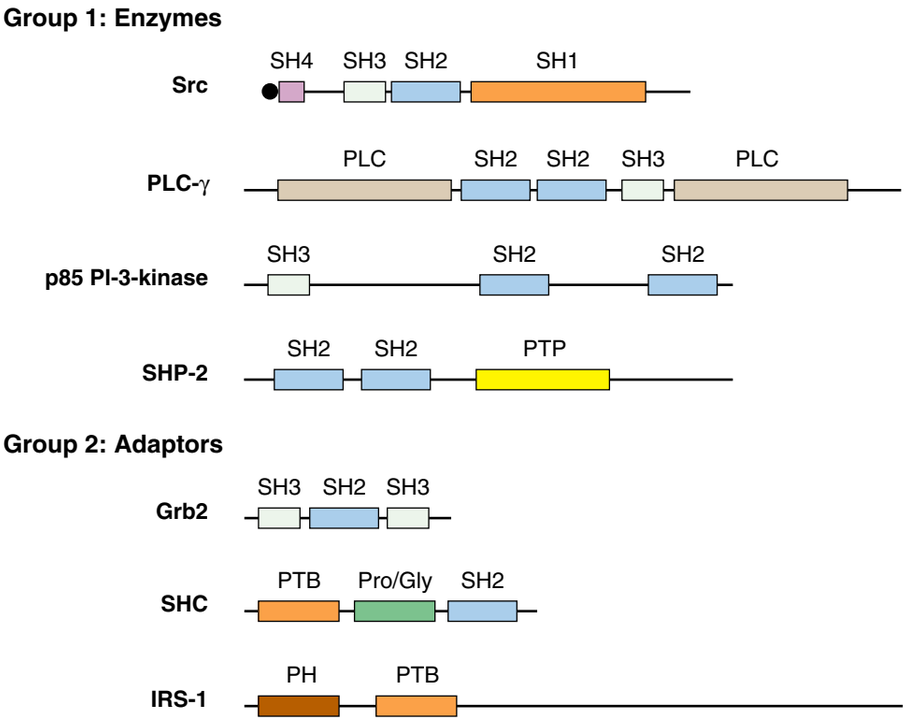

FIGURE 24-4 SH2, SH3 and phosphotyrosine binding (*PTB*) domain-containing signaling proteins. SH2, SH3 and PTB domains are important molecular 'adhesives'. These domains are found in enzymes and play important roles in the regulation of enzyme function. They also are found in proteins lacking any apparent catalytic domain, in which case they may serve as adaptor proteins, assembling signal-transduction complexes. The PTB domain of insulin receptor substrate-1 (*IRS-1*) shares a low degree of homology with the one on SHC. The *black circle* indicates a myristic acid moiety. *PLC*, phospholipase C; *PI3-kinase*, phosphatidylinositol-3-kinase; *PTP*, protein tyrosine phosphatase; *PH*, pleckstrin homology; *SHP*, SH2-containing PTP; *Grb*, growth-factor-receptor-binding protein.

For example, activation of the platelet-derived growth factor receptor (PDGFR) results in autophosphorylation of a number of tyrosine residues, including Y579 in the juxtamembrane region. This phosphotyrosine-containing peptide sequence interacts with the Src SH2 domain and displaces the negative regulatory domain, resulting in Src activation. The displaced Src C-terminal tail is now accessible to PTPs, allowing prolonged activation of Src despite a transient autophosphorylation of the PDGFR. A similar mechanism applies to the activation of Src by autophosphorylated Fak (Fig. 24-5B). Although NRPTKs do not possess an extracellular domain from which they can directly communicate with the extracellular world, they are able to respond to the extracellular stimulation by 'borrowing' extracellular domains from transmembrane proteins that interact with the NRPTKs.

In addition, the phosphotyrosine moiety (Y402) on a proline-rich tyrosine kinase (PYK2, a NRPTK) can apparently compete with phosphoY527 for interaction with SH2 domain on Src and lead to Src activation. PYK2 is a member of the Fak family. It is highly expressed in the nervous system. Its activation depends on both cell adhesion and the presence of calcium or PKC activation. Therefore, certain G-protein-coupled receptors (GPCRs) that release calcium and activate PKC may play a role in the regulation of PYK2 and Src activities (see Ch. 19 for detailed discussion of GPCRs).

Receptor protein tyrosine kinases consist of an extracellular domain, a single transmembrane domain and a cytoplasmic domain. The cytoplasmic domain is composed of a juxtamembrane region, one or two catalytic domains and a C-terminal tail. Like the NRPTKs, the structures outside the catalytic domain are critical for the proper functioning of these enzymes. RPTKs can be classified into at least 20 families [4], including the epidermal growth factor receptor (EGFR), platelet-derived growth factor receptor (PDGFR), fibroblast growth factor receptor (FGFR), nerve growth factor receptor (NGFR), insulin receptor (INSR) and erythropoietin-producing hepatocellular receptor (EphR) (Fig. 24-6) (see also Ch. 27).

The extracellular domain of RPTKs can be composed of different structural motifs. For instance, the EGFR extracellular domain contains two cysteine-rich regions. The PDGFR extracellular domain consists of five immunoglobulin-like repeats. Other domains found in the extracellular region of RPTKs include fibronectin III repeats,

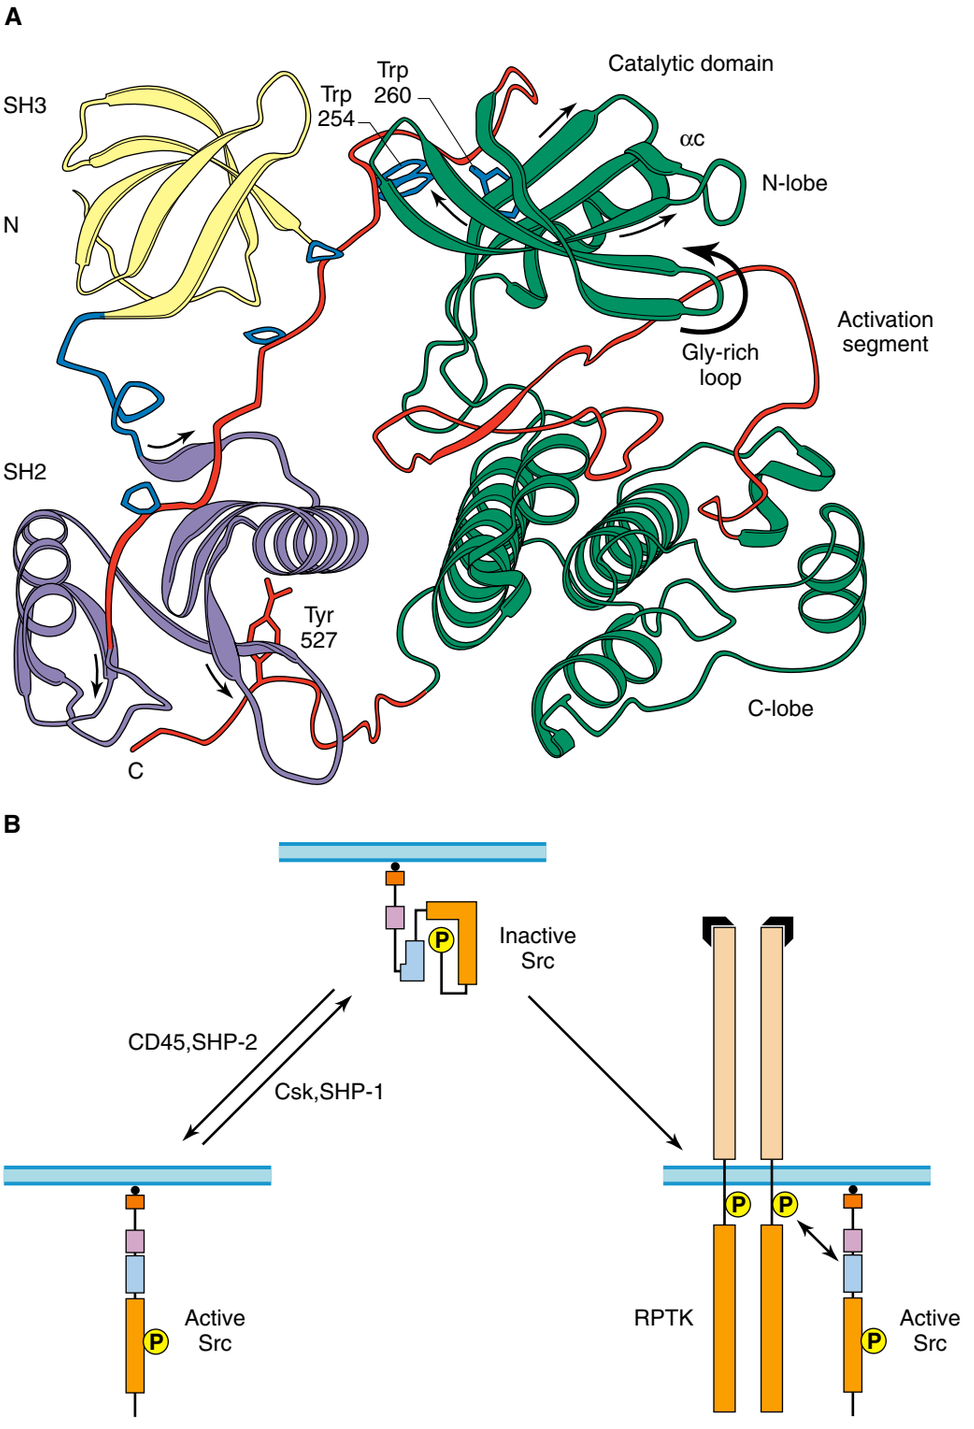

FIGURE 24-5 (**A**) Crystal structure of the Src family kinase hck. The catalytic domain of Src family tyrosine kinases consists of an N-terminal ATP-binding lobe and a C-terminal substrate-binding lobe. There is considerable flexibility in the relative orientation of these two lobes. The active conformation allows the proper alignment of the ATP terminal phosphate, the substrate and a catalytic glutamate residue (Glu310). However, the two lobes of an inactive kinase are swung apart, disrupting proper alignment. (With permission from reference [9].) (**B**) Regulation of Src activity. Src activity can be regulated in a number of ways. In the inactive state, phosphorylated Y527 interacts with the SH2 domain. In addition, the SH3 domain binds the linker region between the SH1 and SH2 domains. These two intramolecular interactions pull the two lobes of the catalytic domain apart and inactivate the kinase. Therefore, dephosphorylation of Y527 by protein tyrosine phosphatases, e.g. CD45 and SHP-2, activates the kinase. Phosphorylation of Y527 by Csk inactivates the kinase. Inactivation is also achieved by dephosphorylating the autophosphorylation site Y416 by SHP-1. Alternatively, Src can be activated by binding to an autophosphorylated receptor protein tyrosine kinase (*RPTK*), such as the platelet-derived growth factor receptor. The RPTK autophosphorylation site binds to the src SH2 domain and thus disrupts the inhibitory intramolecular interactions and activates the kinase. Association of Src with tyrosine-phosphorylated Fak activates the kinase in a similar fashion.

