particularly of crypt cells, is the most common histologic finding. Rarely, total gland destruction occurs, although endocrine cells may persist. Intestinal graft-versus-host disease often presents as a watery diarrhea but may become bloody in severe cases.

Sigmoid Diverticular Disease

Diverticular disease generally refers to acquired pseudo-diverticular outpouchings of the colonic mucosa and submucosa. Unlike true diverticula, such as Meckel diverticulum, they are not invested by all three layers of the colonic wall. Colonic diverticula are rare in persons younger than age 30, but the prevalence approaches 50% in Western adult populations older than age 60. Diverticula are generally multiple and the condition is referred to as diverticulosis. This disease is much less common in Japan as well as developing countries, probably because of dietary differences. Moreover, most diverticula in Asia and Africa occur in the right colon, while right-sided diverticula are uncommon in Western countries. The reasons for this difference in distribution are not well-defined.

Pathogenesis. Colonic diverticula result from the unique structure of the colonic muscularis propria and elevated intraluminal pressure in the sigmoid colon. Where nerves, arterial vasa recta, and their connective tissue sheaths penetrate the inner circular muscle coat, focal discontinuities

in the muscle wall are created. In other parts of the intestine these gaps are reinforced by the external longitudinal layer of the muscularis propria, but, in the colon, this muscle layer is gathered into the three bands termed taeniae coli. Increased intraluminal pressure is probably due to exaggerated peristaltic contractions, with spasmodic sequestration of bowel segments, and may be enhanced by diets low in fiber, which reduce stool bulk, particularly in the sigmoid colon.

MORPHOLOGY

Anatomically, colonic diverticula are small, flask-like outpouchings, usually 0.5 to 1 cm in diameter, that occur in a regular distribution alongside the taeniae coli (Fig. 17-40A). These are most common in the sigmoid colon, but more extensive areas may be affected in severe cases. Because diverticula are compressible, easily emptied of fecal contents, and often surrounded by the fat-containing epiploic appendices on the surface of the colon, they may be missed on casual inspection. Colonic diverticula have a thin wall composed of a flattened or atrophic mucosa, compressed submucosa, and attenuated or, most often, totally absent muscularis propria (Fig. 17-40B, C). Hypertrophy of the circular layer of the muscularis propria in the affected bowel segment is common. Obstruction of diverticula leads to inflammatory changes, producing diverticulitis and peridiverticulitis. Because the wall of the diverticulum is supported only by the muscularis mucosae and a thin layer of subserosal adipose tissue, inflammation and increased pressure within an obstructed diverticulum can lead to perforation. With or without perforation, diverticulitis may cause segmental diverticular disease-associated colitis, fibrotic thickening in and around the colonic wall, or stricture formation. Perforation is uncommon but it can result in pericolic abscesses, sinus tracts, and, occasionally, peritonitis.

Figure 17-40 Sigmoid diverticular disease. **A**, Stool-filled diverticula are regularly arranged. **B**, Cross-section showing the outpouching of mucosa beneath the muscularis propria. **C**, Low-power photomicrograph of a sigmoid diverticulum showing protrusion of the mucosa and submucosa through the muscularis propria.

Clinical Features. Most individuals with diverticular disease remain asymptomatic throughout their lives. However, about 20% of individuals with diverticuli develop manifestations of diverticular disease, such as intermittent cramping, continuous lower abdominal discomfort, constipation, distention, or a sensation of never being able to completely empty the rectum. Patients sometimes experience alternating constipation and diarrhea that can mimic IBS. Occasionally there may be minimal chronic or intermittent blood loss, and, rarely, massive hemorrhage. When present, bleeding is macroscopically visible in the stools. Whether a high-fiber diet prevents such progression or protects against diverticulitis is unclear, but diets supplemented with fiber may provide symptomatic improvement. Even when diverticulitis occurs, it most often resolves spontaneously and relatively few patients require surgical intervention.

KEY CONCEPTS

- **Irritable bowel syndrome (IBS)** is characterized by chronic, relapsing abdominal pain, bloating, and changes in bowel habits without obvious gross or histologic pathology. The pathogenesis of IBS is not defined, but includes contributions by psychologic stressors, diet, the gut microbiome, abnormal GI motility, and increased enteric sensory responses to gastrointestinal stimuli.
- **Inflammatory bowel disease (IBD)** is an umbrella term for **ulcerative colitis** and **Crohn disease**. **Indeterminate colitis** is used for cases of IBD without definitive features of either ulcerative colitis or Crohn disease.
- **Ulcerative colitis is limited to the colon**, is **continuous from the rectum**, and ranges from only rectal disease to pancolitis; neither skip lesions nor granulomas are present.
- **Crohn disease** most commonly affects the **terminal ileum and cecum**, but any site within the gastrointestinal tract can be involved; **skip lesions** are common and **noncaseating granulomas** also occur.
- Both forms of IBD typically present in the **teens and early 20s** and are associated with **extraintestinal manifestations**.
- IBD is thought to arise from a combination of alterations in host interactions with intestinal microbiota, intestinal epithelial dysfunction, and aberrant mucosal immune responses. Molecular analyses have identified more than 160 IBD-associated genes, of which the function of only a few is understood.
- The risk of colonic **epithelial dysplasia and adenocarcinoma** is increased in IBD patients who have had colonic disease for more than 8 to 10 years.
- The two forms of microscopic colitis, **collagenous colitis** and **lymphocytic colitis**, both cause chronic watery diarrhea. The intestines are grossly normal, and the diseases are identified by their characteristic histologic features.
- **Diverticular disease** of the sigmoid colon is common in western populations older than age 60. The causes include low fiber diets, colonic spasm, and the unique anatomy of the colon. Inflammation of diverticula, **diverticulitis**, affects a minority of those with **diverticulosis**, but can cause perforation in its most severe form.

Polyps

Polyps are most common in the colo-rectal region but may occur in the esophagus, stomach, or small intestine. Most, if not all, polyps begin as small elevations of the mucosa. These are referred to as sessile, a term borrowed from botanists who use it to describe flowers and leaves that grow directly from the stem without a stalk. As sessile polyps enlarge, proliferation of cells adjacent to the mass and the effects of traction on the luminal protrusion, may combine to create a stalk. Polyps with stalks are termed pedunculated. In general, intestinal polyps can be classified as non-neoplastic or neoplastic in nature. The most common neoplastic polyp is the adenoma, which has the potential to progress to cancer. The nonneoplastic polyps can be further classified as inflammatory, hamartomatous, or hyperplastic.

Hyperplastic Polyps

Colonic hyperplastic polyps are benign epithelial proliferations that are typically discovered in the sixth and seventh decades of life. The pathogenesis of hyperplastic polyps is incompletely understood, but they are thought to result from decreased epithelial cell turnover and delayed shedding of surface epithelial cells, leading to a “piling up” of goblet cells and absorptive cells. It is now appreciated that these lesions are without malignant potential. **Their chief significance is that they must be distinguished from sessile serrated adenomas, that are histologically similar but have malignant potential, as described later.** It is also important to remember that epithelial hyperplasia can occur as a nonspecific reaction adjacent to or overlying any mass or inflammatory lesion and, therefore, can be a clue to the presence of an adjacent, clinically important lesion.

MORPHOLOGY

Hyperplastic polyps are most commonly found in the left colon and are typically less than 5 mm in diameter. They are smooth, nodular protrusions of the mucosa, often on the crests of mucosal folds. They may occur singly but are more frequently multiple, particularly in the sigmoid colon and rectum. Histologically, hyperplastic polyps are composed of mature goblet and absorptive cells. The delayed shedding of these cells leads to crowding that creates the serrated surface architecture that is the morphologic hallmark of these lesions (Fig. 17-41). Serration is typically restricted to the upper third, or less, of the crypt.

Inflammatory Polyps

Polyps that form as part of the solitary rectal ulcer syndrome are examples of purely inflammatory lesions. Patients present with a clinical triad of rectal bleeding, mucus discharge, and an inflammatory lesion of the anterior rectal wall. The underlying cause is impaired relaxation of the anorectal sphincter that creates a sharp angle at the anterior rectal shelf and leads to recurrent abrasion and ulceration of the overlying rectal mucosa. An inflammatory polyp may ultimately form as a result of chronic cycles of injury and healing. Entrapment of this polyp in

Figure 17-41 Hyperplastic polyp. **A**, Polyp surface with irregular tufting of epithelial cells. **B**, Tufting results from epithelial overcrowding. **C**, Epithelial crowding produces a serrated architecture when crypts are cut in cross-section.

the fecal stream leads to mucosal prolapse. The distinctive histologic features of a typical inflammatory polyp include mixed inflammatory infiltrates, erosion, and epithelial hyperplasia together with lamina propria fibromuscular hyperplasia (Fig. 17-42).

Figure 17-42 Solitary rectal ulcer syndrome. **A**, The dilated glands, proliferative epithelium, superficial erosions, and inflammatory infiltrate are typical of an inflammatory polyp. However, the smooth muscle hyperplasia within the lamina propria suggests that mucosal prolapse has also occurred. **B**, Epithelial hyperplasia. **C**, Granulation tissue-like capillary proliferation within the lamina propria caused by repeated erosion.

Hamartomatous Polyps

Hamartomatous polyps occur sporadically or as components of various genetically determined or acquired syndromes (Table 17-10).

Although they were originally thought to be caused by developmental abnormalities, it is now appreciated that many hamartomatous polyp syndromes are caused by germline mutations in tumor suppressor genes or proto-oncogenes. Some of these syndromes are associated with increased cancer risk, either within the polyps or at other intestinal or extra-intestinal sites. Thus, in some hamartomatous polyp syndromes, the polyps can be considered to be pre-malignant, neoplastic lesions, much like adenomas. In addition, it is important to recognize these polyps because of associated extraintestinal manifestations and the possibility that other family members are affected. Several of these syndromes are discussed below, while other syndromes are summarized in Table 17-10.

Juvenile Polyps

Juvenile polyps are focal malformations of the epithelium and lamina propria. These may be sporadic or syndromic, but the morphology of the two forms is often indistinguishable. The vast majority of juvenile polyps occur in children younger than 5 years of age but they can present at older ages as well. Most juvenile polyps are located in the rectum and typically present with rectal bleeding. In some cases intussusception, intestinal obstruction, or polyp prolapse (through the anal sphincter) may occur.

Sporadic juvenile polyps are usually solitary lesions and may also be referred to as retention polyps. In contrast, individuals with the autosomal dominant syndrome of juvenile polyposis have from 3 to as many as 100 hamartomatous polyps and may require colectomy to limit the chronic and sometimes severe hemorrhage associated with polyp ulceration. A minority of patients also have polyps in the stomach and small bowel that can undergo malignant transformation. Pulmonary arteriovenous malformations and other congenital malformations are recognized extraintestinal manifestation of juvenile polyposis.

Table 17-10 Gastrointestinal Polyposis Syndromes

Syndrome	Mean Age at Presentation (yr)	Mutated Gene(s); Pathway	Gastrointestinal Lesions	Selected Extra-Gastrointestinal Manifestations
Juvenile polyposis	<5	<i>SMAD4</i> , <i>BMPR1A</i> ; TGF- β signaling pathway	Juvenile polyps; risk of gastric, small intestinal, colonic, and pancreatic adenocarcinoma	Congenital malformations, digital clubbing
Peutz-Jeghers syndrome	10-15	<i>STK11</i> ; AMP kinase-related pathways	Arborizing polyps; Small intestine > colon > stomach; colonic adenocarcinoma	Pigmented macules; risk of colon, breast, lung, pancreatic, and thyroid cancer
Cowden syndrome, Bannayan-Ruvalcaba-Riley syndrome*	<15	<i>PTEN</i> ; PI3K/AKT pathway	Hamartomatous/ inflammatory intestinal polyps, lipomas, ganglioneuromas	Benign skin tumors, benign and malignant thyroid and breast lesions; no increase in GI cancers
Cronkhite-Canada syndrome	>50	Nonhereditary, unknown cause	Hamartomatous polyps of stomach, small intestine colon; abnormalities in nonpolypoid mucosa	Nail atrophy, hair loss, abnormal skin pigmentation, cachexia, and anemia. Fatal in up to 50%.
Tuberous sclerosis		<i>TSC1</i> (hamartin), <i>TSC2</i> (tuberin); mTOR pathway	Hamartomatous polyps	Mental retardation, epilepsy, facial angiofibroma, cortical (CNS) tubers, renal angiomyolipoma
Familial adenomatous polyposis (FAP)				
Classic FAP	10-15	<i>APC</i>	Multiple adenomas	Congenital RPE hypertrophy
Attenuated FAP	40-50	<i>APC</i>	Multiple adenomas	
Gardner syndrome	10-15	<i>APC</i>	Multiple adenomas	Osteomas, thyroid and desmoid tumors, skin cysts
Turcot syndrome	10-15	<i>APC</i>	Multiple adenomas	Medulloblastoma, glioblastoma
<i>MYH</i> -associated polyposis	30-50	<i>MYH</i>	Multiple adenomas	

CNS, Central nervous system; mTOR, mammalian target of rapamycin; RPE, retinal pigmented epithelium.

*Also called PTEN Hamartoma-Tumor Syndromes.

MORPHOLOGY

Most juvenile polyps are less than 3 cm in diameter. They are typically pedunculated, smooth-surfaced, reddish lesions with characteristic cystic spaces apparent after sectioning. Microscopic examination shows these cysts to be dilated glands filled with mucin and inflammatory debris (Fig. 17-43). The remainder of the polyp is composed of lamina propria expanded by mixed inflammatory infiltrates. The muscularis mucosae may be normal or attenuated.

Although the morphogenesis of juvenile polyps is incompletely understood, it has been proposed that mucosal hyperplasia is the initiating event. This hypothesis is consistent with the discovery that mutations in pathways that regulate cellular growth cause autosomal dominant juvenile polyposis. The most common mutation identified is of *SMAD4*, which encodes a cytoplasmic intermediate in the TGF- β signaling pathway. *BMPR1A*, a kinase that is a member of the TGF- β superfamily, may be mutated in other cases (Table 17-10). However, these mutations account for fewer than half of patients, suggesting that other genes responsible for autosomal dominant juvenile polyposis remain to be discovered.

Dysplasia is extremely rare in sporadic juvenile polyps. In contrast juvenile polyposis syndrome is associated with dysplasia, both within the juvenile polyps and in separate adenomas. As a result, 30% to 50% of patients with juvenile polyposis develop colonic adenocarcinoma by age 45.

Peutz-Jeghers Syndrome

This rare autosomal dominant syndrome presents at a median age of 11 years with multiple GI hamartomatous polyps and mucocutaneous hyperpigmentation. The latter takes the form of dark blue to brown macules on the lips, nostrils, buccal mucosa, palmar surfaces of the hands, genitalia, and perianal region. These lesions are similar to freckles but are distinguished by their presence in the buccal mucosa. Peutz-Jeghers polyps can initiate intussusception, which is occasionally fatal. Of greater importance, Peutz-Jeghers syndrome is associated with a markedly increased risk of several malignancies. Lifetime risk is approximately 40% for these, and regular surveillance is recommended beginning at birth, for sex cord tumors of the testes; late childhood for gastric and small intestinal cancers; and the second and third decades of life for colon, pancreatic, breast, lung, ovarian, and uterine cancers.

Pathogenesis. Germline heterozygous loss-of-function mutations in the gene *STK11* are present in approximately half of individuals with familial Peutz-Jeghers syndrome as well as a subset of patients with sporadic Peutz-Jeghers syndrome. You will recall from Chapter 7 that *STK11* is a tumor suppressor gene that encodes a kinase that regulates cell polarization and acts as a brake on growth and anabolic metabolism. As is common with other tumor suppressor genes, the function of the second “normal” copy of *STK11* is often lost through somatic mutation in cancers occurring in Peutz-Jeghers syndrome, providing an explanation for the high risk of neoplasia in affected patients. Importantly, colon cancers can also develop at sites without Peutz-Jeghers polyps.

Figure 17-43 Juvenile polyposis. **A**, Juvenile polyp. Note the surface erosion and cystically dilated crypts. **B**, Inspissated mucous, neutrophils, and inflammatory debris can accumulate within dilated crypts.

MORPHOLOGY

The polyps of Peutz-Jeghers syndrome are most common in the small intestine, although they may occur in the stomach and colon, and, with much lower frequency, in the bladder and lungs. Grossly, the polyps are large and pedunculated with a lobulated contour. Histologic examination demonstrates a characteristic arborizing network of connective tissue, smooth muscle, lamina propria, and glands lined by normal-appearing intestinal epithelium (Fig. 17-44). The arborization and presence of smooth muscle intermixed with lamina propria are helpful in distinguishing polyps of Peutz-Jeghers syndrome from juvenile polyps.

Clinical Features. Because the morphology of Peutz-Jeghers polyps can overlap with that of sporadic hamartomatous polyps, the presence of multiple polyps in the small intestine, mucocutaneous hyperpigmentation, and a positive family history are critical to the diagnosis. Detection of *STK11* mutations can be helpful diagnostically in patients with polyps who lack mucocutaneous hyperpigmentation. However, the absence of *STK11* mutations does not exclude the diagnosis, since mutations in other presently unknown genes can also cause the syndrome.

Neoplastic Polyps

Any neoplastic mass lesion in the GI tract may produce a mucosal protrusion, or polyp. This includes adenocarcinomas, neuroendocrine (carcinoid) tumors, stromal tumors, lymphomas, and even metastatic cancers from distant sites. *The most common neoplastic polyps are colonic adenomas, which are precursors to the majority of colorectal adenocarcinomas.*

Adenomas are intraepithelial neoplasms that range from small, often pedunculated, polyps to large sessile lesions. There is a small male predominance, and they are present in approximately 30% of adults living in the Western world by age 60. Because these polyps are precursors to colorectal adenocarcinoma, it is recommended that all adults in the United States undergo surveillance by age 50. Patients at increased risk, including those with a family history of colorectal adenocarcinoma, are typically screened colonoscopically at least 10 years before the youngest age at which a relative was diagnosed. The preferred approach to surveillance varies, but colonoscopy is most common.

Figure 17-44 Peutz-Jeghers polyp. **A**, Polyp surface (top) overlies stroma composed of smooth muscle bundles cutting through the lamina propria. **B**, Complex glandular architecture and the presence of smooth muscle are features that distinguish Peutz-Jeghers polyps from juvenile polyps. Compare to Figure 17-42.

While adenomas are less common in Asia, their frequency has risen (in parallel with an increasing incidence of colorectal adenocarcinoma) in these populations as Western diets and lifestyles become more common.

Colorectal adenomas are characterized by the presence of epithelial dysplasia. Consistent with their being precursor lesions, the prevalence of colorectal adenomas correlates with that of colorectal adenocarcinoma and the distributions of adenomas and adenocarcinoma within the colon are similar. Large studies have demonstrated that regular surveillance colonoscopy and polyp removal reduces the incidence of colorectal adenocarcinoma. Despite this strong relationship, it must be emphasized that majority of adenomas do not progress to become adenocarcinomas. There are no tools presently available to distinguish between adenomas that will or will not undergo malignant transformation, and indeed it may be that transformation is stochastic, being dependent on acquisition of oncogenic mutations merely by chance. Most adenomas are clinically silent, with the exception of large polyps that produce occult bleeding and anemia and rare villous adenomas that cause hypoproteinemic hypokalemia by secreting large amounts of protein and potassium.

MORPHOLOGY

Typical adenomas range from 0.3 to 10 cm in diameter and can be pedunculated (Fig. 17-45A) or sessile, with the surface of both types having a texture resembling velvet or a raspberry (Fig. 17-45B). Histologically, the hallmark of epithelial dysplasia is nuclear hyperchromasia, elongation, and stratification (see Fig. 17-46C). These changes are most easily appreciated at the surface of the adenoma and are often accompanied by prominent nucleoli, eosinophilic cytoplasm, and a reduction in the number of goblet cells. Notably, epithelial cells fail to mature as they migrate from crypt to surface. Pedunculated adenomas have slender fibromuscular stalks (Fig. 17-45C) containing prominent blood vessels derived from the submucosa. The stalk is usually covered by nonneoplastic epithelium, but dysplastic epithelium is sometimes present.

Adenomas can be classified as **tubular**, **tubulovillous**, or **villous** based on their architecture. These categories, however,

have little clinical significance in isolation. Tubular adenomas tend to be small, pedunculated polyps composed of rounded, or tubular, glands (Fig. 17-46A). In contrast, villous adenomas, which are often larger and sessile, are covered by slender villi (Fig. 17-46B). Tubulovillous adenomas have a mixture of tubular and villous elements. Although villous adenomas contain foci of invasion more frequently than tubular adenomas, villous architecture alone does not increase cancer risk when polyp size is considered.

Sessile serrated adenomas overlap histologically with hyperplastic polyps, but are more commonly found in the right colon. Despite their malignant potential, sessile serrated adenomas lack typical cytologic features of dysplasia that are present in other adenomas, prompting some to refer to these lesions as sessile serrated polyps. Histologic criteria for these lesions include serrated architecture throughout the full length of the glands, including the crypt base, crypt dilation, and lateral growth (Fig. 17-46D).

Intramucosal carcinoma occurs when dysplastic epithelial cells breach the basement membrane to invade the lamina propria or muscularis mucosae. Because functional lymphatic channels are absent in the colonic mucosa, intramucosal carcinomas have little or no metastatic potential and complete polypectomy is generally curative (Fig. 17-47A). Invasion beyond the muscularis mucosae, including into the submucosal stalk of a pedunculated polyp (Fig. 17-47B), constitutes invasive adenocarcinoma and carries a risk of spread to other sites. In such cases several factors, including the histologic grade of the invasive component, the presence of vascular or lymphatic invasion, and the distance of the invasive component from the margin of resection, must be considered in planning further therapy.

Although most colorectal adenomas are benign lesions, a small proportion may harbor invasive cancer at the time of detection. *Size is the most important characteristic that correlates with risk of malignancy.* For example, while cancer is extremely rare in adenomas less than 1 cm in diameter, some studies suggest that nearly 40% of lesions larger than 4 cm in diameter contain foci of cancer. High-grade dysplasia is also a risk factor for cancer in an individual polyp,

Figure 17-45 Colonic adenomas. **A**, Pedunculated adenoma (endoscopic view). **B**, Adenoma with a velvety surface. **C**, Low-magnification photomicrograph of a pedunculated tubular adenoma.

Figure 17-46 Histologic appearance of colonic adenomas. **A**, Tubular adenoma with a smooth surface and rounded glands. Active inflammation is occasionally present in adenomas, in this case, crypt dilation and rupture can be seen at the bottom of the field. **B**, Villous adenoma with long, slender projections that are reminiscent of small intestinal villi. **C**, Dysplastic epithelial cells (top) with an increased nuclear-to-cytoplasmic ratio, hyperchromatic and elongated nuclei, and nuclear pseudostratification. Compare to the non-dysplastic epithelium below. **D**, Sessile serrated adenoma lined by goblet cells without cytologic features of dysplasia. This lesion is distinguished from a hyperplastic polyp by extension of the neoplastic process to the crypts, resulting in lateral growth. Compare to the hyperplastic polyp in Figure 17-44A.

but does not confer an increased risk of cancer in other polyps within the same patient.

Adenomatous Polyposis

Familial adenomatous polyposis (FAP) is an autosomal dominant disorder in which patients develop numerous colorectal adenomas as teenagers. It is caused by mutations of the adenomatous polyposis coli, or *APC*, gene, which you will recall is a key negative regulator of the Wnt signaling pathway (Chapter 7). Approximately 75% of cases are inherited, while the remaining appear to be caused by de novo mutations.

At least 100 polyps are necessary for a diagnosis of classic FAP, but as many as several thousand may be present (Fig. 17-48). Except for their remarkable numbers, these growths are morphologically indistinguishable from sporadic adenomas. In addition, however, flat or depressed adenomas are also prevalent in FAP, and microscopic adenomas, consisting of only one or two dysplastic crypts, are frequently observed in otherwise normal-appearing mucosa.

Colorectal adenocarcinoma develops in 100% of untreated FAP patients, often before age 30 and nearly always by age 50. As a result, prophylactic colectomy is the standard therapy for individuals carrying *APC* mutations. Colectomy prevents colorectal cancer, but patients remain at risk for neoplasia at other sites. Adenomas may develop elsewhere in the GI tract, particularly adjacent to the ampulla of Vater and in the stomach.

FAP is associated with a variety of extraintestinal manifestations including congenital hypertrophy of the retinal pigment epithelium, which can generally be detected at birth, and therefore may be an adjunct to early screening. Specific *APC* mutations have been associated with the development of other manifestations of FAP and partly explain variants such as Gardner syndrome and Turcot syndrome (Table 17-11).

Some polyposis patients without *APC* loss have bi-allelic mutations of the base-excision repair gene *MYH* (also referred to as *MUTYH*). This autosomal recessive disorder is termed *MYH*-associated polyposis. The colonic phenotype is similar to attenuated FAP, with polyp development at later ages, the presence of fewer than 100 adenomas, and the delayed appearance of colon cancer, often at ages of 50 or older. In addition, serrated polyps, often with *KRAS*

Figure 17-47 Adenoma with intramucosal carcinoma. **A**, Cribriform glands interface directly with the lamina propria without an intervening basement membrane. **B**, Invasive adenocarcinoma (left) beneath a villous adenoma (right). Note the desmoplastic response to the invasive components.

Figure 17-48 Familial adenomatous polyposis. **A**, Hundreds of small polyps are present throughout this colon with a dominant polyp (right). **B**, Three tubular adenomas are present in this single microscopic field.

mutations, are frequently present in *MUTYH*-associated polyposis.

Hereditary Non-Polyposis Colorectal Cancer

Hereditary non-polyposis colorectal cancer (HNPCC), also known as Lynch syndrome, was originally described based on familial clustering of cancers at several sites including the colorectum, endometrium, stomach, ovary, ureters, brain, small bowel, hepatobiliary tract, pancreas, and skin.

HNPCC is thought to account for 2% to 4% of all colorectal cancers, making it the most common syndromic form of colon cancer. Colon cancers in HNPCC patients tend to occur at younger ages than sporadic colon cancers and are often located in the right colon (Table 17-11). Just as identification of *APC* mutations in FAP has provided molecular insights into the pathogenesis of the majority of sporadic colon cancers, unraveling the defects in HNPCC has shed light on the mechanisms responsible for most of the remaining sporadic cases. **HNPCC is caused by inherited mutations in genes that encode proteins responsible for the detection, excision, and repair of errors that occur during DNA replication (Chapter 7).** There are at least five such mismatch repair genes, but majority of patients with HNPCC have mutations in *MSH2* or *MLH1*. Patients with HNPCC inherit one mutant gene and one normal allele. When the second copy is lost through mutation or epigenetic silencing, defects in mismatch repair lead to the accumulation of mutations at rates up to 1000 times higher than normal, mostly in regions containing short repeating sequences referred to as microsatellites. The human genome contains approximately 50,000 to 100,000 microsatellites, which are prone to undergo expansion during DNA replication and represent the most frequent sites of mutations in HNPCC. The consequences of mismatch repair deficiency and the resulting microsatellite instability are discussed next in the context of colonic adenocarcinoma.

Adenocarcinoma

Adenocarcinoma of the colon is the most common malignancy of the GI tract and is a major cause of morbidity and mortality worldwide. In contrast, the small intestine, which accounts for 75% of the overall length of the GI tract, is an uncommon site for benign and malignant tumors. Among malignant small intestinal tumors, adenocarcinomas and well-differentiated neuroendocrine (carcinoid) tumors have roughly equal incidence, followed by lymphomas and sarcomas.

Epidemiology. Approximately 1.2 million new cases of colorectal adenocarcinoma, and 600,000 associated deaths, occur each year worldwide. Thus, colorectal adenocarcinoma is responsible for nearly 10% of all cancer deaths. The

Table 17-11 Common Patterns of Sporadic and Familial Colorectal Neoplasia

Etiology	Molecular Defect	Target Gene(s)	Transmission	Predominant Site(s)	Histology
Familial adenomatous polyposis	<i>APC</i> /WNT pathway	<i>APC</i>	Autosomal dominant	None	Tubular, villous; typical adenocarcinoma
<i>MUTYH</i> -associated polyposis	DNA mismatch repair	<i>MUTYH</i>	Autosomal recessive	None	Sessile serrated adenoma; mucinous adenocarcinoma
Hereditary nonpolyposis colorectal cancer	DNA mismatch repair	<i>MSH2</i> , <i>MLH1</i>	Autosomal dominant	Right side	Sessile serrated adenoma; mucinous adenocarcinoma
Sporadic colon cancer (70%-80%)	<i>APC</i> /WNT pathway	<i>APC</i>	None	Left side	Tubular, villous; typical adenocarcinoma
Sporadic colon cancer (10%-15%)	DNA mismatch repair	<i>MSH2</i> , <i>MLH1</i>	None	Right side	Sessile serrated adenoma; mucinous adenocarcinoma
Sporadic colon cancer (5%-10%)	Hypermethylation	<i>MLH1</i> , <i>BRAF</i>	None	Right side	Sessile serrated adenoma; mucinous adenocarcinoma

incidence of these tumors is highest in North America, with the United States accounting for approximately 10% of worldwide cases and cancer deaths. This represents nearly 15% of all cancer-related deaths in the United States, second only to lung cancer. Australia, New Zealand, Europe, and, with changes in lifestyle and diet, Japan, also have high incidences of colorectal adenocarcinoma. In contrast, rates are lower in South America, India, Africa, and South Central Asia. Colorectal cancer incidence peaks at 60 to 70 years of age, with fewer than 20% of cases occurring before age 50.

The *dietary factors* most closely associated with increased rates of colorectal cancer are low intake of unabsorbable vegetable fiber and high intake of refined carbohydrates and fat. Although these associations are clear, the mechanistic relationship between diet and risk remains poorly understood. It is theorized that reduced fiber content leads to decreased stool bulk and altered composition of the intestinal microbiota. This change may increase synthesis of potentially toxic oxidative by-products of bacterial metabolism, which would be expected to remain in contact with the colonic mucosa for longer periods of time as a result of reduced stool bulk. High fat intake also enhances hepatic synthesis of cholesterol and bile acids, which can be converted into carcinogens by intestinal bacteria.

In addition to dietary modification, *pharmacologic chemoprevention* has become an area of great interest. Several epidemiologic studies suggest that aspirin or other NSAIDs have a protective effect. This is consistent with studies showing that some NSAIDs cause polyp regression in FAP patients in whom the rectum was left in place after colectomy. It is suspected that this effect is mediated by inhibition of the enzyme cyclooxygenase-2 (COX-2), which is highly expressed in 90% of colorectal carcinomas and 40% to 90% of adenomas. COX-2 is necessary for production of prostaglandin E₂, which promotes epithelial proliferation,

particularly after injury. Of further interest, COX-2 expression is regulated by TLR4, which recognizes lipopolysaccharide and is also overexpressed in adenomas and carcinomas.

Pathogenesis. Studies of colorectal carcinogenesis have provided fundamental insights into the general mechanisms of cancer evolution. These were discussed in [Chapter 7](#); concepts that pertain specifically to colorectal carcinogenesis will be reviewed here.

The combination of molecular events that lead to colonic adenocarcinoma is heterogeneous and includes genetic and epigenetic abnormalities. At least two genetic pathways have been described. In simplest terms, these are the *APC/β-catenin pathway*, which is activated in the classic adenoma-carcinoma sequence; and the *microsatellite instability pathway*, which is associated with defects in DNA mismatch repair and accumulation of mutations in microsatellite repeat regions of the genome ([Table 17-11](#)). Both pathways involve the stepwise accumulation of multiple mutations, but differ in the genes involved and the mechanisms by which mutations accumulate. Epigenetic events, the most common of which is methylation-induced gene silencing, may enhance progression along either pathway.

- **The classic adenoma-carcinoma sequence, accounts for up to 80% of sporadic colon tumors and typically includes mutation of APC early in the neoplastic process ([Fig. 17-49](#)).** Both copies of the APC gene must be functionally inactivated, either by mutation or epigenetic events, for adenomas to develop. APC is a key negative regulator of β-catenin, a component of the Wnt signaling pathway ([Chapter 7](#)). The APC protein normally binds to and promotes degradation of β-catenin. With loss of APC function, β-catenin accumulates and

Figure 17-49 Morphologic and molecular changes in the adenoma-carcinoma sequence. Loss of one normal copy of the tumor suppressor gene APC occurs early. Individuals born with one mutant allele are therefore at increased risk of developing colon cancer. Alternatively, inactivation of APC in colonic epithelium may occur later in life. This is the "first hit" according to the Knudson hypothesis ([Chapter 7](#)). The loss of the intact second copy of APC follows ("second hit"). Other changes, including mutation of KRAS, losses at 18q21 involving SMAD2 and SMAD4, and inactivation of the tumor suppressor gene TP53, lead to the emergence of carcinoma, in which further mutations occur. Although there seems to be a temporal sequence of changes, the accumulation of mutations, rather than their occurrence in a specific order, is most critical.

translocates to the nucleus, where it forms a complex with the DNA-binding factor TCF and activates the transcription of genes, including *MYC* and cyclin D1, that promote proliferation. The critical role of β -catenin in this pathway is demonstrated by the fact that many colon cancers without *APC* mutations harbor β -catenin mutations that allow them to avoid *APC*-dependent degradation, thereby having the same impact as loss of *APC* function. Additional mutations accumulate, including activating mutations in *KRAS* that promote growth and prevent apoptosis. The idea that mutation of *KRAS* is a late event in carcinoma development is supported by the observation that such mutations are present in fewer than 10% of adenomas less than 1 cm in diameter but are found in 50% of adenomas greater than 1 cm in diameter and in 50% of invasive adenocarcinomas. Neoplastic progression is also associated with mutations in other tumor suppressor genes such as those encoding *SMAD2* and *SMAD4*, which are effectors of TGF- β signaling. Because TGF- β signaling normally inhibits the cell cycle, loss of these genes may allow unrestrained cell growth. The tumor suppressor gene *TP53* is mutated in 70% to 80% of colon cancers, but is uncommonly affected in adenomas, suggesting that *TP53* mutations also occur at later stages of tumor progression. Loss of function of *TP53* and other tumor suppressor genes is often caused by chromosomal deletions, supporting the idea that chromosomal instability is a hallmark of the *APC*/ β -catenin pathway. Alternatively, tumor suppressor genes may be silenced by methylation of a CpG-rich zone, or CpG island, a 5' region of some genes that frequently includes the promoter and transcriptional start site. Expression of telomerase also increases as lesions become more advanced.

- **In patients with DNA mismatch repair deficiency, mutations accumulate in microsatellite repeats, a condition referred to as microsatellite instability (MSI).** These are referred to as MSI high, or MSI-H, tumors. Some microsatellite sequences are located in the coding or promoter regions of genes involved in regulation of cell growth, such as those encoding the type II TGF- β receptor and the pro-apoptotic protein *BAX* (Fig. 17-50).

Because TGF- β inhibits colonic epithelial cell proliferation, mutation of type II TGF- β receptor can contribute to uncontrolled cell growth, while loss of *BAX* may enhance the survival of genetically abnormal clones.

- **A subset of microsatellite unstable colon cancers without mutations in DNA mismatch repair enzymes demonstrate the CpG island hypermethylation phenotype (CIMP).** In these tumors, the *MLH1* promoter region is typically hypermethylated, thereby reducing *MLH1* expression and repair function. Activating mutations in the oncogene *BRAF* are common in these cancers. In contrast, *KRAS* and *TP53* are not typically mutated. Thus, the combination of microsatellite instability, *BRAF* mutation, and methylation of specific targets, such as *MLH1*, is the signature of this pathway of carcinogenesis.
- **A small group of colon cancers display increased CpG island methylation in the absence of microsatellite instability.** Many of these tumors harbor *KRAS* mutations, but *TP53* and *BRAF* mutations are uncommon. In contrast, *TP53* mutations are common in colon cancers that do not display a CpG island methylator phenotype.

While morphology cannot reliably define the underlying molecular events that lead to carcinogenesis, certain correlations have been associated with mismatch repair deficiency and microsatellite instability. These molecular alterations are common in sessile serrated adenomas and cancers that arise from them. In addition, invasive carcinomas with microsatellite instability often have prominent mucinous differentiation and peritumoral lymphocytic infiltrates. These tumors, as well as those with a CpG island hypermethylation phenotype, are frequently located in the right colon. Tumors with microsatellite instability can be recognized by the absence of immunohistochemical staining for mismatch repair proteins or by molecular genetic analysis of microsatellite sequences. It is important to identify patients with HNPCC because of the implications for genetic counseling, the elevated risk of a second malignancy of the colon or other organs, and, in some settings, differences in prognosis and therapy.

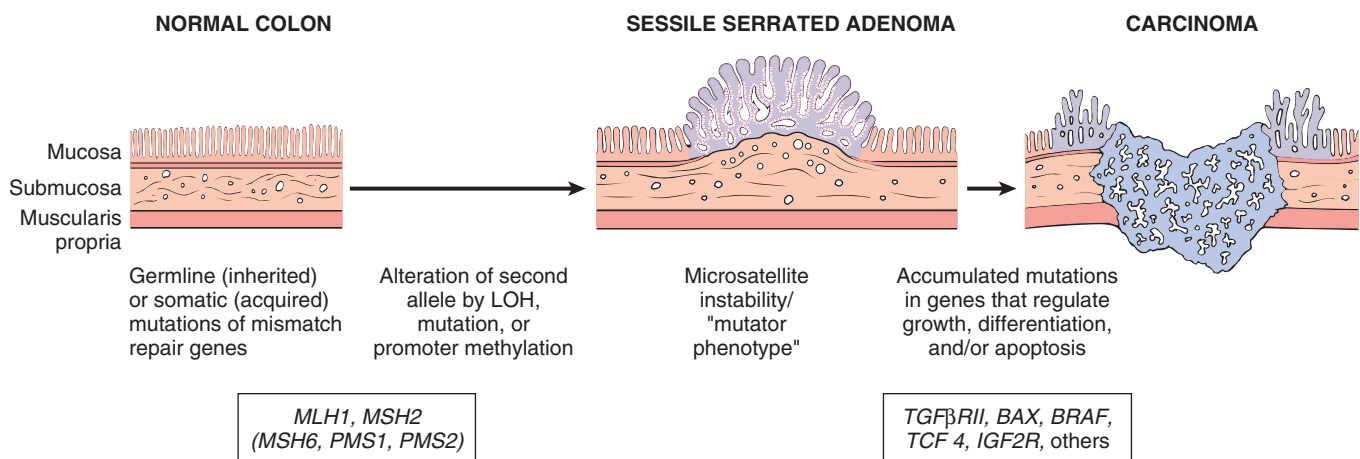

Figure 17-50 Morphologic and molecular changes in the mismatch repair pathway of colon carcinogenesis. Defects in mismatch repair genes result in microsatellite instability and permit accumulation of mutations in numerous genes. If these mutations affect genes involved in cell survival and proliferation, cancer may develop.

Figure 17-51 Colorectal carcinoma. **A**, Circumferential, ulcerated rectal cancer. Note the anal mucosa at the bottom of the image. **B**, Cancer of the sigmoid colon that has invaded through the muscularis propria and is present within subserosal adipose tissue (left). Areas of chalky necrosis are present within the colon wall (arrow).

MORPHOLOGY

Overall, adenocarcinomas are distributed approximately equally over the entire length of the colon. Tumors in the **proximal colon often grow as polypoid, exophytic masses** that extend along one wall of the large-caliber cecum and ascending colon; these tumors rarely cause obstruction. In contrast, **carcinomas in the distal colon tend to be annular lesions** that produce “napkin-ring” constrictions and luminal narrowing (Fig. 17-51), sometimes to the point of obstruction. Both forms grow into the bowel wall over time. The general microscopic characteristics of right- and left-sided colonic adenocarcinomas are similar. Most tumors are composed of tall columnar cells that resemble dysplastic epithelium found in adenomas (Fig. 17-52A). The invasive component of these tumors elicits a strong stromal desmoplastic response, which is responsible for their characteristic firm consistency. Some poorly differentiated tumors form few glands (Fig. 17-52B). Others may produce abundant mucin that accumulates within

the intestinal wall, and these are associated with poor prognosis. Tumors may also be composed of signet-ring cells that are similar to those in gastric cancer (Fig. 17-52C) or may display features of neuroendocrine differentiation.

Clinical Features. The availability of endoscopic screening combined with the knowledge that most carcinomas arise within adenomas presents a unique opportunity for cancer prevention. Unfortunately, colorectal cancers develop insidiously and may go undetected for long periods. Cecal and other *right-sided colon cancers* are most often called to clinical attention by the appearance of *fatigue and weakness due to iron deficiency anemia*. Thus, it is a clinical maxim that the underlying cause of iron deficiency anemia in an older man or postmenopausal woman is GI cancer until proven otherwise. *Left-sided colorectal adenocarcinomas* may produce *occult bleeding, changes in bowel habits, or cramping and left lower quadrant discomfort*.

Although poorly differentiated and mucinous histologies are associated with poor prognosis, *the two most important prognostic factors are depth of invasion and the presence of lymph node metastases*. Invasion into the muscularis propria confers significantly reduced survival that is decreased further by the presence of lymph node metastases (Fig. 17-53A). Metastases may involve regional lymph nodes, lungs (Fig. 17-53B) and bones, but as a result of portal drainage of the colon, the liver is the most common site of metastatic lesions (Fig. 17-53C). The rectum does not drain via the portal circulation, hence carcinomas of the anal region that metastasize often circumvent the liver.

The prognostic factors were originally recognized by Dukes and Kirklind and form the core of the TNM (tumor-nodes-metastasis) classification (Table 17-12). The American Joint Committee on Cancer (AJCC) staging system is compared to the Astler-Coller modification of the Dukes system in Table 17-13. Regardless of stage, it must be remembered that some patients with small numbers of metastases do well for years following resection of distant tumor nodules.

Five-year survival rates vary widely worldwide. The overall 5-year survival rate in the United States is 65%, and ranges from 90% to 40% depending on stage. Survival rates in Europe, Japan and Australia are similar, ranging

Figure 17-52 Histologic appearance of colorectal carcinoma. **A**, Well-differentiated adenocarcinoma. Note the elongated, hyperchromatic nuclei. Necrotic debris, present in the gland lumen, is typical. **B**, Poorly differentiated adenocarcinoma forms a few glands but is largely composed of infiltrating nests of tumor cells. **C**, Mucinous adenocarcinoma with signet-ring cells and extracellular mucin pools.

Figure 17-53 Metastatic colorectal carcinoma. **A**, Lymph node metastasis. Note the glandular structures within the subcapsular sinus. **B**, Solitary subpleural nodule of colorectal carcinoma metastatic to the lung. **C**, Liver containing two large and many smaller metastases. Note the central necrosis within metastases.

from 60% (Switzerland, Japan) to (40%) Poland. Overall survival rates are somewhat lower in other countries, such as China, India, the Philippines, and Thailand (30% to 42%). Sadly, the 5-year survival rate in Gambia is only 4%.

KEY CONCEPTS

Benign and malignant proliferative lesions of the colon

- **Intestinal polyps** can be classified as nonneoplastic or neoplastic. The nonneoplastic polyps can be further defined as hyperplastic, inflammatory, or hamartomatous.
- **Hyperplastic polyps** are benign epithelial proliferations most commonly found in the left colon and rectum. They have no malignant potential, and must be distinguished from sessile serrated adenomas.
- **Inflammatory polyps** form as a result of chronic cycles of injury and healing.
- **Hamartomatous polyps** occur sporadically or as a part of genetic diseases. The latter include **juvenile polyposis** and **Peutz-Jeghers Syndrome**, which are associated with **increased risk of malignancy**.
- Benign epithelial neoplastic polyps of the intestines are termed **adenomas**. The hallmark of these lesions, which

Table 17-12 American Joint Committee on Cancer (AJCC) TNM Classification of Colorectal Carcinoma

TNM	
Tumor	
Tis	In situ dysplasia or intramucosal carcinoma
T1	Tumor invades submucosa
T2	Tumor invades into, but not through, muscularis propria
T3	Tumor invades through muscularis propria
T3a	Invasion < 0.1 cm beyond muscularis propria
T3b	Invasion 0.1 to 0.5 cm beyond muscularis propria
T3c	Invasion > 0.5 to 1.5 cm beyond muscularis propria
T3d	Invasion > 1.5 cm beyond muscularis propria
T4	Tumor penetrates visceral peritoneum or invades adjacent organs
T4a	Penetration into visceral peritoneum
T4b	Invasion into other organs or structures
Regional Lymph Nodes	
NX	Lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in one to three regional lymph nodes
N1a	Metastasis in one regional lymph nodes
N1b	Metastasis in two or three regional lymph nodes
N1c	Tumor deposit(s) in the subserosa, mesentery, or nonperitonealized pericolic or perirectal tissues without regional nodal metastasis
N2	Metastasis in four or more regional lymph nodes
N2a	Metastasis in four to six regional lymph nodes
N2b	Metastasis in seven or more regional lymph nodes
Distant Metastasis	
MX	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis
M1a	Metastasis confined to one organ or site
M1b	Metastases in more than one organ/site or the peritoneum

*Stages not included in original Dukes classification; added later for comparison with AJCC staging.

are the precursors of colonic adenocarcinomas, is cytologic dysplasia.

- In contrast to traditional adenomas, **sessile serrated adenomas** lack cytologic dysplasia and share morphologic features with hyperplastic polyps.

- **Familial adenomatous polyposis (FAP)** and **hereditary non-polyposis colorectal cancer (HNPCC)** are the most common forms of familial colon cancer.
- **FAP** is caused by *APC* mutations. Patients typically have more than 100 adenomas and develop colon cancer before 30 years of age.
- **HNPCC** is caused by mutations in DNA mismatch repair enzymes. HNPCC patients have far fewer polyps and develop cancer at older ages than FAP patients but younger ages than those with sporadic colon cancer.
- FAP and HNPCC typify **distinct pathways of neoplastic transformation and progression** that also contribute to the majority of **sporadic colon cancers**.
- Nearly all colonic cancers are **adenocarcinomas**. The two most important prognostic factors are **depth of invasion** and the presence or absence of **lymph node metastases**.

Tumors of the Anal Canal

The anal canal can be divided into thirds. The upper zone is lined by columnar rectal epithelium; the middle third by transitional epithelium; and the lower third by stratified squamous epithelium. Carcinomas of the anal canal may have typical glandular or squamous patterns of differentiation, recapitulating the normal epithelium of the upper and lower thirds, respectively (Fig. 17-54A). An additional differentiation pattern, termed basaloid, is present in tumors populated by immature cells derived from the basal layer of transitional epithelium (Fig. 17-54B). When the entire tumor displays a basaloid pattern, the archaic term cloacogenic carcinoma is still often applied. Alternatively, basaloid differentiation may be mixed with squamous or mucinous differentiation. All are considered variants of anal canal carcinoma. Pure squamous cell carcinoma of the anal canal is frequently associated with HPV infection, which also causes precursor lesions such as condyloma acuminatum (Fig. 17-54C).

Hemorrhoids

Hemorrhoids affect about 5% of the general population and develop secondary to persistently elevated venous pressure within the hemorrhoidal plexus. The most frequent predisposing influences are straining at defecation, because of constipation, and the venous stasis of pregnancy. Hemorrhoids may also develop in association with portal hypertension. The pathogenesis of hemorrhoids (anal varices) in portal hypertension is similar to that of esophageal varices, although anal varices are both more common and much less serious. Variceal dilations of the anal and perianal venous plexuses form collaterals that connect the portal and caval venous systems, thereby relieving the venous hypertension.

MORPHOLOGY

Collateral vessels within the inferior hemorrhoidal plexus are located below the anorectal line and are termed **external hemorrhoids**, while those that result from dilation of the superior hemorrhoidal plexus within the distal rectum are referred to as **internal hemorrhoids**. Histologically, hemorrhoids consist of thin-walled, dilated, submucosal vessels that protrude beneath the anal or rectal mucosa. In their exposed position, they are subject to trauma and tend to become inflamed, thrombosed, and, in the course of time, recanalized. Superficial ulceration may occur.

Hemorrhoids often present with pain and rectal bleeding, particularly bright red blood seen on toilet tissue. Except for pregnant women, hemorrhoids are rarely encountered in persons younger than age 30. Hemorrhoidal bleeding is not generally a medical emergency and can be treated by sclerotherapy, rubber band ligation, or infrared coagulation. Extensive or severe internal or external hemorrhoids may be removed surgically by hemorrhoidectomy.

Figure 17-54 Anal tumors. **A**, This anal transition zone carcinoma demonstrates a multilayered organization reminiscent of benign squamous mucosa. The adjacent rectal mucosa is intact. **B**, This basaloid anal transition zone tumor is composed of hyperchromatic cells that resemble the basal layer of normal squamous mucosa. **C**, Condyloma acuminatum with verrucous architecture.

Acute Appendicitis

The appendix is a normal true diverticulum of the cecum that is prone to acute and chronic inflammation. Acute appendicitis is most common in adolescents and young adults, with a lifetime risk of 7%; males are affected slightly more often than females. Despite the prevalence of acute appendicitis, the diagnosis can be difficult to confirm preoperatively and may be confused with mesenteric lymphadenitis (often secondary to unrecognized *Yersinia* infection or viral enterocolitis), acute salpingitis, ectopic pregnancy, mittelschmerz (pain caused by minor pelvic bleeding at the time of ovulation), and Meckel diverticulitis.

Pathogenesis. Acute appendicitis is thought to be initiated by progressive increases in intraluminal pressure that compromise venous outflow. In 50% to 80% of cases, acute appendicitis is associated with overt luminal obstruction, usually caused by a small stone-like mass of stool, or fecalith, or, less commonly, a gallstone, tumor, or mass of worms (*oxyuriasis vermicularis*). Stasis of luminal contents, which favors bacterial proliferation, triggers ischemia and inflammatory responses, resulting in tissue edema and neutrophilic infiltration of the lumen, muscular wall, and periappendiceal soft tissues.

MORPHOLOGY

In early acute appendicitis subserosal vessels are congested and there is a modest perivascular neutrophilic infiltrate within all layers of the wall. The inflammatory reaction transforms the normal glistening serosa into a dull, granular, erythematous surface. Although mucosal neutrophils and focal superficial ulceration are often present, these are not specific markers of acute appendicitis. Diagnosis of acute appendicitis requires **neutrophilic infiltration of the muscularis propria**. In more severe cases a prominent neutrophilic exudate generates a serosal fibrinopurulent reaction. As the process continues, focal abscesses may form within the wall (acute suppurative appendicitis). Further compromise of appendiceal vessels leads to large areas of hemorrhagic ulceration and gangrenous necrosis that extends to the serosa creating acute gangrenous appendicitis, which can be followed by rupture and suppurative peritonitis.

Clinical Features. Typically, early acute appendicitis produces periumbilical pain that ultimately localizes to the right lower quadrant, followed by nausea, vomiting, low-grade fever, and a mildly elevated peripheral white cell count. A classic physical finding is the *McBurney sign*, deep tenderness located two thirds of the distance from the umbilicus to the right anterior superior iliac spine (McBurney point).

Regrettably, classic signs and symptoms of acute appendicitis are often absent. In some cases, a retrocecal appendix may generate right flank or pelvic pain, while a malrotated colon may give rise to appendicitis in the left upper quadrant. As with other causes of acute inflammation there is neutrophilic leukocytosis. In some cases the

peripheral leukocytosis may be minimal or, alternatively, so great that other causes are considered. The diagnosis of acute appendicitis in young children and the very old is particularly problematic, since other causes of abdominal emergencies are prevalent in these populations, and the very young and old are also more likely to have atypical clinical presentations.

Given these diagnostic challenges, it should be no surprise that even highly skilled surgeons remove normal appendices. This is preferred to delayed resection of a diseased appendix, given the significant morbidity and mortality associated with appendiceal perforation. Other complications of appendicitis include pyelophlebitis, portal venous thrombosis, liver abscess, and bacteremia.

Tumors of the Appendix

The most common tumor of the appendix is the well-differentiated neuroendocrine (carcinoid) tumor. It is usually discovered incidentally at the time of surgery or examination of a resected appendix. This neoplasm, which is almost always benign, most frequently forms a solid bulbous swelling at the distal tip of the appendix, where it can reach 2 to 3 cm in diameter. Although intramural and transmural extension may be evident, nodal metastases are very infrequent, and distant spread is exceptionally rare. Conventional adenomas or non-mucin-producing adenocarcinomas also occur in the appendix and may cause obstruction and enlargement that mimics acute appendicitis. Mucocele, a dilated appendix filled with mucin, may simply represent an obstructed appendix containing inspissated mucin or be a consequence of mucinous cystadenoma or mucinous cystadenocarcinoma. In the latter instance, invasion through the appendiceal wall can lead to intraperitoneal seeding and spread. In women the resulting peritoneal implants may be mistaken for mucinous ovarian tumors. In the most advanced cases the abdomen fills with tenacious, semisolid mucin, a condition called *pseudomyxoma peritonei* (Chapter 22). This disseminated intraperitoneal disease may be held in check for years by repeated debulking but, in most instances, follows an inexorably fatal course.

KEY CONCEPTS

- **Hemorrhoids** are collateral vessels that develop secondary to persistently elevated venous pressure within the hemorrhoidal plexus. They also occur in portal hypertension.
- **Acute appendicitis** is most common in children and adolescents. It is thought to be initiated by increased intraluminal pressure and compromised venous outflow
- The most common tumor of the appendix is the **benign carcinoid**.
- Peritoneal dissemination of mucinous tumors can cause **pseudomyxoma peritonei**.

PERITONEAL CAVITY

The peritoneal cavity houses the abdominal viscera and is lined by a single layer of mesothelial cells; these cover the visceral and parietal surfaces and are supported by a thin layer of connective tissue to form the peritoneum. Here we discuss inflammatory, infectious, and neoplastic disorders of the peritoneal cavity and retroperitoneal space. Although they are less common than inflammatory and infectious processes, tumors can carry a grave prognosis and, thus, also deserve discussion.

Inflammatory Disease

Peritonitis may result from bacterial invasion or chemical irritation and is most often due to:

- Leakage of bile or pancreatic enzymes, which produces *sterile peritonitis*
- *Perforation or rupture of the biliary system* that evokes a highly irritating peritonitis, usually complicated by bacterial superinfection
- *Acute hemorrhagic pancreatitis* (Chapter 19), which is associated with leakage of pancreatic enzymes and fat necrosis. Damage to the bowel wall may allow bacteria to spread to the peritoneal cavity.
- *Foreign material*, including that introduced surgically (e.g., talc and sutures), that induces foreign body-type granulomas and fibrous scarring
- *Endometriosis*, which causes hemorrhage into the peritoneal cavity, where it acts as an irritant
- *Ruptured dermoid cysts* that release keratins and induce an intense granulomatous reaction
- *Perforation of abdominal viscera*.

Peritoneal Infection

Bacterial peritonitis occurs when bacteria from the gastrointestinal lumen are released into the abdominal cavity, most commonly following perforation. *E. coli*, streptococci, *S. aureus*, enterococci, and *C. perfringens* are implicated most often.

Spontaneous bacterial peritonitis develops in the absence of an obvious source of contamination. It is seen most often in patients with cirrhosis and ascites and less frequently in children with nephrotic syndrome.

MORPHOLOGY

The cellular inflammatory response is composed primarily of dense collections of neutrophils and fibrinopurulent debris that coat the viscera and abdominal wall. Serous or slightly turbid fluid begins to accumulate and becomes suppurative as infection progresses. Subhepatic and subdiaphragmatic abscesses may be formed. With the exception of tuberculous peritonitis, the reaction usually remains superficial.

Sclerosing Retroperitonitis

Sclerosing retroperitonitis, also known as idiopathic retroperitoneal fibrosis or Ormond disease, is characterized by dense fibrosis that may extend to involve the mesentery. Although the cause of sclerosing retroperitonitis is unknown, many cases are now thought to fall within the spectrum of IgG4-related sclerosing disease, an immunoinflammatory disorder that can lead to fibrosis in a wide variety of tissues. Because the process frequently compresses the ureters, this entity is described in more detail in Chapters 6 and 21.

Tumors

Primary malignant tumors arising from peritoneal lining are mesotheliomas that are similar to tumors of the pleura and pericardium. Peritoneal mesotheliomas are almost always associated with significant asbestos exposure. Rarely, primary benign and malignant soft-tissue tumors may also develop within the peritoneum and retroperitoneum. The most common of these is desmoplastic small round cell tumor. This is an aggressive tumor that occurs in children and young adults and bears resemblance to Ewing sarcoma and other small round cell tumors. It is characterized by a reciprocal translocation, t(11;22)(p13;q12) that results in the formation of a fusion gene involving *EWS* and *WT1* genes.

Secondary tumors may involve the peritoneum by direct spread or metastatic seeding, resulting in peritoneal carcinomatosis. Mucinous carcinomas, particularly those of the appendix may cause pseudomyxoma peritonei.

THE LIVER AND BILE DUCTS

The normal adult liver weighs 1400 to 1600 gm. It has a dual blood supply, with the portal vein providing 60% to 70% of hepatic blood flow and the hepatic artery supplying the remaining 30% to 40%. The portal vein and the hepatic artery enter the inferior aspect of the liver through the hilum, or *porta hepatis*. Within the liver, the branches of the portal veins, hepatic arteries, and bile ducts travel in

parallel within *portal tracts*, ramifying variably through 17 to 20 orders of branches.

The most common terminology of the hepatic microarchitecture is based on the lobular model (Fig. 18-1). Accordingly the liver is divided into 1- to 2-mm in diameter *lobules* that are oriented around the terminal tributaries of the hepatic vein (*terminal hepatic veins*), with portal tracts at the lobule's periphery. These are often drawn as hexagonal structures, although in humans the shapes are far more variable; nonetheless, it is a useful oversimplification. The hepatocytes in the vicinity of the terminal hepatic vein are

*The contributions of Dr James Crawford to this chapter in the last several editions of this book are gratefully acknowledged.

Figure 18-1 Models of liver anatomy. In the lobular model, the terminal hepatic vein (CV) is at the center of a “lobule,” while the portal tracts (PV) are at the periphery. Pathologists often refer to the regions of the parenchyma as “periportal” and “centrilobular.” In the acinar model, on the basis of blood flow, three zones can be defined, zone 1 being the closest to the blood supply and zone 3 being the farthest. BD, Bile duct; HA, hepatic artery.

called “centrilobular”; those near the portal tract are “periportal.” *Division of the parenchyma into zones is a useful concept since certain types of hepatic injury tend to preferentially affect particular zones.* This results in part from the zonal gradient of oxygenation and metabolic activities.

Within the lobule, hepatocytes are organized into anastomosing sheets or “plates” extending from portal tracts to the terminal hepatic veins. Between the trabecular plates of hepatocytes are vascular *sinusoids*. Blood traverses the sinusoids and exits into the terminal hepatic veins through numerous orifices in the vein wall. Hepatocytes are thus bathed on two sides by well-mixed, portal venous and hepatic arterial blood. The sinusoids are lined by fenestrated endothelial cells. Beneath the endothelial cells lies the *space of Disse*, into which protrude abundant hepatocyte microvilli. Scattered *Kupffer cells* of the mononuclear phagocyte system are attached to the luminal face of endothelial cells, and fat-containing myofibroblastic *hepatic stellate cells* are found in the space of Disse. Between abutting hepatocytes are *bile canaliculi*, which are channels 1 to 2 μm in diameter, formed by grooves in the plasma membranes of facing hepatocytes and separated from the vascular space by tight junctions. These channels drain into the *canals of Hering* that, in turn, connect to *bile ductules* in the periportal region. The ductules empty into the *terminal bile ducts* within the portal tracts. Large numbers of lymphocytes are also present in normal liver, comprising as much as 22% of cells other than hepatocytes.

General Features of Liver Disease

The liver is vulnerable to a wide variety of metabolic, toxic, microbial, circulatory, and neoplastic insults. The major primary diseases of the liver are viral hepatitis, nonalcoholic fatty liver disease (NAFLD), alcoholic liver disease, and hepatocellular carcinoma (HCC). Hepatic damage also

occurs secondary to some of the most common diseases in humans, such as heart failure, disseminated cancer, and extrahepatic infections. The enormous functional reserve of the liver masks the clinical impact of mild liver damage, but with progression of diffuse disease or disruption of bile flow, the consequences of deranged liver function may become life-threatening.

With the exception of acute liver failure, liver disease is an insidious process in which clinical detection and symptoms of hepatic decompensation may occur weeks, months, or many years after the onset of injury. The ebb and flow of hepatic injury may be imperceptible to the patient and detectable only by abnormal laboratory tests (Table 18-1); liver injury and healing may also occur without clinical detection. Hence, individuals with hepatic abnormalities who are referred to hepatologists most frequently have chronic liver disease.

Mechanisms of Injury and Repair

Hepatocyte and Parenchymal Responses

Hepatocytes can undergo a number of degenerative, but potentially reversible changes, such as accumulation of fat (steatosis) and bilirubin (cholestasis). When injury is not reversible, hepatocytes die principally by two mechanisms: necrosis or apoptosis.

In *hepatocyte necrosis*, the cell swells due to defective osmotic regulation at the cell membrane: fluid flows into the cell, which swells and ruptures. Even before rupture, membrane blebs form, carrying off cytoplasmic contents (without organelles) into the extracellular compartment. Macrophages cluster at such sites of injury and mark the sites of hepatocyte necrosis since the dying cells essentially burst and disappear (Fig. 18-2). This form of injury is the

Table 18-1 Laboratory Evaluation of Liver Disease

Test Category	Serum Measurement

[†]Increased in liver disease.

[‡]Decreased in liver disease.

Figure 18-2 Acute hepatitis B. In this PAS-D stained slide, clusters of macrophages with eosinophilic cytoplasm indicate foci where hepatocytes have undergone necrosis. PAS-D, Periodic acid–Schiff after diastase digestion.

predominant mode of death in ischemic/hypoxic injury and a significant part of the response to oxidative stress.

Hepatocyte apoptosis is an active form of “programmed” cell death resulting in hepatocyte shrinkage, nuclear chromatin condensation (*pyknosis*), fragmentation (*karyorrhexis*), and cellular fragmentation into acidophilic *apoptotic bodies*. These changes are a result of caspase cascades described in detail in [Chapter 2](#). Apoptotic hepatocytes were first clearly described in yellow fever by William Thomas Councilman and therefore have often been referred to as *Councilman bodies*; while apoptosis occurs in many forms of liver disease, by convention this eponym is restricted to that disease. In the more frequent settings in which apoptotic hepatocytes are seen, (e.g., acute and chronic hepatitis), the term *acidophil bodies* is used, due to their deeply eosinophilic staining characteristics ([Fig. 18-3](#)).

When there is widespread parenchymal loss there is often evidence of *confluent necrosis*, a severe, zonal loss of hepatocytes. This may be seen in acute toxic or ischemic injuries or in severe viral or autoimmune hepatitis. Confluent necrosis may begin as a zone of hepatocyte dropout around the central vein. The resulting space is filled by cellular debris, macrophages, and remnants of the reticulin meshwork. In *bridging necrosis* this zone may link central veins to portal tracts or bridge adjacent portal tracts (often with an inapparent central vein within the zone of injury). Even in diseases such as viral hepatitis in which hepatocytes are the principal targets of attack, vascular insults—via inflammation or thrombosis—lead to parenchymal extinction due to large areas of contiguous hepatocyte death ([Fig. 18-4](#)). The process depicted in [Fig. 18-4](#) occurs in many types of liver diseases in which there is extensive hepatocyte loss and collapse of the supporting framework. The resultant cirrhosis is a common form of liver disease. In some cases there is scar regression as depicted in the figure and described in the next section.

Regeneration of lost hepatocytes occurs primarily by mitotic replication of hepatocytes adjacent to those that have died, even when there is significant confluent necrosis. *Hepatocytes are almost stem cell-like in their ability to continue to replicate even in the setting of years of chronic injury and thus stem cell replenishment is usually not a significant part of parenchymal repair.* In the most severe forms of acute liver failure, there is activation of the primary intrahepatic stem cell niche, namely the canal of Hering, but the contribution of stem cells to the replenishment of hepatocytes in such a setting remains unclear. Eventually, however, in many individuals with chronic disease the hepatocytes do reach replicative senescence and then there is clear evidence of stem cell activation seen in the form of *ductular reactions*. These duct like structures, sometimes without any lumens develop from stem cells and contribute significantly to parenchymal restoration. Interestingly, in biliary diseases, the “ductular” progeny of stem cells can give rise to cholangiocytes.

Scar Formation and Regression

The principal cell type involved in scar deposition is the hepatic stellate cell. In its quiescent form, it is a lipid (vitamin A) storing cell. However, in several forms of acute and chronic injury, the stellate cells can become activated and are converted into highly fibrogenic myofibroblasts. Proliferation of hepatic stellate cells and their activation into myofibroblasts is initiated by a series of changes that include an increase in the expression of platelet-derived growth factor receptor β (PDGFR- β) in the stellate cells. At the same time, Kupffer cells and lymphocytes release cytokines and chemokines that modulate the expression of genes in stellate cells that are involved in fibrogenesis. These, include transforming growth factor β (TGF- β) and its receptors, metalloproteinase 2 (MMP-2),

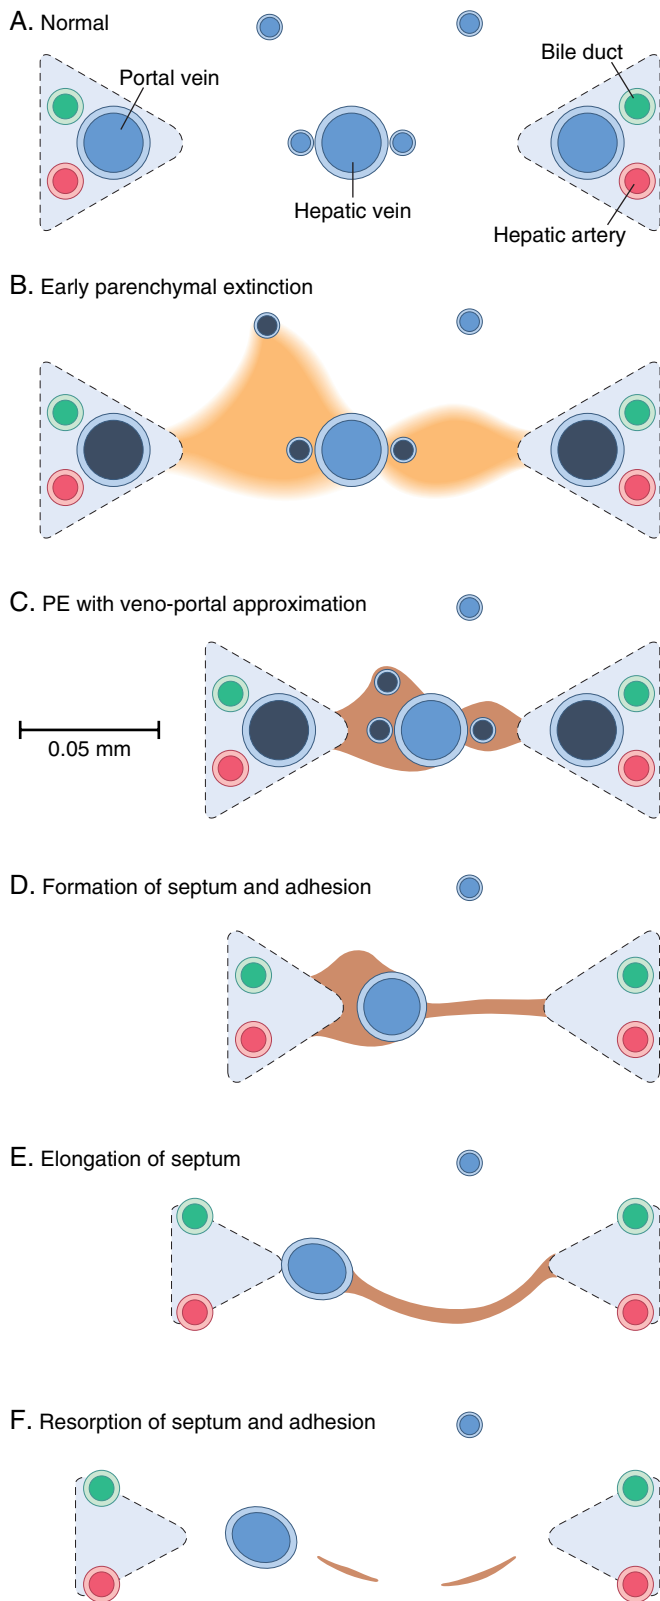

Figure 18-3 Foci of lobular hepatitis in chronic hepatitis C show apoptotic hepatocytes (“acidophil bodies”; arrows) and a focus of mononuclear infiltration surrounding a more darkly stained, injured hepatocyte (double arrows).

and tissue inhibitors of metalloproteinases 1 and 2 (TIMP-1 and -2). As they are converted into myofibroblasts, the cells release chemotactic and vasoactive factors, cytokines, and growth factors. Myofibroblasts are contractile cells; their contraction is stimulated by endothelin-1 (ET-1). The

Figure 18-4 Diagrammatic representation of the natural history of small regions of hepatocellular extinction and the related scarring. **A**, Normal liver with patent portal and hepatic veins (blue). **B**, Extinction occurs when contiguous hepatocytes die, usually after inflammatory injury to their blood supply (ischemic hepatocytes are shown in orange; obstructed veins are black). **C**, Empty parenchyma collapses and begins to scar (brown) and adjacent portal tracts and hepatic veins become approximated. **D**, Scars in regions of extinction contract and condense, becoming fibrous septa. The larger region of extinction (on the left) has formed a short adhesion between the adjacent portal tract and hepatic vein. Obliterated small veins have disappeared. **E**, Septa elongate by the traction caused by hyperplasia of adjacent hepatocytes. Portal tract collagen (light gray) is less than normal as resorption begins. **F**, Septa are resorbed. The resulting tissue has either venoportals fibrous adhesions or hepatic veins that are closely approximated to portal tracts. Portal tracts are remnants, often with no portal vein. (From Wanless IR, et al: Regression of Human Cirrhosis: Morphologic Features and the Genesis of Incomplete Septal Cirrhosis, Arch Pathol Lab Med Vol. 124, page 1606, 2000.)

stimuli for stellate cell activation may originate from several sources (Fig. 18-5): (1) chronic inflammation, with production of inflammatory cytokines such as tumor necrosis factor (TNF), lymphotoxin, and interleukin-1 β (IL-1 β), and lipid peroxidation products; (2) cytokine and chemokine production by Kupffer cells, endothelial cells, hepatocytes, and bile duct epithelial cells; (3) in response to disruption of the extracellular matrix (ECM); and (4) direct stimulation of stellate cells by toxins. If injury persists, scar deposition begins, often in the space of Disse. This is particularly important in alcoholic and nonalcoholic fatty liver diseases, but is also a generalized mechanism of scar formation in other forms of chronic liver injury.

Zones of parenchymal loss transform into dense *fibrous septa* through a combination of the collapse of the underlying reticulin where large swaths of hepatocytes have irrevocably disappeared and hepatic stellate cells have been activated. Eventually, these fibrous septa encircle surviving, regenerating hepatocytes in the late stages of chronic liver diseases that give rise to diffuse scarring described as cirrhosis.

Other cells probably contribute significantly to scar deposition in different settings, including portal fibroblasts. Ductular reactions also play a role, both through activation and recruitment of all these fibrogenic cells, but also, perhaps, through *epithelial-mesenchymal transition*. The relative roles played by these other cells and processes are less well understood.

If the chronic injury leading to scar formation is interrupted (e.g. clearance of hepatitis virus infection, cessation of alcohol use), then stellate cell activation ceases, scars condense, becoming more dense and thin, and then, due to metalloproteinases produced by hepatocytes, begin to break apart. In this way, scar formation can be reversed. It should be kept in mind that in any chronic liver disease there are probably areas of both fibrotic progression and regression, but the balance in active disease favors the former and with remission of disease the latter is favored.

Inflammation and Immunity

Innate and adaptive immune systems are, not surprisingly, involved in all manner of liver injury and repair. Antigens in the liver are taken up by antigen presenting cells,

Figure 18-5 Stellate cell activation and liver fibrosis. Kupffer cell activation leads to secretion of multiple cytokines. Platelet-derived growth factor (PDGF) and tumor necrosis factor (TNF) activate stellate cells, and contraction of the activated stellate cells is stimulated by endothelin-1 (ET-1). Fibrosis is stimulated by transforming growth factor β (TGF- β). Chemotaxis of activated stellate cells to areas of injury is promoted by PDGF and monocyte chemoattractant protein-1 (MCP-1). See text for details.

including, Kupffer cells and blood-derived dendritic cells, and presented to lymphocytes. Toll-like receptors detect host molecules, and also those derived from foreign invaders such as bacteria and viruses. These processes lead to elaboration of proinflammatory cytokines, which have diverse effects on the liver, including recruitment of inflammatory cells, hepatocyte injury, vascular disturbances, promotion of scarring, and perhaps even malignant transformation. Adaptive immunity plays an even more critical role in viral hepatitis. Antigen-specific and CD8+ T cells are involved in eradication of hepatitis B and C, the primary causes of chronic viral hepatitis, largely through elimination of infected hepatocytes. Lymphocytes, however, not only play a destructive role, but also help induce local hepatocyte replication through secretion of cytokines.

Liver Failure

The most severe clinical consequence of liver disease is liver failure. It may be the result of sudden and massive hepatic destruction, acute liver failure, which occurs in about 2000 people per year in the United States, or, more often, chronic liver failure, which follows upon years or decades of insidious, progressive liver injury. In some cases, individuals with chronic liver disease develop *acute-on-chronic liver failure*, in which an unrelated acute injury supervenes on a well-compensated late-stage chronic disease or the chronic disease itself has a flare of activity that leads directly to liver failure. Whatever the sequence, 80% to 90% of hepatic functional capacity must be lost before hepatic failure ensues. When the liver can no longer maintain homeostasis, transplantation offers the best hope for survival; the mortality rate in persons with hepatic failure without liver transplantation is about 80%.

Acute Liver Failure

Acute liver failure is defined as an acute liver illness associated with encephalopathy and coagulopathy that occurs within 26 weeks of the initial liver injury in the absence of pre-existing liver disease. Within this 26 week window, it is useful to know the interval between the onset of symptoms and liver failure, since this may provide helpful clues to the etiology as we shall describe below. Here we should clarify some terminology. Acute liver failure has been referred to as “fulminant liver failure” until recently. The term “acute liver failure” is preferred but since the older term remains entrenched in the literature, these terms are often used interchangeably. Acute liver failure is caused by *massive hepatic necrosis*, most often induced by drugs or toxins. Accidental or deliberate ingestion of acetaminophen (Chapter 9) accounts for almost 50% of cases in the United States, while autoimmune hepatitis, other drugs/toxins, and acute hepatitis A and B infections account for rest of cases. In Asia, acute hepatitis B and E predominate. With acetoaminophen toxicity, the liver failure occurs within a week of the onset of symptoms, whereas failure due to hepatitis viruses takes longer to develop. The mechanism of hepatocellular necrosis may be direct toxic damage (as with acetaminophen), but more often is a variable combination of toxicity and immune-mediated hepatocyte destruction (e.g., hepatitis virus infection).

MORPHOLOGY

Acute liver failure usually displays **massive hepatic necrosis**, with broad regions of parenchymal loss surrounding islands of regenerating hepatocytes (Fig. 18-6). These livers are small and shrunken. The prominence of scar and of ductular reactions in

Figure 18-6 **A**, Massive necrosis, cut section of liver. The liver is small (700 g), bile-stained, soft, and congested. **B**, Hepatocellular necrosis caused by acetaminophen overdose. Confluent necrosis is seen in the perivenular region (zone 3) (large arrow). Residual normal tissue is indicated by the asterisk. (Courtesy Dr. Matthew Yeh, University of Washington, Seattle, Wash.)

these livers depends on the nature and duration of the insult. Toxic injuries, such as acetaminophen overdoses, usually take place within hours to days, too brief a period to allow time for scar formation or regeneration. Acute viral infections may cause failure over weeks to a few months, so that while hepatocyte injury continues to outpace repair, regeneration is often demonstrable. Also, this time scale allows for early scarring in areas of parenchymal loss.

Rarely, there may be diffuse poisoning of liver cells without obvious cell death and parenchymal collapse, such as in **diffuse microvesicular steatosis** related to fatty liver of pregnancy or idiosyncratic reactions to toxins (e.g., valproate, tetracycline). In these settings, usually related to primary mitochondrial dysfunction, hepatocytes are unable to perform their usual metabolic functions. In states of immunodeficiency, such as untreated infection with human immunodeficiency virus (HIV) or posttransplant immunosuppression, non-hepatotropic viruses, particularly cytomegalovirus, herpes simplex viruses, and adenovirus, can cause fulminant liver failure with histologic features specific to each of those viruses. With better treatments for HIV infection, these are declining as a cause of acute liver failure.

Clinical Course. Acute liver failure manifests first with nausea, vomiting, and jaundice, followed by life-threatening encephalopathy, and coagulation defects. Typically, serum liver transaminases are markedly elevated. The liver is initially enlarged due to hepatocyte swelling, inflammatory infiltrates, and edema; as parenchyma is destroyed, however, the liver shrinks dramatically. Decline of serum transaminases as the liver shrinks is often not, therefore, a sign of improvement, but is rather an indication that there are few viable hepatocytes left; this suspicion is confirmed if there is worsening jaundice, coagulopathy, and encephalopathy. With unabated progression, multiorgan system failure occurs and, if transplantation is not possible, death ensues. Other manifestations of acute liver failure are as follows:

- Alterations of bile formation and flow become clinically evident as yellow discoloration of the skin and sclera (*jaundice* and *icterus*, respectively) due to retention of bilirubin, and as *cholestasis* due to systemic retention of not only bilirubin but also other solutes eliminated in bile. Bilirubin metabolism and the pathophysiology of jaundice are discussed in detail later under cholestatic diseases. In the setting of acute liver failure, there is classic yellowing of skin, sclerae, and mucous membranes; cholestasis increases the risk of life-threatening bacterial infection.
- *Hepatic encephalopathy* is a spectrum of disturbances in consciousness, ranging from subtle behavioral abnormalities, to marked confusion and stupor, to deep coma and death. Encephalopathy may progress over days, weeks, or months following acute injury. Associated fluctuating, neurologic signs include rigidity and hyperreflexia. *Asterixis*, a particularly characteristic sign, is manifested as nonrhythmic, rapid extension-flexion movements of the head and extremities, best seen when the arms are held in extension with dorsiflexed wrists. Hepatic encephalopathy is regarded as a disorder of neurotransmission in the central nervous system and neuromuscular system. Elevated ammonia levels in blood and the central nervous system correlate with impaired neuronal function and cerebral edema.
- The liver is responsible for production of vitamin K-dependent and -independent clotting factors (Chapter 4). Thus, with massively impaired hepatic synthetic function, *coagulopathy* develops. Easy bruisability is an early sign of this process, which can lead to life-threatening or fatal intracranial bleeding. The liver is also responsible for helping to remove activated coagulation factors from the circulation, and loss of this function in some instances can lead to disseminated intravascular coagulation (Chapter 14), further exacerbating the bleeding tendency.
- *Portal hypertension* arises when there is diminished flow through the portal venous system, which may occur because of obstruction at the prehepatic, intrahepatic, or posthepatic level. While it can occur in acute liver failure, portal hypertension is more commonly seen with chronic liver failure and is described later. In acute liver failure, if portal hypertension develops within days to weeks, obstruction is predominantly intrahepatic and the major clinical consequences are *ascites* and *hepatic encephalopathy*. In chronic liver disease, portal

hypertension develops over months to years, and its effects are more complex and widespread (see later).

- *Hepatorenal syndrome* is a form of renal failure occurring in individuals with liver failure in whom there are no intrinsic morphologic or functional causes for kidney dysfunction. Sodium retention, impaired free-water excretion, and decreased renal perfusion and glomerular filtration rate are the main renal functional abnormalities. There is decreased renal perfusion pressure due to systemic vasodilation, activation of the renal sympathetic nervous system with vasoconstriction of the afferent renal arterioles, and increased activation of the renin/angiotensin axis, causing vasoconstriction that further decreases glomerular filtration. The syndrome's onset begins with a drop in urine output and rising blood urea nitrogen and creatinine levels.

Chronic Liver Failure and Cirrhosis

The leading causes of chronic liver failure worldwide include chronic hepatitis B, chronic hepatitis C, non-alcoholic fatty liver disease, and alcoholic liver disease. In the United States, chronic liver disease is the twelfth most common cause of mortality, accounting for most liver-related deaths. Liver failure in chronic liver disease is most often associated with cirrhosis, a condition marked by the diffuse transformation of the entire liver into regenerative parenchymal nodules surrounded by fibrous bands and variable degrees of vascular (often portosystemic) shunting.

However, not all cirrhosis leads inexorably to chronic liver failure and not all end-stage chronic liver disease is cirrhotic. For example, chronic diseases such as primary biliary cirrhosis, primary sclerosing cholangitis, nodular regenerative hyperplasia, chronic schistosomiasis, and fibropolycystic liver disease are often not accompanied by fully established cirrhosis, even at end stage. On the other hand, patients with well-treated autoimmune hepatitis or those with suppressed hepatitis B or cured hepatitis C often do not progress to end stage, even though they are cirrhotic. The Child-Pugh classification of cirrhosis distinguishes between class A (well compensated), B (partially decompensated), and C (decompensated), which correlate with different morphologic features histologically. The utility of such a system is that it helps monitor the decline of patients on the path to chronic liver failure.

Even in diseases that are likely to give rise to cirrhosis, such as untreated viral hepatitis, alcoholic liver disease, non-alcoholic fatty liver disease, metabolic diseases—the morphology and pathophysiology of cirrhosis may be different. Thus, while the term cirrhosis implies the presence of severe chronic disease, it is not a specific diagnosis and it lacks clear prognostic implications. The term *cryptogenic cirrhosis* is sometimes used to describe cirrhosis when there is no clear cause.

MORPHOLOGY

As described, **cirrhosis occurs diffusely throughout the liver, which is comprised of regenerating parenchymal nodules surrounded by dense bands of scar and variable degrees of vascular shunting** (Fig. 18-7). The size of the nodules, the pattern of scarring (linking portal tracts to each

Figure 18-7 Cirrhosis resulting from chronic viral hepatitis. Note the depressed areas of dense scar separating bulging regenerative nodules over the liver surface.

other vs. linking portal tracts to central veins), the degree of parenchymal collapse in which no viable liver tissue is present, the range of macroscopic vascular thrombosis (particularly of the portal vein) all vary between diseases and even, in some cases, between individuals with the same disease. Again, to re-emphasize, there is no single cirrhosis, but many cirrhoses. The important details distinguishing cirrhosis of different causes as they pertain to each disease are described in subsequent disease specific sections.

It is becoming increasingly clear that changes identifiable on biopsy in different cirrhotic patients correlate with the prognostically useful Child-Pugh classification mentioned earlier and with portal venous wedge pressures—a new, important, albeit not yet universal method for assessing the presence and degree of portal hypertension. Biopsy specimens demonstrating narrow, densely compacted fibrous septa separated by large islands of intact hepatic parenchyma are likely to have less portal hypertension. Those with broad bands of dense scar, often with dilated lymphatic spaces, with less intervening parenchyma are likely to be progressing toward portal hypertension and, therefore, to end-stage disease.

Clinical implications of these histologic findings and the clinical implications of increased hepatic venous wedge pressures are in the process of being defined. They are expected to play an increasingly important roles in coming years, particularly in patients with chronic hepatitis B and C infections, for whom distinguishing the ebb and flow of cirrhotic features may be essential for determining prognosis as anti-viral treatments improve.

As mentioned earlier stem cell activation is seen in the form of ductular reactions. **In chronic liver disease ductular reactions increase with advancing stage of disease and are usually most prominent in cirrhosis.** There are two correlates of ductular reactions:

- The role of liver stem cells in parenchymal regeneration increases as the preexisting hepatocytes undergo replicative senescence after years to decades of high turnover.
- Ductular reactions may incite some of the scarring in chronic liver disease and thus may have a negative effect on progressive liver disease.

Figure 18-8 Alcoholic cirrhosis in an active drinker (A) and following long-term abstinence (B). **A**, Thick bands of collagen separate rounded cirrhotic nodules. **B**, After a year of abstinence, most scars are gone. (Masson trichrome stain) (Courtesy Drs. Hongfa Zhu and Isabel Fiel, Mount Sinai School of Medicine, New York.)

Although uncommon, regression of fibrosis, albeit rarely, in fully established cirrhosis, does occur; this is another reason why cirrhosis should not be automatically equated with end stage disease. In the past when there were no reliable ways to cure any chronic liver disease, there were no opportunities to see whether cirrhosis could regress. With increasing numbers of effective treatments for cirrhosis-causing conditions, however, we now understand that regression of scars can take place (Figs. 18-4 and 18-8). Scars can become thinner, more densely compacted, and eventually fragment. As fibrous septa break apart, adjacent nodules of regenerating parenchyma coalesce into larger islands. All cirrhotic livers show elements of both progression and regression, the balance determined by the severity and persistence of the underlying disease.

Clinical Features. About 40% of individuals with cirrhosis are asymptomatic until the most advanced stages of the disease. When symptomatic, they present with non-specific manifestations: anorexia, weight loss, weakness, and, in advanced disease, symptoms and signs of liver failure discussed earlier. *The ultimate causes of death in chronic liver failure, whether cirrhotic or not, include those seen in acute liver failure, and additional grim outcomes, such as development of hepatocellular carcinoma in the context of cirrhosis.* Hepatic encephalopathy, bleeding from esophageal varices and bacterial infections (resulting from damage to mucosal barrier in the gut and Kupffer cell dysfunction) are often the the terminal events.

The course and severity of clinical manifestations of cirrhosis vary from patient to patient. In a small number of cases, as noted earlier, cessation of liver injury may give the necessary time for resorption of the fibrous tissue and “regression” of the cirrhosis. Even in such instances, the portal hypertension (from irreversible vascular shunts) and risk of hepatocellular carcinoma usually remain.

Jaundice, encephalopathy, and coagulopathy are very much the same as in acute liver failure. However, there are some significant additional features. Jaundice, when chronic, can lead to *pruritus*, that is, itching, the intensity

of which can be profound. Some patients may even scratch their skin raw and risk repeated bouts of potentially life-threatening infection. Pruritus can be so severe that it can be relieved only by liver transplantation.

Impaired estrogen metabolism and consequent *hyperestrogenemia* in male patients with chronic liver failure can give rise to *palmar erythema* (a reflection of local vasodilatation) and *spider angiomas* of the skin. Each angioma is a central, pulsating, dilated arteriole from which small vessels radiate. In men, hyperestrogenemia also leads to *hypogonadism* and *gynecomastia*. Hypogonadism can also occur in women from disruption of hypothalamic-pituitary axis function, either through nutritional deficiencies associated with the chronic liver disease or primary hormonal alterations.

We next turn to a discussion of portal hypertension which as alluded to earlier can develop in acute liver failure but is much more common in chronic liver failure with cirrhosis.

Portal Hypertension

Increased resistance to portal blood flow may develop in a variety of circumstances, which can be divided into *prehepatic*, *intrahepatic*, and *posthepatic* (Table 18-2). The major *prehepatic conditions* are obstructive thrombosis, narrowing of the portal vein before it ramifies within the liver or massive splenomegaly with increased splenic vein blood flow. The main post-hepatic causes are severe right-sided heart failure, constrictive pericarditis, and hepatic vein outflow obstruction. **The dominant intrahepatic cause is cirrhosis, accounting for most cases of portal hypertension.** Far less frequent intrahepatic causes are schistosomiasis, massive fatty change, diffuse fibrosing granulomatous disease such as sarcoidosis, and diseases affecting the portal microcirculation such as nodular regenerative hyperplasia (discussed later). The pathophysiology of portal hypertension is complex and involves resistance to portal flow at the level of sinusoids and an increase in portal flow caused by hyperdynamic circulation.

The increased resistance to portal flow at the level of the sinusoids is caused by contraction of vascular smooth

Table 18-2 Location and Causes of Portal Hypertension

Prehepatic causes
Obstructive thrombosis of portal vein
Structural abnormalities such as narrowing of the portal vein before it ramifies in the liver
Intrahepatic causes
Cirrhosis from any cause
Nodular regenerative hyperplasia
Primary biliary cirrhosis (even in the absence of cirrhosis)
Schistosomiasis
Massive fatty change
Diffuse, fibrosing granulomatous disease (e.g., sarcoid)
Infiltrative malignancy, primary or metastatic
Focal malignancy with invasion into portal vein (particularly hepatocellular carcinoma)
Amyloidosis
Posthepatic causes
Severe right-sided heart failure
Constrictive pericarditis
Hepatic vein outflow obstruction

muscle cells and myofibroblasts, and disruption of blood flow by scarring and the formation of parenchymal nodules. Alterations in sinusoidal endothelial cells that contribute to the intrahepatic vasoconstriction associated with portal hypertension include a decrease in nitric oxide production, and increased release of endothelin-1 (ET-1), angiotensinogen, and eicosanoids. Sinusoidal remodeling and anastomosis between the arterial and portal system in the fibrous septa contribute to portal hypertension by imposing arterial pressures on the low pressure portal venous system. Sinusoidal remodeling and intrahepatic shunts also interfere with the metabolic exchange between sinusoidal blood and hepatocytes.

Another major factor in the development of portal hypertension is an *increase in portal venous blood flow resulting from a hyperdynamic circulation*. This is caused by arterial vasodilation, primarily in the splanchnic circulation. The increased splanchnic arterial blood flow in turn leads to increased venous efflux into the portal venous system. While various mediators such as prostacyclin and TNF have been implicated in the causation of the splanchnic arterial vasodilation, NO has emerged as the most significant one.

The four major clinical consequences of portal hypertension are (1) ascites, (2) the formation of portosystemic venous shunts, (3) congestive splenomegaly, and (4) hepatic encephalopathy (discussed earlier). These are illustrated in Figure 18-9.

Ascites. The accumulation of excess fluid in the peritoneal cavity is called ascites. In 85% of cases, ascites is caused by cirrhosis. Ascites usually becomes clinically detectable when at least 500 mL have accumulated. The fluid is generally serous, having less than 3 gm/dL of protein (largely albumin), and a serum to ascites albumin gradient of ≥ 1.1 gm/dL. The fluid may contain a scant number of mesothelial cells and mononuclear leukocytes. Influx of neutrophils suggests infection, whereas the presence of blood cells points to possible disseminated intra-abdominal cancer. With long-standing ascites, seepage of peritoneal fluid through trans-diaphragmatic lymphatics may

produce hydro-thorax, more often on the right side. The pathogenesis of ascites is complex, involving the following mechanisms:

Sinusoidal hypertension, altering Starling's forces and driving fluid into the space of Disse, from where it is removed by hepatic lymphatics; this movement of fluid is also promoted by *hypoalbuminemia*.

Percolation of hepatic lymph into the peritoneal cavity: Normal thoracic duct lymph flow approximates 800 to 1000 mL/day. With cirrhosis, hepatic lymphatic flow may approach 20 L/day, exceeding thoracic duct capacity. Hepatic lymph is rich in proteins and low in triglycerides, which explains the presence of protein in the ascitic fluid.

Splanchnic vasodilation and hyperdynamic circulation. These conditions were described earlier, in relationship to the pathogenesis of portal hypertension. Arterial vasodilation in the splanchnic circulation tends to reduce arterial blood pressure. With worsening of the vasodilation, the heart rate and cardiac output are unable to maintain the blood pressure. This triggers the activation of

Figure 18-9 Major clinical consequences of portal hypertension in the setting of cirrhosis, shown for the male. In women, oligomenorrhea, amenorrhea, and sterility as a result of hypogonadism are frequent. Clinically significant findings are bold faced.

vasoconstrictors, including the renin-angiotensin system, and also increases the secretion of antidiuretic hormone. The combination of portal hypertension, vasodilation, and sodium and water retention increases the perfusion pressure of interstitial capillaries, causing extravasation of fluid into the abdominal cavity.

Portosystemic Shunts. With the rise in portal system pressure, the flow is reversed from portal to systemic circulation by dilation of collateral vessels and development of new vessels. Venous bypasses develop wherever the systemic and portal circulation share common capillary beds (Fig. 18-9). Principal sites are veins around and within the rectum (manifest as hemorrhoids), the esophagogastric junction (producing varices), the retroperitoneum, and the falciform ligament of the liver (involving periumbilical and abdominal wall collaterals). Although hemorrhoidal bleeding may occur, it is rarely massive or life-threatening. Much more important are the esophagogastric varices that appear in about 40% of individuals with advanced cirrhosis of the liver and cause massive hematemesis and death in about half of them. Each episode of bleeding is associated with a 30% mortality. Abdominal wall collaterals appear as dilated subcutaneous veins extending from the umbilicus toward the rib margins (*caput medusae*) and constitute an important clinical hallmark of portal hypertension.

Splenomegaly. Long-standing congestion may cause congestive splenomegaly. The degree of splenic enlargement varies widely and may reach as much as 1000 gm, but it is not necessarily correlated with other features of portal hypertension. The massive splenomegaly may secondarily induce hematologic abnormalities attributable to hypersplenism, such as thrombocytopenia or even pancytopenia.

We conclude this discussion with two additional syndromes that occur in chronic liver failure:

- **Hepatopulmonary syndrome** is seen in up to 30% patients with cirrhosis of the liver and portal hypertension. These patients develop intrapulmonary vascular dilations involving capillary and pre-capillary vessels up to 100 μ M in size. The blood flows rapidly through such dilated vessels, giving inadequate time for oxygen diffusion and leading to ventilation-perfusion mismatch and right-to-left shunting, manifesting as hypoxia. Hypoxia and resultant dyspnea occur preferentially in an upright position rather than in the recumbent position, as gravity exacerbates the ventilation-perfusion mismatch. Patients with this syndrome have a poorer prognosis than patients without hepatopulmonary syndrome. The pathogenesis of hepatopulmonary syndrome is unclear, although it has been postulated that the diseased liver may not clear vasoconstrictors such as endothelin-1 or may produce some vasodilators such as NO.
- **Portopulmonary hypertension** refers to pulmonary arterial hypertension arising in liver disease and portal hypertension. Poorly understood, it seems to depend on concomitant portal hypertension and excessive pulmonary vasoconstriction and vascular remodeling. The most common clinical manifestations are dyspnea on exertion and clubbing of the fingers.

Acute-on-Chronic Liver Failure

Some individuals with stable but well-compensated, advanced chronic liver disease, suddenly develop signs of acute liver failure. In such patients there is often established cirrhosis with extensive vascular shunting. Thus, large volumes of functioning liver parenchyma have a borderline vascular supply, leaving them vulnerable to superimposed, potentially lethal insults. The short-term mortality of patients with this form of liver failure is around 50%.

Patients with chronic hepatitis B infection who become superinfected with hepatitis D may undergo sudden decompensation, as can patients with medically suppressed hepatitis B infection in whom viral mutants arise that are resistant to therapy. In either case there is an acute flare of disease. Ascending cholangitis in a patient with primary sclerosing cholangitis or fibropolycystic liver disease (described later) could have the same effect, rapidly propelling a well-compensated yet chronically sick individual into someone facing death or transplant.

Other causes may be systemic rather than primarily intrahepatic. For example, sepsis and its attendant hypotension may further undermine insufficiently vascularized parenchyma leading to superimposed, sometimes severe, acute injury. Likewise, acute cardiac failure or a superimposed drug or toxic injury might tip a well compensated cirrhotic patient to failure. Finally, there is the possibility of malignancy, either an unrelated extrahepatic malignancy metastatic to the chronically diseased liver or secondary to the liver disease itself, particularly hepatocellular carcinoma or cholangiocarcinoma.

KEY CONCEPTS

Liver Failure

- Liver failure may follow acute injury or chronic injury, but may also occur as an acute insult superimposed on an otherwise well-compensated chronic liver disease.
- Mnemonic for causes of acute liver failure:
 - A: Acetaminophen, hepatitis A, autoimmune hepatitis
 - B: Hepatitis B
 - C: Hepatitis C, cryptogenic
 - D: Drugs/toxins, hepatitis D
 - E: Hepatitis E, esoteric causes (Wilson disease, Budd-Chiari)
 - F: Fatty change of the microvesicular type (fatty liver of pregnancy, valproate, tetracycline, Reye syndrome)
- Serious and sometimes fatal sequelae of liver failure include coagulopathy, encephalopathy, portal hypertension, bleeding esophageal varices, hepatorenal syndrome, and portopulmonary hypertension.

Infectious Disorders

Viral Hepatitis

The terminology for acute and chronic viral hepatitis can be confusing, because the same word, *hepatitis*, can be used for several things; careful attention to context can clarify

its meaning in any situation. First, “hepatitis” is the name of each of the *hepatotropic viruses* (hepatitis A, B, C, D, and E) that have a specific affinity for the liver. Second, “hepatitis” stands for the histologic patterns of hepatic injury, both acute and chronic (depending on the specific virus), that are seen in the livers infected by hepatotropic viruses (and in autoimmune and drug or toxin induced hepatitis, as well). Third, to a more minor degree, it is any form of hepatocellular injury due to infection by other, usually systemic viruses, such as (1) mild Epstein-Barr virus hepatitis sometimes seen in infectious mononucleosis; (2) cytomegalovirus, herpes virus, and adenovirus infections, particularly in the newborn or immunosuppressed patient; and (3) yellow fever (yellow fever virus), a major and serious cause of hepatitis in tropical countries. We first present the main features of each hepatotropic virus, followed by a discussion of the clinicopathologic characteristics of acute and chronic viral hepatitis.

Hepatitis A Virus

Hepatitis A virus (HAV) is a usually benign, self-limited disease with an incubation period of 2 to 6 weeks. HAV does not cause chronic hepatitis or a carrier state and only uncommonly causes acute hepatic failure, so the fatality rate associated with HAV is only about 0.1-0.3%. HAV occurs throughout the world and is endemic in countries with poor hygiene and sanitation. Many individuals in these countries have detectable anti-HAV antibodies by the time they are 10 years old. Clinical disease tends to be mild or asymptomatic and is rare after childhood.

In developed countries, the prevalence of seropositivity (indicative of previous exposure) increases gradually with age, reaching 50% by age 50 years in the United States. In this population, acute HAV tends to be a sporadic febrile illness. Affected individuals have nonspecific symptoms such as fatigue and loss of appetite, and often develop jaundice. Overall, HAV accounts for about 25% of clinically evident acute hepatitis worldwide and an estimated 2000 new cases per year in the United States.

Discovered in 1973, HAV is a small, nonenveloped, positive-strand RNA picornavirus that occupies its own genus, *Hepatovirus*. Ultrastructurally, HAV is an icosahedral capsid 27 nm in diameter. The receptor for HAV is HAVcr-1, a 451-amino acid class I integral-membrane mucin-like glycoprotein. HAV is spread by ingestion of contaminated water and foods and is shed in the stool for 2 to 3 weeks before and 1 week after the onset of jaundice. Thus, close personal contact with an infected individual or fecal-oral contamination during this period accounts for most cases and explains the outbreaks in institutional settings such as schools and nurseries, and the water-borne epidemics in places where people live in overcrowded, unsanitary conditions. HAV vaccine, available since 1992, is effective in preventing infection. Immunization of toddlers in Israel has eliminated outbreaks in day care centers.

HAV can also be detected in serum and saliva. *Because HAV viremia is transient, blood-borne transmission of HAV occurs only rarely; therefore, donated blood is not specifically screened for this virus.* In developed countries, sporadic infections may be contracted by the consumption of raw or steamed shellfish (oysters, mussels, clams), which concentrate the virus from seawater contaminated with human sewage. Infected workers in the food industry may also be

Figure 18-10 Temporal changes in serologic markers in acute hepatitis A infection. HAV, Hepatitis A virus.

the source of outbreaks. HAV itself does not seem to be cytopathic. Cellular immunity, particularly CD8+ T cells, plays a key role in hepatocellular injury during HAV infection.

Specific IgM antibody against HAV appears with the onset of symptoms, constituting a reliable marker of acute infection (Fig. 18-10). Fecal shedding of the virus ends as the IgM titer rises. The IgM response usually begins to decline in a few months and is followed by the appearance of IgG anti-HAV. The latter persists for years, perhaps conferring lifelong immunity against reinfection by all strains of HAV. Since there are no routinely available tests for IgG anti-HAV, the presence of IgG anti-HAV is inferred from the difference between total and IgM anti-HAV.

Hepatitis B Virus

Hepatitis B virus (HBV) can produce (1) acute hepatitis followed by recovery and clearance of the virus, (2) non-progressive chronic hepatitis, (3) progressive chronic disease ending in cirrhosis, (4) acute hepatic failure with massive liver necrosis, and (5) an asymptomatic, “healthy” carrier state. HBV-induced chronic liver disease is also an important precursor for the development of hepatocellular carcinoma even in the absence of cirrhosis. The approximate frequencies of clinical outcomes of HBV infection are depicted in Figure 18-11.

Liver disease due to HBV is an enormous global health problem. One third of the world population (2 billion people) have been infected with HBV and 400 million people have chronic infection. Seventy-five percent of all chronic carriers live in Asia and the Western Pacific rim. The global prevalence of chronic hepatitis B infection varies widely, from high (>8%) in Africa, Asia, and the Western Pacific to intermediate (2% to 7%) in southern and eastern Europe, to low (<2%) in Western Europe, North America,

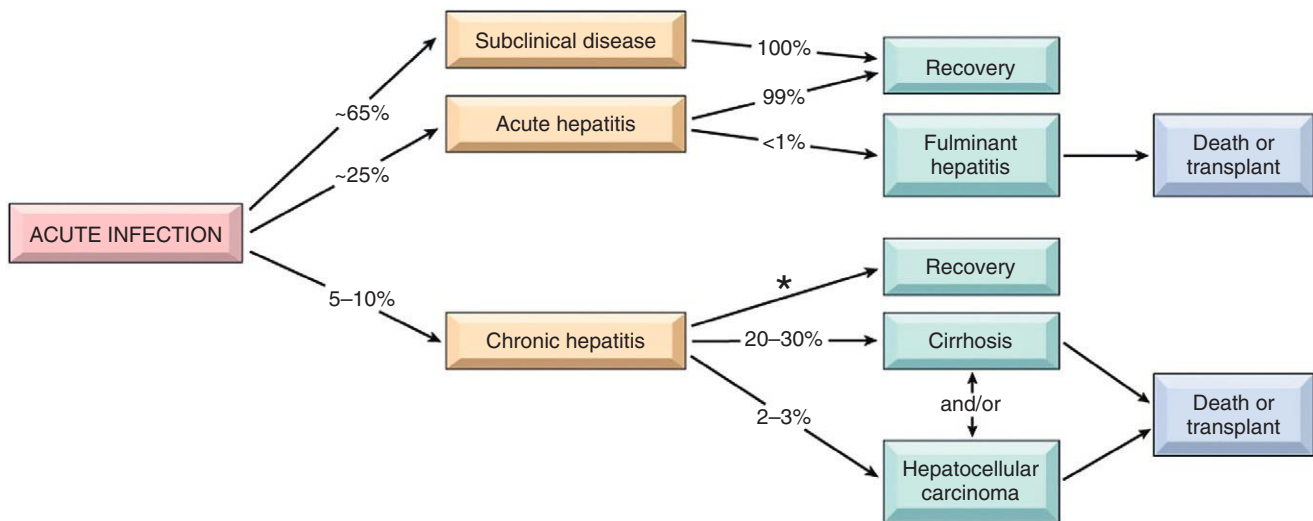

Figure 18-11 Potential outcomes of hepatitis B infection in adults, with their approximate frequencies in the United States. *Spontaneous HBsAg clearance occurs during chronic HBV infection at an estimated annual incidence of 1 to 2% in Western countries. As mentioned in the text, fulminant hepatitis and acute hepatic failure are used interchangeably

and Australia. As discussed later, the carrier rate is largely dictated by the age at infection, being the highest when infection occurs in children perinatally and the lowest when adults are infected.

The mode of transmission of HBV also varies with geographic areas. In high prevalence regions of the world, transmission during childbirth accounts for 90% of cases. In areas with intermediate prevalence, horizontal transmission, especially in early childhood, is the dominant mode of transmission. Such spread occurs through minor breaks in the skin or mucous membranes among children with close bodily contact. In low prevalence areas, unprotected sex and intravenous drug abuse (sharing of needles and syringes) are the chief modes of spread. The incidence of transfusion-related spread has dwindled greatly in recent decades due to screening of donated blood for HBsAg and exclusion of paid blood donors. Vaccination induces a protective anti-HBs antibody response in 95% of infants, children, and adolescents. Universal vaccination has had notable success in Taiwan and Gambia, but unfortunately, has not been adopted worldwide. Broad childhood population vaccination programs in endemic countries (e.g., Taiwan) are expected to curtail the disease in coming years.

HBV has a prolonged incubation period (2 to 26 weeks). Unlike HAV, HBV remains in the blood until and during active episodes of acute and chronic hepatitis. Approximately 65% of adults newly acquiring HBV have mild or no symptoms and do not develop jaundice. The remaining 25% have nonspecific constitutional symptoms such as anorexia, fever, jaundice, and upper right quadrant pain. In almost all cases the infection is self-limited and resolves without treatment. Chronic disease occurs in 5%-10% of infected individuals. Fulminant hepatitis (acute hepatic failure) is rare, occurring in approximately 0.1% to 0.5% of acutely infected individuals.

HBV was first linked to hepatitis in the 1960s when Australia antigen (later known as HBV surface antigen) was identified. The virus is a member of the *Hepadnaviridae*, a family of DNA viruses that cause hepatitis in multiple animal species. There are eight HBV genotypes that are

distributed around the globe. The mature HBV virion is a 42-nm, spherical double-layered “Dane particle” that has an outer surface envelope of protein, lipid, and carbohydrate enclosing an electron-dense, 28-nm, slightly hexagonal core. The genome of HBV is a partially double-stranded circular DNA molecule having 3200 nucleotides with four open reading frames coding for:

- A nucleocapsid “core” protein (HBcAg, hepatitis B core antigen) and a longer polypeptide transcript with a precore and core region, designated HBeAg (hepatitis B e antigen). The precore region directs the secretion of the HBeAg polypeptide, whereas HBcAg remains in hepatocytes, where it participates in the assembly of complete virions.
- Envelope glycoproteins (HBsAg, hepatitis B surface antigen), which consist of three related proteins: large, middle, and small HBsAg. Infected hepatocytes are capable of synthesizing and secreting massive quantities of noninfective surface protein (mainly small HBsAg).
- A polymerase (Pol) that exhibits both DNA polymerase activity and reverse transcriptase activity. Replication of the viral genome occurs via an intermediate RNA template, through a unique replication cycle: DNA → RNA → DNA
- HBx protein, which is necessary for virus replication and may act as a transcriptional transactivator of both viral genes and a subset of host genes. It has been implicated in the pathogenesis of hepatocellular carcinoma in HBV infection.

The natural course of the disease can be followed by serum markers (Fig. 18-12)

- HBsAg appears before the onset of symptoms, peaks during overt disease, and then often declines to undetectable levels in 12 weeks, although it may persist in some individuals for as long as 24 weeks.
- Anti-HBs antibody does not rise until the acute disease is over, concomitant with the disappearance of HBsAg

Figure 18-12 Temporal changes in serologic markers in hepatitis B viral infection. **A**, Acute infection with resolution. **B**, progression to chronic infection. Note in some cases of chronic HBV, serum transaminases may become normal.

(Fig. 18-12A). In some cases, however, Anti-HBs antibody is not detectable for a few weeks to several months after the disappearance of HBsAg. During this window period, serologic diagnosis can be made by detection of IgM anti-HBc antibody (see below and Fig. 18-12). Anti-HBs may persist for life, conferring protection; this is the basis for current vaccination strategies using noninfectious HBsAg.

- HBeAg, HBV-DNA, and DNA polymerase appear in serum soon after HBsAg, and all signify active viral replication. Persistence of HBeAg is an important indicator of continued viral replication, infectivity, and probable progression to chronic hepatitis. The appearance of anti-HBe antibodies implies that an acute infection has peaked and is on the wane.
- IgM anti-HBc antibody becomes detectable in serum shortly before the onset of symptoms, concurrent with the onset of elevated serum aminotransferase levels (indicative of hepatocyte destruction). Over a period of months the IgM anti-HBc antibody is replaced by IgG anti-HBc. As in the case of anti-HAV, there is no direct assay for IgG anti-HBc; its presence is inferred from decline of IgM anti-HBc in the face of rising total anti-HBc.

Occasionally, mutated strains of HBV emerge that do not produce HBeAg but are replication competent and express HBcAg. In such patients, the HBeAg may be low or undetectable despite the presence of serum HBV DNA. A second, ominous development is the appearance of vaccine-induced escape mutants, which replicate in the presence of vaccine-induced immunity.

The host immune response to the virus is the main determinant of the outcome of the infection. Innate immune mechanisms protect the host during the initial phases of the infection, and a strong response by virus-specific CD4+ and CD8+ interferon (IFN)- γ -producing cells is associated with the resolution of acute infection. HBV generally does not cause direct hepatocyte injury. Instead,

injury is caused by CD8+ cytotoxic T cells attacking infected cells.

Age at the time of infection is the best predictor of chronicity. The younger the age at the time of HBV infection, the higher the probability of chronicity. Despite progress in the treatment of chronic HBV infection, complete cure is extremely difficult to achieve even when treated with highly effective antiviral agents. The difficulty in achieving cure has been attributed to the ability of the virus to insert itself in the host DNA, thus limiting the development of an effective immune response (HBsAb development). This allows the virus to persist in the face of drugs that impair its replication. Hence, the goal of the treatment of chronic hepatitis B is to slow disease progression, reduce liver damage, and prevent liver cirrhosis or liver cancer.

Hepatitis B can be prevented by vaccination and by the screening of donor blood, organs, and tissues. Vaccination induces a protective anti-HBs antibody response in 95% of infants, children, and adolescents.

Hepatitis C Virus

Hepatitis C Virus (HCV) is a major cause of liver disease worldwide, with approximately 170 million people affected. Approximately 3.6 million Americans, or 1.3% of the population, have antibodies to HCV, indicative of past or current infection. Of these, 2.7 million have chronic HCV based on presence of HCV RNA. Notably, there has been a decrease in the annual incidence of infection from its mid-1980s peak of more than 230,000 new infections per year to a current 17,000 new infections per year, due primarily to a marked reduction in transfusion-associated cases as a result of donor blood screening. Nevertheless, the number of patients with chronic infection will continue to increase, as a result of potential lifelong persistence of HCV infection.

According to data from the USA Centers for Disease Control, the most common risk factors for HCV infection are:

- Intravenous drug abuse (54%)
- Multiple sex partners (36%)
- Having had surgery within the last 6 months (16%)
- Needle stick injury (10%)
- Multiple contacts with an HCV-infected person (10%)
- Employment in medical or dental fields (1.5%)
- Unknown (32%)

Currently, rate of transmission of HCV by blood transfusion is close to zero in the United States; the risk for acquiring HCV by needle stick is about six times higher than the same risk for acquiring HIV (1.8% vs 0.3%). For children, the major route of infection is perinatal, but this route of infection with HCV is much lower than for HBV (6% vs. 20%). Note that patients may have multiple risk factors (the total of the aforementioned listed risks is greater than 100%), but *one third of individuals have no identifiable risk factors*, an enduring hepatologic mystery.

HCV, discovered in 1989, is a member of the Flaviviridae family. It is a small, enveloped, single-stranded RNA virus with a 9.6-kilobase (kb) genome that codes for a single polyprotein with one open reading frame, which is subsequently processed into functional proteins. Because of the low fidelity of the HCV RNA polymerase, the virus is inherently unstable, giving rise to multiple genotypes and subtypes. Indeed, *within any given individual, HCV exists as closely related genetic variants known as quasispecies*.

Over time, dozens of quasispecies can be detected within one individual all derived from the original HCV strain that infected the patient. The E2 protein of the envelope is the target of many anti-HCV antibodies but is also the most variable region of the entire viral genome, enabling emergent virus strains to escape from neutralizing antibodies. This genomic instability and antigenic variability have seriously hampered efforts to develop an HCV vaccine. In particular, *elevated titers of anti-HCV IgG occurring after an active infection do not confer effective immunity*. A characteristic feature of HCV infection, therefore, is repeated bouts of hepatic damage, the result of reactivation of a

preexisting infection or emergence of an endogenous, newly mutated strain.

The incubation period for HCV hepatitis ranges from 4 to 26 weeks, with a mean of 9 weeks. In about 85% of individuals, the clinical course of the acute infection is asymptomatic and typically missed. HCV RNA is detectable in blood for 1 to 3 weeks, coincident with elevations in serum transaminases. In symptomatic acute HCV infection, anti-HCV antibodies are detected in only 50% to 70% of patients; in the remaining patients, the anti-HCV antibodies emerge after 3 to 6 weeks. The clinical course of acute HCV hepatitis is milder than that of HBV; rare cases may be severe and indistinguishable from HAV or HBV hepatitis. It is not known why only a small minority of individuals are capable of clearing HCV infection.

Persistent infection and chronic hepatitis are the hallmarks of HCV infection, despite the generally asymptomatic nature of the acute illness. In contrast to HBV, chronic disease occurs in the majority of HCV-infected individuals (80% to 90%) and cirrhosis eventually occurs in as many as a 20% of individuals with chronic HCV infection. The mechanisms that lead to the chronicity of HCV infection are not well understood, but it is clear that the virus has developed multiple strategies to evade host antiviral immunity. HCV is able to actively inhibit the IFN-mediated cellular antiviral response at multiple steps, including toll-like receptor signaling in response to viral RNA recognition and signaling downstream of IFN receptors that would otherwise have antiviral effects.

In more than 90% of individuals with chronic HCV infection, circulating HCV RNA persists despite the presence of antibodies (Fig. 18-13). Hence, in persons with chronic hepatitis, HCV RNA testing must be performed to assess viral replication and to confirm the diagnosis of HCV infection. A clinical feature that is quite characteristic of chronic HCV infection is persistent elevations in serum aminotransferases. Their levels wax and wane but almost never become normal. Even rare patients with normal transaminases are at risk for developing permanent liver damage. Therefore, any individual with detectable HCV

Figure 18-13 Temporal changes in serologic markers in hepatitis C viral infection. **A**, Acute infection with resolution. **B**, progression to chronic infection.

RNA in the serum needs close clinical follow-up. A feature unique to hepatitis C infection is the association with the metabolic syndrome, in particular with HCV genotype 3. Apparently, HCV can give rise to insulin resistance and non alcoholic fatty liver disease.

HCV infection is potentially curable. Until recently, treatment has been based on combination of pegylated IFN- α and ribavirin and cure rates depended on the viral genotype; patients with genotype 2 or 3 infection generally have had the best responses. Interestingly, host genotype also influences the response. Certain polymorphism in the IL-28B gene are associated with better response to interferon-alpha and ribavirin. IL-28B encodes interferon lambda, which is involved in resistance to HCV. New drugs targeting viral protease and polymerase have now been approved or are in development. With currently available drugs sustained virologic response (defined as undetectable HCV RNA in the patient's blood 24 weeks after the end of treatment) can be achieved in 50% to 80% of patients. Thus there is every reason to believe that newer regimens, based on principles similar to those used in highly active antiretroviral therapy (HAART) for HIV infection, will change the course of chronic hepatitis C in the coming decade.

Hepatitis D Virus

Also called "the delta agent," hepatitis D virus (HDV) is a unique RNA virus that is dependent for its life cycle on HBV. Infection with HDV arises in the following settings.

- *Co-infection* occurs following exposure to serum containing both HDV and HBV. The HBV must become established first to provide the HBsAg necessary for development of complete HDV virions. Co-infection of HBV and HDV results in acute hepatitis that is indistinguishable from acute hepatitis B. It is self-limited and is usually followed by clearance of both viruses. However, there is a higher rate of acute hepatic failure, in intravenous drug users.
- *Superinfection* occurs when a chronic carrier of HBV is exposed to a new inoculum of HDV. This results in disease 30 to 50 days later presenting either as severe acute hepatitis in a previously unrecognized HBV carrier or as an exacerbation of preexisting chronic hepatitis B infection. Chronic HDV infection occurs in almost all of such patients. The superinfection may have two phases: an acute phase with active HDV replication and suppression of HBV with high transaminase levels, and a chronic phase in which HDV replication decreases, HBV replication increases, transferase levels fluctuate, and the disease progresses to cirrhosis and sometimes hepatocellular carcinoma.

Worldwide, 15 million people are estimated to be infected with HDV (about 5% of 300 million of HBV infected persons). Prevalence varies, being high in the Amazon basin, and in central Africa, the Middle East, and the Mediterranean basin, where 20% to 40% of HbsAg carriers may have anti-HDV antibody; the rate has been declining in recent years. Surprisingly, HDV infection is uncommon in the large population of HBsAg carriers in Southeast Asia and China. In western countries it is largely restricted to intravenous drug abusers and those who have had multiple blood transfusions.

HDV, discovered in 1977, is a 35-nm, double-shelled particle. The external coat antigen of HBsAg surrounds an internal polypeptide assembly, designated delta antigen (HDAg), the only protein produced by the virus. Associated with HDAg is a small circular molecule of single-stranded RNA, whose length is smaller than the genome of any known animal virus. Replication of the virus is through RNA-directed RNA synthesis by host RNA polymerase.

HDV RNA is detectable in the blood and liver just before and in the early days of acute symptomatic disease. IgM anti-HDV antibody is the most reliable indicator of recent HDV exposure, although its appearance is late and frequently short-lived. Nevertheless, acute co-infection by HDV and HBV is best indicated by detection of IgM against both HDAg and HBcAg (denoting new infection with hepatitis B). With chronic delta hepatitis arising from HDV superinfection, HBsAg is present in serum, and anti-HDV antibodies (IgG and IgM) persist for months or longer. Vaccination for HBV also prevents HDV infection.

Hepatitis E Virus

Hepatitis E virus (HEV) is an enterically transmitted, water-borne infection that occurs primarily in young to middle-aged adults. HEV is a zoonotic disease with animal reservoirs, such as monkeys, cats, pigs, and dogs. Epidemics have been reported in Asia and the Indian subcontinent, sub-Saharan Africa, Middle East, China and Mexico, although sporadic cases are seen in industrialized nations, particularly in regions where pig farming is common. Sporadic infection may also occur in travelers to these regions, but, most importantly, HEV infection accounts for more than 30% to 60% of cases of sporadic acute hepatitis in India, exceeding the frequency of HAV. A characteristic feature of HEV infection is the high mortality rate among pregnant women, approaching 20%. In most cases the disease is self-limiting; HEV is not associated with chronic liver disease or persistent viremia in immunocompetent patients. Chronic HEV infection does occur in patients with AIDS and immunosuppressed transplant patients. The average incubation period following exposure is 4 to 5 weeks.

Discovered in 1983, HEV is an unenveloped, positive-stranded RNA virus in the *Hepevirus* genus. Viral particles are 32 to 34 nm in diameter, and the RNA genome is approximately 7.3 kb in size. Virions are shed in stool during the acute illness.

Before the onset of clinical illness, HEV RNA and HEV virions can be detected by PCR in stool and serum. The onset of rising serum aminotransferases, clinical illness, and elevated IgM anti-HEV titers are virtually simultaneous. Symptoms resolve in 2 to 4 weeks, during which time the IgM is replaced with a persistent IgG anti-HEV antibodies.

Clinicopathologic Syndromes of Viral Hepatitis

Several clinical syndromes may develop following exposure to hepatitis viruses: (1) acute asymptomatic infection with recovery (serologic evidence only), (2) acute symptomatic hepatitis with recovery, anicteric or icteric, (3) chronic hepatitis, with or without progression to cirrhosis, and (4) acute liver failure with massive to sub-massive hepatic necrosis. Table 18-3 provides a summary of the salient features of infection by various hepatitis viruses. All of the hepatotropic viruses can cause acute

Table 18-3 The Hepatitis Viruses

Virus	Hepatitis A	Hepatitis B	Hepatitis C	Hepatitis D	Hepatitis E
Type of virus	ssRNA	partially dsDNA	ssRNA	Circular defective ssRNA	ssRNA
Viral family	Hepatovirus; related to picornavirus	Hepadnavirus	Flaviviridae	Subviral particle in Deltaviridae family	Hepevirus
Route of transmission	Fecal-oral (contaminated food or water)	Parenteral, sexual contact, perinatal	Parenteral; intranasal cocaine use is a risk factor	Parenteral	Fecal-oral
Mean incubation period	2 to 6 weeks	2 to 26 weeks (mean 8 weeks)	4 to 26 weeks (mean 9 weeks)	Same as HBV	4 to 5 weeks
Frequency of chronic liver disease	Never	5%-10%	>80%	10% (co-infection); 90%-100% for superinfection	In immunocompromised hosts only
Diagnosis	Detection of serum IgM antibodies	Detection of HBsAg or antibody to HBcAg; PCR for HBV DNA	3rd-generation ELISA for antibody detection; PCR for HCV RNA	Detection of IgM and IgG antibodies; HDV RNA serum; HDAg in liver	Detection of serum IgM and IgG antibodies; PCR for HEV RNA

dsDNA, Double-stranded DNA; ELISA, enzyme-linked immunosorbent assay; HBcAg, hepatitis B core antigen; HBsAg, hepatitis B surface antigen; HBV, hepatitis B virus; HCV, hepatitis C virus; HDAg, hepatitis D antigen; HDV, hepatitis D virus; HEV, hepatitis E virus; IV, intravenous; PCR, polymerase chain reaction; ssRNA, single stranded RNA.

asymptomatic or symptomatic infection. HAV and HEV (in immunocompetent hosts) do not cause chronic hepatitis and only a small number of HBV-infected adult patients develop chronic hepatitis. In contrast, HCV is notorious for chronic infection. Fulminant hepatitis (acute liver failure) is unusual and is seen primarily with HAV, HBV, or HDV infection depending on region. HEV can cause fulminant hepatitis in pregnant women. Although HBV and HCV are responsible for most cases of chronic hepatitis, there are many other causes of similar clinicopathologic presentation, especially autoimmunity and drug/toxin-induced hepatitis, described later. Therefore, *serologic and molecular studies are essential for the diagnosis of viral hepatitis and for distinguishing between the various types.*

Acute Asymptomatic Infection with Recovery. Patients in this group are identified only incidentally on the basis of minimally elevated serum transaminases or, after the fact, by the presence of antiviral antibodies. Worldwide, HAV and HBV infection are frequently subclinical events in childhood, verified only in adulthood by the presence of anti-HAV or anti-HBV antibodies.

Acute Symptomatic Infection with Recovery. Regardless of the virus, the disease is more or less the same and can be divided into four phases: (1) an incubation period, (2) a symptomatic preicteric phase, (3) a symptomatic icteric phase, and (4) convalescence. The incubation period for the different viruses is given in Table 18-3. Peak infectivity occurs during the last asymptomatic days of the incubation period and the early days of acute symptoms.

Acute Liver Failure. Viral hepatitis is responsible for about 10% of cases of acute hepatic failure. The causative virus differs depending on the geographic location. Globally, hepatitis A and E are the most common causes; HBV is more common in Asian and Mediterranean countries. Morphologic details of massive necrosis under these circumstances were previously described in the section on Acute Liver Failure. There are no specific histologic findings which are indicative of hepatotropic virus causation.

Survival for more than a week may permit the replication of residual hepatocytes. Activation of the stem/

progenitor cells in the canals of Hering gives rise to very prominent ductular reactions, although these are usually insufficient to accomplish full restitution; recovery depends on surviving hepatocytes undergoing cell division to restore missing parenchyma. The treatment for acute hepatic failure that follows acute viral hepatitis is to provide supportive care. Liver transplantation is the only option for patients whose disease does not resolve before secondary infection and other organ failure develop.

Chronic Hepatitis. Chronic hepatitis is defined as **symptomatic, biochemical, or serologic evidence of continuing or relapsing hepatic disease for more than 6 months.** Etiology rather than the histologic pattern is the most important determinant of the probability of developing progressive chronic hepatitis. The clinical features of chronic hepatitis are extremely variable and are not predictive of outcome. In some patients the only signs of chronic disease are persistent elevations of serum transaminases. Laboratory studies may also reveal prolongation of the prothrombin time and, in some instances, hyperglobulinemia, hyperbilirubinemia, and mild elevations in alkaline phosphatase levels. In symptomatic individuals, the most common finding is fatigue; less common symptoms are malaise, loss of appetite, and occasional bouts of mild jaundice. In precirrhotic chronic hepatitis, physical findings are few, the most common being mild hepatomegaly, hepatic tenderness, and mild splenomegaly. Occasionally, in cases of HBV and HCV infection, immune complex disease may develop secondary to the presence of circulating antibody-antigen complexes, in the form of vasculitis (Chapter 11) and glomerulonephritis (Chapter 20). Cryoglobulinemia is found in about 35% of individuals with chronic hepatitis C infection.

The Carrier State. A “carrier” is an individual who harbors and can transmit an organism, but has no manifest symptoms. In the case of hepatotropic virus this definition is somewhat confusing, as it can be interpreted to mean: (1) individuals who carry one of the viruses but have no liver disease; (2) those who harbor one of the viruses and have non-progressive liver damage, but are essentially free of symptoms or disability. In both cases, particularly the

latter, these individuals constitute reservoirs for infection. In the case of HBV infection an older, but still often used term is the so called “healthy carrier”. It is defined as an individual with HBsAg, without HBeAg, but with presence of anti-HBe; these patients have normal aminotransferases, low or undetectable serum HBV DNA, and a liver biopsy showing a lack of significant inflammation and necrosis (Fig. 18-11). In non-endemic areas such as the United States, between 5 and 10% of adults who acquire HBV infections become chronically infected, a very small number of whom become such “healthy carriers”; the rest have active disease, with consistent or intermittent signs and symptoms of active hepatitis, 20% of whom will go on to develop cirrhosis. In contrast, HBV infection acquired early in life in endemic areas (such as Southeast Asia, China, and Sub-Saharan Africa) gives rise to carrier states of the two types described above, in more than 90% of cases. It should be kept in mind that “healthy carrier” is probably not a stable state and that re-activation of hepatitis can occur in response to co-infection or alterations of immune function related to age or co-morbid diseases. Because of the confusion generated by the term “healthy carriers” many authorities prefer to use the term “inactive carrier”.

HCV infection in the United States is quite different. Equivalent states to the HBV “healthy carrier” are not recognized. Acute HCV infection progresses to chronic hepatitis in 80% or more of infected individuals, one third of whom may progress to cirrhosis.

HIV and Chronic Viral Hepatitis. Because of the similar transmission mode and the similar high-risk patient population, co-infection of HIV and hepatitis viruses has become a common clinical problem. For example, in the United States, 10% of HIV-infected individuals are co-infected with HBV and 25% with HCV. In fact, chronic HBV and HCV infection are now leading causes of morbidity and mortality for HIV-infected individuals, even those who are on successful anti-HIV therapy. In individuals who are untreated or resistant to treatment and who therefore progress to acquired immunodeficiency syndrome (AIDS), liver disease is the second most common cause of death. It is clear that untreated HIV infection significantly exacerbates the severity of liver disease caused by HBV or HCV. In immunocompetent individuals with HIV infection, the differences in severity and progression of either HBV or HCV may not differ greatly from those who are HIV negative.