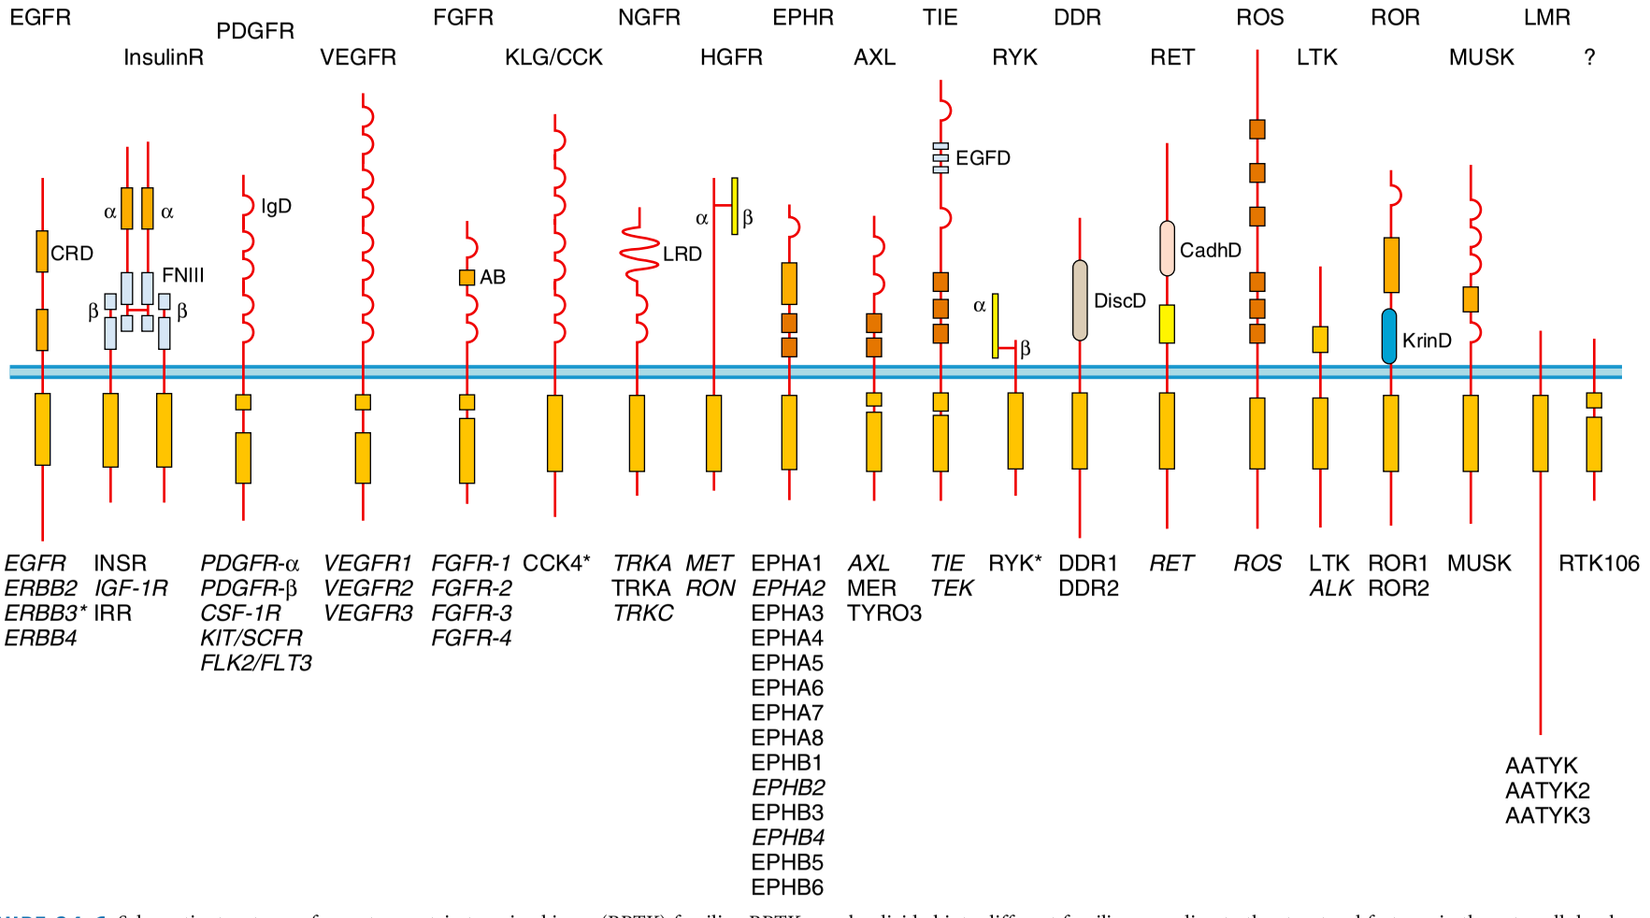

FIGURE 24-6 Schematic structures of receptor protein tyrosine kinase (RPTK) families. RPTKs can be divided into different families according to the structural features in the extracellular domain. Following the extracellular domain are the transmembrane and intracellular domains; the latter contains the catalytic domain. (From reference [5], with permission of *Nature*. © *Nature* 2001.)

kringle domains and leucine-rich motifs. The extracellular domains of members of the insulin receptor subfamily contain disulfide bridges responsible for the formation of a heteroterameric structure ($\alpha_2\beta_2$). The extracellular domains carry the binding sites for RPTK ligands, which range from soluble factors, extracellular matrix proteins, to surface proteins expressed on adjacent cells. The extracellular domain may also be involved in the dimerization of RPTKs, a process critical for the activation of intrinsic tyrosine kinase activity.

The transmembrane domain in the RPTK is a hydrophobic segment of 22–26 amino acids inserted in the cell membrane. It is flanked by a proline-rich region in the N-terminus and a cluster of basic amino acids in the C-terminus. This combination of structures secures the transmembrane domain within the lipid bilayer. There is a low degree of homology in the transmembrane domain, even between two closely related RPTKs, suggesting that the primary sequence contains little information for signal transduction.

The cytoplasmic domain primarily consists of the catalytic domain and various autophosphorylation sites that regulate catalytic function and serve as docking sites for SH2 domain-containing proteins. The protein kinase catalytic domains of RPTKs are highly conserved and similar in structure to those of the NRPTK (see above).

RPTK activation. The activity of RPTKs is normally suppressed in their quiescent state. This suppression is due to the numerous loose and unstructured conformations of the activation loop (A loop) within the catalytic domain; the majority of these conformations interfere with substrate and ATP binding. However, a subset of these conformations is amenable to binding of substrate and ATP, resulting in activation of the RPTKs. Phosphorylation of the tyrosine residue(s) in the A loop shifts the equilibrium towards the active conformation. Because of steric hindrance, PTK catalytic domains appear to be unable to autophosphorylate tyrosine residue(s) in the A loop within the same molecule; rather *trans*-autophosphorylation between two different catalytic domains is necessary for their activation. As a consequence, ligand-induced dimerization is an important step in the activation of RPTKs (Fig. 24-7).

Different RPTKs use different mechanisms to achieve dimerization and *trans*-autophosphorylation. PDGF is a dimer consisting of subunits A and B in different combinations (AA, BB and AB). These dimeric PDGF ligands can physically and directly cross-link two PDGFRs because of their bivalency. In contrast the EGFRs binding to their monomeric ligands may induce a conformational change in the extracellular domain that would subsequently associate with each other. Interestingly, the INSR consists of two catalytic domains already in proximity to each other even in their quiescent state due to their cross-linkage by intermolecular disulfide bonds in the extracellular domains (Fig. 24-6). In this case, the low basal kinase activity in the absence of ligand may be maintained by a suboptimal orientation or distance of the active sites to the A loop. Ligand binding may re-orient or further reduce the distance between the catalytic domains resulting in *trans*-autophosphorylation and activation.

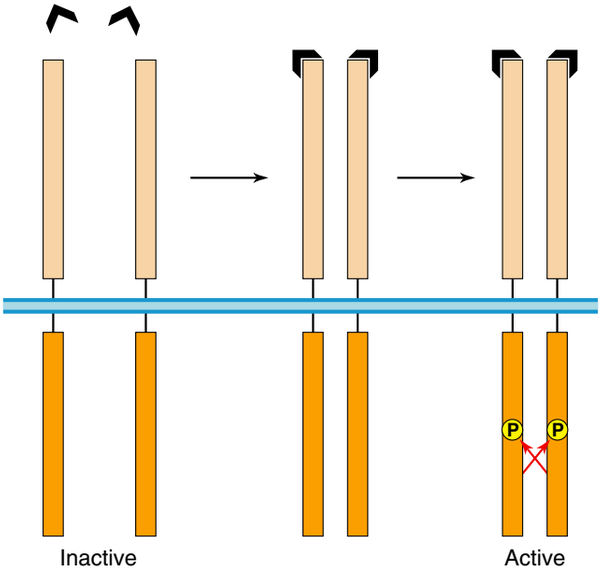

FIGURE 24-7 Activation of receptor protein tyrosine kinase (RPTK) by dimerization and transphosphorylation. Autophosphorylation is a key step in the activation of PTKs. To achieve autophosphorylation, some PTKs dimerize and transphosphorylate each other. Ligand binding induces dimerization of RPTKs so that the catalytic domains are in proximity for transphosphorylation. The autophosphorylated RPTK, thus, is activated. Some nonreceptor protein tyrosine kinases (NRPTKs) can be activated without dimerization (see Fig. 24-5B). However, others, such as Jak/Tyk kinases, are activated by transphosphorylation. Jak/Tyk tyrosine kinases are associated constitutively with transmembrane proteins gp130 and leukemia-inhibitory factor receptor (LIFR)β. Extracellular ciliary neurotrophic factor (CNTF) induces the formation of a quaternary complex consisting of CNTF, LIFRβ, gp130 and another membrane protein known as CNTF receptor α. Consequently, the associated Jak/Tyk are dimerized, allowing transphosphorylation and activation.

RPTK inactivation. Once activated by their ligands, surface RPTKs with their bound ligands are rapidly internalized and degraded. These processes quickly terminate the action of the ligands. The intrinsic tyrosine-kinase activity appears to be important for both internalization and degradation. For example, mutant EGFR without the lysine for ATP binding is neither internalized nor degraded in a mouse fibroblast cell line, NIH3T3 cells. In certain situations, internalized RPTKs continue to mediate signal transduction mechanisms. For instance, in sympathetic neurons, internalized TrkA is transported from the axon terminal to the cell body where it influences signal-transduction cascades that affect gene expression.

Tyrosine phosphorylation of RPTKs. Phosphorylation of specific tyrosine residues on the RPTKs can recruit SH2 domain-containing signaling molecules to the site of action. These signaling molecules include phospholipase C-γ1 (PLC-γ1), phosphatidylinositol-3-kinase (PI-3-kinase), growth factor receptor-binding protein 2 (Grb2), SH2-containing protein (SHC) and Src. Each signaling molecule recognizes a specific tyrosine phosphorylation site on the RPTK, as indicated in Figure 24-8. Recruitment of PLC-γ1 and PI-3-kinase to the membrane brings the enzymes to their substrates in the lipid bilayer. PLC-γ1 is phosphorylated and activated by RPTKs, whereas association of PI-3-kinase with the autophosphorylated RPTKs induces its activity allosterically. PLC-γ1 catalyzes formation of diacylglycerol and inositol trisphosphate (IP_3) from phosphatidylinositol-4,5-bisphosphate (PIP_2) (see also Ch. 20). Diacylglycerol activates PKC, while IP_3 triggers calcium release from intracellular stores. PI-3-kinase incorporates a phosphate group in the 3′ position on the inositol ring of phosphatidylinositol phospholipids. One of the products, PI-3,4-P_2, activates Akt kinase and promotes neuronal survival.

Recruitment of Grb2 to the membrane activates the MAPK pathway. Grb2 is an adaptor molecule carrying one SH2 and two SH3 domains (Fig. 24-4). The Grb2 SH2 domain recognizes the tyrosine-phosphorylated moiety on certain RPTKs, such as EGFR (Fig. 24-8), and anchors itself to these membrane-spanning proteins. The Grb2 SH3 domains interact with son of sevenless (SOS), a guanine nucleotide exchange protein. SOS stimulates the release of GDP and subsequent binding of GTP to the membrane-bound, low-molecular-weight, GTP-binding protein Ras (see Ch. 19). GTP-bound Ras interacts with and translocates the serine–threonine protein kinase Raf to the plasma membrane, where Raf becomes activated. Activated Raf phosphorylates MEK, which in turn stimulates MAPK. One of the substrates of MAPK is p90Rsk. Both MAPK and p90Rsk translocate to the nucleus after phosphorylation, where they phosphorylate and activate transcription factors, such as serum-responsive factor (SRF), T-cell-specific transcription factor and cAMP responsive element-binding protein, and, ultimately, alter gene expression.

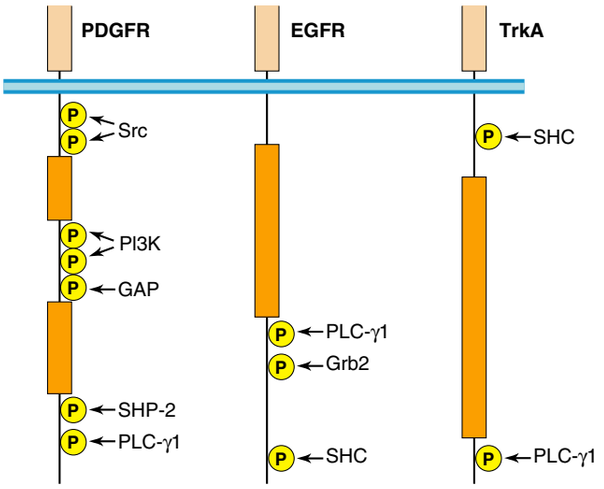

FIGURE 24-8 Recruitment of different signaling molecules to different tyrosine-phosphorylation sites on receptor protein tyrosine kinases (RPTKs). RPTKs usually are autophosphorylated on several different sites. Each tyrosine-phosphorylation site has a unique sequence for interaction with specific signaling molecules containing SH2 or phosphotyrosine-binding (PTB) domains. This provides specificity and diversity for RPTK signaling. *PDGFR*, platelet-derived growth factor receptor; *EGFR*, epidermal growth factor receptor; *PLC*, phospholipase C; *GAP*, GTPase-activating protein; *Grb2*, growth factor receptor binding protein; *PI3K*, phosphatidylinositol-3-kinase; *SHC*, SH2-containing protein; *SHP*, SH-domain containing tyrosine phosphatase.

Some RPTKs cannot interact directly with Grb. They activate the MAPK pathway with the help of an adaptor molecule, such as SHC or insulin receptor substrate-1 (IRS-1). SHC contains a 160-amino-acid phosphotyrosine-binding domain (PTB) that recognizes an autophosphorylation site on some RPTKs. Unlike the SH2 domain, which recognizes the sequence C-terminal of the phosphotyrosine residue, PTB domains recognize amino acid residues upstream of phosphotyrosine. The consensus sequence for interaction with the PTB domain of SHC is ∅NPXpY, where ∅ is a hydrophobic amino acid and X is any amino acid. IRS-1 contains a putative PTB domain that shares a low degree of homology with the PTB domain in SHC. After docking to the phosphotyrosine sites on RPTKs, both IRS-1 and SHC are in turn phosphorylated by their host RPTKs. Tyrosine phosphorylation of these adaptor molecules creates a binding site for Grb2, leading to activation of the MAPK cascade as mentioned above. Similarly, a PTP – SHP-2 – plays a similar adaptor role in mediating the activation of MAPK pathway by RPTKs (see below). RPTKs that interact with a PTB-binding domain-containing adaptor molecule include the nerve growth factor receptor (TrkA), EGFR, INSR and insulin-like growth factor (IGF)-1 receptor. Figure 24-9 shows the role of SHC in RPTK-mediated gene expression.

PROTEIN TYROSINE PHOSPHATASES

The low level of tyrosine phosphorylation in cells is probably attributable to the high specific activity of PTPs, which is about 10–1,000 times that of PTKs. The first PTP purified was PTP1B from human placenta. Based on the sequence of PTP1B, other PTPs were isolated very rapidly using molecular biological techniques, including polymerase chain reaction and low-stringency hybridization. Recent advances in sequencing the human genome have revealed more PTPs; it is estimated that there are in total over 100. PTPs can be divided into those that are specific for phosphotyrosine and those that recognize both phosphotyrosine and

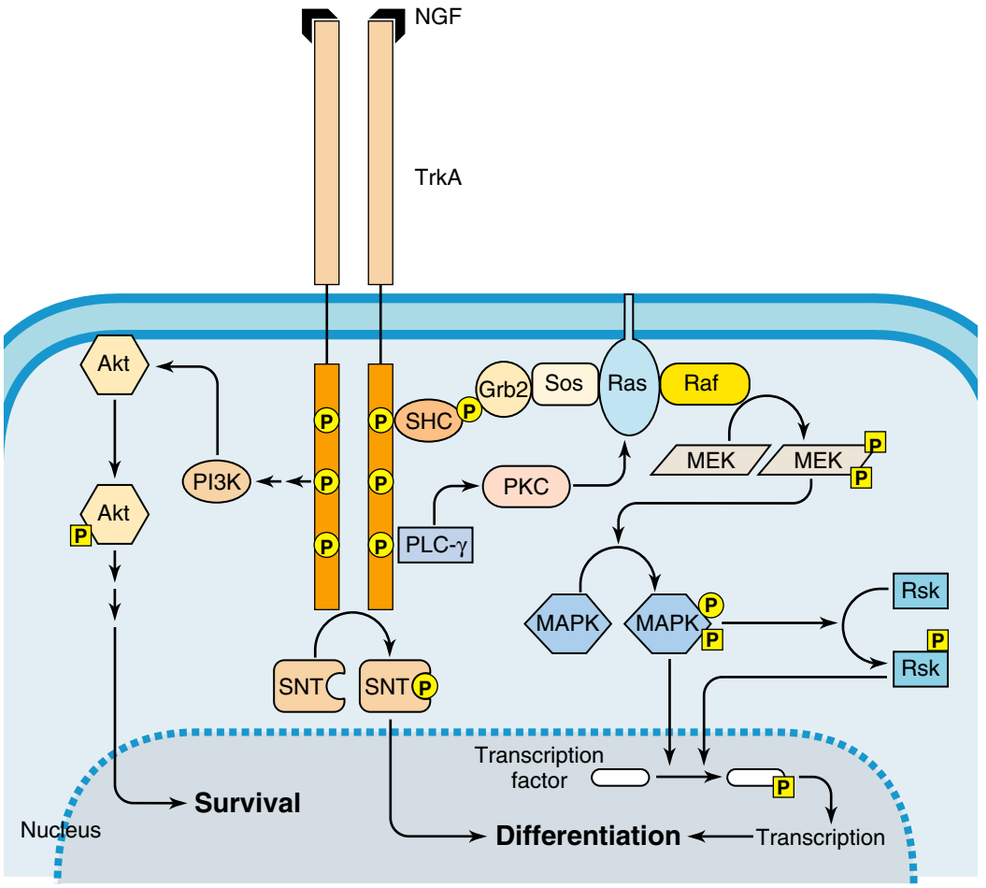

FIGURE 24-9 Signal-transduction mechanisms in nerve growth factor (*NGF*)-mediated neuronal survival and differentiation. NGF binds to TrkA and induces autophosphorylation on three different sites in the intracellular domain. One site interacts with SHC, which eventually leads to the activation of mitogen-activated protein kinase (*MAPK*) and transcription. TrkA also induces tyrosine phosphorylation of *suc*-associated neurotrophic factor-induced target (*SNT*) via a mechanism independent of all known signaling mechanisms. MAPK-induced transcription and SNT tyrosine phosphorylation are believed to be important in neuronal differentiation. TrkA autophosphorylation also activates phosphatidylinositol-3-kinase (*PI3K*) by recruiting it to the membrane. PI3K generates PI-3,4,5-trisphosphate from PI-4,5-bisphosphate. PI-3,4,5-trisphosphate is hydrolyzed to yield PI-3,4-bisphosphate, which activates Akt by translocating it to the membrane. Activated Akt can promote neuronal survival. *Grb2*, growth factor receptor binding protein; *MEK*, MAPK/Erk kinase; *PLC*, phospholipase C; *SHC*, SH2-containing protein; *SOS*, son of sevenless.

phosphoserine/threonine – the dual specificity PTPs (see also Ch. 23). Like PTKs, phosphotyrosine-specific PTPs consist of receptor protein tyrosine phosphatases (RPTPs) and nonreceptor protein tyrosine phosphatases (NRPTPs). Each of these two families of phosphatases can further be divided into subfamilies based on their distinctive structural features (Fig. 24-10).

Nonreceptor protein tyrosine phosphatases are structurally different from serine–threonine phosphatases and contain a cysteine residue in their active sites. The catalytic domains of PTPs are different from those of the serine–threonine phosphatases. The catalytic domains of PTPs are approximately 200–300 amino acids in length and are composed of a central β sheet enclosed by α helices. The highly conserved motif, (I/V)HCXXGXGRS/TG, forms the base of the active-site cleft. The catalytic reaction mechanism is composed of two different steps. First, the nucleophilic thiolate anion of the active-site cysteine residue (Cys215 of PTP1B) attacks the phosphotyrosine on the substrate protein. A thiophosphate intermediate is then formed, accompanied by release of the dephosphorylated product. The second step involves hydrolysis of the thioester bond by an aspartate residue (Asp181 of PTP1B) to regenerate the free cysteine residue and phosphate. A commonly used PTP inhibitor, vanadate, reversibly inhibits PTPs by competing with phosphotyrosine for the active site. On the other hand, pervanadate irreversibly inhibits PTPs by binding to the active site and oxidizing the catalytic cysteine to cysteic acid.