MORPHOLOGY

The general morphologic features of viral hepatitis are depicted schematically in Fig. 18-14. **The morphologic changes in acute and chronic viral hepatitis are shared among the hepatotropic viruses and can be mimicked by drug reactions or autoimmune hepatitis.**

Acute viral hepatitis. On gross inspection, livers involved by mild acute hepatitis appear normal or slightly mottled. At the other end of the spectrum, in massive hepatic necrosis the liver may shrink greatly as described earlier under acute liver failure (Fig. 18-6).

Microscopically, both acute and chronic hepatitis evoke a lymphoplasmacytic (mononuclear) infiltrate. Portal inflammation in acute hepatitis is minimal or absent. Most parenchymal injury

is scattered throughout the hepatic lobule as “spotty necrosis” or **lobular hepatitis**. As described earlier, the hepatocyte injury may result in necrosis or apoptosis. In the former, the cytoplasm appears empty with only scattered wisps of cytoplasmic remnants. Eventually there is rupture of cell membranes leading to “dropout” of hepatocytes, leaving collapsed sinusoidal collagen reticulin framework behind; scavenger macrophages mark sites of dropout (Fig. 18-2). With apoptosis, hepatocytes shrink, becoming intensely eosinophilic, and their nuclei become pyknotic and fragmented; effector T cells may be present in the immediate vicinity (Figs. 18-3 and 18-14).

In severe acute hepatitis, confluent necrosis of hepatocytes is seen around central veins (Fig. 18-6B). In these areas there may be cellular debris, collapsed reticulin fibers, congestion/hemorrhage, and variable inflammation. With increasing severity, there is central-portal bridging necrosis, followed by, even worse, parenchymal collapse (Fig. 18-4B). In some cases massive hepatic necrosis and acute liver failure ensue, as described previously. In occasional cases, the injury is not severe enough to cause death (or necessitate transplantation), and the liver survives, although with abundant scarring, usually with replacement of areas of confluent necrosis. In such cases, some patients rapidly develop posthepatic cirrhosis.

There is considerable morphologic overlap in acute hepatitis caused by various hepatotropic viruses. However, subtle differences may be seen, for example the mononuclear infiltrate in hepatitis A may be especially rich in plasma cells.

Chronic viral hepatitis. The defining histologic feature of chronic viral hepatitis is mononuclear portal infiltration. It may be mild to severe and variable from one portal tract to the next (Fig. 18-14). There is often **interface hepatitis** as well, in addition to lobular hepatitis, distinguished by its location at the interface between hepatocellular parenchyma and portal tract stroma. The hallmark of progressive chronic liver damage is scarring. At first, only portal tracts exhibit fibrosis, but in some patients, with time, fibrous septa—bands of dense scar—extend between portal tracts. In parallel with increasing scarring there is also increasing ductular reaction, reflecting stem cell activation. In the most severe cases, continued scarring and nodule formation leads to the development of cirrhosis as described earlier (Fig. 18-8).

Clinical assessment of chronic hepatitis often requires liver biopsy in addition to clinical and serologic data. Liver biopsy is helpful in confirming the clinical diagnosis, excluding common concomitant conditions (e.g., fatty liver disease, hemochromatosis), assessing histologic features associated with an increased risk of malignancy (e.g., small and large cell change, described later), grading the extent of hepatocyte injury and inflammation, and staging the progression of scarring. Histologic grading and staging of chronic hepatitis in liver biopsy specimens are often central to determinations of whether to treat the underlying disease.

A somewhat greater range of histologic features distinguish one viral infection from another in chronic hepatitis. In chronic hepatitis B, **“ground-glass” hepatocytes**—cells with endoplasmic reticulum swollen by HBsAg—is a diagnostic hallmark. Immunostaining can confirm the presence of viral antigen (Fig. 18-15). Chronic hepatitis C quite commonly shows lymphoid aggregates or fully formed lymphoid follicles (Fig. 18-16). Often, hepatitis C, particularly genotype 3, shows fatty change of scattered hepatocytes, although the infection may also cause systemic alterations leading to metabolic syndrome and, therefore,

Figure 18-14 Diagrammatic representation of the morphologic features of acute and chronic hepatitis. Notice that there is very little portal mononuclear infiltration in acute hepatitis (or sometimes none at all), while in chronic hepatitis the portal infiltrates are dense and prominent—the defining change of chronic hepatitis. Bridging necrosis and fibrosis is shown only for chronic hepatitis, but bridging necrosis may also occur in more severe acute hepatitis. Ductular reactions in chronic hepatitis are minimal in early stages of scarring, but become extensive in late stage disease.

Figure 18-15 Ground-glass hepatocytes in chronic hepatitis B infection caused by accumulation of hepatitis B surface antigen. Note the large pale, finely granular pink cytoplasmic inclusions on hematoxylin and eosin staining; immunostaining (inset) confirms the presence of surface antigen (brown).

Figure 18-16 Chronic viral hepatitis due to HCV showing characteristic portal tract expansion by a lymphoid follicle.

a superimposed non-alcoholic fatty liver disease in the liver (see later). Bile duct injury is also prominent in some individuals with hepatitis C infection, potentially mimicking primary biliary cirrhosis (see later); clinical parameters distinguish these two diseases easily, however.

KEY CONCEPTS

Viral Hepatitis

- In the alphabet of hepatotropic viruses, some easy mnemonic devices may be useful:

- The vowels (hepatitis A and E) never cause chronic hepatitis, only Acute hepatitis, except HEV in immunocompromised hosts and pregnant females.
- Only the consonants (hepatitis B, C, D) have the potential to cause chronic disease (C for consonant and for chronic).
- Hepatitis B can be transmitted by blood, birthing, and “bonking” (as they say in the United Kingdom).
- Hepatitis C is the single virus that is more often chronic than not (almost never detected acutely; 80% or more of patients develop chronic hepatitis, 20% of whom will develop cirrhosis).
- Hepatitis D, the delta agent, is a defective virus, requiring hepatitis B co-infection for its own capacity to infect and replicate.
- Hepatitis E is endemic in equatorial regions and frequently epidemic.
- The inflammatory cells in both acute and chronic viral hepatitis are mainly T cells; it is the pattern of injury that is different between the two time courses, not the nature of the infiltrate.
- Biopsy assessment in chronic viral hepatitis is most important for grading and staging of disease, which are used to decide whether a patient undergoes often arduous antiviral treatments.
- Patients with long-standing HBV or HCV related cirrhosis are at increased risk for the development of hepatocellular carcinoma.

Bacterial, Parasitic, and Helminthic Infections

A multitude of organisms can infect the liver and biliary tree, including bacteria, fungi, helminths and other parasites, and protozoa. Several bacteria can infect the liver directly, including *Staphylococcus aureus* in toxic shock syndrome, *Salmonella typhi* in typhoid fever, and *Treponema pallidum* in secondary or tertiary syphilis. Bacteria may also proliferate in the biliary tree especially when outflow is compromised by partial or complete obstruction. The intra-biliary bacterial composition reflects the gut flora, and the acute inflammatory response within the intrahepatic biliary tree is called *ascending cholangitis*.

Bacteria may give rise to abscesses by spreading from extrahepatic sites, through the vascular supply, or from adjacent infected tissues. Liver abscesses are associated with fever and, in many instances, right upper quadrant pain and tender hepatomegaly. Jaundice may result from extrahepatic biliary obstruction. Although antibiotic therapy may control smaller lesions, surgical drainage is often necessary for the larger lesions. In the past almost 90% of the patients succumbed to the disease, but with early recognition and management, as many as 90% of patients can survive. Extrahepatic bacterial infections, particularly sepsis, can induce mild hepatic inflammation and varying degrees of hepatocellular cholestasis (see later).

Fungi (e.g., histoplasmosis) and mycobacteria can also infect the liver in disseminated disease, with histology showing classical granulomas. Organisms are usually not visible histologically, even with special stains, although serologic studies and tissue or blood cultures can often identify the causative agent.

Parasitic and helminthic infections are major causes of morbidity worldwide, and the liver is frequently involved (Chapter 8). These diseases include malaria, schistosomiasis, strongyloidiasis, cryptosporidiosis, leishmaniasis, echinococcosis, amebiasis, and infections by the liver flukes *Fasciola hepatica*, *Opisthorchis* species, and *Clonorchis sinensis*. *Schistosomiasis*, most commonly found in Asia, Africa, and South America, especially in those areas where the water contains numerous freshwater snails as a vector, is particularly associated with insidious sequelae of chronic liver disease. The liver flukes, most common in Southeast Asia, are notorious for causing a very high rate of cholangiocarcinoma. *Hydatid cysts* are usually caused by echinococcal infections (Chapter 8). They often have calcifications in the cyst walls which may aid radiologic diagnosis. In developed countries, hydatid cysts are uncommon. Cystic liver degeneration or abscesses can be caused by amebas and other protozoal and helminthic organisms. The incidence of amebic infections is low in developed countries and is usually found in immigrants from endemic regions.

Autoimmune Hepatitis

Autoimmune hepatitis is a chronic, progressive hepatitis with all the features of autoimmune diseases in general: genetic predisposition, association with other autoimmune diseases, presence of autoantibodies, and therapeutic response to immunosuppression. Strong HLA-associations for autoimmune hepatitis support a genetic predisposition. In Caucasians, there is a frequent association with DRB1* alleles. As with most other autoimmune diseases, the mechanistic basis of the HLA association are not clear. Triggers for the immune reaction may include viral infections or drug or toxin exposures.

Clinicopathologic Features. The annual incidence is highest among white northern Europeans at 1.9 per 100,000, but all ethnic groups are susceptible. There is a *female predominance* (78%). The diagnostic features are summarized in Table 18-4. As can be seen, a point system is used for the diagnosis of definite and probable autoimmune hepatitis. *Autoimmune hepatitis is classified into types 1 and 2, based on the patterns of circulating antibodies.* Type 1, more common in middle-aged to older individuals, is characterized by the presence of antinuclear (ANA), anti-smooth muscle actin (SMA), anti-soluble liver antigen/liver-pancreas antigen (anti-SLA/LP) antibodies, and less commonly, anti-mitochondrial (AMA) antibodies. In type 2, usually seen in children and teenagers, the main serologic markers are anti-liver kidney microsome-1 (anti-LKM-1) antibodies, which are mostly directed against CYP2D6, and anti-liver cytosol-1 (ACL-1) antibodies.

MORPHOLOGY

Although autoimmune hepatitis shares patterns of injury with acute or chronic viral hepatitis, the time course of histologic progression differs. In viral hepatitis, fibrosis typically follows many years of slowly accumulating parenchymal injury, whereas in autoimmune hepatitis, there is an early phase of severe

Table 18-4 Simplified Diagnostic Criteria (2008) of the International Autoimmune Hepatitis Group

		Points*
Autoantibodies	ANA or ASMA or LKM > 1:80	2
	ANA or ASMA or LKM > 1:40	1
	SLA/LP Positive (>20 units)	0
IgG (or gamma-globulins)	>1.10 times normal limit	2
	Upper normal limit	1
Liver histology†	Typical for autoimmune hepatitis	2
	Compatible with autoimmune hepatitis	1
	Atypical for autoimmune	0
Absence of viral hepatitis	Yes	2
	No	0

*Definite autoimmune hepatitis (AIH): P7; probable AIH: P6.

†Typical: (1) Interface hepatitis, lymphocytic/lymphoplasmacytic infiltrates in portal tracts and extending in the lobule; (2) emperipolesis (active penetration by one cell into and through larger cell); (3) hepatic rosette formation.

Compatible: Chronic hepatitis with lymphocytic infiltration without features considered typical. Atypical: Showing signs of another diagnosis like NAFLD.

ANA, antinuclear antibody; ASMA, anti-smooth muscle actin; LP, liver pancreas; LKM, anti-liver kidney microsomal antibodies; SLA, soluble liver antigen; IgG, immunoglobulin G; AIH, autoimmune hepatitis.

Adapted from Hennes EM, et al. Simplified criteria for the diagnosis of autoimmune hepatitis. *Hepatology* 48:169-176; 2008.

parenchymal destruction followed rapidly by scarring. Features considered typical of autoimmune hepatitis include:

- Severe necroinflammatory activity indicated by extensive interface hepatitis or foci of confluent (perivenular or bridging necrosis) or parenchymal collapse
- Plasma cell predominance in the mononuclear inflammatory infiltrates (Fig. 18-17)
- Hepatocyte “rosettes” in areas of marked activity

The disease may be rapidly progressive or indolent, both giving rise eventually to liver failure. Clinical evolution correlates with a limited number of histologic patterns, any of which may be seen at the time of initial diagnosis:

- Very severe hepatocyte injury with widespread confluent necrosis, but little scarring; this pattern is often seen as symptomatic acute hepatitis and represents the first sign of disease.
- A mix of marked inflammation and some degree of scarring, seen in early or later stage disease
- Burned-out cirrhosis, with little necroinflammatory activity, that has been preceded, presumably, by years of subclinical disease

An acute appearance of clinical illness is common (40%) and a fulminant presentation with hepatic encephalopathy within 8 weeks of disease onset may also occur. The mortality of patients with severe untreated autoimmune hepatitis is approximately 40% within 6 months of diagnosis and cirrhosis develops in at least 40% of survivors. In general, prognosis is better in adults than in children, possibly due to delay in diagnosis in the pediatric population. Hence, diagnosis and intervention are imperative. Immunosuppressive therapy is usually successful, leading to remissions in 80% of patients that permits long term survival. In end stage disease, liver transplantation is indicated. Ten-year survival rate after liver transplant is

75%, but recurrence in the transplanted organ may affect 20% of transplanted patients.

In a small subset of patients, there may be overlap with other autoimmune liver diseases, in particular primary biliary cirrhosis or, less commonly, primary sclerosing cholangitis. *Diagnosis of “overlap” syndromes requires full display of both clinical and histologic features of autoimmune hepatitis and the other, concomitant disease.*

KEY CONCEPTS

Autoimmune Hepatitis

- There are two primary types of autoimmune hepatitis:
 - Type 1 autoimmune hepatitis is most often seen in middle-aged women and is most characteristically associated with antinuclear and anti-smooth muscle antibodies (ANA and ASMA)
 - Type 2 autoimmune hepatitis is most often seen in children or teenagers and is associated with anti-liver kidney microsomal autoantibodies (anti-LKM1)
- Autoimmune hepatitis may either develop with a rapidly progressive acute disease or follow a more indolent path; if untreated, both are likely to lead to liver failure.
- Plasma cells are a prominent and characteristic component of the inflammatory infiltrate in biopsy specimens showing autoimmune hepatitis.

Drug- and Toxin-Induced Liver Injury

As the major drug metabolizing and detoxifying organ in the body, the liver is subject to injury from an enormous array of therapeutic and environmental agents. Injury may result from direct toxicity, occur through hepatic conversion of a xenobiotic to an active toxin, or be produced by immune mechanisms, such as by the drug or a metabolite acting as a hapten to convert a cellular protein into an immunogen. A diagnosis of drug- or toxin-induced liver injury may be made on the basis of a temporal

Figure 18-17 Autoimmune hepatitis. A focus of lobular hepatitis with prominent plasma cells typical for this disease.

Table 18-5 Patterns of Drug- and Toxin-Induced Hepatic Injury

Pattern of Injury	Morphologic Findings	Examples of Associated Agents
Cholestatic	Bland hepatocellular cholestasis, without inflammation	Contraceptive and anabolic steroids, antibiotics, HAART
Cholestatic hepatitis	Cholestasis with lobular necroinflammatory activity; may show bile duct destruction	Antibiotics, phenothiazines, statins
Hepatocellular necrosis	Spotty hepatocyte necrosis Massive necrosis Chronic hepatitis	Methylidopa, phenytoin Acetaminophen, halothane Isoniazid
Fatty liver disease	Large and small droplet fat “Microvesicular steatosis” (diffuse small droplet fat) Steatohepatitis with Mallory-Denk bodies	Ethanol, corticosteroids, methotrexate, total parenteral nutrition Valproate, tetracycline, aspirin (Reye syndrome), HAART Ethanol, amiodarone
Fibrosis and cirrhosis	Periportal and pericellular fibrosis	Alcohol, methotrexate, enalapril, vitamin A and other retinoids
Granulomas	Noncaseating epithelioid granulomas Fibrin ring granulomas	Sulfonamides, amiodarone, isoniazid Allopurinol
Vascular lesions	Sinusoidal obstruction syndrome (veno-occlusive disease): obliteration of central veins Budd-Chiari syndrome Peliosis hepatitis: blood-filled cavities, not lined by endothelial cells	High-dose chemotherapy, bush teas Oral contraceptives Anabolic steroids, tamoxifen
Neoplasms	Hepatocellular adenoma Hepatocellular carcinoma Cholangiocarcinoma Angiosarcoma	Oral contraceptives, anabolic steroids Alcohol, thorotrast Thorotrast Thorotrast, vinyl chloride

association of liver damage with drug or toxin exposure, recovery (usually) upon removal of the inciting agent, and exclusion of other potential causes. *Exposure to a toxin or therapeutic agent should always be included in the differential diagnosis of any form of liver disease.*

Drug-induced liver injury has a global incidence of 1 to 14 per 100,000. Reactions may be mild to very serious, including acute liver failure or chronic liver disease. A large number of drugs and chemicals can produce liver injury (Table 18-5). Alcohol produces more toxic liver injury than any other agent; it is discussed separately later in this chapter. It is also important to keep in mind that not only compounds normally thought of as drugs or medicines may be implicated, but that careful, detailed history taking may identify other potential toxins such as herbal remedies, dietary supplements, topical applications (e.g., ointments, perfumes, shampoo), and environmental exposures (e.g., cleaning solvents, pesticides, fertilizers).

Principles of drug and toxic injury are discussed in Chapter 9. Drug toxic reactions may be classified as *predictable* (intrinsic) or *unpredictable* (idiosyncratic). Predictable reactions affect all people in a dose-dependent fashion. Unpredictable reactions depend on idiosyncrasies of the host, particularly the propensity to mount an immune response to the antigenic stimulus or the rate at which the agent can be metabolized. Both classes of injury may be immediate or take weeks to months to develop.

A classic, predictable hepatotoxin is acetaminophen, now the most common cause of acute liver failure necessitating transplantation in the United States. The toxic agent is not acetaminophen itself but rather a toxic metabolite produced by the cytochrome P-450 system in acinus zone 3 hepatocytes (Fig. 18-1). As these hepatocytes die, the zone 2 hepatocytes take over this metabolic function, in turn becoming injured. In severe overdoses, the zone of injury extends to the periportal hepatocytes, resulting in acute hepatic failure (Fig. 18-6). While suicide attempts with acetaminophen are common, so are accidental overdoses. This is because the cytotoxicity is dependent on the cytochrome P-450 system, which may be upregulated by other agents taken in combination with acetaminophen, such as alcohol (beware acetaminophen as a hangover prophylactic) or codeine in acetaminophen compound tablets.

Examples of drugs that can cause idiosyncratic reactions include *chlorpromazine*, an agent that causes cholestasis in patients who are slow to metabolize it to an innocuous byproduct, and *halothane*, which can cause a fatal immune-mediated hepatitis in some patients exposed to this anesthetic on multiple occasions. Often, idiosyncratic drug reactions involve a variable combination of direct cytotoxicity and immune-mediated hepatocyte or bile duct destruction. Table 18-5 lists the more common drugs and toxins that cause liver injury according to the type of morphologic changes produced. As will be evident from the table, a single agent can produce more than one pattern of injury.

KEY CONCEPTS

Drug- or Toxin-Induced Liver Injury

- Most drugs or toxins affecting the liver may be classified as:
 - Predictable hepatotoxins, acting in a dose-dependent manner and occurring in most individuals.
 - Unpredictable or idiosyncratic hepatotoxins, which happen in rare individuals and which are often independent of dose
- Hepatotoxins may cause harm from direct cell toxicity, through hepatic conversion of a xenobiotic to an active toxin, or by immune mechanisms, such as by the drug or a metabolite acting as a hapten to convert a cellular protein into an immunogen.
- The most common hepatotoxin causing acute liver failure is acetaminophen.
- The most common hepatotoxin causing chronic liver disease is alcohol.

Figure 18-18 Alcoholic liver disease. The interrelationships among hepatic steatosis, alcoholic hepatitis, and alcoholic cirrhosis are shown, along with depictions of key morphologic features. It should be noted that steatosis, alcoholic hepatitis, and steatofibrosis may also develop independently. In particular some patients present initially with cirrhosis without any of the other forms of alcoholic liver disease.

Alcoholic Liver Disease

Excessive alcohol (ethanol) consumption is the leading cause of liver disease in most Western countries. Alcohol accounts for 3.8% of deaths globally, making it the eighth highest risk factor for death (fifth in middle-income countries and ninth in high-income countries). There are three distinctive, albeit overlapping forms of alcoholic liver injury: (1) hepatocellular steatosis or fatty change, (2) alcoholic (or steato-) hepatitis, and (3) steatofibrosis (patterns of scarring typical for all fatty liver diseases including alcohol) up to and including cirrhosis in the late stages of disease (Fig. 18-18). For some unknown reason, cirrhosis develops in only a small fraction of chronic alcoholics. The morphology of the three interrelated forms of alcoholic liver disease is presented first, to facilitate the later discussion of their pathogenesis.

MORPHOLOGY

All changes in alcoholic liver disease begin in acinus zone 3 and extend outward toward the portal tracts with increasing severity of injury.

Hepatic Steatosis (Fatty Liver). After even moderate intake of alcohol, lipid droplets accumulate in hepatocytes increasing with amount and chronicity of alcohol intake. The lipid begins as small droplets that coalesce into large droplets which distend

the hepatocyte and push the nucleus aside (Fig. 18-19). Macroscopically, the fatty liver in individuals with chronic alcoholism is a large (as heavy as 4 to 6 kg), soft organ that is yellow and greasy. **Fatty change is completely reversible if there is abstinence from further intake of alcohol.**

Figure 18-19 Alcoholic steatosis and steatofibrosis. A mix of small and large fat droplets (seen as clear vacuoles) is most prominent around the central vein and extends outward to the portal tracts. Some fibrosis (stained blue) is present in a characteristic perisinusoidal chicken wire fence pattern. (Masson trichrome stain). (Courtesy Dr. Elizabeth Brunt, Washington University, St. Louis, Mo.)

Figure 18-20 **A**, Alcoholic hepatitis with clustered inflammatory cells marking the site of a necrotic hepatocyte. A Mallory Denk body is present in another hepatocyte (arrow). **B**, Alcoholic steatohepatitis with many ballooned hepatocytes (arrowheads). Clusters of inflammatory cells are also present; inset shows immunostaining for keratins 8 and 18 (brown), with most hepatocytes, including those with fat vacuoles, showing normal cytoplasmic staining, but in the ballooned cell (arrow) the ubiquitinated keratins are collapsed into the Mallory-Denk body, leaving the cytoplasm “empty.” (Courtesy Dr. Elizabeth Brunt, Washington University, St. Louis, Mo.)

Alcoholic (Steato-) Hepatitis. Alcoholic hepatitis is characterized by:

1. Hepatocyte swelling and necrosis: Single or scattered foci of cells undergo swelling (ballooning) and necrosis (Fig. 18-20). The swelling results from the accumulation of fat and water, as well as proteins that are normally exported.

2. Mallory-Denk bodies: These are usually present as clumped, amorphous, eosinophilic material in ballooned hepatocytes. They are made up of tangled skeins of intermediate filaments such as keratins 8 and 18 in complex with other proteins such as ubiquitin (Fig. 18-20B). These inclusions are a characteristic but not specific feature of alcoholic liver disease, since they are also present in non-alcoholic fatty liver disease and in periportal distributions in Wilson disease and in chronic biliary tract diseases.

3. Neutrophilic reaction: Neutrophils permeate the hepatic lobule and accumulate around degenerating hepatocytes, particularly those having Mallory-Denk bodies. They may be more or less admixed with mononuclear cells (Fig. 18-20B).

Alcoholic steatofibrosis. Alcoholic hepatitis is often accompanied by prominent activation of sinusoidal stellate cells and portal fibroblasts, giving rise to fibrosis. Fibrosis begins with sclerosis of central veins. Perisinusoidal scar then accumulates in the space of Disse of the centrilobular region, spreading outward, encircling individual or small clusters of hepatocytes in a **chicken wire fence pattern** (Fig. 18-19). These webs of scar eventually link to portal tracts and then begin to condense into central-portal fibrous septa. With developing nodularity, cirrhosis becomes established. When alcohol use continues without interruption over the long term, the continual subdivision of established nodules by new webs of, perisinusoidal scarring leads to a classic micronodular or **Laennec cirrhosis** first described for end-stage alcoholic liver disease (Fig. 18-21). Early stages of scarring can regress with cessation of alcohol use, but the farther along toward cirrhosis the liver gets, the more vascular derangements prevent a full restoration of normal. Complete regression of alcoholic cirrhosis, while reported, is rare (Fig. 18-8).

Pathogenesis. Short-term ingestion of as much as 80 gm of alcohol (six beers or 8 ounces of 80-proof liquor) over one to several days generally produces mild, reversible hepatic steatosis. Daily intake of 80 gm or more of ethanol generates significant risk for severe hepatic injury, and daily ingestion of 160 gm or more for 10 to 20 years is associated more consistently with severe injury. *Only 10% to 15% of alcoholics, however, develop cirrhosis.* Thus, other factors must also influence the development and severity of alcoholic liver disease. These include:

- **Gender.** Women seem to be more susceptible to hepatic injury than men, although the majority of patients are men. This difference may be related to alcohol pharmacokinetics and metabolism, and the estrogen-dependent response to gut-derived endotoxin (LPS) in the liver. Although exact mechanisms are not known, it appears that estrogen increases gut permeability to endotoxins, which, in turn, increase the expression of the LPS receptor CD14 in Kupffer cells. This predisposes to increased production of proinflammatory cytokines and chemokines.
- **Ethnic and genetic differences.** In the United States, cirrhosis rates are higher for African American drinkers than for white Americans drinker. The difference cannot be explained by the amount of alcohol consumption, since there is no significant difference in consumption among the ethnic groups. Studies with twins suggest that there is a genetic component in alcohol-induced liver disease, although it remains difficult to separate genetic from environmental influences. Genetic polymorphisms in detoxifying enzymes and some cytokine promoters may play significant roles and contribute to ethnic differences. ALDH*2, a variant of aldehyde dehydrogenase (ALDH), found in 50% of Asians, has a very low activity. Individuals homozygous for ALDH*2 are unable to oxidize acetaldehyde and do not tolerate alcohol, leading to alcohol intolerance characterized by upper body flushing and, variably, nausea or lethargy.

Figure 18-21 Alcoholic cirrhosis. **A**, The characteristic diffuse nodularity of the surface is induced by the underlying fibrous scarring. The average nodule size is 3 mm in this close-up view, typical of the “micronodular” cirrhosis of alcoholic liver disease. The greenish tint is caused by cholestasis. **B**, Microscopically, this cirrhosis is marked by small nodules entrapped in blue-staining fibrous tissue; fatty accumulation is no longer seen in this “burned out” stage. (Masson trichrome stain.)

- **Comorbid conditions.** Iron overload and infections with HCV and HBV synergize with alcohol, leading to increased severity of liver disease.

The pharmacokinetics and metabolism of alcohol are described in [Chapter 9](#). Pertinent to this discussion are the detrimental effects of alcohol and its byproducts on hepatocellular function. *Exposure to alcohol causes steatosis, dysfunction of mitochondrial and cellular membranes, hypoxia, and oxidative stress.* At millimolar concentrations, alcohol directly affects microtubular and mitochondrial function and membrane fluidity.

Hepatocellular steatosis results from (1) shunting of normal substrates away from catabolism and toward lipid biosynthesis, as a result of increased generation of reduced nicotinamide adenine dinucleotide (NADH) by the two major enzymes of alcohol metabolism, alcohol dehydrogenase and acetaldehyde dehydrogenase; (2) impaired assembly and secretion of lipoproteins; and (3) increased peripheral catabolism of fat, thus releasing free fatty acids into the circulation.

The causes of alcoholic hepatitis are uncertain, but some of the factors that likely play important roles are discussed next. *Acetaldehyde* (the major intermediate metabolite of alcohol) induces lipid peroxidation and acetaldehyde-protein adduct formation, further disrupting cytoskeletal and membrane function. Cytochrome P-450 metabolism produces *reactive oxygen species* (ROS) that react with cellular proteins, damage membranes, and alter hepatocellular function. In addition, alcohol impairs hepatic metabolism of methionine, which *decreases glutathione levels*, thereby sensitizing the liver to oxidative injury. The induction of cytochrome P-450 enzymes in the liver by alcohol increases alcohol catabolism in the endoplasmic reticulum and enhances the conversion of other drugs (e.g., acetaminophen) to toxic metabolites. Alcohol causes the *release of bacterial endotoxin* from the gut into the portal circulation, inducing inflammatory responses in the liver, due to the activation of NF- κ B, and release of TNF, IL-6, and TGF- α . In addition, alcohol stimulates the release of endothelins from sinusoidal endothelial cells, causing vasoconstriction and *contraction of activated,*

myofibroblastic stellate cells, leading to a decrease in hepatic sinusoidal perfusion (already discussed under “Portal Hypertension”).

Alcoholic liver disease, thus, is a chronic disorder featuring steatosis, hepatitis, progressive fibrosis, and marked derangement of vascular perfusion. In essence, alcoholic liver disease can be regarded as a maladaptive state in which cells in the liver respond in an increasingly pathologic manner to a stimulus (alcohol) that originally was only marginally harmful.

Clinical Features. Hepatic steatosis may cause hepatomegaly, with mild elevation of serum bilirubin and alkaline phosphatase levels. Severe hepatic dysfunction is unusual. Alcohol withdrawal and the provision of an adequate diet are sufficient treatment. In contrast, alcoholic hepatitis tends to appear acutely, usually following a bout of heavy drinking. Symptoms and laboratory manifestations may range from minimal to those that mimic acute liver failure. Between these two extremes are the nonspecific symptoms of malaise, anorexia, weight loss, upper abdominal discomfort, and tender hepatomegaly, and the laboratory findings of hyperbilirubinemia, elevated serum aminotransferases and alkaline phosphatase, and often a neutrophilic leukocytosis. In contrast to other chronic liver diseases where serum ALT tends to be higher than serum AST, serum AST levels tend to be higher than serum ALT levels in a 2:1 ratio or higher in alcoholic liver disease. This can be helpful in differential diagnosis of chronic liver injury when adequate history is not available. An acute cholestatic syndrome may appear, resembling large bile duct obstruction.

The outlook is unpredictable; each bout of hepatitis incurs about a 10% to 20% risk of death. With repeated bouts, cirrhosis develops in about one third of patients within a few years. Alcoholic hepatitis also may be superimposed on established cirrhosis. With proper nutrition and total cessation of alcohol consumption, the alcoholic hepatitis may clear slowly. However, in some patients, the hepatitis persists, despite abstinence, and progresses to cirrhosis.

The manifestations of alcoholic cirrhosis are similar to those of other forms of cirrhosis. Laboratory findings reflect hepatic dysfunction, with elevated serum aminotransferases, hyperbilirubinemia, variable elevation of serum alkaline phosphatase, hypoproteinemia (globulins, albumin, and clotting factors), and anemia. In some instances, liver biopsy may be indicated, since in about 10% to 20% of cases of presumed alcoholic cirrhosis, another disease process is found. Finally, cirrhosis may be clinically silent, discovered only at autopsy or when stress such as infection or trauma tips the balance toward hepatic insufficiency.

The long-term outlook for alcoholics with liver disease is variable. Five-year survival approaches 90% in abstainers who are free of jaundice, ascites, or hematemesis; it drops to 50% to 60% in those who continue to imbibe. In the end-stage alcoholic the proximate causes of death are (1) hepatic coma, (2) massive gastrointestinal hemorrhage, (3) intercurrent infection (to which these patients are predisposed), (4) hepatorenal syndrome following a bout of alcoholic hepatitis, and (5) hepatocellular carcinoma (the risk of developing this tumor in alcoholic cirrhosis is 1% to 6% of cases annually).

KEY CONCEPTS

Alcoholic Liver Disease

- Alcoholic liver disease is a chronic disorder that can give rise to steatosis, alcoholic hepatitis, progressive steatofibrosis and marked derangement of vascular perfusion leading eventually to cirrhosis.
- Consumption of 80 gm/day of alcohol is considered to be the threshold for the development of alcoholic liver disease.
- It may take 10 to 15 years of drinking for the development of cirrhosis, which occurs only in a small proportion of chronic alcoholics.
- The multiple pathologic effects of alcohol include changes in lipid metabolism, decreased export of lipoproteins, and cell injury caused by reactive oxygen species and cytokines.

Metabolic Liver Disease

A distinct group of liver diseases is attributable to disorders of metabolism, either acquired or inherited. The most common acquired metabolic disorder is non-alcoholic fatty liver disease. Among inherited metabolic diseases, hemochromatosis, Wilson disease, and α_1 -antitrypsin deficiency are most prominent. Also included among liver metabolic diseases is neonatal hepatitis, a broad disease category encompassing rare inherited diseases and neonatal infections.

Nonalcoholic Fatty Liver Disease (NAFLD)

NAFLD represents a spectrum of disorders that have in common the presence of hepatic steatosis (fatty liver) in individuals who do not consume alcohol or do so in very small quantities (less than 20 g of ethanol/week). NAFLD has become the most common cause of chronic liver disease

Table 18-6 World Health Organization Criteria for the Metabolic Syndrome

One of	Diabetes mellitus or impaired glucose tolerance or impaired fasting glucose or insulin resistance
and two of:	Blood pressure: $\geq 140/90$ mm Hg Dyslipidemia: triglycerides (TG): ≥ 1.695 mmol/L and high-density lipoprotein cholesterol (HDL-C) ≤ 0.9 mmol/L (male), ≤ 1 mmol/L (female) Central obesity: waist-hip ratio > 0.90 (male); > 0.85 (female), or body mass index > 30 kg/m ² Microalbuminuria: urinary albumin excretion rate of ≥ 20 μ g/min or albumin-to-creatinine ratio ≥ 30 mg/gm

in the United States and in its various forms probably affects 3 to 5% of the population. However, these estimates are approximate, because fatty liver without other complications may not be detected clinically. The term “nonalcoholic steatohepatitis” (or its common acronym NASH) is often used to denote overt clinical features of liver injury, such as elevated serum transaminases, but the designation NAFLD is preferred, with *steatohepatitis* reserved for histologic features of hepatocyte injury already described in the section on alcoholic liver disease.

The histologic hallmarks of NAFLD are most consistently associated with the *metabolic syndrome* (Table 18-6). The epidemic of obesity in the United States and, and its overall, dramatic global increase, has resulted in increasing rates of NAFLD. Prevalence in children has also registered a steady rise. NAFLD contributes to the progression of other liver diseases such as HCV and HBV infection. Increasingly, NAFLD is found to increase the risk for hepatocellular carcinoma, although, unlike in chronic viral hepatitis and alcoholic liver disease, it may often do so in the absence of significant scarring.

The prevalence of NAFLD varies among ethnic groups and probably relates, at least in part, to genetic differences. For example, in the United States, Hispanics have the highest prevalence of NAFLD/NASH, followed by African Americans and Caucasians.

Pathogenesis. Currently available data suggests a two hit model for NAFLD.

- Insulin resistance gives rise to hepatic steatosis.
- Hepatocellular oxidative injury resulting in liver cell necrosis and the inflammatory reactions to it.

The interplay of these two factors is discussed below.

Hepatic steatosis, like obesity in general, arises from an overabundance of calorie rich food, diminished exercise, and genetic/epigenetic mechanisms. Data indicate that individuals with NAFLD eat more fast food and exercise less. High fructose corn syrup, a nearly ubiquitous, inexpensive sweetener in manufactured foods, also appears to promote insulin resistance.

In individuals with established insulin resistance and metabolic syndrome, the visceral adipose tissue not only increases, but also becomes dysfunctional, with reduced production of the lipid hormone, adiponectin, and increased

production of inflammatory cytokines such as TNF- α and IL-6. These changes in turn promote hepatocyte apoptosis. Fat laden cells are highly sensitive to lipid peroxidation products generated by oxidative stress which can damage mitochondrial and plasma membranes, causing apoptosis.

Diminished autophagy also contributes to mitochondrial injury and formation of Mallory-Denk bodies. Kupffer cell production of TNF- α and TGF- β activate stellate cells directly leading to deposition of scar tissue (Fig. 18-5). Stellate cell activation also occurs through the hedgehog signaling pathway in part through natural killer T-cell activation. In fact, the level of hedgehog pathway activity correlates with stage of fibrosis in NAFLD.

MORPHOLOGY

Pathologic steatosis is defined as involving more than 5% of hepatocytes. Small, medium, and large droplets of fat, predominantly triglycerides, accumulate within hepatocytes just as they do in alcoholic steatosis. At the most clinically benign end of the spectrum, there is no appreciable hepatic inflammation, hepatocyte death, or scarring, despite persistent elevation of serum liver enzymes. **NASH almost completely overlaps in its histologic features with alcoholic hepatitis** (Fig. 18-22). In NASH, compared with alcoholic hepatitis, mononuclear cells may be more prominent than neutrophils and Mallory-Denk bodies are often less prominent. Steatofibrosis in NAFLD shows precisely the same features and progression as it does in alcoholic liver disease, although portal fibrosis may be more prominent. Cirrhosis may develop, is often subclinical for years, and, when established, the steatosis or steatohepatitis may be reduced or absent. **Greater than 90% of previously described “cryptogenic cirrhosis” (i.e., cirrhosis of unknown cause) is now thought to represent such “burned out” NAFLD.**

Pediatric NAFLD differs significantly from that seen in adults. Typically children show more diffuse steatosis, portal rather than central fibrosis, and portal and parenchymal mononuclear infiltration, rather than parenchymal neutrophils.

Clinical Features. Clinical course of individuals with NAFLD/NASH are summarized in Figure 18-23. Individuals with simple steatosis are generally asymptomatic. Clinical presentation is often related to other signs and symptoms of the metabolic syndrome, in particular insulin resistance or diabetes mellitus. Imaging studies may reveal fat accumulation in the liver. However, liver biopsy is the most reliable diagnostic tool for NAFLD and NASH, and for assessment of scarring. Viral, autoimmune and other metabolic diseases of the liver must be excluded before the diagnosis can be made. Serum AST and ALT are elevated in about 90% of patients with NASH. Despite the enzyme elevations, patients may be asymptomatic. Others have general symptoms such as fatigue or right-sided abdominal discomfort caused by hepatomegaly. Because of the association between NASH and the metabolic syndrome, cardiovascular disease is a frequent cause of death in patients with NASH. The goal of treating individuals with NASH is to reverse the steatosis and prevent cirrhosis by correcting the underlying risk factors, such as obesity and hyperlipidemia, and to treat insulin resistance. NASH also increases the risk of hepatocellular carcinoma as do other metabolic diseases (discussed later).

KEY CONCEPTS

Nonalcoholic Fatty Liver Disease

- The most common metabolic disorder is nonalcoholic fatty liver disease, which is associated with the metabolic syndrome, obesity, type 2 diabetes mellitus or other impairments of insulin responsiveness, dyslipidemia, and hypertension.
- Nonalcoholic fatty liver disease may show all the changes associated with alcoholic liver disease: steatosis, steatohepatitis, and steatofibrosis, even though the features of steatohepatitis (e.g., hepatocyte ballooning, Mallory-Denk bodies, and neutrophilic infiltration) are often less prominent than they are in alcohol-related injury.

Figure 18-22 Nonalcoholic fatty liver disease. **A**, Liver with mixed small and large fat droplets. **B**, Steatosis and steatofibrosis extending along sinusoids in a chicken wire fence pattern in which individual and clustered hepatocytes are surrounded by thin scars (blue fibers). Note the resemblance to alcoholic steatohepatitis depicted in Fig. 18-19. (Masson trichrome stain.)

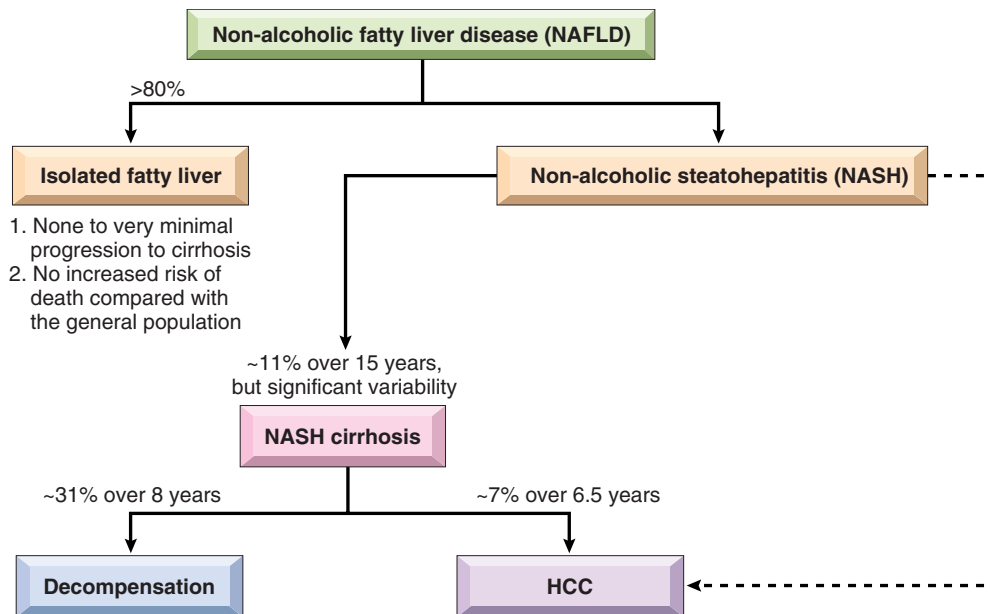

Figure 18-23 Natural history of NAFLD phenotypes. Isolated fatty liver, shows minimal risk for progression to cirrhosis or increased mortality, while non-alcoholic steatohepatitis shows increased overall mortality as well as increased risk for cirrhosis and hepatocellular carcinoma (HCC). DM, Diabetes mellitus.

- Pediatric NAFLD is being increasingly recognized as the obesity epidemic spreads to pediatric age groups, although its histologic features differ somewhat from that seen in adults.

- Because many women do not accumulate clinically relevant amounts of iron within their lifetime, hereditary hemochromatosis affects more males than females (ratio of 5 to 7:1).

Hemochromatosis

Hemochromatosis is caused by excessive iron absorption, most of which is deposited in parenchymal organs such as the liver and pancreas, followed by heart, joints, and endocrine organs. When hemochromatosis results from an inherited disorder, it is referred to as *hereditary hemochromatosis*, of which there are many forms, some more likely than others to lead to overwhelming iron overload. When accumulation occurs as a consequence of parenteral administration of iron, usually in the form of transfusions, or other causes (Table 18-7), it is called as *secondary hemochromatosis*.

As discussed in Chapter 14, the total body iron pool ranges from 2 to 6 gm in normal adults; about 0.5 gm is stored in the liver, 98% of which is in hepatocytes. In the most severe forms of hemochromatosis, total iron accumulation may exceed 50 gm, more than one third of which accumulates in the liver. The following features characterize severe iron overload in the body:

- Fully developed cases exhibit (1) micronodular cirrhosis in all patients; (2) diabetes mellitus in 75% to 80% of patients; and (3) abnormal skin pigmentation in 75% to 80% of patients.
- Iron accumulation in hereditary forms is lifelong but the injury caused by excessive iron is slow and progressive; hence *symptoms usually first appear in the fourth to fifth decades of life in men and later in women since menstrual bleeding counterbalances the accumulation until menopause.*

Pathogenesis. Because there is no regulated iron excretion from the body, the total body content of iron is tightly regulated by intestinal absorption. In *hereditary hemochromatosis*, regulation of intestinal absorption of dietary iron is abnormal, leading to net iron accumulation of 0.5 to 1 gm/year. The disease manifests itself typically after 20 gm of stored

Table 18-7 Classification of Iron Overload

I. Hereditary hemochromatosis
Mutations of genes encoding HFE, transferrin receptor 2 (TfR2), or hepcidin Mutations of genes encoding HJV (hemojuvelin: juvenile hemochromatosis) (Neonatal hemochromatosis)*
II. Hemosiderosis (secondary hemochromatosis)
A. Parenteral iron overload
Transfusions Long-term hemodialysis Aplastic anemia Sickle cell disease Myelodysplastic syndromes Leukemias Iron-dextran injections
B. Ineffective erythropoiesis with increased erythroid activity
β-Thalassemia Sideroblastic anemia Pyruvate kinase deficiency
C. Increased oral intake of iron
African iron overload (Bantu siderosis)
D. Congenital atransferrinemia
E. Chronic liver disease
Alcoholic liver disease Porphyria cutanea tarda
F. Neonatal hemochromatosis

*Neonatal hemochromatosis develops in utero and does not appear to be a hereditary condition.

iron have accumulated. Excessive iron appears to be directly toxic to tissues. Mechanisms of liver injury include (1) lipid peroxidation via iron-catalyzed free radical reactions, (2) stimulation of collagen formation by activation of hepatic stellate cells, and (3) interaction of reactive oxygen species and iron itself with DNA, leading to lethal cell injury and predisposition to HCC. The actions of iron are reversible in cells that are not fatally injured, and removal of excess iron with therapy promotes recovery of tissue function.

The main regulator of iron absorption is the protein hepcidin, encoded by the *HAMP* gene and secreted by the liver (Fig. 18-24). Hepcidin is named for its originally elucidated properties as a hepatocellular protein with bactericidal activities. Transcription of hepcidin is increased by inflammatory cytokines and iron, and decreased by iron deficiency, hypoxia, and ineffective erythropoiesis. Hepcidin binds to the cellular iron efflux channel ferroportin, causing its internalization and proteolysis, thereby inhibiting the release of iron from intestinal cells and

Figure 18-24 A: In normal state HFE, HJV, and TFR2 regulate hepcidin synthesis by hepatocytes maintaining normal circulating hepcidin levels. Hepcidin binds to ferroportin on enterocytes leading to internalization of the complex and ferroportin degradation. This in turn reduces efflux of iron from enterocytes. Through these regulatory interactions normal iron absorption is maintained. **B:** In hereditary hemochromatosis HFE or HJV or TFR2 gene mutations reduce hepcidin synthesis thus diminishing circulating hepcidin. The resulting decreased hepcidin-ferroportin interaction allows for increased ferroportin activity, increased iron efflux from enterocytes, giving rise to systemic iron overload in hereditary hemochromatosis. HFE, HFE protein; HJV, hemojuvelin, TFR1, transferrin receptor 1; TFR2: transferrin receptor 2; DMT1: divalent metal transporter 1.

macrophages. Therefore, hepcidin lowers plasma iron levels. Conversely, a deficiency in hepcidin causes iron overload.

Other proteins involved in iron metabolism, do so by regulating hepcidin levels. These include (1) hemojuvelin (HJV), which is expressed in the liver, heart, and skeletal muscle, (2) transferrin receptor 2 (TFR2), which is highly expressed in hepatocytes, where it mediates the uptake of transferrin-bound iron, and (3) HFE, the product of the hemochromatosis gene. *Decreased hepcidin synthesis caused by mutations in hepcidin, HJV, TFR2, and HFE has a central role in the pathogenesis of hemochromatosis.*

The adult form of hemochromatosis is almost always caused by mutations of HFE; mutation of TFR2 is far less common. The HFE gene is located on the short arm of chromosome 6 at 6p21.3, close to the HLA gene locus; it encodes an HLA class I-like molecule that governs intestinal absorption of dietary iron by regulating hepcidin synthesis. *The most common HFE mutation is a cysteine-to-tyrosine substitution at amino acid 282 (called C282Y).* This mutation, which causes inactivation of the protein, is present in 70% to 100% of the patients diagnosed with hereditary hemochromatosis. *The other common mutation is H63D (histidine at position 63 to aspartate).* The H63D homozygous state and C282Y/H63D compound heterozygous mutations often cause only mild iron accumulation.

The C282Y mutation of the HFE gene is largely confined to white populations of European origin, while the H63D has a worldwide distribution. The frequency of C282Y homozygosity is 0.45% (1 of every 220 persons), and the heterozygous frequency is 11%, making hereditary hemochromatosis one of the most common genetic disorders in humans. However, the penetrance of this disorder is low in patients with the homozygous C282Y mutation, so the genetic change does not lead to clinical disease in all individuals.

Adult hemochromatosis is generally a milder disease than the juvenile form. Mutations of HAMP and HJV cause severe juvenile hemochromatosis.

MORPHOLOGY

Severe hemochromatosis (hereditary or secondary) is characterized principally by (1) **deposition of hemosiderin** in the following organs (in decreasing order of severity) the liver, pancreas, myocardium, pituitary gland, adrenal gland, thyroid and parathyroid glands, joints, and skin; (2) cirrhosis; and (3) pancreatic fibrosis. In the **liver**, iron becomes evident first as golden-yellow hemosiderin granules in the cytoplasm of periportal hepatocytes that stain with Prussian blue (Fig. 18-25). With increasing iron load, there is progressive involvement of the rest of the lobule, along with bile duct epithelium and Kupffer cell pigmentation. Iron is a direct hepatotoxin and inflammation is characteristically absent. In early stages of accumulation, the liver is typically slightly larger than normal, dense, and chocolate brown. Fibrous septa develop slowly, leading ultimately to a small, shrunken liver with a micronodular pattern of cirrhosis. The liver parenchyma in later stages is often dark brown to nearly black due to overwhelming iron accumulation.

Biochemical determination of hepatic tissue iron concentration has been the gold standard for quantitating hepatic iron

Figure 18-25 Hereditary hemochromatosis. In this Prussian blue-stained section, hepatocellular iron appears blue. The parenchymal architecture is normal.

content. In normal individuals, the iron content of liver tissue is less than 1000 μg per gram dry weight of liver. Adult patients with hereditary hemochromatosis exhibit more than 10,000 μg iron per gram dry weight; hepatic iron concentrations in excess of 22,000 μg per gram dry weight are associated with the development of fibrosis and cirrhosis. However, **with newly available genetic testing for these diseases, quantitative assessment of tissue iron content is no longer necessary for confirmation of a suspected diagnosis.**

The **pancreas** becomes intensely pigmented, has diffuse interstitial fibrosis, and may exhibit some parenchymal atrophy. Hemosiderin is found in both the acinar and the islet cells, and sometimes in the interstitial fibrous stroma. The **heart** is often enlarged and has hemosiderin granules within the myocardial fibers, producing a striking brown coloration to the myocardium. A delicate interstitial fibrosis may appear.

Although skin pigmentation is partially attributable to hemosiderin deposition in dermal macrophages and fibroblasts, most of the pigmentation results from increased epidermal melanin production, the mechanism of which is unknown. The combination of these pigments imparts a characteristic slate-gray color to the skin. With hemosiderin deposition in the synovial joint linings, an **acute synovitis** may develop. Excessive deposition of calcium pyrophosphate damages the articular cartilage, producing a disabling polyarthritis referred to as **pseudogout**. The **testes may be small and atrophic**, secondary to a derangement in the hypothalamic-pituitary axis resulting in reduced gonadotropin and testosterone levels.

Clinical Features. The principal manifestations of classic hemochromatosis include **hepatomegaly, abdominal pain, abnormal skin pigmentation (particularly in sun-exposed areas), deranged glucose homeostasis or diabetes mellitus due to destruction of pancreatic islets, cardiac dysfunction (arrhythmias, cardiomyopathy), and atypical arthritis.** In some patients, the presenting complaint is hypogonadism (e.g., amenorrhea in the female, impotence and loss of libido in the male). It is more often a disease of males, for reasons described earlier, and rarely becomes evident before age 40. The classic tetrad of cirrhosis with

hepatomegaly, abnormal skin pigmentation, diabetes mellitus, and cardiac dysfunction might not develop until late in the course of the disease. Death may result from cirrhosis or cardiac disease. *A significant cause of death is hepatocellular carcinoma; the risk is 200-fold greater than in the general population.* Treatment for iron overload does not fully remove the cancer risk presumably because of DNA alterations that occur prior to the time of diagnosis and treatment initiation.

Fortunately, hemochromatosis can be diagnosed long before irreversible tissue damage has occurred. Screening involves demonstration of very high levels of serum iron and ferritin, exclusion of secondary causes of iron overload, and liver biopsy if indicated. *Screening of family members of probands is important.* Heterozygotes also accumulate excessive iron, but not to a level that causes significant tissue damage. Currently most patients with hemochromatosis are diagnosed in the subclinical, precirrhotic stage due to routine serum iron measurements (as part of other diagnostic workup). Treatment by regular phlebotomy steadily depletes tissue iron stores. With treatment, life expectancy is normal.

Neonatal hemochromatosis (also called congenital hemochromatosis) is a disease of unknown origin manifested by severe liver disease and extrahepatic hemosiderin deposition. Neonatal hemochromatosis is not an inherited disease; liver injury, leading to hemosiderin accumulation, occurs in utero, and might be related to maternal alloimmune injury to the fetal liver. Extrahepatic hemosiderin deposition, detected by buccal biopsy, needs to be documented for the correct diagnosis. There is no specific treatment, except for supportive care and liver transplantation in severe cases.

The most common causes of secondary (or acquired) hemochromatosis are disorders associated with ineffective erythropoiesis, such as severe forms of thalassemia (**Chapter 14**) and myelodysplastic syndromes (**Chapter 13**). In these disorders, the excess iron results not only from transfusions, but also from increased absorption. Transfusions alone, when given repeatedly over a period of years (e.g., in patients with chronic hemolytic anemias), can also lead to systemic hemosiderosis and parenchymal organ injury.

Cirrhosis caused by chronic liver diseases in which hepatitis is the predominant form of injury (e.g., chronic viral hepatitis, autoimmune hepatitis) can lead to diminished hepcidin production from loss of hepatocyte mass and, therefore, to cirrhosis-associated increased iron uptake from the gut. However, the increase in stainable iron in alcoholic cirrhosis, cannot be readily explained by decrease in hepcidin production alone. It is suspected that other, yet to be discovered, mechanisms are involved.

Wilson Disease

Wilson disease is an autosomal recessive disorder caused by mutation of the *ATP7B* gene, resulting in impaired copper excretion into bile and a failure to incorporate copper into ceruloplasmin. This disorder is marked by the accumulation of toxic levels of copper in many tissues and organs, principally the liver, brain, and eye. Normally, 40% to 60% of ingested copper (2 to 5 mg/day) is absorbed in

the duodenum and proximal small intestine, and is transported to the portal circulation complexed with albumin and histidine. Free copper dissociates and is taken up by hepatocytes. In the liver copper binds to an α_2 -globulin (apoceruloplasmin) to form *ceruloplasmin*, which is secreted into the blood. Excess copper is transported into the bile. Ceruloplasmin accounts for 90% to 95% of plasma copper. Circulating ceruloplasmin is eventually desialylated, endocytosed by the liver, and degraded within lysosomes, after which the released copper is excreted into bile. This degradation/excretion pathway is the primary route for copper elimination. The estimated total body copper is only 50 to 150 mg.

Pathogenesis. Wilson disease results from mutations in the *ATP7B* gene. Located on chromosome 13, the *ATP7B* gene, encodes a transmembrane copper-transporting ATPase, expressed on the hepatocyte canalicular membrane. More than 300 mutations in the *ATP7B* gene have been identified, but not all cause the disease. *The overwhelming majority of patients are compound heterozygotes containing different mutations on each ATP7B allele.* The overall frequency of mutated alleles is 1:100, and the prevalence of the disease is approximately 1:30,000 to 1:50,000 (approximately 9000 patients in the United States). Deficiency in the *ATP7B* protein causes a decrease in copper transport into bile, impairs its incorporation into ceruloplasmin, and inhibits ceruloplasmin secretion into the blood. These changes cause copper accumulation in the liver and a decrease in circulating ceruloplasmin. The accumulated copper causes toxic liver injury by three mechanisms: 1) Promoting the formation of free radicals by the Fenton reaction (Chapter 2); 2) binding to sulfhydryl groups of cellular proteins; and 3) displacing other metals from hepatic metalloenzymes. Although there is a latent period of variable duration, there may be sudden onset of a severe systemic illness. This is triggered by spillage of non-ceruloplasmin-bound copper from the liver into the circulation, causing hemolysis and pathologic changes at other sites such as the brain, corneas, kidneys, bones, joints, and parathyroids. Concomitantly, urinary excretion of copper markedly increases from its normal miniscule levels.

MORPHOLOGY

The liver often bears the brunt of injury, but the disease may also present as a neurologic disorder. The hepatic changes are variable, ranging from relatively minor to massive damage, and mimic many other disease processes. **Fatty change (steatosis)** may be mild to moderate with focal hepatocyte necrosis. An acute, fulminant hepatitis can mimic acute viral hepatitis. Chronic hepatitis in Wilson disease exhibits moderate to severe inflammation and hepatocyte necrosis, admixed with fatty change and features of steatohepatitis (hepatocyte ballooning with prominent Mallory-Denk bodies). Eventually cirrhosis supervenes.

Excess copper deposition can often be demonstrated by special stains (rhodamine stain for copper, orcein stain for copper-associated protein). Because copper also accumulates in chronic obstructive cholestasis and because histology cannot

reliably distinguish Wilson disease from viral- and drug-induced hepatitis, demonstration of hepatic copper content in excess of 250 μg per gram dry weight is most helpful for making a diagnosis. Unlike in hereditary hemochromatosis, where genetic testing has lessened the need for quantitative metal assessment, the vast range of genetic alterations in Wilson disease means that genetic testing is not yet a primary diagnostic modality; with the advent of next generation sequencing, however, this is likely to change in the near future.

Toxic injury to the brain primarily affects the basal ganglia, particularly the putamen, which shows atrophy and even cavitation. Nearly all patients with neurologic involvement develop eye lesions called **Kayser-Fleischer rings**, green to brown deposits of copper in Descemet membrane in the limbus of the cornea.

Clinical Features. The age at onset and the clinical presentation of Wilson disease are extremely variable (average age is 11.4 years), but the disorder usually manifests in affected individuals between 6 and 40 years of age. Initial presentation may either be with acute or chronic liver disease. Neurologic involvement presents as movement disorders (tremor, poor coordination, chorea or choreoathetosis) or rigid dystonia (spastic dystonia, mask like facies, rigidity and gait disturbances); these symptoms may be confused with Parkinsonism. Patients may also have psychiatric symptoms such as depression, phobias, compulsive behavior, and labile mood. Hemolytic anemia may occur due to toxicity of copper to red cell membranes. *The biochemical diagnosis of Wilson disease is based on a decrease in serum ceruloplasmin, an increase in hepatic copper content (the most sensitive and accurate test), and increased urinary excretion of copper (the most specific screening test).* Serum copper levels are of no diagnostic value, since they may be low, normal, or elevated, depending on the stage of evolution of the disease. Demonstration of Kayser-Fleischer rings further favors the diagnosis. Early recognition and long-term copper chelation therapy (with D-penicillamine or Trientine) or zinc-based therapy (which blocks uptake of copper in the gut) has dramatically altered the usual progressive downhill course. Individuals with hepatitis or unmanageable cirrhosis require liver transplantation, which can be curative.

α_1 -Antitrypsin Deficiency

α_1 -Antitrypsin deficiency is an autosomal recessive disorder of protein folding marked by very low levels of circulating α_1 -Antitrypsin (α_1 AT). The major function of this protein is the inhibition of proteases, particularly neutrophil elastase, cathepsin G, and proteinase 3, which are normally released from neutrophils at sites of inflammation. α_1 AT deficiency leads to the development of pulmonary emphysema, because the activity of destructive proteases is not inhibited (Chapter 15). It also causes liver disease as a consequence of hepatocellular accumulation of the misfolded protein. Cutaneous necrotizing panniculitis also occurs in a minor subset of patients.

α_1 AT is a small 394-amino acid plasma glycoprotein synthesized predominantly by hepatocytes. It is a member of the serine protease inhibitor (serpin) family. The gene, located on chromosome 14, is very polymorphic, and at

Figure 18-26 α_1 -Antitrypsin deficiency. **A**, Periodic acid–Schiff (PAS) stain after diastase digestion of the liver, highlighting the characteristic magenta cytoplasmic granules. **B**, Electron micrograph showing endoplasmic reticulum dilated by aggregates of misfolded protein.

least 75 α_1 AT forms have been identified, denoted alphabetically by their relative migration on an isoelectric gel. The general notation is “Pi” for “protease inhibitor” and an alphabetic letter for the position on the gel; two letters denote the genotype of an individual’s two alleles. The most common genotype is PiMM, occurring in 90% of individuals (the “wild-type”). Most allelic variants show substitutions in the polypeptide chain but produce normal levels of functional α_1 AT. Some deficiency variants, including the PiS variant, result in a moderate reduction in serum concentrations of α_1 AT without clinical manifestations. Rare variants termed *Pi-null* have no detectable serum α_1 AT.

The most common clinically significant mutation is PiZ; homozygotes for the PiZZ protein have circulating α_1 AT levels that are only 10% of normal. These individuals are at high risk for developing clinical disease. Expression of alleles is autosomal codominant, and consequently, PiMZ heterozygotes have intermediate plasma levels of α_1 AT. Among people of northern European descent, the PiS frequency is 6% and the PiZ frequency is 4%; the PiZZ state affects 1 in 1800 live births. Because of its early presentation with liver disease, α_1 AT deficiency is the most commonly diagnosed inherited hepatic disorder in infants and children.

Pathogenesis. With most allelic variants, the protein is synthesized and secreted normally. Deficiency variants show a selective defect in migration of protein from endoplasmic reticulum to Golgi apparatus; this is particularly characteristic of the PiZ polypeptide, resulting from a single amino acid substitution of Glu342 to Lys342. The mutant polypeptide (α_1 AT-Z) is abnormally folded and polymerized, creating endoplasmic reticulum stress and triggering the unfolded protein response, a signaling cascade that may lead to apoptosis (Chapter 2). All individuals with the PiZZ genotype accumulate α_1 AT-Z in the endoplasmic reticulum of hepatocytes, but only 10% to 15% of PiZZ individuals develop overt clinical liver disease. Other genetic factors or environmental factors are thus posited to play a role in the development of liver disease.

MORPHOLOGY

α_1 AT deficiency is characterized by the presence of round-to-oval **cytoplasmic globular inclusions in hepatocytes**, which on routine hematoxylin and eosin stains are acidophilic, but are strongly periodic acid–Schiff (PAS)-positive and diastase-resistant (Fig. 18-26). The globules are also present, but in diminished size and number in the PiMZ and PiSZ genotypes. Periportal hepatocytes contain the mutant proteins in early and mild forms of the disease with accumulation involving progressively more central hepatocytes with duration and more severe forms like the PiZZ variant. However, the number of globule-containing hepatocytes in a patient’s liver is not correlated with the severity of pathologic findings.

The hepatic pathology associated with PiZZ homozygosity is extremely varied, ranging from neonatal hepatitis without or with cholestasis and fibrosis (discussed later), to childhood cirrhosis, to a smoldering chronic hepatitis or cirrhosis that becomes apparent only late in life. The diagnostic α_1 AT globules may be absent in the young infant, although steatosis may be present as a tip-off to the possibility of α_1 AT deficiency.

Clinical Features. Neonatal hepatitis with cholestatic jaundice appears in 10% to 20% of newborns with the deficiency. In adolescence, presenting symptoms may be related to hepatitis, cirrhosis or pulmonary disease. Attacks of hepatitis may subside with apparent complete recovery, or they may become chronic and lead progressively to cirrhosis. Alternatively, the disease may remain silent until cirrhosis appears in middle to later life. Hepatocellular carcinoma develops in 2% to 3% of PiZZ adults, usually, but not always, in the setting of cirrhosis. The treatment, indeed the cure, for severe hepatic disease is orthotopic liver transplantation. In patients with pulmonary disease the single most important preventive measure is avoidance of cigarette smoking, because smoking markedly accelerates emphysema and the destructive lung disease associated with α_1 AT deficiency.

KEY CONCEPTS

Inherited Metabolic Liver Disease

- The inherited metabolic diseases include hemochromatosis, Wilson disease, and α_1 -antitrypsin deficiency.
- **Hereditary hemochromatosis** is caused by a mutation in the *HFE* gene, whose product is involved in intestinal iron uptake by its effect on hepcidin levels. It is characterized by accumulation of iron in liver and pancreas.
- **Wilson disease** is caused by a mutation in the metal ion transporter *ATP7B*, which results in accumulation of copper in the liver, brain (particularly basal ganglia), and eyes (“Kayser-Fleisher rings”).
 - Wilson disease effects on the liver are protean, presenting as acute massive hepatic necrosis, fatty liver disease, or chronic hepatitis and cirrhosis.
- **α_1 -Antitrypsin deficiency** is a disease of protein misfolding that results in impaired secretion of α_1 Antitrypsin into the serum.
 - The Z variant of α_1 -Antitrypsin is the most likely to impair secretion by hepatocytes and cause disease, particularly when homozygous, that is, the *PiZZ* genotype; the main consequences are pulmonary emphysema caused by increased elastase activity and liver injury caused by the accumulation of abnormal α_1 -Antitrypsin.

Cholestatic Diseases

Hepatic bile serves two major functions: (1) the emulsification of dietary fat in the lumen of the gut through the detergent action of bile salts, and (2) the elimination of bilirubin, excess cholesterol, xenobiotics, and other waste products that are insufficiently water-soluble to be excreted into urine. Tissue deposition of bile becomes clinically evident as yellow discoloration of the skin and sclera (*jaundice* and *icterus*, respectively) due to retention of bilirubin, and as *cholestasis*, when there is systemic retention of not only bilirubin but also other solutes eliminated in bile.

Jaundice occurs when there is bilirubin overproduction, hepatitis, or obstruction of the flow of bile, any of which can disturb the equilibrium between bilirubin production and clearance. To understand the pathophysiology of jaundice it is important first to become familiar with the major aspects of bile formation and metabolism. The metabolism of bilirubin by the liver consists of four separate but interrelated events: uptake from the circulation; intracellular storage; conjugation with glucuronic acid; and biliary excretion. These are described next.

Bilirubin and Bile Formation

Bilirubin is the end product of heme degradation (Fig. 18-27). The majority of daily production (0.2 to 0.3 gm, 85%) is derived from breakdown of senescent red cells by the mononuclear phagocytic system, especially in the spleen, liver, and bone marrow. Most of the remainder (15%) of bilirubin is derived from the turnover of hepatic heme or hemoproteins (e.g., the P-450 cytochromes) and from premature destruction of red cell precursors in the bone marrow (Chapter 13). Whatever the source,

Figure 18-27 Bilirubin metabolism and elimination. (1) Normal bilirubin production from heme (0.2 to 0.3 gm/day) is derived primarily from the breakdown of senescent circulating erythrocytes. (2) Extrahepatic bilirubin is bound to serum albumin and delivered to the liver. (3) Hepatocellular uptake and (4) glucuronidation in the endoplasmic reticulum generates bilirubin monoglucuronides and diglucuronides, which are water soluble and readily excreted into bile. (5) Gut bacteria deconjugate the bilirubin and degrade it to colorless urobilinogens. The urobilinogens and the residue of intact pigments are excreted in the feces, with some reabsorption and excretion into urine.

intracellular heme oxygenase converts heme to biliverdin (step 1 in Fig. 18-27), which is immediately reduced to bilirubin by biliverdin reductase. Bilirubin thus formed outside the liver is released and bound to serum albumin (step 2). Albumin binding is necessary to transport bilirubin because bilirubin is virtually insoluble in aqueous solutions at physiologic pH. Hepatic processing of bilirubin involves carrier-mediated uptake at the sinusoidal membrane (step 3), conjugation with one or two molecules of glucuronic acid by bilirubin uridine diphosphate (UDP)

glucuronyl transferase (UGT1A1, step 4) in the endoplasmic reticulum, and excretion of the water-soluble, nontoxic bilirubin glucuronides into bile. Most bilirubin glucuronides are deconjugated in the gut lumen by bacterial β -glucuronidases and degraded to colorless urobilinogens (step 5). The urobilinogens and the residue of intact pigment are largely excreted in feces. Approximately 20% of the urobilinogens formed are reabsorbed in the ileum and colon, returned to the liver, and reexcreted into bile. A small amount of reabsorbed urobilinogen is excreted in the urine.

Two thirds of the organic materials in bile are bile salts, which are formed by the conjugation of bile acids with taurine or glycine. Bile acids, the major catabolic products of cholesterol, are a family of water-soluble sterols with carboxylated side chains. The primary human bile acids are cholic acid and chenodeoxycholic acid. Bile acids in bile salts are highly effective detergents. Their primary physiologic role is to solubilize water-insoluble lipids secreted by hepatocytes into bile, and also to solubilize dietary lipids in the gut lumen. Ninety-five percent of secreted bile acids, conjugated or unconjugated, are reabsorbed from the gut lumen and recirculate to the liver (*enterohepatic circulation*), thus helping to maintain a large endogenous pool of bile acids for digestive and excretory purposes.

Pathophysiology of Jaundice

Both unconjugated bilirubin and conjugated bilirubin (bilirubin glucuronides) may accumulate systemically. There are two important pathophysiologic differences between the two forms of bilirubin. Unconjugated bilirubin is virtually insoluble in water at physiologic pH and exists in tight complexes with serum albumin. This form cannot be excreted in the urine even when blood levels are high. Normally, a very small amount of unconjugated bilirubin is present as an albumin-free anion in plasma. This fraction of unbound bilirubin may diffuse into tissues, particularly the brain in infants, and produce toxic injury. The unbound plasma fraction may increase in severe hemolytic disease or when drugs displace bilirubin from albumin. Hence, hemolytic disease of the newborn (erythroblastosis fetalis) may lead to accumulation of unconjugated bilirubin in the brain, which can cause severe neurologic damage, referred to as *kernicterus* (Chapter 10). In contrast, conjugated bilirubin is water-soluble, nontoxic, and only loosely bound to albumin. Because of its solubility and weak association with albumin, excess conjugated bilirubin in plasma can be excreted in urine.

Serum bilirubin levels in the normal adult vary between 0.3 and 1.2 mg/dL, and the rate of systemic bilirubin production is equal to the rates of hepatic uptake, conjugation, and biliary excretion. Jaundice becomes evident when the serum bilirubin levels rise above 2 to 2.5 mg/dL; levels as high as 30 to 40 mg/dL can occur with severe disease. Mechanisms underlying jaundice are summarized in Table 18-8. Although more than one mechanism may be operative, generally one predominates, so knowledge of the major form of plasma bilirubin is of value in evaluating possible causes of hyperbilirubinemia.

The following two conditions result from specific defects in hepatocellular bilirubin metabolism.

Table 18-8 Causes of Jaundice

Predominantly Unconjugated Hyperbilirubinemia
Excess production of bilirubin
Hemolytic anemias
Resorption of blood from internal hemorrhage (e.g., alimentary tract bleeding, hematomas)
Ineffective erythropoiesis (e.g., pernicious anemia, thalassemia)
Reduced hepatic uptake
Drug interference with membrane carrier systems
Some cases of Gilbert syndrome
Impaired bilirubin conjugation
Physiologic jaundice of the newborn (decreased UGT1A1 activity, decreased excretion)
Breast milk jaundice (β -glucuronidases in milk)
Genetic deficiency of UGT1A1 activity (Crigler-Najjar syndrome types I and II)
Gilbert syndrome
Diffuse hepatocellular disease (e.g., viral or drug-induced hepatitis, cirrhosis)
Predominantly Conjugated Hyperbilirubinemia
Deficiency of canalicular membrane transporters (Dubin-Johnson syndrome, Rotor syndrome)
Impaired bile flow from duct obstruction or autoimmune cholangiopathies
<small>UGT1A1, Uridine diphosphate-glucuronyltransferase family, peptide A1</small>

Neonatal Jaundice. Because the hepatic machinery for conjugating and excreting bilirubin does not fully mature until about 2 weeks of age, almost every newborn develops transient and mild unconjugated hyperbilirubinemia, termed neonatal jaundice or *physiologic jaundice of the newborn*. This may be exacerbated by breastfeeding, as a result of the presence of bilirubin-deconjugating enzymes in breast milk. Nevertheless, sustained jaundice in the newborn is abnormal (discussed later).

Hereditary Hyperbilirubinemias. Multiple genetic mutations can cause hereditary hyperbilirubinemia (Table 18-9). For example, the hepatic conjugating enzyme UGT1A1 is a product of the *UGT1A1* gene located on chromosome 2q37. It is a member of a family of enzymes that catalyze the glucuronidation of an array of substrates such as steroid hormones, carcinogens, and drugs. In humans, UGT1A1, generated from the *UGT1A1* gene, is the only isoform responsible for bilirubin glucuronidation. Mutations of *UGT1A1* cause hereditary unconjugated hyperbilirubinemias: *Crigler-Najjar syndrome types I and II* and *Gilbert syndrome*. Crigler-Najjar syndrome type 1 is caused by severe UGT1A1 deficiency and is fatal around the time of birth, while in Crigler-Najjar type II and Gilbert syndrome there is some UGT1A1 activity and the phenotypes are much milder. In contrast, *Dubin-Johnson syndrome* and *Rotor syndrome* result from other defects that lead to conjugated hyperbilirubinemia. Both are autosomal recessive disorders and innocuous.

Cholestasis

Cholestasis is caused by impaired bile formation and bile flow that gives rise to accumulation of bile pigment in the hepatic parenchyma. It can be caused by extrahepatic or intrahepatic obstruction of bile channels, or by defects in hepatocyte bile secretion. Patients may have jaundice, pruritus, skin xanthomas (focal accumulation of

Table 18-9 Hereditary Hyperbilirubinemias

Disorder	Inheritance	Defects in Bilirubin Metabolism	Liver Pathology	Clinical Course
Unconjugated Hyperbilirubinemia				
Crigler-Najjar syndrome type I	Autosomal recessive	Absent UGT1A1 activity	None	Fatal in neonatal period
Crigler-Najjar syndrome type II	Autosomal dominant with variable penetrance	Decreased UGT1A1 activity	None	Generally mild, occasional kernicterus
Gilbert syndrome	Autosomal recessive	Decreased UGT1A1 activity	None	Innocuous
Conjugated Hyperbilirubinemia				
Dubin-Johnson syndrome	Autosomal recessive	Impaired biliary excretion of bilirubin glucuronides due to mutation in canalicular multidrug resistance protein 2 (MRP2)	Pigmented cytoplasmic globules	Innocuous
Rotor syndrome	Autosomal recessive	Decreased hepatic uptake and storage? Decreased biliary excretion?	None	Innocuous

UGT1A1, Uridine diphosphate-glucuronyltransferase family, peptide A1

cholesterol), or symptoms related to intestinal malabsorption, including nutritional deficiencies of the fat-soluble vitamins A, D, or K. A characteristic laboratory finding is elevated serum alkaline phosphatase and γ -glutamyl transpeptidase (GGT), enzymes present on the apical (canalicular) membranes of hepatocytes and bile duct epithelial cells.

MORPHOLOGY

The morphologic features of cholestasis depend on its severity, duration, and underlying cause. Common to both obstructive and nonobstructive cholestasis is the accumulation of bile pigment within the hepatic parenchyma (Fig. 18-28A, B). Elongated green-brown plugs of bile are visible in dilated bile canaliculi (Fig. 18-28C). Rupture of canaliculi leads to extravasation of bile, which is quickly phagocytosed by Kupffer cells. Droplets of bile pigment also accumulate within hepatocytes, which can take on a fine, foamy appearance, so called “feathery degeneration.”

Large Bile Duct Obstruction

The most common cause of bile duct obstruction in adults is extrahepatic cholelithiasis (gallstones) followed by malignancies of the biliary tree or head of the pancreas, and strictures resulting from previous surgical procedures. Obstructive conditions in children include biliary atresia, cystic fibrosis, choledochal cysts and syndromes in which there are insufficient intrahepatic bile ducts. The initial morphologic features of cholestasis (described below) are entirely reversible with correction of the obstruction. Prolonged obstruction can lead to biliary cirrhosis, described later.

Subtotal or intermittent obstruction may promote *ascending cholangitis*, a secondary bacterial infection of the biliary tree that aggravates the inflammatory injury. Enteric organisms such as coliforms and enterococci are common culprits. Cholangitis usually presents with fever, chills, abdominal pain, and jaundice. *The most severe form of cholangitis is suppurative cholangitis, in which purulent bile fills and distends bile ducts.* Since sepsis rather than cholestasis tends to dominate this potentially grave process, prompt diagnostic evaluation and intervention are imperative.

MORPHOLOGY

Acute biliary obstruction, either intrahepatic or extrahepatic, causes distention of upstream bile ducts, which often become dilated. In addition, bile ductules proliferate at the portal-parenchymal interface, accompanied by stromal edema and infiltrating neutrophils (Fig. 18-28B and 18-29). These labyrinthine ductules reabsorb secreted bile salts, serving to protect the downstream obstructed bile ducts from their toxic detergent action. Indeed, **the histologic hallmark of ascending cholangitis is the influx of these periductular neutrophils directly into the bile duct epithelium and lumen** (Fig. 18-30).

Left uncorrected, secondary inflammation resulting from **chronic biliary obstruction** and ductular reactions initiate periportal fibrosis, eventually leading to hepatic scarring and nodule formation, generating **secondary or obstructive biliary cirrhosis** (Fig. 18-31). Cholestatic features in the parenchyma may be severe, with extensive **feathery degeneration of periportal hepatocytes**, cytoplasmic swelling often with **Mallory-Denk bodies** (differing from those in alcohol-induced liver disease and non-alcoholic fatty liver disease by their periportal predominance), and formation of **bile infarcts** from detergent effects of extravasated bile. However, once regenerative nodules have formed, bile stasis may become less conspicuous. **Ascending cholangitis may be superimposed on this chronic process as well, sometimes triggering acute-on-chronic liver failure.**

Since extrahepatic biliary obstruction is frequently amenable to surgical alleviation, correct and prompt diagnosis is imperative. In contrast, cholestasis due to diseases of the intrahepatic biliary tree or hepatocellular secretory failure (collectively termed intrahepatic cholestasis) is not benefited by surgery (short of transplantation), and the patient's condition may be worsened by an operative procedure. *There is thus some urgency in making a correct diagnosis of the cause of jaundice and cholestasis.*

Cholestasis of Sepsis

Sepsis may affect the liver by several mechanisms (1) through direct effects of intrahepatic bacterial infection (e.g., abscess formation or bacterial cholangitis), (2)

Figure 18-28 Cholestasis. **A**, Morphologic features of cholestasis (right) and comparison with normal liver (left). Cholestatic hepatocytes (1) are enlarged with dilated canalicular spaces (2). Apoptotic cells (3) may be seen, and Kupffer cells (4) frequently contain regurgitated bile pigments. **B**, Intracellular cholestasis showing the bile pigments in the cytoplasm. **C**, Bile plug (arrow) showing the expansion of bile canaliculus by bile.

ischemia relating to hypotension caused by sepsis (particularly when the liver is cirrhotic), or (3) in response to circulating microbial products. The last mentioned is most likely to lead to the cholestasis of sepsis, particularly when the systemic infection is due to gram-negative organisms. The most common form is *canicular cholestasis*, with bile plugs within predominantly centrilobular canaliculi. This entity may be associated with activated Kupffer cells and

Figure 18-29 Acute large duct obstruction. There is marked edema of the portal tract stroma (white spaces) and a ductular reaction with admixed neutrophils at the interface between portal tract and hepatocellular parenchyma.

mild portal inflammation, but hepatocyte necrosis is scant or absent. *Ductular cholestasis* is a more ominous finding, wherein dilated canals of Hering and bile ductules at the interface of portal tracts and parenchyma become dilated and contain obvious bile plugs (Fig. 18-32). This change, which is not a typical feature of biliary obstruction, despite the appearance of bile in large, dilated ductules, often accompanies or even precedes the development of septic shock.

Primary Hepatolithiasis

Hepatolithiasis is a disorder of intrahepatic gallstone formation that leads to repeated bouts of ascending cholangitis, progressive inflammatory destruction of hepatic parenchyma, and predisposes to biliary neoplasia. The disease has a high prevalence in East Asia, but elsewhere is rare. Previously this disease has been called *recurrent*

Figure 18-30 Ascending cholangitis. Individuals with large bile duct obstruction risk bacterial infections of the static bile within the biliary tree. Neutrophils are then seen within the bile duct epithelial lining and within the lumen.

Figure 18-31 Biliary cirrhosis. **A**, Sagittal section through the liver demonstrates the nodularity (most prominent at the right) and bile staining of end-stage biliary cirrhosis. **B**, Unlike other forms of cirrhosis, nodules of liver cells in biliary cirrhosis are often not round but irregular, like jigsaw puzzle shapes.

pyogenic cholangitis focusing on its most common clinical findings and *oriental cholangitis* based on its ethnic predilection, but the underlying disease is one of stone formation, thus the currently accepted name, *hepatolithiasis*. There are regional differences regarding the composition of stones, but the consequences are largely the same.

MORPHOLOGY

Hepatolithiasis has **pigmented calcium bilirubinate stones** in distended intrahepatic bile ducts (Fig. 18-33). The ducts show chronic inflammation, mural fibrosis, and peribiliary gland hyperplasia, all in the absence of extrahepatic duct obstruction. Biliary dysplasia may be seen and may evolve to invasive cholangiocarcinoma.

Clinical Features. Individuals may present with repeated episodes of cholangitis due to secondary infections of the

Figure 18-32 Ductular cholestasis of sepsis. Large, dark, bile concretions within markedly dilated canals of Hering and ductules at the portal-parenchymal interface. (Courtesy Dr. Jay Lefkowitz, Columbia University College of Physicians and Surgeons, New York.)

involved ducts, marked by fever and abdominal pain. Due to repeated rounds of inflammation, parenchymal collapse and scarring, the disease sometimes presents with a mass-like lesion mistaken for malignancy and is thus sometimes diagnosed at resection. This disease seems to increase the risk of cholangiocarcinoma by unknown mechanisms.

Neonatal Cholestasis

Prolonged conjugated hyperbilirubinemia in the neonate, termed neonatal cholestasis affects approximately 1 in 2500 live births. Since physiologic jaundice of the new born abates by two weeks, infants who have jaundice beyond 14-21 days after birth should be evaluated for neonatal cholestasis. The major causes are (1) cholangiopathies, primarily *biliary atresia* (discussed later), and (2) a variety of disorders causing conjugated hyperbilirubinemia in the neonate, collectively referred to as *neonatal hepatitis*.

Neonatal hepatitis is not a specific entity, nor are the disorders necessarily inflammatory. Instead, the finding of

Indian childhood cirrhosis
Ideopathic neonatal hepatitis

neonatal cholestasis should evoke a diligent search for recognizable toxic, metabolic, and infectious liver diseases (Table 18-10). With greater awareness of etiology and better diagnostic tools, *idiopathic neonatal hepatitis* constitutes only 10% to 15% of cases of neonatal hepatitis.

Differentiation of biliary atresia from nonobstructive neonatal cholestasis is very important, since definitive treatment of biliary atresia requires surgical intervention (Kasai procedure), whereas surgery may adversely affect the clinical course of a child with other disorders. Fortunately, discrimination can be made with clinical data in about 90% of cases, without liver biopsy. In 10% of cases, liver biopsy may be critical for distinguishing neonatal hepatitis from an identifiable cholangiopathy. Affected infants have jaundice, dark urine, light or acholic stools, and hepatomegaly. Variable degrees of hepatic synthetic dysfunction, such as hypoprothrombinemia, may be present.

MORPHOLOGY

The morphologic features of neonatal hepatitis (Fig. 18-34) include lobular disarray with focal liver cell apoptosis and necrosis. There is panlobular **giant-cell transformation** of hepatocytes; prominent hepatocellular and canalicular cholestasis; mild mononuclear infiltration of the portal areas; reactive changes in Kupffer cells; and extramedullary hematopoiesis. This predominantly parenchymal pattern of injury may blend imperceptibly into a ductal pattern of injury, with ductular reaction and fibrosis of portal tracts. In these cases distinction from an obstructive biliary atresia may therefore be difficult.

Biliary Atresia

Biliary atresia is defined as a complete or partial obstruction of the lumen of the extrahepatic biliary tree within the first 3 months of life. A major contributor to neonatal cholestasis, worthy of separate mention, it represents one

third of infants with neonatal cholestasis. Although the definition for the disease is based on extrahepatic biliary obstruction, progressive inflammation and fibrosis are not necessarily confined to these locales; in some patients there is also progressive loss of intrahepatic ducts. Biliary atresia is the single most frequent cause of death from liver disease in early childhood and accounts for 50% to 60% of children referred for liver transplantation.

Pathogenesis. Two major forms of biliary atresia are recognized based on the presumed timing of luminal obliteration. The *fetal form* accounts for as many as 20% of cases and is commonly associated with other anomalies resulting from ineffective establishment of laterality of thoracic and abdominal organs during development. These include situs inversus malrotation of abdominal viscera, interrupted inferior vena cava, polysplenia, and congenital heart disease. The presumed cause is aberrant intrauterine development of the extrahepatic biliary tree.

Much more common is the *perinatal form* of biliary atresia, in which a presumed normally developed biliary tree is destroyed following birth. The etiology of perinatal biliary atresia remains unknown; viral infection and autoimmune reactions are leading suspects. Reovirus, rotavirus, and cytomegalovirus have been implicated in some cases. Biliary atresia with organ malformations has genetic basis.

MORPHOLOGY

The salient features of biliary atresia include **inflammation and fibrosing stricture of the hepatic or common bile ducts**; in some individuals, periductular inflammation also progresses into the intrahepatic bile ducts leading, additionally, to progressive destruction of the intrahepatic biliary tree. On liver biopsy, florid features of extrahepatic biliary obstruction as described earlier are evident in about two thirds of cases. In the remainder, inflammatory destruction of intrahepatic ducts leads to duct paucity, often without the accompanying ductular reactions, edema and neutrophils characteristic of obstruction. When biliary atresia is unrecognized or uncorrected, cirrhosis develops within 3 to 6 months of birth.

Figure 18-34 Neonatal hepatitis. Note the multinucleated giant hepatocytes.

There is considerable variability in the anatomy of biliary atresia. When the disease is limited to the common duct (type I) or right and/or left hepatic bile ducts (type II), the disease is surgically correctable (Kasai procedure). Unfortunately, 90% of patients have type III biliary atresia, in which there is also obstruction of bile ducts at or above the porta hepatis. These cases are not correctable, since there are no patent bile ducts amenable to surgical anastomosis. Moreover, in most patients, bile ducts within the liver are initially patent, but then are progressively destroyed.

Clinical Features. Infants with biliary atresia present with neonatal cholestasis, but exhibit normal birth weight and postnatal weight gain. There is a slight female preponderance. Initially normal stools change to acholic stools as the disease evolves. At the time of presentation, serum bilirubin values are usually in the range of 6 to 12 mg/dL, with only moderately elevated aminotransferase and alkaline phosphatase levels. The success of surgical resection and bypass of the biliary tree is limited by ascending cholangitis and/or intrahepatic progression of the disease. Liver transplantation remains the primary hope for salvage of these young patients. Without surgical intervention, death usually occurs within 2 years of birth.

Autoimmune Cholangiopathies

This section discusses the two main autoimmune disorders of intrahepatic bile ducts: primary biliary cirrhosis (PBC) and primary sclerosing cholangitis (PSC). The features of these two conditions are contrasted in Table 18-11. It should be noted that intrahepatic bile ducts are frequently damaged as part of other liver diseases, including

Table 18-11 Main Features of Primary Biliary Cirrhosis and Primary Sclerosing Cholangitis

Parameter	Primary Biliary Cirrhosis	Primary Sclerosing Cholangitis
Age	Median age 50 years (30 to 70)	Median age 30 years
Gender	90% female	70% male
Clinical course	Progressive	Unpredictable but progressive
Associated conditions	Sjögren syndrome (70%) Scleroderma (5%) Thyroid disease (20%)	Inflammatory bowel disease (70%) Pancreatitis ($\leq 25\%$) Idiopathic fibrosing diseases (retroperitoneal fibrosis)
Serology	95% AMA-positive 50% ANA-positive 40% ANCA-positive	0-5% AMA-positive (low titer) 6% ANA-positive 65% ANCA-positive
Radiology	Normal	Strictures and beading of large bile ducts; pruning of smaller ducts
Duct lesion	Florid duct lesions and loss of small ducts only	Inflammatory destruction of extrahepatic and large intrahepatic ducts; fibrotic obliteration of medium and small intrahepatic ducts

AMA, Antimitochondrial antibody; ANA, antinuclear antibody; ANCA, antineutrophil cytoplasmic antibody.

viral hepatitis, drug- or toxin-induced liver injury, liver transplantation, and graft-versus-host disease that follows hematopoietic stem cell transplantation.

Primary Biliary Cirrhosis (PBC)

PBC is an autoimmune disease characterized by nonsuppurative, inflammatory destruction of small and medium-sized intrahepatic bile ducts. Large intrahepatic ducts and the extrahepatic biliary tree are not involved. Most patients are diagnosed in the early stages of disease when cirrhosis is a distant possibility. Moreover, not all end-stage PBC is fully cirrhotic. Thus, the name is a misnomer for many patients. At best this name leads to confusion, at worst patients think they have an imminently fatal disease requiring transplantation, a fate that is not, in fact, the norm.

PBC is primarily a disease of middle-aged women, with a female predominance of 9:1. Occurring between the ages of 30 and 70 years, its peak incidence is between 40 and 50 years of age. The disease is most prevalent in Northern European countries (England and Scotland) and the Northern United States (Minnesota) where the prevalence is as high as 400 cases per million. Recent increases in incidence and prevalence along with geographic clustering suggest that genetic and environmental factors are important in its pathogenesis. Family members of PBC patients have an increased risk for development of the disease.

Pathogenesis. PBC is thought to be an autoimmune disorder, but as with other autoimmune diseases, the triggers that initiate PBC are unknown. *Antimitochondrial antibodies are the most characteristic laboratory finding in PBC.* They recognize the E2 component of the pyruvate dehydrogenase complex (PDC-E2). PDC-E2-specific T cells are also present in these patients, further supporting the notion of an immune-mediated process. Other findings suggestive of altered immunity include aberrant expression of MHC class II molecules on bile duct epithelial cells, accumulation of autoreactive T cells around bile ducts, and antibodies against other cellular components (nuclear pore proteins, and centromeric proteins, among others).

MORPHOLOGY

Interlobular bile ducts are actively destroyed by lymphoplasmacytic inflammation with or without granulomas (the florid duct lesion) (Fig. 18-35). Some biopsy specimens, however, show only absence of bile ducts in portal tracts. The disease is quite patchy in distribution; it is common to see a single bile duct under immune attack in one level of a biopsy specimen, while deeper levels, less than a millimeter away, remain unaffected. Ductular reactions follow duct injury, and these in turn participate in the development of portal-portal septal fibrosis (Fig. 18-36).

In patients who follow a classic path to end stage, there is increasingly widespread duct loss, slowly leading to cirrhosis and, in the end stages, to profound cholestasis (Fig. 18-37). The bile accumulation in such cholestasis is not centrilobular, unlike in drug-induced or sepsis-associated cholestasis, but is periportal/periseptal. It is associated with feathery degeneration and ballooned, bile-stained hepatocytes, often with prominent

Figure 18-35 Primary biliary cirrhosis. A portal tract is markedly expanded by an infiltrate of lymphocytes and plasma cells surrounding a destructive granulomatous reaction centered on a bile duct (the "florid duct lesion").

Mallory-Denk bodies, as seen in chronic duct obstruction. Such end-stage livers show established cirrhosis and intense green pigmentation, matching the patient's icteric state.

Alternatively, some patients develop prominent portal hypertension rather than severe cholestasis. In these individuals there is widespread nodularity without the surrounding scar tissue seen in cirrhosis—a feature called nodular regenerative hyperplasia. Why this takes place in a disease that appears to be primarily biliary in nature is not understood.

In both cases, with little hepatocyte loss and often regenerative hyperplasia, there is **marked hepatomegaly**, a point of distinction from the shrunken, end-stage cirrhotic livers of chronic hepatitis, alcoholism, and non-alcoholic fatty liver disease.

Figure 18-36 Ductular reaction (arrows) in primary biliary cirrhosis. In the earlier stages of disease, these structures may help maintain bile flow past destroyed segments of biliary tree, but later they may contribute to subsequent scarring.

Figure 18-37 Primary biliary cirrhosis. This sagittal section demonstrates liver enlargement, nodularity indicative of cirrhosis, and green discoloration due to cholestasis.

Clinical Features. Most cases are diagnosed when asymptomatic, with elevated serum alkaline phosphatase and γ -glutamyltransferase. Both of these are markers of cholestasis and indicate the need for a liver disease work-up. Hypercholesterolemia is common. Antimitochondrial antibodies are present in 90% to 95% of patients. They are highly characteristic of PBC, although other autoantibodies may be seen in a small number of cases. *The disease is confirmed by liver biopsy, which is considered diagnostic if a florid duct lesion is present.* When symptomatic, the onset is insidious, presenting with fatigue and pruritus, which increase slowly over time.

Over a period of two or more decades, untreated patients follow one of two pathways to end-stage disease, one in which hyperbilirubinemia predominates and another with prominent portal hypertension. However, treatment of early stage disease with oral ursodeoxycholic acid greatly slows progression. Its mechanism of action is uncertain, but is presumably related to the ability of ursodeoxycholate to enter the bile acid pool and alter the biochemical composition of bile.

With progression, secondary features may emerge: skin hyperpigmentation, xanthelasmas, steatorrhea, and vitamin D malabsorption-related osteomalacia and/or osteoporosis. Individuals with PBC may also have extrahepatic manifestations of autoimmunity, including the sicca complex of dry eyes and mouth (Sjögren syndrome), systemic sclerosis, thyroiditis, rheumatoid arthritis, Raynaud phenomenon, and celiac disease. Ursodeoxycholate is not effective in advanced disease, and for these patients liver transplantation is the best form of treatment.

Primary Sclerosing Cholangitis (PSC)

PSC is characterized by inflammation and obliterative fibrosis of intrahepatic and extrahepatic bile ducts with dilation of preserved segments. Characteristic "beading" on radiographs of the intrahepatic and extrahepatic biliary tree is attributable to these irregular, biliary strictures and dilations (Fig. 18-38). *Inflammatory bowel disease (Chapter 17), particularly ulcerative colitis, coexists in approximately 70% of individuals with PSC.* Conversely, the prevalence of PSC in persons with ulcerative colitis is about 4%. Like inflammatory bowel disease, PSC tends to occur in the third through fifth decades of life and males predominate 2:1 (Table 18-11).

Figure 18-38 Imaging studies of a patient with primary sclerosing cholangitis. **A**, Magnetic resonance cholangiography shows focal dilatation in some bile ducts (bright, broad areas) and stricturing of others (thinning or absence). **B**, Endoscopic retrograde cholangiography of the same patient shows nearly identical features as in **A**. The endoscope is visible, giving a sense of scale. (Courtesy Dr. M. Edwyn Harrison, MD, Mayo Clinic, Scottsdale, Ariz.)

Pathogenesis. Several features of PSC suggest immunologically mediated injury to bile ducts, even though environmental triggers presumably also play a role. First degree relatives of patients with PSC have an increased risk of developing the disease suggesting a genetic component. T cells in the periductal stroma, the presence of circulating autoantibodies, association with HLA-B8 and other MHC antigens, and linkage to ulcerative colitis all support an inherent immunologic process.

It has been proposed that T cells activated in the damaged mucosa of patients with ulcerative colitis migrate to the liver where they recognize a cross-reacting bile duct antigen. Autoantibody profiles in PSC are not as characteristic as they are in PBC, although atypical perinuclear antineutrophil cytoplasmic antibodies (pANCA) targeting a nuclear envelope protein are found in approximately 65% of patients; however, the pathogenic relationship of pANCA to PSC is unknown.

MORPHOLOGY

Morphologic changes differ between the large ducts (intrahepatic and extrahepatic) and the smaller intrahepatic ducts. **Large duct inflammation** is similar to that seen in ulcerative colitis: acute, neutrophilic infiltration of the epithelium superimposed on a chronic inflammatory background. Inflamed areas develop strictures because edema and inflammation narrows the lumen or because of subsequent scarring. The **smaller ducts**, however, often have little inflammation and show a striking **circumferential “onion skin” fibrosis** around an increasingly atrophic duct lumen (Fig. 18-39), eventually leading to obliteration by a “tombstone” scar. Because the likelihood of sampling smaller duct lesions on a random needle biopsy is miniscule, diagnosis depends on radiologic imaging of the extrahepatic and larger intrahepatic ducts. As the disease progresses the liver becomes markedly cholestatic, culminating in biliary cirrhosis much like that seen with chronic obstruction and primary biliary cirrhosis. Biliary intraepithelial neoplasia may develop and cholangiocarcinoma appears usually with a fatal outcomes.

Clinical Features. Asymptomatic patients may come to attention only because of persistent elevation of serum alkaline phosphatase, particularly in patients with ulcerative colitis who are being routinely screened. Alternatively, progressive fatigue, pruritus, and jaundice may develop. Acute bouts of ascending cholangitis may also signal the development of PSC. The disease follows a protracted course of 5 to 17 years, and the severely afflicted patients have the usual symptoms of chronic cholestatic liver disease including steatorrhea. Approximately 25% of the patients develop cholelithiasis in the dilated ducts. The annual risk of developing cholangiocarcinoma is 0.6 to 1.5% with a lifetime risk of 20%.

Chronic pancreatitis and chronic cholecystitis from involvement of pancreatic ducts and gallbladder are also seen. A distinctive type of sclerosing cholangitis, with elevated IgG4 levels in association with autoimmune pancreatitis, has been recognized recently. There is no specific medical therapy for PSC. Cholestyramine has been used for pruritus and endoscopic dilation with sphincterotomy or stenting is used for relieving symptoms. Ursodeoxycholic acid has not yet been shown to be effective. Liver transplantation is the definitive treatment for persons with end-stage liver disease.

KEY CONCEPTS

Cholestatic Diseases

- **Cholestasis** occurs with impaired bile flow, leading to accumulation of bile pigment in the hepatic parenchyma. Causes include mechanical or inflammatory obstruction or destruction of the bile ducts or by metabolic defects in hepatocyte bile secretion.
- **Large bile duct obstruction** is most commonly associated with gallstones and malignancies involving the head of the pancreas. Chronic obstruction can lead to cirrhosis. Ascending cholangitis may develop.
- **Cholestasis in sepsis** may arise through direct effects of intrahepatic bacterial infection, ischemia relating to hypotension caused by sepsis, or in response to circulating microbial products.
- **Primary hepatolithiasis** is a disorder of *intrahepatic* gallstone formation, most common in East Asia, that

Figure 18-39 Primary sclerosing cholangitis. A degenerating bile duct is entrapped in a dense, “onion-skin” concentric scar.

leads to repeated bouts of ascending cholangitis and inflammatory parenchymal destruction. It predisposes to cholangiocarcinoma.

- **Neonatal cholestasis** is not a specific entity; it is variously associated with cholangiopathies such as primarily *biliary atresia* and a variety of inherited or acquired disorders causing conjugated hyperbilirubinemia in the neonate, collectively referred to as *neonatal hepatitis*.
- **Primary biliary cirrhosis** is an autoimmune disease with progressive, inflammatory, often granulomatous, destruction of small to medium sized intrahepatic bile ducts.
 - Primary biliary cirrhosis occurs most often in middle aged women, is associated with autoantibodies (particularly AMA), and with other autoimmune diseases such as Sjögren syndrome and Hashimoto thyroiditis.
- **Primary sclerosing cholangitis** is an autoimmune disease with progressive inflammatory and sclerosing destruction of bile ducts of all sizes, intrahepatic and extrahepatic; diagnosis is made not by biopsy, but by radiologic imaging of the biliary tree. It occurs most often in younger men and has strong associations with inflammatory bowel disease, particularly ulcerative colitis.

Structural Anomalies of the Biliary Tree

Choledochal Cysts

Choledochal cysts are congenital dilations of the common bile duct. They present most often in children before age 10 as jaundice and/or recurrent abdominal pain, symptoms that are typical of biliary colic. Approximately 20% of cases become symptomatic only in adulthood. In some cases choledochal cysts occur in conjunction with cystic dilation of the intrahepatic biliary tree (Caroli disease, discussed later). The female-to-male ratio is 3:1 to 4:1. These uncommon cysts may take the form of segmental or cylindrical dilation of the common bile duct, diverticula of the extrahepatic ducts, or choledochoceles, which are cystic lesions that protrude into the duodenal lumen. Choledochal cysts predispose to stone formation, stenosis and stricture, pancreatitis, and obstructive biliary complications within the liver. In older patients the risk of bile duct carcinoma is elevated.

Fibropolycystic Disease

Fibropolycystic disease of the liver is a heterogeneous group of lesions in which the primary abnormalities are congenital malformations of the biliary tree. Lesions may be found incidentally during radiographic studies, surgery, or at autopsy. The most severe forms of fibropolycystic disease may become manifest as hepatosplenomegaly or portal hypertension in the absence of hepatic dysfunction, starting in late childhood or adolescence. Three sets of pathologic findings may be seen, sometimes overlapping with each other:

- *Von Meyenburg complexes* are small bile duct hamartomas (Fig. 18-40). Occasional von Meyenburg complexes

Figure 18-40 Von Meyenburg complex. This bile duct hamartoma is always associated with portal tracts. Note the dilated and irregularly shaped bile ducts.

are common in otherwise normal individuals. When they are diffuse they signal the underlying, more clinically important fibropolycystic disease.

- *Single or multiple, intrahepatic or extrahepatic biliary cysts.* When present in isolation these may be symptomatic due to ascending cholangitis and are referred to as *Caroli disease*. When biliary cysts occur along with congenital hepatic fibrosis, the term *Caroli syndrome* is used (Fig. 18-41). Ducts may be cystically dilated, but true cysts are also present. These may be intrahepatic cysts or choledochal cysts, as already described.
- In *congenital hepatic fibrosis*, portal tracts are enlarged by irregular, broad bands of collagenous tissue, forming septa that divide the liver into irregular islands. Variable numbers of abnormally shaped bile ducts are embedded in the fibrous tissue, although they remain in continuity with the biliary tree (Fig. 18-42). Individuals

Figure 18-41 Congenital hepatic fibrosis with multiple biliary cysts.

Figure 18-42 Congenital hepatic fibrosis. Broad bands of stroma are seen coursing through this liver, which is involved by a variant of fibropolycystic disease. Note the dilated remnants of ductal plates along the margins of the stroma. The intervening parenchyma is comprised of relatively normal parenchyma (Masson Trichrome stain).

with congenital hepatic fibrosis are not truly cirrhotic, despite the serpiginous scarring separating the hepatic parenchyma, but they may still face complications of portal hypertension, particularly bleeding varices.

All of these lesions are related to abnormal development of the biliary tree representing *ductal plate malformations* associated with persistence of the periportal ductal plates from fetal development. The caliber of involved portal tracts determines the different size, morphology, and distributions of lesions. Fibropolycystic liver disease often occurs with autosomal recessive polycystic renal disease. The involved gene encodes a protein called polycystin which is expressed in fetal kidney as well as liver (Chapter 20). Persons with fibropolycystic liver disease have an increased risk for cholangiocarcinoma.

Circulatory Disorders

Given the enormous flow of blood through the liver, it is not surprising that circulatory disturbances have considerable impact on the liver. In most instances, however, clinically significant liver function abnormalities do not develop, but hepatic morphology may be strikingly affected. These disorders can be grouped according to whether blood flow into, through, or from the liver is impaired (Fig. 18-43).

Impaired Blood Flow into the Liver

Hepatic Artery Compromise

Liver infarcts are rare, thanks to the double blood supply to the liver. Nonetheless, thrombosis or compression of an intrahepatic branch of the hepatic artery by embolism (Fig. 18-44), neoplasia, polyarteritis nodosa (Chapter 11), or sepsis may result in a localized infarct that is either pale and anemic or hemorrhagic if there is suffusion with portal blood. Interruption of the main hepatic artery does not always produce ischemic necrosis of the organ, particularly if the liver is otherwise normal. Retrograde arterial flow through accessory vessels, when coupled with the portal

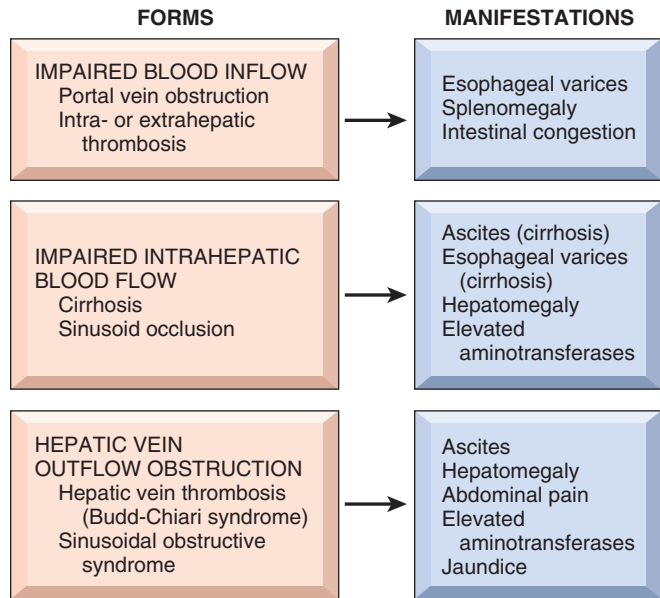

Figure 18-43 Forms and clinical manifestations of hepatic circulatory disorders.

venous supply, is usually sufficient to sustain the liver parenchyma. The one exception is hepatic artery thrombosis in a transplanted liver, which generally leads to infarction of the major ducts of the biliary tree, since their blood supply is entirely arterial.

Portal Vein Obstruction and Thrombosis

Blockage of the extrahepatic portal vein may be insidious and well tolerated or may be a catastrophic and potentially lethal event; most cases fall somewhere in between. Occlusive disease of the portal vein or its major radicles typically produces abdominal pain and, in most instances, other manifestations of portal hypertension, principally esophageal varices that are prone to rupture. Ascites is not common (because the block is presinusoidal), but when present is often massive and intractable.

Figure 18-44 Liver infarct. A thrombus is lodged in a peripheral branch of the hepatic artery (arrow) and compresses the adjacent portal vein; the distal hepatic tissue is pale, with a hemorrhagic margin.

Extrahepatic portal vein obstruction may be may idiopathic (approximately one-third of cases) or may arise from the following conditions:

- Subclinical occlusion of the portal vein, from neonatal umbilical sepsis or umbilical vein catheterization, presenting as variceal bleeding and ascites years later.
- Intraabdominal sepsis, caused by acute diverticulitis or appendicitis, leading to pyelophlebitis in the splanchnic circulation
- Inherited or acquired hypercoagulable disorders, including those arising in myeloproliferative disorders such as polycythemia vera (Chapter 13)
- Trauma, surgical or otherwise
- Pancreatitis and pancreatic cancer that initiate splenic vein thrombosis, which propagates into the portal vein
- Invasion of the portal vein by hepatocellular carcinoma
- Cirrhosis, which is associated with portal vein thrombosis in about 25% of patients. Many such patients have an underlying thrombophilic genotype

Intrahepatic portal vein radicles may be obstructed by acute thrombosis. The thrombosis does not cause ischemic infarction but instead results in a sharply demarcated area of red-blue discoloration called *infarct of Zahn*. There is no necrosis, only severe hepatocellular atrophy and marked stasis in distended sinusoids.

Small portal vein branch diseases include a variety of pathogenetically distinct conditions that are characterized by noncirrhotic portal hypertension with portal fibrosis and obliteration of small portal vein branches. *The most common cause of small portal vein branch obstruction is schistosomiasis;* the eggs of the parasites lodge in and obstruct the smallest portal vein branches. The other diseases in this group are now collectively referred to as *obliterative portal venopathy*, although regional and clinical differences suggest several related but independent diseases. In India, non cirrhotic portal fibrosis has been reported to account for approximately 23 % of cases of portal hypertension but the incidence seems to be declining. The patients often present with upper gastrointestinal bleeding. In East Asia, particularly Japan, there is a female predominance and patients present with splenomegaly, often in association with rheumatologic diseases. The disease is seen in untreated HIV disease and in those being treated with anti-retroviral therapy, in whom it may represent a complication of treatment. Liver transplantation may be necessary to avoid fatal sequelae of the portal hypertension in all these forms.

Impaired Blood Flow Through the Liver

The most common intrahepatic cause of blood flow obstruction is cirrhosis, as described earlier. In addition, physical sinusoidal occlusion occurs in a small group of diseases: *sickle cell disease* (Fig. 18-45), *disseminated intravascular coagulation*, *eclampsia* (discussed later), and *diffuse intrasinusoidal metastatic tumor*. In all of these, obstruction of blood flow may lead to massive necrosis of hepatocytes and acute hepatic failure.

Peliosis hepatis is a peculiar form of sinusoidal dilation that occurs in any condition in which efflux of hepatic blood is impeded. The liver contains blood-filled cystic spaces, either unlined or lined with sinusoidal endothelial cells. The pathogenesis of peliosis hepatis is unknown.

Figure 18-45 Sickle cell crisis in liver. The photomicrograph shows several sinusoids containing “sickled” red cells (arrow).

Bartonella species have been seen in the sinusoidal endothelial cells in AIDS-associated peliosis, but peliosis is also seen in cancer, tuberculosis, and posttransplantation immunodeficiency. Sex hormone administration (e.g., anabolic steroids, oral contraceptives, danazol) sometimes causes peliosis as well. While clinical signs are generally absent, potentially fatal intraabdominal hemorrhage or hepatic failure may occur. Lesions usually disappear after correction of the underlying causes.

Hepatic Venous Outflow Obstruction

Hepatic Vein Thrombosis

The obstruction of two or more major hepatic veins produces liver enlargement, pain, and ascites, a condition known as Budd-Chiari syndrome. Obstruction of a single main hepatic vein by thrombosis is clinically silent. Hepatic damage is the consequence of increased intrahepatic blood pressure. Hepatic vein thrombosis is associated with myeloproliferative disorders such as polycythemia vera (Chapter 13), inherited disorders of coagulation (Chapter 4), antiphospholipid antibody syndrome, paroxysmal nocturnal hemoglobinuria (Chapter 14), and intraabdominal cancers, particularly hepatocellular carcinoma. In pregnancy or with oral contraceptive use, it occurs through interaction with an underlying thrombogenic disorder.

MORPHOLOGY

In the Budd-Chiari syndrome, the liver is swollen and red-purple and has a tense capsule (Fig. 18-46). There may be differential areas of hemorrhagic collapse alternating with areas of preserved or regenerating parenchyma, the patterns are dependent on which small and large hepatic veins are obstructed. Microscopically the affected hepatic parenchyma reveals severe centrilobular congestion and necrosis. Centrilobular fibrosis develops in instances in which the thrombosis is more slowly developing. The major veins may contain totally occlusive fresh thrombi, subtotal occlusion, or, in chronic cases, organized adherent thrombi.

Figure 18-46 Budd-Chiari syndrome. Thrombosis of the major hepatic veins has caused hemorrhagic liver necrosis.

The mortality of untreated acute hepatic vein thrombosis is high. Prompt surgical creation of a portosystemic venous shunt permits reverse flow through the portal vein and improves the prognosis. The chronic form is far less lethal, and more than two thirds of patients are alive after 5 years.

Sinusoidal Obstruction Syndrome

Originally described in Jamaican drinkers of pyrrolizidine alkaloid-containing bush tea and named *veno-occlusive disease*, the disease is now called *sinusoidal obstruction syndrome*. It now occurs primarily in two settings: (1) following allogeneic hematopoietic stem cell transplantation, usually within the first 3 weeks; (2) in cancer patients receiving chemotherapy. The mortality rates can be higher than 30%.

Pathogenesis. Sinusoidal obstruction syndrome arises from toxic injury to the sinusoidal endothelium. Injured, sloughed endothelium obstructs sinusoidal blood flow. Erythrocytes enter into the space of Disse followed by necrosis of perivenular hepatocytes and downstream accumulation of cellular debris in the terminal hepatic vein.

MORPHOLOGY

Sinusoidal obstruction syndrome is characterized by obliteration of the terminal hepatic venules by subendothelial swelling and collagen deposition. In acute disease, there is centrilobular congestion, hepatocellular necrosis, and accumulation of hemosiderin-laden macrophages. As the disease progresses, obliteration of the lumen of the venule is easily identified with special stains for connective tissue (Fig. 18-47). In chronic or healed sinusoidal obstruction syndrome, fibrous obliteration of the venule may follow.

Although histology is the gold standard for diagnosis, in typical settings, diagnosis is frequently made on clinical grounds (tender hepatomegaly, ascites, weight gain, and jaundice), because of the high risk associated with liver biopsy. Early results suggest that treatment with anticoagulants and ursodeoxycholate may lower the incidence and severity of sinusoidal obstruction syndrome in patients undergoing hematopoietic stem cell transplantation.

Figure 18-47 Sinusoidal obstruction syndrome. Collagen stain reveals marked sinusoidal congestion, hepatocyte atrophy and loss, and organizing thrombus within the vein lumen (arrow). (Masson trichrome stain.)

Passive Congestion and Centrilobular Necrosis

These hepatic manifestations of systemic circulatory compromise—passive congestion and centrilobular necrosis—are considered together because they represent a morphologic continuum. Both changes are commonly seen at autopsy because there is an element of preterminal circulatory failure with virtually every nontraumatic death. Components of both left and right sided heart failure can contribute to the injury variably in different clinical settings and with different forms of possibly underlying cardiac disease.

MORPHOLOGY

Right-sided cardiac decompensation leads to passive congestion of the liver. The liver is slightly enlarged, tense, and cyanotic, with rounded edges. Microscopically there is **congestion of centrilobular sinusoids**. With time, centrilobular hepatocytes become atrophic, resulting in markedly attenuated liver cell plates. Left-sided cardiac failure or shock may lead to hepatic hypoperfusion and hypoxia, causing ischemic coagulative necrosis of hepatocytes in the central region of the lobule (centrilobular necrosis). In most instances the only clinical evidence of centrilobular necrosis or its variants is transient elevation of serum aminotransferases, but the parenchymal damage may be sufficient to induce mild to moderate jaundice.

The combination of hypoperfusion and retrograde congestion acts synergistically to cause centrilobular hemorrhagic necrosis. The liver takes on a variegated mottled appearance, reflecting hemorrhage and necrosis in the centrilobular regions (Fig. 18-48A). This finding is known as **nutmeg liver** due to its resemblance to the cut surface of a nutmeg.

By microscopy there is a sharp demarcation of viable periportal and necrotic or atrophic pericentral hepatocytes, with suffusion of blood through the centrilobular region (Fig. 18-48B). Uncommonly, with sustained chronic severe congestive heart failure, **cardiac sclerosis** develops with centrilobular fibrosis, sometimes with central-central linking fibrous septa.

Figure 18-48 Acute passive congestion (“nutmeg liver”). **A**, The cut surface of the liver has a variegated mottled red appearance, representing congestion and hemorrhage in the centrilobular regions of the parenchyma. **B**, On microscopic examination, the centrilobular region is suffused with red blood cells and atrophied hepatocytes are not easily seen. Portal tracts and the periportal parenchyma are intact.

KEY CONCEPTS

Circulatory Disorders

- Circulatory disorders of the liver can be caused by impaired blood inflow, defects in intrahepatic blood flow, and obstruction of blood outflow.
- Portal vein obstruction by intrahepatic or extrahepatic thrombosis may cause portal hypertension, esophageal varices, and ascites.
- The most common cause of impaired intrahepatic blood flow is cirrhosis.
- Obstructions of blood outflow include hepatic vein thrombosis (Budd-Chiari syndrome) and sinusoidal obstruction syndrome, previously known as veno-occlusive disease.

Hepatic Complications of Organ or Hematopoietic Stem Cell Transplantation

The use of transplantation for bone marrow, renal, hepatic and other organ disorders has generated a challenging group of hepatic complications. Although the clinical settings are obviously different for each patient population,

defined by underlying disease and the organ transplanted, the common themes of toxic or immunologically mediated liver damage, opportunistic infection of immunosuppressed hosts, recurrent disease, and posttransplant lymphoproliferative disorder are shared by all.

Graft-Versus-Host Disease and Liver Graft Rejection

The liver has the unenviable position of being attacked by graft-versus-host and host-versus-graft mechanisms, in the setting of bone marrow transplantation and liver transplantation, respectively. These processes are discussed in detail in [Chapter 6](#). More than other solid organs, liver transplants are reasonably well tolerated by recipients. That being said, the hepatic morphologic features that are peculiar to immunological attack after transplantation deserve comment.

MORPHOLOGY

Liver damage after hematopoietic stem cell transplantation is the consequence of acute or chronic **graft-versus-host disease**. In acute graft-versus-host disease, which occurs 10 to 50 days after hematopoietic stem cell transplantation, donor lymphocytes attack the epithelial cells of the liver. This results in hepatitis with necrosis of hepatocytes and bile duct epithelial cells, and inflammation of the parenchyma and portal tracts. In chronic hepatic graft-versus-host disease (usually more than 100 days after transplantation), there is portal tract inflammation, selective bile duct destruction, and eventual fibrosis. Portal vein and hepatic vein radicles may show endothelitis with sub-endothelial lymphocytes lifting the endothelium from its basement membrane. Cholestasis may be observed in both acute and chronic graft-versus-host disease.

In **transplanted livers, acute (cellular) rejection** is characterized by infiltration of a mixed portal inflammatory infiltrate associated with bile duct injury and endothelitis ([Fig. 18-49](#)). With **chronic rejection** an obliterative arteriopathy of small and large arteries leads to ischemic changes in the liver parenchyma. This includes destruction of bile ducts both by immunologic attack and interruption of blood flow; the resulting **vanishing bile duct syndrome** often requires retransplantation.

Hepatic Disease Associated with Pregnancy

Hepatic diseases may occur in women with chronic liver disease who become pregnant, or develop during pregnancy in women who were not affected by liver disease. Abnormal liver tests occur in 3% to 5% of pregnancies. Viral hepatitis (HAV, HBV, HCV, or HBV + HDV) is the most common cause of jaundice in pregnancy. While these women require careful clinical management, pregnancy does not specifically alter the course of the liver disease. The one exception is HEV infection, which, for unknown reasons, runs a more severe course in pregnant patients, with fatality approaching 20%.

Figure 18-49 Transplanted liver with acute cellular rejection. Note the mixed inflammatory cell infiltration including eosinophils in portal tracts, bile duct damage, and endotheliitis. Arrows show subendothelial lymphocytes.

In a very small subgroup of pregnant women (0.1%), hepatic complications develop that are directly attributable to pregnancy. These disorders include preeclampsia and eclampsia, acute fatty liver of pregnancy, and intrahepatic cholestasis of pregnancy. In extreme cases, eclampsia and acute fatty liver of pregnancy may be fatal.

Preeclampsia and Eclampsia

Preeclampsia affects 3% to 5% of pregnancies and is characterized by maternal hypertension, proteinuria, peripheral edema, and coagulation abnormalities (Chapter 22). When hyperreflexia and convulsions occur, the condition is called *eclampsia* and may be life-threatening. Alternatively, subclinical hepatic disease may be the primary manifestation of preeclampsia, as part of a syndrome of hemolysis, elevated liver enzymes, and low platelets, dubbed the *HELLP syndrome*.

MORPHOLOGY

In preeclampsia, the periportal sinusoids contain fibrin deposits associated with hemorrhage into the space of Disse, leading to periportal hepatocellular coagulative necrosis. Blood under pressure may coalesce and expand to form a hepatic hematoma; dissection of blood under Glisson capsule may lead to catastrophic hepatic rupture in eclampsia (Fig. 18-50). Patients with hepatic involvement in preeclampsia may show modest to severe elevation of serum aminotransferases and mild elevation of serum bilirubin. Hepatic dysfunction sufficient to cause a coagulopathy signifies far advanced and potentially lethal disease. Mild cases may be managed conservatively. Termination of pregnancy is required in severe cases. Women who survive mild or severe preeclampsia recover without sequelae.

Acute Fatty Liver of Pregnancy

Acute fatty liver of pregnancy presents with a spectrum of disorders ranging from subclinical or modest hepatic

dysfunction (evidenced by elevated serum aminotransferase levels) to hepatic failure, coma, and death. It is a rare disease affecting 1 in 13,000 deliveries. Affected women present in the latter half of pregnancy, usually in the third trimester. Symptoms are directly attributable to incipient hepatic failure, including bleeding, nausea and vomiting, jaundice, and coma. In 20% to 40% of cases, the presenting symptoms may be those of coexistent preeclampsia.

MORPHOLOGY

The diagnosis of acute fatty liver of pregnancy rests on biopsy identification of the characteristic diffuse microvesicular steatosis of hepatocytes. In severe cases there may be lobular disarray with hepatocyte dropout, reticulin collapse, and portal tract inflammation, making distinction from viral hepatitis difficult.

While this condition most commonly runs a mild course, women with acute fatty liver of pregnancy can progress within days to hepatic failure and death. The primary treatment is termination of the pregnancy. The pathogenesis of this disease is unknown, but mitochondrial dysfunction has been implicated. In a subset of patients, both mother and father carry a heterozygous deficiency in mitochondrial long-chain 3-hydroxyacyl coenzyme A (CoA) dehydrogenase. The homozygous-deficient fetuses fare well during pregnancy but cause hepatic dysfunction in the mother, because long-chain 3-hydroxyacyl metabolites produced by the fetus or placenta enter the maternal circulation and cause hepatic toxicity. This is a rare instance of the fetus causing metabolic disease in the mother.

Intrahepatic Cholestasis of Pregnancy

The onset of pruritus in the third trimester, followed in some cases (10-25%) by darkening of the urine and occasionally light stools and jaundice, heralds the development of this enigmatic syndrome. Serum bilirubin (mostly conjugated) rarely exceeds 5 mg/dL; alkaline phosphatase may be slightly elevated. The level of bile salts is increased greatly. The altered hormonal state of pregnancy seems to combine with biliary defects in the secretion of bile salts or sulfated progesterone metabolites to engender cholestasis.

Figure 18-50 Eclampsia. Subcapsular hematoma dissecting under Glisson capsule in a fatal case. (Courtesy Dr. Brian Blackburne, Office of the Medical Examiner, San Diego, Calif.)

Although this is generally a benign condition, the incidence of fetal distress, stillbirths, and prematurity is modestly increased. Perhaps most importantly, the pruritus resulting from retention of bile salts can be extremely distressing for the pregnant mother.

Nodules and Tumors

Hepatic masses may come to attention for a variety of reasons. They may generate epigastric fullness and discomfort or be detected by routine physical examination or radiographic studies for other indications. Hepatic masses include nodular hyperplasias and true neoplasms.

Nodular Hyperplasias

Solitary or multiple hyperplastic hepatocellular nodules may develop in the noncirrhotic liver. Two such conditions are *focal nodular hyperplasia* and *nodular regenerative hyperplasia*. The common factor in both types of nodules seems to be either focal or diffuse alterations in hepatic blood supply, arising from obliteration of portal vein radicles and compensatory augmentation of arterial blood supply.

MORPHOLOGY

Focal nodular hyperplasia appears as a well-demarcated but poorly encapsulated nodule, ranging up to many centimeters in diameter (Fig. 18-51A). It presents as a spontaneous mass lesion in an otherwise normal liver, most frequently in young to middle-aged adults. The lesion is generally lighter than the surrounding liver and is sometimes yellow indicating steatosis. Typically, there is a central gray-white, depressed stellate scar from which fibrous septa radiate to the periphery.

The central scar contains large vessels, usually arterial, that typically show fibromuscular hyperplasia with eccentric or concentric narrowing of the lumen. The radiating septa show variable ductular reactions along septal margins. The parenchyma between septa is comprised of normal hepatocytes separated

by thickened sinusoidal plates (Fig. 18-51B). The vascular lesion, congenital or acquired, is probably the initiating insult. Resulting areas of hypoperfused parenchyma collapse to become the septa, while hyperperfused regions undergo hyperplasia.

Nodular regenerative hyperplasia denotes a liver entirely transformed into nodules—grossly similar to micronodular cirrhosis—but without fibrosis. Microscopically, plump hepatocytes are surrounded by rims of atrophic hepatocytes. **Nodular regenerative hyperplasia can lead to the development of portal hypertension** and occurs in association with conditions affecting intrahepatic blood flow, including solid-organ (particularly renal) transplantation, hematopoietic stem cell transplantation, and vasculitis. It also occurs in HIV-infected persons and in association with rheumatologic diseases such as SLE. Most such patients are asymptomatic and the condition is found at autopsy.

Benign Neoplasms

Cavernous hemangiomas, blood vessel tumors identical to those occurring elsewhere, are the most common benign liver tumors (Chapter 11). They appear as discrete red-blue, soft nodules, usually less than 2 cm in diameter, generally located directly beneath the capsule. Histologically, the tumor consists of vascular channels in a bed of fibrous connective tissue (Fig. 18-52). Their chief clinical significance is that they might be mistaken radiographically or intraoperatively for metastatic tumors.

Hepatocellular Adenomas

Benign neoplasms developing from hepatocytes are called hepatocellular adenomas (Fig. 18-53). They may be detected incidentally with abdominal imaging or when they cause abdominal pain from their rapid growth, causing pressure on the liver capsule, or following hemorrhagic necrosis as the lesion outstrips its blood supply. Rupture of hepatocellular adenomas may lead to intraabdominal bleeding that is a surgical emergency. Three large subtypes have been defined on the basis of molecular analysis and associated clinical and pathologic findings, each

Figure 18-51 Focal nodular hyperplasia. **A**, Resected specimen showing lobulated contours and a central stellate scar. **B**, Low-power micrograph showing a broad fibrous scar with hepatic arterial and bile duct elements and chronic inflammation present within parenchyma that lacks normal architecture due to hepatocyte regeneration.

Figure 18-52 Hemangioma. Blood-filled vascular channels separated by a dense fibrous stroma.

with a different relative risk of malignant transformation. Both oral contraceptives and anabolic steroids are associated with the development of these adenomas. In fact before the advent of oral contraceptives, hepatocellular adenomas were virtually unknown. The risk of developing these tumors is increased 30-40 fold in users of oral contraceptives. The highest risk is from prolonged use of estrogen rich oral contraceptives. If surgery is not possible or is ill-advised, cessation of exposure to sex hormones often can lead to full regression.

Pathogenesis. Three large subtypes have been defined on the basis of molecular analysis and associated clinical and pathologic findings, each with a different relative risk of malignant transformation.

HNF1- α Inactivated hepatocellular adenomas. Ninety percent of these tumors have inactivating mutations of HNF1- α that are somatic, while 10% have germline mutations. HNF1- α encodes a transcription factor. Heterozygous germline mutations are responsible for

autosomal dominant MODY-3 (maturity onset diabetes of the young, type 3). Patients with MODY-3 who develop hepatocellular adenomas have acquired a second somatic mutation. These lesions are most commonly found in women. Oral contraceptive pills are implicated in some.

β -Catenin Activated Hepatocellular Adenomas. Activating mutations of β -catenin are associated with neoplasia and malignancy in many organs. In the liver they may give rise to hepatocellular adenomas that are considered at very high risk for malignant transformation and should be resected even when asymptomatic. They are associated with oral contraceptive and anabolic steroid use. They are found in men and women.

Inflammatory hepatocellular adenomas. These lesions are found in both men and women and are associated with non-alcoholic fatty liver disease; thus, their incidence seems to be increasing. They have a small but definite risk of malignant transformation and should probably be resected even when asymptomatic. They are characterized by activating mutations in gp130, a co-receptor for IL-6, that lead to constitutive JAK-STAT signaling and overexpression of acute phase reactants, which you will recall are normally upregulated in systemic inflammatory states. As will be discussed later, IL-6 mediated JAK-STAT signaling has also been linked to the pathogenesis of hepatocellular carcinoma, and undoubtedly explains the inflammatory background that characterizes this subtype of hepatocellular adenoma. Ten percent of inflammatory hepatocellular adenomas also have concomitant β -catenin activating mutations and these tumors have a higher risk of malignant transformation.