The phosphotyrosine-recognition subdomain confers substrate specificity of PTPs by creating a deep pocket (9 Å) so that only the phosphotyrosine moiety is long enough to reach the cysteine nucleophile located at the base of this pocket; phosphoserine and phosphothreonine

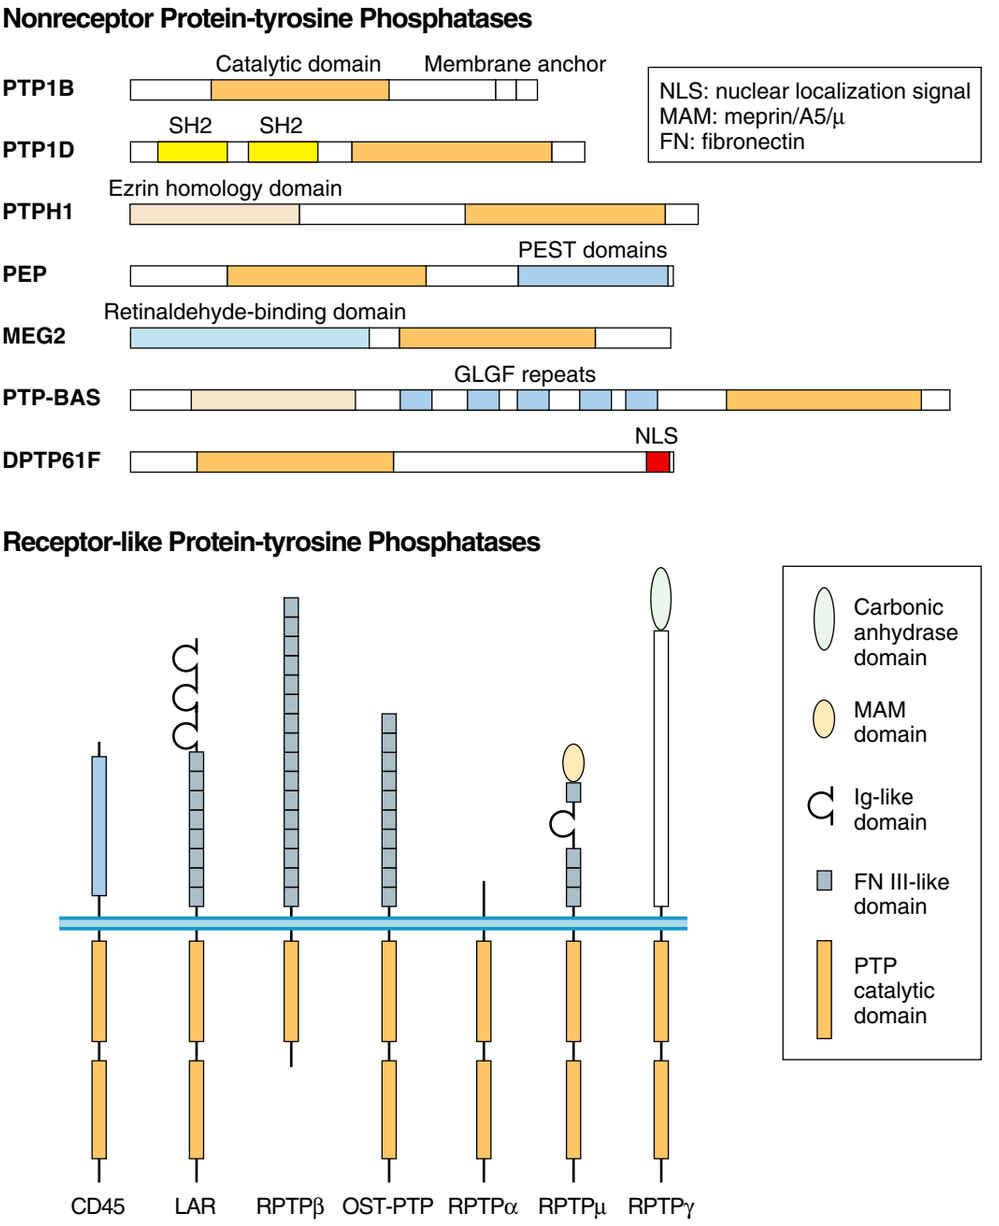

FIGURE 24-10 Schematic structures of nonreceptor protein tyrosine phosphatases (NRPTPs) and receptor protein tyrosine phosphatases (RPTPs). NRPTPs contain a catalytic domain and various regulatory domains. RPTPs are composed of an extracellular domain, a transmembrane domain and an intracellular domain with one or two catalytic domains. Like receptor protein tyrosine kinases, the structural features of the extracellular domains divide the RPTPs into different families. (With permission from reference [12]).

side chains are too short to be dephosphorylated. Dual-specificity PTPs lack the phosphotyrosine-recognition subdomain and have a shallow catalytic-site cleft (6 Å) that is accessible to all three phosphorylated hydroxyamino acids. An example of a dual-specificity protein phosphatase is MAP kinase phosphatase (MKP)-1, which inactivates MAPK by removing phosphate from both the threonine and tyrosine residues in the activation loop.

In addition to their faithfulness to phosphotyrosine, phosphotyrosine-specific NRPTPs appear to have their preferences for substrates. For example, PTP1B prefers EGFR and INSR to many other phosphotyrosine-containing proteins. Such specificity is partly conveyed by a combination of intrinsic properties of the catalytic and regulatory domains that direct the enzyme to specific subcellular compartments where the preferred substrates are enriched. For PTP1B, its hydrophobic C-terminal tail directs this NRPTP to the cytoplasmic face of endoplasmic reticulum. Anchoring PTP1B at this strategic location may ensure that newly synthesized RPTKs are in their

dephosphorylated quiescent state, avoiding unwanted activation before arriving at their final destination in the plasma membrane. Other NRPTPs, SHP-1 and SHP-2, contain SH2 domains that direct the enzyme precisely to specific targets (Fig. 24-4). Despite considerable sequence homology, these two NRPTPs are thought to serve quite different functions. SHP-1 inactivates RPTKs by dephosphorylating autophosphorylation sites while SHP-2 promotes downstream signaling cascades of RPTKs. SHP-2 interacts with the autophosphorylated PDGFR through its SH-2 domain (Fig. 24-8). The activated PDGFR then phosphorylates SHP-2 and creates a binding site for Grb2, eventually resulting in activation of the MAPK pathway.

Regulatory domains that are specific for subcellular targets may have a second function in suppressing the catalytic activity of NRPTPs during the quiescent state. Removal of the C-terminal motif on PTP1B responsible for target specificity is associated with an increase in catalytic activity. Similarly, association of the SH2 domain on SHP-2 with autophosphorylated RPTKs increases its activity by changing the conformation of the enzyme and allowing access of substrates to its active site.

Receptor protein tyrosine phosphatases consist of an extracellular domain, a transmembrane domain and one or two intracellular catalytic domains. RPTPs can be divided into different classes by the structural features of the extracellular domain (Fig. 24-10), which includes the immunoglobulin-like, fibronectin III-like, MAM and carbonic anhydrase domains [12]. The immunoglobulin-like domains contain intramolecular disulfide bonds and a homophilic binding site for cell–cell adhesion molecules, such as neural cell adhesion molecule (NCAM). The fibronectin III-like domains originally were identified in the extracellular matrix protein fibronectin. They consist of conserved hydrophobic residues and may interact with integrins. The MAM domains are named because of their presence in meprins, A5 glycoprotein and PTPμ. These domains contain four conserved cysteine residues. The carbonic anhydrase domains contain only one of the three histidine residues required for catalyzing the hydration of carbon dioxide and are unlikely to be catalytically active. It has been suggested that both the MAM and carbonic anhydrase domains play a role in cell adhesion (Ch. 7).

The catalytic domains of RPTPs are in the intracellular region of the protein. Most RPTP families, except RPTPβ, contain two tandem catalytic domains. The proximal catalytic domain of most RPTPs contains all of the enzymatic activity. The distal catalytic domain appears to be inactive; in some cases, critical catalytic residues are missing. Despite the lack of enzyme activity, the distal catalytic domain may be important for mediating intra- or intermolecular interactions and biological activity of RPTPs. It has been shown that a chimeric CD45 in which the distal catalytic domain is replaced with an equivalent region from LAR becomes deficient in the induction of interleukin-2 secretion and ZAP-70 phosphorylation.

It was originally believed that PTP activity was constitutive and that tyrosine phosphorylation was regulated solely by activating the PTKs. However, it is now clear that PTPs play an active role in the regulation of tyrosine phosphorylation. This was suggested first by the discovery of RPTPs, such as CD45, that have a large extracellular domain reminiscent of that of RPTKs. Their activities are regulated by ligand binding to the extracellular domain. Chimeric studies fusing the intracellular domain of CD45 with the extracellular and transmembrane domains of the EGFR show that the CD45 intracellular catalytic domain is constitutively active. Addition of EGF suppresses the PTP activity of the chimera, suggesting that dimerization may negatively regulate RPTP activity [13]. The mechanism of dimerization-induced inhibition has been revealed by crystallographic studies of a RPTPα fragment consisting of membrane-proximal region and the proximal catalytic domain [14]. These fragments form symmetrical dimers in which the active site of one molecule is blocked by an inhibitory wedge from the membrane-proximal region of the other. Based on this model, the inactive distal catalytic domain may promote tyrosine phosphatase activity of CD45 by competing with and inhibiting homodimerization of the proximal catalytic domain. In summary, activity of RPTPs may be diminished by ligand-induced dimerization, in contrast to activation by dimerization of RPTKs.

ROLE OF TYROSINE PHOSPHORYLATION IN THE NERVOUS SYSTEM

Tyrosine phosphorylation plays a role in virtually every step in the development and functions of a neuron, including survival and differentiation, the extension of axons to their targets and synapse formation and function (Fig. 24-11) (see Chs 25, 27, 28 and 30). Because of the plethora of effects of tyrosine phosphorylation on neuronal function, the following is by no means a comprehensive review but focuses on several examples that demonstrate its significance for the nervous system (Fig. 24-11).

Tyrosine phosphorylation is involved in every stage of neuronal development.

Neuronal survival and differentiation are regulated by many factors including neurotrophins and the Trk family of RPTKs. The prototype neurotrophin, nerve growth factor (NGF), promotes the survival of neurons during a period of programmed cell death in embryonic and early postnatal developmental stages. It is a target-derived neurotrophic factor that modulates the functions of the

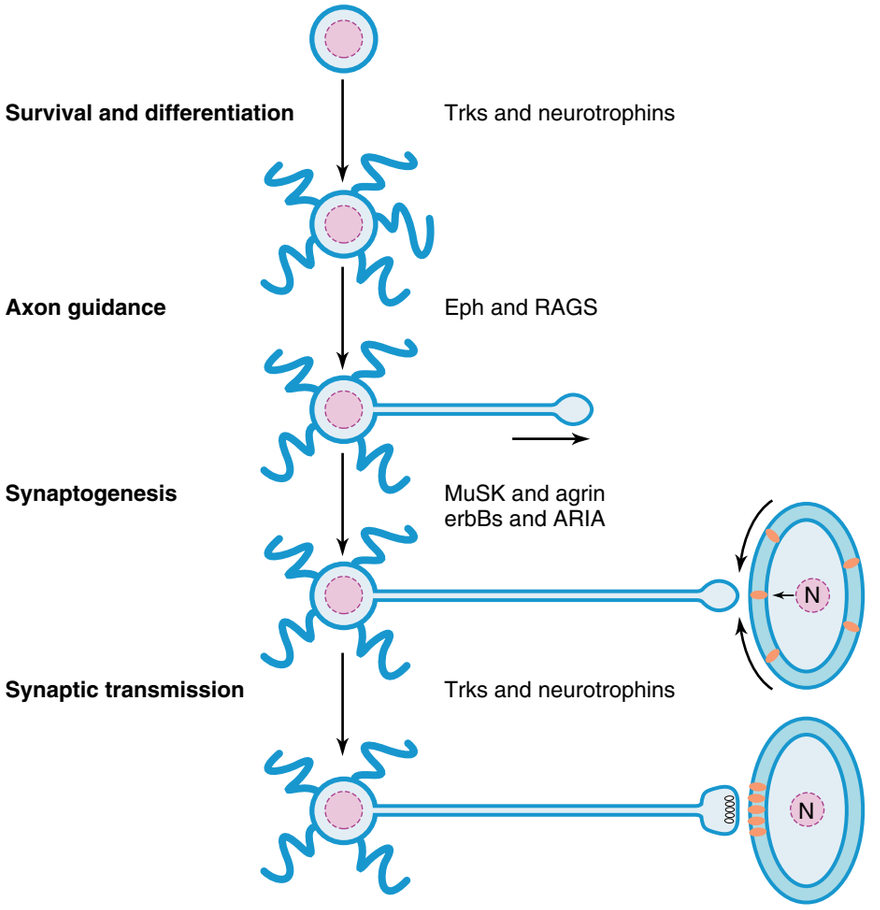

FIGURE 24-11 Examples of the role of protein tyrosine kinases and protein tyrosine phosphatases in the lifetime of a neuron. (*N*). Tyrosine phosphorylation appears to be an important signal-transduction mechanism in every step in the development of a neuron, starting from the survival and differentiation of stem cells, to axon guidance and synaptogenesis and to synaptic transmission at a mature synapse. Examples of each step are given on the right, indicating the receptors and their ligands. *Eph*, erythropoietin-producing hepatocellular factor; *RAGS*, repulsive axon guidance signal, *MuSK*, muscle-specific kinase; *ARIA*, acetylcholine-receptor-inducing activity.

innervating axon terminals as well as gene expression in the distant cell body (Ch. 27).

Although NGF was discovered over half a century ago, its signal transduction mechanism (Fig. 24-9) remained elusive until the identification of a 140 kDa protein, TrkA RPTK, as the NGFR in 1991 [15]. Studies in PC12 cells show that NGF induces autophosphorylation of at least four distinct tyrosine residues on human TrkA. These are Y490 in the juxtamembrane region, Y674, Y675 in the catalytic domain and Y785 in the C-terminal tail. Each phosphotyrosine moiety serves a unique function in the NGF signaling cascade (Fig. 24-8). Y674 and Y675 are the first tyrosine residues phosphorylated and important for subsequent activation of intrinsic kinase activity. Phosphorylation of Y490 and Y785 creates SH2-binding sites for SHC and PLC-γ1, respectively. In addition to SHC, phosphotyrosine 490 is also a binding site for Gab1 and FRS2 (or SNT1). Binding of Gab1 to and subsequent phosphorylation by TrkA recruits PI-3-kinase. Similarly, phosphorylation of FRS2 by TrkA plays a critical role in its subsequent interaction with the Grb2-Sos complex. In summary, association and proximity of signaling molecules to and/or their subsequent phosphorylation by TrkA appear to be an initial and essential part of signal transduction of NGF.

As mentioned above, activation of TrkA by NGF may result in cellular proliferation, differentiation or survival. Exactly how different TrkA-induced signal transduction mechanisms are translated into each one of these functions is incompletely understood. It has been suggested that proliferation and differentiation are mediated by activation of the MAPK cascade while survival is mediated by activation of PI-3-K. The competing actions of neurotrophins on

cellular proliferation versus differentiation largely depend on the duration of MAPK activation: Studies in PC12 cells show that transient activation of the MAPK pathway is associated with a mitogenic response while sustained activation induces differentiation. Interestingly, FRS2 is specifically activated in response to differentiation but not mitogenic factors. Finally, TrkA-induced neuronal survival depends on activation of PI-3-K, generation of 3-phosphoinositides, activation of PDK1 and Akt2, and eventual downregulation of proapoptotic factors (Chs 20 and 35).

Axon guidance. During development, axons often need to navigate through long distances before finding their targets. Through their arduous journey, various extracellular cues serve as signposts in guiding axons through different terrains. Each journey could be divided into shorter stretches for the axons to take one at a time, reaching milestones along the way until they arrive at their final destination. Furthermore, axons may stick together and form fascicles, which can serve as a 'highway' for future traveling axons. Extracellular cues that influence axon guidance can be attractive or repulsive, diffusible or immobilized on the cell surface or the extracellular matrix.

One of the best-studied model systems of axon guidance in vertebrates is perhaps the retinotectal system. Anterior and posterior retinal axons project to the posterior and anterior tectum respectively. Similarly, the dorsal and ventral retinal axons innervate the ventral and dorsal tectum respectively. This reversal of projection is important for the rectification of the upside-down and back-to-front retinal image. Using membrane stripe and growth cone collapse assays, Bonhoeffer and colleagues have identified a 25 kDa protein called repulsive axon guidance signal (RAGS) as an important axon guidance molecule in this system [16]. It is expressed most highly in the posterior tectum and repels the posterior retinal axons from this region. The receptor for RAGS is the Eph RPTK, discovered in the human erythropoietin-producing hepatocellular carcinoma cell line [17]. The ligands for Eph family RPTK are either glycophosphatidylinositol (GPI)-anchored or transmembrane proteins. Their biological activity is lost if they are detached from the membrane. This implies that Eph-mediated axon guidance is limited to short-range contact-dependent activity. Accordingly, the Eph family of receptors can be classified into those (EphA) interacting with GPI-linked ligands (ephrin-A), and those (EphB) with transmembrane ligands (ephrin-B) although crosstalk between these two classes of receptors and ligands has been reported.

Steering of an axon in different directions towards its destination is largely mediated by changes in the cytoskeleton in a structure at the leading edge of an axon known as the growth cone (Chs 8 and 9). The growth cone consists of finger-like protrusions known as filopodia interspaced by web-like structures called lamellipodia. Inside filopodia are organized bundles of actin filaments while a meshwork of actin filaments are found in lamellipodia. Behind the leading edge and into the base of growth cone and the adjacent axon shaft are areas enriched in microtubules. Filopodia and lamellipodia are highly dynamic structures. Attractive extracellular cues favor extension of filopodia by stabilizing and extending the underlying actin filaments while a repulsive cue retracts filopodia by collapsing the actin filaments. The changes in course of a growth cone will subsequently be consolidated by the trailing microtubules.

Mechanisms converting signals from extracellular cues into changes in intracellular cytoskeletal dynamics in the growth cone remain unclear. However, components of this transduction machinery – extracellular cues, corresponding receptors and downstream signaling molecules – are gradually emerging. In addition to the Rho family of small GTPases, others are identified as PTKs, PTPs and their substrates. To date, the extracellular cues for axon guidance can mainly be categorized into four main classes: ephrins, semaphorins, Slits and netrins (reviewed in [18]). Receptors for ephrins (Eph) and some semaphorins (e.g. Met for sema4D) are RPTKs. The Slit receptor family members (Robo) are not RPTKs but are associated with a NRPTK (Abl) and its substrate (Ena), both involved in Robo signaling. Furthermore, Robo itself carries a conserved tyrosine residue, dephosphorylation of which by a RPTP has been suggested to be a prerequisite for Robo to transmit the repulsive signal from Slit. The general involvement of RPTPs in axon guidance has been lucidly demonstrated by genetic manipulation in *Drosophila.*

What is the molecular mechanism linking changes in tyrosine phosphorylation of surface receptors to alterations in the cytoskeletal dynamics in the growth cone – i.e. the steering center of an axon? One of these molecules is Nck, an adaptor molecule consisting of both SH2 and SH3 domains. The SH2 domain of Nck interacts with a phosphotyrosine moiety on activated Eph RPTKs while its SH3 domains recruit PAK and WASP. Since both PAK and WASP regulate reorganization of cytoskeleton, Nck may act as an intermediary between Eph receptor activation and growth cone navigation. Interestingly, the ephrin–eph interaction constitutes a bidirectional communication, i.e., association of this ligand-receptor pair not only activates the eph RPTK but also induces tyrosine phosphorylation of the cytoplasmic domain of the ligand, ephrin, and triggers downstream signal transduction processes. A close homolog of Nck, Grb4, binds to the phosphotyrosine residue on the cytoplasmic tail of ephrin and results in actin depolymerization. Similar to Nck, Grb4 interacts with a number of modulators of cytoskeletal dynamics, including PAK1, Abl-interacting protein-1 (Abi-1) and Cbl-associated protein (CAP).

Tyrosine phosphorylation has a role in the formation of the neuromuscular synapse. For instance, the acetylcholine receptor (AChR) is concentrated at the postsynaptic membrane of the neuromuscular junction at a density of 10,000 receptors/μm^2, which is about three orders of magnitude higher than that of the extrasynaptic region

(Chs 11 and 43). The high concentration of AChRs at the neuromuscular junction allows rapid, reliable and efficient synaptic transmission. The strategic positioning of the AChR right on the crest of junctional folds at the neuromuscular synapse reduces the distance (30–50 nm) for the neurotransmitter to travel before reaching its receptor. Furthermore, the high concentration of AChRs at the neuromuscular junction increases the likelihood that a depolarization is successful in triggering muscle contraction. The significance of this is demonstrated by the pathological condition myasthenia gravis, in which muscle weakness is due to a reduction of the number of AChRs present at the neuromuscular junction. Two mechanisms contribute to the enrichment of AChRs at the neuromuscular junction: (1) clustering of pre-existing, diffusely distributed surface AChRs and (2) local synthesis of receptors by subsynaptic nuclei. Both mechanisms are mediated by tyrosine phosphorylation.

The clustering of pre-existing AChRs on the postsynaptic membrane is triggered by a motor-neuron-derived extracellular matrix protein discovered by McMahan's laboratory in the 1980s called agrin, from the Greek word *ageirein* meaning 'to assemble'. Since then, the agrin hypothesis [19] has gained support from various laboratories and been further elucidated by mice deficient in agrin [20]. These mice are stillborn and immobile, because of the lack of neuronal transmission across the neuromuscular junction where AChR clusters are absent. Nevertheless, small clusters of nonsynaptic AChRs do exist during early stages of embryonic development. These findings suggest that agrin is indispensable to the maturation of these initial AChR clusters and to their alignment with the nerve terminal.

The molar ratio of agrin to AChRs at the neuromuscular junction is between 1:50 and 1:100, suggesting that agrin induces AChR clustering through some intracellular signal transduction mechanisms rather than via any structural constraints. Tyrosine phosphorylation of the AChR has been suggested to play a role in its clustering at the neuromuscular junction. First, agrin induces tyrosine phosphorylation of the AChR prior to clustering of the receptor in muscle. All agents that induce AChR clustering in muscle cells in culture also induce tyrosine phosphorylation of the AChR. These agents include agrin, rapsyn, electrical fields and latex beads. In contrast, PTK inhibitors that inhibit AChR tyrosine phosphorylation also inhibit AChR clustering. Although tyrosine phosphorylation appears to be important to the action of agrin on muscle, a causal relationship between AChR tyrosine phosphorylation and clustering has not been established (see 'Acetylcholine receptors', below).

The putative receptor for agrin is a RPTK known as muscle-specific kinase (MuSK). The extracellular domain of MuSK resembles that of the ROR family of RPTKs, while the kinase domain is similar to that of the Trk neurotrophic receptor (Fig. 24-6). MuSK is expressed at low concentrations in proliferating myoblasts and is induced upon differentiation and fusion. It is downregulated dramatically in mature muscle except at the neuromuscular junction. These properties are consistent with a role of MuSK in muscle development and in the functioning of neuromuscular junctions. MuSK knockout mice show disruption of AChR clusters at the neuromuscular junction [21] similar to that seen in the agrin knockout mice [20], although clusters of nonsynaptic AChR are eliminated. Furthermore, muscle cells from these mutant mice, in culture, are unresponsive to agrin. Expression of MuSK in immature myotubes stimulates agrin binding. These data strongly indicate that MuSK is necessary for the response to agrin. It is postulated that MuSK is only part of the agrin receptor: a myotube-associated specificity component (MASC) is required to form the complete agrin receptor.