MORPHOLOGY

The tumors resulting from **HNF1- α mutations** are often fatty and devoid of cellular or architectural atypia. They have almost no risk of malignant transformation. Liver fatty acid binding protein (LFABP), a downstream regulated protein of HNF1- α , is constitutively expressed in all normal hepatocytes, but is

Figure 18-53 Liver cell adenoma. **A**, Resected specimen presenting as a pendulous mass arising from the liver. **B**, Microscopic view showing cords of hepatocytes, with an arterial vascular supply (arrow) and no portal tracts.

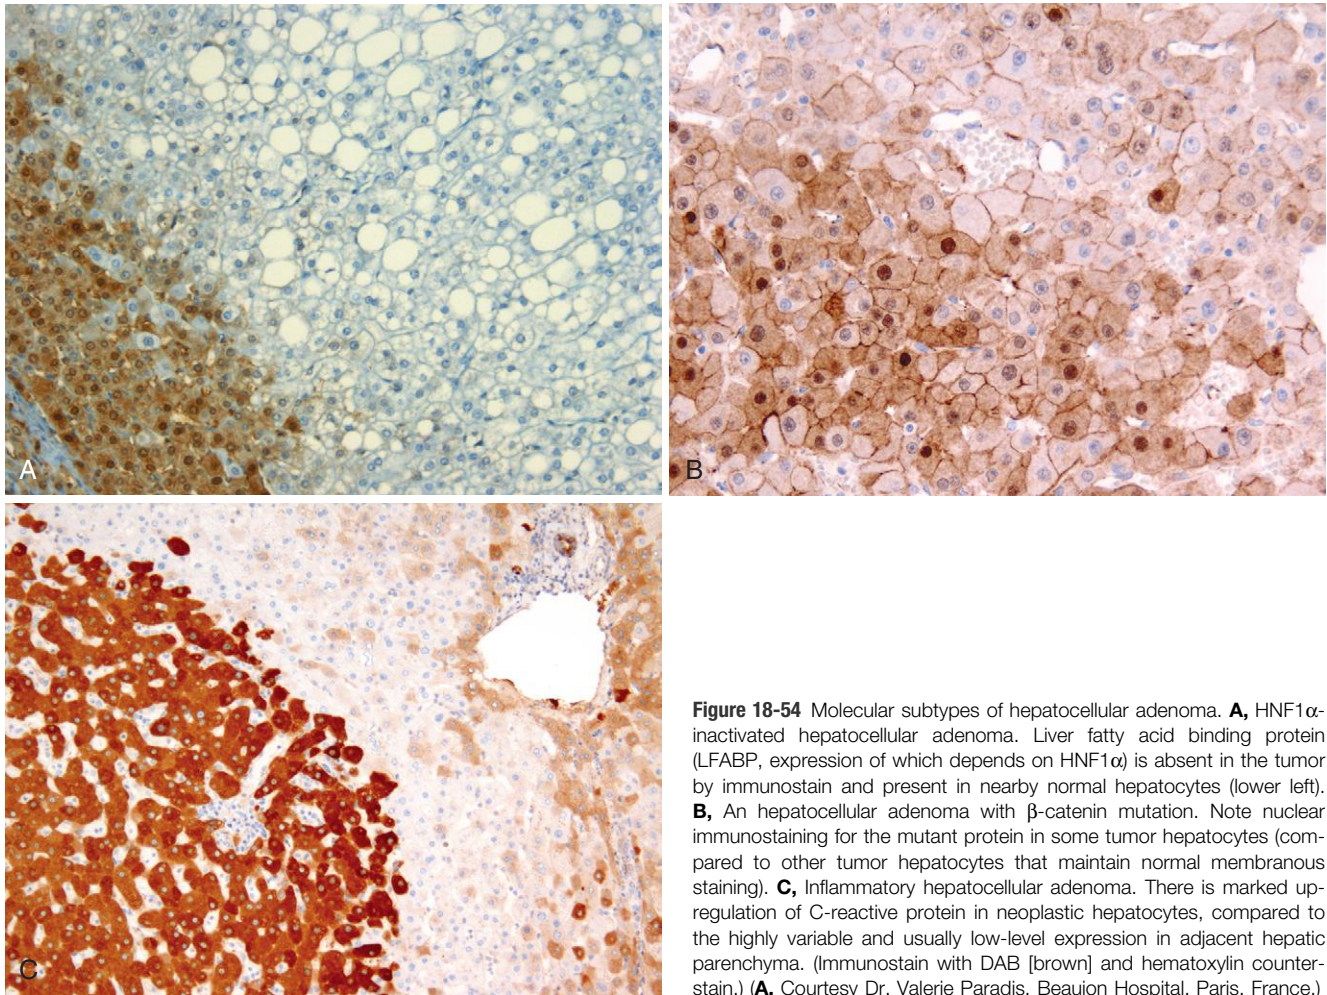

Figure 18-54 Molecular subtypes of hepatocellular adenoma. **A**, HNF1 α -inactivated hepatocellular adenoma. Liver fatty acid binding protein (LFABP, expression of which depends on HNF1 α) is absent in the tumor by immunostain and present in nearby normal hepatocytes (lower left). **B**, An hepatocellular adenoma with β -catenin mutation. Note nuclear immunostaining for the mutant protein in some tumor hepatocytes (compared to other tumor hepatocytes that maintain normal membranous staining). **C**, Inflammatory hepatocellular adenoma. There is marked up-regulation of C-reactive protein in neoplastic hepatocytes, compared to the highly variable and usually low-level expression in adjacent hepatic parenchyma. (Immunostain with DAB [brown] and hematoxylin counterstain.) (**A**, Courtesy Dr. Valerie Paradis, Beaujon Hospital, Paris, France.)

absent in these tumors due to the inactivating mutation of HNF1- α . Thus, immunostaining for LFABP demonstrating its absence in the tumor is diagnostic of the mutation (Fig. 18-54A).

β -Catenin mutated hepatocellular adenomas often have a high degree of cytologic or architectural dysplasia or even overt areas of hepatocellular carcinoma. Immunostain for β -catenin usually shows nuclear translocation indicative of its activated state (Fig. 18-54B). This change is diagnostic. Glutamine synthetase, a target of beta-catenin, (normally only positive in perivenular hepatocytes) is also diffusely positive in these tumors, a change that may be seen even when the activating β -catenin mutation doesn't result in nuclear staining. In such tumors, molecular analysis is necessary for definitive confirmation.

Inflammatory hepatocellular adenomas. Unlike the other hepatocellular adenomas, which are comprised of only hepatocytes and vessels with minor amounts of stroma, these lesions characteristically have in addition areas of fibrotic stroma, mononuclear inflammation, ductular reactions, dilated sinusoids, and telangiectatic vessels. Most of these tumors over-express acute phase reactants such as C-reactive protein and serum amyloid A (Fig. 18-54C). These molecules may also be elevated in the serum. 10% of these HCAs that also have β -catenin activating mutations and, as would be anticipated, also show increased nuclear levels of β -catenin by immunohistochemistry.

Malignant Tumors

Malignant tumors occurring in the liver can be primary or metastatic. Most of the discussion in this section deals with primary hepatic tumors. Most primary liver cancers arise from hepatocytes and are termed *hepatocellular carcinoma* (HCC). Much less common are carcinomas of bile duct origin, *cholangiocarcinomas*.

Before embarking on a discussion of the major forms of malignancy affecting the liver, a rare form of primary liver cancer, hepatoblastoma deserves a brief discussion.

Hepatoblastoma

Hepatoblastoma is the most common liver tumor of early childhood. It rarely occurs over the age of 3 years. Its incidence, which is increasing, is approximately 1 to 2 in 1 million births. Two primary anatomic variants are recognized:

- The *epithelial type*, composed of small polygonal fetal cells or smaller embryonal cells forming acini, tubules, or papillary structures vaguely recapitulating liver development (Fig. 18-55)
- The *mixed epithelial and mesenchymal type*, which contains foci of mesenchymal differentiation that may consist of primitive mesenchyme, osteoid, cartilage, or striated muscle

Figure 18-55 Hepatoblastoma. The photograph shows proliferating hepatoblasts consisting mostly of round “epithelial” type cells.

A characteristic feature of hepatoblastomas is the frequent activation of the WNT signaling pathway. This occurs by a variety of mechanisms involving mutations in molecules downstream of WNT signaling, including mutations in APC gene. Patients with Familial adenomatous polyposis frequently develop hepatoblastomas. Sporadic cases have activation of the beta-catenin signaling through other mechanisms. Chromosomal abnormalities are common in hepatoblastomas, and *FOXG1*, a regulator of the TGF- β pathway, is highly expressed in some tumors. Hepatoblastoma may be associated Beckwith-Wiedemann syndrome as well. The treatment is surgical resection and chemotherapy. Untreated, the tumor is usually fatal within a few years, but therapy has raised the 5-year survival to 80%.

Hepatocellular Carcinoma (HCC)

Worldwide, HCC (also known erroneously as *hepatoma*) accounts for approximately 5.4% of all cancers, but its incidence varies widely in different parts of the world. *More than 85% of cases occur in countries with high rates of chronic HBV infection.* The highest incidences of HCC are found in Asian countries (southeast China, Korea, Taiwan) and sub-Saharan African countries. In these locales, HBV is transmitted vertically and, as already discussed, the carrier state starts in infancy. The peak incidence of HCC in these areas is between 20 and 40 years of age, and in almost 50% of cases, the tumor appears in the absence of cirrhosis. As discussed later, many of these populations are exposed to aflatoxin, which is also a carcinogen (Chapter 7). The risk of HCC is decreasing in China, Singapore and Hong Kong, most likely due to institution of hepatitis B vaccination.

In Western countries, the incidence of HCC is rapidly increasing, largely owing to the hepatitis C epidemic. It tripled in the United States in recent decades, but it is still eightfold to 30-fold lower than the incidence in some Asian countries. In Western populations, HCC rarely manifests before the age of 60, and, in almost 90% of cases, the malignancy emerges after cirrhosis becomes established. There is a pronounced male preponderance throughout the world, about 3:1 in low-incidence areas and as high as 8:1 in high

incidence areas. The reason for the gender imbalance is not known. Worldwide, liver cell cancer is the fifth leading cause of death in males.

Pathogenesis. Chronic liver diseases are the most common setting for emergence of HCC. While usually identified in a background of cirrhosis, cirrhosis per se is not a premalignant lesion. Indeed, cirrhosis is not required for hepatocarcinogenesis (Fig. 18-56). Rather, progression to cirrhosis and hepatocarcinogenesis take place in parallel over years to decades.

The most important underlying factors in hepatocarcinogenesis are viral infections (HBV, HCV) and toxic injuries (aflatoxin, alcohol). Thus where HBV and HCV are endemic, there is a very high incidence of HCC. Co-infection further increases risk. In Africa and Asia, aflatoxin, produced by *Aspergillus* species, is a mycotoxin that contaminates staple food crops. Aflatoxin metabolites are present in the urine of affected individuals as are aflatoxin-albumin adducts in serum. This helps to identify the populations at risk and confirm the important influence of

Figure 18-56 Hepatocellular carcinoma. **A**, Liver removed at autopsy showing a unifocal neoplasm replacing most of the right hepatic lobe. **B**, Malignant hepatocytes growing in distorted versions of normal architecture, including large pseudoacinar spaces (malformed, dilated bile canaliculi) and thickened hepatocyte trabeculae.

aflatoxin for hepatocarcinogenesis. Aflatoxin also synergizes with HBV (perhaps also with HCV) to increase risk further. Alcohol is another toxin which probably, by itself, is a risk factor for HCC, but it also synergizes with HBV and HCV, and even, possibly, cigarette smoking.

Metabolic diseases such as hereditary hemochromatosis and α_1 AT deficiency markedly increase the risk of HCC. Wilson disease probably does so with much less frequency. Of probably greater import is the metabolic syndrome associated with obesity, diabetes mellitus, and non-alcoholic fatty liver disease, all of which increase the risk of HCC.

No single, universal sequence of molecular or genetic alterations leads to emergence of HCC. *Activation of β -catenin and inactivation of p53 are the two most common early mutational events.* Activating β -catenin mutations are identified in up to 40% of persons with HCC. These tumors are more likely to be unrelated to HBV and to demonstrate genetic instability. Inactivation of p53 is present in up to 60% of HCC cases. These tumors are strongly associated with aflatoxin. Neither of these alterations, however, is found in premalignant lesions.

Recent evidence has provided some novel insights into the role of HBV, HCV, alcoholic liver disease and other states of chronic inflammation in the pathogenesis of HCC. Traditional thinking has been that cycles of cell death and regeneration in chronic inflammatory states increases the risk of mutations in regenerating hepatocytes. But the precise molecular mechanisms of such changes have remained obscure. More recent studies implicate a role for signaling through the IL-6/JAK/STAT pathway in the causation of HCC. IL-6 is an inflammatory cytokine that is

overproduced in many chronic hepatitises. Based on some preliminary experiments, it has been proposed that IL-6 can suppress hepatocyte differentiation and promote their proliferation by regulating the function of the transcription factor HNF4- α . In keeping with this, hepatic carcinogenesis can be suppressed by uncoupling HNF4- α from the control of IL-6, in experimental animals. More studies are needed to determine the significance of IL-6/HNF4- α signaling axis in human HCC.

Precursor Lesions of HCC

Several cellular and nodular precursor lesions to HCC have been identified (Table 18-12). Hepatocellular adenoma has already been discussed, in particular those with β -catenin activating mutations. In chronic liver disease there are cellular dysplasias, called *large cell change* and *small cell change* (Fig. 18-57). These may be found at any stage of chronic liver disease, before or after development of cirrhosis, and serve as markers in biopsy specimens to indicate which patients need more aggressive cancer surveillance. *Small cell change is thought to be directly premalignant. Large cell change is at least a marker of increased risk of HCC in the liver as a whole, but in hepatitis B they may also be directly premalignant.*

Dysplastic nodules are usually detected in cirrhosis, either radiologically or in resected specimens (including explants). These are nodules that have a different appearance from the surrounding cirrhotic nodules (Fig. 18-58). The differences are in size or vascular supply (increasingly arterial with increasingly high grade, a defining feature in contrast radiologic studies) or other aspects of appearance (color, texture). *Low-grade dysplastic nodules*, may or may not

Table 18-12 Precursor Lesions of Hepatocellular Carcinoma and Cholangiocarcinoma

	Hepatocellular Carcinoma					Cholangiocarcinoma		
	Hepatocellular Adenoma	Small Cell Change	Large Cell Change	Low Grade Dysplastic Nodule	High Grade Dysplastic Nodule	BilIN-3	Mucinous Cystic Neoplasm	Intraductal Papillary Biliary Neoplasia
Focality in liver	Single or multiple (adenomatosis)	Diffuse	Diffuse	Single or multiple	Single or multiple	Diffuse or multifocal	Single	Focal or diffuse
Premalignant	Yes	Yes	In some HBV*	Uncertain*	Yes	Yes	Yes	Yes
Association with cirrhosis	Rare	Common	Common	Usual	Usual	Sometimes	No	No

Need for surveillance cancer screening	\pm depending on presence of predisposing condition	Yes	Yes	Yes	Yes	Yes	No	Yes

*While these are not certain to be directly premalignant, they are always at least an indication of increased risk for malignancy in the liver as a whole.

BilIN-3, Biliary intraepithelial neoplasia, high grade; NAFLD, nonalcoholic fatty liver disease; HBV, hepatitis B virus; HCV, hepatitis C virus; A1AT, α_1 -antitrypsin deficiency; HH, hereditary hemochromatosis; PBC, primary biliary cirrhosis; PSC, primary sclerosing cholangitis.

Figure 18-57 **A**, Large cell change. Large hepatocytes with large, often atypical nuclei are scattered among normal-size hepatocytes with round, typical nuclei. **B**, Small cell change. The abnormal cells have a high nuclear-to-cytoplasmic ratio and are separated by thickened plates. Normal-appearing hepatocytes are in the lower right corner. (Courtesy Dr. Young Nyun Park, Yonsei Medical College, Seoul, South Korea.)

undergo transformation to higher grade lesions, but they at least indicate a higher risk for HCC in the liver as a whole. *High-grade dysplastic nodules* are probably the most important primary pathway for emergence of HCC in viral hepatitis and alcoholic liver disease. Subnodules of HCC are often found in high-grade dysplastic nodules in biopsy or resection specimens.

MORPHOLOGY

Large cell change shows scattered hepatocytes, usually near portal tracts or septa, that are larger than normal hepatocytes and with large, often multiple, often moderately pleomorphic nuclei; however, the nuclear-cytoplasmic ratio is normal since both nuclei and the cell as a whole become larger (Fig. 18-57A). In **small cell change** the hepatocytes have high nuclear-cytoplasmic ratio and mild nuclear hyperchromasia and/or pleomorphism (Fig. 18-57B). Hepatocytes exhibiting small cell change often form tiny expansile nodules within a single parenchymal lobule.

Low-grade dysplastic nodules are devoid of cytologic or architectural atypia, but have been shown to be clonal and are probably neoplastic, rather than simply large cirrhotic nodules. Portal tracts are still present within these nodules, often in near

normal distribution. Thus, the blood supply remains a mix of portal venous and hepatic arterial blood. **High grade dysplastic nodules** have cytologic (e.g., small cell change) or architectural features (occasional pseudoglands, trabecular thickening) suggestive of, but still insufficient for diagnosis of overt HCC. Such atypia often presents as a subnodule within the larger nodule. Portal tracts are fewer in these higher grade nodules and arteries feeding the growing lesion gradually come to predominate over the portal venous flow. Overt HCC may then arise within the dysplastic nodules (Fig. 18-58B), eventually overgrowing it.

Overall, **HCC may appear grossly as (1) a unifocal (usually large) mass, (2) multifocal, widely distributed nodules of variable size, or (3) a diffusely infiltrative**

Figure 18-58 **A**, Hepatitis C-related cirrhosis with a distinctively large nodule (arrows). Nodule-in-nodule growth suggests an evolving cancer. **B**, Histologically the region within the box in **A** shows a well-differentiated hepatocellular carcinoma (HCC) (right side) and a subnodule of moderately differentiated HCC within it (center, left). (Courtesy Dr. Masamichi Kojiro, Kurume University, Kurume, Japan.)

cancer, permeating widely and sometimes involving the entire liver. All three patterns may cause liver enlargement. The diffusely infiltrative tumor may blend so imperceptibly into a background of cirrhosis that it might not be apparent by imaging, even though most of the liver is replaced. HCCs may be pale compared to surrounding liver or they may have a variegated appearance reflecting different differentiation states (white when there is abundant stroma, yellow when fatty change predominates, green when well-differentiated malignant hepatocytes make abundant bile).

Intrahepatic metastases, by either vascular invasion or direct extension, become more likely once tumors reach 3 cm in size. These metastases are usually small, satellite tumor nodules around the larger, primary mass. The vascular route is also the most likely route for extrahepatic metastasis, especially by the hepatic venous system. Hematogenous metastases, especially to the lung, tend to occur late in the disease. Occasionally, long, snakelike masses of tumor invade the portal vein (causing portal hypertension) or inferior vena cava. The latter can even extend into the right side of the heart. Lymph node metastases are less common routes of extrahepatic spread. If venous invasion is identified in HCC-bearing explanted livers at the time of transplantation, tumor recurrence is likely to occur in the transplanted liver due to seeding of circulating tumor cells in the transplant recipient. Such lesions may appear months after the operation.

HCCs range from well-differentiated to highly anaplastic lesions. The better differentiated HCCs are comprised of cells that look much like normal hepatocytes and grow in structures that are distortions of normal: thickened trabecular structures (recapitulating liver cell plates) or pseudoglandular structures that are poorly formed, ectatic bile canaliculi (Fig. 18-56).

A distinctive variant of HCC is **fibrolamellar carcinoma**, constituting less than 5% of HCCs. 85% occur under the age of 35 years and without gender predilection or identifiable predisposing conditions. It usually presents as single large, hard “scirrhous” tumor with fibrous bands coursing through it. Microscopically, they are composed of well-differentiated cells rich in mitochondria (oncocytes) growing in nests or cords separated by parallel lamellae of dense collagen bundles (hence the name) (Fig. 18-59).

Clinical Features. The clinical manifestations of HCC are seldom characteristic and, in the Western population, often are masked by those related to the underlying cirrhosis or chronic hepatitis. In areas of high incidence such as tropical Africa, in particular where aflatoxin exposure is common, patients usually have no clinical history of liver disease, although cirrhosis may be detected at autopsy. In both populations most patients have ill-defined upper abdominal pain, malaise, fatigue, weight loss, and sometimes awareness of hepatomegaly or an abdominal mass or abdominal fullness. Jaundice, fever, and gastrointestinal or esophageal variceal bleeding are inconstant findings.

Laboratory studies may be helpful but are rarely conclusive. Rising or elevated levels of *serum α -fetoprotein* are found in 50% of persons with advanced HCC. However, it is insensitive as a screening test for premalignant or early lesions as these usually do not produce particularly high levels of the protein.

Figure 18-59 Fibrolamellar carcinoma. **A**, Resected specimen showing a well demarcated nodule. **B**, Microscopic view showing nests and cords of malignant-appearing, oncocytic hepatocytes separated by dense bundles of collagen.

Most valuable for detection of small tumors are imaging studies: ultrasonography to identify distinctive nodules of all kinds, and computed tomography and magnetic resonance imaging with vascular/contrast studies. The increasing arterialization in the process of conversion from high grade dysplastic nodule to early HCC and then to fully developed HCC, form the basis of diagnostic imaging. HCC, even when small, has such characteristic vascular changes that imaging can be diagnostic.

The natural course of HCC involves the progressive enlargement of the primary mass until it disturbs hepatic function or metastasizes to the lungs or to other sites. Death usually occurs from (1) cachexia, (2) gastrointestinal or esophageal variceal bleeding, (3) liver failure with hepatic coma, or, rarely, (4) rupture of the tumor with fatal hemorrhage. The 5-year survival of large tumors is dismal, the majority of patients dying within the first 2 years.

With implementation of screening procedures and advances in imaging, the detection of HCCs less than 2 cm in diameter has increased in countries where such facilities are available. These small tumors can be removed surgically or ablated (e.g., through embolization or with microwave radiation or freezing) with good outcomes. Radiofrequency ablation is used for local control of large tumors, and chemoembolization can also be used.

Cholangiocarcinoma (CCA)

Cholangiocarcinoma (CCA), the second most common primary malignant tumor of the liver after HCC, is a malignancy of the biliary tree, arising from bile ducts within and outside of the liver. It accounts for 7.6% of cancer deaths worldwide and 3% of cancer deaths in the United States. However, in some regions of Southeast Asia such as northeastern Thailand, Laos, and Cambodia where infestation with liver flukes is endemic, cholangiocarcinoma is more common than hepatocellular carcinoma.

All risk factors for cholangiocarcinomas cause chronic inflammation and cholestasis, which presumably promote occurrence of somatic mutations or epigenetic alterations in cholangiocytes. The risk factors include infestation by liver flukes (particularly *Opisthorchis* and *Clonorchis* species), chronic inflammatory disease of the large bile ducts, such as primary sclerosing cholangitis, hepatolithiasis, and fibropolycystic liver disease. It should be noted that patients with hepatitis B and C, and non alcoholic fatty liver disease, not only have a higher risk of developing HCC, but also of cholangiocarcinoma. Globally, cholangiocarcinomas are most often sporadic and not associated with any preexisting condition.

Cholangiocarcinoma may be either intrahepatic or extrahepatic. The extrahepatic forms include perihilar tumors known as *Klatskin tumors*, which are located at the junction of the right and left hepatic ducts. Fifty percent to 60% of all cholangiocarcinomas are perihilar (Klatskin) tumors, 20% to 30% are distal tumors, arising in the common bile duct where it lies posterior to the duodenum. The remaining 10% are intrahepatic. Regardless of site, the prognosis is dismal, with survival rates of about 15% at 2 years after diagnosis for extrahepatic tumors. The median time from diagnosis to death for intrahepatic CCAs is 6 months, even after surgery because intrahepatic CCAs are not usually detected until late in their course. They come to the attention because of obstruction of bile flow or as a symptomatic liver mass. In contrast, hilar and distal tumors present with symptoms of biliary obstruction, cholangitis, and right upper quadrant pain.

Premalignant lesions for cholangiocarcinoma are also known, the most important of which are biliary intraepithelial neoplasias (low to high grade, BillIN-1, -2, or -3). BillIN-3, the highest grade lesion, incurs the highest risk of malignant transformation. More rare are *mucinous cystic neoplasms* and *intraductal papillary biliary neoplasia* (Table 18-12).

MORPHOLOGY

Extrahepatic cholangiocarcinomas are generally small lesions at the time of diagnosis as they rapidly cause obstructive features. Most tumors appear as firm, gray nodules within the bile duct wall; some may be diffusely infiltrative lesions; others are papillary, polypoid lesions. Intrahepatic cholangiocarcinomas occur in the noncirrhotic liver (Fig. 18-60) and may track along the intrahepatic portal tract system creating a branching tumor within a portion of the liver. Alternatively, a massive tumor nodule may develop.

Regardless of site, cholangiocarcinomas are typical adenocarcinomas. They often produce mucin. Most are well-

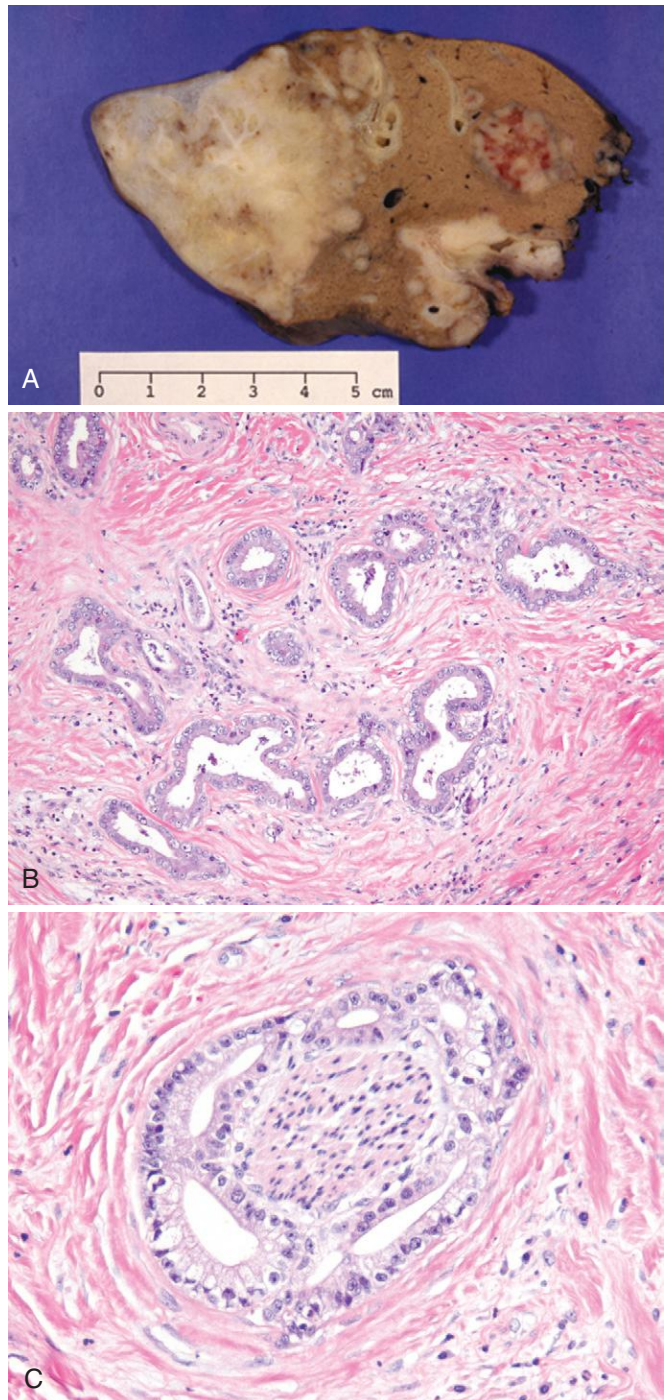

Figure 18-60 Cholangiocarcinoma. **A**, Multifocal cholangiocarcinoma in a liver from a patient with infestation by the liver fluke *Clonorchis sinensis*. **B**, Invasive malignant glands in a reactive, sclerotic stroma. **C**, Perineural invasion by malignant glands, forming a wreathlike pattern around the central, trapped nerve. (A, Courtesy Dr. Wilson M.S. Tsui, Caritas Medical Centre, Hong Kong.)

moderately differentiated with clearly defined glandular/tubular structures lined by malignant epithelial cells (Fig. 18-60B). They typically incite marked desmoplasia. Lymphovascular invasion and perineural invasion (Fig. 18-60C) are both common, each a path to extensive intrahepatic and extrahepatic metastases.

Other Primary Hepatic Malignant Tumors

Other primary liver malignancies are rare, but noteworthy. Some tumors show *combined hepatocellular and cholangiocarcinoma*, suggesting an origin from a multipotent stem cell. *Mucinous cystic neoplasms* and *intraductal papillary biliary neoplasia* may occur as in situ lesions or as invasive cholangiocarcinoma.

Angiosarcoma of the liver resembles those occurring elsewhere and has historical associations with vinyl chloride, arsenic, or Thorotrast (Chapters 9 and 11), although with reduced exposures to these compounds in recent decades, this malignancy is becoming very rare. *Epithelioid hemangioendothelioma*, another form of endothelial malignancy, has a much more variable prognosis than the almost uniformly fatal angiosarcoma. Hepatic lymphomas are primarily diseases of middle aged men and are seen, albeit rarely, in association with hepatitis B and C, HIV, and PBC. Most are *diffuse large B-cell lymphomas*, followed by *MALT lymphomas*. *Hepatosplenic delta-gamma T cell lymphoma*, most common in young adult males, has a predilection for hepatic and splenic sinusoids as well as the marrow.

Metastasis

Involvement of the liver by metastatic malignancy is far more common than primary hepatic neoplasia. Although the most common primary sources are the colon, breast, lung, and pancreas, any cancer in any site of the body may spread to the liver. Typically, multiple nodular metastases are found that often cause striking hepatomegaly and replace much of the normal liver parenchyma. The liver weight can exceed several kilograms. Metastasis may also appear as a single nodule, in which case it may be resected surgically. Always surprising is the amount of metastatic involvement that may be present in the absence of clinical or laboratory evidence of hepatic functional insufficiency. Often the only telltale clinical sign is hepatomegaly. However, with massive destruction of liver substance or direct obstruction of major bile ducts, jaundice and elevations of liver enzymes may appear.

KEY CONCEPTS

Liver Tumors

- The liver is the most common site of **metastatic cancers** from primary tumors of the colon, lung, and breast.
- **Hepatocellular adenomas** are benign tumors of neoplastic hepatocytes. Most can be subclassified on the basis of molecular changes:
 - **HNF1- α inactivated adenomas**, with virtually no risk of malignant transformation, often associated with oral contraceptive pill use or in individuals with MODY-3
 - **β -Catenin activated adenoma**, with mutations in the β -catenin gene leading to marked atypia and associated with a very high risk for malignant transformation
 - **Inflammatory adenomas**, the hallmark of which is up-regulation of C-reactive protein and serum amyloid A (often derived from gp130 mutations); 10% of these have concomitant β -catenin activating mutations. Risk for malignant transformation is intermediate.
- The main **primary malignancies are HCCs and cholangiocarcinomas**; HCCs are by far the most common.
 - HCC is a common tumor in regions of Asia and Africa, and its incidence is increasing in the United States.
 - The main etiologic agents for HCC are chronic hepatitis B and C, alcoholic cirrhosis, non-alcoholic fatty liver disease, and hemochromatosis. In the Western population, about 90% of HCCs develop in cirrhotic livers; in Asia, almost 50% of cases develop in noncirrhotic livers.
 - The chronic inflammation and cellular regeneration associated with viral hepatitis or the activation of IL-6/JAK STAT pathway may be predisposing factors for the development of carcinomas.
 - HCCs may be unifocal or multifocal, tend to invade blood vessels, and recapitulate normal liver architecture to varying degrees.
- **Cholangiocarcinoma** is endemic in areas where liver flukes such as *Opisthorchis* and *Clonorchis* species are endemic. Chronic inflammatory diseases of bile ducts are also risk factors. The tumors may arise from extra hepatic or intrahepatic bile ducts. They have uniformly poor prognosis.

GALLBLADDER

As much as 1 L of bile is secreted by the liver per day. Between meals, bile is stored in the gallbladder, where it is concentrated. The adult gallbladder has a capacity of about 50 mL. The organ is not essential for biliary function, since humans do not suffer from indigestion or malabsorption of fat after cholecystectomy. **More than 95% of biliary tract disease is attributable to cholelithiasis (gallstones).** In the United States, gallstones affect 20 million people, and more than 700,000 cholecystectomies are performed annually at a cost of approximately \$6 billion.

Congenital Anomalies

The gallbladder may be congenitally absent, or there may be gallbladder duplication with conjoined or independent cystic ducts. A longitudinal or transverse septum may

create a bilobed gallbladder. Aberrant locations of the gallbladder occur in 5% to 10% of the population, most commonly partial or complete embedding in the liver substance. A folded fundus is the most common anomaly, creating a *phrygian cap* (Fig. 18-61). *Agnesis* of all or any portion of the hepatic or common bile ducts and hypoplastic narrowing of biliary channels (true “biliary atresia”) may also occur. *Choledochal cysts*, described earlier, may be isolated findings in the gallbladder or associated with other cysts in the extrahepatic biliary tree or with fibropolycystic disease.

Cholelithiasis (Gallstones)

Gallstones afflict 10% to 20% of adult populations in developed countries. It is estimated that more than 20 million

Figure 18-61 Phrygian cap of the gallbladder; the fundus is folded inward.

persons in the United States have gallstones, totaling some 25 to 50 tons in weight. The vast majority of gallstones (>80%) are “silent,” and most individuals remain free of biliary pain or other complications for decades. There are two general classes of gallstones: *cholesterol stones*, containing more than 50% of crystalline cholesterol monohydrate, and *pigment stones* composed predominantly of bilirubin calcium salts.

Prevalence and Risk Factors. Certain populations are far more prone than others to develop gallstones. Cholesterol gallstones are more prevalent in the United States and Western Europe (90%) and uncommon in developing countries. The prevalence rates of cholesterol gallstones approach 75% in Native Americans of the Pima, Hopi, and Navajo groups; pigment stones are rare in these populations. Pigment gallstones, the predominant type of gallstone in non-Western populations, arise primarily in the setting of bacterial infections of the biliary tree and parasitic infestations.

The major risk factors associated with the development of gallstones are listed in [Table 18-13](#) and are briefly described here:

- **Age and sex.** The prevalence of cholesterol gallstones increases throughout life but they predominantly affect individuals of middle to older age. Prevalence is higher in females in any region or ethnicity; in Caucasian women it is about twice as high as in men. Hypersecretion of biliary cholesterol seems to play the major role in both age and gender differences. Significant associations are also seen with the metabolic syndrome and obesity.
- **Environmental factors.** Estrogen exposure, including through oral contraceptive use and during pregnancy, increases the expression of hepatic lipoprotein receptors and stimulates hepatic HMG-CoA reductase activity, enhancing both cholesterol uptake and biosynthesis, respectively. The net result is excess biliary secretion of cholesterol. Obesity and rapid weight loss also are strongly associated with increased biliary cholesterol secretion.
- **Acquired disorders.** Gallbladder stasis, either neurogenic or hormonal, fosters a local environment that is

favorable for both cholesterol and pigment gallstone formation.

- **Hereditary factors.** Genes encoding hepatocyte proteins that transport biliary lipids, known as ATP-binding cassette (ABC) transporters have associations with gallstone formation. In particular, a common variant of the sterol transporter encoded by the *ABCG8* gene is associated with an increased risk for the development of cholesterol gallstones.

Pathogenesis of Cholesterol Stones. Cholesterol is rendered soluble in bile by aggregation with water-soluble bile salts and water-insoluble lecithins, both of which act as detergents. *When cholesterol concentrations exceed the solubilizing capacity of bile (supersaturation), cholesterol can no longer remain dispersed and nucleates into solid cholesterol monohydrate crystals.* Four conditions appear to contribute to formation of cholesterol gallstones (1) supersaturation of bile with cholesterol; (2) hypomotility of the gallbladder; (3) accelerated cholesterol crystal nucleation; (4) and hypersecretion of mucus in the gallbladder, which traps the nucleated crystals, leading to accretion of more cholesterol and the appearance of macroscopic stones.

Pathogenesis of Pigment Stones. Pigment gallstones are complex mixtures of insoluble calcium salts of unconjugated bilirubin along with inorganic calcium salts. Disorders that are associated with elevated levels of unconjugated bilirubin in bile, such as chronic hemolytic anemias, severe ileal dysfunction or bypass, and bacterial contamination of the biliary tree, increase the risk of developing pigment stones. Unconjugated bilirubin is normally a minor component of bile, but it increases when infection of the biliary tract leads to release of microbial β -glucuronidases, which hydrolyze bilirubin glucuronides. Thus, infection of the biliary tract with *Escherichia coli*, *Ascaris lumbricoides*, or the liver fluke *C. sinensis*, increases the likelihood of pigment stone formation. In hemolytic anemias the secretion of conjugated bilirubin into the bile increases. About 1% of bilirubin glucuronides are deconjugated in the biliary tree, and in the setting of chronically increased secretion of conjugated bilirubin, there is

Table 18-13 Risk Factors for Gallstones

Cholesterol Stones

Chronic hemolytic syndromes
Biliary infection
Gastrointestinal disorders: ileal disease (e.g., Crohn disease), ileal resection or bypass, cystic fibrosis with pancreatic insufficiency

sufficiently large amount of deconjugated bilirubin left to allow pigment stones to form.

MORPHOLOGY

Cholesterol stones arise exclusively in the gallbladder and range from 100% pure (which is rare) down to around 50% cholesterol. Pure cholesterol stones are pale yellow, round to ovoid, and have a finely granular, hard external surface (Fig. 18-62), which on transection reveals a glistening radiating crystalline palisade. With increasing proportions of calcium carbonate, phosphates, and bilirubin, the stones take on a gray-white to black color and may be lamellated. Multiple stones are usually present that range up to several centimeters in diameter. Rarely, a very large stone may virtually fill the fundus. Surfaces of multiple stones may be rounded or faceted, because of tight apposition. Stones composed largely of cholesterol are radiolucent; sufficient calcium carbonate is found in 10% to 20% of cholesterol stones to render them radiopaque.

Pigment gallstones are brown to black. In general, black pigment stones are found in sterile gallbladder bile and brown stones are found in infected large bile ducts. Black stones contain oxidized polymers of the calcium salts of unconjugated bilirubin, small amounts of calcium carbonate, calcium phosphate, and mucin glycoprotein, and some cholesterol monohydrate crystals. Brown stones contain similar compounds along with some cholesterol and calcium salts of palmitate and stearate. The black stones are rarely greater than 1.5 cm in diameter, are almost invariably present in great number (with an inverse relationship between size and number; Fig. 18-63), and are quite friable. Their contours are usually spiculated and molded. Brown stones tend to be laminated and soft and may have a soaplike or greasy consistency. Approximately 50% to 75% of black stones are radiopaque due to calcium salts while brown stones, containing calcium soaps, are radiolucent. Mucin glycoproteins constitute the scaffolding and interparticle cement of all types of stones.

Clinical Features. Gallstones may be present for decades before symptoms develop, and 70% to 80% of patients remain asymptomatic throughout their lives. Asymptomatic

Figure 18-62 Cholesterol gallstones. The wall of the gallbladder is thickened and fibrotic due to chronic cholecystitis.

Figure 18-63 Pigment gallstones. Several faceted black gallstones are present in this otherwise unremarkable gallbladder from a patient with a mechanical mitral valve prosthesis, leading to chronic intravascular hemolysis.

individuals probably convert to being symptomatic at a rate of up to 4% per year, although the risk diminishes with time. Prominent among symptoms is *biliary colic* that may be excruciating. Despite its characterization as “colic” it is usually constant and not colicky. It usually follows a fatty meal which forces a stone against the gall bladder outlet leading to increased pressure in the gall bladder causing pain. Pain is localized to right upper quadrant or epigastrium that may radiate to the right shoulder or the back. Inflammation of the gallbladder (cholecystitis, discussed later), in association with stones, also generates pain. More severe complications include *empyema*, *perforation*, *fistulas*, *inflammation of the biliary tree (cholangitis)*, *obstructive cholestasis* and *pancreatitis*. The larger the calculi, the less likely they are to enter the cystic or common ducts to produce obstruction; it is the very small stones, or “gravel,” that are more dangerous. Occasionally a large stone may erode directly into an adjacent loop of small bowel, generating intestinal obstruction (“*gallstone ileus*” or *Bouveret syndrome*). Lastly (but not least), gallstones are associated with an increased risk of gallbladder carcinoma, discussed later.

Cholecystitis

Inflammation of the gallbladder may be acute, chronic, or acute superimposed on chronic. It almost always occurs in association with gallstones. In the United States cholecystitis is one of the most common indications for abdominal surgery. Its epidemiologic distribution closely parallels that of gallstones.

Acute Cholecystitis

Acute calculous cholecystitis is precipitated in 90% of cases by obstruction of the neck or the cystic duct by a stone. It is the primary complication of gallstones and the most common reason for emergency cholecystectomy. *Cholecystitis without gallstones (acalculous cholecystitis) may occur in severely ill patients and accounts for about 10% of patients with cholecystitis.*

Pathogenesis. *Acute calculous cholecystitis results from chemical irritation and inflammation of a gallbladder obstructed by stones.* The action of mucosal phospholipases hydrolyzes luminal lecithins to toxic lysolecithins. The normally protective glycoprotein mucus layer is disrupted, exposing the mucosal epithelium to the direct detergent action of bile salts. Prostaglandins released within the wall of the distended gallbladder contribute to mucosal and mural inflammation; distention and increased intraluminal pressure compromise blood flow to the mucosa. *These events occur in the absence of bacterial infection; only later in the course may bacterial contamination develop.* Acute calculous cholecystitis frequently develops in diabetic patients who have symptomatic gallstones.

Acute acalculous cholecystitis, without stone involvement, is thought to result from ischemia. The cystic artery is an end artery with no collateral circulation. Contributing factors may include inflammation and edema of the wall compromising blood flow, gallbladder stasis, and accumulation of microcrystals of cholesterol (biliary sludge), viscous bile, and gallbladder mucus, causing cystic duct obstruction in the absence of stones. It occurs in patients who are hospitalized for unrelated conditions. Risk factors for acute acalculous cholecystitis include: (1) sepsis with hypotension and multisystem organ failure; (2) immunosuppression; (3) major trauma and burns; (4) diabetes mellitus; (5) infections.

MORPHOLOGY

In **acute cholecystitis** the gallbladder is usually enlarged and tense, and it may assume a bright red or blotchy, violaceous to green-black discoloration, imparted by subserosal hemorrhages. The serosal covering is frequently covered by a fibrinous exudate that may be fibrinopurulent in severe cases. There are no specific morphologic differences between acute acalculous and calculous cholecystitis, save the absence of stones in the acalculous form. In **calculous cholecystitis**, an obstructing stone is usually present in the neck of the gallbladder or the cystic duct. The gallbladder lumen may contain one or more stones and is filled with a cloudy or turbid bile that may contain large amounts of fibrin, pus, and hemorrhage. When the exudate is virtually pure pus, the condition is referred to as **gallbladder empyema**. In mild cases the gallbladder wall is thickened, edematous, and hyperemic. In more severe cases it is transformed into a green-black necrotic organ, termed **gangrenous cholecystitis**, with small-to-large perforations. Inflammation is predominantly neutrophilic. The invasion of gas-forming organisms, notably clostridia and coliforms, may cause an **acute "emphysematous" cholecystitis**.

Clinical Features. Individuals with acute calculous cholecystitis usually, but not always, have experienced previous episodes of pain. An attack of acute cholecystitis begins with progressive right upper quadrant or epigastric pain that lasts for more than six hours. It is frequently associated with mild fever, anorexia, tachycardia, sweating, nausea, and vomiting. Most patients are free of jaundice; the presence of hyperbilirubinemia suggests obstruction of the common bile duct. Mild to moderate leukocytosis may be accompanied by mild elevations in serum alkaline

phosphatase values. *Acute calculous cholecystitis may appear with remarkable suddenness and constitute an acute surgical emergency or may present with mild symptoms that resolve without medical intervention.* In the absence of medical attention, the attack usually subsides in 7 to 10 days and frequently within 24 hours. However, as many as 25% of patients progressively develop more severe symptoms and require immediate surgical intervention. Recurrence is common in patients who recover without surgery.

Clinical symptoms of acute acalculous cholecystitis tend to be more insidious, since they are obscured by the underlying conditions precipitating the attacks. A higher proportion of patients have no symptoms referable to the gallbladder; diagnosis therefore rests on a high index of suspicion. In the severely ill patient, early recognition of the condition is crucial, since failure to do so almost ensures a fatal outcome. As a result of either delay in diagnosis or the disease itself, the incidence of gangrene and perforation is much higher in acalculous than in calculous cholecystitis. In rare instances, primary bacterial infection can give rise to acute acalculous cholecystitis, by agents such as *Salmonella typhi* and staphylococci. A more indolent form of acute acalculous cholecystitis may occur in the setting of systemic vasculitis, severe atherosclerotic ischemic disease in the elderly, in patients with AIDS, and with biliary tract infection.

Chronic Cholecystitis

Chronic cholecystitis may be a sequel to repeated bouts of mild to severe acute cholecystitis, but in many instances it develops in the apparent absence of antecedent attacks. Since it is associated with *cholelithiasis* in more than 90% of cases, the at-risk patient population is the same as that for gallstones. The evolution of chronic cholecystitis is obscure; it is not clear that gallstones play a direct role in the initiation of inflammation or the development of pain, particularly since chronic acalculous cholecystitis shows symptoms and histology similar to those of the calculous form. Rather, supersaturation of bile predisposes to both chronic inflammation and, in most instances, stone formation. Microorganisms, usually *E. coli* and enterococci, can be cultured from the bile in about one third of cases. Unlike acute calculous cholecystitis, obstruction of gallbladder outflow is not a requisite. Since most gallbladders that are removed at elective surgery for gallstones show features of chronic cholecystitis, one must conclude that biliary symptoms often emerge following long-term coexistence of gallstones and low-grade inflammation.

MORPHOLOGY

The morphologic changes in chronic cholecystitis are extremely variable and sometimes minimal. The serosa is usually smooth and glistening but may be dulled by **subserosal fibrosis**. Dense fibrous adhesions may remain as sequelae of preexistent acute inflammation. On sectioning, the wall is variably thickened, and has an opaque gray-white appearance. In the uncomplicated case the lumen contains green-yellow, mucoid bile and usually stones. The mucosa itself is generally preserved.

On histologic examination the degree of inflammation is variable. In the mildest cases, only scattered lymphocytes, plasma

Figure 18-64 Chronic cholecystitis. **A**, The gallbladder mucosa is infiltrated by inflammatory cells. **B**, Outpouching of the mucosa through the wall forms Rokitansky-Aschoff sinus (contains bile).

cells, and macrophages are found in the mucosa and in the subserosal fibrous tissue (Fig. 18-64A). In more advanced cases there is marked subepithelial and subserosal fibrosis, accompanied by mononuclear cell infiltration. Reactive proliferation of the mucosa and fusion of the mucosal folds may give rise to buried crypts of epithelium within the gallbladder wall. Outpouchings of the mucosal epithelium through the wall (**Rokitansky-Aschoff sinuses**) may be quite prominent (Fig. 18-64B). Presence of acute inflammatory changes implies acute exacerbation of an already chronically injured gallbladder.

In rare instances extensive dystrophic calcification within the gallbladder wall may yield a **porcelain gallbladder**, notable for a markedly increased incidence of associated cancer. In **xanthogranulomatous cholecystitis**, the gallbladder has a massively thickened wall and is shrunken, nodular, and chronically inflamed with foci of necrosis and hemorrhage. It is triggered by rupture of Rokitansky-Aschoff sinuses into the wall of the gall bladder followed by an accumulation of macrophages that have ingested biliary phospholipids. Such lipid containing cells with foamy cytoplasm are called xanthoma cells and hence the name of this condition. Finally, an atrophic, chronically obstructed, often dilated gallbladder, may contain only clear secretions, a condition known as **hydrops of the gallbladder**.

Clinical Features. Chronic cholecystitis does not have the striking manifestations of the acute forms and is usually characterized by recurrent attacks of either steady epigastric or right upper quadrant pain. Nausea, vomiting, and intolerance for fatty foods are frequent accompaniments.

Diagnosis of both acute and chronic cholecystitis is important because of the following complications:

- Bacterial superinfection with cholangitis or sepsis
- Gallbladder perforation and local abscess formation
- Gallbladder rupture with diffuse peritonitis
- Biliary enteric (cholecystenteric) fistula, with drainage of bile into adjacent organs, entry of air and bacteria into the biliary tree, and potentially, gallstone-induced intestinal obstruction (ileus)

- Aggravation of preexisting medical illness, with cardiac, pulmonary, renal, or liver decompensation
- Porcelain gallbladder, with increased risk of cancer, although surveys of this risk have yielded widely discrepant frequencies

Carcinoma

Carcinoma of the gallbladder is the most common malignancy of the extrahepatic biliary tract. Approximately 6,000 new cases of gallbladder cancer are diagnosed each year in the United States. There are wide variations in the incidence of gallbladder cancer worldwide, with some regions such as Chile, Bolivia and Northern India, harboring the highest numbers of cases. Even within the United States, areas with large numbers of Native American or Hispanic populations, such as the southwest, have a higher incidence of gallbladder cancer than the rest of the country. *Gallbladder cancer is at least twice as common in women than in men; this gender disparity can be several fold greater in regions of highest incidence.* The overwhelming majority of patients are diagnosed at an advanced, surgically unresectable, stage, and the mean 5-year survival for these patients remains at less than 10%.

Pathogenesis. *The most important risk factor for gallbladder cancer (besides gender and ethnicity) is gallstones which are present in 95% of cases. However, it should be noted that only 1-2% of patients with gallstones develop gallbladder cancer.* In Asia, chronic bacterial or parasitic infections have been implicated as risk factors, and the coexistence of gallstones with gallbladder cancer is much lower. Nonetheless, the common thread that ties gallstones or chronic infections together with gallbladder cancer is chronic inflammation. Gallbladder cancers harbor recurrent molecular alterations that might be “actionable” targets of therapy. One example is the oncoprotein ERBB2 (Her-2/neu) that is overexpressed in a third to two-thirds of cases, and therefore might be targeted with small molecule inhibitors or monoclonal antibodies. Recent deep sequencing of gallbladder cancers has revealed mutations

of chromatin remodeling genes such as *PBRM1* and *MLL3* in up to a quarter of cases. These could potentially provide targets for therapy.

MORPHOLOGY

Carcinomas of the gallbladder show two patterns of growth: **infiltrating** and **exophytic**. The infiltrating pattern is more common and usually appears as a poorly defined area of diffuse mural thickening and induration. Deep ulceration can cause direct penetration into the liver or fistula formation to adjacent viscera into which the neoplasm has grown. These tumors are scirrhous and have a very firm consistency. The exophytic pattern grows into the lumen as an irregular, cauliflower mass, but at the same time invades the underlying wall (Fig. 18-65A).

Most carcinomas of the gallbladder are adenocarcinomas. Some of the carcinomas are papillary in architecture and are well to moderately differentiated; others are infiltrative and poorly differentiated to undifferentiated (Fig. 18-65B). About 5% are squamous cell carcinomas or have adenosquamous differentiation. A minority may show carcinoid or a variety of mesenchymal features (carcinosarcoma). Papillary tumors generally have a better prognosis than other tumors. By the time these neoplasms are discovered, most have invaded the liver centrifugally, and many have extended to the cystic duct and adjacent bile ducts and portal-hepatic lymph nodes. The peritoneum, gastrointestinal tract, and lungs are common sites of seeding.

Figure 18-65 Gallbladder adenocarcinoma. **A**, The opened gallbladder contains a large, exophytic tumor that virtually fills the lumen. **B**, Malignant glands are seen infiltrating a densely fibrotic gallbladder wall.

It is not uncommon to find preneoplastic (dysplastic) lesions in the epithelium adjacent to invasive cancer, or in gallbladders with long-standing cholelithiasis. These are nearly always flat dysplasias, with varying grades of cellular atypia, including carcinoma-in-situ. Although polypoid adenomas of the gallbladder have been reported, these are uncommon precursors to invasive adenocarcinomas, and harbor distinct genetic alterations.

Clinical Features. Preoperative diagnosis of carcinoma of the gallbladder is the exception rather than the rule, occurring in fewer than 20% of patients. Presenting symptoms are insidious and typically indistinguishable from those associated with cholelithiasis: abdominal pain, jaundice, anorexia, and nausea and vomiting. Early detection of the tumor may be possible in patients who develop a palpable gallbladder and acute cholecystitis before extension of the tumor into adjacent structures, or when the carcinoma is an incidental finding during a cholecystectomy for symptomatic gallstones. Surgical resection, often including adjacent liver, is the only effective treatment, when possible, but chemotherapy regimens are also used.

KEY CONCEPTS

Diseases of the Gallbladder

- Gallbladder diseases include cholelithiasis and acute and chronic cholecystitis and gall bladder cancer.
- Gallstones are common in Western countries. The great majority are cholesterol stones. Pigmented stones containing bilirubin and calcium are most common in Asian countries.
- Risk factors for the development of cholesterol stones are advancing age, female gender, estrogen use, obesity, and heredity.
- Cholecystitis almost always occurs in association with cholelithiasis, although in about 10% of cases it occurs in the absence of gallstones. Gall stones are also a risk factor for gall bladder cancer.
- Acute calculous cholecystitis is the most common reason for emergency cholecystectomy.
- Gall bladder cancers are associated with gall stones in the vast majority of cases. Typically they are detected late because of non specific symptoms and hence carry a poor prognosis.

Acinar Cell Carcinoma 895
Pancreatoblastoma 895

The adult pancreas is a transversely oriented retroperitoneal organ extending from the C-loop of the duodenum to the hilum of the spleen (Fig. 19-1A). Although the organ gets its name from the Greek *pankreas* (“all flesh”), it is in fact a complex lobulated organ with distinct exocrine and endocrine components.

The *exocrine pancreas* constitutes 80% to 85% of the organ and is composed of acinar cells that secrete enzymes needed for digestion. Acinar cells are pyramidally shaped epithelial cells containing membrane-bound granules rich in proenzymes (zymogens), including trypsinogen, chymotrypsinogen, procarboxypeptidase, proelastase, kallikreinogen, and prophospholipase A and B. Upon secretion, these proenzymes and enzymes are carried by a series of ductules and ducts to the duodenum, where they are activated by proteolytic cleavage in the gastrointestinal tract (described later).

The *endocrine pancreas* is composed of about 1 million clusters of cells, the islets of Langerhans, scattered throughout the gland. The islet cells secrete insulin, glucagon, and somatostatin and constitute only 1% to 2% of the organ. Diseases of the endocrine pancreas are described in detail in Chapter 24.

Congenital Anomalies

The complex process by which the dorsal and ventral pancreatic primordia fuse during pancreatic development is prone to “imperfections” that frequently gives rise to congenital variations in pancreatic anatomy. The pancreas normally arises from the fusion of dorsal and ventral outpouchings of the foregut. The body, the tail, and the superior/anterior aspect of the head of the pancreas, as well as the accessory duct of Santorini, are derived from

the dorsal primordium. Normally, the ventral primordium gives rise to the posterior/inferior part of the head of the pancreas and drains through the main pancreatic duct into the papilla of Vater.

Pancreas Divisum. *Pancreas divisum* is the most common congenital anomaly of the pancreas, with an incidence of 3% to 10%. In most individuals, the main pancreatic duct (the duct of Wirsung) joins the common bile duct just proximal to the papilla of Vater, and the accessory pancreatic duct (the duct of Santorini) drains into the duodenum through a separate minor papilla (Fig. 19-1A). *Pancreas divisum* is caused by a failure of fusion of the fetal duct systems of the dorsal and ventral pancreatic primordia. As a result, the bulk of the pancreas (formed by the dorsal pancreatic primordium) drains into the duodenum through the small-caliber minor papilla (Fig. 19-1B). The duct of Wirsung in persons with *divisum* drains only a small portion of the head of the gland through the papilla of Vater. Although controversial, it has been suggested that inadequate drainage of the pancreatic secretions through the minor papilla, especially when combined with genetic defects that also increases susceptibility to pancreatitis (described later), predisposes individuals with *pancreas divisum* to chronic pancreatitis.

Annular Pancreas. Annular pancreas is a band-like ring of normal pancreatic tissue that completely encircles the second portion of the duodenum. Annular pancreas can produce duodenal obstruction.

Ectopic Pancreas. Pancreatic tissue that is aberrantly situated, or ectopic, is found in about 2% of careful routine postmortem examinations. The favored sites for ectopia are the stomach and duodenum, followed by the jejunum,

Figure 19-1 Pancreatic ductal anatomy. **A**, The normal ductal anatomy. **B**, The ductal anatomy in pancreatic divisum. (Adapted from Gregg JA, et al: Pancreas divisum: results of surgical intervention. *Am J Surg* 1983; 145:488-492.)

Meckel diverticula, and ileum. Although usually incidental findings, these embryologic rests, composed of normal-appearing pancreatic acini, glands, and sometimes islets of Langerhans, may cause pain from localized inflammation, or, rarely, may incite mucosal bleeding.

Agenesis. Very rarely the pancreas fails to develop (agenesis). Some cases of agenesis are caused by homozygous germline mutations involving *PDX1*, a gene encoding a homeobox transcription factor that is critical for pancreatic development.

Pancreatitis

Pancreatitis is divided into two forms, acute and chronic, each with its own characteristic pathologic and clinical features. As we will discuss, both are initiated by injuries that lead to autodigestion of the pancreas by its own enzymes. Under normal circumstances, the following mechanisms protect the pancreas from self-digestion by its secreted enzymes:

- Most digestive enzymes are synthesized as inactive proenzymes (zymogens), which are packaged within secretory granules.
- Most proenzymes are activated by trypsin, which itself is activated by duodenal enteropeptidase (enterokinase)

Mumps

in the small bowel; thus, intrapancreatic activation of proenzymes is normally minimal.

- Acinar and ductal cells secrete trypsin inhibitors, including serine protease inhibitor Kazal type I (SPINK1), which further limit intrapancreatic trypsin activity.

Pancreatitis occurs when these protective mechanisms are deranged or overwhelmed. As discussed later, the clinical manifestations of pancreatitis vary widely. Acute attacks may be mild and self-limited or present as a life-threatening acute inflammatory process; with recurrent or persistent pancreatitis, there may be permanent loss of pancreatic function.

Acute Pancreatitis

Acute pancreatitis is characterized by reversible pancreatic parenchymal injury associated with inflammation and has diverse etiologies, including toxic exposures (e.g., alcohol), pancreatic duct obstruction (e.g., biliary calculi), inherited genetic defects, vascular injury, and infections. Acute pancreatitis is relatively common; the annual incidence in Western countries is 10 to 20 cases per 100,000 people. Biliary tract disease and alcoholism account for approximately 80% of cases of acute pancreatitis in Western countries (Table 19-1). Gallstones are present in 35% to 60% of cases, and pancreatitis develops in about 5% of patients with gallstones. The proportion of cases of acute pancreatitis caused by excessive alcohol intake varies from 65% in the United States to 20% in Sweden to 5% or less in southern France and the United Kingdom. The male-to-female ratio is 1:3 in the group with biliary tract disease and 6:1 in those with alcoholism.

Pathogenesis. Acute pancreatitis results from inappropriate release and activation of pancreatic enzymes, which destroy pancreatic tissue and elicit an acute

inflammatory reaction. As we discussed, pancreatic enzymes, including trypsin, are synthesized in an inactive proenzyme form. Inappropriate intrapancreatic activation of trypsin can in turn cause the activation of other proenzymes such as prophospholipase and proelastase, which then degrade fat cells and damage the elastic fibers of blood vessels, respectively. Trypsin also converts prekallikrein to its activated form, thus bringing into play the kinin system and, by activation of coagulation factor XII, the clotting and complement systems as well (Chapters 3 and 4). The resulting inflammation and small-vessel thromboses (which may lead to congestion and rupture of already weakened vessels) damage acinar cells, further amplifying intrapancreatic activation of digestive enzymes.

How inappropriate activation of pancreatic enzymes occurs in sporadic forms of acute pancreatitis is not entirely clear, but there is evidence for at least three major initiating events (Fig. 19-2):

- **Pancreatic duct obstruction.** Obstruction is most commonly caused by *gallstones* and biliary sludge, but can also stem from *periampullary neoplasms* (e.g., pancreatic cancer), *choledochoceles* (congenital cystic dilatation of the common bile duct), *parasites* (particularly the *Ascaris lumbricoides* and *Clonorchis sinensis*

organisms), and possibly pancreas divisum. Whatever the cause, obstruction raises intrapancreatic ductal pressure and leads to the accumulation of enzyme-rich fluid in the interstitium. Although most pancreatic enzymes are secreted as inactive zymogens, lipase is produced in an active form and has the potential to cause local fat necrosis. The death of adipocytes is hypothesized to produce “danger” signals locally that stimulate periacinar myofibroblasts and leukocytes to release proinflammatory cytokines and other inflammatory mediators that initiate local inflammation and promote the development of interstitial edema through a leaky microvasculature. Edema may further compromise local blood flow, causing vascular insufficiency and ischemic injury to acinar cells.

- **Primary acinar cell injury,** leading to release of digestive enzymes, inflammation, and autodigestion of pancreatic tissues. As described later, acinar cells can be damaged by a variety of endogenous, exogenous, and iatrogenic insults. Oxidative stress may generate free radicals in acinar cells, leading to membrane lipid oxidation and the activation of transcription factors, including AP1 and NF- κ B, which in turn induce the expression of chemokines that attract mononuclear

Figure 19-2 Three proposed pathways in the pathogenesis of acute pancreatitis.

Table 19-2 Inherited Predisposition to Pancreatitis

Gene (Chromosome Location)	Protein Product	Function
<i>CFTR</i> (7q31)	Cystic fibrosis transmembrane conductance regulator	Epithelial anion channel. Loss-of-function mutations alter fluid pressure and limit bicarbonate secretion, leading to inspissation of secreted fluids and duct obstruction
<i>PRSS1</i> (7q34)	Serine protease 1 (trypsinogen 1)	Cationic trypsin. Gain-of-function mutations prevent self-inactivation of trypsin
<i>SPINK1</i> (5q32)	Serine peptidase inhibitor, Kazal type 1	Inhibitor of trypsin. Mutations cause loss-of-function, increasing trypsin activity
<i>CASR</i> (3q13)	Calcium-sensing receptor	Membrane-bound receptor that senses extracellular calcium levels and controls luminal calcium levels. Mutations may alter calcium concentrations and activate trypsin.
<i>CTRC</i> (1p36)	Chymotrypsin C (caldecrin)	Degrades trypsin, protects the pancreas from trypsin-related injury
<i>CPA1</i> (7q32)	Carboxypeptidase A1	Exopeptidase involved in regulating zymogen activation

cells. Increased calcium flux appears to be another important trigger for inappropriate activation of digestive enzymes. Calcium has a key role in regulating trypsin activation. When calcium levels are low, trypsin tends to cleave and inactivate itself, but when calcium levels are high autoinhibition is abrogated and activation of trypsinogen by trypsin is favored. It is suspected that any factor that causes calcium levels to rise in acinar cells may trigger excessive activation of trypsin, including certain inherited abnormalities that affect calcium levels (Table 19-2).

- **Defective intracellular transport of proenzymes within acinar cells.** In normal acinar cells, digestive enzymes and lysosomal hydrolases are transported in separate pathways. In animal models of acinar injury, the pancreatic proenzymes are inappropriately delivered to the intracellular compartment containing lysosomal hydrolases. Proenzymes are then activated, the lysosomes are disrupted, and the activated enzymes are released. The role of this mechanism in human acute pancreatitis is not clear.

Alcohol consumption may cause pancreatitis through all of these mechanisms. Alcohol consumption transiently increases contraction of the sphincter of Oddi (the muscle at the Papilla of Vater), and chronic alcohol ingestion results in the secretion of protein-rich pancreatic fluid that leads to the deposition of inspissated protein plugs and obstruction of small pancreatic ducts. Alcohol also has direct toxic effects on acinar cells. Alcohol-induced oxidative stress may generate free radicals in acinar cells, leading to membrane lipid oxidation and free radical production, which as already mentioned has been linked to activation of the pro-inflammatory transcription factors AP1 and NF- κ B. Oxidative stress also may promote the fusion of lysosomes and zymogen granules and alter intracellular calcium levels, possibly through mitochondrial damage, promoting the intraacinar activation of trypsin and other digestive enzymes. Nevertheless, it should be noted that most drinkers never develop pancreatitis and those who do usually do so after many years of alcohol abuse. Thus, key aspects of the pathophysiology of alcohol-induced pancreatitis remain obscure.

Other proven or suspected triggers of acute pancreatitis in the remaining sporadic cases include the following (Table 19-1):

- **Metabolic disorders**, such as hypertriglyceridemia, and hypercalcemic states, such as hyperparathyroidism

- **Genetic lesions**, described below
- **Medications.** More than 85 drugs have been implicated, including furosemide, azathioprine, 2',3'-dideoxyinosine, estrogens, and many others. In most cases the mechanism of drug-induced pancreatitis is unknown.
- **Traumatic injury of acinar cells**, either by blunt abdominal trauma or by iatrogenic injury during surgery or endoscopic retrograde cholangiopancreatography
- **Ischemic injury of acinar cells**, caused by shock, vascular thrombosis, embolism, and vasculitis
- **Infections**, including mumps, can lead to acute pancreatitis through direct acinar cell injury

Hereditary factors are increasingly being recognized as a significant cause of pancreatitis. Hereditary pancreatitis is characterized by recurrent attacks of severe acute pancreatitis often beginning in childhood and ultimately leading to chronic pancreatitis. The disorder is genetically diverse, but the **shared feature of most forms is a defect that increases or sustains the activity of trypsin** (Table 19-2). Three genes implicated in hereditary pancreatitis deserve special note: *PRSS1*, *SPINK1*, and *CFTR*. Most hereditary cases are due to gain-of-function mutations in the *trypsinogen* gene (also known as *PRSS1*). Some of these *PRSS1* gene mutations make trypsin resistant to self-inactivation, abrogating an important negative feedback mechanism; other mutations appear to make trypsinogen more prone to proteolytic activation. Hereditary pancreatitis associated with trypsinogen mutation has an autosomal dominant mode of inheritance, as is typically true of disorders associated with gain-of-function mutations.

Hereditary pancreatitis can also be caused by loss-of-function mutations in *SPINK1*, already described as a gene encoding a trypsin inhibitor. As expected, this form of hereditary pancreatitis has an autosomal recessive mode of inheritance.

As discussed in detail in Chapter 5, cystic fibrosis is caused by mutations in the cystic fibrosis transmembrane conductance regulator (*CFTR*) gene, and homozygous and even heterozygous *CFTR* gene mutations are associated with pancreatitis, the latter particularly in patients who also have *SPINK1* mutations. Mutations in *CFTR* decrease bicarbonate secretion by pancreatic ductal cells, thereby promoting protein plugging, duct obstruction, and the development of pancreatitis.

Of note, patients with hereditary pancreatitis have a 40% lifetime risk of developing pancreatic cancer, yet another example of the nefarious association of chronic tissue injury and inflammation with neoplasia.

MORPHOLOGY

The morphology of acute pancreatitis ranges from trivial inflammation and edema to severe extensive necrosis and hemorrhage. The basic alterations are **(1) microvascular leak and edema, (2) fat necrosis, (3) acute inflammation, (4) destruction of pancreatic parenchyma, and (5) destruction of blood vessels and interstitial hemorrhage.** The extent of each of these alterations depends on the duration and severity of the process.

In the milder form, **acute interstitial pancreatitis**, histologic alterations are limited to mild inflammation, interstitial edema, and focal areas of fat necrosis in the pancreas and the peripancreatic fat (Fig. 19-3). Fat necrosis, as we have seen, results from enzymatic activity of lipase. The released fatty acids combine with calcium to form insoluble salts that impart a granular blue microscopic appearance to the fat cells (Chapter 2).

In the more severe form, **acute necrotizing pancreatitis**, there is necrosis of acinar and ductal tissues as well as islets of Langerhans. Vascular injury can lead to hemorrhage into the pancreatic parenchyma. Macroscopically, the pancreatic substance is red-black from hemorrhage and contains interspersed foci of yellow-white, chalky fat necrosis (Fig. 19-4). Focal fat necrosis may also occur adjacent to the pancreas in the omentum and the mesentery of the bowel, and even outside the abdominal cavity, such as in the subcutaneous fat. In most cases the peritoneal cavity contains a serous, slightly turbid, brown-tinged fluid

Figure 19-3 The microscopic field shows a region of fat necrosis on the right and focal pancreatic parenchymal necrosis (center).

Figure 19-4 The pancreas has been sectioned longitudinally to reveal dark areas of hemorrhage in the head of the pancreas and a focal area of pale fat necrosis in the peripancreatic fat (upper left).

containing globules of fat (derived from the action of enzymes on adipose tissue). In its most severe form, **hemorrhagic pancreatitis**, extensive parenchymal necrosis is accompanied by dramatic hemorrhage within the substance of the gland.

Clinical Features. *Abdominal pain* is the cardinal manifestation of acute pancreatitis. Characteristically, the pain is constant and intense and is referred to the upper back and occasionally to the left shoulder. Its severity varies from mild and uncomfortable to severe and incapacitating. Anorexia, nausea, and vomiting frequently accompany the pain. Elevated plasma levels of amylase and lipase support the diagnosis of acute pancreatitis, as does the exclusion of other causes of abdominal pain.

Full-blown acute pancreatitis is a medical emergency. Patients usually have the sudden calamitous onset of an “acute abdomen.” Many of the systemic features of severe acute pancreatitis can be attributed to release of toxic enzymes, cytokines, and other mediators into the circulation and explosive activation of a systemic inflammatory response, resulting in *leukocytosis, disseminated intravascular coagulation, edema, and acute respiratory distress syndrome.* Shock, due to the systemic inflammatory response syndrome (Chapters 4), and acute renal tubular necrosis may occur.

Laboratory findings include *marked elevation of serum amylase* levels during the first 24 hours, followed by a rising serum lipase level by 72 to 96 hours after the beginning of the attack. *Glycosuria* occurs in 10% of cases. *Hypocalcemia* may result from precipitation of calcium soaps in necrotic fat. Direct visualization of the enlarged inflamed pancreas by CT scanning is useful in the diagnosis of pancreatitis.

The key to the management of acute pancreatitis is “resting” the pancreas by total restriction of oral intake and by supportive therapy with intravenous fluids and analgesia. Although most individuals with acute pancreatitis recover fully, about 5% with severe acute pancreatitis die in the first week of illness. Acute respiratory distress syndrome and acute renal failure are ominous complications. Sequelae can include a sterile *pancreatic abscess* and a *pancreatic pseudocyst* (discussed later). In 40% to 60% of patients with acute necrotizing pancreatitis the necrotic debris becomes infected, usually by gram-negative organisms from the alimentary tract, further complicating the clinical course. Systemic organ failure and necrosis in the pancreas are both poor prognostic findings.

KEY CONCEPTS

- Acute pancreatitis is a form of *reversible* pancreatic parenchymal injury associated with inflammation.
- Acute pancreatitis may be caused by
 - Excessive alcohol intake
 - Pancreatic duct obstruction (e.g., gallstones)
 - Genetic factors (e.g., *PRSS1*, *SPINK1*)
 - Traumatic injuries
 - Medications
 - Infections (e.g., mumps)
 - Metabolic disorders leading to hypercalcemia
 - Ischemia

Figure 19-5 Comparison of the mediators in acute and chronic pancreatitis. In acute pancreatitis acinar injury results in release of proteolytic enzymes, leading to a cascade of events including activation of the clotting cascade, acute and chronic inflammation, vascular injury, and edema. In most patients, complete resolution of the acute injury occurs with restoration of acinar cell mass. In chronic pancreatitis, repeated episodes of acinar cell injury lead to the production of profibrogenic cytokines such as transforming growth factor β (TGF- β) and platelet-derived growth factor (PDGF), resulting in the proliferation of myofibroblasts, the secretion of collagen, and remodeling of the extracellular matrix (ECM). Repeated injury produces irreversible loss of acinar cell mass, fibrosis, and pancreatic insufficiency.

- The key feature of all of these causes is that they promote the inappropriate activation of digestive enzymes within the substance of the pancreas
- Clinical features include acute abdominal pain, systemic inflammatory response syndrome, and elevated serum lipase and amylase levels

Chronic Pancreatitis

Chronic pancreatitis is defined as prolonged inflammation of the pancreas associated with irreversible destruction of exocrine parenchyma, fibrosis, and, in the late stages, the destruction of endocrine parenchyma. The prevalence of chronic pancreatitis ranges between 0.04% and 5%; most affected patients are middle-aged males. **The most common cause of chronic pancreatitis by far is long-term alcohol abuse.** In addition to alcohol, chronic pancreatitis has been associated with the following conditions:

- Long-standing *obstruction* of the pancreatic duct by calculi or neoplasms
- *Autoimmune injury* to the gland
- *Hereditary pancreatitis*, as discussed under acute pancreatitis; up to 25% of chronic pancreatitis has a genetic basis

Pathogenesis. Chronic pancreatitis most often follows repeated episodes of acute pancreatitis. It has been proposed that acute pancreatitis initiates a sequence of perilobular fibrosis, duct distortion, and altered pancreatic secretions. Over time and with multiple episodes, this can lead to loss of pancreatic parenchyma and fibrosis.

Chronic pancreatic injury, whatever its cause, leads to local production of inflammatory mediators that promote fibrosis and acinar cell loss. While the cytokines produced

during chronic and acute pancreatitis are similar, fibrogenic factors tend to predominate in chronic pancreatitis. These fibrogenic cytokines include transforming growth factor β (TGF- β) and platelet-derived growth factor, which induce the activation and proliferation of periacinar myofibroblasts (pancreatic stellate cells), resulting in the deposition of collagen and fibrosis (Fig. 19-5).

Autoimmune pancreatitis is a pathogenically distinct form of chronic pancreatitis that is associated with the presence of IgG4-secreting plasma cells in the pancreas. Autoimmune pancreatitis is one manifestation of IgG-related disease (Chapter 6), which may involve multiple tissues. Autoimmune pancreatitis may mimic the signs and symptoms of pancreatic carcinoma. It is important to recognize because it responds to steroid therapy.

MORPHOLOGY

Chronic pancreatitis is characterized by fibrosis, atrophy and dropout of acini, and variable dilation of pancreatic ducts (Fig. 19-6A). Grossly, the gland is hard, sometimes with visibly dilated ducts containing calcified concretions. These changes are typically accompanied by a chronic inflammatory infiltrate around lobules and ducts. The ductal epithelium may be atrophied or hyperplastic or may show squamous metaplasia. Acinar loss is a constant feature. There is usually relative sparing of the islets of Langerhans, which become embedded in the sclerotic tissue and may fuse and appear enlarged, but in advanced disease the islets also are lost. Chronic pancreatitis caused by alcohol abuse is characterized by ductal dilatation and intraluminal protein plugs and calcifications (Fig. 19-6B). **Autoimmune pancreatitis** is characterized by a duct-centric mixed inflammatory cell infiltrate, venulitis, and increased numbers of IgG4-secreting plasma cells.

Figure 19-6 Chronic pancreatitis. **A**, Extensive fibrosis and atrophy has left only residual islets (*left*) and ducts (*right*), with a sprinkling of chronic inflammatory cells and a few islands of acinar tissue. **B**, A higher power view demonstrating dilated ducts with inspissated eosinophilic ductal concretions in a person with alcoholic chronic pancreatitis.

Clinical Features. Chronic pancreatitis may present in many different ways. It may follow repeated bouts of acute pancreatitis. There may be repeated attacks of mild to moderately severe abdominal pain, or persistent abdominal and back pain. Attacks may be precipitated by alcohol abuse, overeating (which increases demand on the pancreas), or the use of opiates and other drugs that increase the tone of the sphincter of Oddi. In other patients the disease may be entirely silent until pancreatic insufficiency and diabetes mellitus develop due to destruction of the exocrine and endocrine pancreas.

The diagnosis of chronic pancreatitis requires a high degree of suspicion. During an attack of abdominal pain there may be mild fever and mild-to-moderate elevations of serum amylase. When the disease has been present for a long time, however, the dropout of acinar cells may be so great as to eliminate these diagnostic clues. Gallstone-induced obstruction may be evident as jaundice or elevations in serum levels of alkaline phosphatase. A very helpful finding is visualization of calcifications within the pancreas by computed tomography and ultrasonography. Weight loss and edema due to low albumin from malabsorption caused by pancreatic exocrine insufficiency also support the diagnosis.

Although chronic pancreatitis is usually not an immediately life-threatening condition, the long-term outlook for individuals with chronic pancreatitis is poor, with a

20- to 25-year mortality rate of 50%. Pancreatic exocrine insufficiency, chronic malabsorption, and diabetes mellitus can all lead to significant morbidity and contribute to mortality. In other patients **severe chronic pain** is a dominant problem. **Pancreatic pseudocysts** (described later) develop in about 10% of patients. As already mentioned, patients with hereditary pancreatitis have a 40% lifetime risk of developing pancreatic cancer; whether this increased cancer risk extends to other forms of chronic pancreatitis is unclear.

KEY CONCEPTS

- Chronic pancreatitis is characterized by *irreversible injury* of the pancreas leading to fibrosis, loss of pancreatic parenchyma, loss of exocrine and endocrine function, and high risk of developing pseudocysts
- Chronic pancreatitis is most often caused by
 - Repeated bouts of acute pancreatitis
 - Chronic alcohol abuse
 - Germline mutations in genes such as *CFTR* (the gene encoding the transporter that is defective in cystic fibrosis), particularly when combined with environmental stressors
 - Clinical features include intermittent or persistent abdominal pain, intestinal malabsorption, and diabetes

Nonneoplastic Cysts

A variety of cysts can arise in the pancreas. Most are non-neoplastic pseudocysts (discussed later), but congenital cysts and neoplastic cysts also occur.

Congenital Cysts

Congenital cysts are unilocular, thin-walled cysts that are believed to result from anomalous development of the pancreatic ducts. They range in size from microscopic lesions to 5 cm in diameter, and are lined by a glistening, uniform cuboidal epithelium or, if the intracystic pressure is high, by a flattened and attenuated cell layer. Congenital cysts are enclosed in a thin, fibrous capsule and are filled with a clear serous fluid. Congenital cysts may be sporadic, or part of inherited conditions such as *autosomal-dominant polycystic kidney disease* (Chapter 20) and *von Hippel-Lindau disease* (Chapter 28). Cysts in the kidney, liver, and pancreas frequently coexist in polycystic kidney disease. In von Hippel-Lindau disease vascular neoplasms are found in the retina and cerebellum or brain stem in association with congenital cysts (and also neoplasms) in the pancreas, liver, and kidney.

Pseudocysts

Pseudocysts are localized collections of necrotic and hemorrhagic material that are rich in pancreatic enzymes and lack an epithelial lining (hence the prefix “pseudo”). Pseudocysts account for approximately 75% of cysts in the pancreas. They usually arise following a bout of acute pancreatitis, particularly one superimposed on chronic alcoholic pancreatitis. Traumatic injury to the pancreas can also give rise to pseudocysts.

Figure 19-7 Pancreatic pseudocyst. **A**, Cross-section revealing a poorly defined cyst with a necrotic brown-black wall. **B**, The cyst lacks a true epithelial lining and instead is lined by fibrin and granulation tissue.

MORPHOLOGY

Pseudocysts are usually solitary and may be situated within the pancreas, or, more commonly, in the lesser omental sac or in the retroperitoneum between the stomach and transverse colon or between the stomach and liver. They can even be subdiaphragmatic (Fig. 19-7A). Pseudocysts are formed when areas of intrapancreatic or peripancreatic hemorrhagic fat necrosis are walled off by fibrous tissue and granulation tissue (Fig. 19-7B). They range in size from 2 to 30 cm in diameter.

While many pseudocysts spontaneously resolve, they may become secondarily infected, and larger pseudocysts may compress or even perforate into adjacent structures.

Neoplasms

A broad spectrum of exocrine neoplasms arises in the pancreas. Such neoplasms may be cystic or solid; some are benign, while others are among the most lethal of all malignancies. Neuroendocrine tumors also occur in the pancreas and are discussed in Chapter 24.

Cystic Neoplasms

Cystic neoplasms are diverse tumors that range from harmless benign cysts to lesions that may be precursors

Figure 19-8 Serous cystic neoplasm (serous cystadenoma). **A**, Cross-section through a serous cystic neoplasm. Only a thin rim of normal pancreatic parenchyma remains. The cysts are relatively small and contain clear, straw-colored fluid. **B**, The cysts are lined by cuboidal epithelium without atypia.

to invasive, potentially lethal, cancers. Only 5% to 15% of all pancreatic cysts are neoplastic (most are pseudocysts; see the previous section), and cystic neoplasms make up fewer than 5% of all pancreatic neoplasms. Serous cystic neoplasms are entirely benign, whereas others, such as intraductal papillary mucinous neoplasms and mucinous cystic neoplasms, are precancerous. Recent whole-exome sequencing has identified genetic alterations specific for each type of cystic neoplasm.

Serous cystic neoplasms are multicystic neoplasms that usually occur in the tail of the pancreas. The cysts are small (1 to 3 mm), lined by glycogen-rich cuboidal cells, and contain clear, thin, straw-colored fluid (Fig. 19-8). They account for about 25% of all cystic neoplasms of the pancreas. These neoplasms arise twice as often in women as in men and typically present in the sixth to seventh decade of life with nonspecific symptoms such as abdominal pain. Many are now being detected incidentally during imaging for another indication. Serous cystic neoplasms, called serous cystadenomas, are almost always benign and, if small, can be safely observed. Surgical resection is curative in the vast majority of patients. Inactivation of the *VHL* tumor suppressor gene is the most common genetic abnormality in serous cystic neoplasms.

Close to 95% of *mucinous cystic neoplasms* arise in women, and, in contrast to serous cystic neoplasms, they

Figure 19-9 Pancreatic mucinous cystic neoplasm with low-grade dysplasia. **A**, Cross-section through a mucinous multiloculated cyst in the tail of the pancreas. The cysts are large and filled with tenacious mucin. **B**, The cysts are lined by columnar mucinous epithelium, and a dense “ovarian” stroma is noted.

can be precursors to invasive carcinomas. These neoplasms usually arise in the tail of the pancreas and present as painless, slow-growing masses. The cystic cavities are larger than those in serous cystic neoplasms. They are filled with thick, tenacious mucin and lined by a columnar mucin-producing epithelium associated with a dense stroma similar to ovarian stroma (Fig. 19-9). Up to one third of surgically resected mucinous cystic neoplasms harbor an associated invasive adenocarcinoma. While surgical resection is curative for noninvasive mucinous cystic neoplasms, half of patients with an invasive carcinoma arising in a mucinous cystic neoplasm will die of their disease. Early detection and treatment before an invasive cancer develops is therefore critical. The *KRAS* oncogene and the *TP53* and *RNF43* tumor suppressor genes are frequently mutated in these neoplasms.

Intraductal papillary mucinous neoplasms (IPMNs) are mucin-producing neoplasms that involve the larger ducts of the pancreas. In contrast to mucinous cystic neoplasms, IPMNs arise more frequently in men than in women, and they involve the head of the pancreas more often than the tail. Ten to twenty percent are multifocal. Two features are

Figure 19-10 Intraductal papillary mucinous neoplasm. **A**, Cross-section through the head of the pancreas showing a prominent papillary neoplasm distending the main pancreatic duct. **B**, The neoplasm involves the main pancreatic duct (left) and extends down into the smaller ducts and ductules (right).

useful in distinguishing IPMNs from mucinous cystic neoplasms: (1) absence of the dense “ovarian” stroma seen in mucinous cystic neoplasms and (2) involvement of a pancreatic duct (Fig. 19-10). Just as with mucinous cystic neoplasms, IPMNs can progress to an invasive cancer. Early detection and treatment of IPMNs before they progress to an invasive cancer is therefore critical. Frequent mutations in the *GNAS* and *KRAS* oncogenes and the *TP53*, *SMAD4*, and *RNF43* tumor suppressor genes have been reported in these neoplasms.

The unusual *solid-pseudopapillary neoplasm* is seen mainly in young women. These large, well-circumscribed malignant neoplasms have solid and cystic components filled with hemorrhagic debris. The neoplastic cells grow in solid sheets or, as the name suggests, as pseudopapillary projections, and often appear to be poorly cohesive. These neoplasms often cause abdominal discomfort because of their large size. Of note, this neoplasm is virtually always associated with hyperactivation of the Wnt signaling pathway due to acquired activating mutations of the *CTNNB1* (β -catenin) oncogene. Surgical resection is the treatment of choice. Although some solid-pseudopapillary neoplasms are locally aggressive, most patients are cured following complete surgical resection of the neoplasm.

KEY CONCEPTS

- Virtually all serous cystic neoplasms are benign.
- Intraductal papillary mucinous neoplasms and mucinous cystic neoplasms are curable noninvasive cystic neoplasms that can progress to incurable invasive carcinoma.
- Each of the major cystic neoplasms has a relatively specific mutational profile.

Pancreatic Carcinoma

Infiltrating ductal adenocarcinoma of the pancreas, more commonly known as pancreatic cancer, is the fourth leading cause of cancer deaths in the United States, trailing only lung, colon, and breast cancers, and has one of the highest mortality rates of any cancer. It was estimated that in 2013 pancreatic cancer would strike approximately 44,000 Americans, virtually all of whom would die of their disease. The 5-year survival rate is dismal, less than 5%.

Precursors to Pancreatic Cancer

Invasive pancreatic cancers are believed to arise from well-defined noninvasive precursor lesions in small ducts referred to as *pancreatic intraepithelial neoplasia* (PanIN, Fig. 19-11). Just as there is a progression in the colorectum from nonneoplastic epithelium to adenoma to invasive carcinoma (Chapters 7 and 17), there is a progression in the pancreas from nonneoplastic epithelium to PanIN to invasive carcinoma. The PanIN-invasive carcinoma sequence is supported by the following observations:

- The genetic and epigenetic alterations identified in PanIN are similar to those found in invasive cancers (described later).
- PanIN is often found in pancreatic parenchyma adjacent to infiltrating carcinoma.
- PanIN precedes the development of invasive cancer in genetically engineered mouse models of pancreatic cancer.
- Isolated case reports have documented individuals with PanIN who later developed an invasive pancreatic cancer.

Figure 19-12 Model for the progression from normal ducts (*far left*) through PanINs (*center*) to invasive carcinoma (*far right*). It is postulated that telomere shortening and mutations of the oncogene *KRAS* occur early, that inactivation of the *CDKN2A* tumor suppressor gene that encodes the cell cycle regulator p16^{sta} occurs in intermediate grade lesions, and that the inactivation of the *TP53*, *SMAD4*, and *BRCA2* tumor suppressor genes occur in higher grade (PanIN-3) lesions. It is important to note that while there is a general temporal sequence of changes, the accumulation of multiple mutations is more important than their occurrence in a specific order. (Adapted from Wilentz RE, et al: Loss of expression of DPC4 in pancreatic intraepithelial neoplasia: evidence that *DPC4* inactivation occurs late in neoplastic progression. *Cancer Res* 2000;60:2002.)

The epithelial cells in PanIN show dramatic telomere shortening. A critical shortening of telomere length in PanIN may predispose these lesions to accumulate progressive chromosomal abnormalities and to develop invasive carcinoma (Chapter 7).

Based on these observations, a model for progression of PanINs has been proposed (Fig. 19-12).

Pathogenesis

Multiple genes are somatically mutated or epigenetically silenced in each pancreatic carcinoma, consistent with their stepwise evolution from precursor lesions, and the patterns of genetic alterations in pancreatic carcinoma as a group differs from those seen in other malignancies. Molecular alterations in pancreatic carcinogenesis are summarized in Table 19-3 and include the following:

***KRAS*.** *KRAS* (chromosome 12p) is the most frequently altered oncogene in pancreatic cancer, with activating point mutations being present in 90% to 95% of cases. These point mutations result in constitutive activation of

Figure 19-11 Pancreatic intraepithelial neoplasia grade 3 (PanIN-3) involving a small pancreatic duct.

Table 19-3 Somatic Molecular Alterations in Invasive Pancreatic Adenocarcinoma

Gene	Chromosomal Region	Percentage of Carcinoma with Genetic Alteration	Gene Function
Oncogenes			
<i>KRAS</i>	12p	90	Growth factor signal transducer
<i>AKT2</i>	19q	10-20	Growth factor signal transducer
<i>MYB</i>	6q	10	Transcription factor
<i>NCOA3/AIB1</i>	20q	10	Chromatin regulator
<i>MAP2K4/MKK4</i>	17p	5	Growth factor signal transducer
Tumor Suppressor and DNA Repair Genes			
<i>p16/CDKN2A</i>	9p	95	Negative cell-cycle regulator
<i>TP53</i>	17p	50-70	Response to DNA damage
<i>SMAD4</i>	18q	55	TGF β pathway
<i>GATA-6</i>	18q	10	Transcription factor
<i>RB</i>	13q	5	Negative cell-cycle regulator
<i>STK11</i>	19p	5	Regulation of cellular metabolism
<i>ATM</i>	11q	5	DNA damage response
<i>ARID1A</i>	1p	4	Chromatin regulator
<i>TGFBR1</i>	9q	2	TGF β pathway
<i>TGFBR2</i>	3p	2	TGF β pathway

KRAS, which is a small, GTP-binding protein that normally participates in signaling events downstream of growth factor receptors with intrinsic tyrosine kinase activity (Chapters 1 and 7). *KRAS* signaling activates a number of downstream pathways that augment cell growth and survival, most notably the MAPK and PI3K/AKT pathways (Chapter 7).

***CDKN2A*.** The *CDKN2A* gene (chromosome 9p) is inactivated in 95% of pancreatic cancers, making it the most frequently inactivated tumor suppressor gene in these tumors. This complex locus encodes two tumor suppressor proteins (Chapter 7): p16/INK4a, a cyclin-dependent kinase inhibitor that antagonizes cell cycle progression, and ARF, a protein that augments the function of the p53 tumor suppressor protein.

***SMAD4*.** The *SMAD4* tumor suppressor gene (chromosome 18q) is inactivated in 55% of pancreatic cancers. *SMAD4* encodes a protein that plays an important role in signal transduction from the TGF- β family of cell surface receptors. *SMAD4* is only rarely inactivated in other cancer types.

***TP53*.** Inactivation of the *TP53* tumor suppressor gene (chromosome 17p) occurs in 70% to 75% of pancreatic cancers. This gene encodes p53, a nuclear DNA-binding protein that can respond to DNA damage by arresting cell

growth, inducing cell death (apoptosis) or causing cellular senescence (Chapter 7).

Other Genes. A growing number of less common, but nonetheless important, genetic loci have been reported to be damaged in pancreatic cancer (Table 19-3).

DNA Methylation Abnormalities. Several DNA methylation abnormalities also occur in pancreatic cancer. Hypermethylation of the promoter of several tumor suppressor genes, including *CDKN2A*, is associated with transcriptional silencing of these genes and loss of their function.

Gene Expression. In addition to DNA alterations, global analyses of gene expression have identified several pathways that seem to be abnormally active in pancreatic cancers. These pathways and their downstream consequences are potential targets for novel therapies and may form the basis of future screening tests. For example, the Hedgehog signaling pathway has been shown to be activated in pancreatic cancer and represents a potential therapeutic target.

Epidemiology and Inheritance. Pancreatic cancer is primarily a disease of older adults, with 80% of cases occurring in people aged 60 to 80 years. It is more common in blacks than in whites, and it is slightly more common in individuals of Ashkenazi Jewish descent.

The strongest environmental influence is *cigarette smoking*, which is believed to double the risk of pancreatic cancer. Even though the magnitude of this increased risk is not great, the impact of smoking on pancreatic cancer is significant because of the large number of people who smoke. Consumption of a diet rich in fats has also been implicated, but less consistently. Chronic pancreatitis and diabetes mellitus are both risk factors for, and complications of, pancreatic cancer. In an individual patient it can be difficult to sort out whether chronic pancreatitis is the cause of pancreatic cancer or an effect of the disease, since small pancreatic cancers may block the pancreatic duct and produce chronic pancreatitis. A similar argument applies to the association of diabetes mellitus with pancreatic cancer, in that diabetes may develop as a consequence of pancreatic cancer and new-onset diabetes mellitus in an older patient may be the first sign that the patient has pancreatic cancer.

Familial clustering of pancreatic cancer has been reported, and a growing number of inherited genetic defects are recognized to increase pancreatic cancer risk (Table 19-4). Germline *BRCA2* mutations account for approximately 10% of pancreatic cancer cases in Ashkenazi Jews. Patients with these mutations may not have a family history of breast or ovarian cancers. Germline mutations in *CDKN2A* are associated with pancreatic cancer and are almost always observed in individuals from families with an increased incidence of melanoma, which also frequently harbors *CDKN2A* loss-of-function mutations.

MORPHOLOGY

Approximately 60% of cancers of the pancreas arise in the head of the gland, 15% in the body, and 5% in the tail; in 20% the neoplasm diffusely involves the entire gland. Carcinomas of the

Table 19-4 Inherited Predisposition to Pancreatic Cancer

Disorder	Gene	Increased Risk of Pancreatic Cancer (Fold)	Risk of Pancreatic Cancer by Age 70 (%)
Peutz-Jeghers syndrome	<i>STK11</i>	130	30-60
Hereditary pancreatitis	<i>PRSS1</i> , <i>SPINK1</i>	50-80	25-40
Familial atypical multiple-mole melanoma syndrome	<i>CDKN2A</i>	20-35	10-17
Strong family history (3 or more relatives with pancreatic cancer)	Unknown	14-32	8-16
Hereditary breast and ovarian cancer	Multiple, including <i>BRCA1</i> , <i>BRCA2</i> , <i>PALP2</i> , <i>BRCA2</i>	4-10	5
Hereditary non-polyposis colorectal cancer (HNPCC)	Multiple, including <i>MLH1</i> , <i>MSH2</i> (2p21)	8-10	4

pancreas are usually hard, stellate, gray-white, poorly defined masses (Fig. 19-13A).

The vast majority of carcinomas are ductal adenocarcinomas that recapitulate to some degree normal ductal epithelium by forming glands and secreting mucin. Two features are characteristic of pancreatic cancer; it is highly invasive (even “early” invasive pancreatic cancers extensively invade peripancreatic tissues), and it elicits an intense host reaction in the form of dense fibrosis (“desmoplastic response”), described later.

Most carcinomas of the head of the pancreas obstruct the distal common bile duct as it courses through the head of the pancreas. As a consequence there is marked distention of the biliary tree in about 50% of patients with carcinoma of the head of the pancreas, and most develop jaundice. In marked contrast, **carcinomas of the body and tail of the pancreas do not impinge on the biliary tract and hence remain silent for some time. They may be quite large and most are widely disseminated by the time they are discovered.** Pancreatic cancers often grow along nerves and invade into blood vessels and the retroperitoneum. They can directly invade the spleen, adrenals, transverse colon, and stomach. Peripancreatic, gastric, mesenteric, omental, and portohepatic lymph nodes are frequently involved. Distant metastases occur, principally to the liver and lungs.

Microscopically, there is no difference between carcinomas of the head of the pancreas and those of the body and tail of the pancreas. The appearance is usually that of a **moderately to poorly differentiated adenocarcinoma forming abortive tubular structures or cell clusters and showing an aggressive, deeply infiltrative growth pattern (Fig. 19-13B).** The malignant glands are poorly formed and are usually lined by pleomorphic cuboidal-to-columnar epithelial cells. Well-differentiated carcinomas are the exception. As noted earlier, a characteristic feature of these cancers is that they elicit an intense desmoplastic reaction with dense stromal fibrosis. The

Figure 19-13 Carcinoma of the pancreas. **A**, A cross-section through the tail of the pancreas showing normal pancreatic parenchyma and a normal pancreatic duct (left), an ill-defined mass in the pancreatic substance (center) with narrowing of the pancreatic duct, and dilatation of the pancreatic duct upstream (right) from the mass. **B**, Poorly formed glands are present in densely fibrotic stroma within the pancreatic substance; some inflammatory cells are also present.

marked degree of desmoplasia can hinder the interpretation of diagnostic biopsies, as much of the tissue present is nonneoplastic. Perineural invasion within and beyond the organ is common, as are lymphatic and large vessel invasion.

Less common morphologic variants of pancreatic cancer include adenosquamous carcinomas, colloid carcinoma, hepatoid carcinoma, medullary carcinoma, signet-ring cell carcinoma, undifferentiated carcinoma, and undifferentiated carcinoma with osteoclast-like giant cells.

Clinical Features. From the preceding discussion it should be evident that **carcinomas of the pancreas remain silent until they invade into adjacent structures.** Pain is usually the first symptom, but by the time pain appears these cancers are usually beyond cure. *Obstructive jaundice* is associated with most cases of carcinoma of the head of the pancreas, but it rarely draws attention to the invasive cancer soon enough. Weight loss, anorexia, and generalized malaise and weakness tend to be signs of advanced disease. *Migratory thrombophlebitis*, known as the *Trousseau sign*, occurs in about 10% of patients and is attributable to the elaboration of platelet-activating factors and procoagulants from the

carcinoma or its necrotic products (Chapter 4). On a sad note, Armand Trousseau (1801-1867, physician at Hotel Dieu, Paris), for whom this sign is named, correctly suspected that he had carcinoma when he developed spontaneously appearing and disappearing (migratory) thromboses.

The course of pancreatic carcinoma is typically brief and progressive. Despite the tendency of lesions of the head of the pancreas to obstruct the biliary system, fewer than 20% of pancreatic cancers overall are resectable at the time of diagnosis. Most have invaded vessels and other structures that cannot be removed surgically, or have metastasized to distant organs. There has long been a search for tests that could be useful in the early detection of pancreatic cancer. Serum levels of several antigens (e.g., carcinoembryonic antigen and CA19-9 antigen) are often elevated in individuals with pancreatic cancer. These markers, while useful in following an individual patient's response to treatment, are relatively nonspecific and also lack the sensitivity needed to be used as tests to screen the wider population. Several imaging techniques, such as endoscopic ultrasonography and computed tomography, have proved of great value in establishing the diagnosis once it is suspected, but are also not useful as screening tests.

KEY CONCEPTS

- Cigarette smoking is the leading preventable cause of pancreatic cancer.
- Pancreatic cancer is one of the most aggressive of the solid malignancies.
- Many invasive pancreatic cancer arises from histologically well-defined precursor lesions called *pancreatic intraepithelial neoplasia* (PanIN).
- Ductal adenocarcinomas elicit an intense desmoplastic response.
- The genes most frequently mutated or otherwise altered in pancreatic cancer include *KRAS*, *p16/CDKN2A*, *TP53*, and *SMAD4*
- Clinically, most patients present with abdominal pain and weight loss, sometimes accompanied by jaundice and deep vein thrombosis, and succumb to the disease within 1 to 2 years.

Acinar Cell Carcinoma

Like normal acinar cells, acinar cell carcinomas form zymogen granules and produce exocrine enzymes such as trypsin and lipase. Fifteen percent of individuals with acinar cell carcinoma develop the syndrome of metastatic fat necrosis caused by the release of lipase into the circulation.

Pancreatoblastoma

Pancreatoblastomas are rare neoplasms that occur primarily in children aged 1 to 15 years. They have a distinct microscopic appearance consisting of squamous islands admixed with acinar cells. They are malignant neoplasms, but survival is better with these tumors than it is for pancreatic ductal adenocarcinomas.

What is a human but an ingenious machine designed to turn, with "infinite artfulness, the red wine of Shiraz into urine?" So said the storyteller in Isak Dinesen's *Seven Gothic Tales*. More accurately but less poetically, human kidneys serve to convert more than 1700 L of blood per day into about 1 L of a highly concentrated fluid called *urine*.

In so doing, the kidney excretes the waste products of metabolism, precisely regulates the body's concentration of water, salt, calcium, phosphorus, and other anions and cations, and maintains the appropriate acid balance of plasma. The kidney also serves as an endocrine organ, secreting such hormones as erythropoietin, renin, and

prostaglandins, and regulating vitamin D metabolism. The physiologic mechanisms that the kidney has developed to carry out these functions require a high degree of structural complexity.

Renal diseases are responsible for a great deal of morbidity and mortality. When last surveyed in 2009, more than 570,000 Americans had end-stage renal disease (ESRD), of whom two thirds are maintained on dialysis, at a cost of approximately \$42.5 billion. The 1-year mortality rate of ESRD, when the enhanced risk for cardiovascular disease conferred by ESRD is considered, exceeds that of most newly diagnosed cancers. Acute kidney injury occurs in more than 2 million people worldwide, and is a major risk factor for the development of chronic kidney disease (CKD) and ESRD. In addition, millions of people are affected annually by nonfatal kidney diseases, most notably infections of the kidney or lower urinary tract, kidney stones, and urinary obstruction. The availability of dialysis and the success of renal transplantation have improved the outlook for patients.

The study of kidney diseases is facilitated by dividing them into those that affect the four basic morphologic components: glomeruli, tubules, interstitium, and blood vessels. This approach is useful, since the early manifestations of disease affecting each of these components tend to be distinct. Further, some components seem to be more vulnerable to specific forms of renal injury; for example, **most glomerular diseases are immunologically mediated, whereas tubular and interstitial disorders are frequently caused by toxic or infectious agents.** However, some disorders affect more than one structure, and the anatomic and functional interdependence of the components of the kidney means that damage to one almost always secondarily affects the others. Primary disorders of the blood vessels, for example, inevitably affect all the structures supplied by these vessels. Severe glomerular damage impairs the flow through the peritubular vascular system; conversely, tubular destruction, by increasing intraglomerular pressure, may induce glomerular injury. Thus, whatever the origin, all forms of chronic kidney disease ultimately damage all four components of the kidney, culminating in what has been called *end-stage kidneys*. The functional reserve of the kidney is large, and much damage may occur before there is evident functional impairment. For these reasons the early signs and symptoms are of particular clinical importance.

Clinical Manifestations of Renal Diseases

The clinical manifestations of renal disease can be grouped into reasonably well-defined syndromes. Some are unique to glomerular diseases, and others are present in diseases that affect any one of the components.

- *Azotemia* is a biochemical abnormality that refers to an elevation of blood urea nitrogen (BUN) and creatinine levels, and is related largely to a decreased glomerular filtration rate (GFR). Azotemia is a consequence of many renal disorders, but it also arises from extrarenal disorders. It is a typical feature of both acute and chronic kidney injury. *Prerenal azotemia* is encountered

when there is hypoperfusion of the kidneys (e.g., hypotension or excessive fluid losses from any cause, or if the effective intravascular volume is decreased due to shock, volume depletion, congestive heart failure or cirrhosis of the liver) that impairs renal function in the absence of parenchymal damage. *Postrenal azotemia* is seen whenever urine flow is obstructed distal to the kidney. Relief of the obstruction is followed by correction of the azotemia.

When azotemia becomes associated with a constellation of clinical signs and symptoms and biochemical abnormalities, it is termed *uremia*. Uremia is characterized not only by failure of renal excretory function but also by a host of metabolic and endocrine alterations resulting from renal damage. Uremic patients frequently manifest secondary involvement of the gastrointestinal system (e.g., uremic gastroenteritis), peripheral nerves (e.g., peripheral neuropathy), and heart (e.g., uremic fibrinous pericarditis).

- *Nephritic syndrome* is a clinical entity caused by glomerular disease and is dominated by the acute onset of either grossly visible hematuria (red blood cells in urine) or microscopic hematuria with dysmorphic red cells and red cell casts on urinalysis, diminished GFR, mild to moderate proteinuria, and hypertension. It is the classic presentation of acute poststreptococcal glomerulonephritis. *Rapidly progressive glomerulonephritis* is characterized as a nephritic syndrome with rapid decline in GFR (within hours to days).
- The *nephrotic syndrome*, also due to glomerular disease, is characterized by heavy proteinuria (more than 3.5 gm/day), hypoalbuminemia, severe edema, hyperlipidemia, and lipiduria (lipid in the urine).
- *Asymptomatic hematuria or proteinuria*, or a combination of these two, is usually a manifestation of subtle or mild glomerular abnormalities.
- *Acute kidney injury* is characterized by rapid decline in GFR (within hours to days), with concurrent dysregulation of fluid and electrolyte balance, and retention of metabolic waste products normally excreted by the kidney including urea and creatinine. In its most severe forms, it is manifested by *oliguria* or *anuria* (reduced or no urine flow). It can result from glomerular, interstitial, vascular or acute tubular injury.
- *Chronic kidney disease* (previously called chronic renal failure) is defined as the presence of a diminished GFR that is persistently less than 60 mL/minute/1.73 m² for at least 3 months, from any cause, and/or persistent albuminuria. It may present with clinically silent decline in renal excretory function in milder forms, and in more severe cases, by prolonged symptoms and signs of uremia. It is the end result of all chronic renal parenchymal diseases.
- In *end-stage renal disease (ESRD)* the GFR is less than 5% of normal; this is the terminal stage of uremia.
- *Renal tubular defects* are dominated by polyuria (excessive urine formation), nocturia, and electrolyte disorders (e.g., metabolic acidosis). They are the result of diseases that either directly affect tubular structures (e.g., the nephronophthisis-medullary cystic disease complex) or cause defects in specific tubular functions. The latter can be inherited (e.g., familial nephrogenic

diabetes, cystinuria, renal tubular acidosis) or acquired (e.g., lead nephropathy).

- *Urinary tract obstruction* and *renal tumors* have varied clinical manifestations based on the specific anatomic location and nature of the lesion. *Urinary tract infection* is characterized by bacteriuria and pyuria (bacteria and leukocytes in the urine). The infection may be symptomatic or asymptomatic, and it may affect the kidney (*pyelonephritis*) or the bladder (*cystitis*).
- *Nephrolithiasis (renal stones)* is manifested by spasms of severe pain (renal colic) and hematuria, often with recurrent stone formation.

Chronic kidney disease is estimated to affect 11% of all adults in the United States, with a particular predominance amongst older adults. It is the end result of a variety of renal diseases, but most commonly diabetes and hypertension, and the major cause of death from renal disease. The evolution from normal renal function to symptomatic chronic kidney injury progresses through a series of stages that are defined by measures of serum creatinine from which estimates of reduction in GFR are derived. Chronic kidney disease causes significant systemic abnormalities, which are listed in [Table 20-1](#).

KEY CONCEPTS

Clinical Manifestations of Renal Diseases

- Azotemia is the biochemical manifestation of acute or chronic kidney injury and is characterized by elevated blood urea nitrogen (BUN) or alternately by an elevated serum creatinine. It reflects a reduction in the glomerular filtration rate.
- Kidney injury that results in azotemia can be either acute or chronic. Acute kidney injury can be reversible or progress to chronic kidney disease; chronic kidney disease is generally irreversible.
- One major manifestation of kidney injury is the nephrotic syndrome, in which injury to the glomerulus results in abnormal filtration, leading to heavy proteinuria, edema and metabolic disturbances.
- Nephritic syndromes are those in which hematuria, azotemia, hypertension, and sub-nephrotic proteinuria are the major manifestations.
- Diseases involving the tubules and interstitium may have clinical manifestations of the nephritic syndrome, or of specific defects in tubular function, or of acute or chronic kidney disease without more specific defining features.

Glomerular Diseases

Glomerular diseases constitute some of the major problems in nephrology; indeed, chronic glomerulonephritis is one of the most common causes of chronic kidney disease in humans. Glomeruli may be injured by a variety of factors and in the course of several systemic diseases. Systemic immunologic diseases such as systemic lupus

erythematosus (SLE), vascular disorders such as hypertension, metabolic diseases such as diabetes mellitus, and some hereditary conditions such as Fabry disease often affect the glomerulus. These are termed *secondary glomerular diseases*. Disorders in which the kidney is the only or predominant organ involved constitute the various types of *primary glomerulonephritis* or, because some do not have a cellular inflammatory component, *glomerulopathy*. However, both the clinical manifestations and glomerular histologic changes in primary and secondary forms can be similar.

In the following sections we discuss the various types of primary glomerulopathies and briefly review the secondary forms covered in other parts of this book. [Table 20-2](#) lists the most common forms of glomerulonephritis that have reasonably well defined morphologic and clinical characteristics. The clinical manifestations of glomerular disease are clustered into the five major glomerular syndromes summarized in [Table 20-3](#). Both the primary glomerulopathies and the systemic diseases affecting the glomerulus can result in these syndromes. Because glomerular diseases are often associated with systemic disorders, mainly *diabetes mellitus*, *SLE*, *vasculitis*, and *amyloidosis*, in any patient with manifestations of glomerular disease it is essential to consider these systemic conditions.

Structure of the Glomerulus

Many clinical manifestations of glomerular diseases result from perturbations of specific components of the glomerular tuft, so we before discussing these diseases we describe the key anatomic structures of glomeruli. The glomerulus consists of an anastomosing network of capillaries lined by fenestrated endothelium invested by two layers of epithelial cells (Fig. 20-1). The visceral epithelial cells (commonly referred to as *podocytes*) are incorporated into and become an intrinsic part of the capillary wall, separated from endothelial cells by a basement membrane. The parietal epithelium, situated on the Bowman capsule, lines the urinary space, the cavity in which plasma filtrate first collects.

The glomerular capillary wall is the filtering membrane and consists of the following structures (Fig. 20-2):

- There is a thin layer of fenestrated *endothelial cells*, with each fenestra being about 70 to 100 nm in diameter.

Table 20-3 Glomerular Syndromes

Syndrome	Manifestations
Nephritic syndrome	Hematuria, azotemia, variable proteinuria, oliguria, edema, and hypertension
Rapidly progressive glomerulonephritis	Acute nephritis, proteinuria, and acute renal failure
Nephrotic syndrome	>3.5 gm/day proteinuria, hypoalbuminemia, hyperlipidemia, lipiduria
Chronic renal failure	Azotemia → uremia progressing for months to years
Isolated urinary abnormalities	Glomerular hematuria and/or subnephrotic proteinuria

- A *glomerular basement membrane* (GBM) with a thick electron-dense central layer, the *lamina densa*, and thinner electron-lucent peripheral layers, the *lamina rara interna* and *lamina rara externa*. The GBM consists of collagen (mostly type IV), laminin, polyanionic proteoglycans (mostly heparan sulfate), fibronectin, entactin, and several other glycoproteins. Type IV collagen forms a network suprastructure to which other glycoproteins attach. The building block (monomer) of this network is a triple-helical molecule composed of one or more of six types of α chains (α_1 to α_6 or COL4A1 to COL4A6). Each molecule consists of a 7S domain at the N terminus, a triple-helical domain in the middle, and a globular noncollagenous domain (NC1) at the C terminus. The NC1 domain is important for helix formation and for assembly of collagen monomers into the basement membrane suprastructure. Glycoproteins (laminin, entactin) and proteoglycans (heparan sulfate, perlecan) attach to the collagenous suprastructure. The biochemical properties of these structural components are critical to understanding glomerular diseases. For example, antigens in the NC1 domain are the targets of antibodies in anti-GBM nephritis; genetic defects in the α -chains underlie some forms of hereditary nephritis; and the proteoglycan content of the GBM may contribute to its permeability characteristics.
- The *visceral epithelial cells* (podocytes) possess interdigitating processes embedded in and adherent to the lamina rara externa of the basement membrane (Fig. 20-1). Adjacent *foot processes* are separated by 20- to 30-nm-wide *filtration slits*, which are bridged by a thin diaphragm (Fig. 20-2).
- The entire glomerular tuft is supported by *mesangial cells* lying between the capillaries. Basement membrane-like *mesangial matrix* forms a meshwork in which the mesangial cells are embedded (Fig. 20-1). These cells, of mesenchymal origin, are contractile, phagocytic, and capable of proliferation, of laying down both matrix and collagen, and of secreting several biologically active mediators. Biologically, they are most akin to vascular smooth muscle cells and pericytes. They are important in many forms of glomerulonephritis.

The normal glomerulus is highly permeable to water and small solutes, because of the fenestrated nature of the endothelium, and impermeable to proteins of the size of albumin (~3.6-nm radius; 70 kilodaltons [kD] molecular weight) or larger. The permeability characteristics of the *glomerular filtration barrier* allow discrimination among various protein molecules, depending on their size (the larger, the less permeable) and charge (the more cationic, the more permeable). This size- and charge-dependent barrier function is accounted for by the structure of the capillary wall. The charge-dependent restriction is important in the virtually complete exclusion of albumin from the filtrate, because albumin is an anionic molecule.

The visceral epithelial cell is important for the maintenance of glomerular barrier function; its slit diaphragm presents a size-selective distal diffusion barrier to the filtration of proteins, and it is the cell type that is largely responsible for synthesis of GBM components. Proteins located in the slit diaphragm or present in assemblies of molecules within visceral epithelial cells that are attached

to the slit diaphragm are illustrated in [Figure 20-3](#). Nephrin is a transmembrane protein with a large extracellular portion made up of immunoglobulin (Ig)-like domains. Nephrin molecules extend toward each other from neighboring foot processes and dimerize across the slit diaphragm. Within the cytoplasm of the foot processes, nephrin forms molecular connections with podocin, CD2-associated protein, and ultimately the actin cytoskeleton of the visceral epithelial cells. More slit diaphragm proteins continue to be identified, and comprehensive descriptions of their structure and interactions have been published. The importance of the slit diaphragm proteins in maintaining glomerular permeability is demonstrated by the observation that mutations in the genes encoding them give rise to defects in permeability and the nephrotic syndrome (discussed later).

Pathologic Responses of the Glomerulus to Injury

Various types of glomerulopathies are characterized by one or more of four basic tissue reactions.

Hypercellularity. Some *inflammatory diseases* of the glomerulus are characterized by an increase in the number of cells in the glomerular tufts. This hypercellularity results from one or more of the following:

- *Proliferation* of mesangial or endothelial cells.
- *Infiltration of leukocytes*, including neutrophils, monocytes, and, in some diseases, lymphocytes. The combination of infiltration of leukocytes and swelling and proliferation of mesangial and/or endothelial cells is often referred to as *endocapillary proliferation*.
- *Formation of crescents*. These are accumulations of cells composed of proliferating glomerular epithelial cells (predominately parietal but including some visceral cells) and infiltrating leukocytes. The epithelial cell proliferation that characterizes crescent formation occurs following an immune/inflammatory injury involving the capillary walls. Plasma proteins leak into the urinary space, where it is believed that exposure to procoagulants such as tissue factor leads to fibrin deposition. Activation of coagulation factors such as thrombin is suspected of being a trigger for crescent formation, but the actual mechanisms are still unknown. Molecules that have been implicated in recruitment of leukocytes into crescents include multiple proinflammatory cytokines.

Basement Membrane Thickening. By light microscopy, this change appears as thickening of the capillary walls, best seen in sections stained with periodic acid-Schiff (PAS). By electron microscopy such thickening takes one of three forms:

- Deposition of amorphous electron-dense material, most often immune complexes, on the endothelial or epithelial side of the basement membrane or within the GBM itself. Fibrin, amyloid, cryoglobulins, and abnormal fibrillary proteins may also deposit in the GBM.
- Increased synthesis of the protein components of the basement membrane, as occurs in diabetic glomerulosclerosis.
- Formation of additional layers of basement membrane matrices, which most often occupy subendothelial locations and may range from poorly organized matrix to fully duplicated lamina densa, as occurs in membranoproliferative glomerulonephritis.

Hyalinosis and Sclerosis. *Hyalinosis*, as applied to the glomerulus, denotes the accumulation of material that is homogeneous and eosinophilic by light microscopy. *Hyalin* is an extracellular, amorphous material composed of plasma proteins that have insudated from the circulation into glomerular structures. When extensive, these deposits may obliterate the capillary lumens of the glomerular tuft. Hyalinosis is usually a consequence of endothelial or capillary wall injury and typically the end result of various forms of glomerular damage.

Sclerosis is characterized by deposition of extracellular collagenous matrix. It may be confined to mesangial areas, as is often the case in diabetic glomerulosclerosis, involve the capillary loops, or both. The sclerosing process may also result in obliteration of some or all of the capillary lumens in affected glomeruli.

Many primary glomerulopathies are classified by their histology, as seen in Table 20-2. The histologic changes can be further subdivided by their distribution into the following categories: *diffuse*, involving all of the glomeruli in the kidney; *global*, involving the entirety of individual glomeruli; *focal*, involving only a fraction of the glomeruli in the kidney; *segmental*, affecting a part of each glomerulus; and *capillary loop* or *mesangial*, affecting predominantly capillary or mesangial regions.

KEY CONCEPTS

Injury of Glomerular Structures

- The glomerular basement membrane is composed of type IV collagen molecules and other matrix proteins. These proteins can be the target of antibodies in some types of glomerulonephritis; genetic abnormalities in their composition are the basis for some forms of hereditary nephritis.
- Visceral epithelial cells (podocytes) are a critical component of the glomerular filtration barrier, and injury to these cells leads to leakage of proteins into the urinary space, clinically manifest as proteinuria.
- The acute glomerular response to injury includes hypercellularity with proliferation of mesangial and/or endothelial cells, influx of leukocytes, and, in severe injuries, formation of crescents.
- Chronic glomerular responses to injury include basement membrane thickening, hyalinosis, and sclerosis.

Pathogenesis of Glomerular Injury

Although much remains unknown about etiologic agents and triggering events, it is clear that **immune mechanisms underlie most forms of primary glomerulopathy and many of the secondary glomerular disorders** (Table 20-4). Glomerulonephritis can be readily induced experimentally by antigen-antibody reactions. Furthermore, glomerular deposits of immunoglobulins, often with components of complement, are found in the majority of individuals with glomerulonephritis. Cell-mediated immune reactions also may play a role, usually in concert with antibody-mediated events. We begin this discussion with a review of antibody-instigated injury.

Two forms of antibody-associated injury have been established: (1) injury by *antibodies reacting in situ within the glomerulus*, either binding to insoluble fixed (intrinsic) glomerular antigens or extrinsic molecules planted within the glomerulus, and (2) injury resulting from *deposition of circulating antigen-antibody complexes in the glomerulus*. It is clear that the major cause of glomerulonephritis resulting from formation of antigen-antibody complexes is the consequence of in situ immune complex formation, and not deposition of circulating complexes as was once thought.

Exogenous antigens (e.g., infectious products)
Cell-Mediated Immune Injury
Activation of Alternative Complement Pathway

GBM, glomerular basement membrane.

Diseases Caused by In Situ Formation of Immune Complexes

In this form of injury, immune complexes are formed locally by antibodies that react with intrinsic tissue antigen or with extrinsic antigens “planted” in the glomerulus from the circulation. Membranous nephropathy is the classic example of glomerular injury resulting from local formation of immune complexes. It has a well-studied experimental counterpart in the Heymann nephritis rat model, from which much of the underlying pathophysiology of glomerular immune complex-mediated diseases has been deduced.

The Heymann model of glomerulonephritis is induced by immunizing rats with an antigen, now known to be *megalin*, that is present in epithelial cell foot processes (Fig. 20-4C). The rats develop antibodies to this antigen, and disease develops from the reaction of antibody with the megalin-containing protein complex located on the basal surface of visceral epithelial cells, leading to localized immune complex formation. A major advance in our understanding of glomerulonephritis came from the identification of the M-type phospholipase A₂ receptor (PLA₂R) as the antigen that underlies most cases of primary human membranous nephropathy. Antibody binding to PLA₂R present in the glomerular epithelial cell membrane is followed by complement activation and then shedding of the immune aggregates from the cell surface to form characteristic deposits of immune complexes along the *sub-epithelial aspect* of the basement membrane (Fig. 20-4C). On electron microscopy the glomerulopathy is characterized by the presence of numerous discrete subepithelial electron-dense deposits (made up largely of immune reactants). **The pattern of immune deposition by immunofluorescence microscopy is granular rather than linear, reflective of the very localized antigen-antibody interaction.** These subepithelial complexes, with resultant host responses, can result in a thickened basement membrane appearance by light microscopy; hence the term *membranous nephropathy* has been applied to both the experimental model and human disease.

In humans, primary membranous nephropathy is an autoimmune disease, caused by antibodies to endogenous

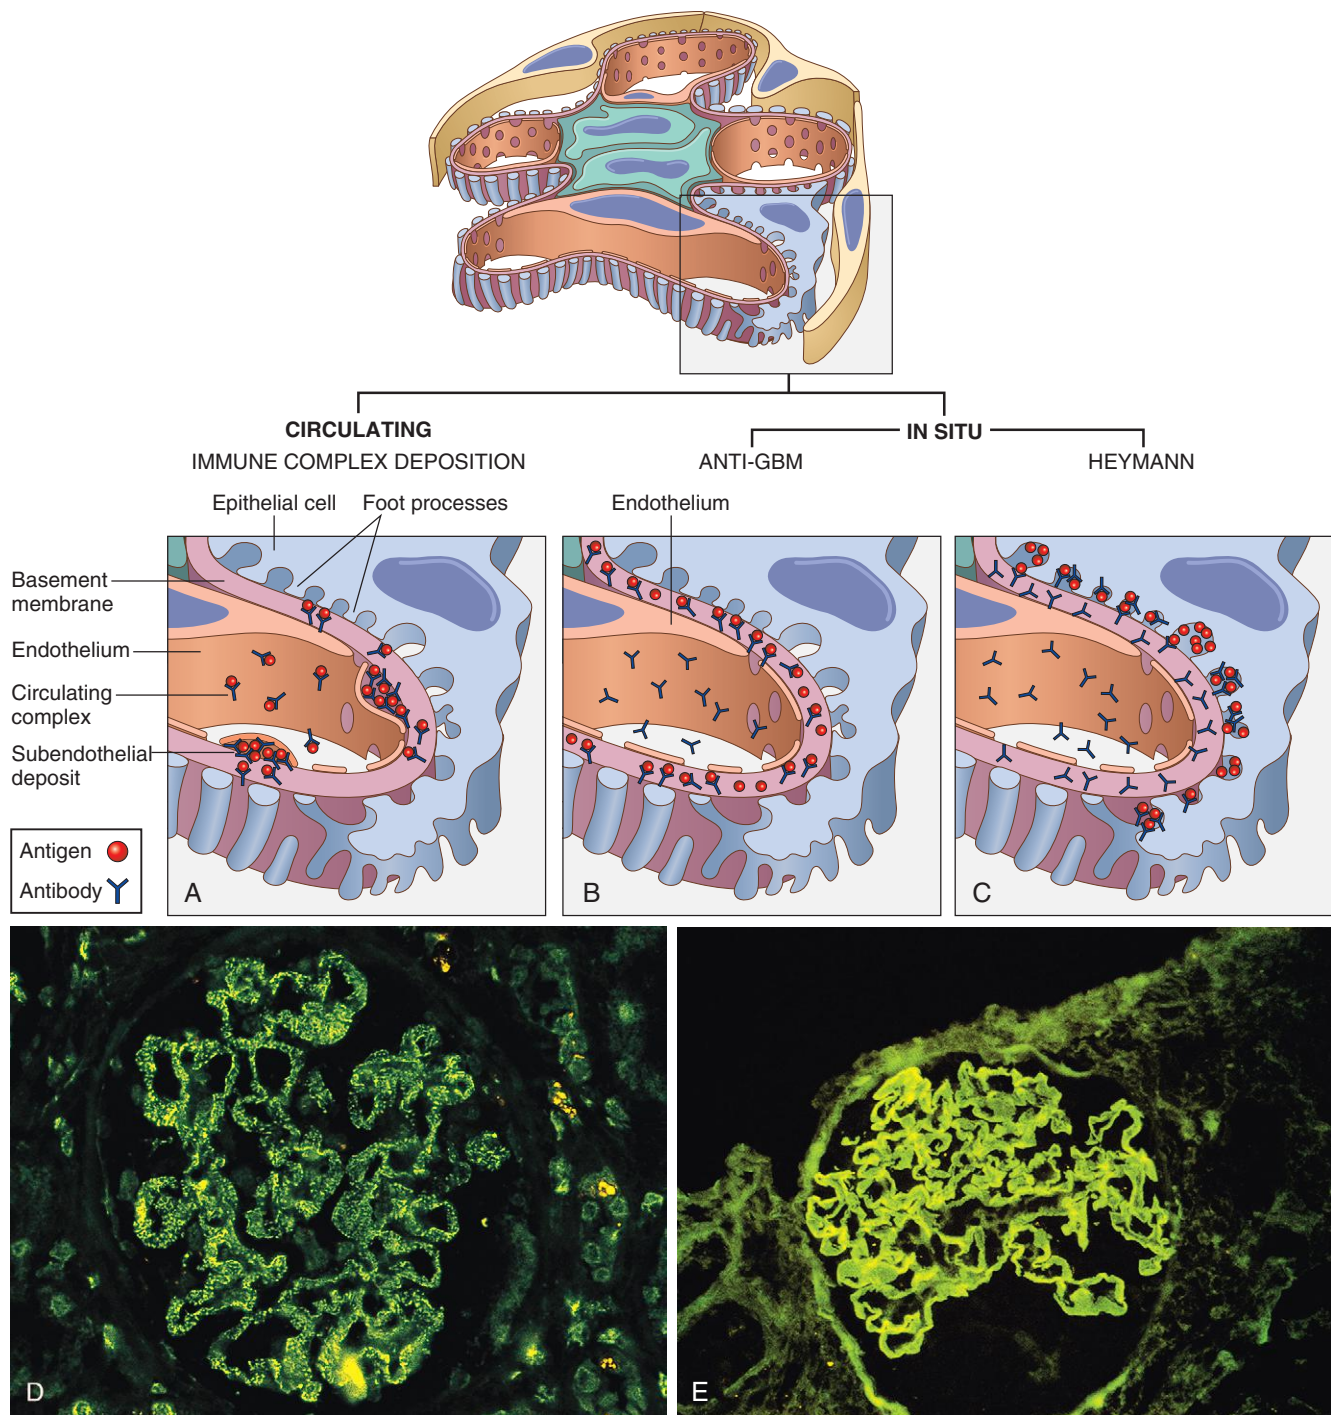

Figure 20-4 Antibody-mediated glomerular injury can result either from the deposition of circulating immune complexes (**A**) or, more commonly, from in situ formation of complexes exemplified by anti-GBM disease (**B**) or Heymann nephritis (**C**). **D** and **E**, Two patterns of deposition of immune complexes as seen by immunofluorescence microscopy: granular, characteristic of circulating and in situ immune complex nephritis (**D**), and linear, characteristic of classic anti-GBM disease (**E**).

tissue components. What triggers these autoantibodies is unclear. Secondary forms of membranous nephropathy can be experimentally induced by drugs (e.g., mercuric chloride), and graft-versus-host disease (Chapter 6). In some of these situations there may be uncontrolled B-cell activation, leading to the production of autoantibodies that react with renal antigens.