In addition to AChRs, agrin recruits and concentrates a host of other proteins to the neuromuscular junction. Among these is the ErbB family of RPTKs. This family contains four known members: ErbB1 (EGFR), ErbB2, ErbB3 and ErbB4. The last three members are expressed in developing muscle and cultured myotubes. Although both AChRs and ErbBs are recruited to the neuromuscular junction by agrin, ErbBs are localized in the troughs of the junctional folds while AChR sits on the tip, suggesting distinct downstream targeting mechanisms. ErbBs at the neuromuscular junction are activated by another motor-neuron-derived factor known as neuregulin. Their activation is responsible for localized transcription of AChR in subsynaptic nuclei. Neuregulin-activated ErbBs are autophosphorylated; the induced phosphotyrosine moiety acts as anchor for an adaptor molecule – SHC – leading to activation of the MAPK pathway and subsequent increased transcription of the AChR gene. In accordance with the significance of tyrosine phosphorylation in this signaling pathway, a PTP, SHP2, has been shown to be a negative regulator.

Tyrosine phosphorylation contributes to the formation of synapses in the central nervous system. This role of tyrosine phosphorylation is well illustrated by studies of neurotrophins – whose signal transduction mechanisms require activation of RPTKs (Ch. 27). The influence of neurotrophins on synapse formation is quite versatile. Neurotrophins affect formation of both excitatory and inhibitory synapses through presynaptic as well as postsynaptic mechanisms. Regarding neurotrophins' role in excitatory synapse formation, it has been shown that addition of exogenous BDNF and NT3 significantly increases the amount of docked synaptic vesicles in cultured hippocampal neurons from E16 embryos. In these neurotrophin-treated cultured neurons functional connectivity can also be ascertained electrophysiologically. Accordingly, transgenic mice overexpressing BDNF experience an increase in synaptic density [22] whereas those deficient in BDNF, TrkB (preferred receptor for BDNF) or TrkC (preferred receptor for NT3) display the opposite [23].

Similar studies have been reported on the potentiation of inhibitory synapse formation by BDNF/TrkB.

Tyrosine phosphorylation plays an important role in synaptic transmission and plasticity. Evidence for this role is that modulators of PTKs and PTPs have been shown to be intimately involved in these synaptic functions. Among the various modulators of PTKs, neurotrophins have been extensively studied in this regard and will be our focus in the following discussion (for details of growth factors, see Ch. 27). BDNF and NT-3 have been shown to potentiate both the spontaneous miniature synaptic response and evoked synaptic transmission in *Xenopus* nerve-muscle cocultures. Neurotrophins have also been reported to augment excitatory synaptic transmission in central synapses. These effects of neurotrophins in the neuromuscular and central synapses are dependent on tyrosine kinase activities since they are inhibited by a tyrosine kinase inhibitor, K-252a. Many effects of neurotrophins on synaptic functions have been attributed to the enhancement of neurotransmitter release; BDNF-induced increase in neurotransmitter release is a result of induced elevation in presynaptic cytosolic calcium. Accordingly, a presynaptic calcium-dependent phenomenon – paired pulse facilitation – is impaired in mice deficient in BDNF.

The significance of tyrosine phosphorylation in synaptic plasticity was perhaps first revealed by the impairment of long-term potentiation (LTP) by tyrosine kinase inhibitors (see Ch. 53 for detailed discussion of memory). Induction of long-term depression (LTD) has subsequently been reported to be susceptible to these inhibitors as well. Genetic knockout experiments have put forth some candidate PTKs involved in these processes. Mutant mice deficient in Fyn exhibit diminished LTP in the hippocampus [24]. Re-introduction of Fyn to the adult brain in Fyn knockout mice restores LTP, suggesting that Fyn plays a direct role in the manifestation of LTP independent of its developmental effects [25]. Conversely, transgenic mice overexpressing Fyn display a lower threshold for the induction of LTP [26]. Mutant mice lacking BDNF or TrkB also exhibit diminished LTP in the CA1 region of the hippocampus [27,28]. Treatment with TrkB-IgG fusion protein, which adsorbs endogenous BDNF, reduces LTP induced in the hippocampus. Furthermore, addition of exogenous BDNF promotes the induction of LTP elicited by paired synaptic stimulation in the dentate gyrus.

The exact mechanisms by which BDNF enhances the induction of LTP remain obscure. Nevertheless, both pre- and postsynaptic mechanisms appear to be possible. As mentioned above, BDNF elevates presynaptic cytosolic calcium level and thus increases vesicular neurotransmitter release. When a postsynaptic neuron is injected with a Trk tyrosine kinase inhibitor (K252a), BDNF-augmented LTP is curtailed; this suggests that a postsynaptic mechanism is adopted by BDNF in the manifestation of LTP. It has been postulated that neurotrophins may act as synaptic morphogens that induce formation of new synaptic contacts. The mechanisms by which Fyn or Src mediate induction of LTP are described in the section below on tyrosine phosphorylation of the NMDA receptors.

Neurotransmitter receptors and voltage-gated ion channels play a pivotal role in modulating synaptic efficacy and plasticity. Many of these receptors and ion channels in both the peripheral and central nervous systems are tyrosine-phosphorylated (reviewed in [29]). Furthermore, tyrosine phosphorylation of these surface-signal-transducing molecules significantly modulates their electrophysiological properties, producing a prominent effect on synaptic transmission and/or plasticity.

Acetylcholine receptors. Because of its enrichment and easy access in the *Torpedo* electric organ, the AChR is one of the best-studied neurotransmitter receptors (Ch. 11). It is located on the postsynaptic side of the mammalian neuromuscular junction. Upon binding acetylcholine, this ligand-gated ion channel depolarizes the sarcolemma and triggers muscle contraction. The AChR is composed of five subunits, $\alpha_2\beta\gamma\delta$ (embryonic) or $\alpha_2\beta\varepsilon\delta$ (adult). Each subunit has four transmembrane domains; both the N- and C-termini are in the extracellular space. Between the third and fourth transmembrane domains is a large cytoplasmic region containing a single conserved tyrosine residue in the cytoplasmic loop of each of the β, γ and δ subunits (Fig. 24-12). In fact, the AChR is highly tyrosine-phosphorylated in intact electric organ and muscle, in contrast to its low tyrosine phosphorylation in cultured rat myotubes, <0.001 mol phosphate/mol subunit; tyrosine phosphorylation of the AChR increases as muscle is innervated during development or in culture. In contrast, denervation results in tyrosine dephosphorylation of the AChR. The motor-neuron-derived agrin and the agrin receptor, MuSK, are responsible for the induction of tyrosine phosphorylation of the AChR.

The physiological functions of the tyrosine-phosphorylated AChR remain unclear. It had been suggested that tyrosine phosphorylation of the AChR β subunit was important for AChR clustering at the neuromuscular junction because of the tight correlation of these two processes. For instance, agrin induced tyrosine phosphorylation of the AChR β subunit and AChR aggregation in the same dose range; the former process preceded the latter. Agrin-induced tyrosine phosphorylation of the β subunit and AChR aggregation were both inhibited by tyrosine kinase inhibitors. Nevertheless, recent evidence shows that tyrosine phosphorylation of the AChR β subunit is neither sufficient nor necessary for AChR clustering. For example, when the extracellular domain of MuSK is replaced by that of TrkC and expressed in myotubes, this chimeric receptor is fully capable of inducing tyrosine phosphorylation of the β subunit of AChR but unable to induce AChR clustering, suggesting that tyrosine phosphorylation of the AChR β subunit is insufficient for clustering. Moreover, mutation of all three cytoplasmic

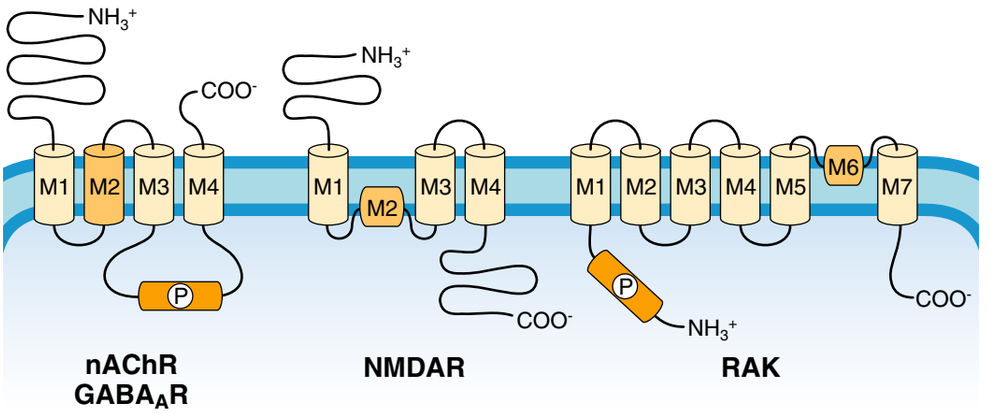

FIGURE 24-12 Transmembrane topology of three ligand-gated ion channel subunits and their potential domains for tyrosine phosphorylation. Both the acetylcholine receptor (*AchR*) and $GABA_A$ receptor (*$GABA_AR$*) subunits have four transmembrane domains with both the N- and C-termini on the outside. Tyrosine phosphorylation sites are present within the large intracellular loop between the third and fourth transmembrane domains. *N*-methyl-D-aspartate (*NMDA*) receptor subunits have a somewhat different topology. They have three transmembrane domains and a membrane-spanning domain. The delayed rectifier potassium channel (*RAK*) has six transmembrane domains and a membrane-spanning domain. Mutagenesis studies have revealed the intracellular N-terminus as the tyrosine-phosphorylation site-bearing region, although other studies have suggested the presence of other tyrosine-phosphorylation sites.

tyrosine residues on the AChR β subunit to phenylalanine does not appear to inhibit AChR aggregation, suggesting that tyrosine phosphorylation of the β subunit is unnecessary for AChR clustering [30]. What, then, is/are the physiological function(s) of AChR tyrosine phosphorylation? First of all, tyrosine phosphorylation of the AChR has been shown to affect the rate of receptor desensitization [31] and may thus regulate receptor sensitivity at the neuromuscular junction. Secondly, since tyrosine-phosphorylated AChR can interact with the SH2 domain on adaptor molecule (e.g. Grb2) and Src family NRPTKs (e.g. Fyn, Fyk), it is likely to play a modulatory role in signal transduction.

***N*-methyl-D-aspartate receptors.** Glutamate is the major excitatory neurotransmitter in the central nervous system (Ch. 15). Its receptors can be divided into three types: AMPA/kainate, NMDA and metabotropic receptors. NMDA receptors are composed of two different types of subunit – NR1 and NR2. They play an important role in the induction of synaptic plasticity and excitotoxicity.

The activity of NMDA receptors can be enhanced by a NRPTK – Src (reviewed in [32]). Application of Src or a Src activating peptide potentiates NMDA receptor activity in cells and inside-out membrane patches. Similar potentiation of NMDA receptor activity can be achieved by the other Src family NRPTK – Fyn. Such increase in NMDA-evoked channel activity is attributed to an increase in probability and duration of channel opening and a decrease in duration of channel closing. Cumulative evidence has suggested that tyrosine phosphorylation of the NR2 subunits regulates NMDA function. For instance, the NR2A and 2B but not NR1 subunits are tyrosine-phosphorylated *in vivo* [3, 33]. NR2A and NR2B can be phosphorylated by Src *in vitro*. Heterologous cells expressing NR1 and NR2A subunits exhibit increased NMDA-induced current in the presence of v-Src, while cells expressing NR1 and other NR2 subunits display no change in NMDA-evoked current. Finally, mutation of tyrosine residues in the cytoplasmic domain of NR2A to phenylalanine abolishes Src-induced NMDA receptor activity.