Antibodies Against Planted Antigens

Antibodies can react in situ with antigens that are not normally present in the glomerulus but are “planted” there. Such antigens may localize in the kidney by interacting with various intrinsic components of the glomerulus. Planted antigens include cationic molecules that bind to anionic components of the glomerulus; DNA,

nucleosomes, and other nuclear proteins, which have an affinity for GBM components; bacterial products; large aggregated proteins (e.g., aggregated immunoglobulins), which deposit in the mesangium because of their size; and immune complexes themselves, since they continue to have reactive sites for further interactions with free antibody, free antigen, or complement.

There is no dearth of other possible planted antigens, including viral, bacterial, and parasitic products and drugs. As an example, membranous nephropathy develops in a small number of infants fed cow's milk. These children have been found to have antibodies to bovine albumin and their lesions contain bovine milk antigens, which presumably become lodged in the glomerular basement membrane following intestinal absorption, where they serve as the substrate for immune complex formation in situ. Antibodies that bind to these planted antigens induce a discrete pattern of Ig deposition detected as granular staining by immunofluorescence microscopy that is indistinguishable from the pattern of staining observed with immune complexes formed from intrinsic antigens.

Disease Caused by Antibodies Directed Against Normal Components of the Glomerular Basement Membrane

In anti-GBM antibody induced glomerulonephritis, antibodies bind to intrinsic antigens homogeneously distributed along the entire length of the GBM, resulting in a diffuse linear pattern of staining for the antibodies by immunofluorescence techniques (Fig. 20-4B and E). This contrasts with the granular pattern of immunofluorescence staining corresponding to the discrete immune complexes seen in membranous nephropathy, or other glomerular diseases in which large complexes of antigens and antibodies form in situ. These intrinsic, fixed antigens cannot be mobilized to form large, discrete complexes.

Often the anti-GBM antibodies cross-react with other basement membranes, especially those in the lung alveoli, resulting in simultaneous lung and kidney lesions (*Goodpasture syndrome*). The GBM antigen that is responsible for classic anti-GBM antibody-induced glomerulonephritis and Goodpasture syndrome is a component of the noncollagenous domain (NC1) of the α_3 chain of type IV collagen that is critical for maintenance of GBM suprastructure. Although anti-GBM antibody-induced glomerulonephritis accounts for fewer than 5% of cases of human glomerulonephritis, it causes severe necrotizing and crescentic glomerular damage and the clinical syndrome of rapidly progressive glomerulonephritis.

Glomerulonephritis Resulting from Deposition of Circulating Immune Complexes

In this type of nephritis, glomerular injury is caused by the trapping of circulating antigen-antibody complexes within glomeruli. The antibodies have no immunologic specificity for glomerular constituents, and the complexes localize within the glomeruli because of their physicochemical properties and the hemodynamic factors peculiar to the glomerulus (Fig. 20-4A).

The antigens that trigger the formation of circulating immune complexes may be of endogenous origin, as in the glomerulonephritis associated with SLE or in IgA

nephropathy, **or they may be exogenous,** as may occur in the glomerulonephritis that follows certain infections. Microbial antigens that are implicated include bacterial products (streptococcal proteins), the surface antigen of hepatitis B virus, hepatitis C virus antigens, and antigens of *Treponema pallidum*, *Plasmodium falciparum*, and several viruses. Some tumor antigens are also thought to cause immune complex-mediated nephritis. In many cases the inciting antigen is unknown. In most instances of immune complex-mediated glomerulonephritis associated with these systemic disorders, evidence is strongest that the inciting event underlying the glomerulonephritis is deposition of the antigens with subsequent formation of immune complexes in situ rather than deposition of preformed immune complexes from the circulation.

Mechanisms of Glomerular Injury Following Immune Complex Formation

The pathogenesis of immune complex diseases is discussed in Chapter 6. Here we briefly review the salient features that relate to glomerular injury. **Whatever the antigen may be, antigen-antibody complexes formed or deposited in the glomeruli may elicit a local inflammatory reaction that produces injury.** It has long been thought that the inflammation and injury are mediated and amplified by the binding of complement, but recent studies in knockout mice also point to the importance of engagement of Fc receptors on leukocytes and perhaps glomerular mesangial or other cells as mediators of the injury process. The glomerular lesions may exhibit leukocytic infiltration and proliferation of mesangial and endothelial cells.

Electron microscopy reveals electron-dense deposits, presumably containing immune complexes, that may lie in the mesangium, between the endothelial cells and the GBM (subendothelial deposits), or between the outer surface of the GBM and the podocytes (subepithelial deposits). Deposits may be located at more than one site in a given case. By immunofluorescence microscopy the immune complexes are seen as granular deposits along the basement membrane (Fig. 20-4D), in the mesangium, or in both locations. Once deposited in the kidney, immune complexes may eventually be degraded, mostly by infiltrating neutrophils and monocytes/macrophages, mesangial cells, and endogenous proteases, and the inflammatory reaction may then subside. Such a course occurs when the exposure to the inciting antigen is short-lived and limited, as in most cases of poststreptococcal glomerulonephritis. However, if immune complexes are deposited for prolonged periods, as may be seen in SLE or viral hepatitis, repeated cycles of injury may occur, leading to a more chronic membranous or membranoproliferative type of glomerulonephritis.

Several factors affect glomerular localization of antigen, antibody or immune complexes. The molecular charge and size of these reactants are clearly important. Highly cationic antigens tend to cross the GBM, and the resultant complexes eventually reside in a subepithelial location. Highly anionic macromolecules are excluded from the GBM and are trapped subendothelially or are not nephritogenic at all. Molecules of neutral charge and immune complexes containing these molecules tend to accumulate in the mesangium. Large circulating complexes are not

Figure 20-5 Localization of immune complexes in the glomerulus: (1) subepithelial humps, as in acute glomerulonephritis; (2) epimembranous deposits, as in membranous nephropathy and Heymann nephritis; (3) subendothelial deposits, as in lupus nephritis and membranoproliferative glomerulonephritis; (4) mesangial deposits, as in IgA nephropathy. EN, Endothelium; EP, epithelium; GBM, glomerular basement membrane; LD, lamina densa; LRE, lamina rara externa; LRI, lamina rara interna; MC, mesangial cell; MM, mesangial matrix. (Modified from Couser WG: Mediation of immune glomerular injury. *J Am Soc Nephrol* 1:13, 1990.)

usually nephritogenic, because they are cleared by the mononuclear phagocyte system and do not enter the GBM in significant quantities. The pattern of localization is also affected by changes in glomerular hemodynamics, mesangial function, and integrity of the charge-selective barrier in the glomerulus. These influences may underlie the variable pattern of immune reactant deposition in various forms of glomerulonephritis (Fig. 20-5). In turn, the distinct patterns of localization of immune complexes is a key determinant of the injury response and the histologic features that subsequently develop. Immune complexes located in subendothelial portions of capillaries and in mesangial regions are accessible to the circulation and more likely to be involved in inflammatory processes that require interaction and activation of circulating leukocytes. Diseases in which immune complexes are confined to the subepithelial locations and for which the capillary basement membranes may be a barrier to interaction with circulating leukocytes, as in the case of membranous nephropathy, typically have a noninflammatory pathology.

In summary, **most cases of immune complex mediated glomerulonephritis are a consequence of deposition of discrete immune complexes, which give rise to granular immunofluorescence staining along the basement membranes or in the mesangium.** However, it may be difficult to determine whether the deposition has occurred in situ, by circulating complexes, or by both mechanisms because, as we discussed earlier, trapping of circulating immune

complexes can initiate further in situ complex formation. Single etiologic agents, such as hepatitis B and C viruses, can cause either a membranous pattern of glomerulonephritis, with subepithelial in situ deposition of antigens, or a membranoproliferative pattern, more indicative of subendothelial deposition of antigens or deposition of circulating complexes. It is best then to consider that **antigen-antibody deposition in the glomerulus is a major pathway of glomerular injury and that in situ immune reactions, trapping of circulating complexes, interactions between these two events, and local hemodynamic and structural determinants in the glomerulus all contribute to the diverse morphologic and functional alterations in glomerulonephritis.**

Cell-Mediated Immunity in Glomerulonephritis

Although antibody-mediated mechanisms may initiate many forms of glomerulonephritis, there is evidence that sensitized T cells cause glomerular injury and are involved in the progression of some glomerulonephritides. Clues to the role of cellular immunity include the presence of activated macrophages and T cells and their products in the glomerulus in some forms of human and experimental glomerulonephritis; in vitro and in vivo evidence of lymphocyte activation on exposure to antigen in human and experimental glomerulonephritis; abrogation of glomerular injury by lymphocyte depletion; and experiments in which glomerular injury may be induced by transfer of T cells from nephritic animals to normal recipients. The evidence is most compelling for certain types of experimental crescentic glomerulonephritis in which antibodies to GBM initiate glomerular injury and activated T lymphocytes then propagate the inflammation. Despite this body of suggestive evidence, proof of glomerulonephritis in humans resulting primarily from T-cell activation remains lacking.

KEY CONCEPTS

Pathogenesis of Immune-mediated Glomerular Injury

- Antibody-mediated immune injury is an important mechanism of glomerular damage, mainly via complement- and leukocyte-mediated pathways. Antibodies may also be directly cytotoxic to cells in the glomerulus.
- The most common forms of antibody-mediated glomerulonephritis are caused by the formation of immune complexes, which may involve either endogenous antigens (e.g., PLA₂R in membranous nephropathy) or exogenous (e.g., microbial) antigens. Immune complexes show a granular pattern of deposition by immunofluorescence.
- Autoantibodies against components of the GBM are the cause of anti-GBM antibody-mediated disease, often associated with severe injury. The pattern of antibody deposition is linear by immunofluorescence.

Activation of Alternative Complement Pathway

Alternative complement pathway activation occurs in the clinicopathologic entity called *dense-deposit disease*, until recently referred to as *membranoproliferative glomerulone-*

Figure 20-6 Mediators of immune glomerular injury.

phritis (MPGN type II), and in an emerging diagnostic category of diseases broadly termed *C3 glomerulopathies*. This is discussed later in the sections describing these diseases.

Mediators of Glomerular Injury

Once immune reactants or sensitized T cells have localized in the glomerulus, how does the glomerular damage ensue? The mediators—both cells and molecules—are the usual suspects involved in acute and chronic inflammation, described in Chapter 3, and only a few are highlighted here (Fig. 20-6).

Cells

- *Neutrophils* and *monocytes* infiltrate the glomerulus in certain types of glomerulonephritis, largely as a result of activation of complement, resulting in generation of chemotactic agents (mainly C5a), but also by Fc-mediated adherence and activation. Neutrophils release proteases, which cause GBM degradation; oxygen-derived free radicals, which cause cell damage; and arachidonic acid metabolites, which contribute to the reductions in GFR.
- *Macrophages* and *T lymphocytes*, which infiltrate the glomerulus in antibody- and cell-mediated reactions, when activated, release a vast number of biologically active molecules.
- *Platelets* may aggregate in the glomerulus during immune-mediated injury. Their release of eicosanoids, growth factors and other mediators may contribute to vascular injury and proliferation of glomerular cells. Antiplatelet agents have beneficial effects in both human and experimental glomerulonephritis.
- *Resident glomerular cells*, particularly mesangial cells, can be stimulated to produce several inflammatory mediators, including reactive oxygen species (ROS), cytokines, chemokines, growth factors, eicosanoids,

nitric oxide, and endothelin. They may initiate inflammatory responses in the glomerulus even in the absence of leukocytic infiltration.

Soluble Mediators

Virtually all the known inflammatory chemical mediators (Chapter 3) have been implicated in glomerular injury.

- *Complement activation* leads to the generation of chemotactic products that induce leukocyte influx (complement-neutrophil-dependent injury) and the formation of C5b-C9, the membrane attack complex. C5b-C9 causes cell lysis but, in addition, stimulates mesangial cells to produce oxidants, proteases, and other mediators. Thus, even in the absence of neutrophils, C5b-C9 can cause proteinuria, as has been demonstrated in experimental membranous glomerulopathy.
- *Eicosanoids*, *nitric oxide*, *angiotensin*, and *endothelin* are involved in the hemodynamic changes.
- *Cytokines*, particularly IL-1 and TNF, which may be produced by infiltrating leukocytes and resident glomerular cells, induce leukocyte adhesion and a variety of other effects.
- *Chemokines* such as monocyte chemoattractant protein 1 promote monocyte and lymphocyte influx. *Growth factors* such as platelet-derived growth factor (PDGF) are involved in mesangial cell proliferation. TGF- β , connective tissue growth factor, and fibroblast growth factor seem to be critical in the ECM deposition and hyalinization leading to glomerulosclerosis in chronic injury. Vascular endothelial growth factor (VEGF) seems to maintain endothelial integrity and may help regulate capillary permeability.
- The *coagulation system* is also a mediator of glomerular damage. Fibrin is frequently present in the glomeruli and Bowman space in glomerulonephritis, indicative of coagulation cascade activation, and activated

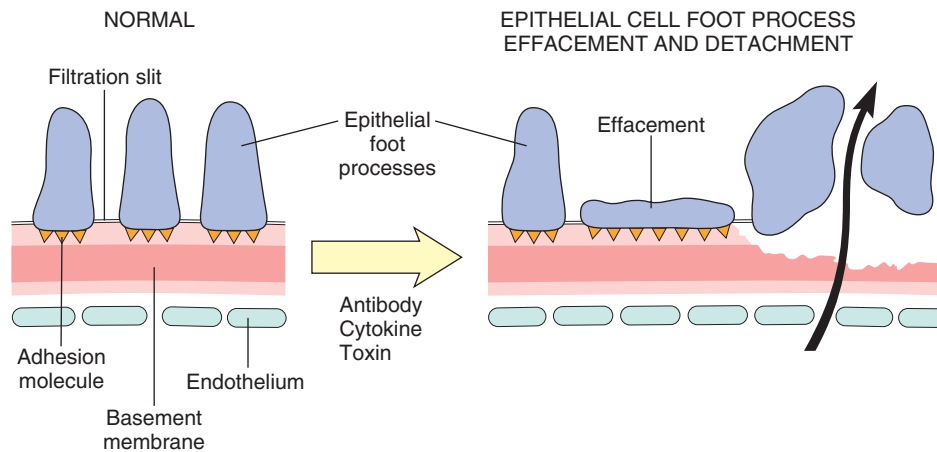

Figure 20-7 Epithelial cell injury. The postulated sequence is a consequence of antibodies specific to epithelial cell antigens, toxins, cytokines, or other factors causing injury; this results in foot process effacement and sometimes detachment of epithelial cells and protein leakage through defective GBM and filtration slits.

coagulation factors, particularly thrombin, may be a stimulus for crescent formation.

Epithelial Cell Injury

Podocyte injury is common to many forms of both primary and secondary glomerular diseases, of both immune and non-immune etiologies. The term *podocytopathy* has been applied to diseases with disparate etiologies whose principal manifestation is injury to podocytes. This can be induced by antibodies to podocyte antigens; by toxins, as in an experimental model of proteinuria induced by puromycin aminonucleoside; conceivably by certain cytokines; by certain viral infections such as human immunodeficiency virus (HIV) or by still inadequately characterized circulating factors, as in some cases of focal segmental glomerulosclerosis. Such injury is reflected by stereotypic morphologic changes in the podocytes, which include effacement of foot processes, vacuolization, and retraction and detachment of cells from the GBM, and functionally by proteinuria (Fig. 20-7).

Loss of podocytes, which have only a very limited capacity for replication and repair, may be a feature of multiple types of glomerular injury including focal and segmental glomerulosclerosis and diabetic nephropathy. Such loss typically cannot be recognized in pathologic specimens unless specialized morphologic techniques are applied. In most forms of glomerular injury, loss of normal slit diaphragms is a key event in the development of proteinuria (Fig. 20-6). Functional abnormalities of the slit diaphragm may also result from mutations in its components, such as nephrin and podocin, without actual inflammatory damage to the glomerulus. Such mutations are the cause of rare hereditary forms of the nephrotic syndrome.

Mechanisms of Progression in Glomerular Diseases

Thus far, the immunologic mechanisms and mediators that *initiate* glomerular injury have been discussed. The outcome of such injury depends on several factors, including the severity of renal damage, the nature and persistence of the antigens, and the immune status, age, and genetic predisposition of the host.

It has long been known that **once any renal disease, glomerular or otherwise, destroys functioning nephrons and reduces the GFR to about 30% to 50% of normal, progression to end-stage renal failure proceeds at a steady rate, independent of the original stimulus or activity of the underlying disease.** The secondary factors that lead to progression are of great clinical interest, since they can be targets of therapy that delays or even prevents the inexorable journey to dialysis or transplantation.

The two major histologic characteristics of such progressive renal damage are *focal segmental glomerulosclerosis* (FSGS) and *tubulointerstitial fibrosis*.

Focal Segmental Glomerulosclerosis (FSGS). Progressive fibrosis involving portions of some glomeruli develops after many types of renal injury and leads to proteinuria and increasing functional impairment. FSGS may be seen even in cases in which the primary disease was nonglomerular. The glomerulosclerosis seems to be initiated by the *adaptive change* that occurs in the relatively unaffected glomeruli of diseased kidneys. Such a mechanism is suggested by experiments in rats subjected to subtotal nephrectomy. *Compensatory hypertrophy* of the remaining glomeruli initially maintains renal function in these animals, but proteinuria and segmental glomerulosclerosis soon develop, leading eventually to total glomerular sclerosis and uremia. The glomerular hypertrophy is associated with *hemodynamic changes*, including increases in glomerular blood flow, filtration, and transcapillary pressure (glomerular hypertension), and often with systemic hypertension.

The sequence of events (Fig. 20-8) that is thought to lead to sclerosis in this setting entails endothelial and visceral epithelial cell injury, visceral epithelial cell loss leading to segments of GBM denuded of overlying foot processes and consequently increased glomerular permeability to proteins, and accumulation of proteins in the mesangial matrix. This is followed by proliferation of mesangial cells, infiltration by macrophages, increased accumulation of extracellular matrix (ECM), and segmental and eventually global sclerosis of glomeruli. With increasing reductions in nephron mass and ongoing compensatory changes, a vicious cycle of continuing glomerulosclerosis sets in. Most of the mediators of chronic inflammation and fibrosis, particularly TGF- β , play a role in the induction of

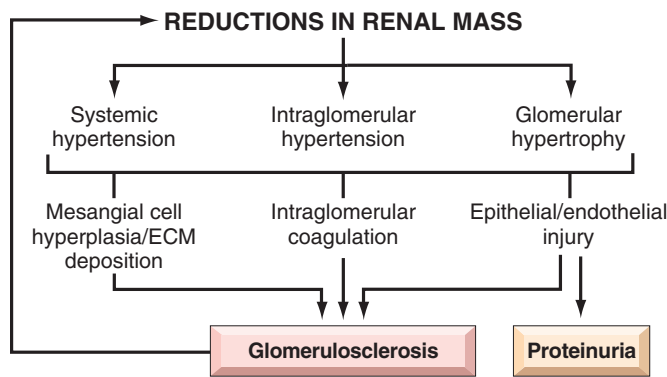

Figure 20-8 Focal segmental glomerulosclerosis associated with loss of renal mass. The adaptive changes in glomeruli (hypertrophy and glomerular capillary hypertension), as well as systemic hypertension, cause epithelial and endothelial injury and resultant proteinuria. The mesangial response, involving mesangial cell proliferation and ECM production, together with intraglomerular coagulation, causes the glomerulosclerosis. This results in further loss of functioning nephrons and a vicious circle of progressive glomerulosclerosis.

sclerosis. Currently, the most successful interventions to interrupt these mechanisms of progressive glomerulosclerosis involve treatment with inhibitors of the renin-angiotensin system, which not only reduce intraglomerular hypertension, but also have direct effects on each of the mechanisms identified above. Importantly, these agents have been shown to ameliorate progression of sclerosis in both animal and human studies.

Tubulointerstitial Fibrosis. Tubulointerstitial injury, manifested by tubular damage and interstitial inflammation, is a component of many acute and chronic glomerulonephritides. Tubulointerstitial fibrosis contributes to progression in both immune and nonimmune glomerular diseases, for example, diabetic nephropathy. Indeed, there is often a much better correlation of decline in renal function with the extent of tubulointerstitial damage than with the severity of glomerular injury. Many factors may lead to such tubulointerstitial injury, including ischemia of tubule segments downstream from sclerotic glomeruli, acute and chronic inflammation in the adjacent interstitium, and damage or loss of the peritubular capillary blood supply. Current work also points to the effects of proteinuria on tubular cell structure and function. It appears that proteinuria can cause direct injury to and activation of tubular cells. Activated tubular cells in turn express adhesion molecules and elaborate pro-inflammatory cytokines, chemokines, and growth factors that contribute to interstitial fibrosis. Filtered proteins that may produce these tubular effects include cytokines, complement products, the iron in hemoglobin, immunoglobulins, lipid moieties, and oxidatively modified plasma proteins.

KEY CONCEPTS

Progression of Glomerular Disease

- Progressive glomerular injury can be the result of either primary or secondary glomerular injuries, of diseases that

are either renal limited or systemic, and of diseases that initially involve renal structures other than glomeruli.

- The principal glomerular manifestation of progressive injury is focal segmental glomerulosclerosis, eventually leading to global glomerular involvement and glomerular obsolescence.
- Progressive injury ensues from a cycle of glomerular and nephron loss, compensatory changes that lead to further glomerular injury and glomerulosclerosis, and eventually end-stage renal disease.
- Progressive glomerular injury is accompanied by chronic injuries to other renal structures, typically manifest as tubulointerstitial fibrosis.

Having discussed the factors involved in the initiation and progression of glomerular injury, we now turn to a discussion of individual glomerular diseases. Table 20-5 summarizes the main clinical and pathologic features of the major forms of primary glomerulopathies.

Nephritic Syndrome

Glomerular diseases presenting with a nephritic syndrome are often characterized by inflammation in the glomeruli. The nephritic patient usually presents with hematuria, red cell casts in the urine, azotemia, oliguria, and mild to moderate hypertension. Proteinuria and edema are common, but these are not as severe as those encountered in the nephrotic syndrome, discussed later. The acute nephritic syndrome may occur in such multi-system diseases as SLE and microscopic polyangiitis. Typically, however, it is characteristic of acute proliferative and exudative glomerulonephritis and is an important component of crescentic glomerulonephritis, which is described later.

Acute Proliferative (Poststreptococcal, Postinfectious) Glomerulonephritis

As the name implies, this cluster of diseases is characterized histologically by diffuse proliferation of glomerular cells associated with influx (exudation) of leukocytes. These lesions are typically caused by immune complexes. The inciting antigen may be exogenous or endogenous. The prototypic exogenous antigen-induced disease pattern is postinfectious glomerulonephritis, whereas an example of an endogenous antigen-induced disease is the nephritis of SLE, described in Chapter 6. The most common underlying infections are streptococcal, but the disorder may also be associated with other infections.

Poststreptococcal Glomerulonephritis

This is a prototypical glomerular disease of immune complex etiology, which is decreasing in frequency in the United States but continues to be a fairly common disorder worldwide. It usually appears 1 to 4 weeks after a streptococcal infection of the pharynx or skin (impetigo). Skin infections are commonly associated with overcrowding and poor hygiene. Poststreptococcal glomerulonephritis occurs most frequently in children 6 to 10 years of age, but children and adults of any age can also be affected.

Table 20-5 Summary of Major Primary Glomerulonephritides

Disease	Most Frequent Clinical Presentation	Pathogenesis	Glomerular Pathology		
			Light Microscopy	Fluorescence Microscopy	Electron Microscopy
Postinfectious glomerulonephritis	Nephritic syndrome	Immune complex mediated; circulating or planted antigen	Diffuse endocapillary proliferation; leukocytic infiltration	Granular IgG and C3 in GBM and mesangium; Granular IgA in some cases	Primarily subepithelial humps; subendothelial deposits in early disease stages.
Goodpasture syndrome	Rapidly progressive glomerulonephritis	Anti-GBM COL4-A3 antigen	Extracapillary proliferation with crescents; necrosis	Linear IgG and C3; fibrin in crescents	No deposits; GBM disruptions; fibrin
Chronic glomerulonephritis	Chronic renal failure	Variable	Hyalinized glomeruli	Granular or negative	
Membranous nephropathy	Nephrotic syndrome	In situ immune complex formation; PLA ₂ R antigen in most cases of primary disease mostly unknown	Diffuse capillary wall thickening	Granular IgG and C3; diffuse	Subepithelial deposits
Minimal change disease	Nephrotic syndrome	Unknown; loss of glomerular polyanion; podocyte injury	Normal; lipid in tubules	Negative	Loss of foot processes; no deposits
Focal segmental glomerulosclerosis	Nephrotic syndrome; nonnephrotic proteinuria	Unknown Ablation nephropathy Plasma factor (?); podocyte injury	Focal and segmental sclerosis and hyalinosis	Focal; IgM + C3 in many cases	Loss of foot processes; epithelial denudation
Membranoproliferative glomerulonephritis (MPGN) type I	Nephrotic/nephritic syndrome	Immune complex	Mesangial proliferative or membranoproliferative patterns of proliferation; GBM thickening; splitting	IgG ++ C3; C1q ++ C4	Subendothelial deposits
Dense-deposit disease (MPGN type II)	Hematuria Chronic renal failure	Autoantibody; alternative complement pathway	Mesangial proliferative or membranoproliferative patterns of proliferation; GBM thickening; splitting	C3; no C1q or C4	Dense deposits
IgA nephropathy	Recurrent hematuria or proteinuria	Unknown	Focal mesangial proliferative glomerulonephritis; mesangial widening	IgA ± IgG, IgM, and C3 in mesangium	Mesangial and paramesangial dense deposits

GBM, Glomerular basement membrane.

Etiology and Pathogenesis. Poststreptococcal GN is caused by immune complexes containing streptococcal antigens and specific antibodies, which are formed *in situ*. Only certain strains of group A β -hemolytic streptococci are nephritogenic, more than 90% of cases being traced to types 12, 4, and 1, which can be identified by typing of the M protein of the bacterial cell walls.

Many lines of evidence support an immunologic basis for poststreptococcal glomerulonephritis. The latent period between infection and onset of nephritis is compatible with the time required for the production of antibodies and the formation of immune complexes. Elevated titers of antibodies against one or more streptococcal antigens are present in a great majority of patients. Serum complement levels are low, compatible with activation of the complement system and consumption of complement components. There are granular immune deposits in the glomeruli, indicative of an immune complex-mediated mechanism.

The streptococcal antigenic component responsible for the immune reaction had long eluded identification, but the preponderance of evidence identifies streptococcal pyogenic exotoxin B (SpeB) as the principal antigenic determinant in most but not all cases of poststreptococcal glomerulonephritis. This protein can directly activate

complement, is commonly secreted by nephritogenic strains of streptococci, and has been localized to the “hump-like” deposits characteristic of this disease (described later). At the outset, the inciting antigens are exogenously planted from the circulation in subendothelial locations in glomerular capillary walls, leading to *in situ* formation of immune complexes, where they elicit an inflammatory response. Subsequently, through mechanisms that are not well understood, the antigen-antibody complexes dissociate, migrate across the GBM, and re-form on the subepithelial side of the GBM.

MORPHOLOGY

The classic histologic picture is one of **enlarged, hypercellular glomeruli** (Fig. 20-9). The hypercellularity is caused by (1) infiltration by leukocytes, both neutrophils and monocytes; (2) proliferation of endothelial and mesangial cells; and (3) in severe cases by crescent formation. The proliferation and leukocyte infiltration are typically global and diffuse, that is, involving all lobules of all glomeruli. There is also swelling of endothelial cells, and the combination of proliferation, swelling, and leukocyte infiltration obliterates the capillary lumens. There may be

Figure 20-9 Acute proliferative glomerulonephritis. **A**, Normal glomerulus. **B**, Glomerular hypercellularity is due to intracapillary leukocytes and proliferation of intrinsic glomerular cells. **C**, Typical electron-dense subepithelial “hump” and a neutrophil in the lumen. **D**, Immunofluorescent stain demonstrates discrete, coarsely granular deposits of complement protein C3 (stain for IgG was similar), corresponding to “humps” illustrated in part **C**. (**A-C**, Courtesy Dr. H. Rennke, Brigham and Women’s Hospital, Boston, Mass. **D**, Courtesy D. J. Kowaleska, Cedars-Sinai Medical Center, Los Angeles, Calif.)

interstitial edema and inflammation, and the tubules often contain red cell casts.

By **immunofluorescence microscopy**, there are granular deposits of IgG, and C3, and sometimes IgM in the mesangium and along the GBM (Fig. 20-9D). Although immune complex deposits are almost universally present, they are often focal and sparse. The characteristic **electron microscopic findings** are discrete, amorphous, electron-dense deposits on the epithelial side of the membrane, often having the appearance of “humps” (Fig. 20-9C), presumably representing the antigen-antibody complexes at the subepithelial cell surface. Subendothelial deposits are also commonly seen, typically early in the disease course, and mesangial and intramembranous deposits may be present.

Clinical Course. In the typical case, a young child abruptly develops malaise, fever, nausea, oliguria, and hematuria (smoky or cola-colored urine) 1 to 2 weeks after recovery from a sore throat. The patients have dysmorphic red cells or red cell casts in the urine, mild proteinuria (usually less than 1 gm/day), periorbital edema, and mild to moderate hypertension. In adults the onset is more likely to be atypical, such as the sudden appearance of hypertension or

edema, frequently with elevation of BUN. The glomerulonephritis is subclinical in some infected individuals, and is discovered only on screening for microscopic hematuria carried out during epidemic outbreaks. Important laboratory findings include elevations of antistreptococcal antibody titers and a decline in the serum concentration of C3 and other components of the complement cascade.

More than 95% of affected children eventually recover renal function with conservative therapy aimed at maintaining sodium and water balance. A small minority of children (perhaps fewer than 1%) do not improve, become severely oliguric, and develop a rapidly progressive form of glomerulonephritis (described later). Some of the remaining patients may undergo slow progression to chronic glomerulonephritis with or without recurrence of an active nephritic picture. Prolonged and persistent heavy proteinuria and abnormal GFR mark patients with an unfavorable prognosis.

In adults the disease is less benign. Although the overall prognosis in epidemics is good, in only about 60% of sporadic cases do the patients recover promptly. In the remainder the glomerular lesions fail to resolve quickly, as manifested by persistent proteinuria, hematuria, and hypertension. In some of these patients, the lesions

eventually clear, but others develop chronic glomerulonephritis or even rapidly progressive glomerulonephritis.

Nonstreptococcal Acute Glomerulonephritis (Postinfectious Glomerulonephritis)

A similar form of glomerulonephritis occurs sporadically in association with other infections, including those of bacterial (e.g., staphylococcal endocarditis, pneumococcal pneumonia, and meningococemia), viral (e.g., hepatitis B, hepatitis C, mumps, HIV infection, varicella, and infectious mononucleosis), and parasitic (malaria, toxoplasmosis) origin. In these settings, granular immunofluorescent deposits and subepithelial humps characteristic of immune complex nephritis are present. Postinfectious glomerulonephritis due to staphylococcal infections differs by sometimes producing immune deposits containing IgA rather than IgG.

Rapidly Progressive (Crescentic) Glomerulonephritis

Rapidly progressive glomerulonephritis (RPGN) is a syndrome associated with severe glomerular injury, but does not denote a specific etiologic form of glomerulonephritis. It is characterized by rapid and progressive loss of renal function associated with severe oliguria and signs of nephritic syndrome; if untreated, death from renal failure occurs within weeks to months. *The most common histologic picture is the presence of crescents in most of the glomeruli (crescentic glomerulonephritis).* As discussed earlier, these are produced predominantly by the proliferation of the parietal epithelial cells lining Bowman capsule and by the infiltration of monocytes and macrophages.

Classification and Pathogenesis. RPGN may be caused by a number of different diseases, some restricted to the kidney and others systemic. Although no single mechanism can explain all cases, there is little doubt that **in most cases the glomerular injury is immunologically mediated.** A practical classification divides RPGN into three groups on the basis of immunologic findings (Table 20-6). In each group the disease may be associated with a known disorder, or it may be idiopathic. The common denominator in all types of RPGN is severe glomerular injury. Several distinct pathogenic mechanisms have been described, as follows:

- *Anti-GBM antibody-mediated disease, characterized by linear deposits of IgG and, in many cases, C3 in the GBM.* In some of these patients, the anti-GBM antibodies cross-react with pulmonary alveolar basement membranes to produce the clinical picture of pulmonary hemorrhage associated with renal failure (*Goodpasture syndrome*). Plasmapheresis to remove the pathogenic circulating antibodies is usually part of the treatment, which also includes therapy to suppress the underlying immune response.

The antigen common to the alveoli and GBM is a peptide within the noncollagenous portion of the α_3 chain of collagen type IV. What triggers the formation of these antibodies is unclear in most patients. Exposure to viruses or hydrocarbon solvents (found in paints and dyes) has been implicated in some patients, as have various drugs and cancers. There is a high prevalence of certain HLA subtypes and haplotypes (e.g.,

Table 20-6 Rapidly Progressive Glomerulonephritides

Type I (Anti-GBM Antibody)
Renal limited Goodpasture syndrome
Type II (Immune Complex)
Idiopathic Postinfectious glomerulonephritis Lupus nephritis Henoch-Schönlein purpura IgA nephropathy Others
Type III (Pauci-Immune)
ANCA-associated Idiopathic Granulomatosis with polyangiitis (formerly Wegener granulomatosis) Microscopic polyangiitis
ANCA, Antineutrophil cytoplasmic antibodies; GBM, glomerular basement membrane.

HLA-DRB1) in affected patients, a finding consistent with the genetic predisposition to autoimmunity.

- *Diseases caused by immune complex deposition.* RPGN can be a complication of any of the immune complex nephritides, including postinfectious glomerulonephritis, lupus nephritis, IgA nephropathy, and Henoch-Schönlein purpura. In all these cases, immunofluorescence studies reveal the granular pattern of staining characteristic of immune complex deposition. This type of RPGN frequently demonstrates cellular proliferation and influx of leukocytes within the glomerular tuft, in addition to crescent formation. These patients usually cannot be helped by plasmapheresis, and they require treatment for the underlying disease.
- *Pauci-immune RPGN, defined by the lack of detectable anti-GBM antibodies or immune complexes by immunofluorescence and electron microscopy.* Most patients with this type of RPGN have circulating *antineutrophil cytoplasmic antibodies* (ANCA) that produce cytoplasmic (c) or perinuclear (p) staining pattern and are known to play a role in some vasculitides (Chapter 11). This type of RPGN may be a component of a systemic vasculitis such as granulomatosis with polyangiitis (formerly called *Wegener granulomatosis*) or microscopic polyangiitis. In many cases, however, pauci-immune crescentic glomerulonephritis is limited to the kidneys and hence *idiopathic*. More than 90% of such idiopathic cases have c-ANCA or p-ANCA in the sera. The presence of circulating ANCA in both idiopathic crescentic glomerulonephritis and cases of crescentic glomerulonephritis that occur as a component of systemic vasculitis, and the similar pathologic features in either setting, have led to the idea that these disorders are pathogenetically related. According to this concept, all cases of crescentic glomerulonephritis of the pauci-immune type are manifestations of small-vessel vasculitis or polyangiitis, which is limited to glomerular and perhaps peritubular capillaries in cases of idiopathic crescentic glomerulonephritis. Since these entities are viewed as part of a spectrum of vasculitic disease, the clinical distinction between systemic vasculitis with pauci-immune renal involvement and idiopathic crescentic

glomerulonephritis has been de-emphasized. ANCA have proved to be invaluable as a highly sensitive diagnostic marker for pauci-immune crescentic glomerulonephritis, but proof of their role as a direct cause of this glomerulonephritis has been elusive. Recent evidence of their pathogenic potential has been obtained by studies in mice showing that transferring antibodies against myeloperoxidase (the target antigen of most p-ANCA) induces a form of RPGN.

To summarize, about one fifth of patients with RPGN have anti-GBM antibody-mediated glomerulonephritis without lung involvement; another one fourth have immune complex-mediated crescentic glomerulonephritis; and the remainder are of the pauci-immune type.

MORPHOLOGY

The kidneys are enlarged and pale, often with petechial hemorrhages on the cortical surfaces. Depending on the underlying cause, the glomeruli often show focal and segmental necrosis, and variably show diffuse or focal endothelial proliferation, and mesangial proliferation. Segmental glomerular necrosis adjacent to glomerular segments uninvolved by inflammatory or proliferative changes is the feature most typical of pauci-immune RPGN. The histologic picture, however, is dominated by distinctive **crests** (Fig. 20-10). Crescents are formed by proliferation of parietal cells and by migration of monocytes and macrophages into the urinary space. Neutrophils and lymphocytes may be present. The crescents may obliterate the urinary space and compress the glomerular tuft. **Fibrin strands are frequently prominent between the cellular layers in the crescents**; indeed, as discussed earlier, the escape of procoagulant factors, fibrin and cytokines into Bowman space may contribute to crescent formation. By immunofluorescence microscopy, immune complex-mediated cases show granular immune deposits; Goodpasture syndrome cases show linear GBM fluorescence for Ig and complement, and pauci-immune cases have little or no deposition of immune reactants. Electron microscopy discloses deposits in those cases due to immune complex deposition (type II). Regardless of type, electron microscopy may show **ruptures in the GBM**, a severe injury that allows leukocytes, plasma proteins such as coagulation factors and complement, and inflammatory mediators to reach the urinary space, where they trigger crescent formation (Fig. 20-11). In time, most crescents undergo organization and foci of segmental necrosis resolve as segmental scars (a type of segmental sclerosis), but restoration of normal glomerular architecture may be achieved with early aggressive therapy.

Clinical Course. The renal manifestations of all forms of crescentic glomerulonephritis include hematuria with red blood cell casts in the urine, moderate proteinuria occasionally reaching the nephrotic range, and variable hypertension and edema. In Goodpasture syndrome the course may be dominated by recurrent hemoptysis or even life-threatening pulmonary hemorrhage. Serum analyses for anti-GBM antibodies, antinuclear antibodies, and ANCA are helpful in the diagnosis of specific subtypes. Although milder forms of glomerular injury may subside, the renal

Figure 20-10 Crescentic glomerulonephritis (PAS stain). (Courtesy Dr. M.A. Venkatachalam, University of Texas Health Sciences Center, San Antonio, Tex.)

involvement is usually progressive over a matter of weeks and culminates in severe oliguria. Recovery of renal function may follow early intensive plasmapheresis (plasma exchange) combined with steroids and cytotoxic agents in Goodpasture syndrome. This therapy can reverse both pulmonary hemorrhage and renal failure. Other forms of RPGN also respond well to steroids and cytotoxic agents. However, despite therapy, many patients eventually require chronic dialysis or transplantation, particularly if the disease is discovered at a late stage.

KEY CONCEPTS

The Nephritic Syndrome

- The nephritic syndrome is characterized by hematuria, oliguria with azotemia, proteinuria, and hypertension.

Figure 20-11 Crescentic glomerulonephritis. Electron micrograph showing characteristic wrinkling of glomerular basement membrane with focal disruptions (arrows).

- The most common causes are immunologically mediated glomerular injury; lesions are characterized by proliferative changes and leukocyte infiltration.
- **Acute postinfectious glomerulonephritis** typically occurs after streptococcal infection in children and young adults but may occur following infection with many other organisms; it is caused by deposition of immune complexes, mainly in the subepithelial spaces, with abundant neutrophils and proliferation of glomerular cells. Most affected children recover; the prognosis is worse in adults.
- **Rapidly progressive glomerulonephritis (RPGN)** is a clinical entity with features of the nephritic syndrome and rapid loss of renal function.
- RPGN is commonly associated with severe glomerular injury with necrosis and GBM breaks and subsequent proliferation of parietal epithelial cells (forming crescents).
- RPGN may be antibody mediated, caused by autoantibodies to the GBM or as a result of immune complex deposition. It can also occur in the absence of significant antibody deposition, although most affected patients with this type of RPGN have circulating antineutrophil cytoplasmic antibodies (ANCA).

Nephrotic Syndrome

Certain glomerular diseases virtually always produce the nephrotic syndrome. In addition, many other forms of primary and secondary glomerulopathies discussed in this chapter may underlie the syndrome. Before the major diseases associated with nephrotic syndrome are presented, the causes and pathophysiology of this clinical complex are briefly discussed.

Pathophysiology. Nephrotic syndrome is caused by a derangement in glomerular capillary walls resulting in increased permeability to plasma proteins. The manifestations of the syndrome include:

- *Massive proteinuria*, with the daily loss of 3.5 gm or more of protein (less in children)
- *Hypoalbuminemia*, with plasma albumin levels less than 3 gm/dL
- *Generalized edema*
- *Hyperlipidemia and lipiduria*

The various components of nephrotic syndrome bear a logical relationship to one another. The glomerular capillary wall, with its endothelium, GBM, and visceral epithelial cells, acts as a size and charge barrier through which the plasma filtrate passes. Increased permeability resulting from either structural or physicochemical alterations in this barrier allows proteins to escape from the plasma into the urinary space, resulting in proteinuria.

Heavy proteinuria depletes serum albumin levels at a rate beyond the compensatory synthetic capacity of the liver, resulting in hypoalbuminemia. Increased renal catabolism of filtered albumin also contributes to the hypoalbuminemia. The generalized edema is a direct consequence of *decreased intravascular colloid osmotic pressure*. There is also *sodium and water retention*, which aggravates the edema (Chapter 4). This seems to be due to several

factors, including compensatory secretion of aldosterone, mediated by the hypovolemia-enhanced renin secretion; stimulation of the sympathetic system; and a reduction in the secretion of natriuretic factors such as atrial peptides. Edema is characteristically soft and pitting, and is most marked in the periorbital regions and dependent portions of the body. If severe, it may also lead to pleural effusions and ascites.

The largest proportion of protein lost in the urine is albumin, but globulins are also excreted in some diseases. The ratio of low- to high-molecular-weight proteins in the urine in various cases of nephrotic syndrome is a manifestation of the *selectivity* of proteinuria. A *highly selective proteinuria* consists mostly of low-molecular-weight proteins (albumin, 70 kD; transferrin, 76 kD molecular weight), whereas a *poorly selective proteinuria* consists of higher molecular-weight globulins in addition to albumin.

The genesis of the hyperlipidemia is complex. Most patients with nephrotic syndrome have increased blood levels of cholesterol, triglyceride, very-low-density lipoprotein, low-density lipoprotein, Lp(a) lipoprotein, and apoprotein, and there is a decrease in high-density lipoprotein concentration in some patients. These defects seem to be due to a combination of increased synthesis of lipoproteins in the liver, abnormal transport of circulating lipid particles, and decreased lipid catabolism. Lipiduria follows the hyperlipidemia, because lipoproteins also leak across the glomerular capillary wall. The lipid appears in the urine either as free fat or as *oval fat bodies*, representing lipoprotein resorbed by tubular epithelial cells and then shed along with injured tubular cells that have detached from the basement membrane.

Nephrotic patients are particularly vulnerable to *infection*, especially staphylococcal and pneumococcal infections, probably due to loss of immunoglobulins in the urine. *Thrombotic and thromboembolic complications* are also common in nephrotic syndrome, due in part to loss of endogenous anticoagulants (e.g., antithrombin III) in the urine. *Renal vein thrombosis*, once thought to be a cause of nephrotic syndrome, is most often a *consequence* of this hypercoagulable state, particularly in patients with membranous nephropathy (see later).

Causes. The incidences of the several causes of the nephrotic syndrome vary according to age and geography. In children younger than 17 years in North America, for example, nephrotic syndrome is almost always caused by a lesion primary to the kidney; among adults, in contrast, it is often associated with a systemic disease. Table 20-7 represents a composite derived from several studies of the causes of the nephrotic syndrome and is therefore only approximate. The most frequent *systemic causes* of the nephrotic syndrome are diabetes, amyloidosis, and SLE. The most important of the *primary glomerular lesions* are *minimal-change disease*, *membranous glomerulopathy*, and *focal segmental glomerulosclerosis*. The first is most common in children in North America, the second is most common in older adults, and focal segmental glomerulosclerosis occurs at all ages. These three lesions are discussed individually in the following sections. Other less common causes of nephrotic syndrome include the various proliferative glomerulonephritides such as MPGN and IgA nephropathy.

Table 20-7 Cause of Nephrotic Syndrome

Causes	Approximate Prevalence (%) [*]	
	Children	Adults
Primary Glomerular Disease		
Membranous nephropathy	3	30
Minimal-change disease	75	8
Focal segmental glomerulosclerosis	10	35
Membranoproliferative glomerulonephritis and dense deposit disease [†]	10	10

Drugs (nonsteroidal anti-inflammatory, penicillamine, heroin)		
Infections (malaria, syphilis, hepatitis B and C, HIV)		
Malignant disease (carcinoma, lymphoma)		
Miscellaneous (bee-sting allergy, hereditary nephritis)		

^{*}Approximate prevalence of primary disease = 95% of nephrotic syndrome in children, 60% in adults. Approximate prevalence of systemic disease = 5% in children, 40% in adults.
[†]Membranoproliferative and other proliferative glomerulonephritides may result in mixed nephrotic/nephritic syndromes.

Membranous Nephropathy

Membranous nephropathy is characterized by diffuse thickening of the glomerular capillary wall due to the accumulation of deposits containing Ig along the subepithelial side of the basement membrane. Approximately 75% of cases of membranous nephropathy are primary. The remaining cases occur in association with other systemic diseases and have identifiable etiologic agents, and hence are referred to as secondary membranous nephropathy. The most notable of these associations are as follows:

- *Drugs* (penicillamine, captopril, gold, nonsteroidal anti-inflammatory drugs (NSAIDs). From 1% to 7% of patients with rheumatoid arthritis treated with penicillamine or gold (drugs now used infrequently for this purpose) develop membranous nephropathy.
- *Underlying malignant tumors*, particularly carcinomas of the lung and colon, and melanoma. According to some studies, these are present in as many as 5% to 10% of adults with membranous nephropathy.
- *SLE*. About 10% to 15% of glomerulonephritis in SLE is of the membranous type.
- *Infections* (chronic hepatitis B, hepatitis C, syphilis, schistosomiasis, malaria)
- *Other autoimmune disorders* such as thyroiditis can be associated with secondary membranous nephropathy.

Pathogenesis. Membranous nephropathy is a form of chronic immune complex-mediated disease. In secondary membranous nephropathy, the inciting antigens can sometimes be identified in the immune complexes. The antigens may be endogenous or exogenous. The endogenous antigens may be renal or non renal. For example, membranous nephropathy in SLE is associated with deposition of complexes of self nuclear proteins and autoantibodies. Another example of an endogenous antigen is neutral

endopeptidase, a membrane protein recognized by placentally transferred maternal antibodies in cases of neonatal membranous nephropathy. Exogenous antigens include those derived from hepatitis B virus and *Treponema pallidum* in patients infected with these microbes.

Primary (also called idiopathic) membranous nephropathy, long thought to be of unknown cause, is now considered to be an *autoimmune disease linked to certain HLA alleles such as HLA-DQA1 and caused in most cases by antibodies to a renal autoantigen*. In many adult cases the autoantigen is the phospholipase A₂ receptor. The lesions bear a striking resemblance to those of experimental Heymann nephritis, which, as you might recall, is induced by antibodies to the megalin antigenic complex present in the rat podocyte, which is the antigenic counterpart of the human phospholipase A₂ receptor.

How does the glomerular capillary wall become leaky in membranous nephropathy? There is a paucity of neutrophils, monocytes, or platelets in glomeruli. The virtually uniform presence of complement and corroborating experimental work suggest that the complement C5b-C9 membrane attack complex has an important role. It is postulated that C5b-C9 activates glomerular epithelial and mesangial cells, inducing them to liberate proteases and oxidants, which cause capillary wall injury and increased protein leakage. A subclass of IgG, IgG₄, which differs from other IgG subclasses in being a poor activator of the classical complement pathway, is the principal immunoglobulin deposited in cases of primary membranous nephropathy. How IgG₄ may activate the complement system is not clear. Perhaps other modes of complement activation may be harnessed.

MORPHOLOGY

By light microscopy the glomeruli either appear normal in the early stages of the disease or exhibit **uniform, diffuse thickening of the glomerular capillary wall** (Fig. 20-12A). By electron microscopy the thickening is seen to be caused by irregular electron dense also deposits containing immune complexes between the basement membrane and the overlying epithelial cells, with effacement of podocyte foot processes (Fig. 20-12B and D). Basement membrane material is laid down between these deposits, appearing as irregular spikes protruding from the GBM. These spikes are best seen by silver stains, which color the basement membrane, but not the deposits, black. In time, these spikes thicken to produce domelike protrusions and eventually close over the immune deposits, burying them within a markedly thickened, irregular membrane. Immunofluorescence microscopy demonstrates that the granular deposits contain both immunoglobulins and complement (Fig. 20-12C). As the disease advances segmental sclerosis may occur; in the course of time glomeruli may become totally sclerosed. The epithelial cells of the proximal tubules contain protein reabsorption droplets, and there may be considerable interstitial mononuclear cell inflammation.

Clinical Features. This disorder usually presents with the insidious onset of the nephrotic syndrome or, in 15% of patients, with nonnephrotic proteinuria. Hematuria and mild hypertension are present in 15% to 35% of cases. It is necessary in any patient to first rule out the secondary causes described earlier, since treatment of the underlying

Figure 20-12 Membranous nephropathy. **A**, Silver methenamine stain. Note the marked diffuse thickening of the capillary walls without an increase in the number of cells. There are prominent “spikes” of silver-staining matrix (*arrow*) projecting from the basement membrane lamina densa toward the urinary space, which separate and surround deposited immune complexes that lack affinity for the silver stain. **B**, Electron micrograph showing electron-dense deposits (*arrow*) along the epithelial side of the basement membrane (B). condition (malignant neoplasm, infection, or SLE) or discontinuance of the offending drug can reverse or ameliorate the injury.

The course of the disease is variable but generally indolent. In contrast to minimal-change disease, described later, the proteinuria is nonselective and usually does not respond well to corticosteroid therapy. Complete or partial remissions may occur in up to 40% of patients, even in some patients without therapy. Progression is associated with increasing sclerosis of glomeruli, rising serum creatinine reflecting renal insufficiency, and development of hypertension. Although proteinuria persists in more than 60% of patients, only about 10% die or progress to renal failure within 10 years, and no more than 40% eventually

develop severe chronic kidney disease or end-stage renal disease. The disease recurs in up to 40% of patients who undergo transplantation for end-stage renal disease. Spontaneous remissions and a relatively benign outcome occur more commonly in women and in those with proteinuria in the nonnephrotic range.

Because of the variable course of the disease, it has been difficult to evaluate the overall effectiveness of corticosteroids or other immunosuppressive therapy in controlling the proteinuria or progression. It is thought that circulating antibodies to PLA₂ receptor may be a useful biomarker of disease activity and thereby aid in the diagnosis and management of primary membranous nephropathy in the future.

Minimal-Change Disease

This relatively benign disorder is characterized by diffuse effacement of foot processes of visceral epithelial cells (podocytes), detectable only by electron microscopy, in glomeruli that appear virtually normal by light microscopy. It is the most frequent cause of nephrotic syndrome in children, but it is less common in adults (Table 20-7). The peak incidence is between 2 and 6 years of age. The disease sometimes follows a respiratory infection or routine prophylactic immunization.

Etiology and Pathogenesis. Although the absence of immune deposits in the glomerulus excludes classic immune complex mechanisms, several features of the disease point to an immunologic basis, including (1) the clinical association with respiratory infections and prophylactic immunization; (2) the response to corticosteroids and/or other immunosuppressive therapy; (3) the association with other atopic disorders (e.g., eczema, rhinitis); (4) the increased prevalence of certain HLA haplotypes in patients with minimal-change disease associated with atopy (suggesting a genetic predisposition); and (5) the increased incidence of minimal-change disease in patients with Hodgkin lymphoma, in whom defects in T cell-mediated immunity are well recognized.

The current leading hypothesis is that minimal-change disease involves some immune dysfunction that results in the elaboration of factors that damage visceral epithelial cells and cause proteinuria. Candidate pathogenic factors such as angiotensin-like-4 have been identified in animal models but none have been proven to cause the human disease. The ultrastructural changes point to a primary *visceral epithelial cell injury* (podocytopathy), and studies in animal models suggest the loss of glomerular polyanions. Thus, defects in the charge barrier may contribute to the proteinuria. The actual route by which protein traverses the epithelial cell portion of the capillary wall remains an enigma. Possibilities include transcellular passage through the epithelial cells, passage

through residual spaces between remaining but damaged foot processes or through abnormal spaces developing underneath the portion of the foot process that directly abuts the basement membrane, or leakage through foci in which the epithelial cells have become detached from the basement.

MORPHOLOGY

The glomeruli are normal by light microscopy (Fig. 20-13). By electron microscopy the GBM appears normal, and no electron-dense material is deposited. **The principal lesion is in the visceral epithelial cells, which show a uniform and diffuse effacement of foot processes**, these being reduced to a rim of cytoplasm with loss of recognizable intervening slit diaphragms (Fig. 20-13). This change, often incorrectly termed “fusion” of foot processes, actually represents simplification of the epithelial cell architecture with flattening, retraction, and swelling of foot processes. Foot process effacement is also present in other proteinuric states (e.g., membranous glomerulopathy, diabetic nephropathy); it is only when effacement is associated with normal glomeruli by light microscopy that the diagnosis of minimal-change disease can be made. The visceral epithelial changes are completely reversible after corticosteroid therapy, concomitant with remission of the proteinuria. The cells of the proximal tubules are often laden with lipid and protein, reflecting tubular reabsorption of lipoproteins passing through diseased glomeruli (thus, the historical name **lipoid nephrosis** for this disease). Immunofluorescence studies show no Ig or complement deposits.

Clinical Features. Despite massive proteinuria, renal function remains good, and there is commonly no hypertension or hematuria. The proteinuria usually is highly selective, most of the protein being albumin. **A characteristic feature is its usually dramatic response to corticosteroid therapy.** Most children (>90%) with minimal-change disease respond rapidly to this treatment. However, proteinuria may recur, and some patients may become

Figure 20-13 Minimal-change disease. **A**, Glomerulus stained with PAS. steroid-dependent or resistant. Nevertheless, the long-term prognosis for patients is excellent, and even steroid-dependent disease usually resolves when children reach puberty. Although adults are slower to respond, their long-term prognosis is also excellent.

As has been noted, minimal-change disease in adults can be associated with Hodgkin lymphoma and, less frequently, other lymphomas and leukemias. In addition, secondary minimal-change disease may follow NSAID therapy, usually in association with acute interstitial nephritis, to be described later in this chapter.

Focal Segmental Glomerulosclerosis (FSGS)

Primary focal segmental glomerulosclerosis is the most common cause of nephrotic syndrome in adults in the United States. It is sometimes considered to be a primary disorder of podocytes, like minimal change disease. As the name implies, this lesion is characterized by sclerosis of some, but not all, glomeruli (thus, it is focal); and in the affected glomeruli, only a portion of the capillary tuft is involved (thus, it is segmental). Focal segmental glomerulosclerosis is frequently manifest clinically by the acute or subacute onset of nephrotic syndrome or nonnephrotic proteinuria. Hypertension, microscopic hematuria, and some degree of azotemia are commonly present when the disease is first clinically recognized.

Classification and Types. Focal segmental glomerulosclerosis occurs in the following settings:

- As a primary disease (idiopathic focal segmental glomerulosclerosis)
- In association with other known conditions, such as HIV infection (HIV-associated nephropathy), heroin addiction (heroin nephropathy), sickle-cell disease, and massive obesity
- As a secondary event, reflecting scarring of previously active necrotizing lesions, in cases of focal glomerulonephritis (e.g., IgA nephropathy)
- As a component of the adaptive response to loss of renal tissue (renal ablation, described earlier), whether from congenital anomalies (e.g., unilateral renal agenesis or renal dysplasia) or acquired causes (e.g., reflux nephropathy), or in advanced stages of other renal disorders, such as hypertensive nephropathy.
- In uncommon inherited forms of nephrotic syndrome where the disease may be caused by mutations in genes that encode proteins localized to the slit diaphragm, e.g., podocin, α -actinin 4, and TRPC6 (transient receptor potential calcium channel-6)

Idiopathic focal segmental glomerulosclerosis accounts for 10% and 35% of cases of nephrotic syndrome in children and adults, respectively. FSGS (both primary and secondary forms) has increased in incidence and is now the most common cause of nephrotic syndrome in adults in the United States, particularly in Hispanic and African-American patients. The clinical signs differ from those of minimal-change disease in the following respects: (1) there is a higher incidence of hematuria, reduced GFR, and hypertension; (2) proteinuria is more often nonselective; (3) there is poor response to corticosteroid therapy; and (4) there is progression to chronic kidney disease, with at least 50% developing ESRD within 10 years.

Pathogenesis. The characteristic degeneration and focal disruption of visceral epithelial cells with effacement of foot processes resemble the diffuse epithelial cell change typical of minimal-change disease and other podocytopathies. *It is this epithelial damage that is the hallmark of FSGS.* Multiple different mechanisms can cause such epithelial damage, including circulating factors and genetically determined defects affecting components of the slit diaphragm complex. The hyalinosis and sclerosis stem from entrapment of plasma proteins in extremely hyperpermeable foci and increased ECM deposition. The recurrence of proteinuria after transplantation, sometimes within 24 hours, with subsequent progression to overt lesions of FSGS, suggests that an unknown circulating factor is the cause of the epithelial damage in some patients.

The discovery of a genetic basis for some cases of FSGS and other causes of the nephrotic syndrome has improved the understanding of the pathogenesis of proteinuria in the nephrotic syndrome and has provided new methods for diagnosis and prognosis of affected patients. Leading examples of this include:

- The first relevant gene to be identified, *NPHS1*, maps to chromosome 19q13 and encodes the protein *nephrin*. Nephrin is a key component of the slit diaphragm (Fig. 20-3), the structure that controls glomerular permeability. Several mutations of the *NPHS* gene have been identified that give rise to *congenital nephrotic syndrome* of the Finnish type, producing a minimal-change disease like glomerulopathy with extensive foot process effacement.
- A distinctive pattern of autosomal recessive FSGS results from mutations in the *NPHS2* gene, which maps to chromosome 1q25-q31 and encodes the protein product *podocin*. Podocin has also been localized to the slit diaphragm. Mutations in *NPHS2* result in a syndrome of steroid-resistant nephrotic syndrome of childhood onset.
- A third set of mutations in the gene encoding the podocyte actin-binding protein α -actinin 4 underlies some cases of autosomal dominant FSGS, which can be insidious in onset but has a high rate of progression to renal insufficiency.
- A fourth type of mutation was found in some kindreds with adult-onset FSGS, in the gene encoding TRPC6. This protein is widely expressed, including in podocytes, and the pathogenic mutations may perturb podocyte function by increasing calcium flux in these cells.

What these proteins have in common is their localization to the slit diaphragm and to adjacent podocyte cytoskeletal structures. Their specific functions and interactions are incompletely understood, but it is clear that the integrity of each is necessary to maintain the normal glomerular filtration barrier. Recently two sequence variants in the apolipoprotein L1 gene (*APOL1*) on chromosome 22 have been strongly associated with an increased risk of FSGS and renal failure in individuals of African descent, although the mechanisms underlying this association are not yet known. These sequence variants are particularly remarkable because the selective pressures for their conservation in people of African descent is a result of resistance to trypanosome infection conferred by these polymorphisms.

Figure 20-14 Focal segmental glomerulosclerosis, PAS stain. **A**, Low-power view showing segmental sclerosis in one of three glomeruli (at 3 o'clock). **B**, High-power view showing hyaline insudation (*arrow*) and lipid (small vacuoles) in sclerotic area.

Renal ablation FSGS, a secondary form of FSGS, occurs as a complication of glomerular and nonglomerular diseases causing reduction in functioning renal tissue. Particularly striking examples where this occurs are reflux nephropathy and unilateral agenesis. These may lead to progressive glomerulosclerosis and renal failure. The pathogenesis of FSGS in this setting is described earlier in this chapter.

MORPHOLOGY

By light microscopy the **focal and segmental lesions may involve only a minority of the glomeruli** and may be missed if the biopsy specimen contains an insufficient number of glomeruli (Fig. 20-14A). In the sclerotic segments there is collapse of capillary loops, increase in matrix and segmental deposition of plasma proteins along the capillary wall (hyalinosis), which may become so pronounced as to occlude capillary lumens. Lipid droplets and foam cells are often present (Fig. 20-14B). Glomeruli that do not show segmental lesions usually appear normal on light microscopy but may show increased mesangial matrix. On electron microscopy both sclerotic and nonsclerotic areas show **diffuse effacement of foot processes**, and there may also be focal detachment of the epithelial cells and denudation of the underlying GBM. By immunofluorescence microscopy IgM and C3 may be present in the sclerotic areas and/or in the mesangium. In addition to the focal sclerosis, there may be pronounced hyalinosis and thickening of afferent arterioles. With the progression of the disease, increased numbers of glomeruli become involved and sclerosis spreads within each glomerulus. In time, this leads to total (i.e., global) sclerosis of glomeruli, with pronounced tubular atrophy and interstitial fibrosis.

A morphologic variant of FSGS, called **collapsing glomerulopathy**, is characterized by retraction and/or collapse of the entire glomerular tuft, with or without additional FSGS lesions of the type described above (Fig. 20-15). A characteristic feature is proliferation and hypertrophy of glomerular visceral epithelial cells. This lesion may be idiopathic, but it also has been associated with some drug toxicities (e.g., pamidronate), and it is the most characteristic lesion of HIV-associated nephropathy. Collapsing glomerulopathy is typically associated with prominent tubular injury with formation of microcysts. It has a particularly poor prognosis.

Clinical Course. There is little tendency for spontaneous remission in idiopathic FSGS, and responses to corticosteroid therapy are variable. In general, children have a better prognosis than adults do. Progression to renal failure occurs at variable rates. About 20% of patients follow an unusually rapid course, with intractable massive proteinuria ending in renal failure within 2 years. Factors associated with rapid progression include the degree of proteinuria, the degree of renal insufficiency at diagnosis, and histologic subtype (the collapsing variant has an unfavorable course; the tip variant has a relatively good prognosis). Recurrences are seen in 25% to 50% of patients receiving allografts.

HIV-Associated Nephropathy

HIV infection can directly or indirectly cause several renal complications, including acute renal failure or acute

Figure 20-15 Collapsing glomerulopathy. Visible are retraction of the glomerular tuft (*arrows*), narrowing of capillary lumens, proliferation and swelling of visceral epithelial cells (*double arrows*), and prominent accumulation of intracellular protein absorption droplets in the visceral epithelial cells (*arrowheads*). Silver methenamine stain. (Courtesy Dr. Jolanta Kowalewska, Cedars-Sinai Medical Center, Los Angeles, Calif.)

interstitial nephritis induced by drugs or the infection, thrombotic microangiopathies, postinfectious glomerulonephritis, and, most commonly, a severe form of the collapsing variant of FSGS, termed *HIV-associated nephropathy*. The latter has been reported in 5% to 10% of HIV-infected individuals in some older series, more frequently in blacks than in whites. With the advent of highly active antiretroviral therapy for HIV infection, the incidence of this lesion has been much reduced. The morphologic features of HIV-associated nephropathy are:

- A high frequency of the collapsing variant of FSGS (Fig. 20-15)
- A striking focal cystic dilation of tubule segments, which are filled with proteinaceous material, and inflammation and fibrosis
- The presence of large numbers of tubuloreticular inclusions within endothelial cells, detected by electron microscopy. Such inclusions, also present in SLE, have been shown to be modifications of endoplasmic reticulum induced by circulating interferon- α . They are not usually present in idiopathic FSGS and therefore may have diagnostic value in a biopsy specimen.

The pathogenesis of HIV-associated FSGS is unclear. There is some data to suggest that HIV can infect tubular epithelial cells and podocytes, but much remains to be known.

Membranoproliferative Glomerulonephritis (MPGN)

MPGN is best considered a pattern of immune-mediated injury rather than a specific disease. An emerging consensus on classification separates one group of disorders MPGN into two groups, one (type I) characterized by deposition of immune complexes containing IgG and complement, and a second (type II, often called *dense deposit disease*) in which activation of complement appears to be the most important factor. The latter belong to a group of disorders called *C3 glomerulopathies*. The criteria that define this group are still evolving.

MPGN is characterized histologically by alterations in the glomerular basement membrane, proliferation of glomerular cells, leukocyte infiltration, and the presence of deposits in mesangial regions and glomerular capillary walls. As will be described later, these deposits are made up of immune complexes in Type I MPGN and some unknown material in type II MPGN. In type II, C3 is present on the GBM but not in the dense deposits. This difference is important and suggests that while morphologically similar, type I and II MPGN are pathogenically distinct. In both types, because the proliferation is predominantly in the mesangium but also may involve the capillary loops, a frequently used synonym is *mesangiocapillary glomerulonephritis*.

MPGN accounts for up to 10% of cases of nephrotic syndrome in children and young adults. Some patients present only with hematuria or proteinuria in the nonnephrotic range, but many others have a combined nephrotic-nephritic picture. MPGN is increasingly recognized to be associated with other systemic disorders and known etiologic agents (secondary MPGN), but there is still a residue of cases of unknown etiology (primary MPGN).

Pathogenesis. In most cases of type I MPGN there is evidence of immune complexes in the glomerulus and

activation of both classical and alternative complement pathways. The antigens involved in idiopathic MPGN are unknown. In many cases they are believed to be proteins derived from infectious agents such as hepatitis C and B viruses, which presumably behave either as “planted” antigens after first binding to or becoming trapped within glomerular structures or are contained in preformed immune complexes deposited from the circulation.

MORPHOLOGY

The **glomeruli are large and hypercellular**. The hypercellularity is produced both by proliferation of cells in the mesangium and so-called endocapillary proliferation involving capillary endothelium and infiltrating leukocytes. The glomeruli have an accentuated “lobular” appearance due to the **proliferating mesangial cells and increased mesangial matrix** (Fig. 20-16). The GBM is thickened, and often shows a “**double-contour**” or “**tram-track**” appearance, especially evident in silver or PAS stains. This is caused by “**duplication**” of the **basement membrane** (also commonly referred to as splitting), usually as the result of new basement membrane synthesis in response to subendothelial deposits of immune complexes. Between the duplicated basement membranes there is inclusion or interposition of cellular elements, which can be of mesangial, endothelial, or leukocytic origin. Such interposition also gives rise to the appearance of “split” basement membranes (Fig. 20-17A). Crescents are present in many cases.

Type I MPGN is characterized by the presence of discrete **subendothelial electron-dense deposits**. Mesangial and occasional subepithelial deposits may also be present (Fig. 20-17A). By immunofluorescence, IgG and C3 are deposited in a granular pattern, and early complement components (C1q and C4) are often also present, indicative of an immune complex pathogenesis.

Figure 20-16 Membranoproliferative glomerulonephritis, showing mesangial cell proliferation, increased mesangial matrix (staining black with silver stain), basement membrane thickening with segmental splitting, accentuation of lobular architecture, swelling of cells lining peripheral capillaries, and influx of leukocytes (endocapillary proliferation).

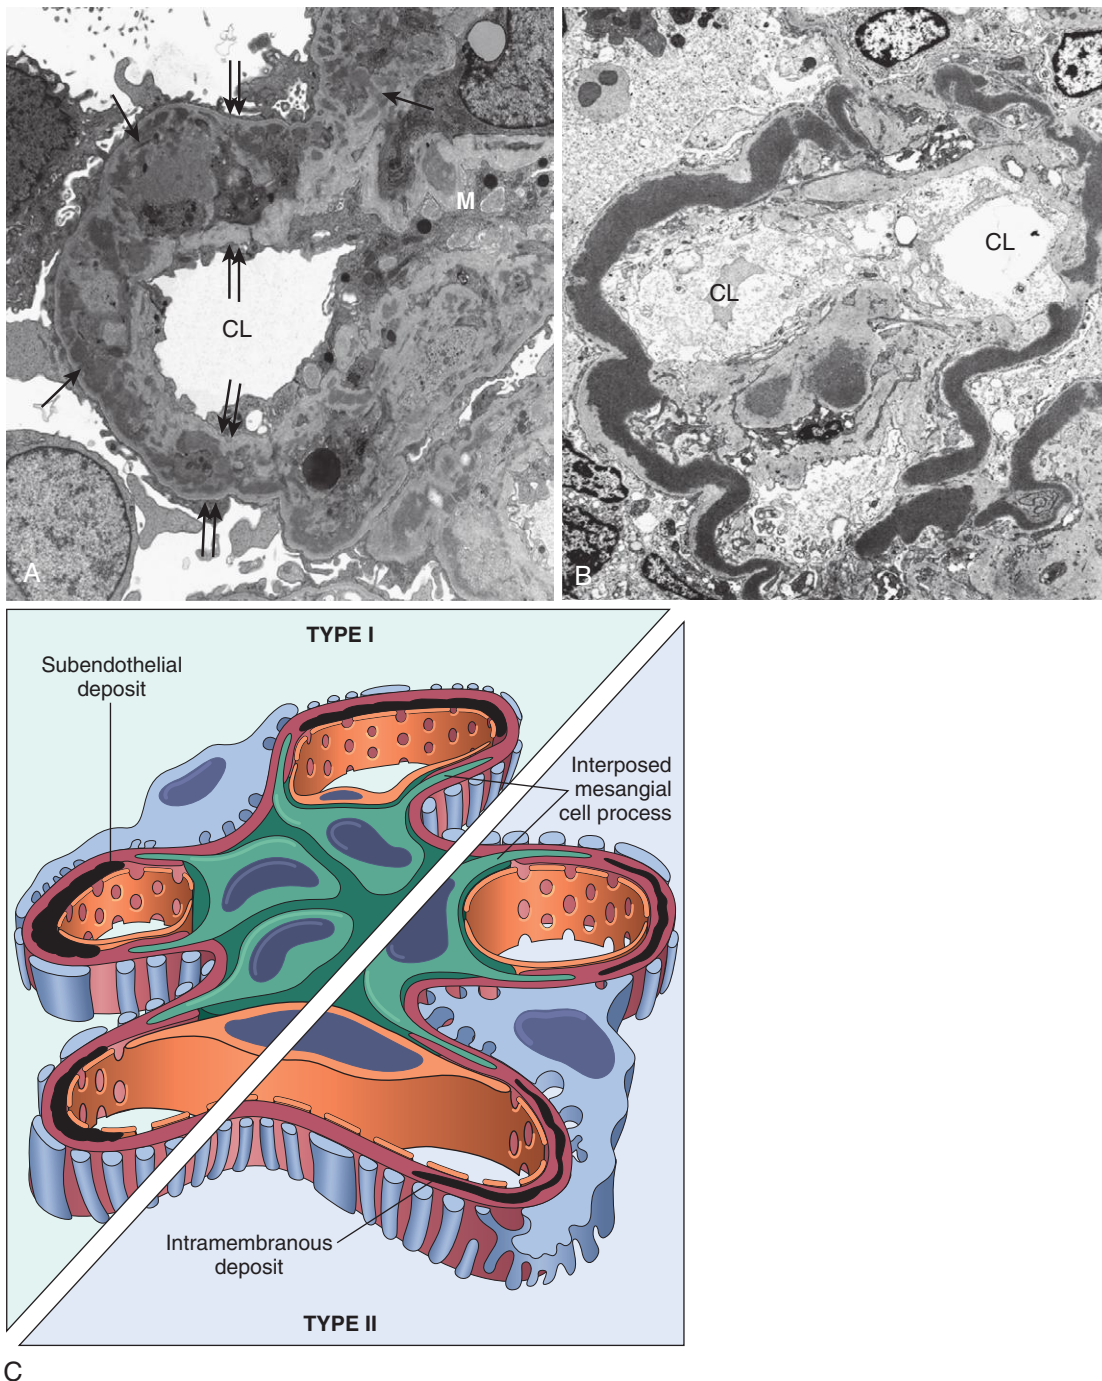

Figure 20-17 **A**, Membranoproliferative glomerulonephritis, type I. Note discrete electron-dense deposits (*arrows*) incorporated into the glomerular capillary wall between duplicated (split) basement membranes (*double arrows*), and in mesangial regions (M); CL, Capillary lumen. **B**, Dense-deposit disease (type II membranoproliferative glomerulonephritis). There are dense homogeneous deposits within the basement membrane. CL, Capillary lumen. In both, mesangial interposition gives the appearance of split basement membranes when viewed in the light microscope. **C**, Schematic representation of patterns in the two types of membranoproliferative glomerulonephritis. In type I there are subendothelial deposits; type II is characterized by intramembranous dense deposits (dense-deposit disease). In both, the basement membranes appear split when viewed in the light microscope. (**A**, Courtesy Dr. Jolanta Kowalewska, Cedars-Sinai Medical Center, Los Angeles, Calif.)

Clinical Features. Most patients with primary MPGN present in adolescence or as young adults with nephrotic syndrome and a nephritic component manifested by hematuria or, more insidiously, as mild proteinuria. Few remissions occur spontaneously in either type, and the disease follows

a slowly progressive but unremitting course. Some patients develop numerous crescents and a clinical picture of RPGN. About 50% develop chronic renal failure within 10 years. Treatments with steroids, immunosuppressive agents, and antiplatelet drugs have not proven to be of any benefit.

Figure 20-18 The alternative complement pathway in dense deposit disease (Type II MPGN). Note that C3NeF, an antibody present in the serum of individuals with membranoproliferative glomerulonephritis, acts at the same step as properdin, serving to stabilize the alternative pathway C3 convertase, thus enhancing C3 activation and consumption, causing hypocomplementemia.

Secondary MPGN

Secondary MPGN (invariably type I) is more common in adults and arises in the following settings:

- Chronic immune complex disorders, such as SLE; hepatitis B infection; hepatitis C infection, usually with cryoglobulinemia; endocarditis; infected ventriculoatrial shunts; chronic visceral abscesses; HIV infection; and schistosomiasis
- α_1 -Antitrypsin deficiency
- Malignant diseases, particularly lymphoid tumors such as chronic lymphocytic leukemia, which are commonly complicated by development of autoantibodies

Dense Deposit Disease

Most patients with dense-deposit disease (formerly called type II MPGN) have abnormalities resulting in excessive activation of the alternative complement pathway. These patients have a consistently decreased serum C3 but normal C1 and C4, the early components of complement. They also have diminished serum levels of Factor B and properdin, components of the alternative complement pathway. In the glomeruli, C3 and properdin are deposited, but IgG is not. Recall that in the alternative complement pathway, C3 is directly cleaved to C3b (Fig. 20-18; see also Chapter 3, Fig. 3-12). The reaction depends on the initial activation of C3 by such substances as bacterial polysaccharides, endotoxin, and aggregates of IgA via a pathway involving Factors B and D. This leads to the generation of C3bBb, the alternative pathway C3 convertase. Normally, this C3 convertase is labile, but more than 70% of patients with dense-deposit disease have a circulating autoantibody termed *C3 nephritic factor* (C3NeF) that binds the alternative pathway C3 convertase and protects it from inactivation (Fig. 20-18). This favors persistent C3 activation and hypocomplementemia. There is also decreased C3 synthesis by the liver, further contributing to the profound hypocomplementemia. The precise nature of the dense deposits is unknown. Mutations in components of the alternate pathway such as Factor H have also been associated with dense deposit disease.

MORPHOLOGY

While some cases of dense deposit disease share histologic features with MPGN, there is a wider spectrum of histologic alterations in dense deposit disease. Many cases have a predominantly mesangial proliferative pattern of injury, while others have an inflammatory and focally crescentic appearance. In some cases, dense deposits of a cellular material can be seen permeating the glomerular basement membranes in histologic sections. The defining feature is revealed by electron microscopy, which demonstrates permeation of the lamina densa of the GBM by a ribbon-like, homogeneous, extremely electron-dense material of unknown composition (Fig. 20-17B). By immunofluorescence C3 is present in irregular granular or linear foci in the basement membranes on either side but not within the dense deposits. C3 is also present in the mesangium in characteristic circular aggregates (mesangial rings). IgG is usually absent, as are components of the classical pathway of complement activation (such as C1q and C4). C3 glomerulopathies other than dense deposit disease can have a similar distribution, with mesangial and capillary wall involvement, but lack the extremely electron dense deposits that define dense deposit disease.

Clinical Features. Dense deposit disease primarily affects children and young adults. The clinical presentation of nephritic syndrome with hematuria and/or nephrotic syndrome with proteinuria overlaps with that of MPGN. The prognosis is poor, with about half of these patients progressing to end-stage renal disease. There is a high incidence of recurrence in transplant recipients; dense deposits may recur in 90% of such patients, although renal failure in the allograft is much less common.

KEY CONCEPTS

The Nephrotic Syndrome

- **Membranous nephropathy** is caused by an autoimmune response, most often directed against the phospholipase A2 receptor on podocytes; it is characterized by granular subepithelial deposits of antibodies with GBM thickening and loss of foot processes but little or no inflammation; the disease is often resistant to steroid therapy.
- The nephrotic syndrome is characterized by proteinuria, which results in hypoalbuminemia and edema.
- Podocyte injury is an underlying mechanism of proteinuria, and may be the result of nonimmune causes (as in minimal-change disease and FSGS) or immune mechanisms (as in membranous nephropathy).
- **Minimal change disease** is the most frequent cause of nephrotic syndrome in children; it is manifested by proteinuria and effacement of glomerular foot processes without antibody deposits; the pathogenesis is unknown; the disease responds well to steroid therapy.
- **Focal and segmental glomerulosclerosis** (FSGS) may be primary (podocyte injury by unknown mechanisms) or secondary (e.g., as a consequence of prior glomerulonephritis, hypertension or infection such as HIV); glomeruli show focal and segmental obliteration of capillary lumens, and loss of foot processes; the disease is often resistant to therapy and may progress to end-stage renal disease.

- **Membranoproliferative glomerulonephritis (MPGN)** in most cases is the result of immune complex deposition in both mesangial regions and capillary walls. It may be associated with systemic infections.
- **Dense deposit disease (type II MPGN)**, defined by a unique permeation of glomerular basement membranes by electron dense material, primarily affects children and young adults. It is associated with acquired or genetic dysregulation of the alternate pathway of complement.

Isolated Glomerular Abnormalities

IgA Nephropathy (Berger Disease)

IgA nephropathy, characterized by the presence of prominent IgA deposits in the mesangial regions and recurrent hematuria, is the most common type of glomerulonephritis worldwide. The disease can be suspected by light microscopic examination, but the diagnosis is made only by the detection of glomerular IgA deposition (Fig. 20-19). Mild proteinuria is usually present, and the nephrotic syndrome may occasionally develop. Rarely, patients may present with crescentic RPGN.

Whereas IgA nephropathy is typically an isolated renal disease, similar IgA deposits are present in a systemic disorder of children, *Henoch-Schönlein purpura*, to be discussed later, which has many overlapping features with

IgA nephropathy. In addition, *secondary IgA nephropathy* occurs in patients with liver and intestinal diseases, as discussed later.

Pathogenesis. Current evidence favors a “multi-hit” etiology for this disorder involving several steps. IgA, the main Ig in mucosal secretions, is present in plasma at low concentrations, mostly in monomeric form, the polymeric forms being catabolized in the liver. In patients with IgA nephropathy, levels of plasma polymeric IgA are increased, but increased production is not sufficient to cause this disease. A clue comes from the observation that in IgA nephropathy, the glomerular deposits consist predominantly of polymeric IgA molecules with aberrant glycosylation. It is believed that a key facet of IgA nephropathy is a hereditary or acquired defect in the normal formation or attachment of galactose-containing sugar chains called O-linked glycans to the hinge region of the IgA molecule (particularly to those of the IgA1 subclass) prior to their secretion by B cells. This aberrantly glycosylated IgA1 is either deposited by itself in glomeruli or it elicits an autoimmune response and forms immune complexes in the circulation with IgG autoantibodies directed against the abnormal IgA molecules. The immune complexes are deposited in the mesangium; alternatively, the abnormal IgA1 is deposited in the mesangium with subsequent formation of immune complexes in situ. The mesangial immune deposits then activate mesangial cells to proliferate, produce increased amounts of extracellular matrix, and secrete numerous cytokines and growth factors. These secreted mediators may not only participate in further mesangial cell activation but may also recruit inflammatory cells into the glomeruli. The recruited leukocytes contribute to glomerular injury and also to a reparative response, which can include opsonization and removal of the immune complexes. The deposited IgA and IgA-containing immune complexes activate the complement system via the alternate pathway, and hence the presence of C3 and the absence of C1q and C4 in glomeruli are typical of this disorder. A genetic influence is suggested by the occurrence of this condition in families and in HLA-identical siblings, the increased frequency of certain HLA and complement genotypes in some populations, and the findings of genome wide association studies linking specific MHC Class II loci to disease susceptibility.

Epidemiologic features of this disorder indicate that the increased synthesis of abnormal IgA may occur in response to respiratory or gastrointestinal exposure to environmental agents (e.g., viruses, bacteria, food proteins). The specific initiating antigens are unknown, and several infectious agents and food products have been implicated. IgA nephropathy occurs with increased frequency in individuals with *gluten enteropathy* (celiac disease), in whom intestinal mucosal defects are well defined, and in *liver disease*, in which there is defective hepatobiliary clearance of IgA complexes (*secondary IgA nephropathy*).

Figure 20-19 IgA nephropathy. **A**, Light microscopy showing mesangial proliferation and matrix increase. **B**, Characteristic deposition of IgA, principally in mesangial regions, detected by immunofluorescence.

MORPHOLOGY

On histologic examination the lesions vary considerably. The glomeruli may be normal or may show mesangial widening and endocapillary proliferation (mesangioproliferative glomerulonephritis), segmental proliferation confined to some glomeruli

(focal proliferative glomerulonephritis), or rarely, overt crescentic glomerulonephritis. The presence of leukocytes within glomerular capillaries is a variable feature. The mesangial widening may be the result of cell proliferation, accumulation of matrix, immune deposits, or some combination of these abnormalities. Healing of the focal proliferative lesion may lead to secondary focal segmental sclerosis. The characteristic immunofluorescent picture is of **mesangial deposition of IgA** (Fig. 20-19B), often with C3 and properdin and lesser amounts of IgG or IgM. Early complement components are usually absent. Electron microscopy confirms the presence of electron-dense deposits predominantly in the mesangium; capillary wall deposits, if present, are usually sparse.

Clinical Features. The disease affects people of any age, most commonly older children and young adults. Many patients present with gross hematuria after an infection of the respiratory or, less commonly, gastrointestinal or urinary tract; 30% to 40% have only microscopic hematuria, with or without proteinuria; and 5% to 10% develop acute nephritic syndrome, including some with rapidly progressive glomerulonephritis. The hematuria typically lasts for several days and then subsides, only to return every few months. The subsequent course is highly variable. Many patients maintain normal renal function for decades. Slow progression to chronic renal failure occurs in 15% to 40% of cases over a period of 20 years. Onset in old age, heavy proteinuria, hypertension, and the extent of glomerulosclerosis on biopsy are clues to an increased risk of progression. Recurrence of IgA deposits in transplanted kidneys is frequent, and in approximately 15% of those with recurrent IgA deposits, the disease runs the same slowly progressive course as that of primary IgA nephropathy.

Hereditary Nephritis

Hereditary nephritis refers to a group of heterogeneous familial renal diseases associated with mutations in collagen genes that manifest primarily with glomerular injury. Two deserve discussion: *Alport syndrome*, because the lesions and genetic defects have been well studied, and *thin basement membrane lesion*, the most common cause of *benign familial hematuria*.

Alport Syndrome

Alport syndrome, when fully developed, is manifest by hematuria with progression to chronic renal failure, accompanied by nerve deafness and various eye disorders, including lens dislocation, posterior cataracts, and corneal dystrophy. The disease is inherited as an X-linked trait in approximately 85% of cases. In the X-linked form, males express the full syndrome, while female heterozygotes typically present with hematuria. Approximately 90% of affected males progress to ESRD before 40 years of age. Autosomal recessive and autosomal dominant pedigrees also exist, in which males and females are equally susceptible to the full syndrome.

Pathogenesis. The disease manifestations are due to mutations in one of several genes coding for subunits of the collagen IV molecule. More than 500 mutations resulting in disease have been identified, resulting in defective

assembly of type IV collagen, which is crucial for function of the GBM, the lens of the eye, and the cochlea. Because the GBM consists of networks of trimeric collagen IV molecules composed of α_3 , α_4 , and α_5 chains, mutations affecting any one chain result in defective assembly of the collagen network. Since type IV collagen chains are encoded on autosomes (chromosomes 2 and 13) and the X-chromosome, the inheritance pattern can be autosomal or X-linked. Mutations of missense, splice site, insertions, and deletion types have all been identified. Genetic analysis has shown that in patients with X-linked disease, large deletions in the collagen IV α_5 chain (COL4A5) are associated with end stage renal disease at an earlier age.

MORPHOLOGY

Fully developed Alport syndrome has characteristic electron microscopic findings. The GBM shows irregular foci of thickening alternating with attenuation (thinning), and pronounced splitting and lamination of the lamina densa, often producing a distinctive basket-weave appearance (Fig. 20-20). Similar alterations can be found in the tubular basement membranes.

Immunohistochemistry can be helpful in cases with absent or borderline basement membrane lesions, because antibodies to α_3 , α_4 , and α_5 collagen fail to stain both glomerular and tubular basement membranes in the classic X-linked form. There is also absence of α_5 staining in skin biopsy specimens from these patients. As the disease progresses there is development of focal segmental and global glomerulosclerosis and other changes of progressive renal injury, including vascular sclerosis, tubular atrophy, and interstitial fibrosis.

Clinical Features. The most common presenting sign is gross or microscopic hematuria, frequently accompanied by red cell casts. Proteinuria may develop later, and rarely, the nephrotic syndrome develops. Symptoms appear at ages 5 to 20 years, and the onset of overt renal failure is between ages 20 and 50 years in men. The auditory defects may be subtle, requiring sensitive testing.

Figure 20-20 Hereditary nephritis (Alport syndrome). Electron micrograph of glomerulus with irregular thickening of the basement membrane, lamination of the lamina densa, and foci of rarefaction. Such changes may be present in other diseases but are most pronounced and widespread in hereditary nephritis. CL, Capillary lumen; Ep, epithelium.

Thin Basement Membrane Lesion (Benign Familial Hematuria)

This is a fairly common hereditary entity manifested *clinically by familial asymptomatic hematuria*—usually uncovered on routine urinalysis—and *morphologically by diffuse thinning of the GBM* to widths between 150 and 225 nm (compared with 300 to 400 nm in healthy adults). Although mild or moderate proteinuria may also be present, renal function is normal and prognosis is excellent. The abnormality is estimated to affect 1% of the general population.

The disorder should be distinguished from IgA nephropathy, another common cause of hematuria, and X-linked Alport syndrome. In contrast to Alport syndrome, hearing loss, ocular abnormalities, and a family history of renal failure are absent.

The anomaly in thin basement membrane lesion has also been traced to mutations in genes encoding α_3 or α_4 chains of type IV collagen. The disease most often has an autosomal inheritance and most patients are heterozygous for the defective gene. The disorder in homozygotes resembles autosomal recessive Alport syndrome. Homozygotes or compound heterozygotes may progress to renal failure. Thus, these diseases illustrate a continuum of changes resulting from mutations in collagen type IV genes.

KEY CONCEPTS

Isolated Glomerular Abnormalities

- **IgA nephropathy**, characterized by mesangial deposits of IgA-containing immune complexes, is the most common cause of glomerulonephritis worldwide. It is a common cause of both a nephritic syndrome and of isolated and frequently recurrent hematuria; it commonly affects children and young adults and has a variable course.
- **Alport syndrome**, a form of **hereditary nephritis**, is caused by mutations in genes encoding GBM type IV collagen. It manifests as hematuria and slowly progressing proteinuria and declining renal function; glomeruli appear normal by light microscopy until late in the disease course.
- **Thin basement membrane lesion** has a benign clinical course and is also the result of mutations in genes coding for GBM type IV collagen and hence may be considered as part of a spectrum of diseases that includes hereditary nephritis.

Chronic Glomerulonephritis

Chronic glomerulonephritis refers to end-stage glomerular disease that may result from specific types of glomerulonephritis or may develop without antecedent history of any of the well-recognized forms of acute glomerulonephritis. Poststreptococcal glomerulonephritis is a rare antecedent of chronic glomerulonephritis, except in adults. Patients with crescentic glomerulonephritis, if they survive the acute episode, usually progress to chronic glomerulonephritis. Membranous nephropathy, MPGN, IgA nephropathy, and FSGS all may progress to chronic renal failure. Nevertheless, **in any series of individuals with chronic glomerulonephritis, a variable percentage of cases arise mysteriously with no antecedent history of acute glomerulonephritis.** These cases may represent the

Figure 20-21 Chronic glomerulonephritis. A Masson trichrome preparation shows complete replacement of virtually all glomeruli by blue-staining collagen. (Courtesy Dr. M.A. Venkatachalam, Department of Pathology, University of Texas Health Sciences Center, San Antonio, Tex.)

end result of relatively asymptomatic forms of glomerulonephritis, either known or still unrecognized, that progress to uremia. Predictably, the proportion of such unexplained cases depends on the availability of renal biopsy material from patients early in their disease.

MORPHOLOGY

The kidneys are symmetrically contracted and have diffusely granular cortical surfaces. On section, **the cortex is thinned**, and there is an increase in peripelvic fat. The glomerular histology depends on the stage of the disease. In early cases, the glomeruli may still show evidence of the primary disease (e.g., membranous nephropathy or MPGN). However, there eventually ensues **obliteration of glomeruli**, transforming them into acellular eosinophilic masses, representing a combination of trapped plasma proteins, increased mesangial matrix, basement membrane-like material, and collagen (Fig. 20-21). Because hypertension is an accompaniment of chronic glomerulonephritis, **arterial and arteriolar sclerosis may be conspicuous.** Marked atrophy of associated tubules, irregular interstitial fibrosis, and mononuclear leukocytic infiltration of the interstitium also occur.

Clinical Course. In most individuals, chronic glomerulonephritis develops insidiously and slowly progresses to renal insufficiency or death from uremia during a span of years or possibly decades (see the discussion of chronic renal failure). Not infrequently, patients present with such nonspecific complaints as loss of appetite, anemia, vomiting, or weakness. In some, the renal disease is suspected with the discovery of proteinuria, hypertension, or azotemia on routine medical examination. In others, the underlying renal disorder is discovered in the course of investigation of edema. Most patients are hypertensive, and sometimes the dominant clinical manifestations relate to cerebral or cardiovascular disease. In all, the disease is relentlessly progressive, though at widely varying rates. In nephrotic patients, as glomeruli become obliterated and therefore the GFR decreases, the protein loss in the urine diminishes. If patients with chronic glomerulonephritis do not receive dialysis or if they do not receive a renal transplant, they invariably succumb to their disease.

Glomerular Lesions Associated with Systemic Diseases

Many immunologically mediated, metabolic, or hereditary systemic disorders are associated with glomerular injury; in some (e.g., SLE and diabetes mellitus), the glomerular involvement is a major clinical manifestation. Most of these diseases are discussed elsewhere in this book. Here we briefly recall some of the lesions and discuss only those not considered in other sections.

Lupus Nephritis

The various types of lupus nephritis were described in [Chapter 6](#). As discussed, SLE gives rise to a wide variety of renal lesions and clinical presentations. The clinical manifestations can include recurrent microscopic or gross hematuria, the nephritic syndrome, rapidly progressive glomerulonephritis, the nephrotic syndrome, acute and chronic renal failure, and hypertension.

Henoch-Schönlein Purpura

This childhood syndrome consists of purpuric skin lesions, abdominal pain and intestinal bleeding, and arthralgias along with renal abnormalities. Skin lesions characteristically involve the extensor surfaces of arms and legs as well as buttocks; abdominal manifestations include pain, vomiting, and intestinal bleeding. The renal manifestations occur in one third of patients and include gross or microscopic hematuria, nephritic syndrome, nephrotic syndrome, or some combination of these. A small number of patients, mostly adults, develop a rapidly progressive form of glomerulonephritis with many crescents. Not all components of the syndrome need to be present for the diagnosis, and individual patients may have purpura, abdominal pain, or urinary abnormalities as the dominant feature. The disease is most common in children 3 to 8 years old, but it also occurs in adults, in whom the renal manifestations are usually more severe. There is a strong background of atopy in about one third of patients, and onset often follows an upper respiratory infection. IgA is deposited in the glomerular mesangium in a distribution similar to that of IgA nephropathy. This has led to the concept that *IgA nephropathy and Henoch-Schönlein purpura are manifestations of the same disease*. The finding of Ig and C3 deposits in glomeruli suggests that immune complexes are involved in the disease.

MORPHOLOGY

On histologic examination, the renal lesions vary from mild focal mesangial proliferation to diffuse mesangial proliferation and/or endocapillary proliferation to crescentic glomerulonephritis. Whatever the histologic lesions, the pathognomonic feature by fluorescence microscopy is the **deposition of IgA, sometimes with IgG and C3, in the mesangial region**, sometimes with deposits extending to the capillary loops. The skin lesions consist of subepidermal hemorrhages and a necrotizing vasculitis involving the small vessels of the dermis. Deposits of IgA, along with IgG and C3, are also present in such vessels. Vasculitis also occurs in other organs, such as the gastrointestinal tract, but is rare in the kidney.

The course of the disease is variable, but recurrences of hematuria may persist for many years after onset. Most children have an excellent prognosis. Patients with the more diffuse lesions, crescents, or the nephrotic syndrome have a somewhat poorer prognosis.

Glomerulonephritis Associated with Bacterial Endocarditis and Other Systemic Infections

Glomerular lesions occurring in the course of bacterial endocarditis or other systemic infections, such as infected atrioventricular shunts, represent a type of immune complex nephritis initiated by complexes of bacterial antigen and antibody. Hematuria and proteinuria of various degrees characterize this entity clinically, but an acute nephritic presentation is not uncommon, and even RPGN may occur in rare instances. The histologic lesions, when present, generally reflect these clinical manifestations. The histologic features may vary from a focal and segmental necrotizing glomerulonephritis to a diffuse and more global exudative and proliferative glomerulonephritis, which may have a MPGN pattern. More severe forms show a diffuse proliferative glomerulonephritis. The lesions may be acute (influx of neutrophils) or chronic (fully developed MPGN pattern with basement membrane changes); the rapidly progressive forms show large numbers of crescents. Immunofluorescence and electron microscopy show the presence of glomerular immune deposits.

Diabetic Nephropathy

Diabetes mellitus is a major cause of renal morbidity and mortality, and diabetic nephropathy is the leading cause of chronic kidney failure in the United States. Advanced or end-stage kidney disease occurs in as many as 40% of both insulin-dependent 1 diabetics and type 2 diabetics. The pathology and pathogenesis of this disorder is discussed in [Chapter 24](#).

Fibrillary Glomerulonephritis

Fibrillary glomerulonephritis is a morphologic variant of glomerulonephritis associated with characteristic fibrillar deposits in the mesangium and glomerular capillary walls that resemble amyloid fibrils superficially but differ ultrastructurally and do not stain with Congo red. The glomerular lesions usually show membranoproliferative or mesangioproliferative patterns by light microscopy. By immunofluorescence microscopy, there is selective deposition of polyclonal IgG, often of the IgG4 subclass, complement C3, and Igκ and Igλ light chains. Clinically, patients develop nephrotic syndrome, hematuria, and progressive renal insufficiency. The disease recurs in kidney transplants. The pathogenesis of this entity is unknown.

Other Systemic Disorders

Goodpasture syndrome ([Chapter 15](#)), *microscopic polyangiitis*, and *granulomatosis with polyangiitis* (formally called *Wegener granulomatosis*) ([Chapter 11](#)) are commonly associated with glomerular lesions, as described in the discussion of these diseases. Suffice it to say here that the glomerular lesions in these three conditions can be histologically similar and are principally characterized by foci of glomerular necrosis and crescent formation. In the early or mild forms of renal

involvement, there is focal and segmental, sometimes necrotizing, glomerulonephritis, and most of these patients will have hematuria with mild decline in GFR. In the more severe cases, which may be associated with RPGN, there is more extensive necrosis, fibrin deposition, and extensive formation of epithelial (cellular) crescents, which can become organized to form fibrocellular and fibrous crescents if the glomerular injury evolves into segmental or global scarring (sclerosis).

Essential mixed cryoglobulinemia is another systemic condition in which deposits of cryoglobulins composed principally of IgG-IgM complexes induce cutaneous vasculitis, synovitis, and a proliferative glomerulonephritis, typically MPGN. Most cases of essential mixed cryoglobulinemia have been associated with infection with hepatitis C virus, and this condition in particular is associated with glomerulonephritis, usually MPGN type I.

Immunoglobulins secreted by plasma cell neoplasms may also induce glomerular lesions, including amyloidosis.

Tubular and Interstitial Diseases

Most forms of tubular injury involve the interstitium as well; therefore, diseases affecting these two components are discussed together. Under this heading we consider two major processes: (1) ischemic or toxic tubular injury, and (2) inflammatory reactions of the tubules and interstitium (*tubulointerstitial nephritis*).

Acute Tubular Injury/Necrosis

Acute tubular injury (ATI) is a clinicopathologic entity characterized clinically by acute renal failure and often, but not invariably, morphologic evidence of tubular injury, in the form of necrosis of tubular epithelial cells. Since necrosis is not invariable, the term ATI is now preferred over the older term acute tubular necrosis (ATN). It is the most common cause of acute kidney injury (acute renal failure). ATI can be caused by a variety of conditions, including

- *Ischemia, due to decreased or interrupted blood flow*, examples of which include diffuse involvement of the intrarenal blood vessels such as in microscopic polyangiitis, malignant hypertension, microangiopathies and systemic conditions associated with thrombosis (e.g., hemolytic uremic syndrome [HUS], thrombotic thrombocytopenic purpura [TTP], and disseminated intravascular coagulation [DIC]), or decreased effective circulating blood volume, as occurs in hypovolemic shock (Chapter 4)
- *Direct toxic injury to the tubules by endogenous* (e.g., myoglobin, hemoglobin, monoclonal light chains, bile/bilirubin) *or exogenous agents* (e.g., drugs, radiocontrast dyes, heavy metals, organic solvents)

ATI accounts for some 50% of cases of acute kidney injury in hospitalized patients. Other causes of acute renal failure are discussed elsewhere in this chapter.

ATI is a reversible process that arises in a variety of clinical settings. Most of these, ranging from severe trauma to acute pancreatitis, have in common a period of inadequate blood flow to the peripheral organs, usually accompanied by marked hypotension and shock. This pattern is called *ischemic ATI*. The second pattern, called *nephrotoxic ATI*, is caused by a multitude of drugs, such as gentamicin; radiographic contrast agents; poisons, including heavy metals (e.g., mercury); and organic solvents (e.g., carbon tetrachloride). Combinations of ischemic and nephrotoxic ATI also can occur, exemplified by mismatched blood transfusions and other hemolytic crises causing *hemoglobinuria* and skeletal muscle injuries causing *myoglobinuria*. Such injuries result in characteristic intratubular hemoglobin or myoglobin casts, respectively; the toxic iron content of these globin molecules contributes to the ATI. In addition to its frequency, the potential reversibility of ATI adds to its clinical importance. Proper management can make the difference between recovery and death.

Pathogenesis. The critical events in both ischemic and nephrotoxic ATI are believed to be (1) tubular injury and (2) persistent and severe disturbances in blood flow (Fig. 20-22).

Figure 20-22 Postulated sequence in ischemic or toxic acute tubular injury.

- **Tubule cell injury:** Tubular epithelial cells are particularly sensitive to ischemia and are also vulnerable to toxins. Several factors predispose the tubules to toxic injury, including an increased surface area for tubular reabsorption, active transport systems for ions and organic acids, a high rate of metabolism and oxygen consumption that is required to perform these transport and reabsorption functions, and the capability for resorption and concentration of toxins.

Ischemia causes numerous structural and functional alterations in epithelial cells, as discussed in [Chapter 2](#). One early reversible result of ischemia is *loss of cell polarity* due to redistribution of membrane proteins (e.g., the enzyme Na,K⁺-ATPase) from the basolateral to the luminal surface of the tubular cells, resulting in abnormal ion transport across the cells and *increased sodium delivery to distal tubules*. The latter incites vasoconstriction via *tubuloglomerular feedback*. In addition, ischemic tubular cells express cytokines and adhesion molecules, thus recruiting leukocytes that appear to participate in the subsequent injury. In time, injured cells detach from the basement membranes and cause *luminal obstruction*, increased intratubular pressure, and decreased GFR. In addition, glomerular filtrate in the lumen of the damaged tubules can leak back into the interstitium, resulting in interstitial edema, increased interstitial pressure, and further damage to the tubule. All these effects, as shown in [Figure 20-22](#), contribute to the decreased GFR.

- **Disturbances in blood flow:** Ischemic renal injury is also characterized by *hemodynamic alterations* that cause reduced GFR. The major one is *intrarenal vasoconstriction*, which results in both reduced glomerular blood flow and reduced oxygen delivery to the functionally important tubules in the outer medulla (thick ascending limb and straight segment of the proximal tubule). Several vasoconstrictor pathways have been implicated, including the renin-angiotensin system, stimulated by increased distal sodium delivery (via *tubuloglomerular feedback*), and *sublethal endothelial injury*, leading to increased release of the vasoconstrictor *endothelin* and decreased production of the vasodilators *nitric oxide* and *prostacyclin* (*prostaglandin I₂*). There is also some evidence of a direct effect of ischemia or toxins on the glomerulus, causing a reduced glomerular ultrafiltration coefficient, possibly due to mesangial contraction.

The patchiness of tubular necrosis and maintenance of the integrity of the basement membrane along many segments allow repair of the injured foci and recovery of function if the precipitating cause is removed. This repair is dependent on the capacity of reversibly injured epithelial cells to proliferate and differentiate. Re-epithelialization is mediated by a variety of growth factors and cytokines produced locally by the tubular cells themselves or by inflammatory cells in the vicinity of necrotic foci.

MORPHOLOGY

ATI is characterized by **focal tubular epithelial necrosis** at multiple points along the nephron, with large skip areas in between, often accompanied by rupture of basement

Figure 20-23 Patterns of tubular damage in ischemic and toxic acute tubular injury. In the ischemic type, tubular necrosis is patchy, relatively short lengths of tubules are affected, and straight segments of proximal tubules (PST) and ascending limbs of Henle's loop (HL) are most vulnerable. In toxic acute tubular injury, extensive necrosis is present along the proximal convoluted tubule segments (PCT) with many toxins (e.g., mercury), but necrosis of the distal tubule, particularly ascending HL, also occurs. In both types, lumens of the distal convoluted tubules (DCT) and collecting ducts (CD) contain casts.

membranes (tubulorrhexis) and **occlusion of tubular lumens by casts** (Figs. 20-23 and 20-24). The distinct patterns of tubular injury in ischemic and toxic ATI are shown in [Figure 20-23](#). The straight portion of the proximal tubule and the ascending thick limb in the renal medulla are especially vulnerable, but focal lesions may also occur in the distal tubule, often in conjunction with casts. It should be noted that the severity

Figure 20-24 Acute tubular injury. Some of the tubular epithelial cells in the tubules are necrotic, and many have become detached (from their basement membranes) and been sloughed into the tubular lumens, whereas others are swollen, vacuolated, and regenerating. (Courtesy Dr. Agnes Fogo, Vanderbilt University, Nashville, Tenn.)

of the morphologic findings often do not correlate well with the severity of the clinical manifestations.

Eosinophilic hyaline casts, as well as pigmented granular casts, are common, particularly in distal tubules and collecting ducts. These casts consist principally of Tamm-Horsfall protein (a urinary glycoprotein normally secreted by the cells of ascending thick limb and distal tubules) in conjunction with other plasma proteins. Other findings in ischemic ATI are interstitial edema and accumulations of leukocytes within dilated vasa recta. There is also evidence of epithelial regeneration in the form of flattened epithelial cells with hyperchromatic nuclei and mitotic figures. In the course of time this regeneration repopulates the tubules so that no residual evidence of damage is seen.

Toxic ATI is manifested by acute tubular injury, most obvious in the proximal convoluted tubules. On histologic examination the tubular necrosis may be nonspecific, but it is somewhat distinctive in poisoning with certain agents. With mercuric chloride, for example, severely injured cells may contain large acidophilic inclusions. Later, these cells become necrotic, are desquamated into the lumen, and may undergo calcification. Carbon tetrachloride poisoning, in contrast, is characterized by the accumulation of neutral lipids in injured cells; again, such fatty change is followed by necrosis. Ethylene glycol produces marked ballooning and hydropic or vacuolar degeneration of proximal convoluted tubules. Calcium oxalate crystals are often also found in the tubular lumens in ethylene glycol poisoning.

Clinical Course. The clinical course of ATI is highly variable, but the classic case may be divided into *three* stages.

- **Initiation phase**, lasting about 36 hours, is dominated by the inciting medical, surgical, or obstetric event. The only indication of renal involvement is a slight decline in urine output with a rise in BUN. At this point, oliguria could be explained by a transient decrease in blood flow and declining GFR.
- **Maintenance phase** is characterized by sustained decreases in urine output to between 40 and 400 mL/day (oliguria), salt and water overload, rising BUN concentrations, hyperkalemia, metabolic acidosis, and other manifestations of uremia. With appropriate management, the patient can overcome this oliguric crisis.
- **Recovery phase** is ushered in by a steady increase in urine volume that may reach up to 3 L/day. The tubules are still damaged, so large amounts of water, sodium, and potassium are lost in the flood of urine. *Hypokalemia, rather than hyperkalemia, becomes a clinical problem.* There is a peculiar increased vulnerability to infection at this stage. Eventually, renal tubular function is restored and concentrating ability improves. At the same time, BUN and creatinine levels begin to return to normal. Subtle tubular functional impairment may persist for months, but most patients who reach this phase eventually recover completely.

The prognosis of ATI depends on the magnitude and duration of injury. Recovery is expected with nephrotoxic ATI when the toxin has not caused serious damage to other organs, such as the liver or heart. With current supportive care, 95% of those who do not succumb to the precipitating cause recover. Conversely, in shock related

to sepsis, extensive burns, or other causes of multi-organ failure, the mortality rate can be more than 50%.

KEY CONCEPTS

Acute Tubular Injury

- Acute tubular injury is the most common cause of acute kidney injury and attributed to ischemia and/or toxicity from an endogenous or exogenous substance.
- Tubular epithelial cell injury and altered intrarenal hemodynamics are the primary contributors to acute tubular injury.
- The clinical outcome is determined by the magnitude and duration of acute tubular injury.

Tubulointerstitial Nephritis

This group of renal diseases involves inflammatory injuries of the tubules and interstitium that are often insidious in onset and are principally manifest by azotemia. We have previously seen that chronic tubulointerstitial damage is an important consequence of progression in diseases that primarily affect the glomerulus (Fig. 20-21). *Secondary tubulointerstitial nephritis* is also present in a variety of vascular, cystic (polycystic kidney disease), and metabolic (diabetes) renal disorders, in which it may also contribute to progressive damage. Here we discuss primary causes of tubulointerstitial injury (Table 20-8). Glomerular

and vascular abnormalities may also be present in advanced stages of these diseases.

Tubulointerstitial nephritis can be acute or chronic. *Acute tubulointerstitial nephritis* has a rapid clinical onset and is characterized histologically by interstitial edema, often accompanied by leukocytic infiltration of the interstitium and tubules, and tubular injury. In *chronic interstitial nephritis* there is infiltration with predominantly mononuclear leukocytes, prominent interstitial fibrosis, and widespread tubular atrophy. Morphologic features that are helpful in separating acute from chronic tubulointerstitial nephritis include edema and, when present, eosinophils and neutrophils in the acute form, while fibrosis and tubular atrophy characterize the chronic form.

These conditions are distinguished clinically from the glomerular diseases by the following hallmarks:

- Absence of nephritic or nephrotic syndrome
- The presence of defects in tubular function. The latter may be subtle and include impaired ability to concentrate urine, evidenced clinically by polyuria or nocturia; salt wasting; diminished ability to excrete acids (metabolic acidosis); and isolated defects in tubular reabsorption or secretion. Advanced forms, however, may be difficult to distinguish clinically from other causes of renal insufficiency.

Specific conditions are listed in [Table 20-8](#) and are discussed elsewhere in this book. This section deals principally with pyelonephritis and interstitial diseases induced by drugs.

Pyelonephritis and Urinary Tract Infection

Pyelonephritis is one of the most common diseases of the kidney and is defined as inflammation affecting the tubules, interstitium, and renal pelvis. It occurs in two forms. *Acute pyelonephritis* is generally caused by bacterial infection and is associated with urinary tract infection. *Chronic pyelonephritis* is a more complex disorder; bacterial infection plays a dominant role, but other factors (vesicoureteral reflux, obstruction) predispose to repeat episodes of acute pyelonephritis.

Pyelonephritis is a serious complication of *urinary tract infections* that affect the bladder (cystitis), the kidneys and their collecting systems (pyelonephritis), or both. Bacterial infections of the lower urinary tract may be asymptomatic (asymptomatic bacteriuria) and often remain localized to the bladder without the development of renal infection. However, lower urinary tract infection can potentially spread to the kidney.

Etiology and Pathogenesis. More than 85% of cases of urinary tract infection are caused by the gram-negative bacilli that are normal inhabitants of the intestinal tract. For most urinary tract infections, the infecting organisms are derived from the patient's own fecal flora. By far the most common is *Escherichia coli*, followed by *Proteus*, *Klebsiella*, and *Enterobacter*. *Streptococcus faecalis*, also of enteric origin, staphylococci, and virtually every other bacterial and fungal agent can also cause lower urinary tract and renal infection. Mycobacterial and fungal organisms induce caseating and non-caseating granulomatous inflammation, respectively. In immunocompromised persons,

Figure 20-25 Schematic representation of pathways of renal infection. Hematogenous infection results from bacteremic spread. More common is ascending infection, which results from a combination of urinary bladder infection, vesicoureteral reflux, and intrarenal reflux.

particularly those with transplanted organs, viruses such as *polyomavirus*, *cytomegalovirus*, and *adenovirus* can also be a cause of renal infection.

There are two routes by which bacteria can reach the kidneys: (1) through the bloodstream (hematogenous infection) and (2) from the lower urinary tract (ascending infection) ([Fig. 20-25](#)). The hematogenous route is less common and results from seeding of the kidneys by bacteria from distant foci in the course of septicemia or localized infections such as infective endocarditis. Hematogenous infection is more likely to occur in the presence of ureteral obstruction, and in debilitated patients. Typically, in patients receiving immunosuppressive therapy, nonenteric organisms, such as staphylococci and certain fungi and viruses, are involved.

Ascending infection is the most common cause of clinical pyelonephritis. Normal human bladder and bladder urine are sterile; therefore, a number of steps must occur for renal infection to occur:

- The first step in ascending infection is the *colonization of the distal urethra and introitus* (in the female) by coliform bacteria. This colonization is influenced by the degree of bacterial adherence to urethral mucosal epithelial, as discussed in [Chapter 8](#), which involves adhesive

molecules (adhesins) on the P-fimbriae (pili) of bacteria that interact with receptors on the surface of urothelial cells. Specific adhesins (e.g., those encoded by the pyelonephritis-associated pili [*pap*] gene) are associated with infection. In addition, certain types of fimbriae promote renal tropism, persistence of infection, or an enhanced inflammatory response.

- *From the urethra to the bladder*, organisms gain entrance during urethral catheterization or other instrumentation. Long-term catheterization, in particular, carries a risk of infection. In the absence of instrumentation, *urinary infections are much more common in females*, and this has been ascribed to the shorter urethra in females, as well as the absence of antibacterial properties found in prostatic fluid, hormonal changes affecting adherence of bacteria to the mucosa, and urethral trauma during sexual intercourse, or a combination of these factors.

The mechanisms by which microbes move *from the bladder to the kidneys* are described below.

- *Urinary tract obstruction and stasis of urine*. Ordinarily, organisms introduced into the bladder are cleared by continual voiding and by antibacterial mechanisms. However, outflow obstruction or bladder dysfunction results in incomplete emptying and residual urine. In the presence of stasis, bacteria introduced into the bladder can multiply unhindered. Accordingly, urinary tract infection is frequent among patients with lower urinary tract obstruction, such as may occur with benign prostatic hypertrophy, tumors, or calculi, or with neurogenic bladder dysfunction caused by diabetes or spinal cord injury.
- *Vesicoureteral reflux*. Although obstruction is an important predisposing factor in ascending infection, it is *incompetence of the vesicoureteral valve* that allows bacteria to ascend the ureter into the renal pelvis. The normal ureteral insertion into the bladder is a one-way valve that prevents retrograde flow of urine when the intravesical pressure rises, as in micturition. An incompetent vesicoureteral orifice allows the reflux of bladder urine into the ureters (*vesicoureteral reflux*) (Fig. 20-26). Reflux is most often due to a congenital absence or shortening of the intravesical portion of the ureter, such that the ureter is not compressed during micturition. In addition, it may be acquired by bladder infection itself. It is postulated that bacteria themselves or the associated inflammation can promote reflux by affecting ureteral contractility, particularly in children. Vesicoureteral reflux is estimated to affect 1% to 2% of otherwise normal children. *Acquired vesicoureteral reflux* in adults can result from persistent bladder atony caused by spinal cord injury. The effect of vesicoureteral reflux is similar to that of an obstruction in that there is residual urine in the urinary tract after voiding, which favors bacterial growth.
- *Intrarenal reflux*. Vesicoureteral reflux also affords a ready mechanism by which the infected bladder urine can be propelled up to the renal pelvis and deep into the renal parenchyma through open ducts at the tips of the papillae (intrarenal reflux). Intrarenal reflux is most common in the upper and lower poles of the kidney, where papillae tend to have flattened or concave tips

Figure 20-26 Vesicoureteral reflux demonstrated by a voiding cystourethrogram. Dye injected into the bladder refluxes into both dilated ureters, filling the pelvis and calyces.

rather than the convex pointed type present in the midzones of the kidney (and depicted in most textbooks). Reflux can be demonstrated radiographically by a voiding cystourethrogram, in which the bladder is filled with a radiopaque dye and films are taken during micturition. Vesicoureteral reflux can be demonstrated by this method in about 30% of infants and children with urinary tract infection (Fig. 20-26).

In the absence of vesicoureteral reflux, infection usually remains localized in the bladder. Thus, the majority of individuals with repeated or persistent bacterial colonization of the urinary tract suffer from cystitis and urethritis (*lower urinary tract infection*) rather than pyelonephritis.

Acute Pyelonephritis

Acute pyelonephritis is a suppurative inflammation of the kidney caused by bacterial and sometimes viral (e.g., polyomavirus) infection, which can reach the kidney by hematogenous spread or, more commonly, through the ureters in association with vesicoureteral reflux.

MORPHOLOGY

The hallmarks of acute pyelonephritis are **patchy interstitial suppurative inflammation, intratubular aggregates of neutrophils, neutrophilic tubulitis and tubular necrosis**. The suppuration may occur as discrete focal abscesses or large wedge-like areas and can involve one or both kidneys (Fig. 20-27).

Figure 20-27 Acute pyelonephritis. Cortical surface shows grayish white areas of inflammation and abscess formation.

In the early stages, the neutrophilic infiltration is limited to the tubules. The tubular lumens are a conduit for the extension of the infection, and soon, the infection extends to the interstitium and produces abscesses that destroy the involved tubules (Fig. 20-28). Characteristically, glomeruli are relatively resistant to the infection. Extensive disease, however, eventually also destroys the glomeruli, and fungal pyelonephritis (e.g., *Candida*) often affects glomeruli and results in granulomatous interstitial inflammation.

Three complications of acute pyelonephritis can be encountered.

- **Papillary necrosis** is seen mainly in diabetics, sickle cell disease, and in those with urinary tract obstruction. Papillary necrosis is usually bilateral but may be unilateral. One or all of the pyramids of the affected kidney may be involved. On cut section, the tips or distal two thirds of the pyramids have areas of gray-white to yellow necrosis (Fig. 20-29). On microscopic examination the necrotic tissue shows characteristic

Figure 20-28 Acute pyelonephritis marked by an acute neutrophilic exudate within tubules and interstitial inflammation.

ischemic coagulative necrosis, with preservation of outlines of tubules. The leukocytic response is limited to the junctions between preserved and destroyed tissue.

- **Pyonephrosis** is seen when there is total or almost complete obstruction, particularly when it is high in the urinary tract. The suppurative exudate is unable to drain and thus fills the renal pelvis, calyces, and ureter with pus.
- **Perinephric abscess** is an extension of suppurative inflammation through the renal capsule into the perinephric tissue.

After the acute phase of pyelonephritis, healing occurs. The neutrophilic infiltrate is replaced by one that is predominantly composed of macrophages, plasma cells, and lymphocytes. The inflammatory foci are eventually replaced by irregular scars that can be seen on the cortical surface as fibrous depressions. Such scars are characterized microscopically by tubular atrophy, interstitial fibrosis, and a lymphocytic infiltrate in a characteristic patchy, jigsaw pattern with intervening preserved parenchyma. **The pyelonephritic scar is almost always associated with inflammation, fibrosis, and deformation of the underlying calyx and pelvis**, reflecting the role of ascending infection and vesicoureteral reflux in the pathogenesis of the disease.

Figure 20-29 Papillary necrosis. Areas of pale-gray necrosis involve the papillae (arrows).

Clinical Features. Acute pyelonephritis is often associated with the following:

- *Urinary tract obstruction*, either congenital or acquired
- *Instrumentation* of the urinary tract, most commonly catheterization
- *Vesicoureteral reflux*
- *Pregnancy.* Between 4% and 6% of pregnant women develop bacteriuria sometime during pregnancy, and 20% to 40% of these eventually develop symptomatic urinary infection if not treated.
- *Gender and age.* After the first year of life (when congenital anomalies in males commonly become evident) and up to around age 40 years, infections are much more frequent in females. With increasing age the incidence in males rises as a result of prostatic hypertrophy and instrumentation.
- *Preexisting renal lesions*, causing intrarenal scarring and obstruction
- *Diabetes mellitus*, in which increased susceptibility to infection, neurogenic bladder dysfunction, and more frequent instrumentation are predisposing factors
- *Immunosuppression and immunodeficiency*

Acute pyelonephritis usually presents with a sudden onset of pain at the costovertebral angle and systemic evidence of infection, such as fever and malaise. There are often indications of bladder and urethral irritation, such as dysuria, frequency, and urgency. The urine contains many leukocytes (pyuria) derived from the inflammatory infiltrate, but pyuria does not differentiate upper from lower urinary tract infection. The finding of leukocyte casts, typically rich in neutrophils (pus casts), indicates renal involvement, because casts are formed only in tubules. The diagnosis of infection is established by quantitative urine culture.

Uncomplicated acute pyelonephritis follows a benign course, and symptoms disappear within a few days after the institution of appropriate antibiotic therapy. Bacteria,

however, may persist in the urine, or there may be recurrence of infection with new serologic types of *E. coli* or other organisms. Such bacteriuria then either disappears or may persist, sometimes for years. In the presence of unrelieved urinary obstruction, diabetes mellitus, or immunodeficiency, acute pyelonephritis may be more serious, leading to repeated septicemic episodes. The superimposition of *papillary necrosis* may lead to acute renal failure.

An emerging viral pathogen causing pyelonephritis in kidney allografts is *polyomavirus*. Latent infection with polyomavirus is widespread in the general population, and immunosuppression of the allograft recipient can lead to reactivation of latent infection and the development of nephropathy resulting in allograft failure in up to 5% of kidney transplant recipients. This form of pyelonephritis, now referred to as polyomavirus nephropathy, is characterized by infection of tubular epithelial cell nuclei, leading to nuclear enlargement and intranuclear inclusions visible by light microscopy (viral cytopathic effect). The inclusions are composed of virions arrayed in distinctive crystalline-like lattices when visualized by electron microscopy (Fig. 20-30). An interstitial inflammatory response is invariably present. Treatment consists of a reduction in immunosuppression.

Chronic Pyelonephritis and Reflux Nephropathy

Chronic pyelonephritis is a disorder in which chronic tubulointerstitial inflammation and scarring involve the calyces and pelvis (Fig. 20-31). Although several diseases produce chronic tubulointerstitial alterations (Table 20-8), only chronic pyelonephritis and analgesic nephropathy affect the calyces, making pelvocalyceal damage an important diagnostic clue. Chronic pyelonephritis at one time accounted for 10% to 20% of patients in renal transplant or dialysis units, until predisposing conditions such as reflux became better recognized. This condition remains an important cause of kidney destruction in children with severe lower urinary tract abnormalities.

Figure 20-30 Polyomavirus nephropathy. **A**, The kidney shows enlarged tubular epithelial cells with nuclear inclusions (arrows) and interstitial inflammation (arrowheads). **B**, Intranuclear viral inclusions visualized by electron microscopy. (Courtesy Dr. Jean Olson, Department of Pathology, University of California San Francisco, San Francisco, Calif.)

Figure 20-31 Typical coarse scars of chronic pyelonephritis associated with vesicoureteral reflux. The scars are usually polar and are associated with underlying blunted calyces.

Chronic pyelonephritis can be divided into two forms:

- **Reflux nephropathy.** This is by far the more common form of chronic pyelonephritic scarring. Reflux nephropathy occurs early in childhood as a result of superimposition of a urinary infection on congenital vesicoureteral reflux and intrarenal reflux. Reflux may be unilateral or bilateral; thus, the continuous renal damage may cause scarring and atrophy of one kidney or involve both, leading to renal insufficiency. Vesicoureteral reflux occasionally causes renal damage in the absence of infection (sterile reflux), but only when obstruction is severe.
- **Chronic obstructive pyelonephritis.** We have seen that obstruction predisposes the kidney to infection. Recurrent infections superimposed on diffuse or localized obstructive lesions lead to repeated bouts of renal inflammation and scarring, resulting in chronic pyelonephritis. In this condition, the effects of obstruction contribute to the parenchymal atrophy; indeed, it is sometimes difficult to differentiate the effects of bacterial infection from those of obstruction alone. The disease can be bilateral, as with posterior urethral valves,

resulting in renal insufficiency unless the anomaly is corrected, or unilateral, as occurs with calculi and unilateral obstructive anomalies of the ureter.

MORPHOLOGY

The characteristic changes of chronic pyelonephritis are seen on gross examination (Figs. 20-31 and 20-32A). The kidneys usually are irregularly scarred; if bilateral, the involvement is asymmetric. In contrast, both kidneys in chronic glomerulonephritis are diffusely and symmetrically scarred. The hallmarks of chronic pyelonephritis are **coarse, discrete, corticomedullary scars overlying dilated, blunted, or deformed calyces, and flattening of the papillae** (Fig. 20-33B). The scars vary from one to several and most are in the upper and lower poles, consistent with the frequency of reflux in these sites.

The microscopic changes involve predominantly tubules and interstitium. The tubules show atrophy in some areas and hypertrophy or dilation in others. Dilated tubules with flattened epithelium may be filled with casts resembling thyroid colloid (thyroidization). There are varying degrees of chronic interstitial inflammation and fibrosis in the cortex and medulla. Arcuate and interlobular vessels demonstrate obliterative intimal sclerosis in the scarred areas; and in the presence of hypertension, hyaline arteriosclerosis is seen in the entire kidney. There is often fibrosis around the calyceal epithelium as well as a marked chronic inflammatory infiltrate. Glomeruli may appear normal except for a variety of ischemic changes, including periglomerular fibrosis, fibrous obliteration and secondary changes related to hypertension. Individuals with chronic pyelonephritis and reflux nephropathy who develop proteinuria in advanced stages show secondary focal segmental glomerulosclerosis, as described later.

Xanthogranulomatous pyelonephritis is a relatively rare form of chronic pyelonephritis characterized by accumulation of foamy macrophages intermingled with plasma cells, lymphocytes, polymorphonuclear leukocytes, and occasional giant cells. Often associated with *Proteus* infections and obstruction, the lesions sometimes produce large, yellowish orange nodules that may be grossly confused with renal cell carcinoma.

Clinical Features. Chronic obstructive pyelonephritis may have a silent onset or present with manifestations of

Figure 20-32 A, Chronic pyelonephritis. The surface (left) is irregularly scarred. The cut section (right) reveals blunting and loss of several papillae. **B,** Low-power view showing a corticomedullary renal scar with an underlying dilated deformed calyx. Note the thyroidization of tubules in the cortex.

acute recurrent pyelonephritis, such as back pain, fever, pyuria, and bacteriuria. These patients receive medical attention relatively late in their disease course because of the gradual onset of renal insufficiency and hypertension. Reflux nephropathy is often discovered in children when the cause of hypertension is investigated. Loss of tubular function—in particular of concentrating ability—gives rise to polyuria and nocturia. Radiographic studies show asymmetrically contracted kidneys with characteristic coarse scars and blunting and deformity of the calyceal system. Significant bacteriuria may be present, but it is often absent in the late stages.

Although proteinuria is usually mild, some individuals with pyelonephritic scars develop secondary *focal segmental glomerulosclerosis* with significant proteinuria, even in the nephrotic range, usually several years after the scarring has occurred and often in the absence of continued infection or persistent vesicoureteral reflux. The onset of proteinuria and focal segmental glomerulosclerosis is a poor prognostic sign, which may progress to ESRD. The glomerulosclerosis, as discussed, is attributable to the adaptive glomerular alterations secondary to loss of renal mass caused by pyelonephritic scarring (renal ablation nephropathy).

KEY CONCEPTS

Pyelonephritis

- Both acute and chronic pyelonephritis may be caused by infection via the ascending (more common) or hematogenous route. Obstructive lesions of the urinary tract are important predisposing factors.
- Bacteria are the most common infectious agent in acute pyelonephritis and induce a prominent neutrophilic inflammatory response; granulomatous interstitial inflammation is characteristic of fungal or mycobacterial infections.
- Chronic pyelonephritis ensues when anatomic anomalies result in urine reflux or urine outflow obstruction; multiple episodes of this injury leads to irregular scarring of the kidney that is typically more prominent at the upper or lower poles where reflux is more common.

Tubulointerstitial Nephritis Induced by Drugs and Toxins

Drug and toxin-induced tubulointerstitial nephritis is the second most common cause of acute kidney injury (after pyelonephritis). Toxins and drugs can injure kidneys in at least three ways: (1) trigger an interstitial immunologic reaction, exemplified by the acute hypersensitivity nephritis induced by drugs such as methicillin; (2) cause acute tubular injury, as described earlier; and (3) cause subclinical but cumulative injury to tubules that takes years to result in chronic renal insufficiency. The last type of damage is especially worrisome, because it may be unrecognized until irreversible renal damage has occurred.

Acute Drug-Induced Interstitial Nephritis

First reported after the use of sulfonamides, acute tubulointerstitial nephritis most frequently occurs with synthetic penicillins (methicillin, ampicillin), other synthetic antibiotics (rifampin), diuretics (thiazides), NSAIDs, and miscellaneous drugs (allopurinol, cimetidine). The chronic tubulointerstitial nephritis caused by phenacetin-containing analgesics, termed *analgesic nephropathy*, is mostly of historical importance as its incidence has substantially diminished due to the withdrawal or restriction of phenacetin in most countries.

Drug-induced acute interstitial nephritis begins about 15 days (range: 2-40) after drug exposure and is characterized by *fever*, *eosinophilia* (which may be transient), a *rash* in about 25% of patients, and *renal abnormalities*. The latter takes the form of hematuria, mild proteinuria, and leukocyturia (often including eosinophils). A rising serum creatinine or acute kidney injury with oliguria develops in about 50% of cases, particularly in older patients.

Pathogenesis. Many features of the disease suggest an idiosyncratic immune mechanism that is not dose-related. Clinical evidence of hypersensitivity includes the latent period, the eosinophilia and rash, the fact that the onset of nephropathy is not dose-related, and the recurrence of clinical and pathologic manifestations after re-exposure to the same or a chemically related drug. In some patients, serum IgE levels are increased, and IgE-containing plasma cells and basophils are present in the lesions, suggesting that the *late-phase reaction of an IgE-mediated (type I) hypersensitivity* may be involved in the pathogenesis (Chapter 6). In other cases, a mononuclear or granulomatous reaction, together with positive results of skin tests to drug haptens, suggest a T cell-mediated (type IV) delayed-hypersensitivity reaction.

The most likely sequence of events is that the drugs function as haptens and covalently bind to some plasma membrane or extracellular component of tubular cells. These modified self antigens then become immunogenic. The resultant injury is due to IgE or cell-mediated immune reactions to tubular cells or their basement membranes.

MORPHOLOGY

On histologic examination the interstitium shows variable but frequently pronounced **edema and infiltration by mononuclear cells**, principally lymphocytes and macrophages.

Eosinophils and neutrophils may be present (Fig. 20-33), often in clusters and large numbers, and smaller numbers of plasma cells and mast cells are sometimes also present. Inflammation may be more prominent in the medulla where the inciting agent is often concentrated. With some drugs (e.g., methicillin, thiazides), interstitial nonnecrotizing granulomas may be seen. Tubulitis, the infiltration of tubules by lymphocytes, is common. Variable degrees of tubular necrosis and regeneration are present. The glomeruli are normal except in some cases caused by NSAIDs, when minimal-change disease and the nephrotic syndrome develop concurrently (see below). In analgesic nephropathy, papillae can show various stages of necrosis, calcification, fragmentation, and sloughing.

Clinical Features. It is important to recognize drug-induced acute interstitial nephritis because withdrawal of the offending drug is followed by recovery, although it may take several months, and irreversible damage can occur. It is also important to remember that while drugs are the leading identifiable cause of acute interstitial nephritis, in many affected patients (approximately 30% to 40%) an offending drug or mechanism cannot be identified.

On occasion, necrotic papillae are excreted, and may cause gross hematuria or renal colic due to ureteric obstruction. Papillary necrosis is not specific for analgesic nephropathy, and is also seen in diabetes mellitus, as well as in urinary tract obstruction, sickle cell disease or trait (described later), and focally in renal tuberculosis. In all cases it is caused by ischemia resulting from compression or obstruction of small blood vessels in the medulla. Such compression may be caused by interstitial edema (as in inflammatory reactions and urinary tract obstruction) or microvascular disease (as in diabetes). Table 20-9 lists the main features of papillary necrosis in these conditions. A small percentage of patients with analgesic nephropathy develop *urothelial carcinoma of the renal pelvis*.

Nephropathy Associated with NSAIDs

NSAIDs, one of the most commonly used classes of drugs, produce several forms of renal injury. Although these complications are uncommon, they should be kept in mind since NSAIDs are frequently administered to patients with other potential causes of renal disease. Many NSAIDs are nonselective cyclooxygenase inhibitors, and their adverse renal effects are related to their ability to inhibit cyclooxygenase-dependent prostaglandin synthesis. The selective COX-2 inhibitors, while sparing the gastrointestinal tract, do affect the kidneys because COX-2 is expressed in human kidneys. NSAID-associated renal syndromes include

- *Acute kidney injury*, due to the decreased synthesis of vasodilatory prostaglandins and resultant ischemia. This is particularly likely to occur in the setting of other renal diseases or conditions causing volume depletion.
- *Acute hypersensitivity interstitial nephritis*, resulting in renal failure, as described earlier.
- *Acute interstitial nephritis and minimal-change disease*. This curious association of two diverse renal conditions, one leading to renal failure and the other to nephrotic syndrome, suggests a hypersensitivity reaction affecting the interstitium and possibly the glomeruli, but also is consistent with injury to podocytes mediated by cytokines released as part of the inflammatory process.
- *Membranous nephropathy*, with the nephrotic syndrome, is a recently appreciated association, also of unclear pathogenesis.

KEY CONCEPTS

Tubulointerstitial Nephritis Induced by Drugs and Toxins

- Drug-induced tubulointerstitial nephritis is the second most common cause of acute kidney injury.
- Prominent interstitial inflammation with associated tubular injury, which may or may not be accompanied by eosinophils or granulomatous inflammation, can be induced by almost any pharmacologic agent.
- NSAIDs can cause tubulointerstitial nephritis and/or glomerular injury, such as minimal change disease or membranous nephropathy.

Other Tubulointerstitial Diseases

Urate Nephropathy

Three types of nephropathy can occur in persons with hyperuricemic disorders:

- *Acute uric acid nephropathy* is caused by the precipitation of uric acid crystals in the renal tubules, principally in collecting ducts, leading to obstruction of nephrons and the development of acute renal failure. This is particularly likely to occur in individuals with leukemias or lymphomas who are undergoing chemotherapy (tumor lysis syndrome); the drugs kill tumor cells, and uric acid is produced as released nucleic acids are broken down. Precipitation of uric acid is favored by the acidic pH in collecting tubules.
- *Chronic urate nephropathy*, or gouty nephropathy, occurs in a subset of patients with protracted forms of

Table 20-9 Causes of Papillary Necrosis

	Diabetes Mellitus	Analgesic Nephropathy	Sickle-Cell Disease	Obstruction
Male-to-female ratio	1:3	1:5	1:1	9:1
Time course	10 years	7 years of abuse	Variable	Variable
Infection	80%	25%	±	90%
Calcification	Rare	Frequent	Rare	Frequent
Number of papillae affected	Several; all of same stage	Almost all; different stages of necrosis	Few	Variable

Data from Seshan S, et al. (eds): *Classification and Atlas of Tubulointerstitial and Vascular Diseases*. Baltimore, Williams & Wilkins, 1999.

Figure 20-34 Granulomatous inflammation and fibrosis outline the slender urate crystals in the renal medulla.

hyperuricemia. The monosodium urate crystals deposit in the acidic milieu of the distal tubules and collecting ducts as well as in the interstitium, and form distinct birefringent needle-like crystals either in the tubular lumens or in the interstitium (Fig. 20-34). The urate deposits evoke a mononuclear response that contains foreign-body giant cells. This lesion is called a *tophus* (Chapter 26). Tubular obstruction by the urates causes cortical atrophy and scarring. Clinically, urate nephropathy is a subtle disease associated with tubular defects that may progress slowly. Some individuals with gout who develop a chronic nephropathy have evidence of increased exposure to lead.

- *Nephrolithiasis*: uric acid stones are present in 22% of individuals with gout and 42% of those with secondary hyperuricemia (see later discussion of renal stones).

Hypercalcemia and Nephrocalcinosis

Disorders associated with hypercalcemia, such as hyperparathyroidism, multiple myeloma, vitamin D intoxication, metastatic cancer, or excess calcium intake (milk-alkali syndrome), may induce the formation of calcium stones and deposition of calcium in the kidney (nephrocalcinosis). Extensive degrees of calcinosis, under certain conditions, may lead to chronic tubulointerstitial disease and renal insufficiency.

The earliest functional defect is an inability to concentrate the urine. Other tubular defects, such as tubular acidosis and salt-losing nephritis, may also occur. With further damage, a slowly progressive renal insufficiency develops. This is usually due to nephrocalcinosis, but many of these patients also have calcium stones and secondary pyelonephritis.

Acute Phosphate Nephropathy

Extensive accumulations of calcium phosphate crystals in tubules can occur in patients consuming high doses of select oral phosphate solutions in preparation for

colonoscopy. These patients are not hypercalcemic, but the excess phosphate load, perhaps complicated by dehydration, causes marked precipitation of calcium phosphate, typically presenting as renal insufficiency several weeks after the exposure. Patients with acute and reversible injury typically recover partial renal function.

Light-Chain Cast Nephropathy (“Myeloma Kidney”)

Nonrenal malignant tumors, particularly those of hematopoietic origin, affect the kidneys in several ways (Table 20-10). The most common involvements are tubulointerstitial, caused by complications of the tumor (hypercalcemia, ureteral obstruction) or therapy (irradiation, hyperuricemia, chemotherapy, hematopoietic cell transplantation, infections in immunosuppressed patients). We limit the discussion here to the tubulointerstitial lesions in *multiple myeloma* patients.

Overt renal insufficiency occurs in half of those with multiple myeloma and related lymphoplasmacytic disorders. Several factors contribute to renal damage:

- *Bence-Jones proteinuria and cast nephropathy*. The main cause of renal dysfunction is related to Bence-Jones (light-chain) proteinuria, and correlates with the degree of proteinuria. Two mechanisms seem to account for the renal toxicity of Bence-Jones proteins. First, some Ig light chains are directly toxic to epithelial cells, apparently because of their intrinsic physicochemical properties. Second, Bence-Jones proteins combine with the urinary glycoprotein (Tamm-Horsfall protein) under acidic conditions to form large, histologically distinct tubular casts that obstruct the tubular lumens and induce a characteristic inflammatory reaction (light-chain cast nephropathy).
- *Amyloidosis* of AL type, formed from free light chains (usually of λ type), which occurs in 6% to 24% of individuals with myeloma.
- *Light-chain deposition disease*. In some patients, light chains (usually of κ type) deposit in GBMs and mesangium in nonfibrillar forms, causing a glomerulopathy (described earlier), and in tubular basement membranes, which may cause tubulointerstitial nephritis.
- *Hypercalcemia* and *hyperuricemia* are often present in these patients.

Effects of Radiation Therapy, Chemotherapy, Hematopoietic Cell Transplantation, Secondary Infection

Figure 20-35 Light-chain cast nephropathy. Note the angulated and tubular casts, surrounded by macrophages, including multinucleate cells.

MORPHOLOGY

The tubulointerstitial changes in light-chain cast nephropathy are characteristic. The Bence-Jones tubular casts appear as pink to blue amorphous masses, sometimes concentrically laminated and often fractured, which fill and distend the tubular lumens. Some casts are surrounded by multinucleate giant cells that are derived from activated macrophages (Fig. 20-35). The adjacent interstitial tissue usually shows an inflammatory response and fibrosis. On occasion, the casts rupture the tubules, evoking a granulomatous inflammatory reaction. Amyloidosis, light-chain deposition disease, nephrocalcinosis, and infection may also be present.

Clinical Features. Clinically, the renal manifestations are of several types. In the most common form, *chronic kidney disease* develops insidiously and progresses slowly during a period of several months to years. Another form occurs suddenly and is manifested by *acute kidney injury* with oliguria. Precipitating factors include dehydration, hypercalcemia, acute infection, and treatment with nephrotoxic antibiotics. *Bence-Jones proteinuria* occurs in 70% of individuals with multiple myeloma; the presence of significant non-light-chain proteinuria (e.g., albuminuria) suggests AL amyloidosis or light-chain deposition disease.

Bile Cast Nephropathy

Hepatorenal syndrome refers to impairment of renal function in patients with acute or chronic liver disease with advanced liver failure. In this setting, serum bilirubin levels can be markedly elevated, particularly in jaundiced patients, with bile cast formation (also known as cholemic nephrosis) in distal nephron segments. The casts can extend to proximal tubules, resulting in both direct toxic effects on tubular epithelial cells and obstruction of the involved nephron. This mechanism of injury is analogous to that with myeloma protein and myoglobin casts. The tubular bile casts can range from yellowish-green to pink and contain variable degrees of sloughed cells or cellular debris. The reversibility of the renal injury depends upon the severity and duration of the liver dysfunction.

Vascular Diseases

Nearly all diseases of the kidney involve the renal blood vessels secondarily. Systemic vascular diseases, such as various forms of vasculitis, also affect renal vessels, and their effects on the kidney are often clinically important. Hypertension, as we discussed in [Chapter 11](#), is intimately linked with the kidney, because kidney disease can be both a cause and consequence of increased blood pressure. In this chapter we discuss nephrosclerosis and renal artery stenosis, lesions associated with hypertension, and sundry lesions involving mostly smaller vessels of the kidney.

Nephrosclerosis

Nephrosclerosis is the term used for the renal pathology associated with sclerosis of renal arterioles and small arteries and is strongly associated with hypertension, which can be both a cause and a consequence of nephrosclerosis. The affected vessels have thickened walls and consequently narrowed lumens, changes that result in focal parenchymal ischemia. Ischemia leads to glomerulosclerosis and chronic tubulointerstitial injury, and produces a reduction in functional renal mass. Nephrosclerosis at autopsy is associated with advanced age, is more frequent in blacks than whites, and may be seen in the absence of hypertension. Hypertension and diabetes mellitus, however, increase the incidence and severity of the lesions.

Pathogenesis. Two processes participate in the arterial lesions:

- Medial and intimal thickening, as a response to hemodynamic changes, aging, genetic defects, or some combination of these
- Hyalinization of arteriolar walls, caused by extravasation of plasma proteins through injured endothelium and by increased deposition of basement membrane matrix

MORPHOLOGY

The kidneys are either normal or moderately reduced in size, with average weights between 110 and 130 gm. The cortical surfaces have a fine, even granularity that resembles grain leather (Fig. 20-36). The loss of mass is due mainly to **cortical scarring and shrinking**.

On histologic examination there is narrowing of the lumens of arterioles and small arteries, caused by thickening and hyalinization of the walls (**hyaline arteriosclerosis**) (Fig. 20-37). Corresponding to the finely granular surface are microscopic subcapsular scars with sclerotic glomeruli and tubular dropout, alternating with better preserved parenchyma. In addition, the interlobular and arcuate arteries show medial hypertrophy, replication of the internal elastic lamina, and increased myofibroblastic tissue in the intima, all of which narrow the lumen. This change, called fibroelastic hyperplasia, often accompanies hyaline arteriosclerosis and increases in severity with age and in the presence of hypertension.

Consequent to the vascular narrowing, there is patchy ischemic atrophy, which consists of (1) foci of **tubular atrophy and interstitial fibrosis** and (2) a variety of **glomerular**

Figure 20-36 Close-up of the gross appearance of the cortical surface in benign nephrosclerosis illustrating the fine, leathery granularity of the surface.

alterations. The latter include collapse of the GBM, deposition of collagen within Bowman space, periglomerular fibrosis, and total sclerosis of glomeruli. When the ischemic changes are pronounced and affect large areas of parenchyma, they can produce wedge shaped infarcts or regional scars with histologic alterations that may resemble those in renal ablation injury, mentioned earlier.

Clinical Features. It is unusual for uncomplicated nephrosclerosis to cause renal insufficiency or uremia. However, three groups of hypertensive patients with nephrosclerosis are at increased risk of developing renal failure: people of

Figure 20-37 Hyaline arteriosclerosis. High-power view of two arterioles with hyaline deposition, marked thickening of the walls, and a narrowed lumen. (Courtesy Dr. M.A. Venkatachalam, Department of Pathology, University of Texas Health Sciences Center, San Antonio, Tex.)

African descent, people with severe blood pressure elevations, and persons with a second underlying disease, especially diabetes. In these groups renal insufficiency may supervene after prolonged hypertension, but rapid renal failure results from the development of the malignant or accelerated phase of hypertension, discussed next.

Malignant Nephrosclerosis

Malignant nephrosclerosis is a renal vascular disorder associated with malignant or accelerated hypertension. It occasionally develops suddenly in previously normotensive individuals but more often is superimposed on preexisting essential hypertension, secondary forms of hypertension, or an underlying chronic renal disease, particularly glomerulonephritis or reflux nephropathy. It is also a frequent cause of renal failure in individuals with systemic sclerosis. Malignant hypertension is relatively uncommon, occurring in 1% to 5% of all people with elevated blood pressure. In its pure form it usually affects younger individuals, and occurs more often in men and in blacks.

Pathogenesis. The fundamental lesion in malignant nephrosclerosis is vascular injury. The initial insult seems to be some form of vascular damage to the kidneys that might result from a variety of disorders, including longstanding hypertension, arteritis, or a coagulopathy, alone or in combination. The initiating event injures endothelium and results in increased permeability of the small vessels to fibrinogen and other plasma proteins, focal death of cells of the vascular wall, and platelet deposition. This can lead to *fibrinoid necrosis* of arterioles and small arteries, with activation of platelets and coagulation factors causing intravascular thrombosis. Mitogenic factors from platelets (e.g., PDGF), plasma, and other cells cause hyperplasia of intimal smooth muscle of vessels, resulting in the hyperplastic arteriosclerosis that is typical of malignant hypertension and responsible for further narrowing of the lumens. The kidneys become markedly ischemic. With severe involvement of the renal afferent arterioles, the renin-angiotensin system receives a powerful stimulus; indeed, **patients with malignant hypertension have markedly elevated levels of plasma renin.** This sets up a self-perpetuating cycle in which angiotensin II causes intrarenal vasoconstriction, and the attendant renal ischemia perpetuates renin secretion.

MORPHOLOGY

The kidney size varies depending on the duration and severity of the hypertensive disease. Small, pinpoint **petechial hemorrhages** may appear on the cortical surface from rupture of arterioles or glomerular capillaries, giving the kidney a peculiar “flea-bitten” appearance.

Two histologic alterations characterize blood vessels in malignant hypertension (Fig. 20-38):

- **Fibrinoid necrosis of arterioles.** In this form of necrosis, cytologic detail is lost and the vessel wall takes on a smudgy eosinophilic appearance due to fibrin deposition. Inflammation is usually not seen or is minimal. Sometimes the glomeruli become necrotic and infiltrated with neutrophils, and the glomerular capillaries may thrombose.

Figure 20-38 Accelerated hypertension. **A**, Fibrinoid necrosis of afferent arteriole (PAS stain). **B**, Hyperplastic arteriolitis (onion-skin lesion). (Courtesy Dr. H. Renneke, Brigham and Women's Hospital, Boston, Mass.)

- In the interlobular arteries and arterioles, there is intimal thickening caused by a proliferation of elongated, concentrically arranged smooth muscle cells, together with fine concentric layering of collagen and accumulation of pale-staining material that probably represents deposition of proteoglycans and plasma proteins. This alteration has been referred to as **onion-skinning** because of its concentric appearance. The lesion, also called **hyperplastic arteriolitis**, correlates with renal failure. There may be superimposed intraluminal thrombosis. The arteriolar and arterial lesions result in considerable narrowing of all vascular lumens, ischemic atrophy and, at times, infarction distal to the abnormal vessels.

- Luminal reduction of the renal vasculature (arteries and arterioles) contributes to glomerulosclerosis (both global and segmental), which can subsequently cause interstitial fibrosis and tubular atrophy.
- Malignant nephrosclerosis is associated with malignant hypertension. The renal lesions manifest as fibrinoid necrosis of arterioles and hyperplastic arteriosclerosis. The latter lesion affects interlobular arteries and arterioles and is characterized by proliferation of smooth muscle cells of the arterial wall that are arranged concentrically.

Clinical Features. The full-blown syndrome of malignant hypertension is characterized by systolic pressures greater than 200 mm Hg and diastolic pressures greater than 120 mm Hg, papilledema, retinal hemorrhages, encephalopathy, cardiovascular abnormalities, and renal failure. Most often, the early symptoms are related to increased intracranial pressure and include headaches, nausea, vomiting, and visual impairments, particularly scotomas or spots before the eyes. “Hypertensive crises” are sometimes encountered, characterized by loss of consciousness or even convulsions. At the onset, there may only be marked proteinuria and microscopic or macroscopic hematuria, but renal failure soon ensues. The syndrome is a medical emergency requiring aggressive and prompt antihypertensive therapy to prevent irreversible renal injury. Before the development of current antihypertensive drugs, malignant hypertension was associated with a 50% mortality rate within 3 months of onset, progressing to 90% within a year. At present, however, about 75% of patients survive 5 years, and 50% survive with restoration of pre-crisis renal function.

KEY CONCEPTS

Nephrosclerosis

- Nephrosclerosis, which is commonly associated with hypertension, is defined by the presence of varying degrees of glomerulosclerosis, interstitial fibrosis and tubular atrophy, arteriosclerosis, and arteriolosclerosis.

Renal Artery Stenosis

Unilateral renal artery stenosis is responsible for 2% to 5% of hypertension cases, and is important to recognize because it is potentially curable by surgery. Furthermore, important insights into renal mechanisms of hypertension came from studies of experimental and human renal artery stenosis.

Pathogenesis. Hypertension secondary to renal artery stenosis is caused by increased production of renin from the ischemic kidney. The classic experiments of Goldblatt and colleagues showed that constriction of one renal artery in dogs results in hypertension and that the magnitude of the effect is proportional to the amount of narrowing. Elevation in blood pressure, at least initially, is due to stimulation of renin secretion by the juxtaglomerular apparatus and the subsequent production of the vasoconstrictor angiotensin II. A large proportion of individuals with renovascular hypertension have elevated renin levels, and almost all show a reduction of blood pressure when given drugs that block angiotensin II activity. Other factors, however, may contribute to the maintenance of renovascular hypertension after the renin-angiotensin system has initiated it, including *sodium retention*.

MORPHOLOGY

The most common cause of renal artery stenosis (70% of cases) is narrowing at the origin of the renal artery by an atheromatous plaque. This occurs more frequently in men, and the incidence increases with advancing age and diabetes mellitus.

Figure 20-39 Fibromuscular dysplasia of the renal artery, medial type (elastic tissue stain). The media shows marked fibrous thickening, and the lumen is stenotic. (Courtesy Dr. Seymour Rosen, Beth Israel Hospital, Boston, Mass.)

The plaque is usually concentrically placed, and superimposed thrombosis often occurs.

The second most frequent cause of stenosis is **fibromuscular dysplasia** of the renal artery. This heterogeneous entity is characterized by fibrous or fibromuscular thickening that may involve the intima, the media, or the adventitia of the artery (Fig. 20-39). The stenoses, as a whole, are more common in women and tend to occur in younger age groups (i.e., in the third and fourth decades).

The ischemic kidney is reduced in size and shows signs of **diffuse ischemic atrophy**, with crowded glomeruli, atrophic tubules, interstitial fibrosis, and focal inflammatory infiltrates. The arterioles in the ischemic kidney are usually protected from the effects of high pressure, thus showing only mild arteriosclerosis. In contrast, the contralateral nonischemic kidney may show more severe arteriosclerosis, depending on the severity of the hypertension.

Clinical Course. Few distinctive features suggest the presence of renal artery stenosis, and in general, these patients resemble those with essential hypertension. On occasion, a bruit can be heard on auscultation of the affected kidneys. Elevated plasma or renal vein renin, response to angiotensin-converting enzyme inhibitor, renal scans, and intravenous pyelography may aid with diagnosis, but arteriography is required to localize the stenotic lesion. The cure rate after surgery is 70% to 80% in well-selected cases.

Thrombotic Microangiopathies

The term *thrombotic microangiopathy* encompasses a spectrum of clinical syndromes that includes thrombotic thrombocytopenic purpura (TTP) and hemolytic-uremic syndrome (HUS). As already discussed in Chapter 14, **HUS and TTP are caused by diverse insults that lead to the excessive activation of platelets, which deposit as thrombi in capillaries and arterioles in various tissue**

beds, including those of the kidney (Fig. 20-40). Widespread “consumption” of platelets leads to thrombocytopenia, and the resulting thrombi create flow abnormalities that shear red cells, producing a microangiopathic hemolytic anemia. Of even greater importance, the thrombi produce microvascular occlusions that cause tissue ischemia and organ dysfunction.

This group of disorders is now classified according to the current understanding of their causes or associations, as follows:

- *Typical HUS (synonyms: epidemic, classic, diarrhea-positive)*, most frequently associated with consumption of food contaminated by bacteria producing Shiga-like toxins
- *Atypical HUS (synonyms: non-epidemic, diarrhea-negative)*, associated with:
 - Inherited mutations of complement-regulatory proteins
 - Diverse acquired causes of endothelial injury, including: antiphospholipid antibodies; complications of pregnancy and oral contraceptives; vascular renal diseases such as scleroderma and hypertension; chemotherapeutic and immunosuppressive drugs; and radiation
- *TTP*, which is often associated with inherited or acquired deficiencies of ADAMTS13, a plasma metalloprotease that regulates the function of von Willebrand factor (vWF)

Pathogenesis. Within the thrombotic microangiopathies, two pathogenetic triggers dominate: (1) *endothelial injury*, and (2) *excessive platelet activation and aggregation*. As will be discussed, endothelial injury appears to be the primary cause of HUS, whereas platelet activation may be the inciting event in TTP.

Endothelial injury. In typical (epidemic, classic, diarrhea-positive) HUS, the trigger for endothelial injury and activation is usually a Shiga-like toxin, while for inherited forms of atypical HUS the cause of the endothelial injury appears to be excessive, inappropriate activation of complement. Many other exposures and conditions can occasionally precipitate a HUS-like picture, presumably also by injuring the endothelium. The endothelial injury in

Figure 20-40 Fibrin stain showing platelet-fibrin thrombi (red) in the glomerular capillaries, characteristic of thrombotic microangiopathic disorders.

HUS appears to cause platelet activation and thrombosis within microvascular beds. There is evidence that reduced endothelial production of prostaglandin I₂ and NO (both inhibitors of platelet aggregation) contributes to thrombosis. The reduction in these two factors and increased production of endothelium-derived endothelin may also promote vasoconstriction, exacerbating the hypoperfusion of tissues.

Platelet aggregation. In contrast to HUS, in TTP the initiating event appears to be platelet aggregation induced by very large multimers of vWF, which accumulate due to a deficiency of ADAMTS13, a plasma protease that cleaves vWF multimers into smaller sizes. The deficiency of ADAMTS13 is most often caused by autoantibodies that inhibit ADAMTS13 function. Less commonly, a chronic relapsing and remitting form of TTP is associated with inherited deficiencies of ADAMTS13. Very large vWF multimers can bind platelet surface glycoproteins and activate platelets spontaneously, providing a pathophysiologic explanation for the microthrombi that are observed in vascular beds.

With this as an introduction, we will now briefly delve into the various subtypes of HUS/TTP and then return to the morphologic features that are common to all.

Typical (epidemic, classic, diarrhea-positive) hemolytic uremic syndrome. This is the best-characterized form of HUS. Most cases occur following intestinal infection with strains of *E. coli* (the most common being O157:H7) that produce Shiga-like toxins, so-called because they resemble those made by *Shigella dysenteriae* (Chapter 17). Epidemics have been traced to various sources, most commonly the ingestion of contaminated ground meat (as in hamburgers), but also drinking water, raw milk, and person-to-person transmission. However, most cases of typical HUS caused by *E. coli* are sporadic. Less commonly, infections by other agents, including *Shigella dysenteriae*, can give rise to a similar clinical picture.

Typical HUS can occur at any age, but children and older adults are at highest risk. Following a prodrome of influenza-like or diarrheal symptoms, there is a sudden onset of bleeding manifestations (especially hematemesis and melena), severe oliguria, and hematuria, associated with microangiopathic hemolytic anemia, thrombocytopenia, and (in some patients) prominent neurologic changes. Hypertension is present in about half the patients.

Precisely how Shiga-like toxin exposure causes HUS is not well understood. According to one model the toxin “activates” endothelial cells, which respond by increasing their expression of leukocyte adhesion molecules and endothelin and decreasing nitric oxide production. In the presence of cytokines such as TNF, Shiga-like toxin may cause endothelial apoptosis. These alterations lead to platelet activation and induce vasoconstriction, resulting in the characteristic microangiopathy. But other possibilities remain. For example, there is some evidence that Shiga-like toxins may bind and activate platelets directly; or alternatively, may bind the regulatory complement protein Factor H and inhibit its activity, causing hyperactivation of complement, an intriguing idea given the clear role of complement activation in some forms of atypical HUS (described below).

In typical HUS, if the renal failure is managed properly with dialysis, most patients recover normal renal function in a matter of weeks. However, due to underlying renal

damage the long-term (15 to 25 year) outlook is more guarded. In one study, only 10 of 25 patients with prior typical HUS had normal renal function, and 7 had chronic kidney disease.

Atypical (non-epidemic, diarrhea-negative) hemolytic-uremic syndrome. Atypical HUS occurs mainly in adults in a number of different settings. More than half of those affected have an inherited deficiency of complement-regulatory proteins, most commonly Factor H, which breaks down the alternative pathway C3 convertase and protects cells from damage by uncontrolled complement activation (Chapter 3). A small number of patients have mutations in two other proteins that regulate complement, complement Factor I and CD46 (membrane cofactor protein). Patients with genetic mutations in complement-regulatory proteins may develop HUS at any age. Roughly half of affected individuals have a course marked by multiple relapses and progression to end-stage renal disease. As the deficiencies in complement-regulatory factors are life-long, it is a mystery why the onset of HUS is delayed; additional unknown co-factors that trigger the development of HUS are suspected.

The remaining cases of atypical HUS arise in association with a variety of miscellaneous conditions or exposures. These include:

- The *antiphospholipid syndrome*, either primary or secondary to SLE (lupus anticoagulant). The syndrome is described in detail in Chapter 4. In this setting the microangiopathy tends to follow a chronic course.
- Complications of pregnancy or the postpartum period. So-called *postpartum renal failure* is a form of HUS that usually occurs after an uneventful pregnancy, 1 day to several months after delivery. The condition has a grave prognosis, although recovery can occur in milder cases.
- *Vascular diseases affecting the kidney*, such as systemic sclerosis and malignant hypertension.
- Chemotherapeutic and immunosuppressive drugs, such as mitomycin, cyclosporine, cisplatin, gemcitabine, and antagonists of VEGF.
- Irradiation of the kidney.

Patients with atypical HUS do not fare as well as those with typical HUS, in large part because the underlying conditions may be chronic and difficult to treat. As in typical HUS, some patients have neurologic symptoms; the disease in these patients can be distinguished from TTP by the presence of normal ADAMTS13 levels in the plasma (see later).

Thrombotic Thrombocytopenic Purpura. TTP is classically manifested by the pentad of fever, neurologic symptoms, microangiopathic hemolytic anemia, thrombocytopenia, and renal failure. The most common cause of deficient ADAMTS13 activity is inhibitory autoantibodies, and the majority with such antibodies are women. Regardless of cause, most patients present as adults at ages younger than 40. Less commonly, patients inherit an inactivating mutation in ADAMTS13. In those with hereditary ADAMTS13 deficiency, the onset is often delayed until adolescence and the symptoms are episodic. Thus, factors other than ADAMTS13 (e.g., some superimposed vascular injury or

prothrombotic state) must be involved in triggering full-blown TTP.

For unknown reasons, in TTP, central nervous system involvement is the dominant feature, whereas renal involvement is seen in about 50% of patients. The clinical findings are dictated by the distribution of the microthrombi, which are found in arterioles throughout the body. With plasma exchange, which removes autoantibodies and provides functional ADAMTS13, TTP (which once was uniformly fatal) can be treated successfully in more than 80% of patients.

MORPHOLOGY

The morphologic findings in the various forms of HUS/TTP show considerable overlap, and vary mainly according to chronicity rather than cause. In acute, active disease the kidney may show patchy or diffuse cortical necrosis (described later) and subcapsular petechiae. On microscopic examination, the glomerular capillaries are occluded by thrombi composed of aggregated platelets and to a lesser extent fibrin. The capillary walls are thickened due to endothelial cell swelling and subendothelial deposits of cell debris and fibrin. Disruption of the mesangial matrix and damage to the mesangial cells often results in mesangiolysis. Interlobular arteries and arterioles often show fibrinoid necrosis of the wall and occlusive thrombi. Chronic disease is confined to patients with atypical HUS or TTP, and has features that stem from continued injury and attempts at healing. The renal cortex reveals various degrees of scarring. By light microscopy the glomeruli are mildly hypercellular and have marked thickening of the capillary walls associated with splitting or reduplication of the basement membrane (so called double contours or tram tracks). The walls of arteries and arterioles often exhibit increased layers of cells and connective tissue ("onion-skinning") that narrow the vessel lumens. These changes lead to persistent hypoperfusion and ischemic atrophy of the parenchyma, which manifests clinically as renal failure and hypertension.

KEY CONCEPTS

Thrombotic Microangiopathy

- Thrombotic microangiopathy encompasses a diverse set of conditions that all lead to platelet activation and deposition of thrombi in the microvasculature, accompanied by red cell hemolysis, tissue ischemia and organ dysfunction, and a consumptive thrombocytopenia.
- In typical HUS, Shiga-like toxin produced by bacteria, most commonly *E. coli* strain O157:H7, is responsible for producing platelet activation and thrombosis.
- In most cases of atypical HUS, aberrant activation of complement due to inherited mutations or acquired autoantibodies is the key pathogenic abnormality.
- In TTP, deficiencies of ADAMTS13, a negative regulator of vWF, permits the formation of abnormally large multimers of vWF that are capable of activating platelets.

Other Vascular Disorders

Atherosclerotic Ischemic Renal Disease

We have seen that atherosclerotic unilateral renal artery stenosis can lead to hypertension. *Bilateral renal artery*

Figure 20-41 Atheroemboli with typical cholesterol clefts in an interlobular artery.

disease, usually diagnosed definitively by arteriography, is a fairly common cause of chronic ischemia with renal insufficiency in older individuals, sometimes in the absence of hypertension. The importance of recognizing this condition is that surgical revascularization can prevent further decline in renal function.

Atheroembolic Renal Disease

Embolization of fragments of atheromatous plaques from the aorta or renal artery into intrarenal vessels occurs in older adults with severe atherosclerosis, especially after surgery on the abdominal aorta, aortography, or intra-aortic cannulization. These emboli can be recognized in the lumens of arcuate and interlobular arteries by their content of cholesterol crystals, which appear as rhomboid clefts (Fig. 20-41). The clinical consequences of atheroemboli vary according to the number of emboli and the preexisting state of renal function. Frequently they are of no significance. However, acute renal injury or failure may develop in older adults in whom renal function is already compromised.

Sickle-Cell Nephropathy

Sickle-cell disease (homozygous) or trait (heterozygous) may lead to a variety of alterations in renal morphology and function, some of which produce clinically significant abnormalities. The various manifestations are grouped under *sickle-cell nephropathy*.

The most common abnormalities are *hematuria* and a *diminished concentrating ability* (hyposthenuria). These are thought to be due to accelerated sickling in the hypertonic hypoxic milieu of the renal medulla; the hyperosmolarity dehydrates red cells and increases intracellular HbS concentrations, which likely explains why even those with sickle trait are affected. Patchy *papillary necrosis* may occur in both homozygotes and heterozygotes; this is sometimes associated with cortical scarring. *Proteinuria* is also common in sickle-cell disease, occurring in about 30% of patients. It is usually mild to moderate, but on occasion the overt nephrotic syndrome arises, associated with sclerosing glomerular lesions.

Figure 20-42 Diffuse cortical necrosis. The pale ischemic necrotic areas are confined to the cortex and columns of Bertin.

Diffuse Cortical Necrosis

This uncommon condition occurs most frequently after an obstetric emergency, such as abruptio placentae (premature separation of the placenta), septic shock, or extensive surgery. The cortical destruction has the features of ischemic necrosis. Glomerular and arteriolar microthrombi are often found and contribute to the necrosis and renal damage. The morphologic features considerably overlap with thrombotic microangiopathy and disseminated intravascular coagulation, but the pathogenic sequence of events remains obscure.

MORPHOLOGY

The gross alterations of massive ischemic necrosis are sharply limited to the cortex (Fig. 20-42). The histologic appearance is that of acute ischemic infarction. The lesions may be patchy, with areas of coagulative necrosis and apparently better preserved cortex. Intravascular and intraglomerular thromboses may be prominent but are usually focal, and acute necroses of small arterioles and capillaries may occasionally be present. Hemorrhages occur into the glomeruli, together with the formation of fibrin plugs in the glomerular capillaries.

Massive acute cortical necrosis is of grave significance, since it gives rise to sudden anuria, terminating rapidly in uremic death. Instances of unilateral or patchy involvement are compatible with survival.

Renal Infarcts

The kidneys are common sites for the development of infarcts. Contributing to this predisposition is the extensive blood flow to the kidneys (one fourth of the cardiac output), but probably more important is the limited collateral circulation from extrarenal sites (small blood vessels penetrating from the renal capsule supply only the very outer rim of the cortex). Although thrombosis in advanced atherosclerosis and the acute vasculitis of polyarteritis nodosa may occlude arteries, most infarcts are due to embolism. A major source of such emboli is mural thrombosis in the left atrium and ventricle as a result of myocardial infarction. Vegetative endocarditis, aortic aneurysms, and aortic atherosclerosis are less frequent sources of emboli.

MORPHOLOGY

Because of the lack of a collateral blood supply, most renal infarcts are of the “white” anemic variety. Within 24 hours infarcts become sharply demarcated, pale, yellow-white areas that may contain small irregular foci of hemorrhagic discoloration. They are usually ringed by a zone of intense hyperemia.

The infarcts are wedge-shaped, with the base against the cortical surface and the apex pointing toward the medulla. In time these acute areas of ischemic necrosis undergo progressive fibrous scarring, giving rise to depressed, pale, gray-white scars that assume a V-shape on section. The histologic changes in renal infarcts are those of ischemic coagulative necrosis, described in Chapter 2.

Many renal infarcts are clinically silent. Sometimes, pain with tenderness localized to the costovertebral angle occurs, associated with showers of red cells in the urine. Large infarcts of one kidney are probably associated with narrowing of the renal artery or one of its major branches, which in turn may cause hypertension.

Congenital and Developmental Anomalies

About 10% of people are born with significant malformations of the urinary system. Renal dysplasias and hypoplasias account for 20% of chronic kidney disease in children.

Congenital renal disease can be hereditary but most often results from an acquired developmental defect during gestation. As discussed in Chapter 10, defects in genes involved in normal renal development, including the Wilms tumor-associated genes, understandably cause urogenital anomalies. As a rule, the resulting developmental abnormalities involve structural components of both the kidney and urinary tract. Other genetic defects primarily produce functional abnormalities in tubular transport, such as cystinuria and renal tubular acidosis. Here, we restrict the discussion to structural anomalies involving primarily the kidney. All except horseshoe kidney are uncommon. Anomalies of the lower urinary tract are discussed in Chapter 21.

Agenesis of the Kidney. Bilateral agenesis is incompatible with life, and usually encountered in stillborn infants. It is often associated with other congenital disorders (e.g., limb defects, hypoplastic lungs). Unilateral agenesis is uncommon and compatible with normal life if no other abnormalities exist. The solitary kidney enlarges as a result of compensatory hypertrophy. Some patients eventually develop progressive glomerular sclerosis in the remaining kidney as a result of the adaptive changes in hypertrophied nephrons, discussed earlier in the chapter, and in time, chronic kidney disease ensues.

Hypoplasia. Hypoplasia refers to failure of the kidneys to develop to a normal size. This anomaly may occur bilaterally, resulting in renal failure in early childhood, but it is more commonly encountered as a unilateral defect. True renal hypoplasia is observed in low birth weight infants and may contribute to their increased lifetime risk for chronic kidney disease. Differentiation between

congenital and acquired atrophic kidneys may be impossible, but a truly hypoplastic kidney shows no scars and has a reduced number of renal lobes and pyramids, usually six or fewer.

Ectopic Kidneys. The development of the metanephros into the kidneys may occur in ectopic foci. These kidneys lie either just above the pelvic brim or sometimes within the pelvis. They are usually normal or slightly small in size but otherwise are not remarkable. Because of their abnormal position, kinking or tortuosity of the ureters may cause obstruction to urinary flow, which predisposes to bacterial infections.

Horseshoe Kidneys. Fusion of the upper (10%) or lower poles (90%) of the kidneys produces a horseshoe-shaped structure that is continuous across the midline anterior to the great vessels. This anomaly is found in 1 in 500 to 1000 autopsies.

- Polycystic kidney disease
 - Autosomal dominant (adult) polycystic disease
 - Autosomal recessive (childhood) polycystic disease
- Medullary cystic disease
 - Medullary sponge kidney
 - Nephronophthisis
- Multicystic renal dysplasia
- Acquired (dialysis-associated) cystic disease
- Localized (simple) renal cysts
- Renal cysts in hereditary malformation syndromes (e.g., tuberous sclerosis)
- Glomerulocystic disease
- Extrarenal renal cysts (pyelocalyceal cysts, hilar lymphangitic cysts)

Only the more important of the cystic diseases are discussed later. [Table 20-11](#) summarizes the characteristic features of the principal renal cystic diseases.

Cystic Diseases of the Kidney

Cystic diseases of the kidney are heterogeneous, comprising hereditary, developmental, and acquired disorders. They are important for several reasons: (1) They are reasonably common and often represent diagnostic problems for clinicians, radiologists, and pathologists; (2) some forms, such as adult polycystic kidney disease, are major causes of chronic kidney disease; and (3) they can occasionally be confused with malignant tumors. A useful classification of renal cysts is as follows:

Autosomal Dominant (Adult) Polycystic Kidney Disease

Autosomal dominant (adult) polycystic kidney disease is a hereditary disorder characterized by multiple expanding cysts of both kidneys that ultimately destroy the renal parenchyma and cause renal failure. It is a common condition affecting roughly 1 of every 400 to 1000 live births and accounting for about 5% to 10% of cases of end-stage renal disease requiring transplantation or dialysis. The inheritance pattern is autosomal dominant with high

Table 20-11 Summary of Renal Cystic Diseases

Disease	Inheritance	Pathologic Features	Clinical Features or Complications	Typical Outcome	Diagrammatic Representation
Adult polycystic kidney disease	Autosomal dominant	Large multicystic kidneys, liver cysts, berry aneurysms	Hematuria, flank pain, urinary tract infection, renal stones, hypertension	Chronic renal failure beginning at age 40-60 years	
Childhood polycystic kidney disease	Autosomal recessive	Enlarged, cystic kidneys at birth	Hepatic fibrosis	Variable, death in infancy or childhood	
Medullary sponge kidney	None	Medullary cysts on excretory urography	Hematuria, urinary tract infection, recurrent renal stones	Benign	
Familial juvenile nephronophthisis	Autosomal recessive	Corticomedullary cysts, shrunken kidneys	Salt wasting, polyuria, growth retardation, anemia	Progressive renal failure beginning in childhood	
Adult-onset medullary cystic disease	Autosomal dominant	Corticomedullary cysts, shrunken kidneys	Salt wasting, polyuria	Chronic renal failure beginning in adulthood	
Multicystic renal dysplasia	None	Irregular kidneys with cysts of variable size	Association with other renal anomalies	Renal failure if bilateral, surgically curable if unilateral	
Acquired renal cystic disease	None	Cystic degeneration in end-stage kidney disease	Hemorrhage, erythrocytosis, neoplasia	Dependence on dialysis	
Simple cysts	None	Single or multiple cysts in normal-sized kidneys	Microscopic hematuria	Benign	

penetrance. Although the susceptibility to develop this disease is inherited as an autosomal dominant trait, as with tumor suppressor genes, both alleles of the involved genes have to be nonfunctional for development of the disease. Thus, individuals prone to autosomal dominant polycystic kidney disease inherit one copy of a mutated *PKD* gene, and mutation of the other allele is acquired in the somatic cells of the kidney. The disease is bilateral; reported unilateral cases probably represent multicystic dysplasia. The cysts initially involve a minority of the nephrons, so renal function is retained until about the fourth or fifth decade of life.

Genetics and Pathogenesis. A wide range of different mutations in *PKD1* and *PKD2* has been described, and this allelic heterogeneity has complicated genetic diagnosis of this disorder.

- The *PKD1* gene is located on chromosome 16p13.3. It encodes a large (460-kD) integral membrane protein named *polycystin-1*, which has a large extracellular region, multiple transmembrane domains, and a short cytoplasmic tail. Polycystin-1 is expressed in tubular epithelial cells, particularly those of the distal nephron. At present its precise function is not known, but it contains domains that are usually involved in cell-cell and cell-matrix interactions. Mutations in *PKD1* account for about 85% of cases. In individuals with these mutations, the likelihood of developing renal failure is less than 5% by 40 years of age, rising to more than 35% by 50 years, more than 70% at 60 years of age, and more than 95% by 70 years of age.
- The *PKD2* gene, located on chromosome 4q21, accounts for most of the remaining cases of polycystic disease. Its product, *polycystin-2*, is an integral membrane protein that is expressed in all segments of the renal tubules and in many extrarenal tissues. Polycystin-2 functions as a Ca²⁺-permeable cation channel. Overall, the disease is less severe than that associated with *PKD1* mutations. Renal failure occurs in less than 5% of patients with *PKD2* mutations at 50 years of age, but this rises to 15% at 60 years of age, and 45% at 70 years of age.

The pathogenesis of polycystic disease is not established, but the currently favored hypothesis places the cilia-centrosome complex of tubular epithelial cells at the center of the disorder (Fig. 20-43). The tubular epithelial cells of the kidney contain a single nonmotile primary cilium, a 2- to 3- μ m long hairlike organelle that projects into the tubular lumen from the apical surface of the cells. The cilium is made up of microtubules, and arises from and is attached to a basal body derived from the centriole. The cilia are part of a system of organelles and cellular structures that sense mechanical signals. The apical cilia function in the kidney tubule as a mechanosensor to monitor changes in fluid flow and shear stress, while intercellular junctional complexes monitor forces between cells, and focal adhesions sense attachment to extracellular matrices. In response to external signals, these sensors regulate ion flux (cilia can induce Ca²⁺ flux in cultured kidney epithelial cells) and cellular behavior, including cell polarity and proliferation. The idea that defects in mechanosensing, Ca²⁺ flux, and signal transduction underlie cyst formation is supported by several observations.

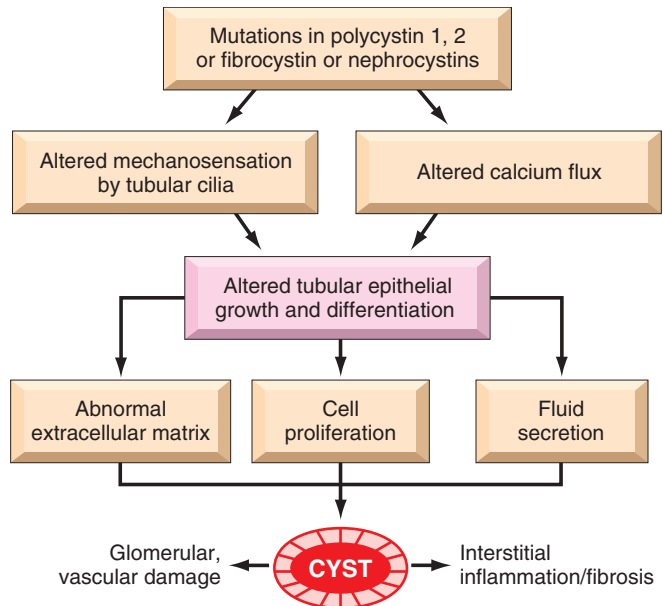

Figure 20-43 Possible mechanisms of cyst formation in cystic kidney diseases (see text).

- Both polycystin-1 and polycystin-2 are localized to the primary cilium.
- Other genes that are mutated in cystic diseases (e.g., the nephrocystin genes, described later) encode proteins that are also localized to cilia and/or basal bodies.
- Knockout of the *PKD1* gene in one model organism (the worm *Caenorhabditis elegans*) results in ciliary abnormalities and cyst formation.
- Tubular cells obtained from mice with a deletion of the *PKD1* gene (which causes embryonic lethality in this species) retain normal architecture of cilia but lack the flow-induced Ca²⁺ flux that occurs in normal tubular cells.

Polycystin-1 and polycystin-2 appear to form a protein complex that regulates intracellular Ca²⁺ in response to fluid flow, perhaps because fluid moving through the kidney tubules causes ciliary bending that opens Ca²⁺ channels. Mutation of either of the *PKD* genes leads to loss of the polycystin complex or formation of an aberrant complex. The consequent disruption of normal polycystin activity results in alterations of intracellular Ca²⁺, which (you will recall) regulates many downstream signaling events, including pathways that directly or indirectly impact cellular proliferation, apoptosis, and secretory functions. The increase in calcium is thought to stimulate proliferation and secretion from epithelial cells lining the cysts, which together result in progressive cyst formation and enlargement. In addition, cyst fluids have been shown to harbor mediators, derived from epithelial cells that enhance fluid secretion and induce inflammation. Finally, the calcium-induced signals also alter the interaction of epithelial cells with extracellular matrix, and this too is thought to contribute to the cyst formation and interstitial fibrosis that are characteristic of progressive polycystic kidney disease.

Figure 20-44 **A** and **B**, Autosomal dominant adult polycystic kidney disease (ADPKD) viewed from the external surface and bisected. The kidney is markedly enlarged and contains numerous dilated cysts. **C**, Autosomal recessive childhood PKD, showing smaller cysts and dilated channels at right angles to the cortical surface. **D**, Liver cysts in adult PKD.

MORPHOLOGY

In gross appearance, the kidneys are bilaterally enlarged and may achieve enormous sizes; weights as much as 4 kg for each kidney have been reported. The external surface appears to be composed solely of a mass of cysts, up to 3 to 4 cm in diameter, with no intervening parenchyma (Fig. 20-44A and B). However, microscopic examination reveals functioning nephrons dispersed between the cysts. The cysts may be filled with a clear, serous fluid or with turbid, red to brown, sometimes hemorrhagic fluid. As these cysts enlarge, they may encroach on the calyces and pelvis to produce pressure defects. The cysts arise from the tubules throughout the nephron and therefore have variable lining epithelia. On occasion, papillary epithelial formations and polyps project into the lumen. Bowman capsules are occasionally involved in cyst formation, and glomerular tufts may be seen within the cystic space.

Clinical Features. Many patients remain asymptomatic until renal insufficiency announces the presence of the disease. In others, hemorrhage or progressive dilation of cysts may produce pain. Excretion of blood clots causes renal colic. The enlarged kidneys, usually apparent on abdominal palpation, may induce a dragging sensation. The disease occasionally begins with the insidious onset of hematuria, followed by other features of progressive chronic kidney disease, such as proteinuria (rarely more than 2 gm/day), polyuria, and hypertension. Patients with *PKD2* mutations tend to have an older age at onset and later development of renal failure. Both genetic and environmental factors influence disease severity. Progression is accelerated in blacks (particularly in those with sickle-cell trait), in males, and in the presence of hypertension.

Individuals with polycystic kidney disease also tend to have extrarenal congenital anomalies. About 40% have one to several cysts in the liver (polycystic liver disease) that are usually asymptomatic. The cysts are derived from biliary epithelium. Cysts occur much less frequently in the spleen, pancreas, and lungs. Intracranial berry aneurysms,

presumably from altered expression of polycystin in vascular smooth muscle, arise in the circle of Willis, and subarachnoid hemorrhages from these account for death in 4% to 10% of individuals. *Mitral valve prolapse* and other cardiac valvular anomalies occur in 20% to 25% of patients, but most are asymptomatic. The diagnosis is made by radiologic imaging techniques.

This form of chronic kidney disease is remarkable in that patients may survive for many years with azotemia slowly progressing to uremia. Ultimately, about 40% of adult patients die of coronary or hypertensive heart disease, 25% of infection, 15% of a ruptured berry aneurysm or hypertensive intracerebral hemorrhage, and the rest of other causes.

Autosomal Recessive (Childhood) Polycystic Kidney Disease

Autosomal recessive (childhood) polycystic kidney disease is genetically distinct from adult polycystic kidney disease. *Perinatal*, *neonatal*, *infantile*, and *juvenile* subcategories have been defined, depending on the time of presentation and presence of associated hepatic lesions. The first two are the most common; serious manifestations are usually present at birth, and the young infant might succumb rapidly to renal failure.

Genetics and Pathogenesis. In most cases, the disease is caused by mutations of the *PKHD1* gene, which maps to chromosome region 6p21-p23. The gene is highly expressed in adult and fetal kidney and also in liver and pancreas. The *PKHD1* gene encodes *fibrocystin*, a 447-kD integral membrane protein with a large extracellular region, a single transmembrane component, and a short cytoplasmic tail. The extracellular region contains multiple copies of a domain forming an Ig-like fold. Like polycystins 1 and 2, fibrocystin also has been localized to the primary cilium of tubular cells. The function of fibrocystin is unknown, but its putative conformational structure indicates it may be a

cell surface receptor with a role in collecting duct and biliary differentiation.

Analysis of autosomal recessive polycystic disease patients has revealed a wide range of different mutations. The vast majority of cases are compound heterozygotes (i.e., inherit a different mutant allele from each of the two parents). This complicates molecular diagnosis of the disorder.

MORPHOLOGY

The kidneys are enlarged and have a smooth external appearance. On cut section, numerous small cysts in the cortex and medulla give the kidney a spongelike appearance. Dilated elongated channels are present at right angles to the cortical surface, completely replacing the medulla and cortex (Fig. 20-44C). On microscopic examination, there is cylindrical or, less commonly, saccular dilation of all collecting tubules. The cysts have a uniform lining of cuboidal cells, reflecting their origin from the collecting ducts. In almost all cases the liver has cysts associated with portal fibrosis (Fig. 20-44D) and proliferation of portal bile ducts.

Patients who survive infancy (infantile and juvenile forms) may develop a peculiar hepatic injury characterized by bland periportal fibrosis and proliferation of well-differentiated biliary ductules, now termed *congenital hepatic fibrosis*. In older children, hepatic disease is the predominant clinical concern. Such patients may develop portal hypertension with splenomegaly. Curiously, congenital hepatic fibrosis sometimes occurs in the absence of polycystic kidneys or has been reported in the presence of adult polycystic kidney disease.

Cystic Diseases of Renal Medulla

The three major types of medullary cystic disease are *medullary sponge kidney*, a relatively common and usually innocuous structural change, *nephronophthisis* and *adult-onset medullary cystic disease*, which are almost always associated with renal dysfunction.

Medullary Sponge Kidney

The term *medullary sponge kidney* is restricted to multiple cystic dilations of the collecting ducts in the medulla. The condition occurs in adults and is usually discovered radiographically. Renal function is usually normal. On gross inspection the papillary ducts in the medulla are dilated, and small cysts may be present. The cysts are lined by cuboidal epithelium or occasionally by transitional epithelium. Unless there is superimposed pyelonephritis, cortical scarring is absent. The pathogenesis is unknown.

Nephronophthisis and Adult-Onset Medullary Cystic Disease

This group of progressive renal disorders is characterized by variable number of cysts in the medulla, usually concentrated at the corticomedullary junction. Initial injury probably involves the distal tubules with tubular basement membrane disruption, followed by chronic and

progressive tubular atrophy involving both medulla and cortex and interstitial fibrosis. Although the medullary cysts are important, the **cortical tubulointerstitial damage is the cause of the eventual renal insufficiency.**

Three variants of the nephronophthisis disease complex are recognized: (1) sporadic, nonfamilial; (2) familial juvenile nephronophthisis (most common); and (3) renal-retinal dysplasia (15%) in which the kidney disease is accompanied by ocular lesions. The familial forms are inherited as autosomal recessive traits and usually become manifest in childhood or adolescence. As a group, the nephronophthisis complex is now the most common genetic cause of end-stage renal disease in children and young adults.

Children affected with nephronophthisis present first with polyuria and polydipsia, which reflect a marked defect in the concentrating ability of renal tubules. Sodium wasting and tubular acidosis are also prominent. Some syndromic variants of nephronophthisis (e.g., Senior-Loken syndrome, Joubert syndrome, Bardet Biedl syndrome, Jeune syndrome, Meckel Gruber syndrome, Mainzer-Saldino syndrome, Sensenbrenner syndrome) can have extrarenal associations, including ocular motor abnormalities, retinal dystrophy, liver fibrosis, and cerebellar abnormalities. The expected course is progression to ESRD in 5 to 10 years.

Genetics and Pathogenesis. Sixteen responsible gene loci, *NPHP1* to *NPHP11* (that encode proteins called nephrocystins, *JBTS2*, *JBTS3*, *JBTS9*, and *JBTS11*, are mutated in the juvenile forms of nephronophthisis and the list continually expands as additional loci that contribute to this ciliopathy are identified. These proteins are present in the primary cilia, basal bodies attached to these cilia, or the centrosome organelle from which the basal bodies originate.

The *NPHP2* gene product has been identified as *inversin*, which mediates left-right patterning during embryogenesis. Adult-onset medullary cystic disease has an autosomal dominant pattern of transmission. At one time it was considered to be part of the nephronophthisis spectrum, but based on its distinctive genetics it is now considered a separate entity. Mutations in two genes (*MCKD1* and *MCKD2*) have been identified as causing medullary cystic disease, which is characterized by progression to end-stage kidney disease in adult life.

MORPHOLOGY

In nephronophthisis, the kidneys are small, have contracted granular surfaces, and show cysts in the medulla, most prominently at the corticomedullary junction (Fig. 20-45). Small cysts are also seen in the cortex. The cysts are lined by flattened or cuboidal epithelium and are usually surrounded by either inflammatory cells or fibrous tissue. In the cortex there is widespread atrophy and thickening of the tubular basement membranes, together with interstitial fibrosis. In general, glomerular structure is preserved.

There are few specific clues to diagnosis, because the medullary cysts might be too small to be visualized radiographically. The disease should be strongly considered in children or adolescents with otherwise unexplained chronic

Figure 20-45 Medullary cystic disease. Cut section of kidney showing cysts at the corticomedullary junction and in the medulla.

renal failure, a positive family history, and chronic tubulointerstitial nephritis on biopsy.

Multicystic Renal Dysplasia

Dysplasia is a sporadic disorder that can be unilateral or bilateral and is almost always cystic. The kidney is usually enlarged, extremely irregular, and multicystic (Fig. 20-46A).

Figure 20-46 Multicystic renal dysplasia. **A**, Gross appearance. **B**, Histologic section showing disorganized architecture, dilated tubules with cuffs of primitive stroma, and an island of cartilage (Hematoxylin and eosin stain). (**A**, Courtesy Dr. D. Schofield, Children's Hospital, Los Angeles, Calif.; **B**, courtesy Dr. Laura Finn, Children's Hospital, Seattle, Wash.)

The cysts vary in size from several millimeters to centimeters in diameter. On histologic examination, they are lined by flattened epithelium. Although normal nephrons are present, many have immature collecting ducts. The characteristic histologic feature is the presence of islands of undifferentiated mesenchyme, often with cartilage, and immature collecting ducts (Fig. 20-46B). Most cases are associated with ureteropelvic obstruction, ureteral agenesis or atresia, and other anomalies of the lower urinary tract.

When unilateral, the dysplasia may mimic a neoplasm and lead to surgical exploration and nephrectomy. The opposite kidney functions normally, and such patients have an excellent prognosis after surgical removal of the affected kidney. In bilateral multicystic renal dysplasia, renal failure may ultimately result.

Acquired (Dialysis-Associated) Cystic Disease

Patients with end-stage renal disease who have undergone prolonged dialysis sometimes show numerous cortical and medullary renal cysts. The cysts measure 0.1 to 4 cm in diameter, contain clear fluid, are lined by either hyperplastic or flattened tubular epithelium, and often contain calcium oxalate crystals. They probably form as a result of obstruction of tubules by interstitial fibrosis or by oxalate crystals. Most are asymptomatic, but sometimes the cysts bleed, causing hematuria. There is a 12- to 18-fold increased risk of renal cell carcinoma, which develops in 7% of dialyzed patients observed for 10 years.

Simple Cysts

Simple cysts may be single or multiple and usually involve the cortex. They are commonly 1 to 5 cm but may reach 10 cm or more in size. They are translucent, lined by a gray, glistening, smooth membrane, and filled with clear fluid. On microscopic examination these membranes are composed of a single layer of cuboidal or flattened cuboidal epithelium, which in many instances may be completely atrophic.

Simple cysts are common postmortem findings without clinical significance. On occasion, hemorrhage into them may cause sudden distention and pain, and calcification of the hemorrhage may give rise to bizarre radiographic shadows. The main importance of cysts lies in their differentiation from kidney tumors. Radiologic studies show that in contrast to renal tumors, renal cysts have smooth contours, are almost always avascular, and give fluid rather than solid signals on ultrasonography.

KEY CONCEPTS

Cystic Diseases

- Autosomal dominant polycystic kidney disease accounts for a small yet significant subset of end stage renal disease.
- Ciliopathies or abnormalities of the cilium-centrosome complex underlie the major cystic kidney diseases, including polycystic kidney disease (both autosomal dominant and autosomal recessive forms), medullary cystic kidney disease, and nephronophthisis.

- Dysfunction of the primary cilium of tubular epithelial cells results in alterations in ion flux and changes in cell proliferation and function, culminating in renal cyst formation.

Urinary Tract Obstruction (Obstructive Uropathy)

Obstructive lesions of the urinary tract increase susceptibility to infection and to stone formation, and unrelieved obstruction almost always leads to permanent renal atrophy, termed *hydronephrosis* or *obstructive uropathy*. Fortunately, many causes of obstruction are surgically correctable or medically treatable.

Obstruction may be sudden or insidious, partial or complete, unilateral or bilateral; it may occur at any level of the urinary tract from the urethra to the renal pelvis. It can be caused by *intrinsic* lesions of the urinary tract or *extrinsic* lesions that compress the ureter. The common causes are as follows (Fig. 20-47):

- **Congenital anomalies:** posterior urethral valves and urethral strictures, meatal stenosis, bladder neck obstruction; ureteropelvic junction narrowing or obstruction; severe vesicoureteral reflux

Figure 20-47 Obstructive lesions of the urinary tract.

- *Urinary calculi*
- *Benign prostatic hypertrophy*
- *Tumors:* carcinoma of the prostate, bladder tumors, contiguous malignant disease (retroperitoneal lymphoma), carcinoma of the cervix or uterus
- *Inflammation:* prostatitis, ureteritis, urethritis, retroperitoneal fibrosis
- *Sloughed papillae or blood clots*
- *Pregnancy*
- *Uterine prolapse and cystocele*
- *Functional disorders:* neurogenic (spinal cord damage or diabetic nephropathy) and other functional abnormalities of the ureter or bladder (often termed *dysfunctional obstruction*)

Hydronephrosis is the term used to describe dilation of the renal pelvis and calyces associated with progressive atrophy of the kidney due to obstruction to the outflow of urine. Even with complete obstruction, glomerular filtration persists for some time because the filtrate subsequently diffuses back into the renal interstitium and perirenal spaces, from where it ultimately returns to the lymphatic and venous systems. Because of this continued filtration, the affected calyces and pelvis become dilated, often markedly so. The high pressure in the pelvis is transmitted back through the collecting ducts into the cortex, causing renal atrophy, but it also compresses the renal vasculature of the medulla, causing a diminution in inner medullary blood flow. The medullary vascular defects are initially reversible, but lead to medullary functional disturbances. Accordingly, the initial functional alterations caused by obstruction are largely tubular, manifested primarily by impaired concentrating ability. Only later does the GFR begin to fall. Obstruction also triggers an interstitial inflammatory reaction, leading eventually to interstitial fibrosis, by mechanisms similar to those discussed earlier (Fig. 20-9).

MORPHOLOGY

When the obstruction is sudden and complete, it leads to mild dilation of the pelvis and calyces and sometimes to atrophy of the renal parenchyma. When the obstruction is subtotal or intermittent, progressive dilation ensues, giving rise to hydronephrosis (Fig. 20-48). Depending on the level of urinary block, the dilation may affect the bladder first, or the ureter and then the kidney.

The kidney may be slightly to massively enlarged, depending on the degree and the duration of the obstruction. The earlier features are those of simple dilation of the pelvis and calyces, but in addition there is often significant interstitial inflammation, even in the absence of infection. In chronic cases the picture is one of cortical tubular atrophy with marked diffuse interstitial fibrosis. Progressive blunting of the apices of the pyramids occurs, and these eventually become cupped. In far-advanced cases the kidney may become transformed into a thin-walled cystic structure having a diameter of up to 15 to 20 cm (Fig. 20-48) with striking parenchymal atrophy, total obliteration of the pyramids, and thinning of the cortex.

Clinical Features. *Acute obstruction* may provoke pain attributed to distention of the collecting system or renal

Figure 20-48 Hydronephrosis of the kidney, with marked dilation of the pelvis and calyces and thinning of the renal parenchyma.

capsule. Most of the early symptoms are produced by the underlying cause of the hydronephrosis. Thus, calculi lodged in the ureters may give rise to renal colic, and prostatic enlargements may give rise to bladder symptoms.

Unilateral complete or partial hydronephrosis may remain silent for long periods, since the unaffected kidney can maintain adequate renal function. Sometimes its existence first becomes apparent in the course of imaging studies. In its early stages, perhaps the first few weeks, relief of obstruction leads to reversion to normal function. *Ultrasonography* is a useful noninvasive technique in the diagnosis of obstructive uropathy.

In *bilateral partial obstruction* the earliest manifestation is inability to concentrate urine, reflected by polyuria and nocturia. Some patients develop distal tubular acidosis, renal salt wasting, secondary renal calculi, and chronic tubulointerstitial nephritis with scarring and atrophy of the papilla and medulla. Hypertension is common.

Complete bilateral obstruction of rapid onset results in oliguria or anuria and is incompatible with survival unless the obstruction is relieved. Curiously, after relief of complete urinary tract obstruction, postobstructive *diuresis* occurs. This can often be massive, with the kidney excreting large amounts of urine that is rich in sodium chloride.

Urolithiasis (Renal Calculi, Stones)

Urolithiasis affects 5% to 10% of Americans in their lifetime and the stones may form anywhere in the urinary tract, but most arise in the kidney. Men are affected more often than women, and the peak age at onset is between 20 and 30 years. Familial and hereditary predisposition to stone formation has long been known. Many inborn errors of metabolism, such as cystinuria and primary hyperoxaluria, provide examples of hereditary disease characterized by excessive production and excretion of stone-forming substances.

Etiology and Pathogenesis. There are four main types of calculi (Table 20-12): (1) *calcium stones* (about 70%), composed largely of calcium oxalate or calcium oxalate mixed with calcium phosphate; (2) another 15% are so-called *triple stones* or *struvite stones*, composed of magnesium ammonium phosphate; (3) 5% to 10% are *uric acid stones*; and (4) 1% to 2% are made up of cystine. An organic mucoprotein matrix, making up 1% to 5% of the stone by weight, is present in all calculi. **Although there are many causes for the initiation and propagation of stones, the most important determinant is an increased urinary concentration of the stones' constituents, such that it exceeds their solubility (supersaturation).** A low urine volume in some metabolically normal patients may also favor supersaturation.

- *Calcium oxalate stones* (Table 20-12) are associated in about 5% of patients with hypercalcemia and hypercalciuria, such as occurs with hyperparathyroidism, diffuse bone disease, sarcoidosis, and other hypercalcemic states. About 55% have hypercalciuria without hypercalcemia. This is caused by several factors, including hyperabsorption of calcium from the intestine (absorptive hypercalciuria), an intrinsic impairment in renal tubular reabsorption of calcium (renal hypercalciuria), or idiopathic fasting hypercalciuria with normal parathyroid function. As many as 20% of calcium oxalate stones are associated with increased uric acid secretion (*hyperuricosuric calcium nephrolithiasis*), with or without hypercalciuria. The mechanism of stone formation in this setting involves “nucleation” of calcium oxalate by uric acid crystals in the collecting ducts. Five percent are associated with *hyperoxaluria*, either hereditary (primary oxaluria) or, more commonly, acquired by intestinal overabsorption in patients with enteric diseases. *Hypocitraturia*, which can be idiopathic or associated with acidosis and chronic diarrhea of unknown cause, may produce calcium stones. In a variable proportion of

Table 20-12 Prevalence of Various Types of Renal Stones

Stone Type	Percentage of All Stones
Calcium Oxalate and Phosphate	70
Idiopathic hypercalciuria (50%)	
Hypercalciuria and hypercalcemia (10%)	
Hyperoxaluria (5%)	
Enteric (4.5%)	
Primary (0.5%)	
Hyperuricosuria (20%)	
Hypocitraturia	
No known metabolic abnormality (15% to 20%)	
Magnesium Ammonium Phosphate (Struvite)	5-10
Uric Acid	5-10
Associated with hyperuricemia	
Associated with hyperuricosuria	
Idiopathic (50% of uric stones)	
Cystine	1-2
Others or Unknown	±5

individuals with calcium stones, no cause can be found (idiopathic calcium stone disease).

- *Magnesium ammonium phosphate stones* are formed largely after infections by urea-splitting bacteria (e.g., *Proteus* and some staphylococci) that convert urea to ammonia. The resultant alkaline urine causes the precipitation of magnesium ammonium phosphate salts. These form some of the largest stones, as the amount of urea excreted normally is very large. Indeed, so-called *staghorn calculi* occupying large portions of the renal pelvis are frequently a consequence of infection.
- *Uric acid stones* are common in individuals with hyperuricemia, such as patients with gout, and diseases involving rapid cell turnover, such as the leukemias. However, **more than half of all patients with uric acid calculi have neither hyperuricemia nor increased urinary excretion of uric acid.** In this group, it is thought that a tendency to excrete urine of pH below 5.5 may predispose to uric acid stones, because uric acid is insoluble in acidic urine. In contrast to the radiopaque calcium stones, uric acid stones are radiolucent.
- *Cystine stones* are caused by genetic defects in the renal reabsorption of amino acids, including cystine, leading to cystinuria. These stones also form at low urinary pH.

It can therefore be appreciated that **increased concentration of stone constituents, changes in urinary pH, decreased urine volume, and the presence of bacteria influence the formation of calculi.** However, many calculi occur in the absence of these factors; conversely, individuals with hypercalciuria, hyperoxaluria, and hyperuricosuria often do not form stones. It has been postulated that stone formation is enhanced by a deficiency in inhibitors of crystal formation in urine. The list of such inhibitors is long, including pyrophosphate, diphosphonate, citrate, glycosaminoglycans, osteopontin, and a glycoprotein called nephrocalcin.

MORPHOLOGY

Stones are unilateral in about 80% of patients. The favored sites for their formation are within the renal calyces and pelves (Fig. 20-49) and in the bladder. If formed in the renal pelvis they tend to remain small, having an average diameter of 2 to 3 mm. These may have smooth contours or may take the form of an irregular, jagged mass of spicules. Often many stones are found within one kidney. On occasion, progressive accretion of salts leads to the development of branching structures known as staghorn calculi, which create a cast of the pelvic and calyceal system.

Clinical Features. Urolithiasis may be asymptomatic, produce severe renal colic and abdominal pain, or may cause significant renal damage. Larger stones often manifest themselves by hematuria. Stones also predispose to superimposed infection, both by their obstructive nature and by the trauma they produce.

Neoplasms of the Kidney

Both benign and malignant neoplasms occur in the kidney. Malignant neoplasms are of great importance clinically. By

Figure 20-49 Nephrolithiasis. A large stone impacted in the renal pelvis. (Courtesy Dr. E. Mosher, Brigham and Women's Hospital, Boston, Mass.)

far the most common malignant tumor is renal cell carcinoma, followed by Wilms tumor, which is found in children and is described in [Chapter 10](#), and finally urothelial carcinomas of the calyces and pelves.

Benign Neoplasms

Renal Papillary Adenoma

Small, discrete adenomas arising from the renal tubular epithelium are found commonly (7% to 22%) at autopsy. They are most frequently papillary and are therefore called *papillary adenomas*.

MORPHOLOGY

These are small tumors, usually less than 0.5 cm in diameter. They are present invariably within the cortex and appear grossly as pale yellow-gray, discrete, well-circumscribed nodules. On microscopic examination, they are composed of complex, branching, papillomatous structures with numerous complex fronds. Cells may also grow as tubules, glands, cords, and sheets of cells. The cells are cuboidal to polygonal in shape and have regular, small central nuclei, scanty cytoplasm, and no atypia.

By histologic criteria, these tumors do not differ from low-grade papillary renal cell carcinoma and indeed share some immunohistochemical and cytogenetic features (trisomies 7 and 17) with papillary cancers, to be discussed later. The size of the tumor is used as a prognostic feature, with a cutoff of 3 cm separating those that metastasize from those that rarely do. However, because of occasional reports of small tumors that have metastasized, the current view is to regard all adenomas, regardless of size, as potentially malignant.

Angiomyolipoma

This is a benign neoplasm consisting of vessels, smooth muscle, and fat originating from perivascular epithelioid cells. **Angiomyolipomas are present in 25% to 50% of patients with tuberous sclerosis**, a disease caused by

loss-of-function mutations in the *TSC1* or *TSC2* tumor suppressor genes. Tuberous sclerosis is characterized by lesions of the cerebral cortex that produce epilepsy and mental retardation, a variety of skin abnormalities, and unusual benign tumors at other sites, such as the heart (Chapters 12 and 28). The clinical importance of angiomyolipoma is due largely to their susceptibility to spontaneous hemorrhage.

Oncocytoma

This is an epithelial neoplasm composed of large eosinophilic cells having small, round, benign-appearing nuclei that have large nucleoli. It is thought to arise from the intercalated cells of collecting ducts, and accounts for approximately 5% to 15% of renal neoplasms. Ultrastructurally the eosinophilic cells have numerous mitochondria. In gross appearance, the tumors are tan or mahogany brown, relatively homogeneous, and usually well encapsulated with a central scar in one-third of cases. However, they may achieve a large size (up to 12 cm in diameter). There are some familial cases in which these tumors are multicentric rather than solitary.

Malignant Neoplasms

Renal Cell Carcinoma

Renal cell carcinomas represent about 3% of all newly diagnosed cancers in the United States and account for 85% of renal cancers in adults. There are approximately 65,000 new cases per year and 13,000 deaths from the disease. The tumors occur most often in older individuals, usually in the sixth and seventh decades of life, and show a 2:1 male preponderance.

Epidemiology. Tobacco is the most significant risk factor. Cigarette smokers have double the incidence of renal cell carcinoma, and pipe and cigar smokers are also more susceptible. An international study has identified additional risk factors, including obesity (particularly in women); hypertension; unopposed estrogen therapy; and exposure to asbestos, petroleum products, and heavy metals. There is also an increased risk in patients with end-stage renal disease, chronic kidney disease, acquired cystic disease (see earlier) and tuberous sclerosis.

Most renal cancer is sporadic, but unusual forms of autosomal dominant familial cancers occur, usually in younger individuals. Although they account for only 4% of renal cancers, familial variants have been instructive in understanding renal carcinogenesis.

- *Von Hippel-Lindau (VHL) syndrome:* Half to two thirds of individuals with VHL (nearly all, if they live long enough) (Chapter 28) develop renal cysts and bilateral, often multiple, renal cell carcinomas. *Current studies implicate the VHL gene in the development of both familial and sporadic clear cell carcinomas.*
- *Hereditary leiomyomatosis and renal cell cancer syndrome:* This autosomal dominant disease is caused by mutations of the *FH* gene, which expresses fumarate hydratase, and is characterized by cutaneous and uterine leiomyomata and an aggressive type of papillary carcinoma with increased propensity for metastatic spread.
- *Hereditary papillary carcinoma.* This autosomal dominant form is manifested by multiple bilateral tumors with papillary histology. These tumors show a series of cytogenetic abnormalities and, as will be described, mutations in the *MET* proto-oncogene.
- *Birt-Hogg-Dubé syndrome:* The autosomal dominant inheritance pattern of this disease is due to mutations involving the *BHD* gene, which expresses folliculin. The syndrome features a constellation of skin (fibrofolliculomas, trichodiscomas, and acrochordons), pulmonary (cysts or blebs), and renal tumors with a wide range of histologic subtypes.

Classification of renal cell carcinoma: histology, cytogenetics, and genetics. The classification of renal cell carcinoma is based on correlative cytogenetic, genetic, and histologic studies of both familial and sporadic tumors. The major types of tumor are as follows (Fig. 20-50):

- *Clear cell carcinoma.* This is the most common type, accounting for 70% to 80% of renal cell cancers. The tumors are made up of cells with clear or granular cytoplasm and are *nonpapillary*. They can be familial, but in most cases (95%) are sporadic. In 98% of these tumors, whether familial, sporadic, or associated with VHL syndrome, there is loss of sequences on the short arm of chromosome 3. The deleted region harbors the *VHL* gene (3p25.3). A second nondeleted allele of the *VHL* gene shows somatic mutations or hypermethylation-induced inactivation in up to 80% of clear cell cancers, indicating that the *VHL* gene acts as a tumor suppressor gene in both sporadic and familial cancers (Chapter 7). The *VHL* gene encodes a protein that is part of a ubiquitin ligase complex involved in targeting other proteins for degradation. Important among the targets of the VHL protein is the transcription factor hypoxia-inducible factor-1 (HIF-1). When *VHL* is inactive, HIF-1 levels remain high, even under normoxic conditions, causing inappropriate expression of a number of genes that are turned on by HIF. These include genes that promote angiogenesis, such as VEGF, and genes that stimulate cell growth, such as insulin-like growth factor-1 (IGF-1). In addition, HIF collaborates in complex ways with the oncogenic factor MYC to “reprogram” cellular metabolism in a way that favors growth. Deep sequencing of renal carcinoma genomes has revealed frequent mutations in a number of genes that regulate histone modifications, indicating that dysregulation of the epigenome also has an important role in clear cell carcinoma.
- *Papillary carcinoma* accounts for 10% to 15% of renal cancers. It is characterized by a papillary growth pattern and also occurs in both familial and sporadic forms. These tumors are not associated with 3p deletions. The most common cytogenetic abnormalities are trisomies 7 and 17 and loss of Y in male patients in the sporadic form, and trisomy 7 in the familial form. The gene on chromosome 7 for the familial form has been mapped to *MET*, a proto-oncogene that encodes the tyrosine kinase receptor for *hepatocyte growth factor*. *MET* is also mutated in a small proportion of sporadic papillary carcinomas. Described in Chapter 3, *hepatocyte growth factor* (also called *scatter factor*) mediates growth, cell

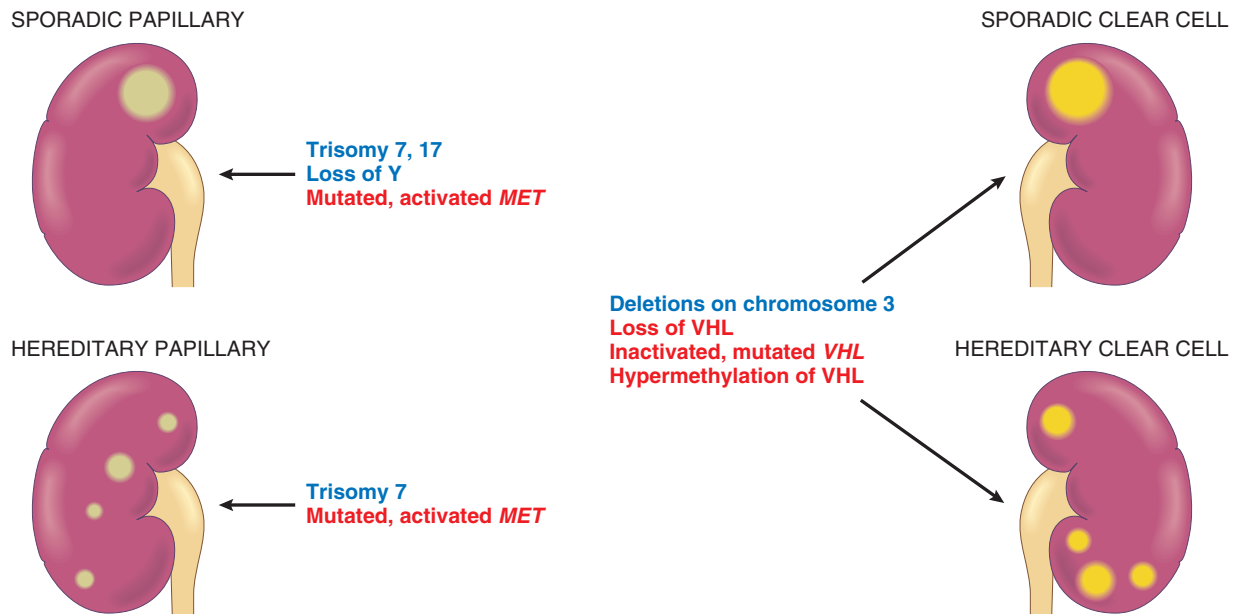

Figure 20-50 Cyto-genetics (blue) and genetics (red) of clear cell versus papillary renal cell carcinoma. (Courtesy Dr. Keith Ligon, Brigham and Women's Hospital, Boston, Mass.)

mobility, invasion, and morphogenetic differentiation. Unlike clear cell carcinomas, papillary carcinomas are frequently multifocal in origin.

- *Chromophobe carcinoma* represents 5% of renal cell cancers and is composed of cells with prominent cell membranes and pale eosinophilic cytoplasm, usually with a halo around the nucleus. On cytogenetic examination these tumors show multiple chromosome losses and extreme hypodiploidy. Like the benign oncocytoma, they are thought to grow from intercalated cells of collecting ducts and have an excellent prognosis compared with that of the clear cell and papillary cancers. Histologic distinction from oncocytoma can be difficult.
- *Xp11 translocation carcinoma* is a genetically distinct subtype of renal cell carcinoma. It often occurs in young patients and is defined by translocations of the *TFE3* gene located at Xp11.2 with a number of partner genes, all of which result in overexpression of the *TFE3* transcription factor. The neoplastic cells consist of clear cytoplasm with a papillary architecture.
- *Collecting duct (Bellini duct) carcinoma* represents approximately 1% or less of renal epithelial neoplasms. They arise from collecting duct cells in the medulla. Several chromosomal losses and deletions have been described, but a distinct pattern has not been identified. Histologically these tumors are characterized by malignant cells forming glands enmeshed within a prominent fibrotic stroma, typically in a medullary location. *Medullary carcinoma* is a morphologically similar neoplasm that is seen in patients with sickle cell trait.

MORPHOLOGY

Renal cell carcinomas may arise in any portion of the kidney, but more commonly affects the poles. **Clear cell carcinomas** most likely arise from proximal tubular epithelium, and usually

occur as solitary unilateral lesions. They are bright yellow-gray-white spherical masses of variable size that distort the renal outline. The yellow color is a consequence of the prominent lipid accumulations in tumor cells. There are commonly large areas of gray-white necrosis and foci of hemorrhagic discoloration. The margins are usually sharply defined and confined within the renal capsule (Fig. 20-51). In clear cell carcinoma the growth pattern varies from solid to trabecular (cordlike) or tubular (resembling tubules). The tumor cells have a rounded or polygonal shape and abundant clear or granular cytoplasm, which contains glycogen and lipids (Fig. 20-52A). The tumors have

Figure 20-51 Renal cell carcinoma. Typical cross-section of yellowish, spherical neoplasm in one pole of the kidney. Note the tumor in the dilated thrombosed renal vein.

Figure 20-52 Renal cell carcinoma. **A**, Clear cell type. **B**, Papillary type. Note the papillae and foamy macrophages in the stalk. **C**, Chromophobe type. (Courtesy Dr. A. Renshaw, Baptist Hospital, Miami, Fla.)

delicate branching vasculature and may show cystic as well as solid areas. Most tumors are well differentiated, but some show nuclear atypia with bizarre nuclei and giant cells.

As tumors enlarge they may bulge into the calyces and pelvis and eventually fungate through the walls of the collecting system to extend into the ureter. **One of the striking characteristics of renal cell carcinoma is its tendency to invade the renal vein (Fig. 20-51)**, in which it may grow as a solid column of cells that extends up the inferior vena cava, sometimes as far as the right side of the heart.

Papillary carcinomas, thought to arise from distal convoluted tubules, can be multifocal and bilateral. They are typically hemorrhagic and cystic, especially when large. The tumor is composed of cuboidal or low columnar cells arranged in

papillary formations. Interstitial foam cells are common in the papillary cores (Fig. 20-52B). Psammoma bodies may be present. The stroma is usually scanty but highly vascularized. **Chromophobe renal carcinoma** is made up of pale eosinophilic cells, often with a perinuclear halo, arranged in solid sheets with a concentration of the largest cells around blood vessels (Fig. 20-52C). **Collecting duct carcinoma** is a rare variant showing irregular channels lined by highly atypical epithelium with a hobnail pattern. Sarcomatoid changes arise infrequently in all types of renal cell carcinoma and are a decidedly ominous feature.

Clinical Features. The classic clinical features of renal cell carcinoma are *costovertebral pain*, *palpable mass*, and *hematuria*, but all three are seen in only 10% of cases. The most reliable clue is hematuria, but it is usually intermittent and may be microscopic; thus, the tumor may remain silent until it attains a large size, often greater than 10 cm. At this time it is often associated with generalized constitutional symptoms, such as fever, malaise, weakness, and weight loss. This pattern of asymptomatic growth occurs in many patients, so the tumor may have reached a diameter of more than 10 cm when it is discovered. Currently, an increasing number of tumors are being discovered in the asymptomatic state by incidental radiologic studies (e.g., computed tomographic scan or magnetic resonance imaging) performed for other indications.

Renal cell carcinoma is considered one of the great mimics in medicine, because it tends to produce a diversity of systemic symptoms not related to the kidney. In addition to fever and constitutional symptoms mentioned earlier, renal cell carcinomas produce a number of syndromes ascribed to abnormal hormone production, including *polycythemia*, *hypercalcemia*, *hypertension*, *hepatic dysfunction*, *feminization or masculinization*, *Cushing syndrome*, *eosinophilia*, *leukemoid reactions*, and *amyloidosis*.

A particularly troublesome feature of renal cell carcinoma is its tendency to metastasize widely before giving rise to any local symptoms or signs. In 25% of new patients with renal cell carcinoma, there is radiologic evidence of metastases at the time of presentation. The most common locations of metastasis are the lungs (more than 50%) and bones (33%), followed in frequency by the regional lymph nodes, liver, adrenal, and brain.

The average 5-year survival rate of persons with renal cell carcinoma is about 70% and as high as 95% in the absence of distant metastases. With renal vein invasion or extension into the perinephric fat, the figure is reduced to approximately 60%. Radical nephrectomy has been the treatment of choice, but partial nephrectomy to preserve renal function is recommended for T1a tumors (<4 cm) as well as larger tumors when technically feasible. Drugs that inhibit VEGF and various tyrosine kinases are used as an adjunct to therapy in patients with metastatic disease.

Urothelial Carcinoma of the Renal Pelvis

Approximately 5% to 10% of primary renal tumors originate from the urothelium of the renal pelvis (Fig. 20-53). These tumors range from apparently benign papillomas to invasive urothelial (transitional cell) carcinomas.

Renal pelvic tumors usually become clinically apparent within a relatively short time, because they lie within the

Figure 20-53 Urothelial carcinoma of the renal pelvis. The pelvis has been opened to expose the nodular irregular neoplasm, just proximal to the ureter.

pelvis and, by fragmentation, produce noticeable hematuria. They are almost invariably small when discovered. These tumors may block the urinary outflow and lead to palpable hydronephrosis and flank pain. On histologic examination, pelvic tumors are the exact counterpart of those found in the urinary bladder; further details are in [Chapter 21](#).

Urothelial tumors may occasionally be multiple, involving the pelvis, ureters, and bladder. In 50% of renal pelvic tumors there is a preexisting or concomitant bladder urothelial tumor. On histologic examination, there are also foci of atypia or carcinoma in situ in grossly normal urothelium remote from the pelvic tumor. There is an increased incidence of urothelial carcinomas of the renal pelvis in individuals with Lynch syndrome and analgesic nephropathy.

Infiltration of the wall of the pelvis and calyces is common. For this reason, despite their apparently small, deceptively benign appearance, the prognosis for these tumors is not good. Reported 5-year survival rates vary from 50% to 100% for low-grade noninvasive lesions to 10% with high-grade infiltrating tumors.

KEY CONCEPTS

Kidney Neoplasms

- Clear cell renal cell carcinoma is the most common subtype of malignant renal neoplasms, which often involves *VHL*, a tumor suppressor gene.
- Papillary renal cell carcinoma is the second most common subtype of malignant renal neoplasms, which may involve the *MET* proto-oncogene.
- Hereditary forms of renal cell carcinoma have led to the discovery of important genes (e.g., *VHL*, *BHD*) in renal carcinogenesis.
- Urothelial tumors resembling similar tumors in the urinary bladder can also originate in the renal pelvis. These tumors have a poor prognosis.

THE LOWER URINARY TRACT

The renal pelves, ureters, bladder, and urethra (except the terminal portion) are lined by a special form of transitional epithelium called *urothelium*. Urothelium is composed of five to six layers of cells with oval nuclei, often with linear nuclear grooves, and a surface layer consisting of large, flattened “umbrella cells” with abundant cytoplasm. This epithelium rests on a well-developed basement membrane, beneath which is a lamina propria. The lamina propria in the urinary bladder contains wisps of smooth muscle that form discontinuous muscularis mucosae. It is important to differentiate the muscularis mucosae from the deeper well-defined larger muscle bundles of the detrusor muscle (muscularis propria), since bladder cancers are staged on the basis of invasion of the latter. If urine flow is obstructed

and intravesical pressures rise, the bladder musculature undergoes hypertrophy.

The ureters lie throughout their course in a retroperitoneal position. Retroperitoneal tumors or fibrosis may entrap the ureters, sometimes obstructing them. As ureters enter the pelvis, they pass anterior to either the common iliac or the external iliac artery. In the female pelvis they lie close to the uterine arteries and are therefore vulnerable to injury in operations on the female genital tract. There are three points of slight narrowing—at the ureteropelvic junction, where they enter the bladder, and where they cross the iliac vessels—all locales where renal calculi may become impacted when they pass from the kidney to the bladder. As the ureters enter the bladder they pursue an

oblique course, terminating in a slitlike orifice. The obliquity of this intramural segment of the ureteral orifice permits the enclosing bladder musculature to act like a sphincteric valve, blocking the upward reflux of urine even in the presence of marked distention of the urinary bladder. As discussed in [Chapter 20](#), a defect in the intravesical portion of the ureter leads to vesicoureteral reflux.

The close relationship of the female genital tract to the bladder makes possible the spread of disease from one tract to the other. In middle-aged and older women, relaxation of pelvic support leads to prolapse (descent) of the uterus, pulling with it the floor of the bladder. In this fashion the bladder is protruded into the vagina, creating a pouch (*cystocele*) that fails to empty readily with micturition. In males, the seminal vesicles and prostate have similar close relationships, being situated just posterior and inferior to the neck of the bladder. Thus, enlargement of the prostate, so common in middle to later life, constitutes an important cause of urinary tract obstruction. Subsequent sections discuss the major pathologic lesions of the ureters, urinary bladder, and urethra.

Ureters

Congenital Anomalies

Congenital anomalies of the ureters are found in about 2% or 3% of all autopsies. Although most have little clinical significance, certain anomalies may contribute to obstruction of the flow of urine and thus cause clinical disease. Anomalies of the ureterovesical junction that potentiate reflux are discussed with pyelonephritis in [Chapter 20](#).

- **Double and bifid ureters.** Double ureters are almost invariably associated with totally distinct double renal pelves or with the anomalous development of a large kidney having a partially bifid pelvis terminating in separate ureters. Double ureters may pursue separate courses to the bladder but commonly are joined within the bladder wall and drain through a single ureteral orifice. Most are unilateral and of no clinical significance.
- **Ureteropelvic junction (UPJ) obstruction** is a congenital disorder that is the most common cause of hydronephrosis in infants and children. Cases that present early in life are bilateral in 20% of cases, are often associated with other congenital anomalies, and preferentially occur in males. There is agenesis of the contralateral kidney in a minority of cases. In adults, UPJ obstruction is more common in women and is most often unilateral. The condition has been ascribed to abnormal organization of smooth muscle bundles at the UPJ, to excess stromal deposition of collagen between smooth muscle bundles, or rarely to congenitally extrinsic compression of the UPJ by renal vessels.
- **Diverticula**, saccular outpouchings of the ureteral wall, are uncommon lesions that may be congenital or acquired. Most are asymptomatic, but urinary stasis within diverticula sometimes leads to recurrent infections. Dilation (*hydroureter*), elongation, and tortuosity of the ureters may occur as congenital anomalies or as acquired defects.

Figure 21-1 Opened ureters showing ureteritis cystica. Note smooth cysts projecting from the mucosa.

Inflammation

Ureteritis, though associated with inflammation, is typically not associated with infection and is of little clinical consequence.

MORPHOLOGY

The accumulation or aggregation of lymphocytes forming germinal centers in the subepithelial region may cause slight elevations of the mucosa and produce a fine granular mucosal surface (**ureteritis follicularis**). At other times the mucosa may become sprinkled with fine cysts varying in diameter from 1 to 5 mm lined by flattened urothelium (**ureteritis cystica**) ([Fig. 21-1](#)).

Tumors and Tumor-like Lesions

Primary tumors of the ureter are rare. Small benign tumors of the ureter are generally of mesenchymal origin. *Fibroepithelial polyp* is a tumor-like lesion that presents as a small mass projecting into the lumen, often in children. This lesion occurs more commonly in the ureters but may also involve the bladder, renal pelves, and urethra. The polyp is composed of loose, vascularized connective tissue overlaid by urothelium.

Primary malignant tumors of the ureter resemble those arising in the renal pelvis, calyces, and bladder. The majority are *urothelial carcinomas* ([Fig. 21-2](#)). They occur most frequently during the sixth and seventh decades of life and cause obstruction of the ureteral lumen. They are sometimes multifocal and commonly occur concurrently with similar neoplasms in the bladder or renal pelvis.

Obstructive Lesions

A great variety of lesions may obstruct the ureters and give rise to *hydroureter*, *hydronephrosis*, and sometimes *pyelonephritis* ([Chapter 20](#)). It is not the ureteral dilation that is of significance in these cases, but the consequent involvement of the kidneys. The more important causes, divided into those of intrinsic or extrinsic origin, are listed in [Table 21-1](#).

Figure 21-2 Papillary transitional cell carcinoma extensively involving the ureter. (Courtesy Dr. Cristina Magi-Galluzzi, The Johns Hopkins Hospital, Baltimore, Md.)

Unilateral obstruction typically results from proximal causes, whereas bilateral obstruction arises from distal causes, such as nodular hyperplasia of the prostate. Only sclerosing retroperitoneal fibrosis is discussed further.

Sclerosing Retroperitoneal Fibrosis. This uncommon cause of ureteral narrowing or obstruction is characterized by a fibrotic proliferative inflammatory process encasing the retroperitoneal structures and causing hydronephrosis. The disorder occurs in middle to late age and is more common in males than females. At least a subset of these cases is related to *IgG4-related disease*, a recently described entity associated with elevated levels serum IgG4 and fibroinflammatory lesions rich in IgG4-secreting plasma cells (Chapter 6). In addition to the retroperitoneum, this

Table 21-1 Major Causes of Ureteral Obstruction

Type of Obstruction	Cause
Intrinsic	
Calculi	Of renal origin, rarely more than 5 mm in diameter Larger renal stones cannot enter ureters Impact at loci of ureteral narrowing—ureteropelvic junction, where ureters cross iliac vessels, and where they enter bladder—and cause excruciating “renal colic”
Strictures	Congenital or acquired (inflammations)
Tumors	Transitional cell carcinomas arising in ureters Rarely, benign tumors or fibroepithelial polyps
Blood clots	Massive hematuria from renal calculi, tumors, or papillary necrosis
Neurogenic	Interruption of the neural pathways to the bladder
Extrinsic	
Pregnancy	Physiologic relaxation of smooth muscle or pressure on ureters at pelvic brim from enlarging fundus
Periureteral inflammation	Salpingitis, diverticulitis, peritonitis, sclerosing retroperitoneal fibrosis
Endometriosis	With pelvic lesions, followed by scarring
Tumors	Cancers of the rectum, bladder, prostate, ovaries, uterus, cervix; lymphomas, sarcomas

disorder often involves other tissues as well, particularly exocrine organs such as the pancreas and salivary glands. Other cases of retroperitoneal fibrosis are associated with drug exposures (ergot derivatives, β -adrenergic blockers), adjacent inflammatory conditions (vasculitis, diverticulitis, Crohn disease), or malignant disease (lymphomas, urinary tract carcinomas). Most, however, have no obvious cause and are considered primary or idiopathic (Ormond disease).

Microscopic examination typically reveals fibrous tissue containing a prominent infiltrate of lymphocytes, often with germinal centers, plasma cells (frequently IgG4-positive), and eosinophils. Treatment initially involves corticosteroids, although many patients eventually become resistant and require ureteral stents or surgical extrication of the ureters from the surrounding fibrous tissue (ureterolysis).

KEY CONCEPTS

Disorders of the Ureters

- Ureteral obstruction is clinically significant because it can subsequently involve the kidney (hydronephrosis or even pyelonephritis), compromising renal function.
- In children, congenital ureteropelvic junction (UPJ) obstruction is the most common obstructive lesion in the ureter.
- In adults, ureteral obstruction may be acute (e.g., due to obstructing calculi), or chronic (e.g., due to intrinsic or extrinsic tumors or rarely idiopathic conditions such as sclerosing retroperitoneal fibrosis).

Urinary Bladder

Diseases of the bladder are often disabling but rarely lethal. Cystitis is particularly common in young women of reproductive age. Tumors of the bladder are an important source of both morbidity and mortality.

Congenital Anomalies

- **Vesicoureteral reflux** is the most common and serious congenital anomaly. As a major contributor to renal infection and scarring, it was discussed earlier, in Chapter 20, in the consideration of pyelonephritis. Abnormal connections between the bladder and the vagina, rectum, or uterus may create *congenital vesicouterine fistulae*.
- **Diverticula** are pouchlike evaginations of the bladder wall that vary from less than 1 cm to 5 to 10 cm in diameter and may be congenital or acquired. *Congenital diverticula* may be due to a focal failure of development of the normal musculature or to some urinary tract obstruction during fetal development. *Acquired diverticula* are most often seen with prostatic enlargement (hyperplasia or neoplasia), producing obstruction to urine outflow and marked muscle thickening of the bladder wall. The increased intravesical pressure causes outpouching of the bladder wall and the formation of diverticula. They are frequently multiple and have narrow necks located

between the interweaving hypertrophied muscle bundles.

Although most diverticula are small and asymptomatic, they may be clinically significant, since they constitute sites of urinary stasis and predispose to infection and the formation of bladder calculi. They may also predispose to vesicoureteral reflux as a result of impingement on the ureter. Rarely, a carcinoma may arise in a bladder diverticulum; such tumors tend to be more advanced in stage as a result of the thin or absent muscle wall of diverticula.

- **Exstrophy of the bladder** is a developmental failure in the anterior wall of the abdomen and the bladder, so that the bladder either communicates directly through a large defect with the surface of the body or lies as an opened sac (Fig. 21-3). The exposed bladder mucosa may undergo colonic glandular metaplasia and is subject to infections that often spread to upper levels of the urinary system. Patients have an increased risk of adenocarcinoma arising in the bladder remnant. These lesions are amenable to surgical correction, and long-term survival is possible.
- **Urachal anomalies.** The urachus (the canal that connects the fetal bladder with the allantois) is normally obliterated after birth, but it sometimes remains patent in part or in whole. When totally patent, a *fistulous urinary tract* connects the bladder with the umbilicus. In other instances, only the central region of the urachus persists, giving rise to *urachal cysts*, lined by either urothelium or metaplastic glandular epithelium. **Carcinomas**, mostly glandular tumors, may arise from such cysts (see “Neoplasms”). These account for only a minority of all bladder cancers (0.1% to 0.3%) but 20% to 40% of bladder adenocarcinomas.

Inflammation

Acute and Chronic Cystitis

Bacterial pyelonephritis is frequently preceded by infection of the urinary bladder, with retrograde spread of microorganisms into the kidneys and their collecting systems

Figure 21-3 Exstrophy of the bladder in a newborn boy. The tied umbilical cord is seen above the hyperemic mucosa of the everted bladder. Below is an incompletely formed penis with marked epispadias. (Courtesy of Dr. John Gearhart, The Johns Hopkins Hospital, Baltimore, MD.)

(discussed in Chapter 20). The common etiologic agents of cystitis are the coliforms: *Escherichia coli*, followed by *Proteus*, *Klebsiella*, and *Enterobacter*. Women are more likely to develop cystitis as a result of their shorter urethras. *Tuberculous cystitis* is almost always a sequel to renal tuberculosis. *Candida albicans* and, much less often, cryptococcal agents cause cystitis, particularly in immunosuppressed patients or those receiving long-term antibiotics. Schistosomiasis (*Schistosoma haematobium*) is rare in the United States but is common in certain Middle Eastern countries, notably Egypt. Viruses (e.g., adenovirus), *Chlamydia*, and *Mycoplasma* may also cause cystitis. Predisposing factors include bladder calculi, urinary obstruction, diabetes mellitus, instrumentation, and immune deficiency. Finally, irradiation of the bladder region gives rise to *radiation cystitis*.

MORPHOLOGY

Most cases of cystitis produce nonspecific acute or chronic inflammation of the bladder. In acute cystitis there is hyperemia of the mucosa and neutrophilic infiltrate, sometimes associated with exudate. Patients receiving **cytotoxic antitumor drugs**, such as cyclophosphamide, may develop **hemorrhagic cystitis**. Adenovirus infection also causes a hemorrhagic cystitis. Persistence of the bacterial infection leads to **chronic cystitis** associated with mononuclear inflammatory infiltrates.

Other patterns of chronic cystitis worthy of brief mention are not always related to infection. **Follicular cystitis** is characterized by the presence of lymphoid follicles within the bladder mucosa and underlying wall. **Eosinophilic cystitis**, manifested by infiltration with submucosal eosinophils, typically is a nonspecific subacute inflammation but may also be a manifestation of a systemic allergic disorder.

All forms of cystitis are characterized by a triad of symptoms: (1) frequency, which in acute cases may necessitate urination every 15 to 20 minutes; (2) lower abdominal pain localized over the bladder region or in the suprapubic region; and (3) dysuria—pain or burning on urination.

The local symptoms of cystitis may be merely disturbing, but these infections may also be antecedents to pyelonephritis, a more serious disorder (Chapter 20). Cystitis is sometimes a secondary complication of an underlying disorder associated with urinary stasis, such as prostatic enlargement, cystocele of the bladder, calculi, or tumors. These primary diseases must be corrected before the cystitis can be relieved.

Special Forms of Cystitis

Several variants of cystitis have distinctive causes or morphologic appearances.

Interstitial Cystitis (Chronic Pelvic Pain Syndrome). This form of chronic cystitis occurs most frequently in women and is characterized by intermittent, often severe, suprapubic pain, urinary frequency, urgency, hematuria and dysuria, and cystoscopic findings of fissures and punctate hemorrhages (glomerulations) in the bladder mucosa after luminal distention. The etiology of this troubling condition is unknown, its evaluation and diagnosis remain controversial, and its treatment is largely empiric. Some

cases are associated with chronic mucosal ulcers (*Hunner ulcers*); this is termed the *late (classic, ulcerative) phase*. Increased numbers of mucosal mast cells are characteristic of this disease, but their pathogenic significance and diagnostic utility are uncertain. Late in the course, transmural fibrosis may appear, leading to a contracted bladder. The pathologic findings are nonspecific, and the main role of biopsy is to rule out carcinoma in situ, which may mimic interstitial cystitis clinically.

Malakoplakia. A distinctive chronic inflammatory reaction that appears to stem from acquired defects in phagocyte function, malakoplakia arises in the setting of chronic bacterial infection, mostly by *E. coli* or occasionally *Proteus* species. It occurs with increased frequency in immunosuppressed transplant recipients.

MORPHOLOGY

In the bladder, malakoplakia takes the form of soft, yellow, slightly raised mucosal plaques, 3 to 4 cm in diameter (Fig. 21-4), that are filled with large, foamy macrophages mixed with occasional multinucleate giant cells and lymphocytes. The **macrophages have an abundant granular cytoplasm** due to phagosomes stuffed with particulate and membranous debris of bacterial origin. In addition, laminated mineralized concretions resulting from deposition of calcium in enlarged lysosomes, known as **Michaelis-Gutmann bodies**, are typically present within the macrophages (Fig. 21-5). The unusual-appearing macrophages and giant phagosomes point to defects in the phagocytic function of macrophages, which become overloaded with undigested bacterial products. Similar lesions have been described in the colon, lungs, bones, kidneys, prostate, and epididymis.

Figure 21-4 Cystitis with malakoplakia showing inflammatory exudate and broad, flat plaques.

Figure 21-5 Malakoplakia, periodic acid-Schiff (PAS) stain. Note the large macrophages with granular PAS-positive cytoplasm and several dense, round Michaelis-Gutmann bodies surrounded by artifactual cleared holes in the upper middle field (arrow).

Polypoid Cystitis. Polypoid cystitis is an inflammatory lesion resulting from irritation of the bladder mucosa. Although indwelling catheters are the most commonly cited culprits, any injurious agent may give rise to this lesion. The urothelium is thrown into broad bulbous polypoid projections as a result of marked submucosal edema. Polypoid cystitis may be confused with papillary urothelial carcinoma both clinically and histologically.

Metaplastic Lesions

- **Cystitis glandularis and cystitis cystica.** These are common lesions of the urinary bladder in which nests of urothelium (Brunn nests) grow downward into the lamina propria. Here, epithelial cells in the center of the nest undergo metaplasia and take on a cuboidal or columnar appearance (*cystitis glandularis*), or retract to produce cystic spaces lined by flattened urothelium (*cystitis cystica*). Because the two processes often coexist, the condition is typically referred to as *cystitis cystica et glandularis*. In a variant of cystitis glandularis goblet cells are present, and the epithelium resembles intestinal mucosa (*intestinal or colonic metaplasia*). Both variants are common incidental findings in normal bladders, but they can also arise in the setting of inflammation and metaplasia.
- **Squamous metaplasia.** As a response to injury, the urothelium is often replaced by nonkeratinizing squamous epithelium, which is a more durable lining. This should be distinguished from glycogenated squamous epithelium that is normally found in women at the trigone.
- **Nephrogenic adenoma.** Nephrogenic adenoma is an unusual lesion that results from implantation of shed renal tubular cells at sites of injured urothelium. The overlying urothelium may be focally replaced by cuboidal epithelium, which can assume a papillary growth pattern. Although the lesions are typically less than a centimeter in size, larger lesions have been reported that can produce signs and symptoms that raise a suspicion of cancer. In addition, the tubular proliferation can

infiltrate the underlying lamina propria and superficial detrusor muscle, mimicking a malignant process.

KEY CONCEPTS

Inflammatory disorders and metaplasias of the bladder

- The bladder can be involved by a number of inflammatory lesions, many of which manifest with frequency and dysuria.
- Acute or chronic bacterial cystitis is extremely common, particularly in women, and results from retrograde spread of colonic bacteria in most cases.
- Other forms of cystitis have iatrogenic causes, such as radiation cystitis and hemorrhagic cystitis due to antitumor chemotherapeutics.
- Some inflammatory or metaplastic bladder lesions are significant in that they may clinically mimic bladder cancer, including malakoplakia, polypoid cystitis, cystitis cystica et glandularis and nephrogenic adenoma.

Neoplasms

Bladder cancer accounts for approximately 7% of cancers and 3% of cancer mortality in the United States. About 95% of bladder tumors are of epithelial origin, the remainder being mesenchymal tumors (Table 21-2). Most epithelial tumors are urothelial (transitional cell) type and are thus interchangeably called *urothelial or transitional tumors*, but squamous and glandular carcinomas also occur. Here we focus on urothelial tumors and touch briefly on the others.

Urothelial Tumors

Urothelial tumors represent about 90% of all bladder tumors and run the gamut from small benign lesions that do not recur to aggressive cancers that are often fatal. Many of these tumors are multifocal at presentation. Though most common in the bladder, all of the urothelial lesions described here may be seen at any site where there is urothelium, from the renal pelvis to the distal urethra.

There are two distinct precursor lesions to invasive urothelial carcinoma: noninvasive papillary tumors and flat noninvasive urothelial carcinoma. The most common precursor lesions are the noninvasive papillary tumors, which originate from papillary urothelial hyperplasia. These tumors have a range of atypical changes, and are graded according to their biologic behavior. The other precursor lesion to invasive carcinoma, flat noninvasive urothelial carcinoma is referred to as carcinoma in situ, or CIS.

As discussed in Chapter 7, CIS is a term used to describe epithelial lesions that have the cytologic features of malignancy but are confined to the epithelium, showing no evidence of basement membrane invasion. Such lesions are considered to be high grade. In about one half of individuals with invasive bladder cancer, the tumor has already invaded the bladder wall at the time of presentation, and precursor lesions are not detected. It is presumed in such cases that the precursor lesion was destroyed by the high-grade invasive component, which typically appears as a large, frequently ulcerated mass. Although invasion into the lamina propria worsens the prognosis, the major decrease in survival is associated with invasion of the muscularis propria (detrusor muscle). Once muscularis propria invasion occurs, there is a 30% 5-year mortality rate.

Table 21-3 lists two of the most common grading systems of these tumors. The World Health Organization (WHO) 1973 classification grades tumors into a rare totally benign papilloma and three grades of transitional cell carcinoma (grades I, II, and III). A more recent classification, based on a consensus reached at a conference by the International Society of Urological Pathology (ISUP) in 1998 and adopted by the WHO in 2004, recognizes a rare benign papilloma, a group of papillary urothelial neoplasms of low malignant potential, and two grades of carcinoma (low and high grade).

Epidemiology and Pathogenesis. The incidence of carcinoma of the bladder is higher in men than in women, in developed than in developing nations, and in urban than in rural dwellers. The male-to-female ratio for urothelial tumors is approximately 3:1. About 80% of patients are between 50 and 80 years of age. Bladder cancer, with rare exceptions, is not familial.

Several factors have been implicated in the causation of urothelial carcinoma. Some of the more important contributors include the following:

- **Cigarette smoking is clearly the most important influence, increasing the risk threefold to sevenfold, depending on the duration and type of tobacco use.** Between 50% and 80% of all bladder cancers among men are associated with the use of cigarettes. Cigars, pipes, and smokeless tobacco are associated with a smaller risk.
- **Industrial exposure to aryl amines, particularly 2-naphthylamine and related compounds, as pointed out in our earlier discussion of chemical carcinogenesis**

(Chapter 7). The cancers appear 15 to 40 years after the first exposure.

- *Schistosoma haematobium* infections in endemic areas (Egypt, Sudan) are an established risk. The ova are deposited in the bladder wall and incite a brisk chronic inflammatory response that induces progressive mucosal squamous metaplasia and dysplasia and, in some instances, neoplasia. Seventy percent of the cancers are squamous, the remainder being urothelial or, least commonly, glandular.
- **Long-term use of analgesics** is implicated, as it is in analgesic nephropathy (Chapter 20).
- **Heavy long-term exposure to cyclophosphamide**, an immunosuppressive agent, induces, as noted, hemorrhagic cystitis, and increases the risk of bladder cancer.
- **Irradiation**, often administered for other pelvic malignancies, increases the risk of urothelial carcinoma. In this setting, bladder cancer occurs many years after the irradiation.

Several acquired genetic alterations have been observed in urothelial carcinoma, many of which lead to constitutive activation of growth factor receptor signaling cascades (Chapter 7). Some of these alterations are strongly associated with tumor histopathology. These include gain-of-function mutations in *FGFR3*, which are found predominantly in noninvasive low-grade papillary carcinomas and result in constitutive activation of the *FGFR3* receptor tyrosine kinase. In contrast, loss-of-function mutations in the *TP53* and *RB* tumor suppressor genes are almost always seen in high-grade and, frequently, muscle invasive tumors. Other genetic alterations are not as tightly associated with tumor histologic features. Activating mutations in the *HRAS* oncogene are frequently found, particularly in low-grade, noninvasive tumors. Recalling that *RAS* signal transducers act downstream of receptor tyrosine kinases such as *FGFR3*, it is not surprising that *HRAS* and *FGFR3* mutations are generally mutually exclusive in bladder cancer.

Particularly common (occurring in 30% to 60% of tumors) are losses of genetic material on chromosome 9 (including monosomy or deletions of 9p and 9q). These abnormalities are often the only chromosomal changes present in superficial noninvasive papillary tumors and occasionally in noninvasive flat tumors, suggesting that these are early events in the evolution of bladder carcinomas. The 9p deletions (9p20) span a region that includes the tumor suppressor gene *CDKN2A*, which encodes the cyclin-dependent kinase inhibitor p16/INK4a and *ARF*, a protein that augments p53 function (Chapter 7). Several different tumor suppressor genes have been proposed to be the target of deletions on chromosome 9q, including *PTCH*, which encodes a negative regulator of the Hedgehog signaling pathway, and *TSC1*, which encodes a negative regulator of mTOR signaling. On the basis of these findings, a model for bladder carcinogenesis has been proposed. In this two-pathway model, low-grade superficial papillary tumors are characterized by *FGFR3* and *RAS* mutations and chromosome 9 deletions. Of these, a minority may then lose *TP53* and/or *RB* function and progress to invasion. In the second more aggressive pathway, noninvasive high-grade flat or papillary lesions are initiated by *TP53* mutations and, with loss of chromosome 9 and

Figure 21-6 Four morphologic patterns of bladder tumors. CIS, Carcinoma in situ.

acquisition of other, still to be characterized mutations, progression to invasion ensues (Chapter 7).

MORPHOLOGY

The appearance of urothelial tumors varies from purely papillary to nodular or flat (Fig. 21-6). Most arise from the lateral or posterior walls at the bladder base. Papillary lesions are red, elevated excrescences ranging in size from less than 1 cm in diameter to large masses up to 5 cm in diameter (Fig. 21-7). Multiple discrete tumors are often present. As noted, the histologic features encompass a spectrum from benign papilloma to highly aggressive anaplastic cancers. Overall, the majority of papillary tumors are low grade.

- **Papillomas** represent 1% or less of bladder tumors, and are usually seen in younger patients. These tumors typically arise singly as small (0.5 to 2 cm), delicate, structures, superficially

Figure 21-7 Cross-section of bladder with upper section showing a large papillary tumor. The lower section demonstrates multifocal smaller papillary neoplasms. (Courtesy Dr. Fred Gilkey, Sinai Hospital, Baltimore, Md.)

Figure 21-8 Papilloma consisting of small papillary fronds lined by normal-appearing urothelium.

attached to the mucosa by a stalk and are referred to as **exophytic papillomas**. The individual finger-like papillae have a central core of loose fibrovascular tissue covered by epithelium that is **histologically identical to normal urothelium** (Fig. 21-8). Recurrences and progression are rare but may occur. In contrast to exophytic papillomas, **inverted papillomas** are completely benign lesions consisting of inter-anastomosing cords of cytologically bland urothelium that extend down into the lamina propria.

- **Papillary urothelial neoplasms of low malignant potential** share many histologic features with papilloma, differing only in having thicker urothelium. At cystoscopy, these tumors tend to be larger than papillomas and may be indistinguishable from low- and high-grade papillary cancers. Recurrent tumors usually show the same morphology; progression to tumors of higher grade may occur but is rare.
- **Low-grade papillary urothelial carcinomas** have an orderly architectural and cytologic appearance. The cells are evenly spaced (i.e., maintain polarity) and cohesive. There is a mild degree of nuclear atypia consisting of scattered hyperchromatic nuclei, infrequent mitotic figures predominantly toward the base, and slight variation in nuclear size and shape (Fig. 21-9). These low-grade cancers may recur and,

Figure 21-9 Low-grade papillary urothelial carcinoma with an overall orderly appearance, with a thicker lining than papilloma and scattered hyperchromatic nuclei and mitotic figures (arrows).

Figure 21-10 High-grade papillary urothelial carcinoma with marked cytologic atypia.

although infrequent, may also invade. Only rarely do these tumors pose a threat to the patient's life.

- **High-grade papillary urothelial cancers** contain dyscohesive cells with large hyperchromatic nuclei. Some of the tumor cells are highly anaplastic (Fig. 21-10). Mitotic figures, including atypical ones, are frequent. Architecturally, there is disarray and loss of polarity. As compared to low-grade lesions, these tumors have a much higher incidence of invasion into the muscular layer, a higher risk of progression, and, when associated with invasion, a significant metastatic potential.

In most series, less than 10% of low-grade cancers invade, but as many as 80% of high-grade urothelial carcinomas are invasive. Aggressive tumors may extend into the bladder wall, and, in more advanced stages, invade the adjacent prostate, seminal vesicles, ureters, and retroperitoneum. Some tumors produce fistulous communications to the vagina or rectum. About 40% of these deeply invasive tumors metastasize to regional lymph nodes. Hematogenous dissemination, principally to the liver, lungs, and bone marrow, may result.

Carcinoma in situ (CIS, or flat urothelial carcinoma) is defined by the presence of cytologically malignant cells within a flat urothelium. CIS may range from full-thickness cytologic atypia to scattered malignant cells in an otherwise normal urothelium, the latter termed **pagetoid spread** (Fig. 21-11). A common feature shared with high-grade papillary urothelial carcinoma is a lack of cohesiveness, which leads to the shedding of malignant cells into the urine. When shedding is extensive, only a few CIS cells may be left clinging to a largely denuded basement membrane. CIS usually appears as an area of mucosal reddening, granularity, or thickening without an evident intraluminal mass. It is commonly multifocal and may involve most of the bladder surface and extend into the ureters and urethra. If untreated, 50% to 75% of CIS cases progress to invasive cancer.

Invasive urothelial cancer (Fig. 21-12) may be associated with papillary urothelial cancer, usually high grade, or adjacent CIS. The extent of the invasion into the muscularis mucosae is of prognostic significance, and understaging on biopsy is a significant problem. The extent of spread (**staging**) at the time

Figure 21-11 **A**, Normal urothelium with uniform nuclei and well-developed umbrella cell layer (arrow). **B**, Flat carcinoma in situ with numerous cells having enlarged and pleomorphic nuclei.

of initial diagnosis is the most important factor in determining the outlook for a patient (Table 21-4). Almost all infiltrating urothelial carcinomas are high grade, and as a result grading of the infiltrating component is not critical, as opposed to the importance of grading noninvasive papillary urothelial carcinoma.

Figure 21-12 Opened bladder showing a high-grade invasive transitional cell carcinoma at an advanced stage. The aggressive multinodular neoplasm has fungated into the bladder lumen and spread over a wide area. The yellow areas represent areas of ulceration and necrosis.

Variants of Urothelial Carcinoma. Unusual variants of urothelial cancer include a nested variant with deceptively bland cytology, lymphoepithelioma-like carcinoma, and micropapillary carcinoma.

Other Epithelial Bladder Tumors. *Squamous cell carcinomas* resembling squamous cancers occurring at other sites make up 3% to 7% of bladder cancers in the United States, but are much more frequent in countries where urinary schistosomiasis is endemic. Pure squamous cell carcinomas are nearly always associated with chronic bladder irritation and infection. *Mixed urothelial carcinomas with areas of squamous carcinoma* are more frequent than pure squamous cell carcinomas. Most are invasive, fungating tumors or are infiltrative and ulcerative. The level of cellular differentiation varies widely, from well differentiated lesions producing abundant keratin to anaplastic tumors with only focal evidence of squamous differentiation.

Adenocarcinomas of the bladder are rare and histologically identical to adenocarcinomas seen in the gastrointestinal tract. Some arise from urachal remnants or in association with extensive intestinal metaplasia (discussed earlier).

Small-cell carcinomas, indistinguishable from small-cell carcinomas of the lung, arise in the bladder often in association with urothelial, squamous, or adenocarcinoma.

Clinical Course of Bladder Cancer. Bladder tumors classically produce *painless hematuria*. This is their dominant and sometimes only clinical manifestation. Frequency, urgency, and dysuria occasionally accompany the hematuria. When the ureteral orifice is involved, pyelonephritis or hydronephrosis may follow. About 60% of neoplasms,

when first discovered, are single, and 70% are localized to the bladder.

Individuals with urothelial tumors, whatever their grade, have a tendency to develop new tumors after excision, and *recurrences* may show a higher grade. The risk of recurrence and progression is related to several variables, including tumor size, stage, grade, multifocality, prior recurrence rate, and associated dysplasia and/or CIS in the surrounding mucosa. Although the term recurrence is used, most of the subsequent tumors arise at different sites from the original lesion. In some instances the recurrences may be entirely independent new tumors, but in other cases they share the same clonal abnormalities as the initial tumor and represent a true recurrence caused (presumably) by shedding and implantation of the original tumor cells at a new anatomic site.

Prognosis depends on the histologic grade and the stage at diagnosis. Papillomas, papillary urothelial neoplasms of low malignant potential, and low-grade papillary urothelial cancer yield a 98% 10-year survival rate regardless of the number of recurrences; only a few patients (<10%) have progression of their disease to higher grade lesions. High-grade papillary urothelial carcinomas invade and lead to death in about 25% of cases. Patients with primary (de novo) CIS, as opposed to CIS associated with infiltrating urothelial carcinoma, are less likely to progress to muscle-invasive cancer (28% versus 59%) or die of disease (7% versus 45%). Invasive urothelial carcinoma is associated with a 30% mortality rate once tumor invades into the lamina propria. Overall, squamous cell carcinoma and adenocarcinoma are associated with a worse prognosis than urothelial carcinoma, yet stage for stage they are all similar.

The clinical challenge with these neoplasms is early detection and adequate follow-up. A significant issue is that 50% of invasive bladder cancers present with muscle-invasive disease and have a relatively poor prognosis despite therapy. For tumors detected at an earlier stage, cystoscopy and biopsy are the mainstays of diagnosis. Subsequently, patients are typically followed with additional surveillance cystoscopies to look for tumor recurrence. Additionally, cytologic examination of cells obtained from urine samples and tests performed on urine to detect chromosomal abnormalities (aneuploidy of chromosome 3, 7, and 17 and 9p deletions) by fluorescent in situ hybridization (FISH) are also helpful screening measures, particularly for CIS that might be missed by cystoscopy. The major limitation of both FISH and cytologic screening is that they often fail to identify low-grade neoplasms.

The selection of treatment for bladder cancer depends on the grade, stage, and whether the lesion is flat or papillary. For small, localized low-grade papillary tumors, the diagnostic transurethral resection is the only surgical procedure done. Patients are followed with cystoscopy and urine cytology for the rest of their lives to detect recurrence. Patients at high risk of recurrence and/or progression (CIS; papillary tumors that are high grade, multifocal, have a history of recurrence, or are associated with lamina propria invasion) receive intravesical instillation of an attenuated strain of *Mycobacterium bovis* called bacillus Calmette-Guérin (BCG). The bacteria elicit a local inflammatory reaction that destroys the tumor. Radical cystectomy is typically reserved for (1) tumor invading the

muscularis propria, (2) CIS or high-grade papillary cancer refractory to BCG, and (3) CIS extending into the prostatic urethra and into the prostatic ducts, where BCG will not come into contact with the neoplastic cells. Metastatic bladder cancer responds to chemotherapy, but is not curable with current agents.

Mesenchymal Tumors

Benign Tumors. A great variety of benign mesenchymal tumors may arise in the bladder, having the histologic features of their counterparts elsewhere. Collectively, they are rare. The most common is *leiomyoma*. They all tend to grow as isolated, intramural, encapsulated, oval-to-spherical masses, varying in diameter up to several centimeters.

Sarcomas. True sarcomas are distinctly uncommon in the bladder. Inflammatory myofibroblastic tumors and various carcinomas may assume sarcomatoid growth patterns and be mistaken histologically for sarcomas. As a group, sarcomas tend to produce large masses (varying up to 10 to 15 cm in diameter) that protrude into the vesicle lumen. Their soft, fleshy, gray-white gross appearance suggests their sarcomatous nature. The most common sarcoma in infancy or childhood is *embryonal rhabdomyosarcoma*. In some of these cases they manifest as a polypoid grapelike mass (*sarcoma botryoides*). The most common sarcoma in the bladder in adults is leiomyosarcoma (Chapter 26).

Secondary Tumors

Secondary malignant involvement of the bladder is most often by direct extension from primary lesions in nearby organs, cervix, uterus, prostate, and rectum. Lymphomas may involve the bladder as a component of systemic disease, but also, rarely, as primary bladder lymphoma.

KEY CONCEPTS

Bladder Tumors

- Bladder cancer is more common in males than in females and cigarette smoking constitutes one of the most important risk factors.
- Painless hematuria is a common presenting symptom of bladder cancer and requires clinical investigation by cystoscopy and/or urine cytology specimens to rule out urothelial neoplasia.
- There are two different noninvasive precursor lesions to invasive urothelial carcinoma: papillary urothelial carcinoma (which may be low- or high-grade) and flat urothelial carcinoma in situ (uniformly high grade).
- Noninvasive high-grade urothelial carcinoma (either papillary or flat) is associated with loss of the *TP53* and *RB* tumor suppressor genes and frequently progresses to muscle-invasive disease with the potential for systemic spread.
- Noninvasive low-grade papillary urothelial carcinoma is associated with gain of function *FGFR3* and *HRAS* mutations. While these tumors are infrequently life-threatening, they may locally recur and a subset may progress to high grade disease.

Figure 21-13 Hypertrophy and trabeculation of bladder wall secondary to polypoid hyperplasia of the prostate.

- Other epithelial bladder tumor variants may occur, either alone or mixed with urothelial carcinoma, including squamous cell carcinoma, adenocarcinoma and small cell carcinoma.

Obstruction

Obstruction of the bladder outlet is of major clinical importance because of its eventual effect on the kidney. In males, the most common cause is enlargement of the prostate gland due to nodular hyperplasia (Fig. 21-13). Bladder obstruction is less common in females and is most often caused by cystocele of the bladder. Infrequent causes are (1) congenital urethral strictures, (2) inflammatory urethral strictures, (3) inflammatory fibrosis and contraction of the bladder, (4) bladder tumors, either benign or malignant, (5) invasion of the bladder neck by tumors arising in contiguous organs, (6) mechanical obstructions caused by foreign bodies and calculi, and (7) injury of nerves controlling bladder contraction (neurogenic bladder).

MORPHOLOGY

In the early stages there is only thickening of the bladder wall due to smooth muscle hypertrophy. With progressive hypertrophy the individual muscle bundles greatly enlarge and produce trabeculation of the bladder wall. In the course of time, crypts form and may be converted into diverticula.

In some cases of acute obstruction or in terminal disease when the patient's normal reflex mechanisms are depressed, the bladder may become extremely dilated. The enlarged bladder may reach the brim of the pelvis or even the level of the umbilicus. In these cases the bladder wall is markedly thinned and lacks trabeculations.

Urethra

Inflammation

Urethritis is classically divided into gonococcal and nongonococcal causes. *Gonococcal urethritis* is one of the earliest

manifestations of this venereal infection. *Nongonococcal urethritis* is common and can be caused by several different organisms. Various strains of *Chlamydia* (e.g., *C. trachomatis*) are the cause of 25% to 60% of nongonococcal urethritis in men and about 20% in women. *Mycoplasma (Ureaplasma urealyticum)* also accounts for the symptoms of urethritis in many cases. Urethritis is often accompanied by cystitis in women and by prostatitis in men. In many instances of suspected bacterial urethritis, no organism can be isolated. Some urethritis is truly noninfectious in origin. An example of such an inflammatory urethritis is a disorder known as *reactive arthritis*, which is associated with the clinical triad of arthritis, conjunctivitis, and urethritis (Chapter 26).

The morphologic changes are entirely typical of inflammation in other sites within the urinary tract. The urethral involvement is not itself a serious clinical problem but may cause considerable local pain, itching, and frequency, and may warn of more serious disease at higher levels of the urogenital tract.

Tumors and Tumor-like Lesions

Urethral caruncle is an inflammatory lesion that presents as a small, red, painful mass about the external urethral meatus, typically in older females. It consists of inflamed granulation tissue covered by an intact but extremely friable mucosa, which may ulcerate and bleed with the slightest trauma. Surgical excision affords prompt relief and cure.