Both NMDA receptor and Fyn have been implicated in the induction of LTP. Since Src family tyrosine kinases are known to tyrosine phosphorylate and activate NMDA receptor, it is enticing to speculate that Src family kinases and NMDA receptors somehow act in a concerted fashion in the expression of LTP. An axon guidance receptor, EphB2, is expressed in adult hippocampus and interacts with the NR1 subunit of the NMDA receptor. Stimulation of EphB2 by ephrin-B1 activates Src and Fyn with a concomitant increase in tyrosine phosphorylation of the NR2A subunit [34]. Activation of EphB2 by ephrin-B2 has also been shown to induce tyrosine phosphorylation of the NR2B subunit with an accompanying increase in NMDA-receptor-mediated calcium ion influx [35]. The additional calcium ion influx may increase postsynaptic responsiveness. Although *in vivo* experiments show that EphB2 is indispensable for hippocampal LTP, some evidence suggests that its tyrosine kinase domain may be nonessential for this function [34, 36].

It is noteworthy that Src-induced increase in NR1-NR2A receptor activity is promoted by the coexpression of postsynaptic density protein known as PSD-95 [37]. PSD-95 is a scaffolding protein consisting of multiple protein–protein interaction domains – three N-terminal PDZ domains, an SH3 domain and a C-terminal guanylate kinase domain. The first two PDZ domains interact with the NR2 C-terminal tails while the third PDZ domain

binds the SH2 domain of Fyn [37]. The PDZ-SH2 domain interaction is atypical since tyrosine phosphorylation of the PDZ domain is nonessential. In this fashion, PSD-95 serves as an adaptor bringing Fyn and its substrate in proximity of each other.

GABA receptors. GABA is one of the major inhibitory neurotransmitters in the central nervous system (see Ch. 16). The subunits of the $GABA_A$ receptor ($GABA_AR$) consist of α, β, γ, δ, ε, θ and π; subunits found in brain are mainly from the first three classes. Similar to AChR, the $GABA_AR$ complex is believed to be heteropentameric with four transmembrane domains in each subunit. The intracellular region between the third and fourth transmembrane domains contains a number of consensus protein phosphorylation sites (Fig. 24-12). Coexpression of $GABA_AR$ subunits α1, β1 and γ2L with v-Src induces tyrosine phosphorylation on both the β and γ subunits, with a concomitant increase in GABA-mediated whole-cell current [38]. Mutation of two tyrosine residues (Y365/367) on the cytoplasmic domain of the γ subunit abolishes not only the induction of tyrosine phosphorylation but also the functional effects of v-Src, suggesting that direct tyrosine phosphorylation of $GABA_AR$ increases its activity [38]. Tyrosine phosphorylation of the $GABA_AR$ and associated functional facilitation have been observed in neurons as well; the latter has been attributed to an increase in duration and probability of channel opening. Although direct tyrosine phosphorylation of the $GABA_AR$ augments channel activity, activation of some RPTKs appears to indirectly inhibit $GABA_AR$ function. For instance, activation of the PDGFR inhibits $GABA_AR$ in hippocampal neurons as a consequence of activating PLC-γ1, generating IP_3 and elevating intracellular calcium.

In addition to direct enhancement of channel activity, PTKs can indirectly increase GABA-evoked inhibitory current by recruiting intracellular $GABA_AR$ to the surface of postsynaptic membrane. Insulin has been shown to increase surface expression $GABA_AR$ in transfected human embryonic kidney cells. In central neurons insulin rapidly increases the expression of functional postsynaptic $GABA_AR$ in a tyrosine kinase-dependent manner, resulting in an increase in the amplitude of the miniature inhibitory postsynaptic currents.

Voltage-gated ion channels. In addition to ligand-gated ion channels described above, many voltage-gated ion channels appear to be regulated by tyrosine phosphorylation. These include voltage-gated calcium, potassium and sodium ion channels whose function can either be enhanced or impeded by tyrosine phosphorylation. For example, voltage-gated L-type calcium ion channel activity is augmented by tyrosine phosphorylation. Voltage-gated calcium ion channels are composed of α_1, $\alpha_2\delta$ and β subunits. The α_1 subunit forms the pore of the calcium ion-selective channel. It consists of six transmembrane domains with both the N- and C-termini in the cytoplasmic side, carrying a number of potential phosphorylation sites. It is believed that both cytoplasmic ends of the channel impose an inhibitory tone on functional activity; upregulation of channel activity by protein phosphorylation may be attributed to relief of this inhibition. The L-type calcium ion channel is tyrosine-phosphorylated and activated in cerebellar granule neurons in response to stimulation by insulin-like growth factor-1 (IGF-1). This potentiation induced by IGF-1 appears to be mediated by phosphorylation of Y2122 on the α_{1C} subunit via the action of Src.

In contrast to the above example of voltage-gated L-type calcium ion channels, a delayed rectifier potassium ion channel, Kv1.2, serves as an example of downregulation by tyrosine phosphorylation. Kv1.2 coexpressed with the M_1 muscarinic AChR in *Xenopus* oocytes is inhibited by carbachol, a nonmetabolizable analog of acetylcholine. Activation of the M_1 muscarinic receptor releases diacylglycerol and IP_3 from the hydrolysis of PIP_2. Diacylglycerol activates PKC and IP_3 releases calcium from intracellular stores. Possibly by their action on a PYK2-related tyrosine kinase, calcium and PKC eventually lead to tyrosine phosphorylation of Kv1.2 on Y132 in the cytoplasmic domain near the N-terminus, resulting in an impaired functional response. Tyrosine phosphorylation of Kv1.2 and its concomitant reduction in channel activity can be reversed by RPTPα. Similarly, a related potassium channel, Kv1.5, is tyrosine-phosphorylated and suppressed when co-expressed with v-Src in transfected cells. *In vivo* association between hKv1.5 and Src is mediated by proline-rich sequences on the potassium ion channel and Src SH3 domain.

Growth factors regulate oligodendrocyte development 453
The Schwann cell lineage is also characterized by sequential and overlapping expression of many stage-specific markers 454

CONCLUSIONS 457

FUNDAMENTAL CONCEPTS UNIFYING DEVELOPMENTAL DIVERSITY

Development is the study of the principles and processes that underlie growth and evolution of a biological organism. Most developmental research has been devoted to studying the early periods of intense and extensive transformations that are associated with the unfolding of an organism from a single fertilized egg through embryogenesis to postnatal maturation. During this period, the immense diversity of neural phenotype emerges [1]. What are the mechanisms that regulate the systematic and highly coherent series of events that fashion the vast neural circuitry? In this chapter, we examine the molecular and cellular processes that give rise to the enormous phenotypic diversity of the brain during these developmental periods in neural tissue.

Two fundamental concepts mold our perspective of how the nervous system develops and functions: the dynamic interdependence of genes and the environment and that of neuronal and neuroglial cells. During development, the systematic expression of the genetic blueprint creates and continuously molds the environment at all levels of its hierarchical organization, extending from the level of the single cell to the surroundings of the organism. The genetic machinery, in turn, relies on feedback from the environment to adjust epigenetic mechanisms. This interaction creates a highly integrated, self-referential process that links the genetic information with the multitude of influences existing at all the different layers of the environment [2]. Great progress has been made in the systematic dissection of individual linear pathways of environmental genetic connections. For example, a growth factor and its receptor activate an intracellular signaling pathway to induce the expression of a specific gene (see Chs 26 and 27). In this way, many

Basic Neurochemistry: Molecular, Cellular and Medical Aspects
0-12-088397-X

environmental signals and numerous cell processes have been correlated with the appearance of different neural phenotypes.

The presumption behind these studies is that knowledge of these single linear paths of environmental genetic linkage will provide an understanding of the basis of phenotypic diversity. As we have discovered and examined the functions of more and more extracellular factors, membrane receptors and intracellular signaling pathways impinging upon an extensive genetic network functioning in a highly complex, combinatorial fashion, our research perspective is being transformed from a simple linear to a more realistic and integrated parallel model (Fig. 25-1). Multiple families of extracellular factors influence many receptors and intracellular signaling pathways, which exhibit considerable interaction, or 'cross-talk.' In addition, a network of transcription factors is being elucidated (Ch. 26). This network is characterized by extensive inter- and intrafamily interactions contributing to multiple levels of control over the expression and functional activity of transcription factors responsible for differential gene expression. Thus, in contrast to the linear model, neural phenotypic diversity arises from highly integrated networks of intracellular processes linked to environmental signals.

Biological interdependence in neural development is also dramatically displayed in the relationship of neuronal and glial cells [2–6]. The intimate coupling of these two types of cell is a major locus of genetic and epigenetic interaction in determining the functioning and the morphological, chemical and electrical development of the nervous system (see also Ch. 31). Students have traditionally been taught that the neuronal cell represents the structural unit of the nervous system, relegating glia to the status of passive packaging. This narrow perspective has now been replaced by the accumulated evidence for glial cell regulation of nearly every aspect of neuronal development and function, supporting the premise that the fundamental functional unit of the nervous system is the dynamic interaction of neuronal and glial cells.

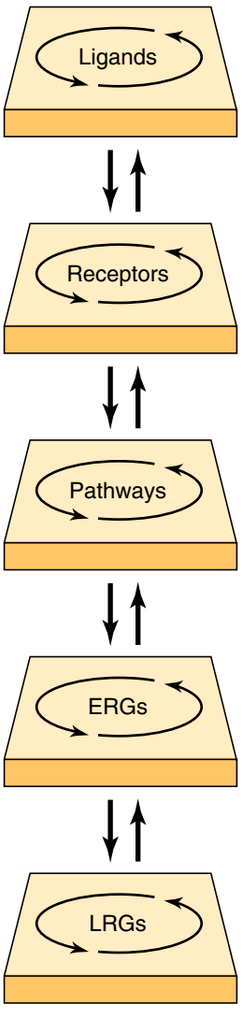

FIGURE 25-1 Hierarchically organized levels of information processing underlying the generation of neural phenotypic diversity. The enormous phenotypic diversity of the nervous system requires a mechanism that can generate increasing degrees of restriction in cell phenotype, such as cell shape and neurotransmitter expression. The original, simple linear perspective of an extracellular factor acting through its receptor to direct the expression of phenotypic characteristics is now being replaced by the recognition that each level of information processing is itself a complex domain of interacting components. In this view, many families of signaling molecules, or factors, bind to a growing number of interacting receptors, with overlapping specificity and component makeup, to activate many different, interacting intracellular signaling pathways, leading to the complex expression pattern of early response genes (*ERGs*). These ERGs, many of which function as transcription factors, in turn interact to regulate the final expression of late response genes (*LRGs*), encoding proteins that are phenotypic determinants. Thus, from this perspective, the developmental fate of each cell is determined by the sum total of the multiple signals and combinatorial intracellular processes.