Benign epithelial tumors of the urethra include squamous and urothelial papillomas, inverted urothelial papillomas, and condylomas.

Primary carcinoma of the urethra is an uncommon lesion (Fig. 21-14). Tumors arising within the proximal urethra tend to show urothelial differentiation and are analogous to those occurring within the bladder, whereas lesions found within the distal urethra are more often squamous cell carcinomas. Adeno carcinomas are infrequent in the urethra and generally occur in women. Some neoplastic lesions of the urethra are similar to those described in the bladder, arising through metaplasia or, less commonly, from periurethral glands. Cancers arising within the prostatic urethra are dealt with in the section on the prostate.

Figure 21-14 Carcinoma of urethra with typical fungating growth.

THE MALE GENITAL TRACT

Penis

The penis can be affected by congenital anomalies, inflammations, and tumors, inflammations and tumors being the most important.

Congenital Anomalies

The penis is involved by many congenital anomalies; only those that are clinically significant are discussed here.

Hypospadias and Epispadias

Malformation of the urethral groove and urethral canal may create an abnormal urethral opening either on the ventral surface of the penis (*hypospadias*) or on the dorsal surface (*epispadias*). Either of these two anomalies may be associated with failure of normal descent of the testes and with malformations of the urinary tract. Hypospadias, the more common of the two, occurs in approximately 1 in 300 live male births. Even when isolated, these urethral defects may have clinical significance, because the abnormal opening is often constricted, resulting in urinary tract obstruction and an increased risk of ascending urinary tract infections. When the orifices are situated near the base of the penis, normal ejaculation and insemination are hampered and may be a cause of sterility.

Phimosis

When the orifice of the prepuce is too small to permit its normal retraction, the condition is designated *phimosis*. An abnormally small orifice may result from anomalous development but is more frequently the result of repeated attacks of infection that cause scarring of the preputial ring. Phimosis is important because it interferes with cleanliness and permits the accumulation of secretions and detritus under the prepuce, favoring the development of secondary infections and possibly carcinoma.

Inflammation

Inflammations of the penis almost invariably involve the glans and prepuce and include a wide variety of specific and nonspecific infections. The specific infections—syphilis, gonorrhea, chancroid, granuloma inguinale, lymphopathia venerea, genital herpes—are sexually transmitted and are discussed in [Chapter 8](#). Only the nonspecific infections causing so-called balanoposthitis are described here.

Balanoposthitis refers to infection of the glans and prepuce caused by a wide variety of organisms. Among the more common agents are *Candida albicans*, anaerobic bacteria, *Gardnerella*, and pyogenic bacteria. Most cases occur as a consequence of poor local hygiene in uncircumcised males, in whom the accumulation of desquamated epithelial cells, sweat, and debris, termed *smegma*, acts as local irritant. Persistence of such infections leads to inflammatory scarring and, as mentioned earlier, is a common cause of phimosis.

Tumors

Tumors of the penis are, on the whole, uncommon. The most frequent neoplasms are carcinomas and a benign epithelial tumor, condyloma acuminatum. Benign proliferations of fibroblasts (Peyronie disease) are also worthy of brief mention.

Benign Tumors

Condyloma Acuminatum

Condyloma acuminatum is a benign sexually transmitted wart caused by human papillomavirus (HPV). It is related to the common wart and may occur on any moist mucocutaneous surface of the external genitals in either sex. HPV type 6, and less frequently type 11, are the most frequent agents that cause condylomata acuminata.

MORPHOLOGY

Condylomata acuminata may occur on the external genitalia or perineal areas. On the penis these lesions occur most often about the coronal sulcus and inner surface of the prepuce. They consist of **single or multiple sessile or pedunculated, red papillary excrescences** that may be up to several millimeters in diameter ([Fig. 21-15](#)). Histologically, a branching, villous, papillary connective tissue stroma is covered by epithelium that may have considerable superficial hyperkeratosis and thickening of the underlying epidermis (**acanthosis**) ([Fig. 21-16](#)). The normal orderly maturation of the epithelial cells is preserved; dysplasia is not evident. Cytoplasmic vacuolization of the squamous cells (**koilocytosis**), characteristic of HPV infection, is noted in these lesions ([Fig. 21-17](#)). Condylomata acuminata tend to recur but only rarely progress into in situ or invasive cancers.

Figure 21-15 Condyloma acuminatum of the penis.

Figure 21-16 Condyloma acuminatum of the penis. Low magnification reveals the papillary (villous) architecture and thickening of the epidermis.

Peyronie Disease

This disorder results in fibrous bands involving the corpus cavernosum of the penis. Although some classify it as a variant of fibromatosis, its etiology remains an enigma. Clinically, the lesion results in penile curvature and pain during intercourse.

Malignant Tumors

Carcinoma in Situ (CIS)

In the external male genitalia, two distinct lesions display histologic features of CIS: Bowen disease and Bowenoid papulosis. These lesions have a strong association with infection by high-risk HPV, most commonly type 16.

- *Bowen disease* occurs in the genital region of both men and women, usually in those older than age 35 years. In men it tends to involve the skin of the shaft of the penis and the scrotum. Grossly it appears as a solitary, thickened, gray-white, opaque plaque. It can also manifest on the glans and prepuce as single or multiple shiny red,

Figure 21-17 Condyloma acuminatum of the penis. The epithelium shows vacuolization (koilocytosis) characteristic of human papillomavirus infection.

Figure 21-18 Bowen disease (carcinoma in situ) of the penis. Note the hyperchromatic, dysplastic dyskeratotic epithelial cells with scattered mitoses above the basal layer. The intact basement membrane is not readily seen in this picture.

sometimes velvety plaques. Histologically the epidermis is hyperproliferative, containing numerous mitoses, some atypical. The cells are markedly dysplastic with large hyperchromatic nuclei and lack of orderly maturation (Fig. 21-18). Nevertheless, the dermal-epidermal border is sharply delineated by an intact basement membrane. Bowen disease transforms into infiltrating squamous cell carcinoma in approximately 10% of patients, usually over a span of many years.

- *Bowenoid papulosis* occurs in sexually active adults. It is distinguished from Bowen disease by the younger age of affected patients and its presentation as multiple (rather than solitary) reddish brown papular lesions. Although Bowenoid papulosis is histologically indistinguishable from Bowen disease and is also related to HPV type 16, it virtually never develops into an invasive carcinoma and in many cases regresses spontaneously.

Invasive Carcinoma

Squamous cell carcinoma of the penis is associated with poor genital hygiene and with high-risk HPV infection. Carcinomas are usually found in patients between the ages of 40 and 70 years. It accounts for less than 1% of cancers in males in the United States. In contrast, in some parts of Asia, Africa, and South America, squamous cell carcinoma of the penis makes up from 10% to 20% of male malignancies. Circumcision confers protection, and hence this cancer is extremely rare among Jews and Muslims and is correspondingly more common in populations in which circumcision is not practiced routinely. It is postulated that circumcision reduces exposure to carcinogens that may be concentrated in smegma and decreases the likelihood of infection with potentially oncogenic types of HPV. HPV DNA can be detected in penile squamous cancer in approximately 50% of patients. HPV type 16 is the most frequent culprit, but HPV 18 is also implicated. The recent availability of a vaccine to both the low-risk (6, 11) and high-risk (16, 18) subtypes of HPV may help reduce the incidence of this tumor, as well as condyloma acuminatum. Cigarette smoking also elevates the risk of developing penile cancer.

Figure 21-19 Carcinoma of the penis. The glans penis is deformed by a firm, ulcerated, infiltrative mass.

MORPHOLOGY

Squamous cell carcinoma of the penis usually begins on the glans or inner surface of the prepuce near the coronal sulcus. Two macroscopic patterns are seen—papillary and flat. The papillary lesions simulate condylomata acuminata and may produce a cauliflower-like fungating mass. Flat lesions appear as areas of epithelial thickening accompanied by graying and fissuring of the mucosal surface. With progression, an ulcerated papule develops (Fig. 21-19). Histologically, both the papillary and the flat lesions are squamous cell carcinomas with varying degrees of differentiation. **Verrucous carcinoma** is an exophytic well-differentiated variant of squamous cell carcinoma that are locally invasive, but rarely metastasize. Other, less common, subtypes of penile squamous carcinoma include basaloid, warty, and papillary variants.

Clinical Features. Invasive squamous cell carcinoma of the penis is a slowly growing, locally invasive lesion that often has been present for a year or more before it is brought to medical attention. The lesions are nonpainful until they undergo secondary ulceration and infection. Metastases to inguinal lymph nodes may occur early in its course, but widespread dissemination is extremely uncommon until the lesion is far advanced. Clinical assessment of regional lymph node involvement is notoriously inaccurate; only 50% of enlarged inguinal nodes detected in men with penile squamous cell carcinoma contain cancer, with the remainder showing only reactive lymphoid hyperplasia when examined histologically. The prognosis is related to the stage of the tumor. Without spread to lymph nodes, the 5-year survival rate is 66%, whereas metastasis to the lymph nodes carries a grim 27% 5-year survival.

KEY CONCEPTS

Lesions of the Penis

- Squamous cell carcinoma and its precursor lesions are the most important penile lesions. Many are associated with HPV infection.

- Squamous cell carcinoma occurs on the glans or shaft of the penis as an ulcerated infiltrative lesion that may spread to inguinal nodes and infrequently to distant sites. Most cases occur in uncircumcised males.
- Other important penile disorders include congenital abnormalities involving the position of the urethra (epispadias, hypospadias) and inflammatory disorders (balanitis, phimosis).

Testis and Epididymis

Distinct pathologic conditions affect the testis and epididymis. In the epididymis, the most important and frequent conditions are inflammatory diseases, whereas in the testis the major lesions are tumors.

Congenital Anomalies

With the exception of undescended testes (cryptorchidism), congenital anomalies are extremely rare and include absence of one or both testes and fusion of the testes (so-called *synorchism*).

Cryptorchidism

Cryptorchidism is a complete or partial failure of the intra-abdominal testes to descend into the scrotal sac and is associated with testicular dysfunction and an increased risk of testicular cancer. It is found in approximately 1% of 1-year-old boys. It usually occurs as an isolated anomaly but may be accompanied by other malformations of the genitourinary tract, such as hypospadias.

Testicular descent occurs in two morphologically and hormonally distinct phases. During the first transabdominal, phase, the testis comes to lie within the lower abdomen or brim of the pelvis. This phase is believed to be controlled by a hormone called *müllerian-inhibiting substance*. In the second inguinoscrotal, phase, the testes descend through the inguinal canal into the scrotal sac. This phase is androgen-dependent and is possibly mediated by androgen-induced release of calcitonin gene-related peptide from the genitofemoral nerve. Although testes may arrest anywhere along their pathway of descent, the most common site is in the inguinal canal; arrest within the abdomen is uncommon, accounting for approximately 5% to 10% of cases. Even though testicular descent is controlled by hormonal factors, cryptorchidism is only rarely associated with a well-defined hormonal disorder.

MORPHOLOGY

Cryptorchidism is unilateral in most cases, being bilateral in 25% of patients. Histologic changes in the malpositioned testis begin as early as 2 years of age. They are characterized by **arrested germ cell development** associated with **marked hyalinization and thickening of the basement membrane** of the spermatic tubules (Fig. 21-20). Eventually the tubules appear as dense cords of hyaline connective tissue outlined by prominent basement membranes. There is concomitant increase in interstitial stroma. Because Leydig cells are spared, they appear to be prominent. As might be expected with

Figure 21-20 **A**, Normal testis shows tubules with active spermatogenesis. **B**, Testicular atrophy in cryptorchidism. The tubules show Sertoli cells but no spermatogenesis. There is thickening of basement membranes and an apparent increase in interstitial Leydig cells.

progressive tubular atrophy, the cryptorchid testis is small in size and is firm in consistency as a result of fibrotic changes. Similar histologic changes may also be seen in the contralateral (descended) testis in males with unilateral cryptorchidism, suggesting that cryptorchidism is a marker of some intrinsic defect in testicular development or function.

- Bilateral or, in some cases, even unilateral cryptorchidism is associated with tubular atrophy and sterility.
- The cryptorchid testis carries a 3- to 5-fold higher risk for testicular cancer, which arises from foci of intratubular germ cell neoplasia within the atrophic tubules. Orchiopexy reduces the risk of sterility and cancer.

Cryptorchidism is completely asymptomatic, and comes to attention when the scrotal sac is discovered to be empty by the patient or an examining physician. In addition to sterility, cryptorchidism may be associated with other morbidity. When the testis lies in the inguinal canal, it is particularly prone to trauma and crushing injuries. A concomitant inguinal hernia accompanies the undescended testis in about 10% to 20% of cases. In addition, the undescended testis is at a greater risk of developing testicular cancer than is the descended testis.

During the first year of life the majority of inguinal cryptorchid testes descend spontaneously into the scrotum. Those that remain undescended require surgical correction, preferably before histologic deterioration sets in at around 2 years of age. Orchiopexy (placement in the scrotal sac) does not guarantee fertility; deficient spermatogenesis has been reported in 10% to 60% of patients in whom surgical repositioning was performed. To what extent the risk of cancer is reduced after orchiopexy is also unclear, and the risk is changing over time as orchiopexy has been offered at an increasingly younger age over the past few decades (current recommendations are for correction at 6 to 12 months of age). Cancer may also develop in the contralateral, normally descended testis, further supporting the idea that cryptorchidism signals the presence of a defect in testicular development and cellular differentiation that is unrelated to anatomic position.

KEY CONCEPTS

Cryptorchidism

- Cryptorchidism refers to incomplete descent of the testis from the abdomen to the scrotum and is present in about 1% of 1-year-old male infants.

Regressive Changes

Atrophy and Decreased Fertility

Testicular atrophy may be caused by one of several conditions, including (1) progressive atherosclerotic narrowing of the blood supply in old age, (2) the end stage of an inflammatory orchitis, (3) cryptorchidism, (4) hypopituitarism, (5) generalized malnutrition or cachexia, (6) irradiation, (7) prolonged administration of antiandrogens (treatment for advanced carcinoma of the prostate), and (8) exhaustion atrophy, which may follow persistent stimulation by high levels of follicle-stimulating pituitary hormone. The gross and microscopic alterations follow the pattern already described for cryptorchidism. Atrophy occasionally occurs as a primary failure of genetic origin, such as in Klinefelter syndrome (Chapter 5).

Inflammation

Inflammations are distinctly more common in the epididymis than in the testis. Of the three major specific inflammatory states that affect the testis and epididymis, gonorrhea and tuberculosis almost invariably arise in the epididymis, whereas syphilis affects the testis first.

Nonspecific Epididymitis and Orchitis

Epididymitis and possible subsequent orchitis are commonly related to infections in the urinary tract (cystitis, urethritis, prostatitis), which reach the epididymis and the testis through either the vas deferens or the lymphatics of the spermatic cord. The cause of epididymitis varies with the age of the patient. Though uncommon in children, epididymitis in childhood is usually associated with a congenital genitourinary abnormality and infection with

Figure 21-21 Acute epididymitis caused by gonococcal infection. The epididymis is replaced by an abscess. Normal testis is seen on the right.

gram-negative rods. In sexually active men younger than age 35 years, the sexually transmitted pathogens *C. trachomatis* and *Neisseria gonorrhoeae* are the most frequent culprits. In men older than age 35 the common urinary tract pathogens, such as *E. coli* and *Pseudomonas*, are responsible for most infections.

MORPHOLOGY

The bacterial invasion induces nonspecific acute inflammation characterized by congestion, edema, and infiltration by neutrophils, macrophages, and lymphocytes. Although the infection, in the early stage, is more or less limited to the interstitial connective tissue, it rapidly extends to involve the tubules and may progress to abscess formation or complete suppurative necrosis of the entire epididymis (Fig. 21-21). Usually, having involved the epididymis, the infection extends into the testis to evoke a similar inflammatory reaction. Such inflammatory involvement of the epididymis and testis is often followed by fibrous scarring, which in many cases leads to sterility. Usually the Leydig cells are not totally destroyed, and as a result androgen production by the testis may be relatively unaffected.

Granulomatous (Autoimmune) Orchitis

Idiopathic granulomatous orchitis presents in middle age as a moderately tender testicular mass of sudden onset sometimes associated with fever. It may appear insidiously, however, as a painless testicular mass mimicking a testicular tumor, hence its importance. Histologically the orchitis is distinguished by granulomas restricted to spermatic tubules. The lesions closely resemble tubercles but differ in that the granulomatous reaction is present diffusely throughout the testis and is confined to the seminiferous tubules. Although an autoimmune basis is suspected, the cause of these lesions remains unknown.

Specific Inflammations

Gonorrhea

Extension of infection from the posterior urethra to the prostate, seminal vesicles, and then to the epididymis is the usual course of a neglected gonococcal infection. In severe

cases epididymal abscesses may develop, leading to extensive destruction and scarring. The infection may also spread to the testis and produce suppurative orchitis.

Mumps

Mumps is a systemic viral disease that most commonly affects school-aged children. Testicular involvement is extremely uncommon in this age group. In postpubertal males, however, orchitis occurs in 20% to 30% of cases. Most often, an acute interstitial orchitis develops about 1 week after the onset of swelling of the parotid glands.

Tuberculosis

When it involves the male genital tract, tuberculosis almost invariably begins in the epididymis, from where it may spread to the testis. The infection invokes the classic morphologic reactions of caseating granulomatous inflammation characteristic of tuberculosis elsewhere.

Syphilis

The testis and epididymis may be affected in both acquired and congenital syphilis, but almost invariably the testis is involved first, and in many cases the epididymis is spared altogether. The morphologic pattern of the reaction takes two forms: (1) the production of gummas or (2) a diffuse interstitial inflammation that produces the histologic hallmark of syphilitic infections, obliterative endarteritis associated with perivascular cuffs of lymphocytes and plasma cells.

Vascular Disorders

Torsion

Twisting of the spermatic cord typically cuts off the venous drainage of the testis. If untreated, it frequently leads to testicular infarction and thus represents one of the few true urologic emergencies. The thick-walled arteries remain patent, producing intense vascular engorgement followed by hemorrhagic infarction.

There are two settings in which testicular torsion occurs. Neonatal torsion occurs either in utero or shortly after birth. It lacks any associated anatomic defect to account for its occurrence. "Adult" torsion is typically seen in adolescence and presents with the sudden onset of testicular pain. It often occurs without any inciting injury and may even occur during sleep. If the testis is manually untwisted within approximately 6 hours of the onset of torsion, there is a good chance that the testis will remain viable. In contrast to neonatal torsion, adult torsion results from a bilateral anatomic defect that leads to increased mobility of the testes (*bell-clapper abnormality*). To prevent the catastrophic recurrence of torsion in the contralateral testis, the testis unaffected by torsion is surgically fixed to the scrotum (*orchiopexy*).

MORPHOLOGY

Depending on the duration of the process, the morphologic changes range from intense congestion to widespread hemorrhage to testicular infarction (Fig. 21-22). In advanced stages the testis is markedly enlarged and consists entirely of soft, necrotic, hemorrhagic tissue.

Figure 21-22 Torsion of testis.

Spermatic Cord and Paratesticular Tumors

Lipomas are common lesions involving the proximal spermatic cord, identified at the time of inguinal hernia repair. Although diagnosed as “lipomas,” many of these lesions probably represent retroperitoneal adipose tissue that has been pulled into the inguinal canal along with the hernia sac, rather than a true neoplasm.

The most common benign paratesticular tumor is *adenomatoid tumor*. Although these lesions are mesothelial in nature, they are not referred to as mesotheliomas to distinguish them from other mesothelial lesions that may occur at this site. Adenomatoid tumors are usually small nodules, typically occurring near the upper pole of the epididymis. Although grossly well circumscribed, microscopically they may be minimally invasive into the adjacent testis. The importance of this lesion is that it is one of the few benign tumors that occur near the testis. If the pathologist can identify the nature of this lesion in intraoperative frozen sections, local excision of the adenomatoid tumor can spare the patient from an orchiectomy.

The most common malignant paratesticular tumors are rhabdomyosarcomas in children and liposarcomas in adults.

Testicular Tumors

Testicular neoplasms span an amazing gamut of anatomic types and can be divided into two major categories: germ cell tumors (95%) and sex cord-stromal tumors (Table 21-5). Germ cell tumors are subdivided into seminomas and nonseminomas. Most germ cell tumors are aggressive cancers capable of rapid, wide dissemination, although

Table 21-5 Pathologic Classification of Common Testicular Tumors

with current therapy most can be cured. Sex cord-stromal tumors, in contrast, are generally benign.

Germ Cell Tumors

In the 15- to 34-year age group, testicular germ cell tumors constitute the most common tumor of men and cause approximately 10% of all cancer deaths. The incidence of testicular tumors in the United States is approximately 6 per 100,000, resulting in approximately 300 deaths per year. For unexplained reasons there has been worldwide increase in the incidence of these tumors in recent years. In the United States these tumors are much more common in whites than in blacks (ratio 5:1).

Environmental Factors. Environmental factors play a role in testicular germ cell tumors, as demonstrated by population migration studies. For example, the incidence of testicular germ cell tumors in Finland is about two times lower than in Sweden, but second generation Finnish immigrants to Sweden have a tumor incidence that approaches that of the Swedish population. Testicular germ cell tumors are associated with a spectrum of disorders collectively known as *testicular dysgenesis syndrome (TDS)*. Components of this syndrome include cryptorchidism, hypospadias, and poor sperm quality. It has been proposed that these conditions are increased by in utero exposures to pesticides and nonsteroidal estrogens. The most important association is with cryptorchidism, which is seen with approximately 10% of testicular germ cell tumors. Curiously, Klinefelter syndrome is associated with a greatly increased risk (50 times normal) for development of mediastinal germ cell tumors, but these patients do not develop testicular tumors.

Genetic Factors. There is a strong familial predisposition associated with the development of testicular germ cell tumors. The relative risk of these tumors is four times higher than normal in fathers and sons of affected patients and is 8 to 10 times higher in brothers. Several genetic loci have been linked to familial germ cell tumor risk, including the genes encoding the ligand for the receptor tyrosine kinase KIT and BAK, which you will recall is an important inducer of apoptotic cell death (Chapter 1). Interestingly, these genes are also thought to play a role in gonadal development.

Classification. A simple classification of the most common types of testicular tumors is presented in Table 21-5. Two broad groups are recognized. *Seminomatous tumors* are composed of cells that resemble primordial germ cells or early gonocytes. The *nonseminomatous tumors* may be composed of undifferentiated cells that resemble embryonic stem cells, as in the case of embryonal carcinoma, but the malignant cells may also differentiate along other lineages, generating yolk sac tumors, choriocarcinomas and teratomas. Germ cell tumors may have a single tissue component, but in approximately 60% of cases the tumors contain mixtures of seminomatous and nonseminomatous components and multiple tissues.

Pathogenesis. Most testicular germ cell tumors originate from a precursor lesion called **intratubular germ cell neoplasia (ITGCN)**. The exceptions to this rule are pediatric yolk sac tumors and teratomas, and adult spermatocytic

seminomas, all of which are of uncertain origin. ITGCN is believed to arise in utero and stay dormant until puberty, after which it may progress to seminoma or nonseminomatous tumors. The lesion consists of atypical primordial germ cells with large nuclei and clear cytoplasm, which are about twice the size of normal germ cells. These cells retain the expression of the transcription factors OCT3/4 and NANOG, which are important in maintenance of pluripotent stem cells. ITGCN shares some of the genetic alterations that are found in germ cell tumors. One that is particularly important is the reduplication of the short arm of chromosome 12 (12p) in the form of an isochromosome i(12p), a cytogenetic alteration that is invariably found in invasive germ cell tumors regardless of histological type. Activating mutations in the gene encoding the KIT receptor tyrosine kinase, which may be present in seminomas, are also frequently present in ITGCN. About 50% of individuals with ITGCN develop invasive germ cell tumors within five years after diagnosis, and it may be that practically all patients with ITGCN will eventually develop invasive tumors.

Seminoma

Seminomas are the most common type of germ cell tumor, making up about 50% of these tumors. The peak incidence is the third decade and they almost never occur in infants. An identical tumor arises in the ovary, where it is called *dysgerminoma* (Chapter 22). Seminomas contain isochromosome 12p and express OCT3/4 and NANOG. Approximately 25% of these tumors have *KIT* activating mutations. *KIT* amplification and *KIT* overexpression through other unknown mechanisms have also been reported.

MORPHOLOGY

If not otherwise specified, “seminoma” refers to “classic” or “typical” seminoma. Spermatocytic seminoma, despite its similar name, is a distinct tumor discussed later. Seminomas produce bulky masses, sometimes ten times the size of the normal testis. The typical seminoma has a homogeneous, gray-white, lobulated cut surface, usually devoid of hemorrhage or necrosis (Fig. 21-23). Generally the tunica albuginea is not penetrated, but occasionally extension to the epididymis, spermatic cord, or scrotal sac occurs.

Figure 21-23 Seminoma of the testis appears as a fairly well-circumscribed, pale, fleshy, homogeneous mass.

Figure 21-24 Seminoma. **A**, Low magnification shows clear seminoma cells divided into poorly demarcated lobules by delicate septa. **B**, Microscopic examination reveals large cells with distinct cell borders, pale nuclei, prominent nucleoli, and a sparse lymphocytic infiltrate.

Microscopically the typical seminoma is composed of sheets of uniform cells divided into poorly demarcated lobules by delicate fibrous septa containing a lymphocytic infiltrate (Fig. 21-24A). **The classic seminoma cell is large and round to polyhedral and has a distinct cell membrane; clear or watery-appearing cytoplasm; and a large, central nucleus with one or two prominent nucleoli** (Fig. 21-24B). Mitoses vary in frequency. The cytoplasm contains varying amounts of glycogen. Some tumors have anaplastic features (anaplastic seminoma), including frequent tumor giant cells and greater mitotic activity, but this does not appear to portend a worse prognosis when matched for stage with classic seminoma. By immunohistochemistry, seminoma cells stain positively for KIT, (regardless of KIT mutational status), OCT4, and placental alkaline phosphatase (PLAP). A few scattered keratin-positive cells may also be present.

Approximately 15% of seminomas contain syncytiotrophoblasts. In this subset of patients, serum human chorionic gonadotropin (HCG) levels are elevated, though not to the extent seen in patients with choriocarcinoma. Seminomas may also be accompanied by an ill-defined granulomatous reaction, in contrast to the well-formed discrete granulomas seen with tuberculosis.

Spermatocytic Seminoma

In contrast to the classic seminoma described earlier, spermatocytic seminoma is a rare, slow-growing germ cell

tumor predominantly affecting older men. Though related by name to seminoma, spermatocytic seminoma is a distinctive tumor both clinically and histologically. Spermatocytic seminoma is uncommon, representing 1% to 2% of all testicular germ cell neoplasms. The age of involvement is much later than for most testicular tumors: Affected individuals are generally older than age 65 years. Because it is a slow-growing tumor that does not produce metastases, the prognosis is excellent.

MORPHOLOGY

Spermatocytic seminoma tends to have a soft, pale gray, cut surface that sometimes reveal mucoid cysts. Spermatocytic seminomas contain three cell populations, all intermixed: (1) medium-sized cells, the most numerous, containing a round nucleus and eosinophilic cytoplasm; (2) smaller cells with a narrow rim of eosinophilic cytoplasm resembling secondary spermatocytes; and (3) scattered giant cells, either uninucleate or multinucleate. The chromatin in some intermediate-sized cells is similar to that seen in the meiotic phase of nonneoplastic spermatocytes (spindle chromatin). In contrast to typical seminomas, spermatocytic seminomas lack lymphocytes, granulomas, syncytiotrophoblasts, extra-testicular sites of origin, admixture with other germ cell tumors, and association with ITGCN.

Embryonal Carcinoma

Embryonal carcinomas occur mostly in the 20- to 30-year age group. These tumors are more aggressive than seminomas.

MORPHOLOGY

Most primary tumors are smaller than seminoma and do not replace the entire testis. However, extension through the tunica albuginea into the epididymis or cord frequently occurs. On cut

Figure 21-25 Embryonal carcinoma. In contrast to the seminoma illustrated in Figure 21-23, embryonal carcinoma is a hemorrhagic mass.

Figure 21-26 Embryonal carcinoma shows sheets of undifferentiated cells as well as primitive glandular differentiation. The nuclei are large and hyperchromatic.

surfaces the tumor is often variegated, poorly demarcated at the margins, and punctuated by foci of hemorrhage or necrosis (Fig. 21-25). **Histologically the cells grow in alveolar or tubular patterns, sometimes with papillary convolutions (Fig. 21-26). More undifferentiated lesions may display sheets of cells.** Well formed glands are absent. The neoplastic cells have an epithelial appearance, are large and anaplastic, and have hyperchromatic nuclei with prominent nucleoli. The cell borders are usually indistinct, and there is considerable variation in cell and nuclear size and shape. Mitotic figures and tumor giant cells are frequently seen. Embryonal carcinomas share some markers with seminomas such as OCT 3/4 and PLAP, but differ by being positive for cytokeratin and CD30, and negative for KIT.

Yolk Sac Tumor

Also known as *endodermal sinus tumor*, yolk sac tumor is of interest because it is the most common testicular tumor in infants and children up to 3 years of age. In this age group it has a very good prognosis. In adults the pure form of this tumor is rare; instead, yolk sac elements frequently occur in combination with embryonal carcinoma.

MORPHOLOGY

These tumors are nonencapsulated and have a homogeneous, yellow-white, mucinous appearance. They are composed of a lacelike (reticular) network of medium-sized cuboidal or flattened cells. In addition, papillary structures, solid cords of cells, and a multitude of other less common patterns may be found. In approximately 50% of tumors, structures resembling endodermal sinuses (**Schiller-Duval** bodies) may be seen; these consist of a mesodermal core with a central capillary and a visceral and parietal layer of cells resembling primitive glomeruli. Present within and outside the cytoplasm are eosinophilic, hyaline-like globules in which α -fetoprotein (AFP) and α_1 -antitrypsin can be demonstrated by immunocytochemical staining. The presence of AFP in the tumor cells is highly characteristic, and underscores resemblance to yolk sac cells.

Figure 21-27 Choriocarcinoma shows cytotrophoblastic cells (*arrowhead*) with central nuclei and syncytiotrophoblastic cells (*arrow*) with multiple dark nuclei embedded in eosinophilic cytoplasm. Hemorrhage and necrosis are seen in the *upper right field*.

Choriocarcinoma

Choriocarcinoma is a highly malignant form of testicular tumor. In its “pure” form, choriocarcinoma is rare, constituting less than 1% of all germ cell tumors.

MORPHOLOGY

Choriocarcinomas often cause no testicular enlargement and are detected only as a small palpable nodule. Typically, these tumors are small, rarely larger than 5 cm in diameter. Hemorrhage and necrosis are extremely common. Histologically the tumors contain two cell types, **syncytiotrophoblasts** and **cytotrophoblasts** (Fig. 21-27). Syncytiotrophoblasts are large multinucleated cells with abundant eosinophilic vacuolated cytoplasm containing HCG, which is readily detected by immunohistochemistry. Cytotrophoblasts are more regular and tend to be polygonal, with distinct borders and clear cytoplasm; they grow in cords or masses and have a single, fairly uniform nucleus. This neoplasm can also arise in the female genital tract (Chapter 21).

Teratoma

The designation *teratoma* refers to testicular tumors having various cellular or organoid components reminiscent of the normal derivatives of more than one germ layer. They may occur at any age from infancy to adult life. Pure forms of teratoma are fairly common in infants and children, second in frequency only to yolk sac tumors. In adults, pure teratomas are rare, constituting 2% to 3% of germ cell tumors. However, the frequency of teratomas mixed with other germ cell tumors is approximately 45%.

MORPHOLOGY

Grossly, teratomas are usually large, ranging from 5 to 10 cm in diameter. Because they are composed of various tissues, the gross appearance is heterogeneous with solid, sometimes

Figure 21-28 Teratoma of testis. The variegated cut surface with cysts reflects the multiplicity of tissue types found histologically.

cartilaginous, and cystic areas (Fig. 21-28). Hemorrhage and necrosis usually indicate admixture with embryonal carcinoma, choriocarcinoma, or both.

Teratomas are composed of a heterogeneous, helter-skelter collection of differentiated cells or organoid structures, such as **neural tissue, muscle bundles, islands of cartilage, clusters of squamous epithelium, structures reminiscent of thyroid gland, bronchial or bronchiolar epithelium, and bits of intestinal wall or brain substance**, all embedded in a fibrous or myxoid stroma (Fig. 21-29). Elements may be mature (resembling various adult tissues) or immature (sharing histologic features with fetal or embryonal tissue).

Rarely, malignant non-germ cell tumors arise in teratomas, a phenomenon that is referred to as “teratoma with malignant transformation”. Transformation may take the form of a squamous cell carcinoma, mucin-secreting adenocarcinoma, sarcoma, or other cancers. The importance of recognizing a non-germ cell malignancy arising in a teratoma is that these secondary tumors are chemoresistant; thus, the only hope for cure resides in the resectability of the tumor. These non-germ cell malignancies retain isochromosome 12p, proving a clonal relationship to the preceding teratoma.

Figure 21-29 Teratoma of the testis consisting of a disorganized collection of glands, cartilage, smooth muscle, and immature stroma.

In the child, differentiated mature teratomas usually follow a benign course. **In the postpubertal male all teratomas are regarded as malignant**, capable of metastatic behavior whether the elements are mature or immature. Consequently, it is not critical to detect immaturity in a testicular teratoma of a postpubertal male.

Mixed Tumors

About 60% of testicular tumors are composed of more than one of the “pure” patterns. Common mixtures include: teratoma, embryonal carcinoma, and yolk sac tumor; seminoma with embryonal carcinoma; and embryonal carcinoma with teratoma (*teratocarcinoma*). In most instances the prognosis is worsened by the presence of the more aggressive element.

Clinical Features of Testicular Germ Cell Tumors. Although painless enlargement of the testis is a characteristic feature of germ cell neoplasms, any solid testicular mass should be considered neoplastic until proven otherwise. Biopsy of a testicular neoplasm is associated with a risk of tumor spillage, which would necessitate excision of the scrotal skin in addition to orchiectomy. Consequently, the standard management of a solid testicular mass is radical orchiectomy based on the presumption of malignancy.

Testicular tumors have a characteristic mode of spread. *Lymphatic spread* is common to all forms of testicular tumors. In general, retroperitoneal para-aortic nodes are the first to be involved. Subsequent spread may occur to mediastinal and supraclavicular nodes. *Hematogenous spread* is primarily to the lungs, but liver, brain, and bones may also be involved. The histology of metastases may differ from that of the testicular lesion. For example, an embryonal carcinoma may present a teratomatous picture in the secondary deposits. As discussed earlier, because all these tumors are derived from pluripotent germ cells, the apparent “forward” and “backward” differentiation seen in different locations is not entirely surprising. Another explanation for the differing morphologic patterns in the primary and metastatic site is that minor components in the primary tumor that were unresponsive to chemotherapy survive and subsequently become the dominant metastatic pattern.

Because of differing behaviors, tumors of the testis are segregated clinically into two broad categories: seminoma and nonseminomatous germ cell tumors (NSGCTs).

- Seminomas tend to remain localized to the testis for a long time, and hence approximately 70% present in clinical stage I (see later). In contrast, approximately 60% of males with NSGCTs present with advanced clinical disease (stages II and III).
- Metastases from seminomas typically involve lymph nodes. Hematogenous spread occurs later in the course of dissemination. NSGCTs not only metastasize earlier but also use the hematogenous route more frequently.
- The rare pure choriocarcinoma is the most aggressive NSGCT. It may not cause any testicular enlargement but instead spreads predominantly and rapidly by the bloodstream. Therefore, lungs and liver are involved early in virtually every case.

To summarize, as compared with seminomas, NSGCTs are biologically more aggressive and in general have a poorer prognosis.

In the United States, three clinical stages of testicular tumors are defined:

- Stage I: tumor confined to the testis, epididymis, or spermatic cord
- Stage II: distant spread confined to retroperitoneal nodes below the diaphragm
- Stage III: metastases outside the retroperitoneal nodes or above the diaphragm

Biomarkers. Germ cell tumors of the testis often secrete polypeptide hormones and certain enzymes that can be detected in blood by sensitive assays. Such biologic markers include HCG, AFP, and lactate dehydrogenase, which are valuable in the diagnosis and management of testicular cancer. The elevation of lactate dehydrogenase correlates with the mass of tumor cells, and provides a tool to assess tumor burden. Marked elevation of serum AFP or HCG levels are produced by yolk sac tumor and choriocarcinoma elements, respectively. Both of these markers are elevated in more than 80% of individuals with NSGCT at the time of diagnosis. As stated earlier, approximately 15% of seminomas have syncytiotrophoblastic giant cells and minimal elevation of HCG levels, which does not affect prognosis. In the context of testicular tumors, the value of serum markers is fourfold:

- In the evaluation of testicular masses
- In the staging of testicular germ cell tumors. For example, after orchiectomy, persistent elevation of HCG or AFP concentrations indicates stage II disease even if the lymph nodes appear of normal size by imaging studies.
- In assessing tumor burden
- In monitoring the response to therapy. After eradication of tumors there is a rapid fall in serum AFP and HCG. With serial measurements it is often possible to predict recurrence before the patients become symptomatic or develop any other clinical signs of relapse.

The therapy and prognosis of testicular tumors depend largely on clinical stage and on the histologic type. Seminoma, which is radiosensitive and tends to remain localized for long periods, has the best prognosis. More than 95% of patients with stage I and II disease can be cured. Among NSGCTs, the histologic subtype does not influence the prognosis significantly, and hence these are treated as a group. Approximately 90% of patients with NSGCTs can achieve complete remission with aggressive chemotherapy, and most can be cured. Pure choriocarcinoma has a poor prognosis. However, when it is a minor component of a mixed germ cell tumor, the prognosis is less adversely affected. With all testicular tumors, distant metastases, if present, usually occur within the first 2 years after treatment.

Tumors of Sex Cord-Gonadal Stroma

As indicated in [Table 21-5](#), sex cord-gonadal stroma tumors are subclassified based on their presumed histogenesis and differentiation. The two most important members of this

group—Leydig cell tumors and Sertoli cell tumors—are described here.

Leydig Cell Tumors

Tumors of Leydig cells are particularly interesting, because they may elaborate androgens and in some cases both androgens and estrogens, and even corticosteroids. They may arise at any age, although most cases occur between 20 and 60 years of age. As with other testicular tumors, the most common presenting feature is testicular swelling, but in some patients gynecomastia may be the first symptom. In children, hormonal effects, manifested primarily as sexual precocity, are the dominant features.

MORPHOLOGY

These neoplasms form circumscribed nodules, usually less than 5 cm in diameter. They have a distinctive golden brown, homogeneous cut surface. Histologically, neoplastic Leydig cells have an appearance that is similar to their normal counterparts. They are large in size and have round or polygonal cell outlines, abundant granular eosinophilic cytoplasm, and a round central nucleus. The cytoplasm frequently contains lipid droplets, vacuoles, or lipofuscin pigment, and, most characteristically, rod-shaped **crystalloids of Reinke**, which are seen in about 25% of the tumors. Approximately 10% of the tumors in adults are invasive and produce metastases; most are benign.

Sertoli Cell Tumors

Most Sertoli cell tumors are hormonally silent and present as a testicular mass. These neoplasms appear as firm, small nodules with a homogeneous gray-white to yellow cut surface. Histologically the tumor cells are arranged in distinctive trabeculae that tend to form cordlike structures and tubules. Most Sertoli cell tumors are benign, but approximately 10% pursue a malignant course.

Gonadoblastoma

Gonadoblastomas are rare neoplasms comprised of a mixture of germ cells and gonadal stromal elements that almost always arise in gonads with some form of testicular dysgenesis (discussed earlier). In some cases the germ cell component becomes malignant, giving rise to seminoma.

Testicular Lymphoma

Aggressive non-Hodgkin lymphomas account for 5% of testicular neoplasms, and are the most common form of testicular neoplasms in men older than age 60 years. Although an uncommon tumor of the testis, testicular lymphoma is included here because affected patients may present with only a testicular mass, mimicking other, more common, testicular tumors. In most cases, the disease is already disseminated at the time of detection. The most common testicular lymphomas, in decreasing order of frequency, are diffuse large B-cell lymphoma, Burkitt lymphoma, and EBV-positive extranodal NK/T cell lymphoma (Chapter 13). Testicular lymphomas have a higher propensity for central nervous system involvement than do similar tumors arising at other sites.

KEY CONCEPTS

Testicular Tumors

- Testicular tumors are the most common cause of painless testicular enlargement. They occur with increased frequency in association with undescended testis and with testicular dysgenesis.
- Germ cells are the source of 95% of testicular tumors; most the remainder arise from Sertoli or Leydig cells. Germ cell tumors may be composed of a single histologic pattern (60% of cases) or mixed patterns (40%).
- The most common “pure” histologic patterns of germ cell tumors are seminoma, embryonal carcinoma, yolk sac tumors, choriocarcinoma, and teratoma. Mixed tumors contain more than one element, most commonly embryonal carcinoma, teratoma, and yolk sac tumor.
- Clinically, testicular germ cell tumors can be divided into two groups: seminomas and nonseminomatous tumors. Seminomas remain confined to the testis for a long time and spread mainly to paraaortic nodes—distant spread is rare. Nonseminomatous tumors tend to spread earlier, by both lymphatics and blood vessels.
- HCG is produced by syncytiotrophoblasts and is always elevated in patients with choriocarcinomas or seminomas containing syncytiotrophoblasts. AFP is elevated when there is a yolk sac tumor component.
- Non-germ cell tumors include sex cord-gonadal stroma tumors and non-Hodgkin lymphomas.
- Non-Hodgkin lymphoma is the most common testicular tumor in men older than 60 years.

Miscellaneous Lesions of Tunica Vaginalis

Brief mention should be made of the tunica vaginalis, which is a mesothelial-lined surface exterior to the testis that may accumulate serous fluid (*hydrocele*) causing considerable enlargement of the scrotal sac. By transillumination it is usually possible to define the clear, translucent character of the contained fluid. Hydrocele sacs are frequently lined by mesothelial cells. Rarely, malignant mesotheliomas also can arise from the tunica vaginalis.

Hematocele indicates the presence of blood in the tunica vaginalis. It is an uncommon condition usually encountered following testicular trauma or torsion, or in individuals with systemic bleeding disorders. *Chylocele* refers to the accumulation of lymph in the tunica and is almost always found in patients with elephantiasis who have widespread, severe lymphatic obstruction caused, for example, by filariasis (Chapter 8). *Spermatocele* refers to a small cystic accumulation of semen in dilated efferent ducts or ducts of the rete testis. *Varicocele* is a dilated vein in the spermatic cord. Varicoceles may be asymptomatic but have also been implicated in some men as a contributing factor to infertility. They can be corrected by surgical repair.

Prostate

In the normal adult the prostate weighs approximately 20 gm. The prostate is a retroperitoneal organ encircling the

Figure 21-30 Adult prostate. The normal prostate contains several distinct regions, including a central zone (CZ), a peripheral zone (PZ), a transitional zone (TZ), and a periurethral zone. Most carcinomas arise from the peripheral zone and may be palpable during digital examination of the rectum. Nodular hyperplasia, in contrast, arises from the more centrally situated transitional zone and often produces urinary obstruction.

neck of the bladder and urethra, and is devoid of a distinct capsule. In the adult, prostatic parenchyma can be divided into four biologically and anatomically distinct zones or regions: the peripheral, central, transitional, and periurethral zones (Fig. 21-30). The types of proliferative lesions are different in each region. For example, most hyperplasias arise in the transitional zone, whereas most carcinomas originate in the peripheral zone.

Histologically the prostate is composed of glands lined by two layers of cells: a basal layer of low cuboidal epithelium covered by a layer of columnar secretory cells (Fig. 21-31). In many areas there are small papillary infoldings of the epithelium. These glands are separated by abundant fibromuscular stroma. Testicular androgens control the

Figure 21-31 Benign prostate gland with basal cell and secretory cell layer.

growth and survival of prostatic cells. Castration leads to atrophy of the prostate caused by widespread apoptosis.

Only three pathologic processes affect the prostate gland with sufficient frequency to merit discussion: inflammation, benign nodular enlargement, and tumors. Of these three, the benign nodular enlargements are by far the most common and occur so often in advanced age that they can almost be construed as a “normal” aging process. Prostatic carcinoma is also an extremely common lesion in men and therefore merits careful consideration. We begin our discussion with consideration of the inflammatory processes.

Inflammation

Prostatitis may be divided into several categories: acute and chronic bacterial prostatitis, chronic abacterial prostatitis, and granulomatous prostatitis.

- **Acute bacterial prostatitis** typically results from bacteria similar to those that cause urinary tract infections. Thus, most cases are caused by various strains of *E. coli*, other gram-negative rods, enterococci, and staphylococci. The organisms become implanted in the prostate usually by intraprostatic reflux of urine from the posterior urethra or from the urinary bladder, but occasionally they seed the prostate by lymphohematogenous routes from distant foci of infection. Prostatitis sometimes follows surgical manipulation of the urethra or prostate gland itself, such as catheterization, cystoscopy, urethral dilation, or resection procedures on the prostate. Clinically, acute bacterial prostatitis is associated with fever, chills, and dysuria. On rectal examination the prostate is exquisitely tender and boggy. The diagnosis can be established by urine culture and clinical features.
- **Chronic bacterial prostatitis** is difficult to diagnose and treat. It may present with low back pain, dysuria, and perineal and suprapubic discomfort. Alternatively, it may be virtually asymptomatic. Patients often have a history of recurrent urinary tract infections (cystitis, urethritis) caused by the same organism. Because most antibiotics penetrate the prostate poorly, bacteria find safe haven in the parenchyma and constantly seed the urinary tract. Diagnosis of chronic bacterial prostatitis depends on the demonstration of leukocytosis in the expressed prostatic secretions, along with positive bacterial cultures. In most cases, there is no antecedent acute attack, and the disease appears insidiously and without obvious provocation. The implicated organisms are the same as those cited as causes of acute prostatitis.
- **Chronic abacterial prostatitis** is the most common form of prostatitis seen today. It is indistinguishable from chronic bacterial prostatitis in terms of signs and symptoms, but there is no history of recurrent urinary tract infection. Expressed prostatic secretions contain more than 10 leukocytes per high-power field, but bacterial cultures are uniformly negative.
- **Granulomatous prostatitis** may be specific, where an etiologic infectious agent may be identified, or nonspecific. In the United States the most common cause is instillation of BCG within the bladder for treatment of

superficial bladder cancer, discussed earlier in this chapter. BCG is an attenuated mycobacterial strain that gives rise to a histologic picture indistinguishable from that seen with systemic tuberculosis. However, in the setting of BCG treatment the finding of granulomas in the prostate is of no clinical significance and requires no treatment. Fungal granulomatous prostatitis is typically seen only in immunocompromised hosts. Nonspecific granulomatous prostatitis is relatively common and represents a reaction to secretions from ruptured prostatic ducts and acini. Although some of these men have a recent history of urinary tract infection, bacteria are not seen within the tissue in nonspecific granulomatous prostatitis.

MORPHOLOGY

Acute prostatitis may appear as minute, disseminated abscesses; as large, coalescent focal areas of necrosis; or as diffuse edema, congestion, and boggy suppuration of the entire gland.

In men with symptoms of acute or chronic prostatitis, biopsy or surgical specimens are usually not obtained, because the diagnosis is made on clinical and laboratory findings. In fact biopsy in suspected acute prostatitis is contraindicated, as it may lead to sepsis. It is common in prostate specimens removed surgically to find histologic evidence of acute or chronic inflammation in men with no clinical symptoms of acute or chronic prostatitis. In these instances etiologic infectious agents have yet to be identified. So as not to be confused with the clinical syndromes of acute and chronic prostatitis, these prostate specimens are instead diagnosed using descriptive terms such as “acute inflammation” or “chronic inflammation” and not as “prostatitis.”

KEY CONCEPTS

Prostatitis

- Bacterial prostatitis may be acute or chronic; the responsible organism usually is *E. coli* or another gram-negative rod.
- Chronic abacterial prostatitis, despite sharing symptomatology with chronic bacterial prostatitis, is of unknown etiology and does not respond to antibiotics.
- Granulomatous prostatitis has a multifactorial etiology, including infectious and noninfectious causes.

Benign Enlargement

Benign Prostatic Hyperplasia or Nodular Hyperplasia

BPH is the most common benign prostatic disease in men older than age 50 years. It results from nodular hyperplasia of prostatic stromal and epithelial cells and often leads to urinary obstruction. It is characterized by the formation of large, fairly discrete nodules in the periurethral region of the prostate, which, when sufficiently large, compress and narrow the urethral canal to cause partial, or sometimes virtually complete, obstruction of the urethra. Nodular hyperplasia is not considered to be a premalignant lesion.

Incidence. Histologic evidence of BPH can be seen in approximately 20% of men 40 years of age, a figure that increases to 70% by age 60 and to 90% by age 80. There is no direct correlation, however, between histologic changes and clinical symptoms. Only 50% of those who have microscopic evidence of BPH have clinically detectable enlargement of the prostate, and of these individuals, only 50% develop clinical symptoms. BPH is a problem of enormous magnitude, with approximately 30% of white American men older than 50 years of age having moderate to severe symptoms.

Etiology and Pathogenesis. Despite the fact that there are an increased number of epithelial cells and stromal components in the periurethral area of the prostate, there is no clear evidence of increased epithelial cell proliferation in human BPH. Instead, it is believed that hyperplasia mainly stems from impaired cell death, resulting in the accumulation of senescent cells in the prostate. In keeping with this idea, androgens (discussed later), which are required for the development of BPH, not only increase cellular proliferation, but also inhibit cell death.

The main androgen in the prostate, constituting 90% of total prostatic androgens, is dihydrotestosterone (DHT). DHT is formed in the prostate from testosterone through the action of an enzyme called type 2 5 α -reductase. This enzyme is located almost entirely in stromal cells; with the exception of a few basal cells, prostatic epithelial cells do not express type 2 5 α -reductase. Thus, stromal cells are responsible for androgen-dependent prostatic growth. Type 1 5 α -reductase is not detected in the prostate, or is present at very low levels. However this enzyme may produce DHT from testosterone in liver and skin, and circulating DHT may act in the prostate by an endocrine mechanism.

DHT binds to the nuclear androgen receptor (AR) present in both stromal and epithelial prostate cells. DHT is more potent than testosterone because it has a higher affinity for AR and forms a more stable complex with the receptor. Binding of DHT to AR stimulates the transcription of androgen-dependent genes, which includes several growth factors and their receptors. Most important among these are members of the fibroblast growth factor (FGF) family and transforming growth factor (TGF)- β (Chapter 3). FGFs, produced by stromal cells, are paracrine regulators of androgen-stimulated epithelial growth during embryonic prostatic development, and some of these pathways may be “reawakened” in adulthood to produce prostatic growth in BPH. TGF- β serves as a mitogen for fibroblasts and other mesenchymal cells, but inhibits epithelial proliferation. Although the ultimate cause of BPH is unknown, it is believed that DHT-induced growth factors act by increasing the proliferation of stromal cells and decreasing the death of epithelial cells.

MORPHOLOGY

In the usual case of benign prostatic enlargement, the prostate weighs between 60 and 100 gm. Nodular hyperplasia of the prostate originates almost exclusively in the inner aspect of the prostate gland (transition zone). The early nodules are composed almost entirely of stromal cells, and later predominantly

Figure 21-32 Simplified scheme of the pathogenesis of prostatic hyperplasia. The central role of the stromal cells in generating dihydrotestosterone (DHT) should be noted. DHT may also be produced in skin and liver by both type 1 and 2 5 α -reductase.

epithelial nodules arise. From their origin in this strategic location the nodular enlargements may encroach on the lateral walls of the urethra to compress it to a slitlike orifice (Fig. 21-33). In some cases, nodular enlargement may project up into the floor of the urethra as a hemispheric mass directly beneath the mucosa of the urethra, which is termed **median lobe hypertrophy**.

On cross-section, the nodules vary in color and consistency depending on their cellular content (Fig. 21-33B). Nodules that contain mostly glands are yellow-pink and soft, and exude a milky white prostatic fluid. Nodules composed primarily of fibromuscular stroma are pale gray and tough; these nodules do not exude fluid and are less clearly demarcated from the surrounding prostatic tissue. Although the nodules do not have true capsules, the compression of surrounding prostatic tissue creates a plane of cleavage about them.

Microscopically, glandular proliferation takes the form of aggregations of small to large to cystically dilated glands lined by two layers of cells, an inner columnar layer and an outer layer of cuboidal or flattened epithelium (Fig. 21-33C). Occasionally foci of reactive squamous metaplasia mimicking urothelial carcinoma are seen adjacent to prostatic infarcts in prostates with prominent BPH. The diagnosis of BPH cannot usually be made on needle biopsy because such biopsies are too small to appreciate the nodularity of the process and do not usually sample the transition zone where BPH occurs.

Clinical Features. The major clinical problem in those with BPH is urinary obstruction, which stems from the increased size of the prostate and the smooth muscle-mediated prostatic contraction. The increased resistance to urinary outflow leads to bladder hypertrophy and distention, accompanied by urine retention. The inability to empty the bladder completely creates a reservoir of residual urine that is a common source of infection. Patients

experience increased urinary frequency, nocturia, difficulty in starting and stopping the stream of urine, overflow dribbling, dysuria (painful micturition), and have an increased risk of developing bacterial infections of the bladder and kidney. In many cases, sudden, acute urinary retention occurs that requires emergency catheterization for relief.

Mild cases of BPH may be treated without medical or surgical therapy, such as by decreasing fluid intake, especially before bedtime; moderating the intake of alcohol and caffeine-containing products; and following timed voiding schedules. The most commonly used and effective medical therapy for symptoms relating to BPH are α -blockers, which decrease prostate smooth muscle tone via inhibition of α_1 -adrenergic receptors. Another common pharmacologic therapy aims to decrease symptoms by physically shrinking the prostate with an agent that inhibits the synthesis of DHT. Inhibitors of 5 α -reductase fall into this category. For moderate to severe cases recalcitrant to medical therapy, a wide range of more invasive procedures exist. Transurethral resection of the prostate (TURP) has been the gold standard in terms of reducing symptoms, improving flow rates, and decreasing post-voiding residual urine. It is indicated as a first line of therapy in certain circumstances, such as recurrent urinary retention. As a result of its morbidity and cost, alternative procedures have been developed. These include high-intensity focused ultrasound, laser therapy, hyperthermia, transurethral electrovaporization, and transurethral needle ablation using radiofrequency.

KEY CONCEPTS

Benign Prostatic Hyperplasia

- BPH is characterized by proliferation of benign stromal and glandular elements. DHT, an androgen derived from testosterone, is the major hormonal stimulus for proliferation.
- BPH most commonly affects the inner periurethral zone of the prostate, producing nodules that compress the prostatic urethra. On microscopic examination, the nodules exhibit variable proportions of stroma and glands. Hyperplastic glands are lined by two cell layers, an inner columnar layer and an outer layer composed of flattened basal cells.
- Clinical symptoms and signs are reported by 10% of affected patients and include hesitancy, urgency, nocturia, and poor urinary stream. Chronic obstruction predisposes to recurrent urinary tract infections. Acute urinary obstruction may occur.

Tumors

Adenocarcinoma

Adenocarcinoma of the prostate is the most common form of cancer in men, accounting for 29% of cancer in the United States in 2012. Prostate cancer is tied with colorectal cancer in terms of cancer mortality, causing 9% of cancer deaths in the United States in 2012. There is a one in six lifetime probability of being diagnosed with prostate cancer. It demonstrates a remarkably wide range of clinical

Figure 21-33 Nodular prostatic hyperplasia. **A**, Well-defined nodules of benign prostatic hypertrophy compress the urethra into a slitlike lumen. **B**, A microscopic view of a whole mount of the prostate shows nodules of hyperplastic glands on both sides of the urethra. **C**, Under high power the characteristic dual cell population: the inner columnar and outer flattened basal cell can be seen.

behaviors, from very aggressive lethal cancers to incidentally discovered clinically insignificant cancers.

Incidence. Cancer of the prostate is typically a disease of men older than age 50 years, in whom it is quite common. Based on autopsy studies, its incidence increases from 20% in men in their 50s to approximately 70% in men between the ages of 70 and 80 years. There are some remarkable and puzzling national and racial differences in the incidence of the disease. Prostatic cancer is uncommon in Asians and occurs most frequently among blacks. In addition to hereditary factors, environment plays a role, as evidenced by the rise in the incidence of the disease in Japanese immigrants to the United States, though not nearly to the level of that of native-born Americans. Also, as the diet in Asia becomes more westernized, the incidence of clinically significant prostate cancer in this region of the world seems to be increasing. Whether this is due to dietary factors or other lifestyle changes is not clear.

Etiology and Pathogenesis. Our knowledge of the causes of prostate cancer is far from complete. Several factors, including age, race, family history, hormone levels, and environmental influences are suspected to play a role. The increased incidence of this disease upon migration from a low-incidence region to one with a high incidence is consistent with a role for environmental influences. There are many candidate environmental factors, but none has been proven to be causative. For example, increased consumption of fats or carcinogens present in charred red meats has been implicated. Other dietary products suspected of preventing or delaying prostate cancer development include lycopenes (found in tomatoes), soy products, and vitamin D.

Androgens play an important role in prostate cancer.

Like their normal counterparts, the growth and survival of prostate cancer cells depends on androgens, which bind to the androgen receptor (AR) and induce the expression of pro-growth and pro-survival genes. Of interest with respect to differences in prostate cancer risk among races, the X-linked AR gene contains a polymorphic sequence composed of repeats of the codon CAG (which codes for glutamine). Very large expansions of this stretch of CAGs cause a rare neurodegenerative disorder, Kennedy disease, characterized by muscle cramping and weakness. However, even in normal individuals, there is sufficient variation in the length of the CAG repeats to affect AR function. ARs with the shortest stretches of polyglutamine have the highest sensitivity to androgens. The shortest polyglutamine repeats on average are found in African Americans, while Caucasians have an intermediate length and Asians have the longest, paralleling the incidence and mortality of prostate cancer in these groups. More directly, the length of the repeats is inversely related to rate at which prostate cancer develops in mouse models.

The importance of androgens in maintaining the growth and survival of prostate cancer cells can be seen in the therapeutic effect of castration or treatment with antiandrogens, which usually induce disease regression. Unfortunately, most tumors eventually become resistant to androgen blockade. Tumors escape through a variety of mechanisms, including acquisition of hypersensitivity to low levels of androgen (e.g., through AR gene amplification); ligand-independent AR activation (e.g., via splice variants that lack the ligand binding domain); mutations in AR that allow it to be activated by non-androgen ligands; and other mutations or epigenetic changes that activate alternative signaling pathways, which may bypass the

need for AR altogether. Among the latter are changes that lead to increased activation of the PI3K/AKT signaling pathway (such loss of the *PTEN* tumor suppressor gene), which is observed most often in tumors that have become resistant to antiandrogen therapy.

There is much interest in the role of other inherited polymorphisms in the development of prostate cancer. Compared with men with no family history, men with one first-degree relative with prostate cancer have twice the risk and those with two first-degree relatives have five times the risk of developing prostate cancer. Men with a strong family history of prostate cancer also tend to develop the disease at an earlier age. Men with germline mutations of the tumor suppressor *BRCA2* have a 20-fold increased risk of prostate cancer, and a germline mutation in *HOXB13*, a homeobox gene encoding a transcription factor that regulates prostatic development, also confers substantially increased risk in the small percentage of families that carry it. However, the vast majority of familial prostate cancers are due to variation in other loci that confer a small increase in cancer risk. Family and genome-wide association studies have identified more than 40 risk-associated loci, which explain approximately 25% of the familial risk. Of possible interest, a number of the candidate genes in these regions are involved in innate immunity, leading to speculation that inflammation, an emerging hallmark of cancer (Chapter 7) may set the stage for the development of prostate carcinoma.

Other work is focused on the role of tumor-specific acquired mutations and epigenetic changes. **One very common structural genetic change in prostate cancer is chromosomal rearrangements that juxtapose the coding sequence of an ETS family transcription factor gene (most commonly *ERG* or *ETV1*) next to the androgen-regulated *TMPRSS2* promoter.** These rearrangements, which occur in approximately half of prostate cancer cases in Caucasian cohorts, place the involved ETS gene under the control of the *TMPRSS2* promoter and lead to its overexpression in an androgen-dependent fashion. Overexpression of ETS transcription factors does not directly transform prostate epithelial cells, but it does make normal prostate epithelial cells more invasive, possibly through the upregulation of matrix metalloproteases. The clinical significance of these gene rearrangements remains unclear, as most studies show that in surgically treated cohorts, the presence of ETS gene rearrangement alone does not portend a worse prognosis.

In contrast to breast and colon cancer, recent whole genome sequencing efforts have demonstrated that genomic deletions and amplifications are more common in prostate cancer than point mutations involving oncogenes. Common genetic alterations in prostate cancer include amplification of the 8q24 locus containing the *MYC* oncogene, and deletions involving the *PTEN* tumor suppressor. In late stage disease, loss of *TP53* (by deletion or mutation), and deletions involving *RB* are common, as are amplifications of the androgen receptor gene locus.

The most common epigenetic alteration in prostate cancer is hypermethylation of the glutathione *S*-transferase (*GSTP1*) gene, which down-regulates *GSTP1* expression. The *GSTP1* gene is located on chromosome 11q13 and is an important part of the pathway that prevents damage from a wide range of carcinogens. Other genes silenced

by epigenetic modifications in a subset of prostate cancers include a number of tumor suppressor genes, including genes involved in cell cycle regulation (*RB*, *CDKN2A*, maintenance of genomic stability (*MLH1*, *MSH2*), and suppression of Wnt pathway signaling (*APC*).

As can be surmised from the multiplicity of abnormalities, prostate carcinoma (like other cancers) is the product of some critical combination of acquired genomic structural changes, somatic mutations and epigenetic changes. A putative precursor lesion, prostatic intraepithelial neoplasia (PIN), has been described. There are several lines of evidence relating PIN to invasive cancer. First, both PIN and cancer typically predominate in the peripheral zone and are relatively uncommon in other zones. Prostates containing cancer have a higher frequency and a greater extent of PIN, which is also often seen in proximity to cancer. Studies have revealed that many of the molecular changes seen in invasive cancers are present in PIN (for example, rearrangements involving *ETS* genes are found in a subset), strongly supporting the argument that PIN is a precursor of invasive cancer. Despite all this evidence, we do not know the natural history of PIN, and in particular how often it progresses to cancer. Thus, unlike in cancer of the cervix, the term “carcinoma in situ” is not used for PIN.

MORPHOLOGY

When the terms “**prostate cancer**” or “**prostate adenocarcinoma**” are used without qualifications it refers to the common or acinar variant of prostate cancer. In approximately 70% of cases, carcinoma of the prostate arises in the peripheral zone of the gland, classically in a posterior location, where it may be palpable on rectal examination (Fig. 21-34). Characteristically, on cross-section of the prostate **the neoplastic tissue is gritty and firm, but when embedded within the prostatic substance it may be extremely difficult to visualize and be more readily apparent on palpation.** Local extension most commonly involves periprostatic tissue, seminal vesicles, and the base of the urinary bladder, which in advanced disease may produce ureteral obstruction. Metastases spread via lymphatics to the obturator nodes and eventually to the para-aortic

Figure 21-34 Adenocarcinoma of the prostate. Carcinomatous tissue is seen on the posterior aspect (*lower left*). Note solid whiter tissue of cancer in contrast to spongy appearance of benign peripheral zone in the contralateral side.

Figure 21-35 Metastatic osteoblastic prostatic carcinoma within vertebral bodies.

nodes. Hematogenous spread occurs chiefly to the bones, particularly the axial skeleton, but some lesions spread widely to viscera. Massive visceral dissemination is an exception rather than the rule. The bony metastases are typically osteoblastic, a feature that in men points strongly to a prostatic origin (Fig. 21-35). The bones commonly involved, in descending order of frequency, are lumbar spine, proximal femur, pelvis, thoracic spine, and ribs.

Histologically, most lesions are adenocarcinomas that produce well-defined, readily demonstrable gland patterns. The glands are typically smaller than benign glands and are lined by a single uniform layer of cuboidal or low columnar epithelium. In contrast to benign glands, prostate cancer glands are more crowded, and characteristically lack branching and papillary infolding. **The outer basal cell layer typical of benign glands is absent.** The cytoplasm of the tumor cells ranges from pale-clear to a distinctive amphophilic appearance. Nuclei are large and often contain one or more large nucleoli. There is some variation in nuclear size and shape, but in general pleomorphism is not marked. Mitotic figures are uncommon.

The diagnosis of prostate cancer on biopsy specimens can be challenging due to several factors. There is often only a scant amount of tissue available for histologic examination in needle biopsies, and malignant glands may be admixed with numerous benign glands (Fig. 21-36). Moreover, the histologic findings pointing to malignancy may be subtle (leading to underdiagnosis), and there are also benign mimickers of cancer that can lead to a misdiagnosis of cancer. A few histologic findings on biopsy are specific for prostate cancer, such as perineural invasion, but in general the diagnosis is made based on a

constellation of architectural, cytologic, and ancillary findings (Fig. 21-37). As discussed earlier, one distinguishing feature between benign and malignant prostate glands is that benign glands contain basal cells, which are absent in cancer (compare benign and malignant glands in Fig. 21-36A, and benign glands in Fig. 21-33C with cancerous glands in Fig. 21-36B). This distinction can be brought out by using various immunohistochemical markers to label basal cells. Another useful immunohistochemical marker is α -methylacyl-coenzyme A-racemase (AMACR), which is up-regulated in prostate cancer. The majority of prostate cancers are positive for AMACR, the sensitivity varying among studies from 82% to 100%. Such markers, while improving diagnostic accuracy, are still prone to false-positive and false-negative results and must be used in conjunction with the routine hematoxylin and eosin–stained sections.

In approximately 80% of cases, prostatic tissue removed for carcinoma also harbors presumptive precursor lesions, referred to as **high-grade prostatic intraepithelial neoplasia (PIN)**. PIN consists of architecturally benign large, branching prostatic acini lined by cytologically atypical cells with prominent nucleoli. Cytologically PIN and carcinoma may be identical. Unlike malignant glands, PIN glands are surrounded by a patchy layer of basal cells and an intact basement membrane.

Figure 21-36 A, Photomicrograph of small focus of adenocarcinoma of the prostate demonstrating small glands crowded in between larger benign glands. **B**, Higher magnification shows several small malignant glands with enlarged nuclei, prominent nucleoli, and dark cytoplasm, compared with larger benign gland (top).

Figure 21-37 Carcinoma of prostate showing perineural invasion by malignant glands. Compare to benign gland (left).

Grading and Staging. Grading is of particular importance in prostatic cancer, because grade and stage (discussed below) are the best prognostic predictors. Prostate cancer is graded using the Gleason system, which stratifies prostate cancer into five grades on the basis of glandular patterns of differentiation. Grade 1 represents the most well differentiated tumors, in which the neoplastic glands are uniform and round in appearance and are packed into well-circumscribed nodules (Fig. 21-38A). In contrast, grade 5 tumors show no glandular differentiation, with

tumor cells infiltrating the stroma in the form of cords, sheets, and nests (Fig. 21-38C). The other grades fall in between these extremes. Most tumors contain more than one pattern; in such instances, a primary grade is assigned to the dominant pattern and a secondary grade to the second most frequent pattern. The two numeric grades are then added to obtain a combined Gleason grade or score. Thus, for example, a tumor with a dominant grade 3 and a secondary grade 4 has a Gleason score of 7. Tumors with only one pattern are treated as if their primary and secondary grades are the same, and hence, the number is doubled. An exception to the rule is if three patterns are present on biopsy, the most common and highest grades are added together to arrive at the Gleason score. Thus, under this schema the most well-differentiated tumors have a Gleason score of 2 (1 + 1), and the least-differentiated tumors merit a score of 10 (5 + 5). Gleason scores are often combined into groups with similar biologic behavior, with grades 2 through 6 representing well-differentiated tumors with an excellent prognosis, 3 + 4 = 7 moderately differentiated tumors, 4 + 3 = 7 moderately to poorly differentiated tumors, and 8 through 10 poorly to undifferentiated tumors with aggressive biologies. In surgical specimens, Gleason scores of 2 through 4 are typically small tumors found incidentally in TURP performed for symptoms of BPH. The majority of potentially treatable cancers detected on needle biopsy as a result of screening have Gleason scores of 6 through 7. Tumors with Gleason scores 8 through 10 tend to be advanced cancers that are less likely to be cured. Although there is some evidence that prostate cancers can become more aggressive with time, most

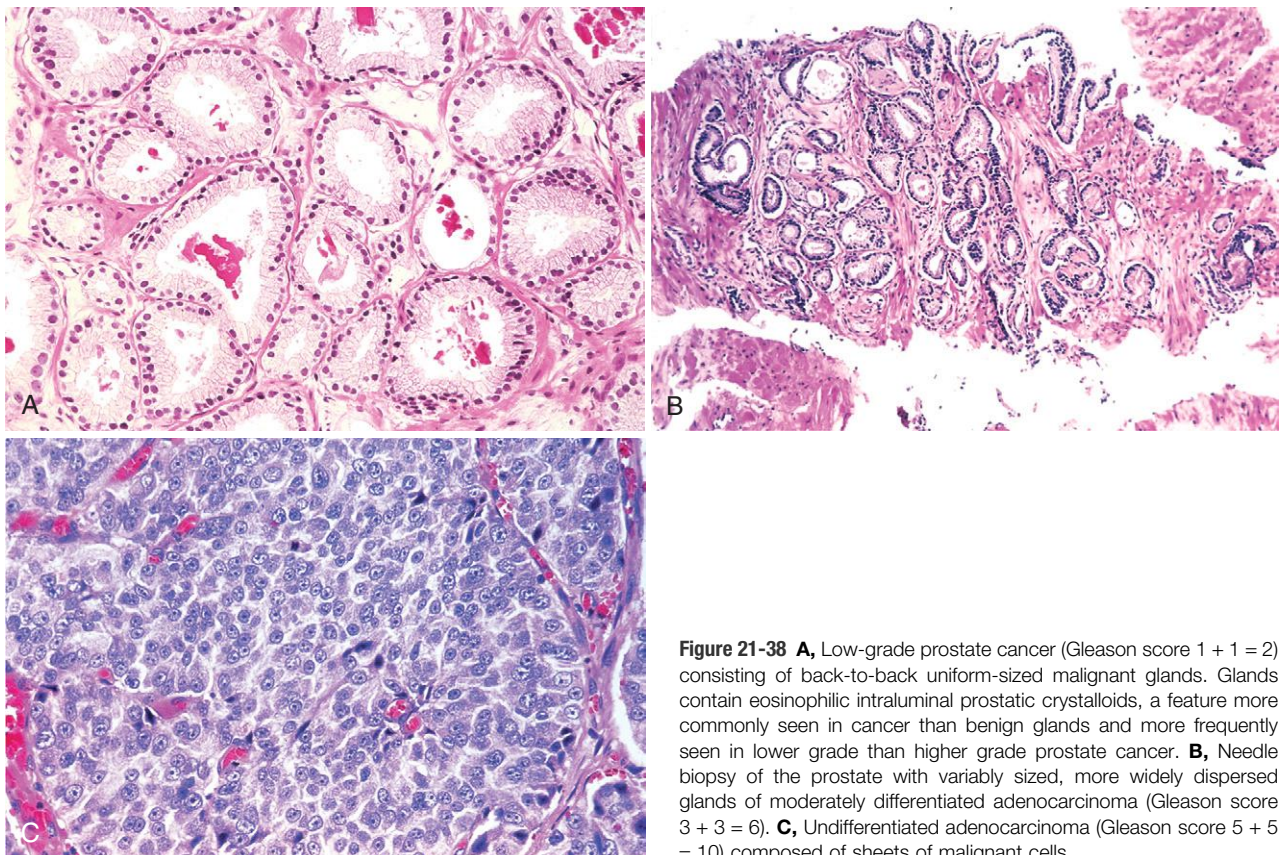

Figure 21-38 **A**, Low-grade prostate cancer (Gleason score 1 + 1 = 2) consisting of back-to-back uniform-sized malignant glands. Glands contain eosinophilic intraluminal prostatic crystalloids, a feature more commonly seen in cancer than benign glands and more frequently seen in lower grade than higher grade prostate cancer. **B**, Needle biopsy of the prostate with variably sized, more widely dispersed glands of moderately differentiated adenocarcinoma (Gleason score 3 + 3 = 6). **C**, Undifferentiated adenocarcinoma (Gleason score 5 + 5 = 10) composed of sheets of malignant cells.

Table 21-6 Staging of Prostatic Adenocarcinoma Using the TNM System

TNM Designation	Anatomic Findings
Extent of Primary Tumor (T)	
T1	Clinically inapparent lesion (by palpation/imaging studies)
T1a	Involvement of \leq 5% of resected tissue
T1b	Involvement of $>$ 5% of resected tissue
T1c	Carcinoma present on needle biopsy (following elevated PSA)
T2	Palpable or visible cancer confined to prostate
T2a	Involvement of \leq 5% of one lobe
T2b	Involvement of $>$ 5% of one lobe, but unilateral
T2c	Involvement of both lobes
T3	Local extraprostatic extension
T3a	Extracapsular extension
T3b	Seminal vesical invasion
T4	Invasion of contiguous organs and/or supporting structures including bladder neck, rectum, external sphincter, levator muscles, or pelvic floor
Status of Regional Lymph Nodes (N)	
N0	No regional nodal metastases
N1	Metastasis in regional lymph nodes
Distant Metastases (M)	
M0	No distant metastases
M1	Distant metastases present
M1a	Metastases to distant lymph nodes
M1b	Bone metastases
M1c	Other distant sites

PSA, Prostate-specific antigen.

commonly, the Gleason score remains stable over a period of several years.

Staging of prostatic cancer is also important in the selection of the appropriate form of therapy (Table 21-6). Stage T1 refers to incidentally found cancer, either on TURP done for BPH symptoms (T1a and T1b depending on the extent and grade) or on needle biopsy typically performed for elevated serum prostate-specific antigen (PSA) levels (stage T1c). Stage T2 is organ-confined cancer. Stage T3a and T3b tumors show extra-prostatic extension, with and without seminal vesicle invasion, respectively. Stage T4 reflects direct invasion of contiguous organs. Any spread of tumor to the lymph nodes regardless of extent is eventually associated with a fatal outcome, such that the staging system merely records the presence or absence of this finding (N0/N1).

Clinical Course. It is generally accepted that most incidentally discovered focal (stage T1a) cancers found on TURP do not progress when followed for 10 or more years. Older patients with stage T1a disease are typically followed, but younger men with a longer life expectancy may undergo needle biopsy to look for additional cancer in the peripheral zone of the prostate. Stage T1b lesions are more ominous and are treated the same as tumors that are found

on needle biopsy, since they have a mortality of 20% if left untreated.

Localized prostate cancer is asymptomatic, and is usually discovered by the detection of a suspicious nodule on rectal examination or elevated serum PSA level (discussed later). Most prostatic cancers arise peripherally away from the urethra, and therefore urinary symptoms occur late. Patients with clinically advanced prostatic cancer may present with urinary symptoms, such as difficulty in starting or stopping the stream, dysuria, frequency, or hematuria. Today it is uncommon for patients to come to attention because of back pain caused by vertebral metastases. As already mentioned, **the finding of osteoblastic metastases by skeletal surveys or the much more sensitive radionuclide bone scanning is virtually diagnostic of this form of cancer in men.** These cancers pursue a universally fatal course.

Digital rectal examination may detect some early prostatic carcinomas because of their posterior location, but the test suffers from both low sensitivity and specificity. Likewise, while transrectal ultrasonography and other imaging modalities show characteristic findings in those with cancerous prostates, the poor sensitivity and specificity of these tests also limit their diagnostic utility. Typically a transrectal needle biopsy is required to confirm the diagnosis.

Measurement of serum PSA levels is widely used to assist with the diagnosis and management of prostate cancer. PSA is a product of prostatic epithelium and is normally secreted in the semen. It is an androgen-regulated serine protease whose function is to cleave and liquefy the seminal coagulum formed after ejaculation. In normal men, only minute amounts of PSA circulate in the serum. Elevated blood levels of PSA occur in association with localized as well as advanced cancer. However, as a screening test for prostate cancer, the use of PSA remains controversial in that it lacks both sensitivity and specificity. Importantly, PSA is organ specific, but not cancer specific. Although serum levels of PSA are elevated to a lesser extent in BPH than in prostatic carcinomas, there is considerable overlap. Other factors such as prostatitis, infarction of nodular hyperplasias, instrumentation of the prostate, and ejaculation also increase serum PSA levels. If the cut-off between normal and abnormal PSA levels is too low, this may falsely indicate the need for a prostate biopsy in some men and result in the detection and potentially unnecessary treatment of indolent and non-life-threatening tumors. In most laboratories, a serum level of 4 ng/mL is reported as the cut-off between normal and abnormal; however, this cut-off may be too high because 20% to 40% of patients with organ-confined prostate cancer have a PSA value of 4 ng/mL or less, which is not detected by this simple screening test. Thus, some guidelines consider PSA values above 2.5 ng/mL abnormal.

Several refinements in the estimation and interpretation of PSA values are currently used. These include the ratio between the serum PSA value and volume of prostate gland (*PSA density*), the rate of change in PSA value with time (*PSA velocity*), the use of age-specific reference ranges, and the ratio of free and bound PSA in the serum. Men with enlarged hyperplastic prostate glands have higher total serum PSA levels than men with small glands. The measurement of serum PSA density factors out the

contribution of benign prostatic tissue to serum PSA levels. It is calculated by dividing the total serum PSA level by the estimated gland volume (usually determined by transrectal ultrasound measurements) to estimate the PSA produced per gram of prostate tissue. As men age, their prostates tend to enlarge with BPH. One would then anticipate that, overall, older men would have higher serum PSA levels than younger men. The upper *age-specific PSA* reference ranges are 2.5 ng/mL for men 40 to 49 years of age, 3.5 ng/mL for men 50 to 59 years, 4.5 ng/mL for men 60 to 69 years, and 6.5 ng/mL for men 70 to 79 years. Consequently, a serum PSA value of 3.5, while it will appear as a normal value on a laboratory test, is a worrisome finding in a man in his 40s, warranting additional evaluation. Another means of interpreting serum PSA tests is to assess PSA velocity or the rate of change of PSA. Men with prostate cancer demonstrate a more rapid increase in PSA levels over time than do men who do not have prostate cancer. The rate of change in PSA that best distinguishes between men with and without prostate cancer is 0.75 ng/mL per year. For this measurement to be valid, at least three PSA measurements must be performed over a period of 1.5 to 2 years, as there is substantial short-term variability (up to 20%) between repeat PSA measurements. A man who has a significant increase in serum PSA levels, even if the latest serum PSA test is below the normal cut-off (<4 ng/mL), should undergo additional work-up. Studies have revealed that immunoreactive PSA (the form detected by the widely used antibody test) exists in two forms: a major fraction bound to α_1 -antichymotrypsin and a minor free fraction. The percentage of free PSA (free PSA/total PSA \times 100) is lower in men with prostate cancer than in men with benign prostatic diseases.

Because many small cancers localized to the prostate may never progress to clinically significant invasive cancers, there is considerable uncertainty regarding the management of small lesions that are detected because of an elevated PSA level. This has created controversy about the role of widespread screening for prostate cancer. Much effort is therefore focused in devising criteria by which those localized lesions most likely to advance can be distinguished from those that remain innocuous.

In contrast to its role in screening, there is no controversy about the value of serial measurements of PSA in assessing the response to therapy. For example, a rising PSA level after radical prostatectomy or radiotherapy for localized disease is indicative of recurrent or disseminated disease. Immunohistochemical localization of PSA on tissue sections can also help the pathologist to determine whether a metastatic tumor originated in the prostate.

In addition to prostate specific antigen, other genes that may serve as biomarkers in prostate cancer have emerged. *PCA3* is a noncoding RNA which is overexpressed in 95% of prostate cancers. A diagnostic test that quantifies urine *PCA3* is currently used as an additional biomarker in patients suspected to have prostate cancer because of elevated PSA, but who have had a negative prostate biopsy. Elevated urine *PCA3* scores have been shown to be associated with an increased risk of a positive repeat biopsy in this setting. The combination of urinary *PCA3* with screening of urine for *TMPRSS2-ERG* fusion DNA (see earlier) may have increased sensitivity and specificity compared to PSA screening alone.

Cancer of the prostate is treated by surgery, radiation therapy, and hormonal manipulations. More than 90% of patients who receive such therapy can expect to live for 15 years. Currently, the most common treatment for clinically localized prostate cancer is radical prostatectomy. The prognosis following radical prostatectomy is based on the pathologic stage, margin status, and Gleason grade. Alternative treatments for localized prostate cancer are either external-beam radiation therapy or interstitial radiation therapy, the latter consisting of placing radioactive seeds throughout the prostate (brachytherapy). External-beam radiation therapy is also used to treat prostate cancer that is too locally advanced to be cured by surgery. Since some prostate cancers have a relatively indolent course, wherein it may take 10 years to see benefit from surgery or radiation therapy, active surveillance is appropriate for many older men or those with significant co-morbidity or even some younger men with low serum PSA values and limited lower grade cancer on biopsy. Advanced, metastatic carcinoma is treated by androgen deprivation therapy. Androgen deprivation may be achieved by orchiectomy, or by administration of synthetic analogs of luteinizing hormone-releasing hormone (LHRH) which suppress normal LHRH, achieving, in effect, a pharmacologic orchiectomy. Other agents decrease levels of local and circulating androgens by inhibiting systemic steroid hormone synthesis. Finally, pharmacologic blockade of the androgen receptor constitutes an additional means of treatment. Although androgen deprivation therapy induces remissions, eventually tumors become resistant to testosterone withdrawal, an event that is a harbinger of disease progression and death.

KEY CONCEPTS

Carcinoma of the Prostate

- Carcinoma of the prostate is a common cancer of older men between 65 and 75 years of age. Aggressive, clinically significant disease is more common in American blacks than in whites, while clinically insignificant occult lesions appear to occur at equal frequencies in these two races.
- Prostate carcinomas range from indolent lesions that will never cause harm to aggressive fatal tumors.
- The most common acquired genetic lesions in prostatic carcinomas are *TPRSS2-ETS* fusion genes and mutations or deletions that activate the PI3K/AKT signaling pathway.
- Carcinomas of the prostate arise most commonly in the outer, peripheral gland and may be palpable by rectal examination.
- Microscopically, they are adenocarcinomas with variable differentiation. Neoplastic glands are lined by a single layer of cells.
- Grading of prostate cancer by the Gleason system correlates with pathologic stage and prognosis.
- Most localized cancers are clinically silent and are detected by routine monitoring of PSA concentrations in older men. Bone metastases, often osteoblastic, typify advanced prostate cancer.

- Serum PSA measurement is a useful but imperfect cancer-screening test, with significant rates of false-negative and false-positive results. Evaluation of PSA concentrations after treatment has great value in monitoring progressive or recurrent disease.

Miscellaneous Tumors and Tumor-like Conditions

Prostate adenocarcinomas may also arise from prostatic ducts. Ductal adenocarcinomas arising in peripheral ducts may present in a fashion similar to ordinary prostate cancer, whereas those arising in the larger periurethral ducts may show signs and symptoms similar to urothelial cancer, causing hematuria and urinary obstructive symptoms. Ductal adenocarcinomas are associated with a relatively poor prognosis. Prostate cancers may show squamous differentiation, either following hormone therapy or de novo, resulting in either adenosquamous or pure squamous cancer. Prostate cancer that reveal abundant mucinous secretions are termed *colloid carcinoma of the prostate*. The most aggressive variant of prostate cancer is small-cell cancer (also known as neuroendocrine carcinoma). Almost all cases of small-cell carcinoma are rapidly fatal.

The most common tumor to secondarily involve the prostate is urothelial cancer. Two distinct patterns of involvement exist. Large invasive urothelial cancers can directly invade from the bladder into the prostate. Alternatively, carcinoma in situ of the bladder can extend into the prostatic urethra and down into the prostatic ducts and acini.

The same mesenchymal tumors described earlier that involve the bladder may also manifest in the prostate. In addition, there exist unique mesenchymal tumors of the prostate derived from the prostatic stroma. Although lymphomas may appear to first arise in the prostate, most patients shortly thereafter demonstrate systemic disease.

A brief review of the development and anatomy of the female genital tract is fundamental to understanding the diseases that affect this complex organ system. Normal development of the female genital tract proceeds through a series of tightly choreographed events involving the primordial germ cells, the müllerian (paramesonephric) ducts, the wolffian (mesonephric) ducts, and the urogenital sinus (Fig. 22-1).

- *Germ cells* arise in the wall of the yolk sac by the fourth week of gestation. By the fifth or sixth week they migrate into the urogenital ridge and induce proliferation of the mesodermal epithelium, which gives rise to the epithelium and stroma of the ovary.
- The lateral *müllerian ducts* form at about the sixth week of development through invagination and fusion of the coelomic lining epithelium. The ducts progressively grow caudally into the pelvis, where they swing medially to fuse with the urogenital sinus at the müllerian tubercle (Fig. 22-1A). Further caudal growth brings these fused ducts into contact with the urogenital sinus. The unfused upper portions of the müllerian ducts mature into the fallopian tubes, while the fused lower portion develops into the uterus, cervix and upper vagina.
- The *urogenital sinus* develops when the cloaca is subdivided by the uorectal septum; it eventually forms the lower part of the vagina and the vestibule of the external genitalia (Fig. 22-1B).
- The *mesonephric ducts* normally regress in the female, but remnants may persist into adult life as epithelial inclusions adjacent to the ovaries, tubes, and uterus. In the cervix and vagina these rests may be cystic and are termed *Gartner duct cysts*.

The epithelial lining of the female genital tract as well as the ovarian surface share a common origin from coelomic epithelium (mesothelium), which may explain why

morphologically similar benign and malignant lesions arise in various sites within the female genital tract and the adjacent peritoneal surfaces.

Diseases of the female genital tract are extremely common and include complications of pregnancy, infections, tumors, and hormonally induced abnormalities. The following discussion presents the pathology of the major diseases that result in clinical problems. Additional details can be found in current textbooks of gynecologic pathology and clinical obstetrics and gynecology. We will discuss the pathologic conditions peculiar to each segment of the female genital tract separately, but before doing so will briefly review infections and pelvic inflammatory disease because they can affect many of the various anatomic structures concomitantly.

Infections

A large variety of organisms can infect the female genital tract. Some infections with microorganisms such as *Candida*, *Trichomonas*, and *Gardnerella* are very common and may cause significant discomfort, but are without serious sequelae. Others, such as *Neisseria gonorrhoeae* and *Chlamydia* infections, are major causes of female infertility, and others still, such as *Ureaplasma urealyticum* and *Mycoplasma hominis* infections, are implicated in preterm deliveries. Viruses, especially herpes simplex viruses (HSVs) and human papillomaviruses (HPVs), also account for considerable morbidity; HSVs cause painful genital ulcerations, whereas HPVs are involved in the pathogenesis of cervical, vaginal, and vulvar cancers.

Many of these infections are sexually transmitted, including trichomoniasis, gonorrhea, chancroid, granuloma inguinale, lymphogranuloma venereum, syphilis, *Mycoplasma*, *Chlamydia*, HSV, and HPV. Most of these conditions are considered in Chapter 8; HPV is also discussed

Figure 22-1 Embryology and anatomy of the female genital tract. **A**, Early in development, the mesonephric (blue) and müllerian (red) ducts merge at the urogenital sinus to form the müllerian tubercle. **B**, By birth, the müllerian ducts have fused to form the fallopian tubes, uterus, and endocervix (red), merging with the vaginal squamous mucosa. The mesonephric ducts regress, but may be found as a remnant in the ovary, adnexa, and cervix (Gartner duct). (Adapted from Langman J: Medical Embryology. Baltimore, Williams and Wilkins, 1981.)

in [Chapter 7](#) due to its important role as a transforming virus. Here we touch only on aspects relevant to the female genital tract, including pathogens confined to the lower genital tract (vulva, vagina, and cervix) and those that involve the entire genital tract and are implicated in pelvic inflammatory disease.

Infections of the Lower Genital Tract

Herpes Simplex Virus. Genital herpes simplex virus (HSV) infection is common and involves, in order of frequency, the cervix, vagina, and vulva. HSVs are DNA viruses that include two serotypes, HSV-1 and HSV-2. HSV-1 typically results in oropharyngeal infection, whereas HSV-2 usually involves genital mucosa and skin; however, depending on the sexual practices HSV-1 may be detected in the genital region and HSV-2 may cause oral infections as well ([Chapter 8](#)). By age 40 years, approximately 30% of women are seropositive for antibodies against HSV-2.

About one third of newly infected individuals are symptomatic. Lesions typically develop 3 to 7 days after transmission and are often associated with systemic symptoms such as fever, malaise, and tender inguinal lymph nodes. The earliest lesions usually consist of red papules that progress to vesicles and then to painful coalescent ulcers. The lesions are easily visible on vulvar skin and mucosa, while cervical or vaginal lesions present with severe purulent discharge and pelvic pain. Lesions around the urethra may cause painful urination and urinary retention. The vesicles and ulcers contain numerous viral particles, accounting for the high transmission rate during active infection. The mucosal and skin lesions heal spontaneously in 1 to 3 weeks, but during the acute infection the virus migrates to the regional lumbosacral nerve ganglia and establishes a latent infection. Because of viral latency, HSV infections persist indefinitely and any decrease in immune function, as well as stress, trauma, ultraviolet radiation, and hormonal changes, can trigger reactivation of the virus and recurrence of the skin and mucosal lesions. As expected, recurrences are much more common in immunosuppressed individuals.

MORPHOLOGY

By the time an HSV lesion is biopsied it is typically in the phase of an ulcer. The epithelium is desquamated and marked acute inflammation is present at the ulcer bed. Smears of the inflammatory exudate from the active lesions show characteristic HSV cytopathic changes consisting of multinucleated squamous cells containing eosinophilic to basophilic viral inclusions with a “ground-glass” appearance ([Fig. 22-2](#)).

Transmission of HSV takes place mainly during the active phase, but occasionally may also occur during the latent phase due to subclinical virus shedding. Condoms and antiviral therapies can reduce the risk of transmission, but do not prevent it. As with other sexually transmitted diseases, women are more susceptible to transmission than men. Previous infection with HSV-1 seems to reduce susceptibility to HSV-2 infection. The gravest consequence of HSV infection is transmission to the neonate during birth. This risk is highest if the infection is active during delivery and particularly if it is a primary (initial) infection in the

Figure 22-2 Herpes simplex virus infection (cervical smear). The cell in the center shows HSV cytopathic effect. Infected cells become multinucleated and contain intranuclear viral inclusions with a characteristic “ground-glass” appearance.

mother. Cesarean section is warranted in such cases. In addition, HSV-2 infection enhances HIV-1 acquisition and transmission.

The diagnosis is based on typical clinical findings and HSV detection. The purulent exudate is aspirated from the lesions and inoculated into a tissue culture. After 48 to 72 hours the viral cytopathic effect can be seen and the virus may then be serotyped. In addition, some laboratories offer more sensitive polymerase chain reaction, enzyme-linked immunosorbent assays, and direct immunofluorescent antibody tests for detection of HSV in the lesional secretions. Individuals with primary, acute-phase HSV infection do not have serum anti-HSV antibodies. Detection of anti-HSV antibodies in the serum is indicative of recurrent/latent infection.

There is no effective treatment for latent HSV; however, antiviral agents like acyclovir or famciclovir may shorten the length of the initial and recurrent symptomatic phase. The ultimate solution is an effective vaccine, a tantalizing goal that is yet to be realized.

Other Lower Female Genital Tract Infections. As mentioned, a variety of other viruses, fungi, and bacteria can also cause symptomatic infections of the lower genital tract. Those that are most common include the following:

- *Molluscum contagiosum* is a skin or mucosal lesion caused by poxvirus ([Fig. 22-3A](#)). There are four types of molluscum contagiosum viruses (MCVs), MCV-1 to -4, with MCV-1 being the most prevalent and MCV-2 being most often sexually transmitted. The infections are common in young children between 2 and 12 years of age and are transmitted through direct contact or shared articles (e.g., towels). Molluscum may affect any area of the skin but is most common on the trunk, arms, and legs. In adults, molluscum infections are typically sexually transmitted and affect the genitals, lower abdomen, buttocks, and inner thighs. The average incubation period is 6 weeks. Diagnosis is based on the characteristic clinical appearance of pearly, dome-shaped papules with a

Figure 22-3 Molluscum contagiosum infection. **A**, Low power appearance of a dome-shaped papule with dimpled center. **B**, High power magnification reveals intracytoplasmic viral inclusions.

dimpled center. The papules measure 1 to 5 mm in diameter, and their central waxy core contains cells with *cytoplasmic viral inclusions* (Fig. 22-3B).

- **Fungal infections**, especially those caused by yeast (*Candida*), are extremely common; in fact, **yeast are part of many women's normal vaginal microflora and the development of symptomatic candidiasis is typically a result of a disturbance in the patient's vaginal microbial ecosystem.** Diabetes mellitus, antibiotics, pregnancy, and conditions resulting in compromised neutrophil or T_H17 T-cell function are permissive to symptomatic fungal infection, which manifests itself by marked vulvovaginal pruritus, erythema, swelling, and curdlike vaginal discharge. Severe infection may result in mucosal ulcerations. The diagnosis is made by finding the pseudospores or filamentous fungal hyphae in wet KOH mounts of the discharge or on Papanicolaou (Pap) smear. Even though sexual transmission of yeast infection has been documented, candidiasis is not considered a sexually transmitted disease.
- *Trichomonas vaginalis* is a large, flagellated ovoid protozoan that is usually transmitted by sexual contact and develops within 4 days to 4 weeks. The patients may be asymptomatic or may complain of yellow, frothy vaginal discharge, vulvovaginal discomfort, dysuria (painful urination), and dyspareunia (painful intercourse). The vaginal and cervical mucosa typically has a fiery-red appearance, with marked dilatation of cervical mucosal vessels resulting in characteristic colposcopic appearance of "strawberry cervix."
- *Gardnerella vaginalis* is a gram-negative bacillus that is implicated as the main cause of *bacterial vaginosis* (vaginosis). Patients typically present with thin, green-gray, malodorous (fishy) vaginal discharge. Pap smears reveal superficial and intermediate squamous cells covered with a shaggy coating coccobacilli. Bacterial cultures in such cases reveal *G. vaginalis* and other bacteria, including anaerobic peptostreptococci and aerobic α -hemolytic streptococci. In pregnant patients, bacterial vaginosis has been implicated in premature labor.

- *Ureaplasma urealyticum* and *Mycoplasma hominis* species account for some cases of vaginitis and cervicitis, and have been implicated in chorioamnionitis and premature delivery in pregnant patients
- *Chlamydia trachomatis* infections mainly take the form of cervicitis. However, in some patients the infection may ascend to the uterus and fallopian tubes, resulting in endometritis and salpingitis; thus Chlamydia is one of the causes of pelvic inflammatory disease, as discussed later.

Infections Involving the Lower and Upper Genital Tract

Pelvic Inflammatory Disease

Pelvic inflammatory disease (PID) is an infection that begins in the vulva or vagina and spreads upward to involve most of the structures in the female genital system, resulting in pelvic pain, adnexal tenderness, fever, and vaginal discharge. *Neisseria gonorrhoeae* continues to be a common cause of PID, the most serious complication of gonorrhea in women. *Chlamydia* infection is another well-recognized cause of PID. Infections after spontaneous or induced abortions and normal or abnormal deliveries (called *puerperal infections*) are also important causes of PID. In these situations the infections are typically polymicrobial and may be caused by staphylococci, streptococci, coliforms, and *Clostridium perfringens*.

With gonococcus, inflammatory changes start to appear approximately 2 to 7 days after inoculation. The initial infection most commonly involves the endocervical mucosa, but it may also begin in the Bartholin gland and other vestibular, or periurethral, glands. From these sites the organisms may spread upward to involve the fallopian tubes and tubo-ovarian region. The non-gonococcal bacterial infections that follow induced abortion, dilation and curettage of the uterus, and other surgical procedures are thought to spread upwards from the uterus through the lymphatics or venous channels rather than on the mucosal

Figure 22-4 Acute salpingitis. **A**, Note the dilated tube lumen and edematous tubal plicae expanded by inflammatory cell infiltrates. Pus fills the center of the fallopian tube. **B**, Chronic salpingitis showing scarring and fusion of the plicae. Such scarring may cause infertility or ectopic tubal pregnancy.

surfaces. Therefore, these infections tend to produce more inflammation within the deeper layers of the organs than gonococcal infections.

MORPHOLOGY

Gonococcal infection is characterized by marked acute inflammation of involved mucosal surfaces. Smears of the inflammatory exudate disclose phagocytosed gram-negative diplococci within neutrophils; however, definitive diagnosis requires culture or detection of gonococcal RNA or DNA. If infection spreads, the endometrium is usually spared (for unclear reasons), but within the fallopian tubes, an **acute suppurative salpingitis** ensues (Fig. 22-4A). The tubal mucosa becomes congested and diffusely infiltrated by neutrophils, plasma cells, and lymphocytes, resulting in epithelial injury and sloughing of the plicae. The tubal lumen fills with purulent exudate that may leak out of the fimbriated end. The infection may then spread to the ovary to create a **salpingo-oophoritis**. Collections of pus may accumulate within the ovary and tube (**tubo-ovarian abscesses**) or tubal lumen (**pyosalpinx**) (Fig. 22-4A). With time the infecting organisms may disappear, but the tubal plicae, denuded of epithelium, adhere to one another and slowly fuse in a reparative, scarring process that forms glandlike spaces and blind pouches, referred to as **chronic salpingitis** (Fig. 22-4B). The scarring of the tubal lumen and fimbriae may prevent the uptake and passage of oocytes, leading to infertility or ectopic pregnancy. **Hydrosalpinx**

may also develop as a consequence of the fusion of the fimbriae and the subsequent accumulation of the tubal secretions and tubal distention.

As compared to gonococcal infections, PID caused by staphylococci, streptococci, and the other puerperal invaders tends to show less involvement of the mucosa and the tube lumen, and more inflammation within the deeper tissue layers. These infections often spread throughout the wall to involve the serosa and the broad ligaments, pelvic structures, and peritoneum. Bacteremia is a more frequent complication of streptococcal or staphylococcal PID than of gonococcal infections.

The acute complications of PID include peritonitis and bacteremia, which in turn may result in endocarditis, meningitis, and suppurative arthritis. The chronic sequelae of PID include infertility and tubal obstruction, ectopic pregnancy, pelvic pain, and intestinal obstruction due to adhesions between the bowel and pelvic organs.

In the early stages, gonococcal infections are readily controlled with antibiotics, although penicillin-resistant strains have regrettably emerged. Infections that become walled off in tubo-ovarian abscesses are difficult to eradicate with antibiotics, and it sometimes becomes necessary to remove the organs surgically. Postabortion and postpartum PIDs may also be amenable to treatment with antibiotics, but are far more difficult to control because of the broad spectrum of pathogens that may be involved.

VULVA

Diseases of the vulva in the aggregate constitute only a small fraction of gynecologic practice. Many inflammatory diseases that affect skin elsewhere on the body also occur on the vulva, such as psoriasis, eczema, and allergic dermatitis. Because it is constantly exposed to secretions and moisture, the vulva is more prone to superficial infections than skin elsewhere on the body. Nonspecific vulvitis is

particularly likely to occur in the setting of immunosuppression. Most skin cysts (epidermal inclusion cysts) and skin tumors such as squamous cell carcinoma, basal cell carcinoma and melanoma can also occur in the vulva. Here we discuss relatively specific and common vulvar disorders, including Bartholin cyst, nonneoplastic epithelial disorders, benign exophytic lesions, and tumors of the vulva.

Figure 22-5 Nonneoplastic epithelial vulvar disorders. **A**, Lichen sclerosus. There is marked thinning of the epidermis, sclerosis of the superficial dermis and chronic inflammatory cells in deeper dermis. **B**, Squamous cell hyperplasia, displaying thickened epidermis and hyperkeratosis.

Bartholin Cyst

Infection of the Bartholin gland produces an acute inflammation (adenitis) and may result in an abscess. Bartholin duct cysts are relatively common, occur at all ages, and result from obstruction of the duct by an inflammatory process. These cysts are usually lined by transitional or squamous epithelium. They may become large, up to 3 to 5 cm in diameter, and produce pain and local discomfort. Bartholin duct cysts are either excised or opened permanently (marsupialization).

Nonneoplastic Epithelial Disorders

Leukoplakia is a descriptive clinical term for opaque, white, plaque-like epithelial thickening that may produce pruritus and scaling. Leukoplakia (literally, *white plaques*) may be caused by a variety of benign, premalignant, or malignant disorders, including:

- Inflammatory dermatoses (e.g., psoriasis, chronic dermatitis)
- Lichen sclerosus and squamous cell hyperplasia
- Neoplasias, such as vulvar intraepithelial neoplasia (VIN), Paget disease, and invasive carcinoma

Inflammatory dermatoses associated with leukoplakia are described in [Chapter 25](#), while neoplastic disorders are discussed later in this chapter. Here the major nonneoplastic causes of leukoplakia—lichen sclerosus and squamous cell hyperplasia—are briefly discussed.

Lichen Sclerosus

Lichen sclerosus presents as smooth, white plaques or macules that in time may enlarge and coalesce, producing a surface that resembles porcelain or parchment. When the entire vulva is affected, the labia become atrophic and agglutinated, and the vaginal orifice constricts.

Histologically the lesion is characterized by marked thinning of the epidermis ([Fig. 22-5A](#)); degeneration of the basal cells; excessive keratinization (hyperkeratosis); sclerotic changes of the superficial dermis; and a bandlike lymphocytic infiltrate in the underlying dermis. The disease occurs in all age groups but is most common in postmenopausal women. It may also be encountered elsewhere on the skin. Its pathogenesis is uncertain, but the presence of activated T cells in the subepithelial inflammatory infiltrate and the increased frequency of autoimmune disorders in affected women suggest that an autoimmune reaction is involved. Although lichen sclerosus is not itself a premalignant lesion, women with symptomatic lichen sclerosus have a slightly increased chance of developing squamous cell carcinoma of the vulva.

Squamous Cell Hyperplasia

Previously called hyperplastic dystrophy or *lichen simplex chronicus*, squamous cell hyperplasia is a nonspecific condition resulting from rubbing or scratching of the skin to relieve pruritus. Clinically it presents as leukoplakia and histologic examination reveals thickening of the epidermis (acanthosis), and hyperkeratosis ([Fig. 22-5B](#)). Lymphocytic infiltration of the dermis is sometimes present. The hyperplastic epithelium may show mitotic activity but lacks cellular atypia. While squamous cell hyperplasia is not considered premalignant, it is sometimes present at the margins of vulvar cancers.

Benign Exophytic Lesions

Benign raised (exophytic) or wartlike lesions of the vulva may be caused by infection or may be reactive conditions of unknown etiology. *Condyloma acuminatum*, a papillomavirus-induced lesion, also called a *genital wart*, and syphilitic *condyloma latum* (described in [Chapter 21](#)) are consequences of sexually transmitted infections. Vulvar

Figure 22-6 Condyloma acuminatum. **A**, Low-power view showing exophytic, papillary architecture. **B**, High-power view reveals HPV cytopathic effect (koilocytic atypia) characterized by atypical, enlarged, hyperchromatic nuclei with perinuclear halos (arrow).

fibroepithelial polyps, or skin tags, are similar to skin tags occurring elsewhere on the skin. Vulvar *squamous papillomas* are benign exophytic proliferations covered by nonkeratinized squamous epithelium, which develop on vulvar surfaces and may be single or numerous (vulvar papillomatosis). The etiology of fibroepithelial polyps and squamous papillomas is unknown.

Condyloma Acuminatum

Condylomata acuminata are benign genital warts caused by low oncogenic risk HPVs, mainly types 6 and 11. They may be solitary, but are more frequently multifocal, and may involve vulvar, perineal, and perianal regions as well as the vagina and, less commonly, the cervix. The lesions are identical to those found on the penis and around the anus in males (Chapter 21). On histologic examination, they consist of papillary, exophytic, treelike cores of stroma covered by thickened squamous epithelium (Fig. 22-6A). The surface epithelium shows characteristic viral cytopathic changes referred to as *koilocytic atypia* (Fig. 22-6B), which manifest as nuclear enlargement, hyperchromasia and a cytoplasmic perinuclear halo (see also “Cervix”). Condylomata acuminata are not precancerous lesions.

Squamous Neoplastic Lesions

Vulvar Intraepithelial Neoplasia and Vulvar Carcinoma

Carcinoma of the vulva is an uncommon malignant neoplasm (approximately one eighth as frequent as cervical cancer) representing about 3% of all genital cancers in the female; approximately two thirds occur in women older than 60 years. Squamous cell carcinoma is the most common histologic type of vulvar cancer. In terms of etiology,

pathogenesis, and histologic features, vulvar squamous cell carcinomas are divided into two groups:

- Basaloid and warty carcinomas related to infection with high risk HPVs (30% of cases), most commonly HPV-16. These are less common and occur at younger ages.
- Keratinizing squamous cell carcinomas unrelated to HPV infection (70% of cases). These are more common and occur in older women.

Basaloid and warty carcinomas develop from an in situ precursor lesion called *classic vulvar intraepithelial neoplasia* (VIN). This form of VIN occurs mainly in reproductive age women and includes lesions designated formerly as carcinoma in situ or Bowen disease. The risk factors for VIN are the same as those associated with cervical squamous intraepithelial lesions (e.g., young age at first intercourse, multiple sexual partners, male partner with multiple sexual partners), as both are related to HPV infection. VIN is frequently multicentric, and 10% to 30% of patients with VIN also have vaginal or cervical HPV-related lesions. Spontaneous regression of classic VIN has been reported, usually in younger women. The risk of progression to invasive carcinoma is higher in women older than 45 years of age or in women who are immunosuppressed. The peak age for basaloid and warty vulvar cancer is in the sixth decade.

Keratinizing squamous cell carcinoma occurs most often in individuals with long-standing lichen sclerosus or squamous cell hyperplasia and is not related to HPV. The peak occurrence is in the eighth decade. It arises from a precursor lesion referred to as *differentiated vulvar intraepithelial neoplasia* (differentiated VIN) or *VIN simplex*. It is postulated that chronic epithelial irritation in lichen sclerosus or squamous cell hyperplasia may contribute to a gradual evolution to the malignant phenotype, presumably through acquisition of driver mutations in oncogenes and tumor suppressors. In line with this idea, some investigators have reported a high frequency of *TP53* mutations in differentiated VIN.

Figure 22-7 Variants of vulvar intraepithelial neoplasia. **A**, Classic vulvar intraepithelial neoplasia (HPV positive), showing nuclear enlargement, hyperchromasia, and small immature basaloid cells extending up to the epithelial surface. **B**, Basaloid vulvar carcinoma (HPV positive), composed of small, immature (basaloid) cells. This invasive tumor has an area of central necrosis.

MORPHOLOGY

Classic VIN presents either as a discrete white (hyperkeratotic) or a slightly raised, pigmented lesion. Microscopically, it is characterized by epidermal thickening, nuclear atypia, increased mitoses, and lack of cellular maturation (Fig. 22-7A), features analogous to those seen in cervical squamous intraepithelial lesions (SILs, see under “Cervix”). Invasive carcinomas that arise from classic VIN may be exophytic or indurated with central ulceration. On histologic examination, basaloid carcinoma (Fig. 22-7B) consists of nests and cords of small, tightly

packed cells that lack maturation and resemble the basal layer of the normal epithelium. The tumor may have foci of central necrosis. By contrast, warty carcinoma is characterized by exophytic, papillary architecture and prominent koilocytic atypia.

Differentiated VIN is characterized by marked atypia of the basal layer of the squamous epithelium and normal-appearing differentiation of the more superficial layers (Fig. 22-8A). Invasive keratinizing squamous cell carcinomas that arise in differentiated VIN contain nests and tongues of malignant squamous epithelium with prominent central keratin pearls (Fig. 22-8B).

Figure 22-8 **A**, Differentiated vulvar intraepithelial neoplasia (HPV negative), showing maturation of the superficial layers, hyperkeratosis, and basal cell atypia. This is in-situ lesion; no invasion is present. **B**, Well-differentiated, keratinizing squamous cell carcinoma of the vulva (HPV negative).

The risk of cancer development in VIN depends on duration and extent of disease, and the immune status of the patient. Invasive carcinomas associated with lichen sclerosus, squamous cell hyperplasia, and differentiated VIN may develop in an insidious fashion and may be misinterpreted as dermatitis or leukoplakia for long periods. Once invasive cancer develops, the risk of metastatic spread is linked to the size of tumor, depth of invasion, and involvement of lymphatic vessels. The initial spread is to inguinal, pelvic, iliac, and periaortic lymph nodes. Ultimately, lymphohematogenous dissemination to the lungs, liver, and other internal organs may occur. Patients with lesions less than 2 cm in diameter have a 90% 5-year survival after treatment with vulvectomy and lymphadenectomy; however, larger lesions with lymph node involvement have poor prognosis.

Glandular Neoplastic Lesions

Like the breast, the vulva contains modified apocrine sweat glands. Presumably because of these “breastlike” features, the vulva may be involved by two tumors with counterparts in the breast, namely papillary hidradenoma and extramammary Paget disease.

Papillary Hidradenoma

Papillary hidradenoma presents as a sharply circumscribed nodule, most commonly on the labia majora or interlabial folds, and may be confused clinically with carcinoma because of its tendency to ulcerate. *Its histologic appearance is identical to that of intraductal papilloma of the breast* and consists of papillary projections covered with two layers of cells: an upper layer of columnar secretory cells covering a deeper layer of flattened myoepithelial cells. These myoepithelial elements are characteristic of sweat glands and sweat gland tumors (Fig. 22-9).

Extramammary Paget Disease

This curious and rare lesion of the vulva is *similar in its manifestations to Paget disease of the breast* (Chapter 23). In the vulva, it presents as a pruritic, red, crusted, maplike area, usually on the labia majora.

MORPHOLOGY

Paget disease is a distinctive intraepithelial proliferation of malignant cells. Paget cells are larger than surrounding keratinocytes and are seen singly or in small clusters within the epidermis (Fig. 22-10A). The cells have pale cytoplasm containing mucopolysaccharide that stains with periodic acid–Schiff (PAS), Alcian blue, or mucicarmine stains. In addition, the cells express cytokeratin 7 (Fig. 22-10B). Ultrastructurally, Paget cells display apocrine, eccrine, and keratinocyte differentiation and presumably arise from multipotent cells found within the mammary-like gland ducts of the vulvar skin.

Figure 22-9 Papillary hidradenoma of the vulva, a well-circumscribed tumor composed of benign papillary projections covered with columnar secretory epithelium and underlying myoepithelial cells.

In contrast to Paget disease of the nipple, in which 100% of patients have an underlying ductal breast carcinoma, vulvar Paget is typically not associated with underlying cancer and is confined to the epidermis of vulvar skin. The treatment consists of wide local excision. Paget cells spread laterally within the epidermis and may be present beyond the confines of the grossly visible lesion. As a result, the tumor cells may not be completely excised and the disease can recur. Intraepidermal Paget disease may persist for many years or even decades without invasion or metastases. In the rare instances when invasion develops, the prognosis is poor.

KEY CONCEPTS

- Approximately 30% of vulvar cancers are caused by infection with high risk HPVs, principally HPV-16. These cancers develop from an in situ lesion termed *classic vulvar intraepithelial neoplasia* (classic VIN).
- Most vulvar cancers (70%) are not related to HPV and develop in a background of lichen sclerosus or squamous cell hyperplasia from the premalignant lesion called *differentiated vulvar intraepithelial neoplasia* (differentiated VIN).

Figure 22-10 Paget disease of the vulva. **A**, The epidermis is infiltrated by large cells with pale-pink cytoplasm that are spreading along the basal portion of the squamous epithelium. There is inflammation in the underlying dermis. **B**, Immunostaining for cytokeratin 7 highlights the intraepidermal Paget cells.

VAGINA

The vagina is a portion of the female genital tract that is remarkably free from primary disease. In the adult, inflammation often affects the vulva and perivulvar structures and spreads to the cervix without significant involvement of the vagina. Primary lesions of the vagina are rare, the most serious being vaginal squamous cell carcinoma; they are discussed only briefly here.

Developmental Anomalies

Septate, or double, vagina is an uncommon anomaly that arises from a failure of müllerian duct fusion and is accompanied by a double uterus (uterus didelphys). These and other anomalies of the external genitalia may be the manifestations of genetic syndromes, in utero exposure to diethylstilbestrol (DES, used to prevent threatened abortions in the 1940s through 1960s), or other unknown factors that perturb reciprocal epithelial-stromal signaling during fetal development.

During embryonal development, the vagina is initially covered by columnar, endocervical-type epithelium. This is normally replaced by squamous epithelium advancing upwards from the urogenital sinus. Small patches of residual glandular epithelium may persist into adult life and is recognized as *vaginal adenosis*. It presents clinically as red, granular areas that stand out from the surrounding normal pale-pink vaginal mucosa. On microscopic examination, adenosis consists of columnar mucinous epithelium indistinguishable from endocervical epithelium. Adenosis is found in only a small percentage of adult women, but has been reported in 35% to 90% of women exposed to DES in utero. Rare cases of clear cell carcinoma arising in DES-related adenosis were recorded in teenagers and young adult women in the 1970s and 1980s, resulting in discontinuation of DES treatment.

Gartner duct cysts are relatively common lesions found along the lateral walls of the vagina and are derived from

wolffian (mesonephric) duct rests. They are 1- to 2-cm fluid-filled cysts that occur in the submucosal location. Other cysts, including mucus cysts, which occur in the proximal vagina, are derived from müllerian epithelium. Another müllerian-derived lesion, endometriosis (described later), may occur in the vagina and clinically simulate a neoplasm.

Premalignant and Malignant Neoplasms of the Vagina

Most of the benign tumors of the vagina occur in reproductive-age women and include stromal tumors (stromal polyps), leiomyomas, and hemangiomas. The most common malignant tumor to involve the vagina is carcinoma spreading from the cervix, followed by primary squamous cell carcinoma of the vagina. Infants may develop a unique, rare malignancy—embryonal rhabdomyosarcoma (sarcoma botryoides).

Vaginal Intraepithelial Neoplasia and Squamous Cell Carcinoma

Virtually all primary carcinomas of the vagina are squamous cell carcinomas associated with high risk HPVs. It is an extremely uncommon cancer (about 0.6 per 100,000 women yearly) that accounts for about 1% of malignant neoplasms in the female genital tract. The greatest risk factor is a previous carcinoma of the cervix or vulva; 1% to 2% of women with an invasive cervical carcinoma eventually develop a vaginal squamous cell carcinoma. Squamous cell carcinoma of the vagina arises from a premalignant lesion, *vaginal intraepithelial neoplasia*, analogous to cervical squamous intraepithelial lesions (SILs, see under “*Cervix*”). Most often the invasive tumor affects the upper vagina,

particularly the posterior wall at the junction with the ectocervix. The lesions in the lower two thirds of the vagina metastasize to the inguinal nodes, whereas lesions in the upper vagina tend to spread to regional iliac nodes.

Embryonal Rhabdomyosarcoma

Also called *sarcoma botryoides*, this uncommon vaginal tumor composed of malignant embryonal rhabdomyoblasts is most frequently found in infants and in children younger than 5 years of age. These tumors tend to grow as polypoid, rounded, bulky masses that have the appearance and consistency of grapelike clusters (hence the designation *botryoides*, or grapelike) (Fig. 22-11). The tumor cells are small and have oval nuclei, with small protrusions of cytoplasm from one end, resembling a tennis racket. Rarely, striations (indicative of muscle differentiation) can be seen within the cytoplasm. Beneath the vaginal epithelium, the tumor cells are crowded in a so-called cambium layer, but in the deep regions they lie within a loose fibromyxomatous stroma that is edematous and may contain many inflammatory cells. Such lesions can be mistaken for benign inflammatory polyps. The tumors tend to invade locally and cause death by penetration into the peritoneal cavity or by obstruction of the urinary tract. Conservative surgery coupled with chemotherapy offer the best hope, particularly in cases diagnosed sufficiently early.

CERVIX

Anatomically the cervix consists of the external vaginal portio (ectocervix) and the endocervical canal. The ectocervix is visible on vaginal examination and is covered by a mature squamous epithelium that is continuous with the vaginal wall. The squamous epithelium converges centrally at a small opening termed the *external os* that leads to the endocervical canal. The endocervix is lined by columnar, mucus-secreting epithelium. The point where the squamous and columnar epithelium meet is referred to as the *squamocolumnar junction* (Fig. 22-12). The position of

Figure 22-12 Cervical squamocolumnar junction showing mature, glycogenized squamous epithelium, immature squamous metaplastic cells, and columnar endocervical glandular epithelium.

the junction is variable and changes with age and hormonal influence, but in general the junction moves upwards into the endocervical canal with time. The replacement of the glandular epithelium by advancing squamous epithelium is a process called squamous metaplasia. The area of the cervix where the columnar epithelium abuts the squamous epithelium is termed the "*transformation zone*." The unique epithelial environment of the cervix renders it highly susceptible to infections with HPV, the main cause of cervical cancer. Immature squamous metaplastic epithelial cells in the transformation zone are most susceptible to HPV infection, and as a result this is where cervical precursor lesions and cancers develop.

Inflammations

Acute and Chronic Cervicitis

At the onset of menarche, the production of estrogens by the ovary stimulates maturation of the cervical and vaginal squamous mucosa and formation of intracellular glycogen vacuoles in the squamous cells. As these cells are shed, the glycogen provides a substrate for various endogenous vaginal aerobes and anaerobes, but particularly lactobacilli, which are the dominant microbial species in the normal vagina. Lactobacilli produce lactic acid, which maintains the vaginal pH below 4.5, suppressing the growth of other saprophytic and pathogenic organisms. In addition, at low pH, lactobacilli produce bacteriotoxic hydrogen peroxide (H_2O_2). If the pH becomes alkaline due to bleeding, sexual

Figure 22-13 Endocervical polyp composed of a dense fibrous stroma covered with endocervical columnar epithelium.

intercourse, or vaginal douching, H_2O_2 production by lactobacilli decreases. Antibiotic therapy that suppress lactobacilli can also cause the pH to rise. In each of these settings the altered vaginal environment promotes the overgrowth of other microorganisms, which may result in cervicitis or vaginitis. Some degree of cervical inflammation may be found in virtually all women, and it is usually of little clinical consequence. However, *infections by gonococci, chlamydiae, mycoplasmas, and HSV may produce significant acute or chronic cervicitis* and are important to identify due to their association with upper genital tract disease, complications during pregnancy, and sexual transmission. Marked cervical inflammation produces reparative and reactive changes of the epithelium and shedding of atypical-appearing squamous cells, and therefore may cause an abnormal Pap test result.

Endocervical Polyps

Endocervical polyps are common benign exophytic growths that arise within the endocervical canal. They vary from small, sessile “bumps” to large polypoid masses that may protrude through the cervical os. Histologically, they are composed of a loose fibromyxomatous stroma covered by mucus-secreting endocervical glands, often accompanied by inflammation (Fig. 22-13). Their main significance is that they may be the source of irregular vaginal “spotting” or bleeding that arouses suspicion of some more ominous lesion. Simple curettage or surgical excision is curative.

Premalignant and Malignant Neoplasms of the Cervix

Worldwide, cervical carcinoma is the third most common cancer in women, with an estimated 530,000 new cases in 2008, of which more than half are fatal. In the United States, 12,410 women were diagnosed with cervical cancer and 4000 women died of the disease in 2008. Fifty years ago, carcinoma of the cervix was the leading cause of cancer deaths in women in the United States, but the death rate has declined by two thirds to its present rank as the thirteenth cause of cancer mortality. No form of cancer better documents the remarkable benefits of effective screening, early diagnosis, and curative therapy than does cancer of

the cervix. Much credit for these dramatic gains belongs to the effectiveness of the Pap test in detecting cervical precursor lesions, some of which would have progressed to cancer if not treated; in addition, the Pap test can also detect low-stage, highly curable cancers. The accessibility of the cervix to Pap testing and visual exam (colposcopy) as well as the slow progression from precursor lesions to invasive carcinoma (typically over the course of years) provides ample time for screening, detection, and preventive treatment.

Pathogenesis. High-risk HPVs are by far the most important factor in the development of cervical cancer. HPVs are DNA viruses that are typed based on their DNA sequence and grouped into those of high and low oncogenic risk. There are 15 high risk HPVs that are currently identified, but HPV-16 alone accounts for almost 60% of cervical cancer cases, and HPV-18 accounts for another 10% of cases; other HPV types contribute to less than 5% of cases, individually. *High risk HPVs are also implicated in squamous cell carcinomas arising at many other sites, including the vagina, vulva, penis, anus, tonsil, and other oropharyngeal locations (Chapter 16).* As noted earlier, low oncogenic risk HPVs are the cause of the sexually transmitted vulvar, perineal, and perianal warts (condyloma acuminatum).

Genital HPV infections are extremely common; most of them are asymptomatic, do not cause any tissue changes, and therefore are not detected on Pap test. The prevalence of HPV in cervical smears in women with normal Pap test results peaks between the ages of 20 and 24 years, a relationship that is related to the onset of sexual activity, while the subsequent decrease in prevalence reflects acquisition of immunity and entry into monogamous relationships with age. Most HPV infections are transient and are eliminated by the immune response in the course of months. *On average, 50% of HPV infections are cleared within 8 months, and 90% of infections are cleared within 2 years.* The duration of the infection is related to HPV type; on average, infections with high-risk HPVs last longer than infections with low oncogenic risk HPVs (13 months versus 8 months, respectively). Persistent infection increases the risk of the development of cervical precursor lesions and subsequent carcinoma.

HPVs infect immature basal cells of the squamous epithelium in areas of epithelial breaks, or immature metaplastic squamous cells present at the squamocolumnar junction (Fig. 22-11). HPVs cannot infect the mature superficial squamous cells that cover the ectocervix, vagina, or vulva. Establishment of HPV infection in these sites requires damage to the surface epithelium, which allows the virus access to the immature cells in the basal layer of the epithelium. The cervix, with its relatively large areas of immature squamous metaplastic epithelium, is particularly vulnerable to HPV infection as compared to, for example, vulvar skin and mucosa that are covered by mature squamous cells. This difference in epithelial susceptibility to HPV infection accounts for the wide range in incidence of HPV-related cancers arising in various sites, and explains the high frequency of cervical cancer in women and anal cancer in homosexual men and a relatively low frequency of vulvar and penile cancer.

The ability of HPV to act as a carcinogen depends on the viral proteins E6 and E7, which interfere with the activity of tumor suppressor proteins that regulate cell growth and survival. Although HPV infects immature

squamous cells, viral replication occurs in maturing squamous cells. Normally, these more mature cells are arrested in the G₁ phase of the cell cycle, but they continue to actively progress through the cell cycle when infected with HPV, which uses the host cell DNA synthesis machinery to replicate its own genome. As you will recall from [Chapter 7](#), viral E7 protein binds the hypophosphorylated (active) form of RB and promotes its degradation via the proteasome pathway, and also binds and inhibits p21 and p27, two important cyclin-dependent kinase inhibitors. Removal of these controls not only enhances cell cycle progression, but also impairs the ability of cells to repair DNA damage. This defect in DNA repair is exacerbated by the viral E6 proteins of high-risk HPV subtypes, which bind to the tumor suppressor protein p53 and promote its degradation by the proteasome. In addition, E6 up-regulates the expression of telomerase, which leads to cellular immortalization. The net effect is increased proliferation of cells that are prone to acquire additional mutations that may lead to cancer development. By contrast to high-risk HPVs, the E7 proteins of low risk HPVs bind RB with lower affinity, while the E6 proteins of low-risk HPVs fail to bind p53 altogether and instead appear to dysregulate growth and survival by interfering with the Notch signaling pathway.

Another factor that contributes to malignant transformation by HPV is the physical state of the virus. The viral DNA is integrated into the host cell genome in most cancers. This configuration increases the expression of E6 and E7 genes, and may also dysregulate oncogenes near the sites of viral insertion, such as *MYC*. By contrast, viral DNA is extrachromosomal (episomal) in precursor lesions associated with high risk HPVs and in condylomata associated with low risk HPVs.

Even though HPV has been firmly established as a common cause of cervical cancer, it is not sufficient to cause cancer. This conclusion is supported by the fact that a high percentage of young women are infected with one or more HPV types during their reproductive years, but only a few develop cancer. Thus, other factors, such as exposure to co-carcinogens and host immune status, influence whether an HPV infection regresses or persists and eventually progresses to cancer.

Cervical Intraepithelial Neoplasia (Squamous Intraepithelial Lesions)

The classification of cervical precursor lesions has evolved over time and the terms from the different classification systems are currently used interchangeably. Hence a brief review of the terminology is warranted. The oldest classification system grouped lesions as having mild dysplasia on one end and severe dysplasia/carcinoma in situ on the other. This was followed by the *cervical intraepithelial neoplasia* (CIN) classification, with mild dysplasia termed *CIN I*, moderate dysplasia *CIN II*, and severe dysplasia termed *CIN III*. Because the decision with regard to patient management is two-tiered (observation versus surgical treatment), the three-tier classification system has been recently simplified to a two-tiered system, with CIN I renamed low-grade squamous intraepithelial lesion (LSIL) and CIN II and CIN III combined into one category referred to as high-grade squamous intraepithelial lesion (HSIL) ([Table 22-1](#)).

Table 22-1 Classification Systems for Squamous Cervical Precursor Lesions

Dysplasia/Carcinoma in Situ	Cervical Intraepithelial Neoplasia (CIN)	Squamous Intraepithelial Lesion (SIL), Current Classification
Mild dysplasia	CIN I	Low-grade SIL (LSIL)
Moderate dysplasia	CIN II	High-grade SIL (HSIL)
Severe dysplasia	CIN III	High-grade SIL (HSIL)
Carcinoma in situ	CIN III	High-grade SIL (HSIL)

CIN, Cervical intraepithelial neoplasia; SIL, squamous intraepithelial lesion.

LSIL is associated with a productive HPV infection. In LSIL, there is a high level of viral replication and only mild alterations in the growth of host cells. *LSIL does not progress directly to invasive carcinoma and in fact most cases regress spontaneously; only a small percentage progress to HSIL.* For these reasons, LSIL is not treated like a premalignant lesion. In HSIL, on the other hand, there is a progressive deregulation of the cell cycle by HPV, which results in increased cellular proliferation, decreased or arrested epithelial maturation, and a lower rate of viral replication, as compared with LSIL. Derangement of the cell cycle in HSIL may become irreversible and lead to a fully transformed malignant phenotype, and thus *all HSILs are considered to be at high risk for progression to carcinoma.* LSILs are ten times more common than HSILs.

MORPHOLOGY

The diagnosis of SIL is based on identification of nuclear atypia characterized by nuclear enlargement, hyperchromasia (dark staining), coarse chromatin granules, and variation in nuclear size and shape ([Fig. 22-14](#)). The nuclear changes are often accompanied by cytoplasmic “halos.” At an ultrastructural level, these “halos” consist of perinuclear vacuoles, a cytopathic change created in part by an HPV-encoded protein called E5 that localizes to the membranes of the endoplasmic reticulum. Nuclear alterations with an associated perinuclear halo are termed **koilocytic atypia**. The grading of SIL into low or high grade is based on expansion of the immature cell layer from its normal, basal location. If the immature squamous cells are confined to the lower one third of the epithelium, the lesion is graded as LSIL; if they expand to the upper two thirds of the epithelial thickness, it is graded as HSIL.