GENERAL DEVELOPMENT OF THE NERVOUS SYSTEM

During animal development, a single fertilized egg cell divides and differentiates to produce all the cells and tissues of the mature organism. Genetic information contained in the fertilized egg provides all the instructions to produce these tissues. The initial divisions of a fertilized egg produce a blastula. The blastula undergoes gastrulation to produce the three primary germ layers of the developing embryo. During gastrulation, cells migrate inward between the upper and lower layers of the blastula through the primitive streak, resulting in a trilaminar 'sandwich'. The initial point of inward migration is established by the organizer, which in *Xenopus* is the dorsal lip

of the blastopore and which in birds and mammals is the node. The resulting gastrula has three layers, the ectoderm, the endoderm and the mesoderm. The nervous system develops from the ectoderm following an inductive signal from the mesoderm. The initial mesodermal cells condense to form the notochord, which elongates under the primitive streak along the anterior posterior axis of the developing embryo. Signals are released from the notochord, which signals induce the ectoderm to thicken into neural ectoderm in the area immediately overlying the notochord (Fig. 25-2). This neural ectoderm is now committed to develop into neural tissue, as can be demonstrated by transplantation experiments in which neural ectoderm surgically placed into other areas of the developing embryo produces auxiliary neural tissue. In addition, neural ectoderm arising in different places along the anterior–posterior axis of the developing embryo is predestined to develop into specific brain regions. Three proteins secreted by the organizer can induce production of anterior neural plate markers in undifferentiated ectodermal cells. These three proteins, noggin, follistatin and chordin, may establish anterior neural domains by inactivating two neural inhibitors: bone morphogenetic protein (BMP)2 and BMP4. The establishment of posterior domains within the neural plate may stem from signaling by basic fibroblast growth factor (bFGF) or by retinoic acid. Neither of these molecules is by itself sufficient to generate regional posterior identity, but both may mediate signals established by some other mechanism. An additional mechanism used to regionalize the neural plate may be the expression of head-specific genes. Deletion of several of these genes, notably *lim-1* and *otx-I*, deletes all head structures, suggesting a role for these genes in establishing the most anterior portion of a developing animal. Cerberus, a secreted protein expressed in the gastrulating endomesoderm, also has forebrain-inducing activity.

Once the neural plate has been induced by the underlying mesoderm, it begins to differentiate into the neural tube, the primary rudiment of the developing CNS [6]. The center of the neural plate develops a groove in the direction of the anterior posterior axis and the edges of the plate rise up, forming the neural folds (Fig. 25-2). The neural folds fuse together along the dorsal edge of the animal and the neural tube separates from the overlying dorsal ectoderm. During neural tube formation, the adjacent mesoderm is segmented into blocks of tissue called somites. The somites provide precursor cells for axial and appendicular skeletal elements and attached musculature. During neural tube closure, a population of cells separates from the neural folds and migrates into the periphery (Fig. 25-2). These cells are the neural crest (NC), which provides a progenitor population for the developing peripheral nervous system (PNS). The NC migrates away from the neural tube along defined pathways through the anterior half of each adjacent somite and along a dorsal pathway under the ectoderm. NC cells that migrate through the somites populate the dorsal root ganglia as neurons and glia, contribute Schwann cells to the peripheral nerves and provide neurons and glia for the sympathetic ganglia. NC cells that migrate along the dorsal pathway develop into melanocytes.

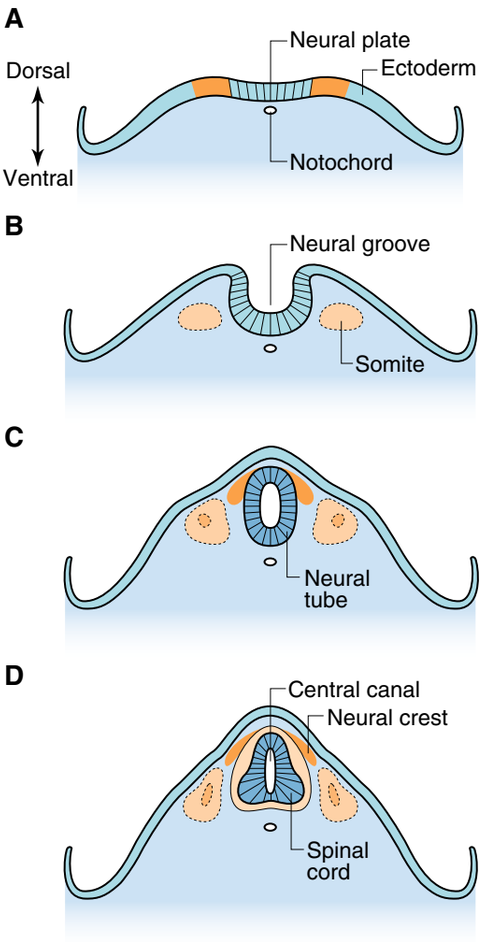

FIGURE 25-2 Four stages in the development of the neural tube. (**A**) After gastrulation, the mesodermally derived notochord induces the overlying ectoderm to form the neural plate. The most lateral portions of the neural plate will give rise to the neural crest (*dark orange areas*). (**B**) The neural plate invaginates to form the neural groove. (**C**) The neural tube fuses at its dorsal margin and separates from the overlying ectoderm. Neural crest cells (*dark orange*) separate from the neural tube and begin to migrate into the periphery. (**D**) At trunk levels, the neural tube forms the spinal cord surrounding a central canal. (Modified from Cowan [6], with permission.)

The neural tube is a pseudostratified epithelium, with cells extending between the apical and basal surfaces of the epithelial wall. The neuroepithelium contains undifferentiated populations of stem cells and radial glia (see Ch. 29). With time, both of these cell types give rise to the three main lineages for neurons, astrocytes and oligodendrocytes. After the final mitotic division, neurons migrate away from the ventricular surface of the neural

tube to form the mantle zone. This outward migration is mostly guided by radial glial fibers, which provide a scaffold extending from the ventricular zone to the surface of the developing brain. The accumulation of postmitotic neuronal cells results in the progressive thickening of the neural tube to produce expansions of the CNS, brain and spinal cord.

DEVELOPMENTAL PROCESSES: ENVIRONMENTAL FORCES MOLDING GENETIC POTENTIAL

Developing cells of the nervous system are embedded in complex fields of mechanical tension, biochemical signals and electrical current. This constantly changing pattern of spatial and temporal information for each cell is created, in large part, by the chemistry of the neural cells themselves and represents the major environmental forces that drive the sequence of developmental processes. The dynamic interaction between these environmental influences and the machinery of neural cells forces the cells to undergo considerable transformation during periods of growth and survival, migration and sorting and morphological and biochemical differentiation [7, 8].

Selective cell survival and proliferation determine the number of each type of nerve cell. A basic tactic in creating complex biological systems is to generate an excess of elements and then, through a set of selective processes, to determine which elements will remain to participate in the final organizational pattern. This strategy is widely used in the construction of the vertebrate nervous system. During development, the interaction between genetic and epigenetic forces is expressed, in part, as the balance between cell survival and cell death [9]. Intimately linked to this balance is the control of cell proliferation (see also apoptosis, Ch. 35).

For invertebrate development, genetic instructions are the prime controller of population size and diversity. Because of the short life-span and the relatively simple nervous system necessary to control the organism in a relatively constant ecological niche, the most reliable and economical approach is to rapidly generate simple, preprogrammed neuronal/glial circuitry. The development of the nematode *Caenorhabditis elegans* is an example of a cell lineage that is generated independently of the environment. Precursor cells undergo cycles of stereotyped divisions, creating a number of restricted, preprogrammed cellular lineages. Cell death appears due to intrinsic instructions that select specific pathways to terminate in senescence [10] (see apoptosis, Ch. 35).

Vertebrate development reflects the other extreme of the genetic/epigenetic continuum: unlike invertebrates, numerous environmental cues are employed to direct lineage decisions, including the decisions for survival, division and death. Prolonged gestation and the plasticity inherent in allowing outside influences to guide developmental decisions permit the construction of large-scale, highly interconnected, activity-dependent circuitries.

Early experiments demonstrated that the presence and size of the target tissue are critical in determining the number and functions of the surviving neuronal cells [9]. Removal of limb buds or transplantation of an extra limb bud results in a predictable decrease or increase, respectively, of the innervating motor and sensory neurons. Each set of neuronal cells exhibits a characteristic degree of target-dependent cell death during development: some groups remain quite stable in number, while others lose up to two-thirds of the cell progeny. What are the factors that influence the balance between cellular survival and death? The nature of the microenvironment of the cell soma and the environment into which the cell process grows are both important. Critical factors produced in the innervated target tissue contribute to the regulation of cell survival: limited amounts of soluble factor(s) released by target cells lead to competition among cells dependent on the factor. Thus, during specific periods of early cell development, trophic factors are necessary for survival (see Ch. 27).

Specific paths of cell migration to final target environments are controlled by gradients of diffusible and substrate-bound neurochemical signals. Migration of cells plays a significant role in brain morphogenesis. Most neurons travel long distances through the complex extracellular terrain of the developing embryo to reach their final position. What mechanisms are used by neurons to move along the path, and what signals are used to guide them? The most common mechanism for cell translocation is a combination of (1) the extension of a cell process and its attachment to the substratum, followed by (2) the pulling of the entire cell toward the point of attachment by means of contractile proteins associated with an intracellular network of microfilaments (Chs 7, 8 and 28).

Directional control of cell movement appears to be of two types: (1) cells moving along other 'guide' cells arranged as scaffolding and (2) cells moving across a multicellular terrain guided by concentration gradients of particular molecules. For example, small molecules diffusing through or attached to the extracellular matrix (see Ch. 2) can alter the behavior of a cell (see Chs 7, 27, 29 and 30). In the complex neuropil of the cerebral cortex, molecular signals undoubtedly permit neurons to distinguish radial glial processes along which they travel from the other neuronal, glial and endothelial surfaces.

NC cell movement is another model of molecular control of cell migration and contrasts with that seen in cortical systems. Since there are no glial cells to create highways for the crest cells, the migration of these cells into the spaces surrounding the neural tube depends on the nature of the extracellular matrix. In order to migrate to specific destinations, a number of signals must be regulated in a

coordinated fashion both temporally and spatially [11]. Nearly all the major components of the matrix – collagen, fibronectin, laminin, proteoglycans and hyaluronic acid – regulate NC cell migration. For example, NC cell migration correlates with the appearance of high amounts of hyaluronic acid.

A variety of substrate- and cell-attached factors influence neural development by regulating adhesion properties of cells (see Ch. 7). Interactions occur directly between cells or between a cell and the extracellular matrix (see Ch. 2). The molecules mediating these interactions have been implicated in regulating the specificity and timing of cell–cell adhesion and the consequences on cell morphology and physiology. Hence, they influence the ability of cells not only to migrate but to sort themselves out and to stabilize spatial relationships considered important for the process of differentiation.

Cell process outgrowth determines the cytoarchitecture and circuitry of the nervous system. Cell process elongation and branching determine the final morphological phenotype of the cell and its participation in the local and global neural circuitries [12, 14]. On average, each of the billions of neuronal cells forms more than 10,000 specific interconnections. This process of morphological differentiation requires the directed growth of a considerable number of cell processes to multiple specific targets, often at great distances from the cell body. Control over the active elongation of a cell process creates the final size and geometry of the neuronal axon and dendritic tree. What are the molecular mechanisms that control the progressive elongation of a cell process? What environmental signals are present to guide the processes through a complex, three-dimensional, multicellular terrain? What are the processes that determine the time and place of branching? Are the molecules implicated in regulating cellular migration involved in controlling neurite outgrowth? In general, many of the same soluble and matrix components that regulate cell proliferation, survival and migration have been shown to also mediate process outgrowth *in vivo* and *in vitro*.

Growth cones are located at the leading edge of a neurite and display two types of motile structure: long spike-like structures called filopodia and thin, broad sheets of membrane called lamellipodia. These delicate structures are important in pathfinding and outgrowth branching (see Ch. 8). Growth cone movement can be influenced by small soluble factors (see Ch. 27). Local concentration gradients of nerve growth factor (NGF) and/or FGF can initiate and direct growth and movement. Specific neurotransmitters, such as serotonin and dopamine, can also alter neurite elongation and growth cone movement. For example, serotonin inhibits neuronal outgrowth of specific subsets of neurons. Inhibition of neurite outgrowth can also be suppressed by electrical activity.