The histologic features of LSIL correlate with HPV replication and changes in host cell growth and gene expression ([Fig. 22-15](#)).

- The highest viral loads (assessed by HPV DNA in situ hybridization, [Fig. 22-15B](#)) are found in maturing keratinocytes in the upper half of the epithelium.
- HPV E6 and E7 proteins prevent cell cycle arrest. As a result, cells in the upper portion of the epithelium express markers of actively dividing cells, such as Ki-67 ([Fig. 22-15C](#)), that are normally confined to the basal layer of the epithelium. Disturbed growth regulation also leads to overexpression of p16, a cyclin-dependent kinase inhibitor ([Fig. 22-15D](#)).
- Both Ki-67 and p16 staining are highly correlated with HPV infection and are useful for confirmation of the diagnosis in equivocal cases of SIL.

Figure 22-14 Spectrum of cervical intraepithelial neoplasia: normal squamous epithelium for comparison; LSIL (CIN I) with koilocytic atypia; HSIL (CIN II) with progressive atypia and expansion of the immature basal cells above the lower third of the epithelial thickness; HSIL (CIN III) with diffuse atypia, loss of maturation, and expansion of the immature basal cells to the epithelial surface.

More than 80% of LSILs and 100% of HSILs are associated with high-risk HPVs, with HPV-16 being the most common HPV type in both categories of lesions. Table 22-2 shows rates of regression and progression of SILs within 2-year follow-up. Although the majority of HSILs develop from LSILs, approximately 20% of cases of HSIL develop de novo, independent of any preexisting LSIL. The rates of progression are by no means uniform, and although HPV type—especially HPV 16—is associated with increased risk, it is difficult to predict the outcome in an individual patient. These findings underscore that the risk of developing precursor lesions and cancer is conferred only in part by HPV type. Progression to invasive carcinoma, when it occurs, takes place over a period of a few years to more than a decade.

Cervical Carcinoma

The average age of patients with invasive cervical carcinoma is 45 years. Squamous cell carcinoma is the most common histologic subtype, accounting for approximately 80% of cases. The second most common tumor type is adenocarcinoma, which constitutes about 15% of cervical cancer cases and develops from a precursor lesion called *adenocarcinoma in situ*. Adenosquamous and neuroendocrine carcinomas are rare cervical tumors that account for the remaining 5% of cases. All of the aforementioned tumor types are caused by high-risk HPVs. The progression time from in situ to invasive adenosquamous and neuroendocrine carcinomas is shorter than in squamous cell carcinoma, and patients with these tumors often

Figure 22-15 **A**, Low-grade squamous intraepithelial lesion (LSIL)—Routine hematoxylin and eosin staining shows marked koilocytic change, seen as perinuclear “halos” in suprabasilar cells. **B**, In situ hybridization test for HPV DNA. The dark granular staining denotes HPV DNA, which is typically most abundant in the koilocytes. **C**, Diffuse positivity for the proliferation marker Ki-67 (seen as brown nuclear staining), illustrates abnormal expansion of the proliferating cells from the normal basal location to the superficial layers of the epithelium. **D**, Upregulation of the cyclin-dependent kinase inhibitor p16 (seen here as brown staining) characterizes high-risk HPV infections.

Table 22-2 Natural History of Squamous Intraepithelial Lesions with Approximate 2-Year Follow-up

Lesion	Regress	Persist	Progress
LSIL	60%	30%	10% to HSIL
HSIL	30%	60%	10% to carcinoma*

HSIL, High-grade squamous intraepithelial lesion; LSIL, low-grade squamous intraepithelial lesion.

*Progression within 2 to 10 years.

present with advanced disease and have a less favorable prognosis.

MORPHOLOGY

Invasive cervical carcinoma may manifest as either fungating (exophytic) or infiltrative masses. **Squamous cell carcinoma** is composed of nests and tongues of malignant squamous epithelium, either keratinizing or nonkeratinizing, which invade the underlying cervical stroma (Fig. 22-16A,B). **Adenocarcinoma** is characterized by proliferation of glandular epithelium composed of malignant endocervical cells with large, hyperchromatic nuclei and relatively mucin-depleted cytoplasm, resulting in a dark appearance of the glands, as compared to the normal endocervical epithelium (Fig. 22-17A,B). Adenosquamous carcinoma is composed of intermixed malignant glandular and squamous epithelium. Neuroendocrine cervical carcinoma has

Figure 22-16 Squamous cell carcinoma of the cervix. **A**, Microinvasive squamous cell carcinoma with invasive nest breaking through the basement membrane of high-grade squamous intraepithelial lesion. **B**, Invasive squamous cell carcinoma.

Figure 22-17 Adenocarcinoma of the cervix. **A**, Adenocarcinoma in situ (arrow) showing dark glands adjacent to normal pale endocervical glands. **B**, Invasive adenocarcinoma.

an appearance similar to small cell carcinoma of the lung (Chapter 15), but differs in being positive for high risk HPVs.

Advanced cervical carcinoma spreads by direct extension to contiguous tissues, including paracervical soft tissue, urinary bladder, ureters (resulting in hydronephrosis), rectum, and vagina. Lymphovascular invasion results in local and distant lymph nodes metastases. Distant metastases may also be found in the liver, lungs, bone marrow, and other organs.

Cervical cancer is staged as follows:

Stage 0—Carcinoma in situ (CIN III, HSIL)

Stage I—Carcinoma confined to the cervix

Ia—Preclinical carcinoma, that is, diagnosed only by microscopy

Ia1—Stromal invasion no deeper than 3 mm and no wider than 7 mm (so-called microinvasive carcinoma)

Ia2—Maximum depth of invasion of stroma deeper than 3 mm and no deeper than 5 mm taken from base of epithelium; horizontal invasion not more than 7 mm

Ib—Histologically invasive carcinoma confined to the cervix and greater than stage Ia2

Figure 22-18 The cytology of cervical intraepithelial neoplasia as seen on the Papanicolaou smear. Normal cytoplasmic staining in superficial cells (**A** and **B**) may be either red or blue. **A**, Normal exfoliated superficial squamous cells. **B**, Low-grade squamous intraepithelial lesion (LSIL)—koilocytes. **C**, High-grade squamous intraepithelial lesion (HSIL; CIN II). **D**, HSIL (CIN III). Note the reduction in cytoplasm and the increase in the nucleus-to-cytoplasm ratio, which occurs as the grade of the lesion increases. This reflects the progressive loss of cellular differentiation on the surface of the lesions from which these cells are exfoliated. (Courtesy Dr. Edmund S. Cibas, Brigham and Women's Hospital, Boston, Mass.)

Stage II—Carcinoma extends beyond the cervix but not to the pelvic wall. Carcinoma involves the vagina but not the lower third.

Stage III—Carcinoma has extended to the pelvic wall. On rectal examination there is no cancer-free space between the tumor and the pelvic wall. The tumor involves the lower third of the vagina.

Stage IV—Carcinoma has extended beyond the true pelvis or has involved the mucosa of the bladder or rectum. This stage also includes cancers with metastatic dissemination.

Clinical Features. More than half of invasive cervical cancers are detected in women who did not participate in regular screening. While early invasive cancers of the cervix (microinvasive carcinomas) may be treated by cervical cone excision alone, most invasive cancers are managed by hysterectomy with lymph node dissection and, for advanced lesions, radiation and chemotherapy. The prognosis and survival for invasive carcinomas depend on the stage of the cancer at diagnosis and to some degree on histologic subtype, with small-cell neuroendocrine tumors having a very poor prognosis. With current treatments the 5-year survival rate is 100% for microinvasive carcinomas and less than 50% for tumors extending beyond pelvis.

Most patients with advanced cervical cancer die of the consequences of local tumor invasion (e.g., ureteral obstruction, pyelonephritis, and uremia) rather than distant metastases.

Cervical Cancer Screening and Prevention

As is well known, cytologic cancer screening has significantly reduced mortality from cervical cancer. In countries where such screening is not widely practiced, cervical cancer continues to exact a high toll. The reason that cytologic screening is so effective in preventing cervical cancer is that most cancers arise from precursor lesions over the course of years. These lesions shed abnormal cells that can be detected on cytologic examination. Using a spatula or brush, the transformation zone of the cervix is circumferentially scraped and the cells are smeared or spun down onto a slide. Following fixation and staining with the Papanicolaou method, the smears are screened microscopically by eye or (increasingly) with automated image analysis systems. The cellular changes seen on the Pap test, illustrating the spectrum from LSIL to HSIL, are shown in [Figure 22-18](#).

Testing for the presence of HPV DNA in the cervical scrape is a molecular method of cervical cancer screening. HPV testing has a higher sensitivity but lower specificity, as compared to Pap test. HPV DNA testing may be added to cervical cytology for screening in women aged 30 years or older. HPV testing of women younger than 30 is not recommended because of the high incidence of infection, and thus the particularly low specificity of HPV test results in this age group.

- Cervical cancer screening and preventive measures are carried out in a step wise fashion. Recommendations for the frequency of Pap screening vary, but in general the first smear should be at age 21 years or within 3 years of onset of sexual activity, and thereafter every 3 years. After age 30, women who have had normal cytology results and are negative for HPV may be screened every 5 years. Women with a normal cytology result, but test positive for high-risk HPV DNA, should have cervical cytology repeated every 6 to 12 months.
- When the result of a Pap test is abnormal, a colposcopic examination of the cervix and vagina is performed to identify the lesion. The mucosa is examined with a magnifying glass following application of acetic acid, which highlights abnormal epithelium as white spots (*acetowhite areas*). Abnormal appearing areas are biopsied. Women with biopsy confirmed LSIL can be followed in a conservative fashion. Some gynecologists will perform local ablation (e.g., cryotherapy) of LSIL, particularly if there is concern about the reliability of patient follow-up. HSILs are treated with cervical conization (superficial excision).

- **A new aspect of cervical cancer prevention is vaccination against high-risk oncogenic HPVs, which is now recommended for all girls and boys by age 11 to 12 years, as well as young men and women up to age 26 years.** Two HPV vaccines are now FDA-licensed. Both provide nearly complete protection against high-risk oncogenic HPV types 16 and 18 (together accounting for approximately 70% of cervical cancers), and one also provides protection against HPV types 6 and 11, which are responsible for genital warts. Vaccination is now recommended for boys as well as girls due to the role of that males play in the spread of HPV to women and the toll that HPV-related anal and oropharyngeal cancers take in men. The vaccines offer protection for up to 10 years; longer follow-up studies are still pending. Since the HPV vaccine does not protect against all high-risk HPV types, current guidelines recommend that cervical cancer screening be continued as in the past.

KEY CONCEPTS

- Cervical low-grade squamous intraepithelial lesions (LSILs) are productive HPV infections that usually regress spontaneously, but occasionally progress to high-grade squamous intraepithelial lesions (HSILs).
- HSILs are characterized by progressive deregulation of the cell cycle and increasing cellular atypia. HSILs may progress to invasive carcinoma.
- Almost all cervical precursor lesions and cervical carcinomas are caused by high-risk HPV types, most commonly HPV-16.

BODY OF UTERUS AND ENDOMETRIUM

The uterus has two major components: the myometrium and the endometrium. The myometrium is composed of tightly interwoven bundles of smooth muscle that form the wall of the uterus. The internal cavity of the uterus is lined by the endometrium, which is composed of glands embedded in a cellular stroma. The uterus is affected by a variety of disorders, the most common of which results from endocrine imbalances, complications of pregnancy, and neoplastic proliferation.

Endometrial Histology in the Menstrual Cycle

The endometrium undergoes dynamic physiologic and morphologic changes during the menstrual cycle in response to sex steroid hormones coordinately produced in the ovary. The ovary is influenced by hormones produced by the pituitary due to signals from the hypothalamus. Together the hypothalamic, pituitary, and ovarian factors and their interactions regulate maturation of ovarian follicles, ovulation, and menstruation.

“Dating” the endometrium by its histologic appearance may be used to assess hormonal status, document ovulation, and determine causes of endometrial bleeding and

infertility (Fig. 22-19). Progression through a normal menstrual cycle is correlated with the following histologic features:

- The cycle commences with *menses*, during which the superficial portion of the endometrium, referred to as the functionalis, is shed.
- The *proliferative phase* is marked by rapid growth of glands and stroma arising from the deeper portion of the endometrium (basalis). During the proliferative phase the glands are straight, tubular structures lined by regular, tall, pseudostratified columnar cells. Mitotic figures are numerous, and there is no evidence of mucus secretion or vacuolation. The endometrial stroma is composed of spindle cells with scant cytoplasm that are also actively proliferating (Fig. 22-19A).
- At *ovulation*, endometrial proliferation ceases and differentiation commences in response to the effects of progesterone made by the corpus luteum in the ovary.
- *Postovulation* is initially marked by the appearance of *secretory vacuoles* beneath the nuclei in the glandular epithelium (Fig. 22-19B). Secretory activity is most prominent during the third week of the menstrual cycle, when the basal vacuoles progressively move to the apical surface. When secretion is maximal, between 18 and 24 days, the glands are dilated. By the fourth week

Figure 22-19 Histology of the menstrual cycle. **A**, Proliferative phase with mitoses (*arrow*). **B**, Early secretory phase with subnuclear vacuoles (*arrow*). **C**, Late secretory exhaustion and predecidual changes (*arrow*). **D**, Menstrual endometrium with stromal breakdown (*arrow*) (see text).

the glands are tortuous, producing a serrated appearance. This serrated or “saw-toothed” appearance is accentuated by secretory exhaustion and shrinkage of the glands.

- *Stromal changes in the late secretory phase*, due predominantly to progesterone, are important for dating the endometrium. Prominent spiral arterioles appear by days 21 to 22 accompanied by an increase in ground substance and edema between the stromal cells. By days 23 to 24, stromal cell hypertrophy, increased cytoplasmic eosinophilia (*predecidual change*) and a resurgence of stromal mitoses appear (*Fig. 22-19C*). Predecidual changes spread throughout the functionalis during days 24 to 28 and are accompanied by a sparse infiltrate of neutrophils and lymphocytes, which in this context are considered normal.
- With the dissolution of the corpus luteum and the subsequent drop in progesterone levels, the functionalis degenerates and bleeding into the stroma occurs, followed by stromal breakdown and onset of the next menstrual cycle (*Fig. 22-19D*).

Much of the action of the ovarian hormones on the endometrium occurs through their cognate nuclear receptors and perhaps even by receptor-independent mechanisms. During the proliferative phase, estrogen

drives the proliferation of both glands and stroma, sometimes by promoting “cross-talk” between these two cell types. For example, much of the effect of estrogen on glandular proliferation occurs via stromal cells, which in response to estrogen produce growth factors (e.g., insulin-like growth factor 1 and epidermal growth factor) that bind receptors expressed on the epithelial cells. During the secretory phase, progesterone down-regulates the expression of estrogen receptor in both the glands and the stroma, and as a result endometrial proliferation is suppressed. Progesterone also promotes the differentiation of the glands and causes functional changes in the stromal cells. Endometrial stem cells have been identified and there is recent data to suggest that they play a central role in the regeneration of the endometrium after menses. They may also contribute to the development of ectopic endometrial tissue and endometrial cancer.

Functional Endometrial Disorders (Dysfunctional Uterine Bleeding)

Although abnormal uterine bleeding can be caused by well-defined pathologic conditions, such as chronic endometritis, endometrial polyps (*Fig. 22-20C*), submucosal

Figure 22-20 Common causes of abnormal uterine bleeding. **A**, The most common is dysfunctional uterine bleeding, seen here as anovulatory endometrium with stromal breakdown. Note breakdown associated with proliferative glands. **B**, Chronic endometritis with numerous plasma cells (*arrow*). **C**, Endometrial polyp. **D**, Submucosal leiomyoma with attenuation of the endometrial lining (*arrow*).

leiomyomas (Fig. 22-20D), or endometrial neoplasms, it most commonly stems from hormonal disturbances that produce *dysfunctional uterine bleeding* (Table 22-3). This is a clinical term for uterine bleeding that lacks an underlying organic (structural) abnormality. As discussed earlier, the normal cyclical proliferation, differentiation, and shedding

of the endometrium requires that all the involved pituitary and ovarian hormones be released at the proper time in the right amounts. Any disturbance of this finely tuned system may result in dysfunctional uterine bleeding, the most common causes of which are discussed in the following sections.

Anovulatory Cycle

The most frequent cause of dysfunctional bleeding is anovulation (failure to ovulate). Anovulatory cycles result from subtle hormonal imbalances and are most common at menarche and in the perimenopausal period. Less commonly, anovulation is the result of:

- *Endocrine disorders*, such as thyroid disease, adrenal disease, or pituitary tumors
- *Ovarian lesions*, such as a functioning ovarian tumor (granulosa cell tumors) or polycystic ovaries (see “Ovaries”)
- *Generalized metabolic disturbances*, such as obesity, malnutrition, or other chronic systemic diseases

Failure of ovulation results in excessive endometrial stimulation by estrogens that is unopposed by progesterone. Under these circumstances the endometrial glands undergo mild architectural changes, including cystic dilation, that usually resolve due to a subsequent ovulatory cycle.

Table 22-3 Causes of Abnormal Uterine Bleeding by Age Group

Age Group	Causes
Prepuberty	Precocious puberty (hypothalamic, pituitary, or ovarian origin)
Adolescence	Anovulatory cycle, coagulation disorders
Reproductive age	Complications of pregnancy (abortion, trophoblastic disease, ectopic pregnancy) Anatomic lesions (leiomyoma, adenomyosis, polyps, endometrial hyperplasia, carcinoma) Dysfunctional uterine bleeding Anovulatory cycle Ovulatory dysfunctional bleeding (e.g., inadequate luteal phase)
Perimenopausal	Dysfunctional uterine bleeding Anovulatory cycle Anatomic lesions (carcinoma, hyperplasia, polyps)
Postmenopausal	Endometrial atrophy Anatomic lesions (carcinoma, hyperplasia, polyps)

However, repeated anovulation may result in bleeding that, in certain clinical situations, may prompt an endometrial biopsy. In this setting biopsies reveal stromal condensation and eosinophilic epithelial metaplasia similar to those seen in menstrual endometrium. However, unlike menstrual endometrium, the endometrium of women with anovulatory cycles lacks progesterone-dependent morphologic features (e.g., glandular secretory changes and stromal pre-decidualization), since the source of progesterone, the corpus luteum, does not develop without ovulation. Most commonly the endometrium is comprised of pseudostratified glands and contains scattered mitotic figures (Fig. 22-20A). More severe consequences of repeated anovulation are discussed under “Endometrial Hyperplasia.”

Inadequate Luteal Phase

This term refers to a condition that manifests clinically as infertility associated with either increased bleeding or amenorrhea. The cause is believed to be inadequate progesterone production during the post-ovulatory period. Endometrial biopsy performed at an estimated postovulatory date shows secretory endometrium with features that lag behind those expected for the estimated date.

Inflammatory Disorders

The endometrium and myometrium are relatively resistant to infections, primarily because the endocervix forms a barrier to ascending infection. Thus, although chronic inflammation in the cervix is an expected and frequently insignificant finding, it is of concern in the endometrium, excluding the menstrual phase.

Acute Endometritis

Acute endometritis is uncommon and limited to bacterial infections that arise after delivery or miscarriage. Retained products of conception are the usual predisposing influence; the causative agents include group A hemolytic streptococci, staphylococci, and other bacteria. The inflammatory response is chiefly limited to the stroma and is entirely nonspecific. Removal of the retained gestational fragments by curettage, accompanied by antibiotic therapy, promptly clears the infection.

Chronic Endometritis

Chronic endometritis occurs in association with the following disorders:

- Chronic pelvic inflammatory disease (PID)
- Retained gestational tissue, postpartum or post-abortion
- Intrauterine contraceptive devices
- Tuberculosis, either from miliary spread or, more often, from drainage of tuberculous salpingitis. Both are rare in Western countries.

The diagnosis of chronic endometritis rests on the identification of plasma cells in the stroma, which are not seen in normal endometrium (Fig. 22-20B). In about 15% of

cases no cause is apparent. Some women with this so-called “nonspecific” chronic endometritis have gynecologic complaints such as abnormal bleeding, pain, discharge, and infertility. *Chlamydia* may be involved and is commonly associated with both acute (e.g., neutrophils) and chronic (e.g., lymphocytes, plasma cells) inflammatory cell infiltrates. The responsible organisms may or may not be detected by culture. If infection is suspected on clinical grounds, antibiotic therapy is indicated even in the face of negative cultures, as it may prevent other sequelae (e.g., salpingitis).

Endometriosis and Adenomyosis

Endometriosis is defined by the presence of “ectopic” endometrial tissue at a site outside of the uterus. The abnormal tissue most commonly includes both endometrial glands and stroma, but may consist only of stroma in some cases. It occurs in the following sites, in descending order of frequency: (1) ovaries, (2) uterine ligaments, (3) rectovaginal septum, (4) cul de sac, (5) pelvic peritoneum, (6) large and small bowel and appendix, (7) mucosa of the cervix, vagina, and fallopian tubes, and (8) laparotomy scars.

Endometriosis takes a significant toll on the afflicted; it often causes *infertility*, *dysmenorrhea* (painful menstruation), *pelvic pain*, and other problems. The disorder is principally a disease of women in active reproductive life, most often in the third and fourth decades, and affects approximately 6% to 10% of women. Uncommonly endometriosis may “invade” and “spread,” behaviors that often contribute to significant complications. For example, involvement of the muscular wall of the bowel by endometriosis can result in intestinal symptoms (Fig. 22-21).

Pathogenesis. The pathogenesis of endometriosis remains elusive. Proposed origins of endometriotic lesions fall into two main categories: (1) those that propose an origin from the uterine endometrium and (2) those that propose an origin from cells outside the uterus that have the capacity to give rise to endometrial tissue. The leading theories are as follows:

- *The regurgitation theory* proposes that endometrial tissue implants at ectopic sites via retrograde flow of menstrual endometrium. Retrograde menstruation through the fallopian tubes occurs regularly even in normal women and can explain the distribution of endometriosis within the peritoneal cavity.
- *The benign metastases theory* holds that endometrial tissue from the uterus can “spread” to distant sites (e.g., bone, lung, and brain) via blood vessels and lymphatic channels.
- *The metaplastic theory* suggests that endometrium arises directly from coelomic epithelium (mesothelium of pelvis or abdomen), from which the müllerian ducts and ultimately the endometrium itself originate during embryonic development. In addition, mesonephric remnants may undergo endometrial differentiation and give rise to ectopic endometrial tissue.
- *The extrauterine stem/progenitor cell theory* is a recent idea that proposes that stem/progenitor cells from the bone marrow differentiate into endometrial tissue.

Figure 22-21 Endometriosis. **A**, Endometriosis involving the mucosa of the colon. **B**, Higher magnification reveals endometrial glands and stroma adjacent to normal colonic mucosa.

The regurgitation theory provides a plausible explanation for the anatomic location of ectopic endometrial tissue in the vast majority of cases. However, it cannot explain all cases, such as endometriosis in women who are amenorrheic because of a variety of underlying etiologies (e.g., gonadal dysgenesis); endometriosis in the urogenital tract of men treated with high-dose estrogens for prostate cancer; and endometriosis in distant sites like the brain, lung and bone. In addition, the relatively low incidence of endometriosis, despite the common occurrence of retrograde menstruation (up to 90% of women), suggests that additional factors must be involved in the pathogenesis of the disorder.

Molecular analyses have provided additional insights into the pathogenesis of endometriosis. The endometriotic implants show certain differences when compared to the endometria of women without endometriosis (Fig. 22-22). These include the following:

- Release of proinflammatory and other factors, including PGE₂, IL-1 β , TNF α , IL-6 and -8, NGF, VEGF, MCP-1, MMPs, and TIMPs.
- Increased estrogen production by endometriotic stromal cells, due in large part to high levels of the key steroidogenic enzyme aromatase, which is absent in normal endometrial stroma. Estrogen enhances the survival and persistence of endometriotic tissue, and inhibitors of aromatase are beneficial in the treatment of endometriosis. A link between inflammation and estrogen production is made plausible by the ability of prostaglandin E₂ to stimulate local synthesis of estrogen.

The expression of these factors contributes to the survival of ectopic endometrial tissue by promoting invasion and the establishment of neurovascular networks and by decreasing immune clearance. In addition, epigenetic alterations have been described that lead to increase responsiveness to estrogen and decreased responsiveness to progesterone, alterations that promote endometrial proliferation and survival. These abnormalities are present not only in ectopic endometriotic tissue, but also, albeit to a lesser degree, in

the uterine endometrium of patients with endometriosis, suggesting that there is a fundamental defect in the endometrium.

- An association between endometriosis and ovarian cancer of the endometrioid and clear cell types (discussed later) has been noted in a number of epidemiologic studies with an approximate threefold increase in women with endometriosis. More recent molecular studies have demonstrated shared mutations in specific genes (*PTEN* and *ARID1A*) in endometriotic cysts, atypical endometriosis (see later) and associated carcinomas. These studies suggest a common origin of abnormal

Figure 22-22 Pathogenesis of endometriosis. The factors expressed in endometriotic implants, eutopic endometrium and activated macrophages that play a role in the establishment and maintenance of endometriotic implants.

endometriotic tissue and ovarian cancers in some cases, as described below.

MORPHOLOGY

Endometriotic lesions bleed periodically in response to both extrinsic cyclic (ovarian) and intrinsic hormonal stimulation. This bleeding produces nodules with a red-blue to yellow-brown appearance on or just beneath the mucosal and/or serosal surfaces at sites of involvement. When lesions are extensive, organizing hemorrhage causes extensive fibrous adhesions between tubes, ovaries, and other structures and obliterates the pouch of Douglas. The ovaries may become markedly distorted by large cystic masses (3 to 5 cm in diameter) filled with brown fluid resulting from previous hemorrhage; these are often referred to clinically as **chocolate cysts** or **endometriomas**. Aggressive forms of endometriosis can invade tissues and cause fibrosis and subsequent adhesions.

The histologic diagnosis of endometriosis is usually straightforward but may be difficult in long-standing cases in which the endometrial tissue is obscured by secondary fibrosis. The diagnosis is readily made when both endometrial glands and stroma are present (Fig. 22-21B), with or without the presence of hemosiderin. In rare cases only stroma is identified. If only glands are present, other diagnoses with different clinical ramifications, such as endosalpingiosis, must be considered.

Atypical endometriosis, the likely precursor to endometriosis-related ovarian carcinoma, has two morphologic appearances. One consists of cytologic atypia of the epithelium lining the endometriotic cyst without major architectural changes. The second is marked by glandular crowding due to excessive epithelial proliferation, often associated with cytologic atypia, producing an appearance that resembles complex atypical endometrial hyperplasia (discussed later).

Clinical Features. Clinical signs and symptoms usually include severe dysmenorrhea, dyspareunia (pain with intercourse), and pelvic pain due to the intrapelvic bleeding and periuterine adhesions. Pain on defecation occurs with rectal wall involvement and dysuria results from involvement of the bladder serosa. Menstrual irregularities are common, and infertility is the presenting complaint in 30% to 40% of women. In addition, although uncommon, malignancies can develop in this setting, suggesting that endometriosis contains “at-risk” epithelium.

A related disorder, *adenomyosis*, is defined as the presence of endometrial tissue within the uterine wall (myometrium). Adenomyosis remains in continuity with the endometrium, presumably signifying downgrowth of endometrial tissue into and between the smooth muscle fascicles of the myometrium. Adenomyosis occurs in up to 20% of uteri. On microscopic examination, irregular nests of endometrial stroma, with or without glands, are arranged within the myometrium, separated from the basalis by at least 2 to 3 mm. Like endometriosis, the clinical symptoms of adenomyosis include menometrorrhagia (irregular and heavy menses), colicky dysmenorrhea, dyspareunia, and pelvic pain, particularly during the premenstrual period. It can coexist with endometriosis.

KEY CONCEPTS

Endometriosis

- Endometriosis is defined as endometrial glands and stroma outside of the uterus. The “ectopic” endometrial tissue may undergo cyclic bleeding.
- Most common sites of endometriosis are within the abdominal cavity, but occasionally it is found at distant sites.
- Several theories (regurgitation, metaplasia, metastasis, and stem cell origin) are proposed to explain the distribution of endometriosis.
- It commonly results in dysmenorrhea, pelvic pain, and infertility.
- Endometriosis may be a precursor to carcinoma (endometrioid and clear cell carcinoma).

Endometrial Polyps

Endometrial polyps are exophytic masses of variable size that project into the endometrial cavity. They may be single or multiple and are usually sessile, measuring from 0.5 to 3 cm in diameter, but are occasionally large and pedunculated. Polyps may be asymptomatic or may cause abnormal bleeding (intramenstrual, menometrorrhagia, or postmenopausal) if they ulcerate or undergo necrosis.

Cytogenetic studies indicate that the stromal cells in endometrial polyps contain certain chromosomal rearrangements that are similar to those found in other benign mesenchymal tumors. These findings suggest that the polyp stroma is neoplastic, and that the associated glands are reactive, merely “coming along for the ride.” The glands in polyps may be hyperplastic or atrophic, and may occasionally demonstrate secretory changes (functional polyps). Polyps may become hyperplastic in association with generalized endometrial hyperplasia and are responsive to estrogen but show little or no response to progesterone (Fig. 22-20C). Endometrial polyps have been observed in association with the administration of tamoxifen, which is often used in the therapy of breast cancer due to its anti-estrogenic activity on the breast. However, tamoxifen has weak pro-estrogenic effects in the endometrium. Atrophic polyps, which mainly occur in postmenopausal women, likely represent the atrophic remnants of previously hyperplastic polyps. Rarely, adenocarcinomas arise within endometrial polyps.

Endometrial Hyperplasia

Endometrial hyperplasia is an important cause of abnormal bleeding and a frequent precursor to the most common type of endometrial carcinoma. It is defined as an increased proliferation of the endometrial glands relative to the stroma, resulting in an increased gland-to-stroma ratio when compared with normal proliferative endometrium. Clinicopathologic and epidemiologic studies have supported the malignant potential of endometrial hyperplasia and the concept of a continuum of

proliferative glandular lesions culminating, in some cases, in carcinoma. Molecular studies have confirmed this relationship, since endometrial hyperplasia and carcinoma share specific acquired genetic alterations in genes linked to oncogenesis (described later).

Endometrial hyperplasia is associated with *prolonged estrogenic stimulation of the endometrium*, which can be due to anovulation, increased estrogen production from endogenous sources, or exogenous estrogen. Associated conditions include:

- Obesity (peripheral conversion of androgens to estrogens)
- Menopause
- Polycystic ovarian syndrome
- Functioning granulosa cell tumors of the ovary
- Excessive ovarian cortical function (cortical stromal hyperplasia)
- Prolonged administration of estrogenic substances (estrogen replacement therapy)

These are the same influences postulated to be of pathogenic significance in some endometrial carcinomas, discussed later.

Inactivation of the *PTEN* tumor suppressor gene is a common genetic alteration in both endometrial hyperplasias and endometrial carcinomas. As discussed in [Chapter 7](#), *PTEN* encodes a lipid phosphatase that is an important negative regulator of phosphatidylinositol 3-kinase (PI3K)/AKT growth-regulatory pathway. When *PTEN* function is lost, the PI3K/AKT pathway becomes overactive. Mutations in *PTEN* are found in more than 20% of hyperplasias, both with and without atypia, and in 30% to 80% of endometrial carcinomas, suggesting that alterations in *PTEN* occur at an early stage in endometrial tumorigenesis (although they are not predictive of progression of hyperplasia to carcinoma). Of note, patients with Cowden syndrome, which is caused by germline mutations in *PTEN*, have a high incidence of endometrial carcinoma and certain other tumors, particular breast cancer. As with many other tumor suppressors, it is not entirely clear why the loss of *PTEN* (which is expressed in many tissues) is so highly associated with particular tumors. It is interesting to note, however, that PI3K/AKT signaling enhances the ability of the estrogen receptor to turn on the expression of its target genes. Thus, loss of *PTEN* function may stimulate estrogen-dependent gene expression, leading to overgrowth of cell types that depend on estrogen for trophic signals, such as endometrial and mammary epithelial cells.

The classification of endometrial hyperplasia has undergone a number of changes over the years to keep pace with new insights into the disorder. In the recent past, the most widely used system divided endometrial hyperplasia into four categories: simple hyperplasia without atypia; complex hyperplasia without atypia; simple atypical hyperplasia; and complex atypical hyperplasia. However, the most current World Health Organization (WHO) classification recommends collapsing the four categories into two major categories: Non-atypical hyperplasia and atypical hyperplasia (also referred to as *endometrial intraepithelial neoplasia*), which differ in appearance and in their propensity to progress to carcinoma.

MORPHOLOGY

Non-atypical hyperplasia has a wide-range of appearances, but the cardinal feature is an increase in the gland-to-stroma ratio. The glands show variation in size and shape and may be dilated ([Fig. 22-23A](#)). Although there may be back-to-back glands focally, some intervening stroma is usually retained ([Fig. 22-23B](#)). These lesions reflect an endometrial response to persistent estrogen stimulation and rarely progress to adenocarcinoma (approximately 1% to 3%). Non-atypical hyperplasia may evolve into cystic atrophy when estrogen is withdrawn.

Atypical hyperplasia (endometrial intraepithelial neoplasia) is composed of complex patterns of proliferating glands displaying nuclear atypia. The glands are commonly back-to-back and often have complex outlines due to branching structures. Individual cells are rounded and lose the normal perpendicular orientation to the basement membrane. In addition, the nuclei have open (vesicular) chromatin and conspicuous nucleoli. The features of atypical hyperplasia have considerable overlap with those of well-differentiated endometrioid adenocarcinoma (discussed later), and accurate distinction from cancer may not be possible without hysterectomy ([Fig. 22-23C and D](#)). Indeed, approximately 23% to 48% of women with a diagnosis of atypical hyperplasia are found to have carcinoma when a hysterectomy is performed.

A proportion of endometrial hyperplasias are less easily classified, including complex lesions without cellular atypia (uncommon) and those with altered cellular differentiation, such as squamous, ciliated cell, eosinophilic, and mucinous metaplasias. Metaplastic epithelium is benign and the diagnosis of hyperplasia is based on the appearance of the nonmetaplastic areas.

Currently, atypical hyperplasia is managed by hysterectomy or, in young women who desire fertility, a trial of progestin therapy and close follow-up. Most often, hopefully after a successful pregnancy, lack of regression prompts removal of the uterus.

KEY CONCEPTS

Endometrial Hyperplasia

- Endometrial hyperplasia is defined as an increase in the number of glands relative to the stroma, appreciated as crowded glands, often with abnormal shapes.
- It is most commonly caused by unopposed estrogen stimulation and is an important cause of abnormal vaginal bleeding.
- It is divided into non-atypical and atypical hyperplasia based on nuclear atypia. Atypical hyperplasia is associated with an increased risk of endometrial carcinoma.
- The *PTEN* tumor suppressor gene is mutated in approximately 20% of endometrial hyperplasias.

Malignant Tumors of the Endometrium

Carcinoma of the Endometrium

Endometrial carcinoma is the most common invasive cancer of the female genital tract. It accounts for 7% of

Figure 22-23 Endometrial hyperplasia. **A**, Hyperplasia without atypia. Note architectural abnormalities including mild glandular crowding and cystic glandular dilatation. **B**, Hyperplasia without atypia demonstrating increased glandular crowding with areas of back-to-back glands and cytologic features similar to proliferative endometrium. **C**, Atypical hyperplasia with further increase in glandular crowding and abnormal cytologic features. **D**, High magnification of atypical hyperplasia showing rounded, vesicular nuclei with prominent nucleoli (arrow).

all invasive cancer in women, excluding skin cancer. At one time endometrial carcinoma was far less common than cancer of the cervix, but earlier detection and eradication of the precursor lesions of cervical carcinoma, coupled with an increase in endometrial carcinomas in younger women, have reversed this ratio. In 2012 in the United States, 47,130 new endometrial cancers and 8010 deaths were predicted. Worldwide there are approximately 280,000 new cases of endometrial cancer per year.

Pathogenesis. Clinicopathologic studies and molecular analyses support the classification of endometrial carcinoma into two broad categories referred to as type I and type II (summarized in Table 22-4). Because of their distinct pathogenesis, they are discussed separately.

Type I (Endometrial) Carcinoma. These are the most common type, accounting for approximately 80% of cases. Most are well differentiated and mimic proliferative endometrial glands and, as such, are referred to as *endometrioid carcinoma*. As discussed earlier, they typically arise in the

setting of endometrial hyperplasia and like endometrial hyperplasia they are associated with (1) obesity, (2) diabetes (abnormal glucose tolerance is found in more than 60%), (3) hypertension, (4) infertility, and (5) unopposed estrogen stimulation.

As with other cancers, development of endometrial carcinoma involves the stepwise acquisition of several genetic alterations in tumor suppressor genes and oncogenes. In hysterectomy specimens containing both atypical hyperplasia and carcinoma, identical *PTEN* mutations have been identified in each component, supporting the view that atypical hyperplasia is a precursor to carcinoma and that *PTEN* mutations occur before the development of overt carcinoma (Fig. 22-24A).

Sequencing of the genomes of type I endometrioid carcinomas has shown that the most common mutations act to increase signaling through the PI3K/AKT pathway, which is a hallmark of this particular tumor type. As mentioned earlier, PI3K/AKT signaling somehow augments expression of estrogen receptor-dependent target genes in endometrial cells. Type I endometrial carcinomas

Table 22-4 Characteristics of Type I and Type II Endometrial Carcinoma

Characteristics	Type I	Type II
Age	55-65 yr	65-75 yr
Clinical setting	Unopposed estrogen Obesity Hypertension Diabetes	Atrophy Thin physique
Morphology	Endometrioid	Serous Clear cell Mixed müllerian tumor
Precursor	Hyperplasia	Serous endometrial intraepithelial carcinoma
Mutated genes/ genetic abnormalities	<i>PTEN</i> <i>ARID1A</i> (regulator of chromatin) <i>PIK3CA</i> (PI3K) <i>KRAS</i> <i>FGF2</i> (growth factor) MSI* <i>CTNNB1</i> (Wnt signaling) <i>TP53</i>	<i>TP53</i> Aneuploidy <i>PIK3CA</i> (PI3K) <i>FBXW7</i> (regulator of MYC, cyclin E) <i>CHD4</i> (regulator of chromatin) <i>PPP2R1A</i> (PP2A)
Behavior	Indolent Spreads via lymphatics	Aggressive Intraperitoneal and lymphatic spread

*MSI, Microsatellite instability; *CTNNB1*, beta-catenin gene

are somewhat unique in that individual tumors may harbor multiple mutations that increase PI3K/AKT signaling, suggesting that tumor development and progression is fostered by successive increases in signal strength. Among the mutations that impact the PI3K/AKT pathway in endometrial carcinomas are the following:

- Mutations in the *PTEN* tumor suppressor gene have been identified in 30% to 80% of endometrioid carcinomas.
- *PIK3CA*, an oncogene that encodes the catalytic subunit of PI3K, harbors activating mutations in approximately 40% of endometrioid carcinomas. *PIK3CA* mutations rarely occur in atypical hyperplasias, suggesting that mutations in *PIK3CA* play a role in invasion.
- Mutations that activate *KRAS*, which also stimulates PI3K/AKT signaling, are found in approximately 25% of cases.
- Loss-of-function mutations in *ARID1A*, a regulator of chromatin structure, occur in approximately one-third of tumors. Of interest, *ARID1A* is also frequently mutated in ovarian endometrioid and clear cell carcinomas, tumors that arise within endometriosis. Although the mechanisms are not yet clear, loss of *ARID1A* function also enhances PI3K/AKT signaling.

Defects involving *DNA mismatch repair genes* are found in about 20% of sporadic tumors and are particularly prevalent in endometrial carcinomas arising in women from

Figure 22-24 **A**, Schematic depicting the development of type I endometrial carcinoma arising in the setting of hyperplasia. **B**, Schematic diagram of the development of type II endometrial carcinoma. The most common molecular genetic alterations are shown at the time they are most likely to occur during the progression of the disease. *MI, Microsatellite instability. *CTNNB1*, beta-catenin gene; *PPP2R1A*, PP2A gene; *CCNE1*, cyclin E gene.

families with hereditary nonpolyposis colorectal carcinoma (HNPCC, discussed in [Chapter 17](#)). This defect creates a mutator phenotype, leading to more rapid accumulation of mutations that may by chance alter the function of cancer genes and thereby drive tumor development. In sporadic endometrioid carcinomas, loss of expression of DNA mismatch repair genes is commonly caused by epigenetic silencing (via promoter hypermethylation). Finally, loss-of-function mutations in *TP53* are present in approximately 50% of poorly differentiated carcinomas. Since *TP53* mutations are lacking in well-differentiated endometrioid carcinomas, these mutations are thought to be late events involved in tumor progression.

MORPHOLOGY

Endometrioid carcinoma can take the form of a localized polypoid tumor or a tumor that diffusely infiltrates the endometrial lining ([Fig. 22-25A](#)). Spread generally occurs by myometrial invasion followed by direct extension to adjacent structures/organs. Invasion of the broad ligaments may create a palpable mass. Dissemination to the regional lymph nodes eventually

occurs, and in the late stages, the tumor may metastasize to the lungs, liver, bones, and other organs.

Endometrioid adenocarcinomas demonstrate glandular growth patterns resembling normal endometrial epithelium. There are three histologic grades: **well differentiated** (grade 1) ([Fig. 22-25B](#)), composed almost entirely of well-formed glands; **moderately differentiated** (grade 2) ([Fig. 22-25C](#)), showing well-formed glands mixed with areas composed of solid sheets of cells, which by definition make up 50% or less of the tumor; and **poorly differentiated** (grade 3) ([Fig. 22-25D](#)), characterized by greater than 50% solid growth pattern. Well differentiated tumors may be distinguished from hyperplasias by lack of intervening stroma.

Up to 20% of endometrioid carcinomas contain foci of squamous differentiation. Squamous elements may be histologically benign-appearing when they are associated with well-differentiated adenocarcinomas. Less commonly, moderately or poorly differentiated endometrioid carcinomas contain squamous elements that appear frankly malignant. Current classification systems grade the carcinomas based on glandular differentiation alone and ignore areas of solid squamous differentiation.

Figure 22-25 Type I endometrial carcinoma. **A**, Endometrial adenocarcinoma presenting as a fungating mass in the fundus of the uterus. **B**, Well-differentiated (grade 1) endometrioid adenocarcinoma with preserved glandular architecture but lack of intervening stroma. **C**, Moderately differentiated (grade 2) endometrioid adenocarcinoma with glandular architecture admixed with solid areas. **D**, Poorly differentiated (grade 3) endometrioid adenocarcinoma with a predominantly solid growth pattern.

Figure 22-26 Type II endometrial carcinoma. **A**, Endometrial intraepithelial carcinoma, the precursor to serous carcinoma showing malignant cells (*arrow*) with morphologic features identical to serous carcinoma lining the surfaces of the endometrial glands without obvious stromal invasion. **B**, Strong, diffuse expression of p53 as detected by immunohistochemistry in endometrial intraepithelial carcinoma. **C**, Serous carcinoma of the endometrium with papillary growth pattern consisting of malignant cells with marked cytologic atypia including high nuclear-to-cytoplasmic ratio, atypical mitotic figures, and hyperchromasia. **D**, As with the previous lesion, there is an accumulation of p53 protein in the nucleus.

Pathologic staging of both type I and II endometrial adenocarcinoma and malignant mixed müllerian tumors (described later) is as follows:

Stage I—Carcinoma is confined to the corpus uteri itself.

Stage II—Carcinoma involves the corpus and the cervix.

Stage III—Carcinoma extends outside the uterus but not outside the true pelvis.

Stage IV—Carcinoma extends outside the true pelvis or involves the mucosa of the bladder or the rectum.

Type II (Serous) Carcinoma. These generally occur in women who are about 10 years older than those with type I carcinomas, and in contrast to type I carcinomas they usually arise in the setting of *endometrial atrophy* (Fig. 22-24B). Type II tumors are by definition poorly differentiated (grade 3) tumors and account for approximately 15% of cases of endometrial carcinoma. The most common subtype is *serous carcinoma*, referred to as such because of morphologic and biologic overlap with ovarian serous

carcinoma. Several less common histologic subtypes (clear cell carcinoma and malignant mixed müllerian tumor) are also included within this category.

Mutations in the tumor suppressor *TP53* are present in at least 90% of serous endometrial carcinoma. The majority are missense mutations that result in an accumulation of the altered protein (Fig. 22-26B and D). The precursor of serous carcinoma, serous endometrial intraepithelial carcinoma, consists of cells identical to those of serous carcinoma but lacks identifiable stromal invasion. Mutations in *TP53* are also found in approximately 75% of endometrial intraepithelial carcinoma, suggesting that mutation of *TP53* is an early event in the evolution of serous endometrial carcinoma. Thus, serous carcinoma presumably begins as a surface epithelial neoplasm that extends into adjacent gland structures and later invades endometrial stroma. Their generally poorer prognosis is thought to be a consequence of a propensity to exfoliate, travel through the fallopian tubes, and implant on peritoneal surfaces like their ovarian counterparts. They have often spread outside of the uterus at the time of diagnosis. Recent whole-exome sequencing studies have detected mutations in a number of

additional genes, including those encoding PI3K and PP2A (a tumor suppressive phosphatase that is the target of the certain viral oncoproteins), in a significant number of serous carcinomas. Mutations in the genes encoding these two proteins are also found in serous endometrial intraepithelial carcinoma, suggesting that (like *TP53* mutations) they occur early in the development of this aggressive type of endometrial carcinoma.

MORPHOLOGY

Generally, serous carcinomas arise in small atrophic uteri and are often large bulky tumors or deeply invasive into the myometrium. The precursor lesion, **serous endometrial intraepithelial carcinoma**, consists of malignant cells identical to those of serous carcinoma that are confined to the epithelial surfaces (Fig. 22-26A and B). The invasive lesions may have a papillary growth pattern composed of cells with marked cytologic atypia including high nuclear-to-cytoplasmic ratio, atypical mitotic figures, hyperchromasia, and prominent nucleoli (Fig. 22-26C and D). However, they can also have a predominantly glandular growth pattern; in such cases they are distinguished from endometrioid carcinoma by the marked cytologic atypia. All of the tumors in this category are classified as grade 3 irrespective of histologic pattern. Serous carcinoma, despite relatively superficial endometrial involvement, may be associated with extensive peritoneal disease, suggesting spread by routes (i.e., tubal or lymphatic transmission) other than direct invasion.

Clinical Features. Carcinoma of the endometrium is uncommon in women younger than 40 years of age; the peak incidence is in postmenopausal women 55 to 65 years of age. There is no currently available screening test for carcinoma of the endometrium. Although it may be asymptomatic for a period of time, it usually produces irregular or postmenopausal vaginal bleeding with excessive leukorrhea. Fortunately, postmenopausal bleeding often leads to early detection, and cures are possible in most patients. Uterine enlargement may be absent in the early stages. The diagnosis of endometrial cancer must be established by histologic examination of tissue obtained by biopsy or curettage.

As would be anticipated, the prognosis depends heavily on the clinical stage at diagnosis, as well as histologic grade and subtype. In the United States, most tumors (about 80%) are stage I well-differentiated or moderately differentiated endometrioid carcinomas. Surgery, alone or in combination with irradiation, gives about 90% 5-year survival in stage I (grade 1 or 2) disease. This rate drops to approximately 75% for grade 3/stage I tumors and to 50% or less for stage II and III endometrial carcinomas.

As mentioned, serous carcinoma has a propensity for extrauterine (lymphatic or transtubal) spread, even when apparently confined to the endometrium or its surface epithelium. For unknown reasons, serous carcinoma occurs more frequently in women of African American descent, a difference that accounts for a two fold higher mortality rate in African American women compared with Caucasian women. Overall, the 5-year survival for women with serous carcinoma is 18% to 27% and even when it is confined to the uterus the recurrence rate is as high as 80%. Adjuvant radiation is often used to reduce local recurrence and

chemotherapy is given to women with endometrioid carcinoma when it has spread beyond the uterus. However, because of the aggressive nature of serous carcinoma, women may be treated with chemotherapy even in the absence of detectable extrauterine spread. Inhibitors of the PI3K/AKT pathway are being tested in clinical trials and the continued identification of biologic targets is likely to expand the roster of rational therapies in the future.

Malignant Mixed Müllerian Tumors

Malignant mixed müllerian tumors (MMMTs) (also referred to as *carcinosarcomas*) are endometrial adenocarcinomas with a malignant mesenchymal component. The mesenchymal component can take a number of forms. Some contain tumor cells resembling uterine mesenchymal elements (stromal sarcoma, leiomyosarcoma), while others contain heterologous malignant cell types (rhabdomyosarcoma, chondrosarcoma). The epithelial and stromal components appear to be derived from the same founding cell, a concept supported by molecular studies showing the presence of shared mutations. Both clinicopathologic and molecular studies suggest that the vast majority of these tumors are carcinomas with sarcomatous differentiation. Mutations found in MMMTs tend to involve the same genes that are mutated in endometrial carcinoma, such as *PTEN*, *TP53*, and *PIK3CA*, while alterations typical of those found in sarcomas are absent. At present, the mechanisms underlying the sarcomatous transformation are unknown, but some abnormality of epigenetic regulation seems likely.

MORPHOLOGY

MMMTs are often bulky and polypoid, and may protrude through the cervical os. On histology, the tumors usually consist of adenocarcinoma (endometrioid, serous, or clear cell) mixed with the malignant mesenchymal (sarcomatous) elements (Fig. 22-27A); alternatively, the tumor may contain two distinct and separate epithelial and mesenchymal components. Sarcomatous components may also mimic extrauterine tissues (e.g., striated muscle, cartilage, adipose tissue, and bone). Metastases usually contain only epithelial components (Fig. 22-27B).

MMMTs occur in postmenopausal women and present with bleeding. Outcome is determined primarily by depth of invasion and stage. The only other known prognostic factor is the differentiation of the mesenchymal component; patients with tumors that have heterologous mesenchymal components do worse than those whose tumors do not. Overall 5-year survival rates are 25% to 30% for patients with high-stage disease.

KEY CONCEPTS

Endometrial Carcinoma

- Endometrial carcinoma is the most common malignancy of the female genital tract.
- There are two major types of endometrial carcinoma: type I and type II. Type I tumors are low-grade and usually indolent; type II tumors are high-grade aggressive tumors and have a poor prognosis.

Figure 22-27 Malignant mixed müllerian tumor (MMMT). **A**, Micrograph showing both malignant epithelial and stromal components. **B**, Lymph node metastasis from a MMMT showing only the epithelial component, as is typically the case.

- Endometrioid (type I) carcinoma is often preceded by atypical hyperplasia and commonly has mutations in the *PTEN*, *PIK3CA*, *KRAS*, and *ARID1A* genes.
- Serous (type II) carcinoma is associated with serous endometrial intraepithelial carcinoma and the most common mutations are in *TP53*. *TP53* mutations are also found in precursor lesions.
- Stage remains the most important factor in outcome; serous tumors are much more likely to present at advanced stage and have a decidedly worse prognosis.
- Malignant mixed müllerian tumors (MMMTs) are carcinosarcomas that resemble endometrial carcinoma genetically and have poor outcomes with current therapies.

Tumors of Endometrial Stroma

These relatively uncommon tumors comprise less than 5% of endometrial cancers and include stromal neoplasms admixed with benign glands (adenosarcomas) and pure stromal neoplasms.

Adenosarcomas

Adenosarcomas present most commonly as large broad-based endometrial polypoid growths that may prolapse through the cervical os. The diagnosis is based on the presence of malignant-appearing stroma, which coexists with benign but abnormally shaped endometrial glands. These tumors predominate in women between the fourth and fifth decades and are generally considered to be a low-grade malignancy; recurrences develop in one fourth of cases and are nearly always confined to the pelvis. The principal diagnostic dilemma is distinguishing these tumors from large benign polyps. The distinction is important, because adenosarcoma is estrogen-sensitive and responds to oophorectomy.

Stromal Tumors

The endometrium occasionally gives rise to neoplasms that resemble normal stromal cells. Endometrial stromal

neoplasms are divided into two categories: (1) benign stromal nodules and (2) endometrial stromal sarcomas. The stromal sarcomas may be further divided into low-grade and high-grade types depending on their differentiation.

Clues to the pathogenesis of stromal sarcomas have come from the identification of several recurrent chromosomal aberrations that are quite specific for these malignancies. As with many sarcomas, stromal sarcomas are associated with chromosomal translocations that create fusion genes. Low-grade endometrial stromal sarcomas usually have translocations in which portions of the *JAZF1* gene, which encode a transcriptional repressor, is fused to a second gene belonging to the polycomb gene family, such as *SUZ12*. Polycomb proteins participate in complexes that introduce repressive histone marks into chromatin, thereby silencing genes, and it is hypothesized that the *JAZF1* fusion proteins act by disrupting the function of the polycomb complex, leading to misexpression of oncogenic genes. Recently, high-grade endometrial stromal sarcomas have been observed to contain different chromosomal translocations that also result in the formation of fusion genes, which are presumed to be pathogenically significant but are currently of unknown function.

About half of stromal sarcomas recur; relapse rates range from 36% to more than 80% for stage I and stage III/IV tumors, respectively. Unfortunately, relapse is not reliably predicted by either mitotic index or the degree of cytologic atypia. Distant metastases may announce their presence decades after the initial diagnosis, and death from metastatic tumor occurs in about 15% of cases. Five-year survival rates average 50% for low-grade tumors and are even lower for high-grade tumors.

Tumors of the Myometrium

Leiomyomas

Uterine leiomyoma (commonly called fibroids) is perhaps the most common tumor in women. They are benign smooth muscle neoplasms that may occur singly, but more often are multiple. Most leiomyomas have normal

karyotypes, but approximately 40% have a simple chromosomal abnormality. Several cytogenetic subgroups are recognized, including tumors with rearrangements of chromosomes 12q14 and 6p involving the *HMGIC* and *HMGII* genes, respectively, which are also implicated in a variety of other benign neoplasms. Both genes encode closely related DNA-binding factors that regulate chromatin structure. Recently, mutations in the *MED12* gene have been identified in up to 70% of uterine leiomyomas. The *MED12* gene encodes a component of Mediator, a multiprotein complex that stimulates gene expression by serving as a bridge between long-range DNA regulatory elements (so-called enhancers) and gene promoters. The effect of *MED12* mutations on gene expression in leiomyomas is an area of active investigation.

MORPHOLOGY

Leiomyomas are sharply circumscribed, discrete, round, firm, gray-white tumors varying in size from small, barely visible nodules to massive tumors that fill the pelvis. Except in rare instances, they are found within the myometrium of the corpus. Only infrequently do they involve the uterine ligaments, lower uterine segment, or cervix. They can occur within the myometrium (intramural), just beneath the endometrium (submucosal) or beneath the serosa (subserosal) (Fig. 22-28A).

Whatever their size, the characteristic whorled pattern of smooth muscle bundles on cut section usually makes these lesions readily identifiable. Large tumors may develop areas of yellow-brown to red softening.

Leiomyomas are typically composed of bundles of smooth muscle cells that resemble the uninvolved myometrium (Fig. 22-28B). Usually, the individual muscle cells are uniform in size and shape and have the characteristic oval nucleus and long, slender bipolar cytoplasmic processes. Mitotic figures are scarce. Benign variants of leiomyoma include atypical or bizarre (symplastic) tumors with nuclear atypia and giant cells, and cellular leiomyomas. Both have a low mitotic index, helping to distinguish these benign tumors from leiomyosarcomas. An

extremely rare variant, **benign metastasizing leiomyoma**, is a uterine leiomyoma that extends into vessels and spreads hematogenously to other sites, most commonly the lung. Another variant, **disseminated peritoneal leiomyomatosis**, presents as multiple small peritoneal nodules. Both are considered benign despite their unusual behavior.

Leiomyomas of the uterus, even when large or numerous, may be asymptomatic. Common signs and symptoms include abnormal bleeding, urinary frequency due to compression of the bladder, sudden pain from infarction of a large or pedunculated tumor, and impaired fertility. Myomas in pregnant women increase the frequency of spontaneous abortion, fetal malpresentation, uterine inertia (failure to contract with sufficient force), and postpartum hemorrhage. Malignant transformation to leiomyosarcoma, if it occurs at all, is extremely rare.

Leiomyosarcomas

These uncommon malignant neoplasms are thought to arise from the myometrium or endometrial stromal precursor cells, rather than leiomyomas. In contrast to leiomyomas, leiomyosarcomas have complex, highly variable karyotypes that frequently include deletions. Like leiomyomas, a subset contains *MED12* mutations, a genetic aberration that appears to be virtually unique to uterine smooth muscle tumors.

MORPHOLOGY

Leiomyosarcomas grow within the uterus in two somewhat distinctive patterns: (1) bulky, fleshy masses that invade the uterine wall or (2) polypoid masses that project into the uterine lumen (Fig. 22-29A). They exhibit a wide range of cytologic atypia, from extremely well differentiated to highly anaplastic (Fig. 22-29B). The distinction from leiomyoma is based on nuclear atypia, mitotic index, and zonal necrosis. With few

Figure 22-28 Leiomyomas of the uterine myometrium **A**, The uterus is opened to reveal multiple tumors in submucosal (bulging into the endometrial cavity), intramural, and subserosal locations that display a firm white appearance on sectioning. **B**, Leiomyoma showing well-differentiated, regular, spindle-shaped smooth muscle cells associated with hyalinization.

exceptions, the presence of 10 or more mitoses per 10 high-power (400×) fields indicates malignancy, particularly if accompanied by cytologic atypia and/or necrosis. If the tumor contains nuclear atypia or large (epithelioid) cells, five mitoses per 10 high-power (400×) fields are sufficient to justify a diagnosis of malignancy. Rare exceptions include mitotically active leiomyomas in young or pregnant women, and caution should be exercised in interpreting such neoplasms as malignant. A proportion of smooth muscle neoplasms may be impossible to classify and are called smooth muscle tumors of “uncertain malignant potential.”

Leiomyosarcomas occur both before and after menopause, with a peak incidence at 40 to 60 years of age. These tumors often recur following surgery, and more than half eventually metastasize hematogenously to distant organs, such as lungs, bone, and brain. Dissemination throughout the abdominal cavity is also encountered. The overall 5-year survival rate is about 40%, but the anaplastic lesions have a 5-year survival rate of only 10% to 15%.

KEY CONCEPTS

- Endometrial stromal tumors include stromal nodules, low-grade stromal sarcomas, and high-grade stromal sarcomas.
 - Stromal nodules are benign, well-circumscribed tumors.
 - Low-grade stromal sarcomas resemble stromal nodules, but infiltrate into the surrounding myometrium. They are associated with fusion of the *JAZF1* gene and various polycomb factor genes, usually *SUZ12*.
 - High-grade stromal sarcomas show marked atypia and are associated with other gene fusions.
 - Both low- and high-grade stromal sarcomas are prone to late recurrences.
- Leiomyomas are common benign smooth muscle tumors that cause significant morbidity and are often associated with *MED12* mutations.
- Leiomyosarcomas (malignant smooth muscle tumors) are uncommon, highly malignant myometrial tumors that usually arise de novo

Figure 22-29 Leiomyosarcoma. **A**, A large hemorrhagic tumor mass distends the lower corpus and is flanked by two leiomyomas. **B**, The tumor cells are irregular in size and have hyperchromatic nuclei. Numerous mitotic figures are present (arrows).

FALLOPIAN TUBES

The most common disorders affecting the fallopian tube are infections and associated inflammatory conditions, followed in frequency by ectopic (tubal) pregnancy and endometriosis.

Inflammations

Suppurative salpingitis may be caused by any pyogenic organism, and in some cases more than one organism is involved. *Gonococcus* is the causative organism in more than 60% of cases of this disorder, with *Chlamydiae* being responsible for many of the remaining cases. These tubal infections are a part of pelvic inflammatory disease, described earlier in this chapter.

Tuberculous salpingitis is rare in the United States, accounting for not more than 1% to 2% of all forms of salpingitis. It is more common, however, in parts of the world where tuberculosis is prevalent and is an important cause of infertility in these areas.

Tumors and Cysts

The most common primary lesions of the fallopian tube (excluding endometriosis) are minute, 0.1- to 2-cm translucent cysts filled with clear serous fluid, called *paratubal cysts*. Larger varieties are found near the fimbriated end of the tube or in the broad ligaments and are referred to as *hydatis of Morgagni*. These cysts, lined by benign

serous (tubal type) epithelium, are presumed to arise in remnants of the müllerian duct and are of little significance.

Tumors of the fallopian tube are uncommon. Benign tumors include *adenomatoid tumors* (mesotheliomas), which occur subserosally on the tube or sometimes in the mesosalpinx. These small nodules are the exact counterparts of the adenomatoid tumors that occur in the testes or epididymis (Chapter 21). Primary *adenocarcinoma* of the fallopian tubes is rare. It usually presents as a dominant tubal mass that may be detected by pelvic examination.

OVARIES

The most common lesions encountered in the ovary are functional or benign cysts and tumors. Neoplastic disorders can be grouped according to their origin from each of the three main ovarian cell types: (1) müllerian epithelium, (2) germ cells, and (3) sex cord-stromal cells. Primary inflammations of the ovary (oophoritis) are uncommon, and on rare occasions may have an autoimmune basis (autoimmune oophoritis); the autoimmune reactions affect the ovarian follicles and may lead to infertility.

Nonneoplastic and Functional Cysts

Follicle and Luteal Cysts

Cystic follicles are very common in the ovary. They originate from unruptured graafian follicles or in follicles that have ruptured and immediately sealed.

MORPHOLOGY

These cysts are usually multiple. They range in size up to 2 cm in diameter, are filled with a clear serous fluid, and are lined by a gray, glistening membrane. On occasion, larger cysts exceeding 2 cm (follicle cysts) may be diagnosed by palpation or ultrasonography; these may cause pelvic pain. Granulosa lining cells are present if the intraluminal pressure has not been so great as to cause their atrophy. The outer theca cells may be conspicuous due to increased amounts of pale cytoplasm (a change referred to as luteinization). As discussed subsequently, when luteinization is pronounced (hyperthecosis), it may be associated with increased estrogen production and endometrial abnormalities.

Luteal cysts (corpora lutea) are present in the normal ovaries of women of reproductive age. These cysts are lined by a rim of bright yellow tissue containing luteinized granulosa cells. They occasionally rupture and cause a peritoneal reaction. Sometimes the combination of old hemorrhage and fibrosis may make their distinction from endometriotic cysts difficult.

Polycystic Ovaries and Stromal Hyperthecosis

Polycystic ovarian syndrome (PCOS) is a complex endocrine disorder characterized by hyperandrogenism,

Other fallopian adenocarcinomas come to attention due to abnormal discharge, bleeding, or (occasionally) abnormal cells in a Pap smear. Approximately one half of tumors are stage I at diagnosis, but nearly 40% of affected patients are dead within 5 years, with higher stage tumors pursuing an even more aggressive course. Patients are typically treated with ovarian cancer chemotherapy protocols. Recently, data have accumulated to suggest that at least a subset of “serous ovarian cancers” actual arise from the epithelium of the fallopian tube (discussed later).

menstrual abnormalities, polycystic ovaries, chronic anovulation, and decreased fertility. Formerly called Stein Leventhal syndrome, it affects 6-10% of reproductive age women worldwide. It is also associated with obesity, type 2 diabetes, and premature atherosclerosis, all of which may be indicative of an underlying metabolic disorder. The etiology of PCOS remains incompletely understood. It is marked by a dysregulation of enzymes involved in androgen biosynthesis and excessive androgen production, which is considered to be a central feature of this disorder. In addition, women with PCOS show insulin resistance and altered adipose tissue metabolism, which contribute to the development of both diabetes and obesity.

The central morphologic abnormality of PCOS is numerous cystic follicles or follicle cysts that enlarge the ovaries. However, polycystic ovaries are detected in 20% to 30% of all women, so this finding is not specific. In addition, due to an increase in free serum estrone levels, women with PCOS are at risk for endometrial hyperplasia and carcinoma.

Stromal hyperthecosis, also called cortical stromal hyperplasia, is a disorder of ovarian stroma most often seen in postmenopausal women, but it may overlap with PCOS in younger women. The disorder is characterized by uniform enlargement of the ovary (up to 7 cm), which has a white to tan appearance on sectioning. The involvement is usually bilateral and microscopically shows hypercellular stroma and luteinization of the stromal cells, which are visible as discrete nests of cells with vacuolated cytoplasm. The clinical presentation and effects on the endometrium are similar to those of PCOS, although virilization may be even more striking.

A physiologic condition mimicking the aforementioned syndromes is *theca lutein hyperplasia of pregnancy*. In response to pregnancy hormones (gonadotropins), theca cells proliferate and the perifollicular zone expands. As the follicles regress, the concentric theca-lutein hyperplasia may appear nodular. This change is not to be confused with true luteomas of pregnancy (see later).

Ovarian Tumors

There are numerous types of ovarian tumors. About 80% are benign, and these occur mostly in young women between the ages of 20 and 45 years. Borderline tumors

occur at slightly older ages. Malignant tumors are more common in older women, between the ages of 45 and 65 years. Ovarian cancer accounts for 3% of all cancers in females and is the fifth most common cause of death due to cancer in women in the United States. **Because most ovarian cancers have spread beyond the ovary by the time of diagnosis, they account for a disproportionate number of deaths from cancer of the female genital tract.**

Classification. The classification of ovarian tumors given in Table 22-5 is a simplified version of the World Health Organization Histological Classification, which separates ovarian neoplasms according to the most probable tissue of origin. It is now believed that most tumors of the ovary arise ultimately from one of three ovarian components:

Table 22-5 WHO Classification of Ovarian Neoplasms

Surface Epithelial-Stromal Tumors
Serous tumors
Benign (cystadenoma, cystadenofibroma)
Borderline (serous borderline tumor)
Malignant (low- and high-grade serous adenocarcinoma)
Mucinous tumors, endocervical-like and intestinal type
Benign (cystadenoma, cystadenofibroma)
Borderline (mucinous borderline tumor)
Malignant (mucinous adenocarcinoma)
Endometrioid tumors
Benign (cystadenoma, cystadenofibroma)
Borderline (endometrioid borderline tumor)
Malignant (endometrioid adenocarcinoma)

Granulosa cell tumor	5	5
Teratoma		15
Benign (96%)	1	Rare
Malignant (4%)		
Metastatic	5	>50
Others	3	—

- surface/fallopian tube epithelium and endometriosis
- germ cells, which migrate to the ovary from the yolk sac and are pluripotent
- stromal cells, including the sex cords, which are forerunners of the endocrine apparatus of the postnatal ovary

There is also a group of tumors that defy classification, and finally there are secondary or metastatic tumors to the ovary.

Although some of the specific tumors have distinctive features and are hormonally active, most are nonfunctional and tend to produce relatively mild symptoms until they reach a large size. Some of these tumors, principally epithelial tumors, tend to be bilateral. Table 22-6 lists the tumors and their subtypes. Abdominal pain and distention, urinary and gastrointestinal tract symptoms due to compression by the tumor or cancer invasion, and vaginal bleeding are the most common symptoms. The benign forms may be entirely asymptomatic and occasionally are found unexpectedly on abdominal or pelvic examination or during surgery.

Epithelial Tumors

Most primary ovarian neoplasms arise from müllerian epithelium. The classification of these tumors is based on both differentiation and extent of proliferation of the epithelium. There are three major histologic types based on the differentiation of the neoplastic epithelium: *serous*, *mucinous*, and *endometrioid tumors*. These epithelial proliferations are classified as benign, borderline, and malignant. The benign tumors are often further subclassified based on the components of the tumors, which may include cystic areas (cystadenomas), cystic and fibrous areas (cystadenofibromas), and predominantly fibrous areas (adenofibromas). The borderline tumors and the malignant tumors can also have a cystic component, and when malignant they are sometimes referred to as *cystadenocarcinomas*.

Figure 22-30 Schematic diagram of the pathogenesis of ovarian epithelial tumors. Type I tumors progress from benign tumors through borderline tumors that may give rise to a low-grade carcinoma. These include low-grade serous, endometrioid and mucinous carcinomas. Type II tumors arise from inclusion cysts/fallopian tube epithelium via intraepithelial precursors that are often not identified. They demonstrate high-grade features and are most commonly of serous histology. STIC, serous tubal intraepithelial carcinoma.

The tumors can be relatively small, or they can grow to fill the entire pelvis before they are detected.

Clinicopathologic and molecular studies have suggested that ovarian carcinomas may be broadly categorized into two different types, referred to as type I and type II (Fig. 22-30). Type I carcinomas are low-grade tumors that often arise in association with borderline tumors or endometriosis. These tumors demonstrate several different histologic subtypes including low-grade serous, endometrioid, and mucinous tumors, as discussed later. Type II tumors are most often high-grade serous carcinomas that arise from serous intraepithelial carcinoma (see later).

Serous Tumors

These cystic neoplasms include the most common malignant ovarian tumors and account for approximately 40% of all cancers of the ovary. Although the term *serous* appropriately describes the cyst fluid, it has become synonymous with the tubal-like epithelium in these tumors. Together the benign, borderline, and malignant types account for about 30% of all ovarian tumors and just over 50% of ovarian epithelial tumors. About 70% are benign or borderline, and 30% are malignant. Benign and borderline tumors are most common between the ages of 20 and 45 years. Serous carcinomas occur later in life on average, but often occur at earlier ages in familial cases.

Pathogenesis. Little is known about the risk factors for benign and borderline tumors. Risk factors for malignant serous tumors (serous carcinomas) are also incompletely understood, but *nulliparity, family history, and heritable mutations play a role in tumor development.* There is a higher frequency of carcinoma in women with low parity. Women 40 to 59 years of age who have taken oral contraceptives

or undergone tubal ligation have a reduced risk of developing ovarian cancer. The most intriguing risk factors are genetic. As discussed in Chapters 7 and 23, inherited germline mutations in both *BRCA1* and *BRCA2* increase susceptibility to ovarian cancer. *BRCA1* mutations are present in about 5% of patients younger than 70 years of age with ovarian cancer. The estimated risk of ovarian cancer in women bearing *BRCA1* or *BRCA2* mutations is 20% to 60% by the age of 70 years.

Serous ovarian carcinoma is divided into two major groups: (1) low-grade (well-differentiated) carcinoma and (2) high-grade (moderately to poorly differentiated) carcinoma. This distinction is made based on the degree of nuclear atypia and correlates with patient survival. Low-grade carcinomas may arise in association with serous borderline tumors, while high-grade carcinomas arise from in situ lesions in the fallopian tube fimbriae or from serous inclusion cysts within the ovary.

The concept of a fallopian tube origin for high-grade serous carcinomas arose initially from studies on women with *BRCA1/2* germline mutations who were discovered at the time of prophylactic salpingo-oophorectomy to have areas of marked epithelial atypia in their fallopian tubes. The lesions, called serous tubal intraepithelial carcinoma (STIC), have since been described in association with sporadic high-grade serous ovarian cancers, leading to the idea that at least some high-grade serous carcinomas arise from the fallopian tube. What then is the origin of high-grade serous carcinomas that involve the ovary, without concomitant involvement of the fallopian tube? Historically it was thought that the vast majority of serous ovarian carcinomas arose from cortical inclusion cysts (Fig. 22-31). These cysts were thought to arise through invagination of the surface epithelium, followed by serous metaplasia. A recent alternative hypothesis is that the cysts arise from implantation of detached fallopian tube epithelium at sites where ovulation has disrupted the surface of the ovary (Fig. 22-30).

The percentage of sporadic high-grade serous carcinomas that arise in the fallopian tube or from ovarian inclusion cysts is currently unknown, as is the origin of the cortical inclusion cysts. Studies attempting to address these unsettled issues are being pursued. However, this paradigm shift has already altered the management of

Figure 22-31 Cortical inclusion cysts of the ovary.

women at high-risk for ovarian carcinoma (*BRCA* mutation carriers and women with a strong family history of breast/ovarian cancer), as these women now undergo salpingo-oophorectomy, instead of simple oophorectomy.

Regardless of their origin, studies have shown that low- and high-grade serous carcinomas have distinct mutational profiles, as follows:

- Low-grade tumors arising in serous borderline tumors have mutations in the *KRAS*, *BRAF*, or *ERBB2* oncogenes, and usually have wild type *TP53* genes.
- High-grade tumors have a high frequency of *TP53* mutations and lack mutations in either *KRAS* or *BRAF*. Genomic imbalances are very common and include amplifications of a number of oncogenes (e.g., *PIK3CA*, the gene encoding the catalytic subunit of PI3K) and deletions of tumor suppressor genes (e.g., *RB*). Almost all ovarian carcinomas arising in women with *BRCA1* or *BRCA2* mutations are high-grade serous carcinomas with *TP53* mutations. Interestingly, *BRCA1/2* mutations are rare in sporadic high-grade serous carcinoma.

MORPHOLOGY

Serous tumors may present as either a multicystic lesion in which papillary epithelium is contained within a few fibrous walled cysts (intracystic) (Fig. 22-32A) or as a mass projecting from the ovarian surface. Benign tumors typically have a smooth glistening cyst wall with no epithelial thickening or with small papillary projections. Borderline tumors contain an increased number of papillary projections (Fig. 22-32A and C). Larger areas of solid or papillary tumor mass, tumor irregularity, and fixation or nodularity of the capsule are features associated with malignancy (Fig. 22-32B). Bilaterality is common, occurring in 20% of benign serous cystadenomas, 30% of serous borderline tumors, and approximately 66% of serous carcinomas. A significant proportion of both serous borderline tumors and malignant serous tumors involve the surface of the ovary (Fig. 22-32C).

Microscopically, the cysts are lined by columnar epithelium, which has abundant cilia in benign tumors (Fig. 22-33A). Microscopic papillae may be found. **Serous borderline tumors** exhibit increased complexity of the stromal papillae, stratification of the epithelium and mild nuclear atypia, but invasion of the stroma is not seen (Fig. 22-33B). This epithelial proliferation often grows in a delicate, papillary pattern referred

to as “micropapillary carcinoma,” which is thought to be the precursor to **low-grade serous carcinoma** (Fig. 22-33C).

High-grade serous carcinomas are distinguished from low-grade tumors by having more complex growth patterns and widespread infiltration or frank effacement of the underlying stroma (Fig. 22-33D). The individual tumor cells display marked nuclear atypia, including pleomorphism, atypical mitotic figures, and multinucleation. The serous tubal intraepithelial carcinomas consist of cells morphologically identical to high-grade serous carcinomas but are distinguished by the lack of invasion. The cells of invasive high-grade serous carcinoma can even become so undifferentiated that serous features are no longer recognizable. Concentric calcifications (psammoma bodies) characterize serous tumors, but are not specific for neoplasia. Ovarian serous tumors, both low- and high-grade, have a propensity to spread to the peritoneal surfaces and omentum and are commonly associated with the presence of ascites. As with other tumors, the extent of the spread outside the ovary determines the stage of the disease.

The biologic behavior of serous tumors depends on the degree of differentiation and the distribution and characteristics of the disease in the peritoneum, if present. Importantly, serous tumors may occur on the surface of the ovaries and, rarely, as primary tumors of the peritoneal surface, which are referred to as primary peritoneal serous carcinoma. As discussed, at least some of these carcinomas may originate from the fallopian tube. Predictably, unencapsulated serous tumors of the ovarian surface are more likely to spread to the peritoneal surfaces, and prognosis is closely related to the histologic appearance of the tumor and its growth pattern on the peritoneum. Borderline serous tumors may arise from or extend to the peritoneal surfaces as noninvasive implants, remaining localized and causing no symptoms, or slowly spread, producing intestinal obstruction or other complications after many years. As discussed earlier, low-grade serous carcinomas can arise in borderline serous tumors and may be associated with spread to the peritoneal surfaces. However, low-grade carcinomas, even after spread outside the ovary, often progress slowly, and patients may survive for relatively long periods before dying of disease. In contrast, high-grade tumors are often widely metastatic throughout the abdomen at the time of presentation, a picture

associated with rapid clinical deterioration. Consequently, pathologic classification of the tumor, even if it has extended to the peritoneum, is relevant to both prognosis and selection of therapy. The 5-year survival rate for borderline and malignant tumors confined to the ovary is, respectively, 100% and 70%, whereas the 5-year survival rate for the same tumors involving the peritoneum is about 90% and 25%, respectively. Because of their protracted course, borderline tumors may recur after many years, and 5-year survival is not synonymous with cure.

Mucinous Tumors

Mucinous tumors account for about 20% to 25% of all ovarian neoplasms. They occur principally in middle adult life and are rare before puberty and after menopause. The vast majority are benign or borderline tumors. Primary ovarian mucinous carcinomas are uncommon and account for approximately 3% of all ovarian cancers.

Pathogenesis. Mutation of the *KRAS* proto-oncogene is a consistent genetic alteration in mucinous tumors of the ovary, including the majorities of benign mucinous cystadenomas (58%), mucinous borderline tumors (75% to 86%), and ovarian mucinous carcinomas (85%). Interestingly, one study showed that several tumors with distinct areas of epithelium showing benign, borderline, and carcinoma had identical *KRAS* mutations in each area. Thus, *KRAS* mutations may initiate the development of these neoplasms. The mutations that collaborate with *KRAS* mutations to generate mucinous tumors are largely unknown.

MORPHOLOGY

Mucinous tumors differ from the serous variety in several ways. The surface of the ovary is rarely involved and only 5% of primary mucinous cystadenomas and mucinous carcinomas are bilateral. Mucinous tumors also tend to produce larger cystic masses; some have been recorded with weights of more than 25 kg. They are multiloculated tumors filled with sticky, gelatinous fluid rich in glycoproteins (Fig. 22-34A).

Microscopically, benign mucinous tumors are characterized by a lining of tall, columnar epithelial cells with apical mucin that lack cilia. The vast majority demonstrates gastric or intestinal type differentiation, with uncommon tumors showing endocervical type mucinous differentiation instead (Fig. 22-34B). Mucinous borderline tumors are distinguished from cystadenomas by epithelial stratification, tufting, and/or papillary intraglandular growth, often producing an appearance strikingly similar to tubular adenomas or villous adenomas of the intestine.

Mucinous carcinomas characteristically demonstrate confluent glandular growth that is now recognized as a form of “expansile” invasion. Some authors use the term intraepithelial carcinomas for tumors with marked epithelial atypia that lack invasive features. Approximate 10-year survival rates for stage I, noninvasive “intraepithelial carcinomas” and for frankly invasive malignant tumors are greater than 95% and 90%, respectively. Mucinous carcinomas that have spread beyond the ovary are usually fatal, but as previously stated, these tumors are uncommon and must be distinguished from metastatic mucinous adenocarcinomas.

Figure 22-34 Mucinous cystadenoma **A**, Note the multicystic appearance, delicate septa, and the presence of glistening mucin within the cysts. **B**, Columnar cells lining the cysts.

A clinical condition referred to as *pseudomyxoma peritonei* is marked by extensive mucinous ascites, cystic epithelial implants on the peritoneal surfaces, adhesions, and frequent involvement of the ovaries (Fig. 22-35). Pseudomyxoma peritonei, if extensive, may result in intestinal obstruction and death. Historically, it was thought that many cases in women were due to the spread of primary ovarian mucinous neoplasms. However, recent evidence points to the source being, in almost all cases, extraovarian (usually appendiceal) (Chapter 18). Because the majority of primary mucinous ovarian tumors are unilateral, bilateral presentation of mucinous tumors always requires exclusion of a nonovarian origin.

Endometrioid Ovarian Tumors

Endometrioid carcinoma accounts for approximately 10% to 15% of all ovarian cancers. Benign endometrioid tumors, called *endometrioid adenofibromas*, and borderline endometrioid tumors also occur, but are uncommon. Endometrioid tumors are distinguished from serous and mucinous tumors by the presence of tubular glands resembling benign or malignant endometrium. Endometrioid carcinomas may arise in the setting of endometriosis and are occasionally associated with areas of borderline tumor.

Although these tumors are less common than either serous or mucinous tumors, more is known about the molecular genetic alterations associated with their development. This is due to the recent development of mouse models that closely mimic the human disease and molecular genetic overlap with endometrioid carcinomas of the endometrium. In fact, 15% to 30% of ovarian endometrioid carcinomas are accompanied by carcinoma of the endometrium, and the relatively good prognosis in such cases suggests that the two arise independently rather than by metastatic spread.

Pathogenesis. About 15% to 20% of cases with endometrioid carcinoma coexist with endometriosis. The peak incidence of tumors associated with endometriosis occurs a decade earlier than that of endometrioid carcinomas that are not associated with endometriosis. Molecular studies have found striking similarities to endometrial endometrioid carcinoma; shared features include relatively frequent alterations that increase PI3K/AKT pathway signaling (mutations in *PTEN*, *PIK3CA*, *ARID1A*, and *KRAS*) and mutations in mismatch DNA repair genes and *CTNNB1* (β -catenin). As mentioned earlier, mutations in *PTEN* have also been found in atypical endometriosis suggesting that it occurs early in the pathogenesis of ovarian endometrioid carcinoma, as it does in endometrioid carcinoma of the endometrium. Also similar to endometrioid carcinomas of the endometrium, *TP53* mutations are common in poorly differentiated tumors.

MORPHOLOGY

Endometrioid carcinomas typically present with solid and cystic areas of growth. Forty percent involve both ovaries, and such bilaterality usually implies extension of the neoplasm beyond the genital tract. These are low-grade tumors that reveal glandular patterns bearing a strong resemblance to those of endometrial origin. The 5-year survival rate for patients with stage I tumors is approximately 75%.

(A, Courtesy Dr. Paul H. Sugarbaker, Washington Hospital Cancer Center, Washington, D.C.)

Clear Cell Carcinoma

Benign and borderline clear cell tumors are exceedingly rare, and clear cell carcinomas are uncommon. They are composed of large epithelial cells with abundant clear cytoplasm, an appearance that resembles hypersecretory gestational endometrium. Because these tumors sometimes occur in association with endometriosis or endometrioid carcinoma of the ovary and resemble clear cell carcinoma of the endometrium, they are now thought to be variants of endometrioid adenocarcinoma. In line with this idea, the most common genetic aberrations (*PIK3CA*, *ARID1A*, *KRAS*, *PTEN*, and *TP53*) are shared with endometrioid carcinoma, albeit at somewhat different frequencies. Clear cell tumors of the ovary can be predominantly solid or cystic. In the solid neoplasms, the clear cells are arranged in sheets or tubules, while in the cystic variety, the neoplastic cells line the spaces. Clear cell carcinoma confined to the ovaries has a 90% 5-year survival, but in advanced stage disease it appears that clear cell morphology portends a poor outcome. Clear cell carcinoma is treated like other types of ovarian carcinoma.

Cystadenofibroma

Cystadenofibromas are uncommon variants in which there is more pronounced proliferation of the fibrous stroma that underlies the columnar lining epithelium. These benign tumors are usually small and multilocular and have simple papillary processes that do not become as complicated and branching as those found in the ordinary cystadenoma. They may contain mucinous, serous, endometrioid, and transitional (Brenner tumors) epithelium. Borderline lesions with cellular atypia and, rarely, tumors with focal areas of carcinoma occur, but metastatic spread of either is extremely uncommon.

Transitional Cell Tumors

Transitional cell tumors contain neoplastic epithelial cells resembling urothelium and are usually benign. They comprise roughly 10% of ovarian epithelial tumors and are also referred to as Brenner tumors. Uncommon transitional cell carcinomas also occur in the ovary.

MORPHOLOGY

These neoplasms may be solid or cystic, are usually unilateral (approximately 90%), and vary in size from small lesions less than 1 cm in diameter to massive tumors up to 20 to 30 cm in diameter (Fig. 22-36A). The fibrous stroma, resembling that of the normal ovary, is marked by sharply demarcated nests of epithelial cells resembling the epithelium of the urinary tract, often with mucinous glands in their center (Fig. 22-36B). Infrequently, the stroma is composed of somewhat plump fibroblasts resembling theca cells; such neoplasms may have hormonal activity. Most Brenner tumors are benign, but borderline (atypical proliferative Brenner tumor) and malignant counterparts have been reported. Tumors with benign Brenner nests admixed with malignant tumor cells are referred to as malignant Brenner tumors, while tumors with greater than 50% malignant transitional type epithelium are considered transitional cell carcinomas of the ovary.

Brenner tumors are often detected incidentally and even when large behave in a benign fashion. Malignant Brenner tumors generally present in stage 1 and for prognostic purposes are considered to be equivalent to low-grade (type I) carcinomas. The uncommon transitional cell carcinomas are considered to be equivalent to high-grade (type II) ovarian carcinomas; these often present at advanced stage and are treated like high-grade serous carcinomas.

Clinical Course, Detection, and Prevention of Ovarian Epithelial Tumors

All ovarian carcinomas produce similar clinical manifestations, most commonly lower abdominal pain and abdominal enlargement. Gastrointestinal complaints, urinary frequency, dysuria, pelvic pressure, and many other symptoms may appear. Benign lesions are easily resected and cured. The malignant forms tend to cause progressive weakness, weight loss, and cachexia. If the carcinomas extend through the capsule of the tumor to seed the peritoneal cavity, massive ascites is common. Characteristically, the ascitic fluid is filled with exfoliated

Figure 22-36 Brenner tumor **A**, Brenner tumor (*right*) associated with a benign cystic teratoma (*left*). **B**, Histologic detail of characteristic epithelial nests within the ovarian stroma. (Courtesy Dr. M. Nucci, Brigham and Women's Hospital, Boston, Mass.)

tumor cells. The peritoneal pattern of spread is distinctive: all serosal surfaces are diffusely seeded with 0.1- to 0.5-cm nodules of tumor that only rarely invade deeply into the underlying parenchyma. The regional nodes are often involved, and metastases may be found in the liver, lungs, gastrointestinal tract, and elsewhere. Metastasis across the midline to the opposite ovary is discovered in about half the cases at surgery and heralds a progressive downhill course and death within a few months or years.

Most women with ovarian carcinoma present with high stage disease. This is the primary reason for the relatively poor 5- and 10-year survival rates of patients with these tumors, compared with rates for patients with cervical or endometrial carcinoma. For these reasons, development of new assays that permit early diagnosis is a top priority. Biochemical tests for tumor antigens or tumor products in the plasma of these patients are being sought vigorously, but none proposed to date has sufficient sensitivity and specificity to be useful. The serum marker CA-125 is used in patients with known disease to monitor disease recurrence/progression.

Prevention of ovarian cancer also remains an elusive goal. Screening to identify women at risk (positive for *BRCA* mutations or with strong family histories) and treatment with prophylactic salpingo-oophorectomy are currently standard, but the long-term impact of these approaches remains to be determined.

KEY CONCEPTS

- Epithelial ovarian tumors are classified into benign, borderline or malignant.
- About 80% of all ovarian epithelial tumors are benign and occur in young women. The malignant tumors occur most commonly in older women and account for approximately 3% of all cancers in women in the United States.
- The majority of the malignant epithelial tumors are high-grade serous carcinomas, which have a poor prognosis in large part due to the fact that they are detected after they have spread beyond the ovary.
- There are three major histologic types of epithelial ovarian tumors: serous, mucinous and endometrioid, all of which have a benign, borderline and malignant category.
- Benign tumors are composed of well-differentiated epithelial cells with minimal proliferation. Borderline tumors show increased cell proliferation, but lack stromal invasion. Malignant tumors show increased epithelial atypia and are defined by the presence of stromal invasion.
- Ovarian carcinomas are currently divided into Type I (low grade) and Type II (high-grade) tumors.
- The origin of ovarian tumors is still under investigation, but it is clear that *BRCA1*- and *BRCA2*-related tumors as well as a subset of sporadic, ovarian serous tumors are likely to arise from fallopian tube epithelium instead of ovarian epithelium.

Germ Cell Tumors

Germ cell tumors constitute 15% to 20% of all ovarian tumors. *Most are benign cystic teratomas*, but others, found principally in children and young adults, may show

Figure 22-37 Histogenesis and interrelationships of tumors of germ cell origin.

malignant behavior and pose problems in histologic diagnosis and in therapy. They bear a remarkable similarity to germ cell tumors in the male testis (Chapter 21) and arise in a similar manner (Fig. 22-37).

Teratomas

Teratomas are divided into three categories: (1) mature (benign), (2) immature (malignant), and (3) monodermal or highly specialized.

Mature (Benign) Teratomas. Most benign teratomas are cystic and are often referred to as *dermoid cysts*, because they are almost always lined by skin-like structures. Cystic teratomas are usually found in young women during the active reproductive years. They may be discovered incidentally, but are occasionally associated with clinically important paraneoplastic syndromes, such as inflammatory limbic encephalitis, which may remit upon removal of the tumor.

MORPHOLOGY

Benign teratomas are bilateral in 10% to 15% of cases. Characteristically they are unilocular cysts containing hair and sebaceous material (Fig. 22-38). Sectioning reveals a thin wall lined by an opaque, gray-white, wrinkled epidermis, frequently with protruding hair shafts. Within the wall, it is common to find grossly evident tooth structures and areas of calcification.

Microscopically, the cyst wall is composed of stratified squamous epithelium with underlying sebaceous glands, hair shafts, and other skin adnexal structures (Fig. 22-39). In most cases tissues from other germ layers can be identified, such as cartilage, bone, thyroid, and neural tissue. Dermoid cysts are sometimes incorporated within the wall of a mucinous cystadenoma. **About 1% of the dermoids undergo malignant transformation, most commonly to squamous cell carcinoma, but also to other cancers as well (e.g., thyroid carcinoma, melanoma).**

In rare instances a benign teratoma is solid and composed entirely of benign-looking heterogeneous collections of tissues and organized structures derived from all three germ layers. These tumors presumably have the same histogenetic origin as dermoid cysts but lack preponderant differentiation into ectodermal derivatives. These neoplasms may be difficult to distinguish, on gross inspection, from malignant immature teratomas.

Figure 22-38 Opened mature cystic teratoma (dermoid cyst) of the ovary. Hair (bottom) and a mixture of tissues are evident.

The origin of teratomas has been a matter of fascination for centuries. Some common beliefs blamed witches, nightmares, or adultery with the devil. The karyotype of almost all benign ovarian teratomas is 46,XX. Genetic analyses indicate that the majority of teratomas arise from an ovum after the first meiotic division, while a minority arises before the first division.

Monodermal or Specialized Teratomas. The specialized teratomas are a remarkable, rare group of tumors, the most common of which are *struma ovarii* and *carcinoid*. They are always unilateral, although a contralateral teratoma may be present. *Struma ovarii* is composed entirely of mature thyroid tissue, which may be functional and cause hyperthyroidism. The ovarian carcinoid, which presumably arises from intestinal tissue found in teratomas, may also be functional; particularly if large (>7 cm), they can produce sufficient 5-hydroxytryptamine to cause the carcinoid syndrome even in the absence of hepatic metastases, since ovarian veins are directly connected to systemic circulation. Primary ovarian carcinoid must be distinguished from metastatic intestinal carcinoid, which is virtually always bilateral. Even rarer is the strumal carcinoid, a combination of *struma ovarii* and carcinoid in the same ovary. Only about 2% of carcinoids in teratomas metastasize.

Figure 22-39 Benign cystic teratoma. Low-power view of skin (right edge), beneath which there is brain tissue (left edge).

Immature Malignant Teratomas. These are rare tumors that differ from benign teratomas in that the component tissues resemble embryonal and immature fetal tissue. The tumor is found chiefly in prepubertal adolescents and young women, the mean age being 18 years.

MORPHOLOGY

The tumors are bulky and have a smooth external surface and tend to be solid on sectioning. Hair, sebaceous material, cartilage, bone, and calcification may be present, along with areas of necrosis and hemorrhage. On microscopic examination there are varying amounts of immature neuroepithelium, cartilage, bone, muscle, and other elements. An important risk for subsequent extraovarian spread is the histologic grade of tumor (I through III), which is based on the proportion of tissue containing immature neuroepithelium (Fig. 22-40).

Immature teratomas grow rapidly, frequently penetrate the capsule, and spread either locally or distantly. Stage I tumors, however, particularly those with low-grade (grade 1) histology, have an excellent prognosis. Higher-grade tumors confined to the ovary are generally treated with prophylactic chemotherapy. Most recurrences develop in the first 2 years, and absence of disease beyond this period carries an excellent chance of cure.

Dysgerminoma

Dysgerminoma is the ovarian counterpart of testicular seminoma. Dysgerminomas account for about 2% of ovarian cancers and roughly 50% of malignant ovarian germ cell tumors. They may occur in childhood, but 75% occur in the second and third decades. Some occur in patients with gonadal dysgenesis, including pseudohermaphroditism. Most of these tumors have no endocrine function. A few produce elevated levels of chorionic gonadotropin, a finding that correlates with the presence of syncytiotrophoblastic giant cells. Like seminomas, dysgerminomas express OCT-3, OCT4, and NANOG. These transcription factors are implicated in maintenance of pluripotency. They also express the receptor tyrosine kinase KIT and approximately one third have activating mutations in the *KIT* gene. These proteins are useful diagnostic

Figure 22-40 Immature teratoma of the ovary illustrating primitive neuroepithelium.

Figure 22-41 Dysgerminoma showing polyhedral tumor cells with round nuclei and adjacent inflammation.

markers and, in the case of KIT, may also serve as a therapeutic target.

MORPHOLOGY

Most dysgerminomas (80% to 90%) are unilateral tumors ranging in size from barely visible nodules to masses that virtually fill the entire abdomen. On cut surface they have a solid yellow-white to gray-pink appearance and are often soft and fleshy. Like seminoma, it is composed of large vesicular cells having a clear cytoplasm, well-defined cell boundaries, and centrally placed regular nuclei. The tumor cells grow in sheets or cords separated by scant fibrous stroma (Fig. 22-41), which is infiltrated by mature lymphocytes and may contain occasional granulomas. On occasion, small nodules of dysgerminoma are encountered in the wall of an otherwise benign cystic teratoma; conversely, a predominantly dysgerminomatous tumor may contain a small cystic teratoma.

All dysgerminomas are malignant, but the degree of histologic atypia is variable, and only about one third are aggressive. A unilateral tumor that has not broken through the capsule or spread outside the ovary has an excellent prognosis (up to 96% cure rate) after simple salpingo-oophorectomy. These neoplasms are responsive to chemotherapy, and even those that have extended beyond the ovary can often be cured. Overall survival exceeds 80%.

Yolk Sac Tumor

Though rare, yolk sac tumor (also known as *endodermal sinus tumor*) still ranks as the second most common malignant tumor of germ cell origin. It is thought that to be derived from malignant germ cells that are differentiating along the extraembryonic yolk sac lineage (Fig. 22-37). Similar to the normal yolk sac, the tumor cells elaborate α -fetoprotein. Its characteristic histologic feature is a glomerulus-like structure composed of a central blood vessel enveloped by tumor cells within a space that is also lined by tumor cells (*Schiller-Duval body*) (Fig. 22-42). Conspicuous intracellular and extracellular hyaline droplets are present in all tumors, and some of these stain for α -fetoprotein by immunoperoxidase techniques.

Most patients are children or young women presenting with abdominal pain and a rapidly growing pelvic mass that usually appears to involve a single ovary. With combination chemotherapy, there is greater than 80% survival independent of disease stage.

Choriocarcinoma

More commonly of placental origin, choriocarcinoma, like the yolk sac tumor, is an example of extraembryonic differentiation of malignant germ cells. It is generally held that a germ cell origin can be confirmed only in prepubertal females, because after this age an origin from an ovarian ectopic pregnancy cannot be excluded.

Most ovarian choriocarcinomas exist in combination with other germ cell tumors, and pure choriocarcinoma is extremely rare. They are histologically identical to the more common placental lesions (described later). The ovarian tumors are aggressive and have usually metastasized hematogenously to the lungs, liver, bone, and other sites by the time of diagnosis. Like all choriocarcinomas they elaborate high levels of *chorionic gonadotropins*, which may be helpful in establishing the diagnosis or detecting recurrences. In contrast to choriocarcinomas arising in placental tissue, those arising in the ovary are generally unresponsive to chemotherapy and are often fatal.

Other Germ Cell Tumors

These include (1) embryonal carcinoma, a highly malignant tumor of primitive embryonal elements that is histologically similar to embryonal carcinoma arising in the testes (Chapter 21); (2) polyembryoma, a malignant tumor containing so-called embryoid bodies; and (3) mixed germ cell tumors containing various combinations of dysgerminoma, teratoma, yolk sac tumor, and choriocarcinoma.

KEY CONCEPTS

Germ Cell Tumors

- Germ cell tumors constitute 15% to 20% of ovarian tumors.
- The majority are mature cystic teratomas (dermoid cysts) in women of reproductive age.

Figure 22-42 A Schiller-Duval body in yolk sac carcinoma.

Figure 22-43 Granulosa cell tumor. **A**, The tumor cells are arranged in sheets punctuated by small follicle-like structures (Call-Exner bodies). **B**, Strong immunohistochemical positivity with an antibody to inhibin characterizes these tumors.

- The remainder occur in young women and children; in these age groups, malignant tumors dominate.
- Immature teratomas are distinguished from mature teratomas by the presence of immature elements, most often consisting of primitive neuroepithelium.
- Germ cell tumors show various lines of differentiation toward oogonia (dysgerminoma), extraembryonic yolk sac (yolk sac tumors), placenta (choriocarcinoma), or multiple germ layers (teratoma).

The granulosa cell component of these tumors has many histologic patterns. The small, cuboidal to polygonal cells may grow in anastomosing cords, sheets, or strands (Fig. 22-43A). In occasional cases, small, distinctive, glandlike structures filled with an acidophilic material recall immature follicles (**Call-Exner bodies**). When these structures are evident, the diagnosis is straightforward. Occasionally, there is a predominant thecoma component that consists of clusters or sheets of cuboidal to polygonal cells (see later). In some tumors, the granulosa or theca cells may appear plumper and have ample cytoplasm characteristic of luteinization (i.e., luteinized granulosa-theca cell tumors).

Sex Cord-Stromal Tumors

These ovarian neoplasms are derived from the ovarian stroma, which in turn is derived from the sex cords of the embryonic gonad. The undifferentiated gonadal mesenchyme eventually produces specific types of cells in both male (Sertoli and Leydig) and female (granulosa and theca) gonads, and tumors resembling all of these cell types can be identified in the ovary. Moreover, because some of these cells normally secrete estrogens (granulosa and theca cells) or androgens (Leydig cells), their corresponding tumors may be either feminizing (granulosa/theca cell tumors) or masculinizing (Leydig cell tumors).

Granulosa Cell Tumors

Granulosa cell tumors are composed of cells that resemble granulosa cells of a developing ovarian follicle. They are broadly divided into adult and juvenile granulosa cell tumors largely based on the age of the patient, but also on morphologic findings. Collectively, these neoplasms account for about 5% of all ovarian tumors and adult granulosa cell tumors make up 95% of all granulosa cell tumors. Although they may be discovered at any age, approximately two thirds occur in postmenopausal women.

MORPHOLOGY

Granulosa cell tumors are usually unilateral and vary from microscopic foci to large, solid, and cystic encapsulated masses. Tumors that are hormonally active have a yellow coloration to their cut surfaces, due to intracellular lipids.

Granulosa cell tumors are of clinical importance for two reasons: (1) they may elaborate large amounts of estrogen, and (2) they may behave like low-grade malignancies. Functionally active tumors in prepubertal girls (juvenile granulosa cell tumors) may produce precocious sexual development. In adult women they may be associated with proliferative breast disease, endometrial hyperplasia, and endometrial carcinoma, which eventually develops in about 10% to 15% of women with steroid-producing tumors. Occasionally, granulosa cell tumors produce androgens, masculinizing the patient.

All granulosa cell tumors are potentially malignant. It is difficult to predict their biologic behavior from histology. The likelihood of malignant behavior (recurrence, extension) ranges from 5% to 25%. In general, malignant tumors pursue an indolent course in which local recurrences may be amenable to surgical therapy. Recurrences within the pelvis and abdomen may appear 10 to 20 years after removal of the original tumor. The 10-year survival rate is approximately 85%. Tumors composed predominantly of theca cells are almost never malignant.

Elevated tissue and serum levels of *inhibin*, a product of granulosa cells, are associated with granulosa cell tumors. This biomarker may be useful for identifying granulosa and other sex cord-stromal tumors, and for monitoring patients being treated for these neoplasms (Fig. 22-43B). Recent studies reported mutations of the *FOXL2* gene in 97% of adult granulosa cell tumors. Although details remain to be worked out, *FOXL2* encodes a transcription

Figure 22-44 Ovarian fibromas **A**, Thecoma-fibroma composed of plump, differentiated stromal cells with thecal appearance. **B**, Large bisected fibroma of the ovary apparent as a white, firm mass (right). The fallopian tube is attached.

factor that is important in granulosa cell development, which presumably explains its strong association with this tumor type. Interestingly, mutations in *FOXL2*, in one small study, were uncommon in juvenile granulosa tumor, suggesting that it is genetically distinct from the adult type.

Fibromas, Thecomas, and Fibrothecomas

Tumors arising in the ovarian stroma that are composed of either fibroblasts (fibromas) or plump spindle cells with lipid droplets (thecomas) are relatively common and account for about 4% of all ovarian tumors (Fig. 22-44A). Many tumors contain a mixture of these cells and are termed *fibrothecomas*. Pure thecomas are rare, but tumors in which these cells predominate may be hormonally active. By contrast, fibromas as a rule are hormonally inactive.

Fibromas of the ovary are unilateral in about 90% of cases and are usually solid, spherical or slightly lobulated, encapsulated, hard, gray-white masses covered by glistening, intact ovarian serosa (Fig. 22-44B). On histologic examination, they are composed of well-differentiated fibroblasts and a scant interspersed collagenous stroma. Focal areas of thecal differentiation may be identified.

Most of these tumors come to attention as a pelvic mass, sometimes accompanied by pain and two decidedly curious associations. The first is ascites, found in about 40% of cases in which the tumors measure more than 6 cm in diameter. Uncommonly there is also a hydrothorax, usually only on the right side. This combination of findings (ovarian tumor, hydrothorax, and ascites) is designated *Meigs syndrome*. Its genesis is unknown. The second association is with the basal cell nevus syndrome, described in Chapter 25. The vast majority of fibromas, fibrothecomas, and thecomas are benign. Rarely, cellular fibromas with mitotic activity and increased nuclear-to-cytoplasmic ratio are identified; because they may pursue a malignant course, they are termed *fibrosarcomas*.

Sertoli-Leydig Cell Tumors

These tumors are often functional and commonly produce masculinization or defeminization, but a few have estrogenic effects. The tumor cells recapitulate, to a certain extent, testicular sertoli or Leydig cells at various stages of development. They occur in women of all ages, although the peak incidence is in the second and third decades. In

over half of cases, the tumor cells have mutations in *DICER1*, a gene that you will recall encodes an endonuclease that is essential for proper processing of micro-RNAs (Chapter 1). The presence of *DICER1* mutations suggests the genesis of male-directed stromal cells may involve abnormalities of gene expression related to dysregulation of micro-RNAs.

MORPHOLOGY

These tumors are unilateral and may resemble granulosa cell tumors grossly. The cut surface is usually solid and varies from gray to golden brown in appearance (Fig. 22-45A). Microscopically, a range of differentiation is seen. Well-differentiated tumors show tubules composed of Sertoli cells or Leydig cells interspersed with stroma (Fig. 22-45B). The intermediate forms show only outlines of immature tubules and large eosinophilic Leydig cells. The poorly differentiated tumors have a sarcomatous pattern with a disorderly disposition of epithelial cell cords. Leydig cells may be absent. Heterologous elements, such as mucinous glands, bone, and cartilage, may be present in some tumors.

The incidence of recurrence or metastasis by Sertoli-Leydig cell tumors is less than 5%. These neoplasms may block normal female sexual development in children and may cause defeminization of women, manifested by atrophy of the breasts, amenorrhea, sterility, and loss of hair. The syndrome may progress to striking virilization (hirsutism) associated with male distribution of hair, hypertrophy of the clitoris, and voice changes.

Other Sex Cord-Stromal Tumors

There are several other uncommon but distinctive ovarian tumors of sex cord or stromal origin that often produce steroid hormones.

- *Hilus cell tumors (pure Leydig cell tumors)* are usually derived from clusters of polygonal cells arranged around hilar vessels. These rare, unilateral tumors are comprised of large lipid-laden Leydig cells with distinct borders and characteristic cytoplasmic structures called Reinke crystalloids. Women with hilus cell tumors usually present with evidence of masculinization in the form of

Figure 22-45 Sertoli cell tumor. **A**, Gross photograph illustrating characteristic golden-yellow appearance of the tumor. **B**, Photomicrograph showing well-differentiated Sertoli cell tubules. (Courtesy Dr. William Welch, Brigham and Women's Hospital, Boston, Mass.)

hirsutism, voice changes, and clitoral enlargement, but these changes are milder than those seen in association with Sertoli-Leydig cell tumors. The tumors produce predominantly testosterone. Treatment is surgical excision. True hilus cell tumors are almost always benign.

- *Pregnancy luteoma* refers to a rare tumor that closely resembles the corpus luteum of pregnancy. These tumors may produce virilization in pregnant patients and their female infants.
- *Gonadoblastoma* is an uncommon tumor composed of germ cells and sex cord-stroma derivatives resembling immature Sertoli and granulosa cells. It occurs in individuals with abnormal sexual development and in gonads of indeterminate nature. Eighty percent of patients are phenotypic females, and 20% are phenotypic males with undescended testicles and female internal secondary organs. A coexistent dysgerminoma occurs in 50% of the cases. The prognosis is excellent if the tumor is completely excised.

KEY CONCEPTS

Sex Cord-Stromal Tumors

- Granulosa cells tumors are the most common malignant tumor in this category. They are indolent tumors, but can

recur 10 to 20 years after resection of the primary tumor. They are often hormonally active and are associated with endometrial hyperplasia/cancer.

- Fibromas are relatively common benign tumors composed of fibroblasts. They are predominantly unilateral and are generally hormonally inactive.
- Pure thecomas are rare but may be hormonally active.
- Sertoli-Leydig cell tumors commonly present with masculinization and less than 5% recur or metastasize.

Metastatic Tumors

The most common metastatic tumors of the ovary are derived from tumors of müllerian origin: the uterus, fallopian tube, contralateral ovary, or pelvic peritoneum. The most common extra-müllerian tumors metastatic to the ovary are carcinomas of the breast and gastrointestinal tract, including colon, stomach, biliary tract, and pancreas. Also included in this group are the rare cases of pseudomyxoma peritonei, derived from appendiceal tumors. A classic metastatic gastrointestinal carcinoma involving the ovaries is termed *Krukenberg tumor*, characterized by bilateral metastases composed of mucin-producing, signet-ring cancer cells, most often of gastric origin.

GESTATIONAL AND PLACENTAL DISORDERS

Diseases of pregnancy and pathologic conditions of the placenta are important causes of fetal intrauterine or perinatal death, congenital malformations, intrauterine growth retardation, maternal death, and morbidity for both mother and child. Only those disorders for which recognition of morphologic features contribute to an understanding of the clinical problem are discussed here. These include selected disorders of early pregnancy, late pregnancy, and trophoblastic neoplasia.

Understanding placental disorders requires a working knowledge of normal placental anatomy. The placenta is

composed of chorionic villi (Fig. 22-46A, B) that sprout from the chorion to provide a large contact area between the fetal and maternal circulations. In the mature placenta, the maternal blood enters the intervillous space through endometrial arteries (spiral arteries) and circulates around the villi to allow gas and nutrient exchange (Fig. 22-47). The deoxygenated blood flows back from the intervillous space to the decidua and enters the endometrial veins. Deoxygenated fetal blood enters the placenta through two umbilical arteries that branch radially to form chorionic arteries. Chorionic arteries branch further as they enter the

Figure 22-46 Normal placenta. **A**, First-trimester chorionic villi composed of delicate mesh of central stroma surrounded by two discrete layers of epithelium—the outer layer consisting of syncytiotrophoblast (*two arrows*) and the inner layer consisting of cytotrophoblast (*arrow*). **B**, Third-trimester chorionic villi composed of stroma with dense network of dilated capillaries surrounded by markedly thinned-out syncytiotrophoblast and cytotrophoblast (same magnification as **A**.)

villi. In the chorionic villi they form an extensive capillary system, bringing fetal blood in close proximity to maternal blood. The gas and nutrient diffusion occurs through the villous capillary endothelial cells and thinned-out syncytiotrophoblast and cytotrophoblast. Under normal circumstances there little or no mixing between the fetal and maternal blood, though sufficient free fetal DNA reaches the maternal circulation to permit prenatal genetic testing ([Chapter 5](#)). Blood oxygenated in the placenta returns to the fetus through the single umbilical vein.

Disorders of Early Pregnancy

Spontaneous Abortion

Spontaneous abortion, or “miscarriage,” is defined as pregnancy loss before 20 weeks of gestation. Most of these occur before 12 weeks. Ten to fifteen percent of clinically recognized pregnancies terminate in spontaneous abortion. However, using sensitive chorionic gonadotropin

Figure 22-47 Diagram of placental anatomy. Within the outer boundary of myometrium is a layer of decidua, from which the maternal vessels originate and deliver blood to and from the intervillous spaces. Umbilical vessels branch and terminate in placental villi, where nutrient exchange takes place.

assays, it has been determined that an additional 20% of early pregnancies in otherwise healthy women terminate spontaneously, many without notice. In most individual instances, the mechanisms leading to early loss of pregnancy are unknown. However, multiple fetal and maternal causes of spontaneous abortion have been identified. Among the most important are the following:

- *Fetal chromosomal anomalies*, such as aneuploidy, polyploidy, and translocations, are present in approximately 50% of early abortuses. More subtle genetic defects, for which routine genetic testing is not readily available, account for an additional fraction of abortions.
- *Maternal endocrine factors*, including luteal-phase defect, poorly controlled diabetes, and other uncorrected endocrine disorders
- *Physical defects of the uterus*, such as submucosal leiomyomas, uterine polyps, or uterine malformations, may prevent or disrupt implantation
- *Systemic disorders affecting the maternal vasculature*, such as antiphospholipid antibody syndrome, coagulopathies, and hypertension
- *Infections* with protozoa (*Toxoplasma*), bacteria (*Mycoplasma*, *Listeria*), or a number of viruses. Ascending infection is particularly common in second-trimester losses.

Ectopic Pregnancy

Ectopic pregnancy refers to implantation of the fetus in a site other than the normal intrauterine location; the most common site is the extrauterine fallopian tube (approximately 90% of cases). Other sites include the ovary, the abdominal cavity, and the intrauterine portion of the fallopian tube (cornual pregnancy). Ectopic pregnancies account for 2% of confirmed pregnancies. The most important predisposing condition, present in 35% to 50% of patients, is prior *pelvic inflammatory disease* resulting in intraluminal fallopian tube scarring (chronic salpingitis). The risk of ectopic pregnancy is also increased with peritubal scarring and adhesions, which may be caused by appendicitis, endometriosis, and previous surgery. In some cases, however, the fallopian tubes are apparently normal. Use of an intrauterine contraceptive device is associated with twofold increase of ectopic pregnancy.

Ovarian pregnancy results from the fertilization and trapping of the ovum within the follicle just at the time of its rupture. Abdominal pregnancies occur when the fertilized ovum fails to enter or drops out of the fimbriated end of the tube. In each abnormal location, the fertilized ovum develops as usual, forming placental tissue, amniotic sac, and fetus. The host implantation site may also develop decidual changes.

MORPHOLOGY

Tubal pregnancy is the most common cause of hematosalpinx (blood-filled fallopian tube) and should always be suspected when a tubal hematoma is present. Initially the embryonal sac, surrounded by immature chorionic villi, implants within the lumen of the fallopian tube. Trophoblastic cells and

chorionic villi then invade the wall of the fallopian tube as they would do in the uterus during normal pregnancy. **With time the growth of the gestational sac distends the fallopian tube, causing thinning of the wall and rupture. The rupture frequently results in massive intraperitoneal hemorrhage, which sometimes is fatal.** Less commonly the tubal pregnancy may undergo spontaneous regression and resorption, or be extruded through the fimbriated end of the tube into the abdominal cavity (tubal abortion).

Clinical Features. Rupture of a tubal pregnancy is a medical emergency. The clinical course of ectopic tubal pregnancy is characterized by the onset of moderate to severe abdominal pain and vaginal bleeding 6 to 8 weeks after last menstrual period, correlating with distention and then rupture of the fallopian tube. In such cases the patient may rapidly develop *hemorrhagic shock* with signs of an acute abdomen, and therefore early diagnosis is critical. Diagnosis is based on determination of chorionic gonadotropin titers, pelvic sonography, endometrial biopsy (which shows decidua without chorionic villi or implantation site) and/or laparoscopy. Despite advances in early diagnosis, ectopic pregnancy still accounts for 4% to 10% of pregnancy-related deaths.

Disorders of Late Pregnancy

Disorders that occur in the third trimester of pregnancy are related to the complex anatomy of the maturing placenta. Complete interruption of blood flow through the umbilical cord from any cause (e.g., constricting knots or compression) can be lethal to the fetus. Ascending infections involving the chorioamniotic membranes may lead to premature rupture of amniotic membranes and delivery. Retroplacental hemorrhage at the interface of placenta and myometrium (*abruptio placentae*) threatens both mother and fetus. Disruption of the fetal vessels in terminal villi may produce a significant loss of fetal blood with resultant fetal injury or death. Uteroplacental malperfusion can be precipitated by abnormal placental implantation or development, or maternal vascular disease; the effects may range from mild intrauterine growth retardation to severe uteroplacental ischemia, and maternal preeclampsia.

Twin Placentas

Twin pregnancies arise from fertilization of two ova (dizygotic) or from division of one fertilized ovum (monozygotic). There are three basic types of twin placentas (Fig. 22-48): diamniotic dichorionic (which may be fused), diamniotic monochorionic, and monoamniotic monochorionic. Monochorionic placentas imply monozygotic (identical) twins, and the time at which splitting of the developing embryo occurs determines whether one or two amnions are present. Dichorionic placentation may occur with either monozygotic or dizygotic twins and is not specific.

One complication of monochorionic twin pregnancy is *twin-twin transfusion syndrome*. Monochorionic twin placentas have vascular anastomoses that connect the

Figure 22-48 Diagrammatic representation of the various types of twin placentation and their membrane relationships. (Adapted from Gersell D, et al: Diseases of the placenta. In Kurman R (ed): Blaustein's Pathology of the Female Genital Tract. New York, Springer-Verlag, 1994.)

circulations of the twins, and in some cases these connections include one or more arteriovenous shunts. If these shunts preferentially increase blood flow to one twin at the expense of the second, one twin will be underperfused, while the second will be fluid overloaded. It is this phenomenon that constitutes the twin-twin transfusion syndrome, which if severe may result in the death of one or both fetuses.

Abnormalities of Placental Implantation

Several types of abnormal placental implantations are associated with significant complications. *Placenta previa* is a condition in which the placenta implants in the lower uterine segment or cervix, often leading to serious third-trimester bleeding. A complete placenta previa covers the internal cervical os and thus requires delivery via cesarean

section to avert placental rupture and fatal maternal hemorrhage during vaginal delivery. *Placenta accreta* is caused by partial or complete absence of the decidua, such that the placental villous tissue adheres directly to the myometrium, which leads to a failure of placental separation at birth. It is an important cause of severe, potentially life-threatening postpartum bleeding. Common predisposing factors are placenta previa (in up to 60% of cases) and history of previous cesarean section.

Placental Infections

Infections in the placenta develop by two pathways: (1) ascending infection through the birth canal and (2) hematogenous (transplacental) infection. Ascending infections are by far the most common and are virtually always bacterial; in many such instances, localized infection of the membranes produces premature rupture of membranes and preterm delivery. The amniotic fluid may be cloudy with purulent exudate, and histologically the chorion-amnion contains an infiltrate of neutrophils accompanied by edema and congestion of the vessels (Fig. 22-49A, B). The infection frequently elicits a fetal response consisting of a "vasculitis" of the umbilical and fetal chorionic plate vessels. Uncommonly, bacterial infections may result from hematogenous spread to the placenta, leading to acute villitis (Fig. 22-49C).

Several hematogenous infections, classically components of the TORCH group (*toxoplasmosis* and others [syphilis, tuberculosis, listeriosis], rubella, cytomegalovirus, herpes simplex), can affect the placenta. They give rise to chronic inflammatory cell infiltrates in the chorionic villi (chronic villitis) and are described in Chapter 10.

Preeclampsia and Eclampsia

Preeclampsia is a systemic syndrome characterized by widespread maternal endothelial dysfunction that presents during pregnancy with hypertension, edema, and

Figure 22-49 Placental infections derived from ascending and blood-borne routes. Acute chorioamnionitis. **A**, On gross examination the placenta contains greenish opaque membranes. **B**, A photomicrograph illustrates a dense bandlike inflammatory exudate on the amniotic surface (arrow). **C**, Acute necrotizing intervillitis, from a fetal-maternal infection by *Listeria*.

proteinuria. It occurs in about 3% to 5% of pregnant women, usually in the last trimester and more commonly in primiparas (women pregnant for the first time). Some of these women become more seriously ill, developing convulsions; this more severe form of the disorder is termed *eclampsia*. Other complications stemming from systemic endothelial dysfunction include hypercoagulability, acute renal failure, and pulmonary edema. Approximately 10% of women with severe preeclampsia develop microangiopathic hemolytic anemia, elevated liver enzymes, and low platelets, referred to as the HELLP syndrome (Chapter 17). Preeclampsia should be distinguished from gestational hypertension that can develop in pregnancy without proteinuria.

Pathogenesis. While the exact mechanisms leading to development of preeclampsia are still being investigated, it is clear that the placenta plays a central role in the pathogenesis of the syndrome, since the symptoms disappear rapidly after delivery of the placenta. The critical abnormalities in preeclampsia are diffuse endothelial dysfunction, vasoconstriction (leading to hypertension), and increased vascular permeability (resulting in proteinuria and edema). Recent work has demonstrated that these effects are most likely mediated by placenta-derived factor(s) released into the maternal circulation. Although the release of these factors and the clinical syndrome develop late in gestation, the pathogenesis of the disease appears to be closely tied to the earliest events of pregnancy and placentation. The principal pathophysiologic aberrations appear to be the following:

- **Abnormal placental vasculature.** The precipitating events in the pathogenesis of preeclampsia are abnormal trophoblastic implantation and a failure of physiologic remodeling of the maternal vessels, which is required for adequate perfusion of the placental bed. In normal pregnancy, fetal extravillous trophoblastic cells (trophoblastic cells not associated with chorionic villi) at the implantation site invade the maternal decidua and decidual vessels, destroy the vascular smooth muscle, and replace the maternal endothelial cells with fetal trophoblastic cells (forming hybrid fetomaternal blood vessels). This process converts the decidual spiral arteries from small-caliber resistance vessels to large capacity uteroplacental vessels lacking a smooth muscle coat (Fig. 22-50). In preeclampsia, this remodeling fails to occur, leaving the placenta ill equipped to meet the increased circulatory demands of late gestation and setting the stage for the development of placental ischemia.
- **Endothelial dysfunction and imbalance of angiogenic and antiangiogenic factors.** Although not formally proven, it is postulated that in response to hypoxia, the ischemic placenta releases factors into the maternal circulation that cause an imbalance in circulating angiogenic and anti-angiogenic factors; this in turn leads to systemic maternal endothelial dysfunction and the clinical symptoms of the disease. In support of this, the blood levels of two placenta-derived antiangiogenic factors, soluble FMS-like tyrosine kinase (sFlt1) and endoglin, which antagonize the effects of VEGF and TGF β , respectively, are several orders of magnitude higher in women

Figure 22-50 The physiologic alterations in the uterine spiral arteries and the failure of their remodeling in preeclampsia. (Modified from Maynard S, et al: Preeclampsia and angiogenic imbalance. *Ann Rev Med* 59:61, 2008.)

with preeclampsia than in healthy controls. In preeclampsia, high levels of sFlt1 and soluble endoglin bring about a decrease in angiogenesis much earlier than in normal pregnancy. The result is defective vascular development in the placenta. Furthermore, TGF β induces endothelial production of NO, a potent vasodilator; thus, inhibition of TGF β by endoglin may directly contribute to systemic vasoconstriction, hypertension, and tissue hypoperfusion.

Studies in animal models also implicate sFlt1 and soluble endoglin in the pathogenesis of endothelial dysfunction. When sFlt1 and endoglin are overexpressed together, rats develop nephrotic-range proteinuria, severe hypertension, and fetal growth restriction, the hallmarks of severe preeclampsia, as well as features of the HELLP syndrome, including elevated liver enzymes, decreased platelet counts, and hemolysis. Thus, it seems that sFlt1 and soluble endoglin are key mediators that link the placenta to the characteristic maternal endothelial dysfunction of preeclampsia.

- **Coagulation abnormalities.** Preeclampsia is associated with a hypercoagulable state that may lead to the

formation of thrombi in arterioles and capillaries throughout the body, but particularly in the liver, kidneys, brain, and pituitary. Hypercoagulability is likely related to the reduced endothelial production of PGI₂, a potent antithrombotic factor, and increased release of procoagulant factors. Production of PGI₂ is stimulated by VEGF, and women with preeclampsia have decreased endothelial production of PGI₂, presumably due to antagonism of VEGF by sFlt1.

MORPHOLOGY

The **placenta** reveals various microscopic changes, most of which reflect malperfusion, ischemia, and vascular injury. These include (1) **infarcts**, which are larger and more numerous than those that may be seen in normal full-term placentas, (2) **exaggerated ischemic changes** in the chorionic villi and trophoblast, consisting of increased syncytial knots, (3) frequent **retroplacental hematomas** due to bleeding and instability of uteroplacental vessels, and (4) **abnormal decidual vessels**, which may show thrombi, lack of normal physiologic conversion (described earlier), fibrinoid necrosis, or intraintimal lipid deposition (acute atherosclerosis) (Fig. 22-51).

The **liver** lesions, when present, take the form of irregular, focal, subcapsular, and intraparenchymal hemorrhages. On histologic examination there are fibrin thrombi in the portal capillaries and foci of hemorrhagic necrosis.

The **kidney** lesions are variable. The glomeruli show marked swelling of endothelial cells, amorphous dense deposits on the endothelial side of the basement membrane, and mesangial cell hyperplasia. Immunofluorescent studies show an abundance of fibrin in glomeruli. In advanced cases, fibrin thrombi are present in the glomeruli and capillaries of the cortex. If widespread and severe, these thrombi may produce complete destruction of the cortex in the pattern referred to as bilateral renal cortical necrosis (Chapter 20). The **brain** may have gross or microscopic foci of hemorrhage along with small-vessel thromboses. Similar changes are often found in the **heart** and the **anterior pituitary**.

Figure 22-51 Acute atherosclerosis of uterine vessels in eclampsia. Note fibrinoid necrosis of the vessel walls, subendothelial macrophages, and perivascular lymphocytic infiltrate. (Courtesy Dr. Drucilla J. Roberts, Massachusetts General Hospital, Boston, Mass.)

Clinical Features. Preeclampsia most commonly starts after 34 weeks of gestation but begins earlier in women with hydatidiform mole (discussed later) or preexisting kidney disease, hypertension, or coagulopathies. The onset is typically insidious, characterized by hypertension and edema, with proteinuria following within several days. Headaches and visual disturbances are serious events and are indicative of severe preeclampsia, often requiring delivery. Eclampsia is heralded by central nervous system involvement, including convulsions and eventual coma.

Management of preeclampsia differs depending on the gestational age and severity of disease. For term pregnancies, delivery is the treatment of choice regardless of disease severity. In preterm pregnancies, where delivery may not be in the best interest of the fetus, patients with mild disease can be managed expectantly by closely monitoring the mother and fetus. However, eclampsia, severe preeclampsia with maternal end-organ dysfunction, fetal compromise, or the HELLP syndrome are indications for delivery regardless of gestational age. Antihypertensive therapy does not affect the disease course or improve outcomes. Proteinuria and hypertension usually disappear within 1 to 2 weeks after delivery except when they predate the pregnancy. Although in most instances preeclampsia has no lasting sequelae, recent studies indicate that about 20% of affected women develop hypertension and microalbuminuria within 7 years of a pregnancy complicated by preeclampsia. There is also a twofold increase in the long-term risk of vascular diseases of the heart and the brain.

Gestational Trophoblastic Disease

Gestational trophoblastic disease encompasses a spectrum of tumors and tumor-like conditions characterized by proliferation of placental tissue, either villous or trophoblastic. The major disorders of this type are hydatidiform mole (complete and partial), invasive mole, choriocarcinoma, and placental site trophoblastic tumor (PSTT).

Hydatidiform Mole

Hydatidiform moles are important to recognize because they are associated with an increased risk of persistent trophoblastic disease (invasive mole) or choriocarcinoma. Moles are characterized histologically by cystic swelling of the chorionic villi, accompanied by variable trophoblastic proliferation. They are usually diagnosed during early pregnancy (average 9 weeks) by pelvic sonogram. Molar pregnancy can develop at any age, but the risk is higher at the two ends of reproductive life, in teenagers and between the ages of 40 and 50 years. For poorly explained reasons, the incidence varies considerably in different parts of the world. Hydatidiform mole occurs about once in every 1000 to 2000 pregnancies in the United States, but it is twice as common in Southeast Asia. Two types of benign, noninvasive moles—complete and partial—can be identified by cytogenetic and histologic studies.

Complete Mole

Complete mole results from fertilization of an egg that has lost its female chromosomes, and as a result the genetic material is completely paternally derived (Fig. 22-52A, B).

Figure 22-52 Origin of complete and partial hydatidiform moles. **A**, Complete moles most commonly arise from fertilization of an empty ovum by a single sperm that undergoes duplication of its chromosomes. **B**, Less commonly, complete moles arise from dispermy in which two sperm fertilize an empty ovum. **C**, Partial moles arise from two sperm fertilizing a single ovum.

Ninety percent have a 46,XX karyotype stemming from the duplication of the genetic material of one sperm (a phenomenon called androgenesis). The remaining 10% result from the fertilization of an empty egg by two sperm; these may have 46,XX or 46,XY karyotype. In complete moles the embryo dies very early in development and therefore is usually not identified. Patients have 2.5% risk of subsequent choriocarcinoma and 15% risk of persistent or invasive mole.

Partial Mole

Partial moles result from fertilization of an egg with two sperm (Fig. 22-52C). In these moles the karyotype is triploid (e.g., 69,XXY) or occasionally tetraploid (92,XXXXY). Fetal tissues are typically present. Partial moles have an increased risk of persistent molar disease, but are not associated with choriocarcinoma.

MORPHOLOGY

The classic appearance of hydatidiform moles is that of a delicate, friable mass of thin-walled, translucent, cystic, grapelike structures consisting of swollen edematous (hydropic) villi (Figs. 22-53 and 22-54). In complete mole, the microscopic abnormalities involve all or most of the villous tissue. The chorionic villi are enlarged, scalloped in shape with central cavitation (cisterns), and are covered by extensive trophoblast proliferation

Figure 22-53 Complete hydatidiform mole. Note marked distention of the uterus by vesicular chorionic villi. Adnexa (ovaries and fallopian tubes) are visible on the left and right side of the uterus.

that involves the entire circumference of the villi. In contrast, in partial moles, only a fraction of the villi are enlarged and edematous. The trophoblastic hyperplasia is focal and less marked than in complete moles.

Clinical Features. Most women with partial and early complete moles present with spontaneous miscarriage or undergo curettage because of ultrasound findings of abnormal villous enlargement. In complete moles, human chorionic gonadotropin (HCG) levels greatly exceed those of a normal pregnancy of similar gestational age. In addition, the rate at which HCG levels rise over time in molar pregnancies exceeds those seen with normal single or even multiple pregnancies. Most moles are successfully removed by curettage. The patients are subsequently monitored for 6 months to a year to ensure that HCG levels decrease to non-pregnant levels. Continuous elevation of HCG may be indicative of *persistent or invasive mole*, which develops in up to 15% of molar pregnancies and is seen more frequently with complete moles. In addition, 2.5% of complete moles give rise to gestational choriocarcinoma.

Figure 22-54 Complete hydatidiform mole demonstrating marked villous enlargement, edema, and circumferential trophoblast proliferation.

Invasive Mole

Invasive mole is defined as a mole that penetrates or even perforates the uterine wall. There is invasion of the myometrium by hydropic chorionic villi, accompanied by proliferation of both cytotrophoblasts and syncytiotrophoblasts. The tumor is locally destructive and may invade parametrial tissue and blood vessels. Hydropic villi may embolize to distant sites, such as lungs and brain, but do not grow in these organs as true metastases, and even without chemotherapy they eventually regress. The tumor is manifested clinically by vaginal bleeding and irregular uterine enlargement. It is always associated with a persistently elevated serum HCG. The tumor responds well to chemotherapy but may result in uterine rupture and necessitate hysterectomy.

Choriocarcinoma

Gestational choriocarcinoma is a malignant neoplasm of trophoblastic cells derived from a previously normal or abnormal pregnancy, such as an extrauterine ectopic pregnancy. Choriocarcinoma is rapidly invasive and metastasizes widely, but once identified responds well to chemotherapy.

Incidence. Gestational choriocarcinoma is an uncommon condition that arises in 1 in 20,000 to 30,000 pregnancies in the United States. It may be preceded by several conditions; 50% arise in complete hydatidiform moles, 25% in previous abortions, approximately 22% follow normal pregnancies, with the remainder occurring in ectopic pregnancies. Very rarely, a nongestational choriocarcinoma may develop from germ cells in the ovaries or the mediastinum.

MORPHOLOGY

Choriocarcinoma is a soft, fleshy, yellow-white tumor that usually has large pale areas of necrosis and extensive hemorrhage (Fig. 22-55A). Histologically, it does not produce chorionic villi and consists entirely of proliferating syncytiotrophoblasts

and cytotrophoblasts (Fig. 22-55B). Mitoses are abundant and sometimes abnormal. The tumor invades the underlying myometrium, frequently penetrates blood vessels, and in some cases extends out onto the uterine serosa and into adjacent structures.

Clinical Features. Uterine choriocarcinoma usually manifests as irregular vaginal spotting of a bloody, brown fluid. This discharge may appear in the course of an apparently normal pregnancy, after a miscarriage, or after curettage. Sometimes the tumor does not appear until months after these events. This tumor has high propensity for hematogenous spread, and by the time it is discovered, radiographs of the chest and bones may disclose the presence of metastatic lesions. The HCG levels are typically elevated to levels above those encountered in hydatidiform moles, but occasional tumors produce little hormone, and some tumors are so necrotic that HCG levels are low. Widespread metastases are characteristic; the most common sites are the lungs (50%) and vagina (30% to 40%), followed by, in descending order of frequency, the brain, liver, bone and kidney.

The treatment of gestational choriocarcinoma depends on the stage of the tumor and usually consists of evacuation of the contents of the uterus and chemotherapy. The results of chemotherapy are spectacular and result in nearly 100% remission and a high rate of cures. Many of the cured patients have had normal subsequent pregnancies and deliveries. By contrast, nongestational choriocarcinomas that arise outside of the uterus are much more resistant to therapy.

Placental Site Trophoblastic Tumor (PSTT)

PSTTs comprise less than 2% of gestational trophoblastic neoplasms. They are neoplastic proliferations of extravillous trophoblasts, also called *intermediate trophoblasts*. In normal pregnancy, extravillous (intermediate) trophoblasts are found in nonvillous sites such as the implantation site, in islands of cells within the placental parenchyma, and in the placental membranes. Normal extravillous

trophoblasts are polygonal mononuclear cells that have abundant cytoplasm and produce human placental lactogen. PSTT presents as a uterine mass, accompanied by either abnormal uterine bleeding or amenorrhea and moderately elevated HCG. Histologically, PSTT is composed of malignant trophoblastic cells diffusely infiltrating the endomyometrium. It may follow a normal pregnancy (half of the cases), spontaneous abortion, or hydatidiform mole. Patients with localized disease have an excellent prognosis, however about 10% to 15% of women die of disseminated disease.

Three important features distinguish the breast from other organs. First, the major function is the nutritional support of another individual, the infant. Second, the structure of the organ undergoes marked periodic changes during adulthood, particularly during pregnancy, before involuting with age. Finally, breasts are visible and, as a result, have a social, cultural, and personal significance not shared by other organs. All of these features play a role when considering the origins, presentations, and treatment of breast disease.

Understanding diseases of the breast requires a working knowledge of its normal anatomy and cellular constituents, which include two major structures (ducts and lobules), two types of epithelial cells (luminal and myoepithelial), and two types of stroma (interlobular and intralobular). Each element is the source of both benign and malignant lesions (Fig. 23-1). Six to 10 major duct orifices open onto the skin surface at the nipple. The superficial portions are lined by keratinizing squamous cells that abruptly change to the double-layered epithelium (luminal and myoepithelial cells) of the remainder of the duct/lobular system. Successive branching of the large ducts eventually leads to the terminal duct lobular unit. In adult

women, the terminal duct branches into a grapelike cluster of small acini to form a lobule (Figs. 23-1 and 23-2B). In some women, ducts extend into the subcutaneous tissue of the chest wall and into the axilla.

In the prepubertal female breast and in males, the large duct system ends in terminal ducts. Changes in the breast are most dynamic and profound during the reproductive years of females (Fig. 23-2). Just as the endometrium grows and ebbs with each menstrual cycle, so does the breast. In the first half of the menstrual cycle the lobules are relatively quiescent. After ovulation, under the influence of estrogen and rising progesterone levels, cell proliferation increases, as does the number of acini per lobule. The intralobular stroma becomes markedly edematous. Upon menstruation, the fall in hormone levels induces the regression of the lobules and the disappearance of edema.

Only with the onset of pregnancy does the breast become completely mature and functional. Lobules increase progressively in number and size. By the end of the pregnancy the breast is composed almost entirely of lobules separated by relatively scant stroma (Fig. 23-2C). Immediately after parturition, the lobules produce

Figure 23-1 Anatomic origins of common breast lesions.

colostrum (high in protein), changing to milk (higher in fat and calories) over the next 10 days as progesterone levels drop. The permanent changes produced by pregnancy may explain the reduction in breast cancer risk that is observed in women who give birth to children at young ages. Upon the cessation of lactation, epithelial cells undergo apoptosis and lobules regress. However, full regression does not occur, and as a result pregnancy causes a permanent increase in the size and number of lobules.

After the third decade, long before menopause, lobules and their specialized stroma start to involute (**Fig. 23-2D**) and the interlobular stroma converts from radiodense fibrous stroma (**Fig. 23-2A**) to radiolucent adipose tissue (**Fig. 23-2E**). To some extent, these changes are obscured by either endogenous sources of hormones (e.g., estrogen

from fat stores in obese women) or exogenous sources (e.g., menopausal hormone replacement therapy).

Disorders of Development

Milk Line Remnants

Supernumerary nipples or breasts result from the persistence of epidermal thickenings along the milk line, which extends from the axilla to the perineum. The disorders that affect the normally situated breast rarely arise in these heterotopic, hormone-responsive foci, which most commonly come to attention as a result of painful premenstrual enlargements.

Figure 23-2 Life cycle changes. **A**, Mammograms in young women are typically radiodense or white in appearance, making mass-forming lesions or calcifications (which are also radiodense) difficult to detect. **B**, The density of a young woman's breast stems from the predominance of fibrous interlobular stroma and the paucity of adipose tissue. Before pregnancy the lobules are small and are invested by loose cellular intralobular stroma. **C**, During pregnancy, branching of terminal ducts produces more numerous, larger lobules. Luminal cells within lobules undergo lactational change, a precursor to milk formation. **D**, With increasing age the lobules decrease in size and number, and the interlobular stroma is replaced by adipose tissue. **E**, Mammograms become more radiolucent with age as a result of the increase in adipose tissue, which facilitates the detection of radiodense mass-forming lesions and calcifications. (**A**, **E**, Courtesy of Dr. Darrell Smith, Brigham and Women's Hospital, Boston, MA.)

Accessory Axillary Breast Tissue

In some women the normal ductal system extends into the subcutaneous tissue of the chest wall or the axillary fossa (the “axillary tail of Spence”), outside of the area clinically identified as breast tissue. Because breast tissue may not be removed in these areas, prophylactic mastectomies markedly reduce, but do not completely eliminate, the risk of breast cancer.

Congenital Nipple Inversion

The failure of the nipple to evert during development is common and may be unilateral. Congenitally inverted nipples are usually of little significance since they correct spontaneously during pregnancy, or can sometimes be everted by simple traction. Acquired nipple retraction is of more concern, since it may indicate the presence of an invasive cancer or an inflammatory nipple disease.

Clinical Presentations of Breast Disease

The most common symptoms reported by women with disorders of the breast are pain, a palpable mass, “lumpiness” (without a discrete mass), or nipple discharge (Fig. 23-3A). All are nonspecific but must be evaluated because of the possibility of malignancy.

- *Pain* (mastalgia or mastodynia) is a common symptom that may be cyclic with menses or noncyclic. Diffuse cyclic pain may be due to premenstrual edema. Noncyclic pain is usually localized to one area of the breast and may be caused by ruptured cysts, physical injury, and infections, but often no specific lesion is identified. Although almost all painful masses are benign, about 10% of breast cancers present with pain.
- *Palpable masses* are also common and must be distinguished from the normal nodularity (or “lumpiness”) of the breast. **The most common palpable lesions are cysts, fibroadenomas, and invasive carcinomas.** Benign

palpable masses are most common in premenopausal women and the likelihood of a malignancy increases with age. Only 10% of breast masses in women younger than age 40 are malignant as compared with 60% of masses in women older than age 50. Approximately 50% of carcinomas are located in the upper outer quadrant, 10% in each of the remaining quadrants, and about 20% in the central or subareolar region. Although about one third of cancers are first detected as a palpable mass, screening by breast examination has little effect on reducing breast cancer mortality. Unfortunately, the majority of cancers that have the capacity to metastasize will have done so by the time they reach a size that can be palpated—generally around 2 to 3 cm.

- *Nipple discharge* is a less common finding that is most worrisome for carcinoma when it is spontaneous and unilateral. A small discharge is often produced by the manipulation of normal breasts. Milky discharges (galactorrhea) are associated with elevated prolactin levels (e.g., by a pituitary adenoma), hypothyroidism, or endocrine anovulatory syndromes, and also occur in patients taking oral contraceptives, tricyclic antidepressants, methyldopa, or phenothiazines. Repeated nipple stimulation can also induce lactation. Galactorrhea is not associated with malignancy. Bloody or serous discharges are most commonly due to large duct papillomas and cysts. During pregnancy, a bloody discharge can result from the rapid growth and remodeling of the breast. The risk of malignancy in a woman with nipple discharge increases with age; it is associated with carcinoma in 7% of women younger than age 60 but in 30% of older women.

Mammographic screening was introduced in the 1980s as a means to detect small, nonpalpable, asymptomatic breast carcinomas and is currently the most common means to detect breast cancer (Fig 23-3B). The sensitivity and specificity of mammography increase with age, as a result of replacement of the fibrous, radiodense tissue of youth with the fatty, radiolucent tissue of older women (Fig. 23-2). At age 40, the probability that a mammographic

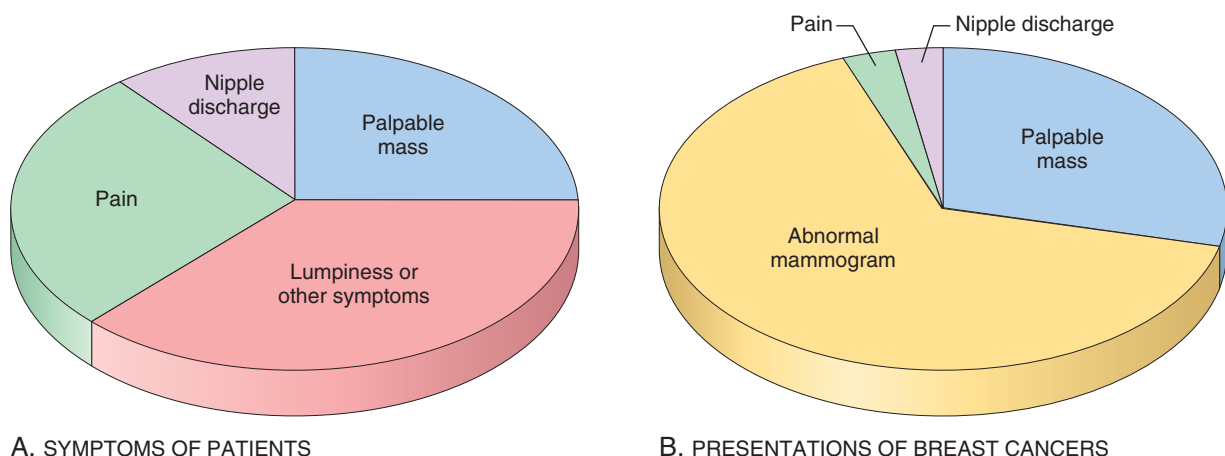

Figure 23-3 Symptoms of breast disease and presentations of breast cancer. **A**, Common symptoms of breast disease. Although pain, “lumpiness,” and nipple discharge often cause concern, these symptoms are associated with cancer in less than 10% of affected women. **B**, Presentations of breast cancer. In the United States, more than half of cancers are asymptomatic and are detected by mammographic screening and about another one third present as palpable masses—almost all discovered by the patient.

lesion is cancer is only 10%, but this rises to greater than 25% in women older than 50. **The principal mammographic signs of breast carcinoma are densities and calcifications:**

- **Densities.** Breast lesions that replace adipose tissue with radiodense tissue form mammographic densities. Rounded densities are most commonly benign lesions such as fibroadenomas or cysts (see Fig. 23-27), whereas invasive carcinomas generally form irregular masses (see Fig. 23-22). Mammography can identify small, nonpalpable cancers that are, on average, about half the size of invasive carcinomas detected by palpation (i.e., 1 cm rather than 2 to 3 cm).
- **Calcifications.** Calcifications form on secretions, necrotic debris, or hyalinized stroma. Calcifications are often associated with benign lesions such as clusters of apocrine cysts, hyalinized fibroadenomas, and sclerosing adenosis (see Fig. 23-6). Calcifications associated with malignancy are usually small, irregular, numerous, and clustered. Screening has increased the diagnosis of ductal carcinoma in situ (DCIS), since it is most commonly detected as mammographic calcifications (see Figs. 23-14 and 23-17).

Approximately 10% of invasive carcinomas are not detected by mammography. The principal causes are the presence of surrounding radiodense tissue obscuring the tumor (especially in younger women), small size, a diffuse infiltrative pattern with little or no desmoplastic response, or a location close to the chest wall or in the periphery of the breast. The inability to image a palpable mass does not indicate that it is benign, and all palpable masses require further investigation. Other imaging modalities can be useful adjuncts. For example, ultrasonography distinguishes between solid and cystic lesions and defines more precisely the borders of solid lesions, while magnetic resonance imaging (MRI) detects cancers by the rapid uptake of contrast agents due to increased tumor vascularity and blood flow.

Although the recent downward trend in deaths from breast cancer is partially attributed to earlier diagnosis due to mammography, the beneficial effect of screening has been smaller than originally anticipated for several reasons. Seventy percent to 80% of cancers detected by mammography are already invasive, and many of these have already metastasized. In addition, the cancers most likely to cause death are those least likely to be detected by mammography. These lethal cancers arise in young women of pre-screening age, or are rapidly growing cancers that present during the interval between mammograms. In turn, some cancers detected by mammography are clinically unimportant, as they have such indolent biologies that they would never have caused the patient any harm (a situation reminiscent of many prostate cancers in men, Chapter 21). Although the magnitude is debated, it is estimated that between 10% and 30% of invasive cancers detected by mammography fall into this category.

Inflammatory Disorders

Inflammatory diseases of the breast are rare (accounting for less than 1% of breast symptoms) and are caused

by infections, autoimmune disease, or by foreign body type reactions to extravasated keratin or secretions. “Inflammatory breast cancer” mimics inflammation by obstructing dermal vasculature with tumor emboli, and should always be considered in women with an erythematous swollen breast.

Acute Mastitis

Acute bacterial mastitis typically occurs during the first month of breastfeeding and is caused by a local bacterial infection when the breast is most vulnerable due to cracks and fissures in the nipples. From this portal of entry, *Staphylococcus aureus* or, less commonly, streptococci invade the breast tissue. The breast is erythematous and painful, and fever is often present. At the outset only one duct system or sector of the breast is involved. If not treated the infection may spread to the entire breast. Staphylococcal abscesses may be single or multiple whereas Streptococci cause spreading infection in the form of cellulitis.

Most cases of lactational mastitis are easily treated with appropriate antibiotics and continued expression of milk from the breast. Rarely, surgical drainage is required.

Squamous Metaplasia of Lactiferous Ducts

Squamous metaplasia of lactiferous ducts is known by a variety of names, including recurrent subareolar abscess, periductal mastitis, and Zuska disease. Women, and sometimes men, present with a painful erythematous subareolar mass that clinically appears to be a bacterial abscess. In recurrent cases, a characteristic fistula tract often tunnels under the smooth muscle of the nipple and opens onto the skin at the edge of the areola. Many women have an inverted nipple, most likely as a secondary effect of the underlying inflammation. More than 90% of the afflicted are smokers. It has been suggested that a relative deficiency of vitamin A associated with smoking or toxic substances in tobacco smoke alter the differentiation of the ductal epithelium.

MORPHOLOGY

The key feature is **keratinizing squamous metaplasia** of the nipple ducts (Fig. 23-4). Keratin shed from these cells plugs the ductal system, causing dilation and eventually rupture of the duct. An intense chronic granulomatous inflammatory response develops once keratin spills into the surrounding periductal tissue. With recurrences, a secondary anaerobic bacterial infection may supervene and cause acute inflammation.

Simple incision drains the abscess cavity, but the offending keratinizing epithelium remains and recurrences are common. In most cases, en bloc surgical removal of the involved duct and contiguous fistula tract is curative. If secondary bacterial infection is present, antibiotics also have a therapeutic role.

Duct Ectasia

Duct ectasia presents as a palpable periareolar mass that is often associated with thick, white nipple secretions and occasionally with skin retraction. Pain and erythema are

Figure 23-4 Squamous metaplasia of lactiferous ducts. When squamous metaplasia extends deep into a nipple duct, keratin becomes trapped and accumulates. If the duct ruptures, the ensuing intense inflammatory response to keratin results in an erythematous painful mass. A fistula tract may burrow beneath the smooth muscle of the nipple to open at the edge of the areola.

uncommon. This disorder tends to occur in the fifth or sixth decade of life, usually in multiparous women. Unlike squamous metaplasia of lactiferous ducts, it is not associated with cigarette smoking.

MORPHOLOGY

Ectatic dilated ducts are filled with inspissated secretions and numerous lipid-laden macrophages. When ruptured, a marked periductal and interstitial chronic inflammatory reaction ensues, consisting of lymphocytes, macrophages, and variable numbers of plasma cells (Fig. 23-5). Granulomas may form around cholesterol deposits and secretions. Subsequent fibrosis produces an irregular mass with skin and nipple retraction.

The principal significance of this disorder is that the irregular palpable mass mimics the clinical and radiographic appearance of invasive carcinoma.

Fat Necrosis

The presentations of fat necrosis are protean and can closely mimic cancer—as a painless palpable mass, skin thickening or retraction, or mammographic densities or calcifications. About half of affected women have a history of breast trauma or prior surgery.

MORPHOLOGY

Acute lesions may be hemorrhagic and contain central areas of liquefactive fat necrosis with neutrophils and macrophages. Over the next few days proliferating fibroblasts and chronic inflammatory cells surround the injured area. Subsequently, giant cells, calcifications, and hemosiderin make their appearance, and eventually the focus is replaced by scar tissue or is encircled and walled off by fibrous tissue. Ill-defined, firm, gray-white nodules containing small chalky-white foci are seen grossly.

Lymphocytic Mastopathy (Sclerosing Lymphocytic Lobulitis)

This condition presents with single or multiple hard palpable masses or mammographic densities. It can be difficult to obtain tissue with a needle biopsy due to the dense collagenized stroma. Atrophic ducts and lobules have thickened basement membranes and are surrounded by a prominent lymphocytic infiltrate. This condition is most common in women with type 1 (insulin-dependent) diabetes or autoimmune thyroid disease and is hypothesized to have an autoimmune basis. Its only clinical significance is that it must be distinguished from breast cancer.

Granulomatous Mastitis

Granulomatous inflammation of the breast can be a manifestation of systemic granulomatous diseases (e.g., granulomatosis with polyangiitis, sarcoidosis, tuberculosis) or of disorders that are localized to the breast (granulomatous lobular mastitis, rare infections). *Granulomatous lobular mastitis* is an uncommon disease that only occurs in parous women. The granulomas are closely associated with lobules, suggesting that the disease may be caused by a hypersensitivity reaction to antigens expressed during lactation. Treatment with steroids is sometimes effective. A similar histologic pattern is seen in *cystic neutrophilic granulomatous mastitis* caused by *Corynebacteria*. Localized infections by mycobacteria or fungi are very rare and are most common in immunocompromised patients or adjacent to foreign objects such as breast prostheses or nipple piercings.

Figure 23-5 Duct ectasia. Chronic inflammation and fibrosis surround an ectatic duct filled with inspissated debris. The fibrotic response can produce a firm irregular mass that mimics invasive carcinoma on palpation or mammogram.

KEY CONCEPTS

Inflammatory Disorders

- Inflammatory diseases of the breast are rare outside of the lactational period.
- The specific cause must be determined as appropriate treatment may be antibiotics, steroids, or surgery.
- The possibility of inflammatory carcinoma mimicking a non-neoplastic inflammatory disorder should always be considered.

Benign Epithelial Lesions

Benign epithelial lesions are classified into three groups, according to the subsequent risk of developing breast cancer: (1) *nonproliferative breast changes*, (2) *proliferative breast disease*, and (3) *atypical hyperplasia*. Most come to clinical attention when detected by mammography or as incidental findings in surgical specimens.

Nonproliferative Breast Changes
(Fibrocystic Changes)

This group includes common morphologic alterations that are often grouped under the term *fibrocystic changes*. To the clinician the term might mean “lumpy bumpy” breasts on palpation; to the radiologist, a dense breast with cysts; and to the pathologist, benign histologic findings. These lesions are termed *nonproliferative* to indicate that they are not associated with an increased risk of breast cancer.

MORPHOLOGY

There are three principal morphologic changes: (1) cystic change, often with apocrine metaplasia, (2) fibrosis, and (3) adenosis.

- **Cysts.** Small cysts form by the dilation of lobules and in turn may coalesce to form larger cysts. Unopened cysts contain turbid, semi-translucent fluid of a brown or blue color (blue-dome cysts) (Fig. 23-6B). Cysts are lined either by a flattened atrophic epithelium or by metaplastic apocrine cells. The latter cells have abundant granular, eosinophilic cytoplasm and round nuclei and closely resemble the normal apocrine epithelium of sweat glands (Fig. 23-6C). Calcifications are common and may be detected by mammography (Fig. 23-6A). Cysts may cause concern when they are solitary and firm to palpation. The diagnosis is confirmed by the disappearance of the mass after fine-needle aspiration of its contents.
- **Fibrosis.** Cysts frequently rupture, releasing secretory material into the adjacent stroma. The resulting chronic inflammation and fibrosis contribute to the palpable nodularity of the breast.
- **Adenosis.** Adenosis is defined as an increase in the number of acini per lobule. It is a normal feature of pregnancy. In nonpregnant women, adenosis can occur as a focal change. Calcifications are occasionally present within the lumens.

Figure 23-6 Apocrine cysts. **A**, Clustered, rounded calcifications are seen in a specimen radiograph. **B**, Gross appearance of typical cysts filled with dark, turbid fluid contents. **C**, Cysts are lined by apocrine cells with round nuclei and abundant granular cytoplasm. Note the luminal calcifications, which form on secretory debris.

The acini are lined by columnar cells, which may appear benign or show nuclear atypia (“**flat epithelial atypia**”). Flat epithelial atypia is a clonal proliferation associated with deletions of chromosome 16q. This lesion is thought to be the earliest recognizable precursor of low-grade breast cancers, but does not convey an increased cancer risk, presumably because other steps in cancer development are rate limiting.

Lactational adenomas present as palpable masses in pregnant or lactating women. They consist of normal-appearing breast tissue with lactational changes. These lesions are not proven to be neoplastic and may simply represent an exaggerated local response to gestational hormones.

Proliferative Breast Disease Without Atypia

Lesions characterized by proliferation of epithelial cells, without atypia, are associated with a small increase in the risk of subsequent carcinoma in either breast. They are commonly detected as mammographic densities, calcifications, or as incidental findings in biopsies performed for other reasons. These lesions are not clonal and are not commonly found to have genetic changes. Thus they are predictors of risk but unlikely to be true precursors of carcinoma.

Figure 23-7 **A**, A normal duct or acinus with a single basally located myoepithelial cell layer (cells with dark, compact nuclei and scant cytoplasm) and a single luminal cell layer (cells with larger open nuclei, small nucleoli, and more abundant cytoplasm). **B**, Epithelial hyperplasia. The lumen is filled by a heterogeneous, mixed population of luminal and myoepithelial cell types. Irregular slitlike fenestrations are prominent at the periphery.

MORPHOLOGY

Epithelial Hyperplasia. Normal breast ducts and lobules are lined by a double-layer of myoepithelial cells and luminal cells (Fig. 23-7A). In epithelial hyperplasia, increased numbers of both luminal and myoepithelial cell types fill and distend ducts and lobules. Irregular lumens can often be discerned at the periphery of the cellular masses (Fig. 23-7B). Epithelial hyperplasia is usually an incidental finding.

Sclerosing Adenosis. There are an increased number of acini that are compressed and distorted in the central portion of the lesion. On occasion, stromal fibrosis may completely compress the lumens to create the appearance of solid cords or double strands of cells lying within dense stroma, a histologic pattern that at times closely mimics invasive carcinoma (Fig. 23-8). Sclerosing adenosis can come to attention as a palpable mass, a radiologic density, or calcifications.

Complex Sclerosing Lesion. These lesions have components of sclerosing adenosis, papillomas, and epithelial hyperplasia. One member of this group, the radial sclerosing lesion (“radial scar”), has an irregular shape and can closely mimic invasive carcinoma mammographically, grossly, and histologically (Fig. 23-9). A central nidus of entrapped glands in a hyalinized stroma is surrounded by long radiating projections into stroma. The term *radial scar* is a misnomer, as these lesions are not associated with prior trauma or surgery.

Papilloma. Papillomas grow within a dilated duct and are composed of multiple branching fibrovascular cores (Fig. 23-10). Epithelial hyperplasia and apocrine metaplasia are frequently present. Large duct papillomas are situated in the lactiferous sinuses of the nipple and are usually solitary. Small duct papillomas are commonly multiple and located deeper within the ductal system.

More than 80% of large duct papillomas produce a nipple discharge. Some discharges are bloody if the stalk undergoes torsion causing infarction. Serous discharge results from intermittent blockage and release of normal breast secretions or irritation of the duct by the papilloma. Most small duct papillomas come to clinical attention as small palpable masses, or as densities or calcifications seen on mammograms.

Gynecomastia

Gynecomastia (enlargement of the male breast) is the only benign lesion seen with any frequency in the male breast. It presents as a button-like subareolar enlargement and may be unilateral or bilateral. Microscopically, there is an increase in dense collagenous connective tissue associated with epithelial hyperplasia of the duct lining with characteristic tapering micropapillae (Fig. 23-11). Lobule formation is almost never observed.

Gynecomastia occurs as a result of an imbalance between estrogens, which stimulate breast tissue, and androgens, which counteract these effects. It may appear during

Figure 23-8 Sclerosing adenosis. The involved terminal duct lobular unit is enlarged, and the acini are compressed and distorted by dense stroma. Calcifications are present within some of the lumens. Unlike carcinomas, the acini are arranged in a swirling pattern, and the outer border is well circumscribed.

Figure 23-9 Radial sclerosing lesion. **A**, The radiograph shows an irregular central mass with long radiodense projections. **B**, Grossly the mass appears solid and has irregular borders, but it is not as firm as an invasive carcinoma. **C**, The mass consists of a central nidus of small tubules entrapped in a densely fibrotic stroma and numerous projections containing epithelium with varying degrees of cyst formation and hyperplasia.

puberty, in the very aged, or at any time during adult life when there is cause for hyperestrinism. The most important of these is cirrhosis of the liver, since this organ is responsible for metabolizing estrogen. In older males, gynecomastia may stem from a relative increase in estrogens as testicular androgen production falls. Drugs such as alcohol, marijuana, heroin, antiretroviral therapy, and anabolic steroids have been associated with gynecomastia. Rarely, gynecomastia occurs as part of Klinefelter syndrome (XXY karyotype) or in association with functioning testicular neoplasms, such as Leydig cell or Sertoli cell tumors. Similar to proliferative disease in women, gynecomastia may be associated with a small increased risk of breast cancer.

Proliferative Breast Disease with Atypia

Atypical hyperplasia is a clonal proliferation having some, but not all, of the histologic features that are required for the diagnosis of carcinoma in situ. It is associated with a moderately increased risk of carcinoma and includes two forms, atypical ductal hyperplasia and atypical lobular hyperplasia. Atypical ductal hyperplasia is

Figure 23-10 Intraductal papilloma. A central fibrovascular core extends from the wall of a duct. The papillae arborize within the lumen and are lined by myoepithelial and luminal cells.

present in 5% to 17% of specimens from biopsies performed for calcifications. Atypical lobular hyperplasia is an incidental finding and is found in fewer than 5% of biopsies.

MORPHOLOGY

Atypical ductal hyperplasia is recognized by its histologic resemblance to ductal carcinoma in situ (DCIS). It consists of a relatively monomorphic proliferation of regularly spaced cells, sometimes with cribriform spaces. It is distinguished from DCIS in that it only partially fills involved ducts (Fig. 23-12A).

Atypical lobular hyperplasia consists of cells identical to those of lobular carcinoma in situ (described later), but the cells do not fill or distend more than 50% of the acini within a lobule (Fig. 23-12B). In atypical lobular hyperplasia, atypical lobular cells may lie between the ductal basement membrane and overlying normal luminal cells.

Figure 23-11 Gynecomastia. Breast enlargement in males is due to an increase in the number of ducts accompanied by loose cellular stroma. Lobule formation is absent.

Figure 23-12 **A**, Atypical ductal hyperplasia. A duct is filled with a mixed population of cells consisting of oriented columnar cells at the periphery and more rounded cells within the central portion. Although some of the spaces are round and regular, the peripheral spaces are irregular and slitlike. These features are highly atypical, but fall short of a diagnosis of ductal carcinoma in situ. **B**, Atypical lobular hyperplasia. A population of monomorphic small, round, loosely cohesive cells partially fills a lobule. Although the cells are morphologically identical to the cells of lobular carcinoma in situ, the extent of involvement is not sufficient for this diagnosis.

Atypical ductal and atypical lobular hyperplasias may have acquired chromosomal aberrations such as loss of 16q or gain of 17p, changes also found in carcinoma in situ. Atypical lobular hyperplasia also shows loss of E-cadherin expression, a feature it shares with lobular carcinoma in situ (discussed later). This form of intraepithelial spread is called “pagetoid” because of its resemblance to Paget disease, described later.

Clinical Significance of Benign Epithelial Changes

Epidemiologic studies have established the association of benign histologic changes with the later development of invasive cancer (Table 23-1). Nonproliferative changes do not increase the risk of cancer. Proliferative disease is associated with a 1.5- to two-fold increased risk, while proliferative disease with atypia confers a four- to five-fold increased risk. Both breasts are at increased risk, although the risk to the ipsilateral breast may be slightly higher. Risk reduction can be achieved by bilateral prophylactic mastectomy or treatment with estrogen antagonists, such as tamoxifen. However, fewer than 20% of women with atypical hyperplasia develop breast cancer, and therefore many choose careful clinical and radiologic surveillance over intervention.

KEY CONCEPTS

Benign Epithelial Lesions

- Benign epithelial lesions usually do not cause symptoms but are frequently detected as mammographic calcifications or densities.
- These lesions are classified according to the subsequent risk of cancer in either breast.
- The majority are not precursors of cancer.
- Although risk reduction can be achieved by surgery or chemoprevention, the majority of women will not develop cancer and many women choose surveillance instead of intervention.

Carcinoma of the Breast

Carcinoma of the breast is the most common non-skin malignancy in women and is second only to lung cancer as a cause of cancer deaths. A woman who lives to age 90 has a one in eight chance of developing breast cancer. In 2012, approximately 226,000 women in the United States were diagnosed with invasive breast cancer, 63,000 with carcinoma in situ, and almost 40,000 women died of the

Table 23-1 Epithelial Breast Lesions and the Risk of Developing Invasive Carcinoma

Pathologic Lesion	Relative Risk (Absolute Lifetime Risk)*
Nonproliferative Breast Changes (Fibrocystic changes)	1 (3%)
Duct ectasia	
Cysts	
Apocrine change	
Mild hyperplasia	
Adenosis	
Fibroadenoma without complex features	
Proliferative Disease Without Atypia	1.5 to 2 (5%-7%)
Moderate or florid hyperplasia	
Sclerosing adenosis	
Papilloma	
Complex sclerosing lesion (radial scar)	
Fibroadenoma with complex features	
Proliferative Disease with Atypia	4 to 5 (13%-17%)
Atypical ductal hyperplasia (ADH)	
Atypical lobular hyperplasia (ALH)	
Carcinoma in Situ	8 to 10 (25%-30%)
Lobular carcinoma in situ (LCIS)	
Ductal carcinoma in situ (DCIS)	

*Relative risk is the risk compared to women without any risk factors. Absolute lifetime risk is the percentage of patients expected to develop invasive carcinoma if untreated.

disease (Surveillance Epidemiology and End Results [SEER] data at <http://seer.cancer.gov/>). It is both ironic and tragic that a neoplasm arising in an exposed organ, readily accessible to self-examination and clinical surveillance, continues to exact such a heavy toll.

Almost all breast malignancies are adenocarcinomas and based on the expression of estrogen receptor and HER2 can be divided into three major biologic subgroups: *estrogen receptor (ER)-positive, HER2-negative* (50% to 65% of tumors); *HER2-positive* (10% to 20% of tumors, which may either be ER-positive or ER-negative); and *ER-negative, HER2-negative* (10% to 20% of tumors). These groups (described in detail later) show striking differences with regard to patient characteristics, pathologic features, treatment response, and outcome.

Incidence and Epidemiology

Breast cancer is rare in women younger than age 25, but the incidence increases rapidly after age 30 (Fig. 23-13). ER-positive cancers continue to increase with age whereas the incidence of ER-negative cancers and HER2-positive cancers remains relatively constant. The number of ER-positive cancers detected in older women has risen as a result of mammographic screening (which preferentially detects ER-positive cancers) and menopausal hormone therapy (which is associated with an increase in these cancers). As a result, ER-negative and HER2-positive cancers comprise almost half of cancers in young women but fewer than 20% of cancers in older women.

Ductal carcinoma in situ (DCIS) is rarely palpable and is almost always detected by mammography. The increased diagnosis of invasive carcinoma and DCIS after 1980 is related to the introduction of mammographic screening and is confined to older women (Fig. 23-14). Rates of screening levelled off recently at 65% to 75% of eligible women, and the number of new breast cancer diagnoses has also plateaued. In the age of screening, the number of stage I cancers (small node-negative carcinomas) has

Figure 23-13 Incidence of ER-positive, ER-negative, and HER2-positive breast cancers according to age. Rates are per 100,000 women. ER-negative and HER2-positive cancers have a relatively constant incidence after age 40 years. In contrast, ER-positive cancers show a marked increase in incidence starting at around age 40 that peaks between the ages of 70 and 80.

Figure 23-14 Changing incidences of ductal carcinoma in situ (DCIS) and invasive carcinoma during the years 1973 to 2009 in women older than 50 years of age. Rates are per 100,000 women and are age-adjusted to the 2000 US standard million population. (Data from SEER Cancer Statistics Review; <http://seer.cancer.gov/>.) Following introduction of mammographic screening in the 1980s, the number of cases of DCIS and invasive carcinoma increased in older women. The number of women screened has recently plateaued, as has the incidence of breast cancer.

increased in frequency, while the number of large node-positive or advanced-stage breast carcinomas (stages II to IV) has fallen.

Invasive cancer is less common overall in non-white women, especially in older women (Fig. 23-15). The average age at diagnosis is 61 years for white women, 56 for

Figure 23-15 Breast cancer incidence and mortality in different ethnic groups (Data from North American Association of Central Cancer Registries). White women have the highest incidence of breast cancer, while African American women have the highest mortality rate. Likely contributors to these differences include socioeconomic factors (better access to care in white women) and biologic factors, particularly the higher incidence of aggressive, high grade, ER-negative tumors in younger African American women.

Hispanic women, and 46 for African American women. Only 20% of non-Hispanic white women are diagnosed at ages younger than 50 years, compared with 35% of African American women and 31% of Hispanic women. The incidence of ER-negative and HER2-positive cancers is relatively constant in all ethnic groups, but the number of ER-positive cancers is lower in non-white women.

The risk of death from breast cancer in those diagnosed with the disease remained constant for many years, but since 1994 has gradually declined from 30% to about 20%. This decrease is attributed to mammographic screening as well as more effective treatment modalities. However, the decline in the death rate has been less impressive for African American women, who have the highest mortality rate (Fig. 23-15). Although this difference is explained partly by unequal access to care, breast cancers in African American women are also on average more biologically aggressive, as they are more likely to be ER-negative and to have a high nuclear grade.

The incidence of breast cancer is four to seven times higher in the United States and Europe than in other countries, but rates are rising worldwide and by 2020 it is estimated that 70% of cases will be in developing countries. This change in incidence likely stems from adoption of Western social lifestyles, including delayed pregnancy, fewer pregnancies, and decreased breastfeeding.

Risk Factors. Beyond female sex (99% of those affected are female), the major risk factors are related to hereditary factors, lifetime exposure to estrogen and, to a lesser extent, environmental or lifestyle factors. Among the large number of identified risk factors are the following:

- **Germline mutations.** Approximately 5% to 10% of breast cancers occur in persons with germline mutations in tumor suppressor genes (discussed later). For these individuals, the lifetime risk of breast cancer can be more than 90%.
- **First-degree relatives with breast cancer.** About 15% to 20% of women with breast cancer have an affected first-degree relative (mother, sister, or daughter), but do not carry an identified breast cancer gene mutation. This increased risk is probably due to the interaction of low-risk susceptibility genes and shared environmental factors. Genome-wide association studies are being used to identify candidate genetic variants. It is important to note that risk is not increased if the only affected relative is a postmenopausal mother with cancer.
- **Race/ethnicity.** Ethnic background is correlated with breast cancer risk. Non-Hispanic white women have the highest incidence in the United States (Fig. 23-15). Variation in the frequency of breast cancer genes across ethnic groups is partly responsible for these differences. For example, germline *BRCA1* and *BRCA2* mutations are particularly prevalent in Ashkenazi Jewish populations.
- **Age.** Breast cancer risk rises throughout a woman's lifetime, peaking at 70 to 80 years and then declining slightly thereafter (Fig. 23-13).
- **Age at menarche.** Menarche at ages younger than 11 years increases risk by 20% compared to menarche at ages greater than 14. Late menopause also increases risk.
- **Age at first live birth.** A full-term pregnancy before the age of 20 halves the risk compared to nulliparous women or women who are older than the age of 35 at the time of their first birth.
- **Benign breast disease.** A prior breast biopsy revealing atypical hyperplasia or proliferative changes increases the risk of invasive carcinoma (Table 23-1).
- **Estrogen exposure.** Menopausal hormone therapy increases the risk of breast cancer, particularly when estrogen and a progestin are given together for a period of years. Most excess cancers are small ER-positive carcinomas. In contrast, oral contraceptives do not appear to increase the risk of breast cancer. Reducing endogenous estrogens by oophorectomy decreases the risk of developing breast cancer by up to 75%. Drugs that block estrogenic effects (e.g., tamoxifen) or block the formation of estrogen (e.g., aromatase inhibitors) also decrease the risk of ER-positive breast cancer.
- **Breast density.** Women with very dense breasts on mammography have a four- to six-fold higher risk of both ER-positive and ER-negative breast cancer compared to women with the lowest density. High breast density clusters in families and is correlated with other risk factors such as older age at first birth, fewer children, and menopausal hormone therapy. Persistently high breast density in older women may stem from a failure of normal breast involution.
- **Radiation exposure.** Radiation to the chest, whether for cancer therapy, due to atomic bomb exposure, or nuclear accidents, results in a higher rate of breast cancer. The risk is greatest with exposure at young ages and with high radiation doses. For example, women in their teens and early 20s who received radiation to the chest for Hodgkin lymphoma have a 20% to 30% risk of developing breast cancer over 10 to 30 years. Older women undergoing radiation do not incur this risk.
- **Carcinoma of the contralateral breast or endometrium.** Approximately 1% of women with breast cancer develop a second contralateral breast carcinoma per year. Breast and endometrial carcinomas have several risk factors in common, the most important of which is exposure to prolonged estrogenic stimulation.
- **Diet.** Large studies have failed to find strong correlations between breast cancer risk and dietary intake of any specific type of food. Moderate or heavy alcohol consumption increases risk.
- **Obesity.** Obese women under the age of 40 have a decreased risk as a result of anovulatory cycles and lower progesterone levels. In contrast, postmenopausal obese women are at an increased risk, which is attributed to the synthesis of estrogens in fat depots.
- **Exercise.** There is a probable small protective effect for women who are physically active.
- **Breastfeeding.** The longer women breastfeed, the greater the reduction in risk. Lactation suppresses ovulation and may trigger terminal differentiation of luminal cells. The lower incidence of breast cancer in developing countries can largely be explained by the more frequent and longer nursing of infants.
- **Environmental toxins.** There is concern that environmental contaminants, such as organochlorine pesticides, have estrogenic effects on humans. Possible links to

breast cancer risk are being investigated intensively, but definitive associations have yet to be made.

Etiology and Pathogenesis

Like other cancers, breast cancers are clonal proliferations that arise from cells with multiple genetic aberrations, acquisition of which is influenced by hormonal exposures and inherited susceptibility genes. Breast cancers may be hereditary, arising in women with germline mutations in tumor suppressor genes, or sporadic. However, environmental factors clearly influence the penetrance of hereditary forms of breast cancer, and both genetic and environmental factors contribute to sporadic forms of breast cancer. The identification of breast cancer susceptibility genes has provided important insights into the pathogenesis of both familial and sporadic forms of breast cancer. We begin our discussion with hereditary breast cancer and the major susceptibility genes.

Familial Breast Cancer

Approximately 12% of breast cancers occur due to inheritance of an identifiable susceptibility gene or genes. The probability of a hereditary etiology increases when there are multiple affected first-degree relatives, early onset cancers, multiple cancers, or family members with other specific cancers. As with other familial forms of cancer (Chapter 7), in some instances cancer risk is an autosomal dominant trait that is conferred by inheritance of a defective copy of a tumor suppressor gene. In such instances, a

single sporadic mutation in the remaining normal allele is all that is required to completely lose tumor suppressor function, which is likely to be the initiating driver mutation in these forms of breast cancer. The major known susceptibility genes for familial breast cancer—*BRCA1*, *BRCA2*, *TP53*, and *CHEK2*—are all tumor suppressor genes that have normal roles in DNA repair and maintenance of genomic integrity (Chapter 7 and Table 23-2). It is likely that complete loss-of-function of these proteins creates a “mutator” phenotype, an increased propensity to accumulate genetic damage that speeds cancer development.

Mutations in *BRCA1* and *BRCA2* are responsible for 80% to 90% of “single gene” familial breast cancers and about 3% of all breast cancers. Penetrance (the percentage of carriers who develop breast cancer) varies from 30% to 90% depending on the specific mutation present. Mutations in *BRCA1* also markedly increase the risk of developing ovarian carcinoma, which occurs in as many as 20% to 40% of carriers. *BRCA2* confers a smaller risk for ovarian carcinoma (10% to 20%) but is associated more frequently with male breast cancer. *BRCA1* and *BRCA2* carriers are also at higher risk for other epithelial cancers, such as prostatic and pancreatic carcinomas.

BRCA1 (on chromosome 17q21) and *BRCA2* (on chromosome 13q12.3) are both large genes, and hundreds of different mutations distributed throughout their coding regions have been associated with familial breast cancers. The frequency of mutations that increase breast cancer risk is only about 1 in 400 persons in the general population,

Table 23-2 Most Common “Single Gene” Mutations Associated with Hereditary Susceptibility to Breast Cancer

Gene (Location) Syndrome (Incidence)*	% of “Single Gene” Hereditary Cancers†	Breast Cancer Risk by Age 70‡	Changes in Sporadic Breast Cancer	Other Associated Cancers	Functions	Comments
<i>BRCA1</i> (17q21) Familial breast and ovarian cancer (1 in 860)	52% (~2% of all breast cancers)	40%- 90%	Mutations rare; inactivated in 50% of some subtypes (e.g., medullary and metaplastic) by methylation	Ovarian, male breast cancer (but lower than <i>BRCA2</i>), prostate, pancreas, fallopian tube	Tumor suppressor, transcriptional regulation, repair of double-stranded DNA breaks	Breast carcinomas are commonly poorly differentiated and triple negative (basal-like), and have <i>TP53</i> mutations
<i>BRCA2</i> (13q12-13) Familial breast and ovarian cancer (1 in 740)	32% (~1% of all breast cancers)	30%-90%	Mutations and loss of expression rare	Ovarian, male breast cancer, prostate, pancreas, stomach, melanoma, gallbladder, bile duct, pharynx	Tumor suppressor, transcriptional regulation, repair of double-stranded DNA breaks	Biallelic germline mutations cause a rare form of Fanconi anemia
<i>TP53</i> (17p13.1) Li-Fraumeni (1 in 20,000)	3% (~1% of all breast cancers)	>90%	Mutations in 20%, LOH in 30%-42%; most frequent in triple negative cancers	Sarcoma, leukemia, brain tumors, adrenocortical carcinoma, others	Tumor suppressor with critical roles in cell cycle control, DNA replication, DNA repair, and apoptosis	<i>TP53</i> is the most commonly mutated gene in sporadic breast cancers 53% ER- and HER2-positive
<i>CHEK2</i> (22q12.1) (1 in 100)	5% (~1% of all breast cancers)	10%-20%	Mutations in 5%	Prostate, thyroid, kidney, colon	Cell cycle checkpoint kinase, recognition and repair of DNA damage, activates <i>BRCA1</i> and p53 by phosphorylation	May increase risk for breast cancer after radiation exposure 70%-80% ER-positive

*Frequency of heterozygotes in the U.S. population; the incidence of gene mutations is higher in some ethnic populations (e.g., *BRCA1* and *BRCA2* mutations occur at high frequencies in Ashkenazi Jews).

†Defined as familial breast cancers showing a pattern of inheritance consistent with a major effect of a single gene.

‡Risk varies with specific mutations and is likely modified by other genes. *LOH*, loss of heterozygosity.

and inconsequential polymorphisms are common. As a result, genetic testing is difficult and generally restricted to individuals with a strong family history or those belonging to certain ethnic groups. For example, in Ashkenazi Jewish populations, about 1 in 40 individuals carry one of three specific mutations, two in *BRCA1* and one in *BRCA2*. Identification of carriers is important, since increased surveillance, prophylactic mastectomy, and salpingo-oophorectomy can reduce cancer-related morbidity and mortality.

BRCA1-associated breast cancers are commonly poorly differentiated, have “medullary features” (a syncytial growth pattern with pushing margins and a lymphocytic response, described later), and are biologically very similar to ER-negative/HER2-negative breast cancers identified as “basal-like” by gene expression profiling (described later), as well as to serous ovarian carcinomas (Chapter 22). *BRCA2*-associated breast carcinomas also tend to be relatively poorly differentiated, but are more often ER-positive than *BRCA1* cancers.

The remaining known susceptibility genes accounts for fewer than 10% of hereditary breast carcinomas (Table 23-2). Germline mutations in *TP53* (Li-Fraumeni syndrome) and mutations in *CHEK2* together account for about 8% of breast cancers caused by single genes. Three other tumor suppressor genes—*PTEN* (Cowden syndrome), *STK11* (Peutz-Jeghers syndrome), and *ATM* (ataxia telangiectasia)—are mutated in less than 1% of all familial breast cancers.

Most of these genes play complex and interrelated roles in maintaining genomic integrity. After a cell sustains DNA damage, it must undergo cell cycle arrest and either repair its DNA or die by apoptosis. *ATM* senses DNA damage and with p53 and *CHEK2* induces cell cycle arrest. *BRCA1*, *BRCA2*, and *CHEK2* all have important functions in repair of double stranded DNA breaks. If any of these functions are impaired, the likelihood that cells with permanent DNA damage will survive is increased and the mutation will be propagated.

Yet it must be admitted that it is unknown why malfunction of these genes, particularly *BRCA1* and *BRCA2*, is more highly associated with breast cancer than other cancers. *BRCA1* and *BRCA2* are part of a large complex of proteins that are required to repair double stranded DNA breaks through a process called homologous recombination, in which a normal sister chromatid is used as a template for repairing the broken stretch of DNA. *BRCA1* and *BRCA2* are expressed ubiquitously, so the link to breast cancer is not obviously explained by tissue-specific patterns of gene expression. An alternative possibility is that breast (and ovarian) epithelial cells may be particularly prone to suffer the type of DNA damage that *BRCA1* and *BRCA2* are required to repair. *BRCA1* also interacts with protein complexes that regulate chromatin structure, and it remains possible that its tumor suppressive role involves functions that are independent of DNA repair.

Sporadic Breast Cancer

The major risk factors for sporadic breast cancer are related to hormone exposure: gender, age at menarche and menopause, reproductive history, breastfeeding, and exogenous estrogens. Other environmental risk factors, proven or suspected, include radiation exposure

(discussed under risk factors) and exposure to chemicals with estrogen-like effects (Chapter 9).

Estrogen clearly functions as a promoter of breast cancers (Chapter 7), probably through several different effects on the breast. Hormonal exposure stimulates breast growth during puberty, menstrual cycles, and pregnancy, thereby increasing the number of cells that can potentially give rise to a cancer. The proliferation of breast epithelium during the menstrual cycle is also conducive to the accumulation of DNA damage, and the temporary lull in cell division that occurs during the latter part of the menstrual cycle may allow time for defective DNA repair to occur and for mutations to become “fixed” in the genome. Repeated rounds of this process during each cycle may underlie the association between the cumulative number of menstrual cycles a woman experiences and her risk of developing breast cancer. Once premalignant or malignant cells are present, hormones can stimulate their growth as well as the growth of normal stromal cells that may aid and abet tumor development.

Molecular Mechanisms of Carcinogenesis and Tumor Progression

The diverse histologic appearances of breast carcinomas and putative precursor lesions are the outward manifestations of the complex genetic and epigenetic changes that drive carcinogenesis. As with other cancers, resident breast tissue stem cells have been hypothesized to be the cell of origin for all breast cancers. Once the process is initiated in such cells by a driver mutation, there appear to be three major genetic pathways of carcinogenesis (Fig. 23-16).

- **ER-positive, HER2-negative cancers arise via the dominant pathway of breast cancer development, constituting 50% to 65% of cases.** This is the most common subtype of breast cancer in individuals who inherit germline mutations in *BRCA2*. They are often associated with gains of chromosome 1q, losses of chromosome 16q, and activating mutations in *PIK3CA*, a gene that encodes phosphoinositide-3 kinase (PI3K), which is an important component of signaling pathways downstream of growth factor receptors (Chapter 7). These same genetic lesions are often found in flat epithelial atypia and atypical ductal hyperplasia, which are hypothesized to be precursor lesions for this subtype of breast cancer. ER-positive cancers are termed “luminal,” as these cancers most closely resemble normal breast luminal cells in terms of their mRNA expression pattern, which is dominated by genes that are regulated by estrogen. As discussed later, tumors arising through this pathway include at least two major molecular subtypes that differ in their proliferation rate and response to therapy.
- **HER2-positive cancers arise through a pathway that is strongly associated with amplifications of the HER2 gene on chromosome 17q.** They constitute approximately 20% of all breast cancers and may be either ER-positive or ER-negative. This is the most common subtype of breast cancer in patients with germline mutations in *TP53* (Li-Fraumeni syndrome). A putative precursor lesion termed atypical apocrine adenosis has

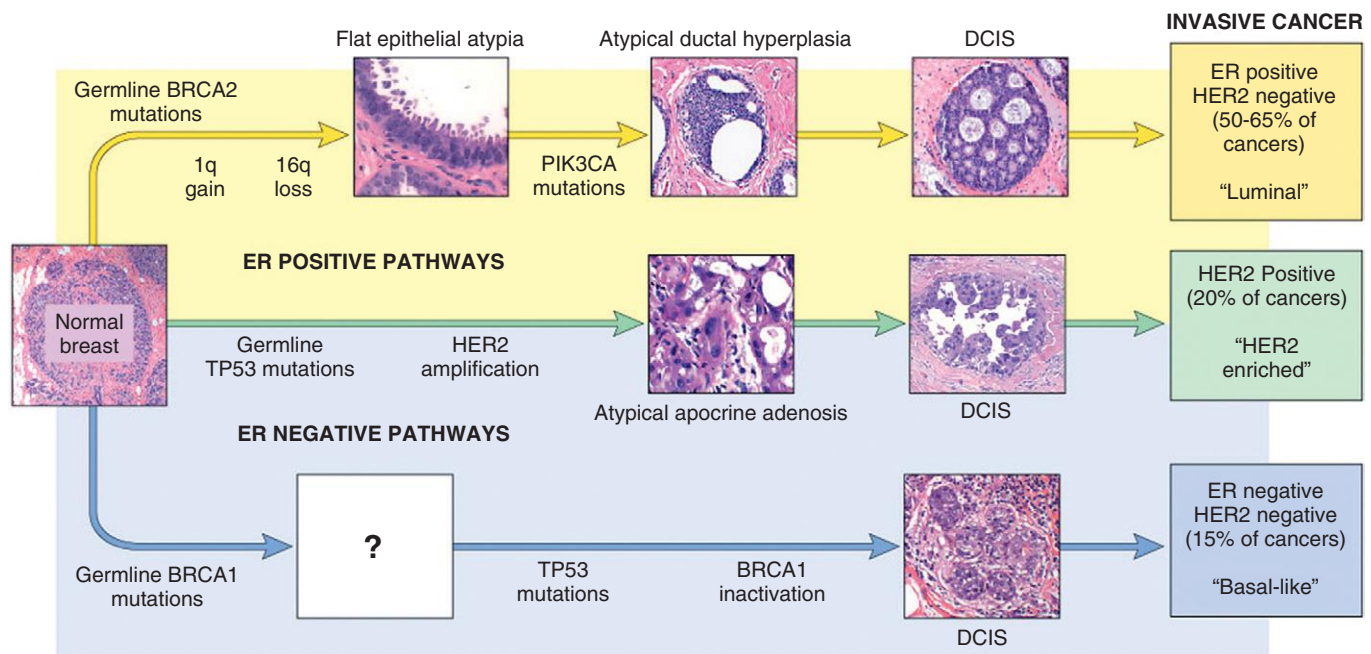

Figure 23-16 Major pathways of breast cancer development. Three main pathways have been identified. The most common pathway (yellow arrow) leads to ER-positive carcinomas. Recognizable precursor lesions include flat epithelial atypia and atypical hyperplasia. A less common pathway (blue arrow) leads to carcinomas that are negative for ER and HER2. The box with the question mark indicates that no precursor lesions have been identified—perhaps because lesions progress quickly to carcinoma. The third pathway (green arrow) consists of HER2-positive cancers, which may be ER-positive or ER-negative. Amplification of the *HER2* gene is also present in a subset of atypical apocrine lesions, which may represent a precursor lesion. Each molecular subtype has a characteristic gene expression profile termed luminal, HER2 enriched, and basal-like, respectively. See text for other details.

been described. These cancers have a distinct gene expression pattern that is dominated by genes related to proliferation that are regulated by signaling pathways lying downstream of the HER2 receptor tyrosine kinase.

- **ER-negative, HER2-negative cancers arise through a distinct pathway that is independent of ER-mediated changes in gene expression and HER2 gene amplifications.** Precursor lesions have yet to be described and as a result this is the least understood of the pathways. These tumors comprise about 15% of breast cancers overall, but are the most common tumor type observed in patients with germline *BRCA1* mutations; they also occur with increased frequency in African American women. Sporadic tumors of this type often have loss-of-function mutations in *TP53*; mutations in *BRCA1* are uncommon, but *BRCA1* may be silenced in sporadic tumors through epigenetic mechanisms. These tumors have a “basal-like” pattern of mRNA expression that includes many genes that are expressed in normal myoepithelial cells.

Deep sequencing of breast cancer genomes has been used to reconstruct the genetic events that occur during tumor development and progression. The most common driver mutations involve the proto-oncogenes *PIK3CA*, *HER2*, *MYC*, and *CCND1* (which encodes cyclin D1), and the tumor suppressor genes *TP53* and (in familial cancers) *BRCA1* and *BRCA2*. Once a founding tumor clone is established, subclonal heterogeneity arising by chance due to genomic instability undoubtedly contributes to both tumor progression and resistance to therapy. As with many solid tumors, the profound genetic heterogeneity of breast cancer is a major challenge to the success of therapy, as it

increases the likelihood of emergence of more aggressive, therapy-resistant subclones.

Neoplastic epithelial cells do not develop in isolation, but are dependent on interactions with stromal cells in the local microenvironment. Cancers occur in the areas of greatest mammographic density, suggesting that increased amounts of fibrous stroma is both a marker of risk and biologically important for tumorigenesis. The role of stroma is not yet completely understood. The stroma is a complex mixture of fibroblasts, blood vessels, lymphatics, inflammatory cells, and extracellular matrix. Focal alterations in the stroma may play a direct role by creating a microenvironment conducive to tumor development and growth. Angiogenesis and tumor-associated inflammation are commonly associated with carcinoma, starting at the in situ stage. With better understanding of the role played by stroma, it may be possible to develop therapies that target stromal components.

The final step of carcinogenesis, the transition of carcinoma in situ to invasive carcinoma, is both the most important and the least understood. The majority of genetic changes observed in invasive carcinomas are already present in the associated carcinoma in situ (Fig. 23-16). It is possible that the same molecular events that allow for the normal formation of new ductal branch points and lobules during pregnancy—abrogation of the basement membrane, increased proliferation, escape from growth inhibition, angiogenesis, and invasion of stroma—may be replicated during invasion. Remodeling of the breast during post-pregnancy involution, which involves inflammatory and “wound healing-like” tissue reactions and is known to increase the risk of tumor invasion, may also facilitate the transition of carcinoma in situ to invasive carcinoma.

As can be surmised from this discussion, breast cancer is not one disease, but many, each with its own clinical characteristics and optimal prevention and treatment strategies. This recognition has led to the introduction of new molecular classification systems, which are discussed later.

KEY CONCEPTS

Breast Cancer Incidence, Epidemiology, and Etiology

- Breast cancer is the most common non-skin malignancy in women and the second most common cause of cancer deaths.
- The most important risk factors are estrogenic stimulation and age.
- All cancers arise by the accumulation of DNA alterations and epigenetic changes.
- Tumorigenesis also requires changes in the normal supporting cells—alteration of the normal crosstalk and function of stromal cells may be an important determinant of stromal invasion.
- The hormonal milieu of the breast plays an important role in expanding populations of potential precursor cells, altering stroma during pregnancy, and driving the proliferation of cancers.

Types of Breast Carcinoma

Almost all (>95%) of breast malignancies are adenocarcinomas that first arise in the duct/lobular system as carcinoma in situ; at the time of clinical detection the majority (at least 70%) will have breached the basement membrane and invaded the stroma. Carcinoma in situ refers to a neoplastic proliferation of epithelial cells that is confined to ducts and lobules by the basement membrane. Invasive carcinoma (synonymous with “infiltrating” carcinoma) has penetrated through the basement membrane and grows within stroma. Here, the cells have the potential to invade into the vasculature and thereby reach regional lymph nodes and distant sites.

The terms *ductal* and *lobular* are still used to describe subsets of both in situ and invasive carcinomas, but most evidence suggests all breast carcinomas actually arise from cells in the terminal duct lobular unit. Carcinoma in situ was originally classified as DCIS or lobular carcinoma in situ (LCIS) based on the resemblance of the involved spaces to normal ducts or lobules. It is now recognized that these growth patterns are not related to the cell of origin, but rather reflect differences in tumor cell genetics and biology. By current convention, “lobular” refers to invasive carcinomas that are biologically related to LCIS, and “ductal” is used more generally for adenocarcinomas that cannot be classified as a special histologic type.

Carcinoma in Situ

Ductal Carcinoma in Situ (DCIS)

DCIS is a malignant clonal proliferation of epithelial cells limited to ducts and lobules by the basement

membrane. The term “ductal” was used to describe this lesion because when it involves lobules, the expanded acini take on an appearance resembling small ducts. Myoepithelial cells are preserved in involved ducts/lobules, although they may be diminished in number. DCIS can spread throughout the ductal system and produce extensive lesions involving an entire sector of a breast.

DCIS is almost always detected by mammography. Without screening, fewer than 5% of all carcinomas are detected when in situ, but DCIS comprises 15% to 30% of carcinomas in screened populations (Fig. 23-14). Most are identified as a result of calcifications associated with secretory material or necrosis; less commonly, periductal fibrosis surrounding DCIS forms a mammographic density or a vaguely palpable mass. Rarely, DCIS (often of micropapillary or papillary types) produces a nipple discharge or is detected as an incidental finding upon biopsy for another lesion.

MORPHOLOGY

DCIS can be divided into two major architectural subtypes, comedo and noncomedo (Fig. 23-17). Some cases of DCIS have a single growth pattern, but most are comprised of a mixture of patterns. Nuclear grade and necrosis are better predictors of local recurrence and progression to invasion than architectural type.

Comedo DCIS may occasionally produce vague nodularity, but more often it is detected on mammography as clustered or linear and branching areas of calcification (Fig. 23-17A). It is defined by two features: (1) tumor cells with pleomorphic, high-grade nuclei and (2) areas of central necrosis (Fig. 23-17B).

Noncomedo DCIS lacks either high-grade nuclei or central necrosis. Several patterns may be seen. Cribriform DCIS may have rounded (cookie cutter–like) spaces (Fig. 23-17C) within the ducts, or a solid DCIS pattern. Micropapillary DCIS produces bulbous protrusions without a fibrovascular core, often arranged in complex intraductal patterns (Fig. 23-17D). In other cases, DCIS produces true papillae with fibrovascular cores that lack a myoepithelial cell layer. Calcifications may also be seen in noncomedo forms of DCIS in association with focal necrosis or intraluminal secretions.

Paget disease of the nipple is a rare manifestation of breast cancer (1% to 4% of cases) that presents as a unilateral erythematous eruption with a scale crust. Pruritus is common, and the lesion may be mistaken for eczema. Malignant cells (Paget cells) extend from DCIS within the ductal system via the lactiferous sinuses into nipple skin without crossing the basement membrane (Fig. 23-18). The tumor cells disrupt the normal epithelial barrier, allowing extracellular fluid to seep out onto the nipple surface. The Paget cells are readily detected by nipple biopsy or cytologic preparations of the exudate.

A palpable mass is present in 50% to 60% of women with Paget disease, and almost all of these women have an underlying invasive carcinoma. The carcinomas are usually poorly differentiated, ER-negative, and overexpress HER2. In contrast, the majority of women without a palpable mass have only DCIS. Prognosis of Paget disease depends on the features of the underlying carcinoma and is not affected by the presence or absence of DCIS involving the skin when matched for other prognostic factors.

Figure 23-17 Ductal carcinoma in situ (DCIS). **A and B**, Comedo type. **A**, The specimen radiogram reveals linear and branching calcifications within the ductal system. **B**, A high-grade proliferation associated with large central zones of necrosis and calcifications fills several ducts. **C and D**, Noncomedo types. **C**, Cribriform DCIS. Note the round, regular (“cookie cutter”) spaces containing calcifying secretory material. **D**, Micropapillary DCIS. The papillary projections lack fibrovascular cores.

The natural history of DCIS has been difficult to determine because, until recently, all women were treated with mastectomy, and the current practice of surgical excision, usually followed by radiation, is largely curative. If untreated, women with small, low-grade DCIS develop invasive cancer at a rate of about 1% per year. The majority of these invasive cancers occurs in the same quadrant and have a similar grade and expression pattern of ER and HER2 as the associated DCIS. Tumors with high-grade or extensive DCIS are believed to have a higher risk for progression to invasive carcinoma.

Remarkably, the overall death rate for women with DCIS is lower than that for women in the population as a whole, possibly because mammographic screening is a “marker” for better access to medical care or other socioeconomic factors that are associated with longevity. Death

from metastatic breast cancer after a diagnosis of DCIS occurs in 1% to 3% of women. The origin of metastatic disease may be a second invasive carcinoma in the ipsilateral or contralateral breast or occult foci of invasion that were not detected at the time of DCIS diagnosis.

Mastectomy is curative in greater than 95% of women. Breast conservation is appropriate for most women but has a slightly higher risk of recurrence—about half of which are DCIS and half invasive carcinoma. The major risk factors for recurrence are (1) high nuclear grade and necrosis, (2) extent of disease, and (3) positive surgical margins. Ensuring complete excision of DCIS is not straightforward, since its distribution in the breast is not reliably predicted by imaging and it is usually not grossly evident at surgery. Postoperative radiation therapy and tamoxifen also reduce the risk of recurrence.

Figure 23-18 Paget disease of the nipple. Ductal carcinoma in situ arising within the ductal system of the breast can extend up the lactiferous ducts and into the skin of the nipple without crossing the basement membrane. The malignant cells disrupt the normally tight squamous epithelial cell barrier, allowing extracellular fluid to seep out and form an oozing scaly crust.

Lobular Carcinoma in Situ

LCIS is a clonal proliferation of cells within ducts and lobules that grow in a discohesive fashion, usually due to an acquired loss of the tumor suppressive adhesion protein E-cadherin. The term “lobular” was used to describe this lesion because the cells expand but do not distort involved spaces and, thus, the underlying lobular architecture is preserved. LCIS is always an incidental biopsy finding, since it is not associated with calcifications or stromal reactions that produce mammographic densities. As a result, its incidence (1% to 6% of all carcinomas) did not increase after the introduction of mammographic screening. When both breasts are biopsied, LCIS is bilateral in 20% to 40% of cases, compared with 10% to 20% of cases of DCIS.

The cells of atypical lobular hyperplasia, LCIS, and invasive lobular carcinoma are morphologically identical. In most cases, loss of cellular adhesion is due to dysfunction of E-cadherin, a transmembrane protein that contributes to the cohesion of normal epithelial cells in the breast and other glandular tissues. E-cadherin functions as a tumor suppressor protein in such tissues, and may be lost in neoplastic proliferations through a variety of mechanisms, including mutation of the E-cadherin gene (*CDH1*). In rare cases, there is dysregulation of other proteins, such as catenins, that are also needed for E-cadherin-mediated cellular cohesion.

MORPHOLOGY

LCIS consists of a uniform population of cells with oval or round nuclei and small nucleoli involving ducts and lobules (Fig. 23-19A). Mucin-positive signet-ring cells are commonly present. The lack of E-cadherin results in a rounded shape without attachment to adjacent cells (Fig. 23-19B). The cells cannot form cribriform spaces or papillae, such as are seen in DCIS. Pagetoid spread, the presence of neoplastic cells between the basement membrane and overlying luminal cells, is commonly seen in the breast, but LCIS does not involve nipple skin (Fig. 23-19B). Necrosis and secretory activity are not seen with classic LCIS and, thus, substrates for calcification are not present. LCIS almost always expresses ER and PR. Overexpression of HER2 is not observed.

LCIS is a risk factor for invasive carcinoma. Invasive carcinoma develops in 25% to 35% of women over 20 to 30 years time, or at a rate of about 1% per year, similar to that observed for untreated DCIS. However, unlike DCIS, the risk is almost as high in the contralateral breast as in the ipsilateral breast. Invasive carcinomas developing in women after LCIS are three-fold more likely to be lobular carcinoma; however, most are of other morphologies. Treatment choices include bilateral prophylactic mastectomy, tamoxifen, or, more typically, close clinical follow-up and mammographic screening.

Figure 23-19 Lobular carcinoma in situ. **A**, A monomorphic population of small, rounded, loosely cohesive cells fills and expands the acini of a lobule. The underlying lobular architecture can still be recognized. The cells extend into the adjacent lobule by pagetoid spread. **B**, An immunoperoxidase study shows E-cadherin-positive normal luminal cells that have been undermined by E-cadherin-negative LCIS cells spreading along the basement membrane.

Rare variants of LCIS have high-grade nuclei and/or central necrosis. The cells may be ER negative and some overexpress HER2. The natural history of this type of LCIS is not well known and may well be different from typical LCIS.

Invasive (Infiltrating) Carcinoma

Invasive carcinomas can be divided based on molecular and morphologic characteristics into several clinically important subgroups. Breast carcinomas have a wide variety of morphologic appearances. One third can be classified morphologically into special histologic types, some of which are strongly associated with clinically relevant biologic characteristics (discussed later). The remainder are grouped together and called “ductal” or no special type (NST). Recent detailed description of genomic alterations and gene and protein expression in large cohorts of breast cancers has provided a framework for a molecular classification for this group of breast cancers (Fig. 23-20 and Table 23-3). These breast cancers fall into three major molecular subtypes, each with important associations with clinical features, response to treatment, and outcome (Table 23-3).

ER-positive, HER2-negative (also termed “luminal,” 50% to 65% of cancers) is the most common form of invasive breast cancer. Based on proliferation rates, it is further divided into two subgroups.

- **ER-positive, HER2-negative, low proliferation (40% to 55% of cancers): This group of breast cancers makes up the majority of cancers in older women and in men.** It is also the most common type detected by mammographic screening and in women treated with menopausal hormone therapy. The gene expression signature of this group of cancers is dominated by genes that are directly regulated by estrogen receptor. Many of these cancers are detected at an early stage. They have the lowest incidence of local recurrence and are often cured by surgery. When these carcinomas do metastasize, it is

often after a long period of time (over 6 years) and typically to bone. They respond well to hormonal treatment and long survival with metastatic disease is possible, despite the fact that incomplete responses to chemotherapy are the rule. Indeed, in most patients chemotherapy appears to add little to hormone therapy, which is standard in this subtype of disease.

- **ER-positive, HER2-negative, high proliferation (approximately 10% of cancers):** Although these tumors are ER-positive, ER levels may be low and progesterone receptor expression may be low or absent. This is the most common type of carcinoma associated with *BRCA2* germline mutations. The mRNA expression pattern is similar to other ER-positive cancers, but there is higher expression of genes related to proliferation. These tumors tend to have a much higher burden of chromosomal aberrations than low-grade ER-positive tumors. However, unlike low-grade ER-positive cancers, about 10% of these carcinomas show a complete response to chemotherapy; such patients have a much better prognosis than patients with cancers that do not respond.

HER2-positive (approximately 20% of cancers) is the second most common molecular subtype of invasive breast cancer. About half of these cancers are ER-positive. When present, ER expression is usually low; progesterone receptor expression is often absent. These cancers are relatively more common in young women and in non-white women. More than half (53%) of familial breast cancers in patients with germline *TP53* mutations (Li-Fraumeni syndrome) develop carcinomas that are positive for both ER and HER2. The mRNA profile shows increased expression of *HER2* and flanking genes on the same amplicon, as well as genes related to proliferation. These cancers characteristically have complex interchromosomal translocations, high-level amplifications of *HER2*, and a high mutational load. Identification of cancers belonging to this subtype is achieved through assays of HER2 protein overexpression or *HER2* gene amplification (Fig. 23-21). Cancers in this

Table 23-3 Molecular Subtypes of Invasive Breast Cancer

Defining Features	ER-positive, HER2-negative		HER2-Positive (ER-Positive or Negative*)	ER-Negative† HER2-Negative
Frequency	~40-55% (Low proliferation)	~10% (High proliferation)	~20%	~15%
Included special histologic types	Well or moderately differentiated lobular, tubular, mucinous	Poorly differentiated lobular	Some apocrine	Medullary,‡ adenoid cystic,‡ secretory,‡ metaplastic
Typical patient groups	Older women, men, cancers detected by mammographic screening	<i>BRCA2</i> mutation carriers	Young women, non-white women, <i>TP53</i> mutation carriers (ER positive)	Young women, <i>BRCA1</i> mutation carriers, African American and Hispanic women
Metastatic pattern	Bone (70%), more common than visceral (25%) or brain (<10%)	Bone (80%) more common than visceral (30%) or brain (10%)	Bone (70%), visceral (45%), and brain (30%) are all common	Bone (40%), visceral (35%), brain (25%) are all common
Relapse pattern	Late, >10 years, long survival possible with metastases	Intermediate	Usually short, <10 years, survival with metastases rare	Usually short, <5 years, survival with metastases rare
Complete response to chemotherapy	<10%	~10%	ER positive—15% ER negative—>30%	~30%

*About half of HER2-positive cancers are ER positive and half ER negative. ER and PR levels tend to be low in this group.

†This group is also referred to as “triple negative” carcinoma.

‡Some special histologic types have a more favorable prognosis than this group as a whole.

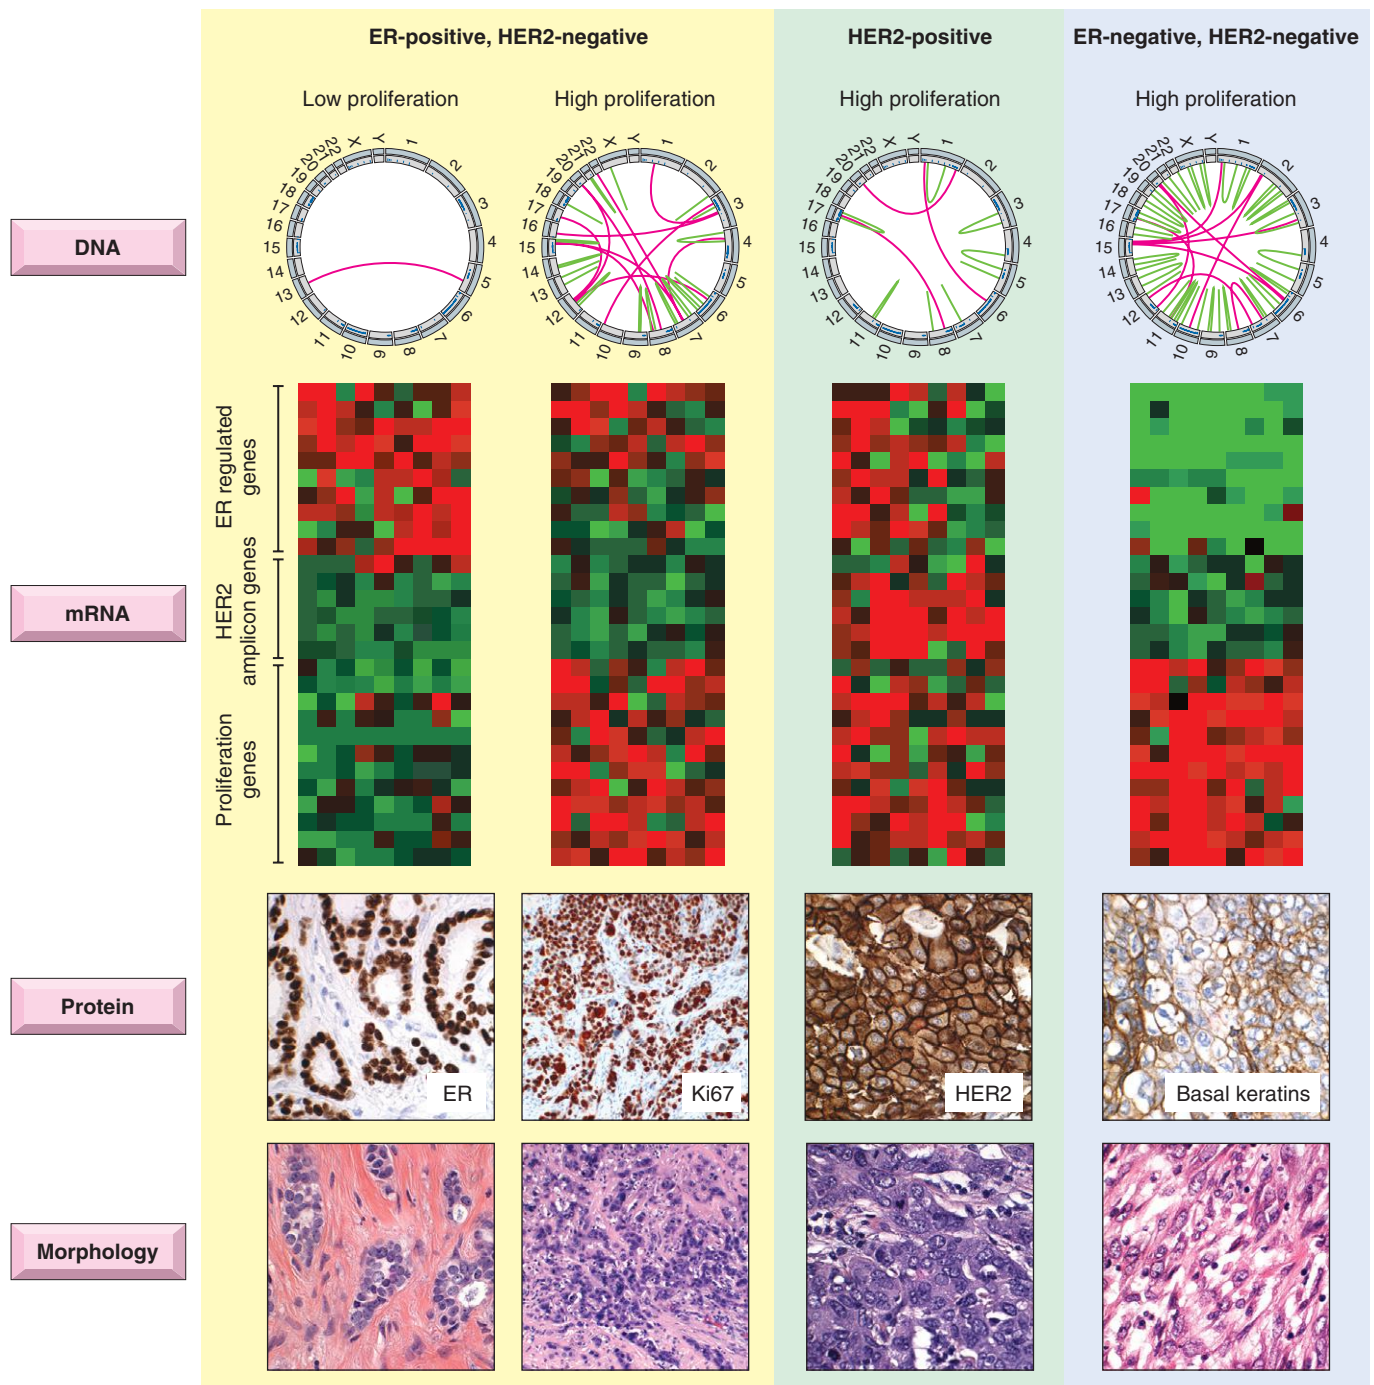

Figure 23-20 Major molecular subtypes of invasive breast cancer. Three major subtypes of breast cancer are distinguished by characteristic changes in genomic DNA, mRNA, protein, and morphology. Genomic abnormalities are shown in circos plots (Chapter 7), which present a snapshot of all of the genomic abnormalities within a particular tumor; these abnormalities are mapped onto the chromosomes, which are displayed at the periphery of a circle. Green loops show intrachromosomal rearrangements, while red loops show interchromosomal rearrangements. Gene expression profiling measures relative levels of mRNA expression. Red indicates a relative increase, green a relative decrease, and black no change in levels. Genes are arrayed from top to bottom and tumors from left to right. Immunohistochemical studies detect proteins using specific antibodies visualized by a brown chromogen. *ER-positive HER2-negative tumors* are diverse, ranging from well-differentiated cancers with low proliferative rates and few chromosomal changes to poorly differentiated cancers with high proliferative rates and large numbers of chromosomal rearrangements. All of these cancers express ER (an estrogen-dependent transcription factor). Proliferation is estimated by counting mitoses or by staining for cell cycle-specific proteins such as Ki-67. *HER2-positive cancers* may be ER-positive or ER-negative, but when ER is present, levels are typically low. HER2 positivity can be detected as an increase in HER2 gene copy number, an increase in HER2 mRNA, or an increase in HER2 protein, as shown here. *ER-negative, HER2-negative ("triple negative" or "basal-like") carcinomas* are characterized by genomic instability (denoted by numerous chromosomal changes), a high proliferative rate, and expression of many proteins typical of myoepithelial cells (e.g., basal keratins).

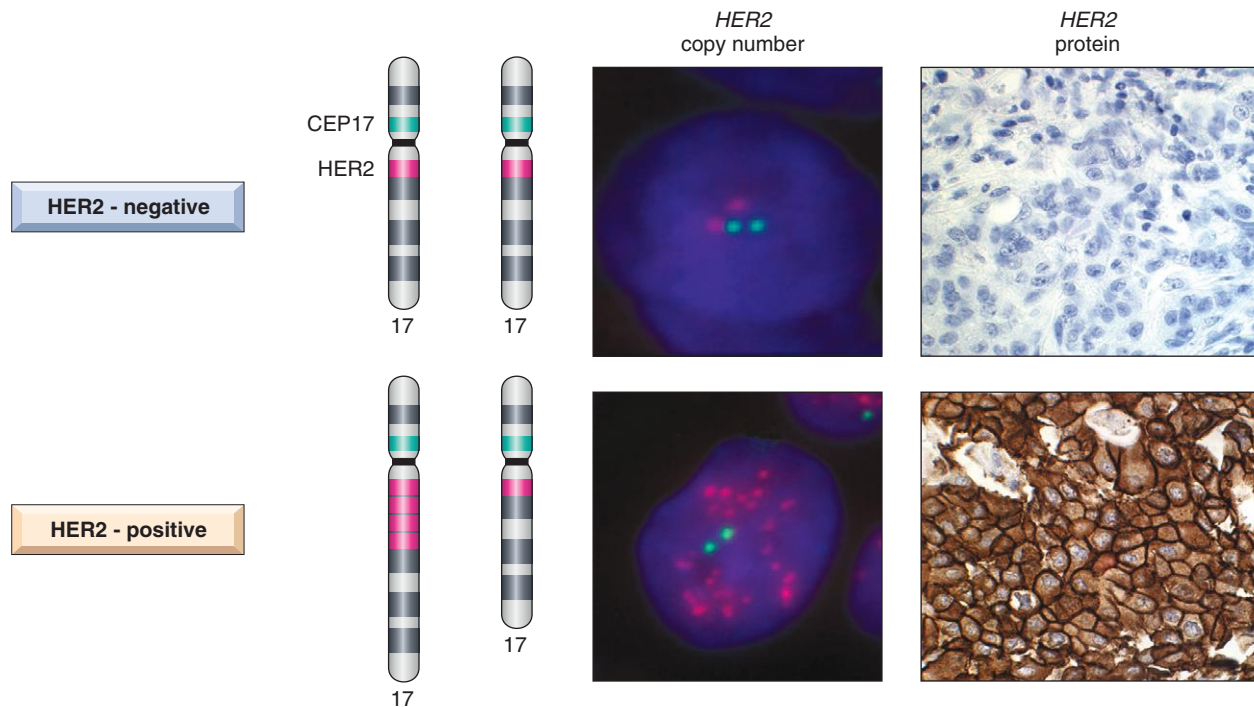

Figure 23-21 Identification of HER2-positive breast cancer. HER2 protein overexpression is virtually always caused by amplification of the region of chromosome 17q that contains the *HER2* gene. The increase in *HER2* gene copy number is detected by fluorescence in situ hybridization (FISH) using a *HER2*-specific probe (red signal), which is typically co-hybridized to tumor cell nuclei with a second probe specific for the centromeric region of chromosome 17 (green signal), allowing the chromosome 17 copy number to be determined. Alternatively, HER2 protein overexpression in tumor cells can be detected by immunohistochemical staining with antibodies specific for HER2.

group can metastasize when small in size and early in the course, often to viscera and brain.

Before the implementation of HER2-targeted therapy, HER2-positive cancers were associated with a poor clinical outcome. However, one third or more of these carcinomas respond completely to antibodies that bind and block HER2 activity, and such patients now have an excellent prognosis. The remarkable efficacy of this form of therapy proves the importance of HER2 as an oncogenic “driver.”

While the introduction of trastuzumab (Herceptin), a humanized monoclonal antibody that specifically binds and inhibits HER2, markedly improved the outlook for patients with HER2 overexpressing cancers, not all HER2-positive carcinomas respond and some that do become resistant to treatment. Multiple mechanisms of primary or acquired resistance have been described. Some tumors express a truncated form of HER2 that lacks the trastuzumab-binding site but retains kinase activity, while others upregulate downstream pathways, such as the PI-3 kinase pathway. Numerous therapeutic agents are under investigation to improve response and overcome resistance to trastuzumab, including new antibodies that bind different HER2 epitopes; dual tyrosine kinase inhibitors that target both EGFR and HER2; antibody-toxin conjugates (one of which is now approved for use); and inhibitors of downstream signaling components, such as PI-3 kinase and AKT.

ER-negative, HER2-negative tumors (“basal-like” triple negative carcinoma; approximately 15% of cancers) are the third major molecular subtype. These cancers are more common in young premenopausal women as well as African American (20% to 25% of carcinomas in this group)

and Hispanic women (17% of carcinomas in this group). The majority of carcinomas arising in women with *BRCA1* mutations are of this type. Due to high proliferation and rapid growth, this type of cancer is particularly likely to present as a palpable mass in the interval between mammographic screenings.

ER-negative, HER2-negative tumors are the most distinctive group of breast cancers. They share a number of genetic similarities with serous ovarian carcinomas, including the association of familial cancers of both types with germline *BRCA1* mutations. Nevertheless, in some cases features are present that overlap with other molecular subgroups. For example, about 10% of basal-like cancers (as defined by gene expression profiling) express ER and about 15% express HER2. Thus, assays for protein expression or gene amplification must be done to determine whether treatment targeting ER or HER2 is indicated. These cancers can metastasize when small in size, frequently to viscera and to the brain. However, approximately 30% completely respond to chemotherapy and cure may be possible in this chemosensitive subgroup. Recurrences are generally diagnosed within 5 years of treatment. Local recurrence is common, even after mastectomy. Prolonged survival after distant metastasis is rare.

MORPHOLOGY

Invasive carcinomas presenting on mammography as calcifications without an associated density are generally less than 1 cm in size. In the absence of mammographic screening, invasive carcinoma usually presents as a mass of at

Figure 23-22 Invasive carcinoma of no special type. The majority of invasive carcinomas have a haphazard pattern of stromal invasion that produce masses with irregular margins on imaging (**A**) and gross examination (**B**). Microscopically, such tumors are marked by an exuberant desmoplastic stromal response (**C**). A subset of carcinomas grows as masses that appear to be well circumscribed or lobulated by imaging (**D**) and by gross inspection (**E**). Microscopically, such cancers typically take on the appearance of expansile masses of cells with pushing borders; stromal response is often limited to a narrow zone of fibrosis at the tumor margin (**F**). Rarely, invasive cancers produce little or no stromal response. Such cancers may only show subtle architectural distortion on mammography (**G**) and may not produce palpable masses or be identifiable grossly (**H**). Microscopically, tumor cells are found scattered within normal appearing fibroadipose tissue (**I**). (**B**, Courtesy of Dr. David Hicks, University of Rochester Medical Center, Rochester, NY.)

least 2 to 3 cm in size. The mammographic and gross appearance of invasive carcinoma varies widely depending on the stromal reaction to the tumor (Fig. 23-22). They most commonly present as a hard, irregular radiodense mass (Fig. 23-22A, B) associated with a desmoplastic stromal reaction (Fig. 23-22C). When cut or scraped, such tumors typically produce a

characteristic grating sound (similar to cutting a water chestnut) due to small, central pinpoint foci or streaks of chalky-white desmoplastic stroma and occasional foci of calcification. Less commonly, tumors present as deceptively well-circumscribed (Fig. 23-22D, E) masses composed of sheets of tumor cells with scant stromal reaction (Fig. 23-22F), or may be almost

Figure 23-23 Grading of invasive carcinoma. **A**, A well-differentiated carcinoma of no special type consists of tubules or a cribriform pattern of cells with small monomorphic nuclei. **B**, A moderately differentiated carcinoma of no special type shows less tubule formation and more solid nests of cells and pleomorphic nuclei. **C**, A poorly differentiated carcinoma of no special type infiltrates as ragged sheets of pleomorphic cells and contains numerous mitotic figures and central areas of tumor necrosis.

imperceptible (Fig. 23-22G, H), being comprised of scattered neoplastic glands or single tumor cells infiltrating otherwise unremarkable fibrofatty tissue (Fig. 23-22I).

Larger carcinomas may invade the pectoralis muscle and be fixed to the chest wall or invade into the dermis and cause dimpling of the skin. When the tumor involves the central portion of the breast, retraction of the nipple may develop. Rarely, breast cancer presents as metastasis to an axillary node or distant metastasis before cancer is detected in the breast. In such cases, the primary carcinoma may be small, or be obscured by dense breast tissue, or fail to produce a desmoplastic response, making it difficult to detect by palpation or mammography. In most cases, these “occult” primary tumors can now be detected by imaging studies using ultrasound or MRI.

All types of invasive carcinoma are graded using the Nottingham Histologic Score. Carcinomas are scored for tubule formation, nuclear pleomorphism, and mitotic rate and the points added to divide carcinomas into grade I (well differentiated), grade II (moderately differentiated), and grade III (poorly differentiated) types. **Grade I** carcinomas grow in a tubular pattern with small round nuclei and have a low proliferative rate (Fig. 23-23A). **Grade II** carcinomas may also show some tubule formation, but solid clusters or single infiltrating cells are also present. There is a greater degree of nuclear pleomorphism and mitotic figures are present (Fig. 23-23B). **Grade III** carcinomas invade as ragged nests or solid sheets of cells with enlarged irregular nuclei. A high proliferative rate and areas of tumor necrosis are common (Fig. 23-23C).

ER-positive, HER2-negative carcinoma. Many morphologic patterns are possible, with grades ranging from well to poorly differentiated. Essentially all well differentiated carcinomas are in this group. Mucinous, papillary, cribriform, and lobular patterns may be present and may be so prominent as to prompt classification as a special histologic type (described later).

HER2-positive carcinoma. The majority of these carcinomas are poorly differentiated with only a few classified as moderately differentiated. There is no specific morphologic pattern associated with this cell type. About 50% of apocrine carcinomas and 40% of micropapillary carcinomas (described later) are in this group. The associated DCIS is often more extensive than that associated with other types of invasive carcinoma.

ER-negative, HER2-negative carcinomas. Almost all of these tumors are poorly differentiated and several typical histologic patterns are recognized. Many have circumscribed pushing borders with a central fibrotic or necrotic center. Others have a similar appearance but with a prominent lymphocytic infiltrate and fall into the group of “carcinomas with medullary features” (described later). Spindle cell, squamous, and matrix producing patterns can also be seen. DCIS is generally very limited or not present.

Special Histologic Types of Invasive Carcinoma

Multiple subtypes of invasive carcinoma are recognized with distinctive morphologies and relatively unique biologic characteristics. Like breast cancers of “no special type,” these special tumors can be organized into groups based on expression of ER and HER2, which carry their usual therapeutic implications. However, special histologic types of breast cancer often harbor unique genetic aberrations, sometimes have distinct gene signatures, and frequently show associations with clinical behavior and prognosis that break the “rules” that have been established for breast cancers of no special type. Although relatively uncommon, study of these tumors has also provided important insights into breast cancer pathogenesis, some of which merit brief discussion.

Lobular carcinoma is the subtype with the clearest association of phenotype and genotype. Most cases show biallelic loss of expression of *CDH1*, the gene that encodes E-cadherin. Due to loss of E-cadherin, lobular carcinomas are discohesive and often fail to incite a desmoplastic response. They also have characteristic patterns of metastatic spread, often involving the peritoneum and retroperitoneum, the leptomeninges (carcinomatous meningitis), the gastrointestinal tract, and the ovaries and uterus. Males and females with heterozygous germline mutations in *CDH1* also have a greatly increased risk of gastric signet ring cell carcinoma.

Medullary carcinoma is of great interest due to the finding that many tumors of this type have features that are characteristic of *BRCA1*-associated carcinomas. Among cancers arising in *BRCA1* carriers, 13% are of medullary type, and up to 60% have a subset of medullary features (Table 23-3). Although the majority of medullary carcinomas are not associated with germline *BRCA1* mutations, hypermethylation of the *BRCA1* promoter leading to downregulation of *BRCA1* expression is observed in 67% of these tumors. The basis for the relatively good prognosis of this subtype compared to other poorly differentiated carcinomas is not known, but it has been noted that the presence of lymphocytic infiltrates within the tumors is associated with higher survival rates and a greater response to chemotherapy, suggesting that improved outcomes may be related to a host immune response to tumor antigens.

Micropapillary carcinoma shows a characteristic pattern of anchorage-independent growth. Although the cells are adherent to each other and express E-cadherin, they lack adhesion to the stroma.

Many of the other special histologic types of breast cancer (too numerous to list) also have unique biologic, genetic and clinical features. There is much that remains

to be learned about the biology and pathogenesis of these tumors, some of which are described below.

MORPHOLOGY

Some special histologic types of cancer are almost always ER-positive and have gene expression profiles that resemble luminal cancers. These include lobular carcinoma, mucinous carcinoma, tubular carcinoma, and papillary carcinoma.

Lobular carcinoma most commonly forms hard irregular masses similar to other breast cancers, but (as already mentioned) may also have a diffuse infiltrative pattern with minimal desmoplasia. Such cancers can be difficult to palpate or detect by imaging. This is the most common type of breast carcinoma to present as an occult primary. The histologic hallmark is the presence of discohesive infiltrating tumor cells, often including signet-ring cells containing intracytoplasmic mucin droplets (Fig. 23-24A). Tubule formation is absent. Alveolar and solid variants consist of circumscribed clusters of tumor cells.

Mucinous (colloid) carcinoma is soft or rubbery and has the consistency and appearance of pale gray-blue gelatin. The borders are pushing or circumscribed. The tumor cells are arranged in clusters and small islands of cells within large lakes of mucin (Fig. 23-24B).

Tubular carcinoma consists exclusively of well-formed tubules and is sometimes mistaken for a benign sclerosing lesion (Fig. 23-24C). A cribriform pattern may also be present. Apocrine snouts are typical, and calcifications may be present within the lumens. Tubular carcinomas are frequently associated with flat epithelial atypia, atypical lobular hyperplasia, LCIS, or low-grade DCIS.

Papillary carcinoma, as the name implies, produces true papillae, fronds of fibrovascular tissue lined by tumor cells (Fig. 23-24D).

Figure 23-24 Special histologic types of invasive carcinoma. **A**, Lobular carcinoma. **B**, Mucinous carcinoma. **C**, Tubular carcinoma. **D**, Papillary carcinoma. **E**, Apocrine carcinoma. **F**, Micropapillary carcinoma. **G**, Medullary carcinoma. **H**, Secretory carcinoma. See text for morphologic descriptions.

Two special histologic types frequently overexpress HER2. The tumor cells of **apocrine carcinoma** resemble the cells that line sweat glands. These cells have enlarged round nuclei with prominent nucleoli and abundant eosinophilic, occasionally granular, cytoplasm (Fig. 23-24E). **Micropapillary carcinoma** (a misnomer) forms hollow balls of cells that float within intercellular fluid, creating structures that mimic the appearance of true papillae (Fig. 23-24F).

ER-negative, HER2-negative tumors often correspond to one of several special histologic types. Chief among these is **medullary carcinoma**. Medullary carcinoma is softer than other carcinomas (*medulla* is Latin for “marrow”) due to minimal desmoplasia, and often presents as a well-circumscribed mass. It is characterized by (1) solid, syncytium-like sheets of large cells with pleomorphic nuclei, and prominent nucleoli, which compose more than 75% of the tumor mass; (2) frequent mitotic figures; (3) a moderate to marked lymphoplasmacytic infiltrate surrounding and within the tumor; and (4) a pushing (noninfiltrative) border (Fig. 23-24G). DCIS is minimal or absent. Due to difficulties in defining this subtype, the current World Health Organization classification system recommends grouping medullary carcinomas with similar carcinomas into one group termed “carcinomas with medullary features.”

Other ER-negative, HER2-negative special histologic types include secretory carcinoma, spindle cell carcinoma, low-grade adenosquamous carcinoma, and adenoid cystic carcinoma. **Secretory carcinoma** mimics lactating breast by forming dilated spaces filled with eosinophilic material (Fig. 23-24H).

Another clinical and morphologic subtype that merits brief mention is **inflammatory carcinoma**. As discussed earlier, these tumors show extensive invasion and proliferation within lymphatic channels, causing swelling that mimics non-neoplastic inflammatory lesions. These tumors are usually of high grade, but do not belong to any particular molecular subtype.

Male Breast Cancer

The incidence in breast cancer in men is only 1% of that in women, which translates to a lifetime risk of 0.11%. There are about 2000 cases and 400 deaths in the United States each year. Risk factors are similar to those in women and include increasing age, first-degree relatives with breast cancer, exposure to exogenous estrogens or ionizing radiation, infertility, obesity, prior benign breast disease, and residency in Western countries. From 3% to 8% of cases are associated with Klinefelter syndrome and decreased testicular function. The typical age at diagnosis is between 60 and 70 years. From 4% to 14% of cases in males are attributed to germline *BRCA2* mutations. There is a 60% to 76% chance of a *BRCA2* mutation in families with at least one affected male. Male breast cancer is also observed in *BRCA1* families, although not as frequently (Table 23-2).

The pathology of male breast cancer is remarkably similar to that of cancers seen in women. However, ER positivity is more common (81% of tumors). Prognostic factors are similar in men and women.

Because breast epithelium in men is limited to large ducts near the nipple, carcinomas usually present as a palpable subareolar mass, 2 to 3 cm in size and/or as nipple discharge. The carcinoma is situated close to the overlying skin and underlying thoracic wall, and even small

carcinomas can invade these structures and cause ulceration. Dissemination follows the same pattern as in women, and axillary lymph node involvement is present in about half of cases at the time of diagnosis. Distant metastases to the lungs, brain, bone, and liver are common. Although men present at higher stages, prognosis is similar in men and women when they are matched stage for stage. Most cancers are treated locally with mastectomy and axillary node dissection. The same systemic treatment guidelines are used for men and women, and response rates are similar.

Prognostic and Predictive Factors

The outcome for women with breast cancer depends on the biologic features of the carcinoma (molecular or histologic type) and the extent to which the cancer has spread (stage) at the time of diagnosis. Many women with breast cancer have a normal life expectancy, whereas others have only a 10% chance of being alive in 5 years. Tumors that present with distant metastasis (<10% of breast cancer cases) or with inflammatory carcinoma (<5%) have a particularly poor prognosis. For all other women, prognosis is determined by pathologic examination of the primary carcinoma and the axillary lymph nodes.

Prognostic information is important in counseling patients about the likely outcome of their disease, choosing appropriate treatment, and the design of clinical trials. Prognostic factors fall into two groups—those related to the extent of carcinoma (tumor burden or stage) and those related to the underlying biology of the cancer. Prognostic factors related to extent of carcinoma are as follows:

- **Invasive carcinoma versus carcinoma in situ.** Women with in situ carcinoma understandably have an excellent prognosis. Only rarely do such patients die due to the subsequent development of invasive carcinoma or areas of invasion that were not detected at the time of diagnosis.
- **Distant metastases.** Once distant metastases are present, cure is unlikely, although long-term remissions and palliation can be achieved, especially in women with ER-positive tumors. As discussed earlier, the tumor type influences the timing and location of metastases (Table 23-3).
- **Lymph node metastases. Axillary lymph node status is the most important prognostic factor for invasive carcinoma in the absence of distant metastases.** The clinical assessment of lymph node status is unreliable due to both false positives (e.g., palpable reactive nodes) and false negatives (e.g., lymph nodes with small metastatic deposits). Therefore, biopsy is necessary for accurate assessment. With no nodal involvement, the 10-year disease-free survival rate is close to 70% to 80%; the rate falls to 35% to 40% with one to three positive nodes, and to 10% to 15% when more than 10 nodes are positive. Lymphatic vessels in most breast carcinomas drain first to one or two *sentinel nodes*, which can be identified with radiotracer or colored dyes. If a biopsy restricted to the sentinel nodes is negative for metastasis, it is unlikely that other more distant nodes will be involved and the patient can be spared the morbidity of a complete axillary dissection. Approximately 10% to 20% of women

without axillary lymph node metastases recur with distant metastasis. In these patients, metastasis may occur via the internal mammary lymph nodes or hematogenously. Up until recently, nodal status has been a major determinant of treatment choice. As this decision shifts to being based on the molecular type of carcinoma (discussed below), the information gained from nodal status is becoming less important. It is likely that in the future many women will not undergo node sampling.

- **Tumor size.** The risk of axillary lymph node metastases increases with the size of the primary tumor, but both are independent prognostic factors. Women with node-negative carcinomas less than 1 cm in size have a 10-year survival rate of more than 90%, whereas survival drops to 77% for cancers greater than 2 cm. Size is less important for HER2-positive and ER-negative carcinomas, as these carcinomas can metastasize even when quite small.
- **Locally advanced disease.** Carcinomas invading into skin or skeletal muscle are usually large and may be difficult to treat surgically. With increased awareness of breast cancer detection, such cases have fortunately decreased in frequency and are now rare at presentation.
- **Inflammatory carcinoma.** Breast cancers presenting with breast erythema and skin thickening have a very poor prognosis, as most patients prove to have distant metastases. The edematous skin is tethered to the breast by Cooper ligaments and mimics the surface of an orange peel, an appearance referred to as *peau d'orange*. These clinical signs are caused by dermal lymphatics filled with metastatic carcinoma that blocks lymphatic drainage. The 3-year survival rate is only 3% to 10%. Fewer than 3% of cancers are in this group, but the incidence is higher in African American women and younger women. The underlying carcinoma is usually diffusely infiltrative and typically does not

Figure 23-25 Ten-year survival according to AJCC/UICC stage (Table 23-4). Survival is strongly correlated with the extent of disease at the time of diagnosis.

form a discrete palpable mass. The presentation of a swollen breast without a mass can be confused with a breast infection, leading to delayed diagnosis. These carcinomas are not of a uniform specific histologic or molecular type, and thus are classified as “inflammatory” based on the clinical presentation. More than half (60%) are ER-negative and 40% to 50% overexpress HER2.

- **Lymphovascular invasion.** Tumor cells are present within vascular spaces (either lymphatics or small capillaries) in about half of all invasive carcinomas. This finding is strongly associated with the presence of lymph node metastases. It is a poor prognostic factor for overall survival in women without lymph node metastases and a risk factor for local recurrence. As already mentioned, extensive plugging of the lymphovascular spaces of the dermis with carcinoma cells (inflammatory carcinoma) bodes a very poor prognosis.

Other prognostic factors are related to tumor biology, as follows:

- **Molecular subtype.** The molecular subtype, determined by expression of ER and HER2 and proliferation, is an important prognostic factor
- **Special histologic types.** The survival rate of women with some special types of invasive carcinomas (tubular, mucinous, lobular, papillary, adenoid cystic) is greater than that of women with cancers of no special type. Alternatively, women with metaplastic carcinoma or micropapillary carcinoma have a poorer prognosis. In other special subtypes, particularly adenoid cystic carcinoma, low-grade adenosquamous carcinoma, and secretory carcinoma in young women, the histologic

Figure 23-26 Biologic (intrinsic) breast cancer type predicts clinical outcome. Overall survival and disease-free survival are shown for the most favorable biologic type (well-differentiated, ER-positive, HER2-negative, low proliferation) and least favorable biologic type (poorly differentiated, ER-negative and/or HER2-positive). See text for other details.

Table 23-4 American Joint Committee on Cancer and Union Contre Le Cancer Staging*

Stage	T: Primary Cancer	N: Lymph Nodes	M: Distant Metastasis	10-Year Survival (%)
0	DCIS or LCIS	No metastases	Absent	92
I	Invasive carcinoma ≤2 cm	No metastases or only micrometastases	Absent	87
II	Invasive carcinoma >2 cm	1 to 3 positive LNs	Absent	65
	Invasive carcinoma >5 cm but ≤5 cm	0 to 3 positive LNs	Absent	
III	Invasive carcinoma >5 cm	Negative or positive LNs	Absent	40
	Any size invasive carcinoma	≥4 positive LNs	Absent	
	Invasive carcinoma with skin or chest wall involvement or inflammatory carcinoma	Negative or positive LNs	Absent	
IV	Any size invasive carcinoma	Negative or positive lymph nodes	Present	5

DCIS, Ductal carcinoma in situ; LCIS, lobular carcinoma in situ.

*The groups listed in the table are based on the characteristics of the primary carcinoma and the axillary lymph nodes. For rare women with involved internal mammary lymph nodes or supraclavicular lymph nodes, there are additional staging criteria.

type is more strongly correlated with prognosis than the molecular type.

- **Histologic grade.** All invasive carcinomas are graded using the Nottingham Histologic Score (already described). Nuclear grade, tubule formation, and mitotic rate classify invasive carcinomas into three groups that are highly correlated with disease free and overall survival.
- **Proliferative rate.** Proliferation can be measured by mitotic counts (e.g., as part of histologic grading), by immunohistochemical detection of proteins that are specifically expressed by actively dividing cells (e.g., cyclins, Ki-67). Proliferation is primarily important for ER-positive, HER2-negative carcinomas, as the majority of ER-negative and/or HER2 positive carcinomas have high proliferative rates. Carcinomas with high proliferation rates have a poorer prognosis but may respond better to chemotherapy.
- **Estrogen and progesterone receptors.** Eighty percent of carcinomas that are both ER- and PR-positive respond to hormonal manipulation, whereas only about 40% of those positive for only ER or PR respond. Strongly ER-positive cancers are less likely to respond to chemotherapy. Conversely, cancers that fail to express either ER or PR have a less than 10% likelihood of responding to hormonal therapy but are more likely to respond to chemotherapy.
- **HER2.** HER2 overexpression is associated with poorer survival, but its main importance is as a predictor of response to agents that target this receptor.

For decades, the prognosis of breast cancer patients has been estimated by gauging the extent of disease in the breast, the involvement of regional lymph nodes, and the presence of distant metastases. The five stages (0 to IV) defined by the American Joint Committee on Cancer (AJCC) and Union Contre Le Cancer (UICC) are highly correlated with survival (Table 23-4 and Fig. 23-25). More recently, insights gained by studying the molecular biology of breast cancers has improved outcome prediction (Fig. 23-26).

In the absence of adequate surgery, the majority of patients with breast cancer die with extensive local disease causing ulceration of the skin. *Carcinoma en cuirasse* (literally “carcinoma of the breastplate”) is a dreaded

complication that must be prevented in order to maintain the best possible quality of life, even in women with distant metastatic disease. Unfortunately, it remains a common presentation for women living in areas with limited resources. With earlier detection, local control of the disease can be achieved in the majority of women with breast conserving surgery and radiation. Carcinoma in situ and small node negative invasive carcinomas are often cured by this treatment alone. For those who require mastectomy, skin- and nipple-sparing procedures provide cosmetically superior results.

KEY CONCEPTS

Types of Carcinoma, Prognostic Factors

- DCIS is treated locally, as subsequent invasive carcinomas usually occur at the same site, whereas LCIS confers bilateral risk.
- Invasive carcinomas can be classified into molecular types based on expression of hormone receptors and HER2 along with proliferative rate.
- Molecular types have important clinical, biologic, and therapeutic associations.
- Special histologic types of carcinomas tend to have distinctive pathways of tumorigenesis and are providing additional clues linking biologic changes to clinical behavior.
- Prognosis is dependent on both the biologic type of cancer (molecular or histologic type) and the extent of cancer at the time of diagnosis (stage).
- Effective treatment requires both local and systemic control of disease.
- Improvements in treatment are being made as new targeted therapies are being developed and response to treatment is better understood.

Stromal Tumors

The two types of stroma in the breast, intralobular and interlobular give rise to distinct types of neoplasms. The breast-specific biphasic tumors fibroadenoma and phyllodes tumor arise from intralobular stroma. This

specialized stroma may elaborate growth factors for epithelial cells, resulting in the proliferation of the non-neoplastic epithelial component of these tumors. Interlobular stroma is the source of the same types of tumors found in connective tissue in other sites of the body (e.g., lipomas and angiosarcomas) as well as tumors arising more commonly in the breast (e.g., pseudoangiomatous stromal hyperplasia, myofibroblastomas, and fibrous tumors).

Fibroadenoma

Fibroadenomas are the most common benign tumor of the female breast. Most occur in women in their 20s and 30s, and they are frequently multiple and bilateral. Young women usually present with a palpable mass and older women with a mammographic density (Fig. 23-27A) or clustered calcifications. The epithelial component is hormonally responsive and there is typically an increase in size due to lactational changes during pregnancy. Such increases in size may be complicated by infarction and inflammation, and may raise a false suspicion of carcinoma.

Figure 23-27 Fibroadenoma. **A**, The radiograph shows a characteristically well-circumscribed mass. **B**, Grossly, a rubbery, white, well-circumscribed mass is clearly demarcated from the surrounding yellow adipose tissue. The absence of adipose tissue accounts for the radiodensity of the lesion. **C**, The proliferation of intralobular stroma surrounds, pushes, and distorts the associated epithelium. The border is sharply delimited from the surrounding tissue.

MORPHOLOGY

Fibroadenomas vary in size from less than 1 cm to large tumors that replace most of the breast. The tumors are well-circumscribed, rubbery, grayish white nodules that bulge above the surrounding tissue and often contain slitlike spaces (Fig. 23-27B).

The delicate and often myxoid stroma resembles normal intralobular stroma. The epithelium may be surrounded by stroma (pericanicular pattern) or compressed and distorted by it (intracanicular pattern) (Fig. 23-27C). In older women, the stroma typically becomes densely hyalinized and the epithelium atrophic.

Many fibroadenomas are polyclonal hyperplasias of lobular stroma. For example, almost half of women receiving cyclosporin A after renal transplantation develop multiple and bilateral fibroadenomas that regress after cessation of treatment. Other fibroadenomas are benign neoplasms associated with clonal cytogenetic aberrations that are confined to the stromal component. No consistent cytogenetic changes have been found.

Fibroadenomas are grouped with “proliferative changes without atypia” in conferring a mildly increased risk of subsequent cancer. However, in one study the increased risk was limited to fibroadenomas associated with cysts larger than 0.3 cm, sclerosing adenosis, epithelial calcifications, or papillary apocrine change (“complex fibroadenomas”) (Table 23-1).

Phyllodes Tumor

Phyllodes tumors, like fibroadenomas, arise from intralobular stroma, but are much less common. Although they can occur at any age, most present in the sixth decade, 10 to 20 years later than the peak age for fibroadenomas. The majority are detected as palpable masses, but a few are found by mammography. *Cystosarcoma phyllodes* is a term sometimes used for these lesions. However, *phyllodes tumor* is preferred, since most behave in a relatively benign fashion and are not cystic.

Phyllodes tumors are associated with clonal acquired chromosomal changes, with gains in chromosome 1q being the most frequent. Increased numbers of chromosomal aberrations and overexpression of the homeobox transcription factor HOXB13 are associated with higher tumor grade and more aggressive clinical behavior.

MORPHOLOGY

The tumors vary in size from a few centimeters to massive lesions involving the entire breast. The larger lesions often have bulbous protrusions (*phyllodes* is Greek for “leaflike”) due to the presence of nodules of proliferating stroma covered by epithelium (Fig. 23-28). In some tumors these protrusions extend into a cystic space. This growth pattern can also occasionally be seen in larger fibroadenomas and is not an indication of malignancy. Phyllodes tumors are distinguished from fibroadenomas on the basis of higher cellularity, higher mitotic rate, nuclear pleomorphism, stromal overgrowth, and infiltrative borders. Low-grade lesions resemble fibroadenomas but are more

Figure 23-28 Phyllodes tumor. Compared to a fibroadenoma, there is increased stromal cellularity and overgrowth, giving rise to the typical leaflike architecture.

cellular and are mitotically active. High-grade lesions may be difficult to distinguish from malignant sarcomas and may have foci of mesenchymal differentiation (e.g., resembling rhabdomyosarcoma or liposarcoma).

Most phyllodes tumors are low-grade; these occasionally recur locally but do not metastasize. In contrast, intermediate and high-grade phyllodes tumors often recur locally unless they are treated with wide excision or mastectomy. Regardless of grade, lymphatic spread is rare and axillary lymph node dissection is contraindicated. The uncommon high-grade lesions give rise to distant hematogenous metastases in about one third of cases. Only the stromal component metastasizes.

Lesions of Interlobular Stroma

Tumors of the interlobular stroma of the breast are composed of stromal cells without an accompanying epithelial component. These include benign tumors as well as malignant tumors, all uncommon and hence considered briefly. *Myofibroblastoma* consists of myofibroblasts and is unusual in that it is the only breast tumor that is equally common in males. *Lipomas* are often palpable but can also be detected mammographically as fat-containing lesions. The only importance of these lesions is to distinguish them from malignancies.

Fibromatosis is a clonal proliferation of fibroblasts and myofibroblasts. It presents as an irregular, infiltrating mass that can involve both skin and muscle. Though locally aggressive, this lesion does not metastasize. Some cases are associated with prior trauma or surgery. Other cases occur as part of familial adenomatous polyposis, hereditary desmoid syndrome, and Gardner syndrome.

Malignant Tumors of Interlobular Stroma

Malignant stromal tumors include angiosarcoma, rhabdomyosarcoma, liposarcoma, leiomyosarcoma, chondrosarcoma, and osteosarcoma. The only sarcoma that occurs

with any frequency in the breast is angiosarcoma—however, it accounts for less than 0.05% of breast malignancies. *Angiosarcomas of the breast* can be sporadic or arise as a complication of therapy. Most sporadic angiosarcomas occur in the breast parenchyma of young women (mean age 35), are of high grade, and have a poor prognosis. Treatment related tumors arise secondary to radiation or edema. After radiation therapy, approximately 0.3% of women develop angiosarcomas in breast skin, with most cases being diagnosed 5 to 10 years after treatment.

Other Malignant Tumors of the Breast

Malignancies of the breast arising from lymphocytes or skin, or metastatic from another site, comprise less than 5% of breast cancers. *Non-Hodgkin lymphoma* may arise primarily in the breast, or the breasts may be secondarily involved by systemic disease. Most primary breast lymphomas are of B-cell type, while rare T cell lymphomas may arise in the scar capsule that is associated with breast implants, possibly due to chronic inflammation, which is known to stimulate lymphoma development in other contexts. Young women with Burkitt lymphoma may present with massive bilateral breast involvement and are often pregnant or lactating. Malignant tumors may arise from the skin and dermis of the breast; these tumors are identical to their counterparts found in skin elsewhere (Chapter 25). Metastases to the breast are rare and most commonly arise from melanomas and ovarian cancers.

KEY CONCEPTS

Stromal Lesions and Other Malignant Tumors

- Intralobular stroma is the origin of the biphasic tumors, fibroadenoma and phyllodes tumor.
- Fibroadenomas are the most common benign tumor of the breast.
- Tumors of interlobular stroma consist only of stromal cells and include both benign and malignant lesions.
- Angiosarcoma is the most common stromal malignancy and can either be sporadic or associated with radiation exposure or lymphedema.

PINEAL GLAND 1137

- Pinealomas 1137

The endocrine system consists of a highly integrated and widely distributed group of organs that orchestrate a state of metabolic equilibrium among the various organs of the body. Signaling by secreted molecules can be classified into three types—autocrine, paracrine, or endocrine—on the basis of the distance over which the

signal acts. **In endocrine signaling, the secreted molecules, also known as hormones, act on target cells that are distant from their sites of synthesis.** An endocrine hormone is frequently carried by the blood from its site of release to its target. In response, the target tissue often secretes factors that down-regulate the activity of the gland

that produces the stimulating hormone, a process known as *feedback inhibition*.

Several processes can disturb the normal activity of the endocrine system, including impaired synthesis or release of hormones, abnormal interactions between hormones and their target tissues, and abnormal responses of target organs. Endocrine diseases can be generally classified as (1) diseases of *underproduction or overproduction* of

hormones and their resulting biochemical and clinical consequences, and (2) diseases associated with the development of *mass lesions*. Such lesions might be nonfunctional, or they might be associated with overproduction or underproduction of hormones. The study of endocrine diseases requires integration of morphologic findings with biochemical measurements of the levels of hormones, their regulators, and other metabolites.

PITUITARY GLAND

The pituitary gland is composed of two morphologically and functionally distinct components: the anterior lobe (adenohypophysis) and the posterior lobe (neurohypophysis). The *anterior pituitary* constitutes about 80% of the gland. The production of most pituitary hormones is controlled in large part by positively and negatively acting factors from the hypothalamus (Fig. 24-1), which are carried to the anterior pituitary by a portal vascular system.

In routine histologic sections of the anterior pituitary, a colorful array of cells is present that contain eosinophilic cytoplasm (*acidophil*), basophilic cytoplasm (*basophil*), or poorly staining cytoplasm (*chromophobe*) cells (Fig. 24-2). There are six terminally differentiated cell types in the anterior pituitary, including:

- Somatotrophs, producing growth hormone (GH)
- Mammosomatotrophs, producing GH and prolactin (PRL)
- Lactotrophs, producing PRL
- Corticotrophs, producing adrenocorticotropic hormone (ACTH) and pro-opiomelanocortin (POMC), melanocyte-stimulating hormone (MSH)
- Thyrotrophs, producing thyroid-stimulating hormone (TSH), and
- Gonadotrophs, producing follicle-stimulating hormone (FSH) and luteinizing hormone (LH). FSH stimulates

the formation of graafian follicles in the ovary, and LH induces ovulation and the formation of corpora lutea in the ovary. The same two hormones also regulate spermatogenesis and testosterone production in males

Specific *transcription factors* have been identified that regulate the differentiation of pluripotent stem cells within the Rathke's pouch into these terminally differentiated cell types. For example, somatotrophs, mammosomatotrophs, and lactotrophs are derived from stem cells that express the pituitary transcription factor, PIT-1. By contrast steroidogenic factor -1 (SF-1) and GATA-2 are factors that are required for gonadotroph differentiation.

The *posterior pituitary* consists of modified glial cells (termed *pituicytes*) and axonal processes extending from the hypothalamus through the pituitary stalk to the posterior lobe (*axon terminals*). Two peptide hormones are secreted from the posterior pituitary, *oxytocin* and *antidiuretic hormone* (ADH, also called *vasopressin*). These are actually synthesized in the hypothalamus and stored within the axon terminals residing in the posterior pituitary. In response to appropriate stimuli, the preformed hormones are released directly into the systemic circulation through the venous channels of the pituitary. For example, dilation of the cervix in pregnancy results in massive oxytocin release, leading to contraction of the

Figure 24-1 Hormones released by the anterior pituitary. The adenohypophysis (anterior pituitary) releases five hormones that are in turn under the control of various stimulatory and inhibitory hypothalamic releasing factors. TSH, Thyroid-stimulating hormone (thyrotropin); PRL, prolactin; ACTH, adrenocorticotropic hormone (corticotropin); GH, growth hormone (somatotropin); FSH, follicle-stimulating hormone; LH, luteinizing hormone. The stimulatory releasing factors are TRH (thyrotropin-releasing hormone), CRH (corticotropin-releasing hormone), GHRH (growth hormone-releasing hormone), GnRH (gonadotropin-releasing hormone). The inhibitory hypothalamic influences comprise PIF (prolactin inhibitory factor or dopamine) and growth hormone inhibitory factor (GIH or somatostatin).

Figure 24-2 A, Photomicrograph of normal pituitary. The gland is populated by several distinct cell populations containing a variety of stimulating (tropic) hormones. Each of the hormones has different staining characteristics, resulting in a mixture of cell types in routine histologic preparations. **B**, Immunostain for human growth hormone.

uterine smooth muscle, facilitating parturition (uterine labor). Similarly, oxytocin released upon nipple stimulation in the postnatal period acts on the smooth muscles surrounding the lactiferous ducts of the mammary glands and facilitates lactation. Synthetic oxytocin can be given to pregnant women to induce labor. The most important function of ADH is to conserve water by restricting diuresis during periods of dehydration and hypovolemia. Decreased blood pressure, sensed by *baroreceptors* (pressure-sensing receptors) in the cardiac atria and carotids, stimulates ADH release. An increase in plasma osmotic pressure detected by *osmoreceptors* also triggers ADH secretion. In contrast, states of hypervolemia and increased atrial distention result in inhibition of ADH secretion.

Clinical Manifestations of Pituitary Disease

The manifestations of pituitary disorders are related to either excess or deficiency of pituitary hormones, or to mass effects.

Hyperpituitarism: Arising from excess secretion of trophic hormones. The causes of hyperpituitarism include pituitary adenoma, hyperplasia and carcinomas of the anterior pituitary, secretion of hormones by nonpituitary tumors, and certain hypothalamic disorders. The symptoms of hyperpituitarism are discussed later in the context of individual tumors.

Hypopituitarism: Arising from deficiency of trophic hormones. This may be caused by destructive processes, including ischemic injury, surgery or radiation, inflammatory reactions, and nonfunctional pituitary adenomas.

Local mass effects: Among the earliest changes referable to mass effect are radiographic abnormalities of the sella turcica, including sellar expansion, bony erosion, and disruption of the diaphragma sella. Because of the close proximity of the optic nerves and chiasm to the sella, expanding pituitary lesions often compress decussating

fibers in the optic chiasm. This gives rise to *visual field abnormalities*, classically in the form of defects in both lateral (temporal) visual fields, so-called *bitemporal hemianopsia*. In addition, a variety of other visual field abnormalities may be caused by asymmetric growth of many tumors. Like any expanding intracranial mass, pituitary adenomas can produce signs and symptoms of *elevated intracranial pressure*, including headache, nausea, and vomiting. On occasion, acute hemorrhage into an adenoma is associated with clinical evidence of rapid enlargement of the lesion, a situation appropriately termed *pituitary apoplexy*. Acute pituitary apoplexy is a neurosurgical emergency, in that it can cause sudden death (see later).

Diseases of the posterior pituitary often come to clinical attention because of increased or decreased secretion of ADH.

Pituitary Adenomas and Hyperpituitarism

The most common cause of hyperpituitarism is an adenoma arising in the anterior lobe. These benign tumors are classified on the basis of the hormones that are produced by the neoplastic cells, which are detected by immunohistochemical stains (Table 24-1). Some pituitary adenomas can secrete two hormones (GH and prolactin being the most common combination), and rarely, pituitary adenomas are plurihormonal. Pituitary adenomas can be *functional* (i.e., associated with hormone excess and clinical manifestations thereof) or *nonfunctioning* (i.e., without clinical symptoms of hormone excess). Less common causes of hyperpituitarism include pituitary carcinomas and some hypothalamic disorders. Large pituitary adenomas, and particularly nonfunctioning ones, may cause hypopituitarism by encroaching on and destroying the adjacent anterior pituitary parenchyma.

Pituitary adenomas are usually found in adults; the peak incidence is from 35 to 60 years of age. They are designated, somewhat arbitrarily, *microadenomas* if they are less than 1 cm in diameter and *macroadenomas* if they

Table 24-1 Classification of Pituitary Adenomas

Pituitary Cell Type	Hormone	Adenoma Subtypes	Associated Syndrome*
Lactotroph	Prolactin	Lactotroph adenoma Silent lactotroph adenoma	Galactorrhea and amenorrhea (in females) Sexual dysfunction, infertility
Somatotroph	GH	Densely granulated somatotroph adenoma Sparsely granulated somatotroph adenoma Silent somatotroph adenoma	Gigantism (children) Acromegaly (adults)
Mammotroph	Prolactin, GH	Mammotroph adenomas	Combined features of GH and prolactin excess
Corticotroph	ACTH and other POMC-derived peptides	Densely granulated corticotroph adenoma Sparsely granulated corticotroph adenoma Silent corticotroph adenoma	Cushing syndrome Nelson syndrome
Thyrotroph	TSH	Thyrotroph adenomas Silent thyrotroph adenomas	Hyperthyroidism
Gonadotroph	FSH, LH	Gonadotroph adenomas Silent gonadotroph adenomas (“null cell,” oncocytic adenomas)	Hypogonadism, mass effects, and hypopituitarism

ACTH, Adrenocorticotrophic hormone; FSH, follicle-stimulating hormone; GH, growth hormone; LH, luteinizing hormone; POMC, pro-opiomelanocortin; TSH, thyroid-stimulating hormone.

*Note that nonfunctional (silent) adenomas in each category express the corresponding hormone(s) within the neoplastic cells, as determined by special immunohistochemical staining on tissues. However, these adenomas do not produce the associated clinical syndrome, and typically present with *mass effects* accompanied by *hypopituitarism* due to destruction of normal pituitary parenchyma. These features are particularly common with gonadotroph adenomas.

Partially adapted from Asa SL, Essat S: The pathogenesis of pituitary tumors. *Annu Rev Pathol Medch Dis* 4:97; 2009.

exceed 1 cm in diameter. Non-functional adenomas are likely to come to clinical attention at a later stage than those associated with endocrine abnormalities and are therefore more likely to be macroadenomas. Based on autopsy studies, the prevalence of pituitary adenomas in the population is estimated to be about 14%, but the vast majority of these lesions are clinically silent microadenomas (“pituitary incidentaloma”).

With recent advances in molecular techniques, substantial insight has been gained into *the genetic abnormalities associated with pituitary adenomas* (Table 24-2):

- **G-protein mutations are one of the most common alterations in pituitary adenomas.** G proteins are described in Chapter 1; here their function in the context of endocrine neoplasms is reviewed. G proteins play a

Table 24-2 Genetic Alterations in Pituitary Tumors

Gene	Protein Function	Mechanism of Alteration	Most Commonly Associated Pituitary Tumor
Gain of Function			
GNAS	GNAS encodes for alpha subunit of stimulatory G-protein, G α_s . Oncogenic mutation of GNAS constitutively activates G α_s , leading to upregulation of intracellular cyclic AMP (cAMP) activity	Activating mutation	GH adenomas
Protein kinase A, regulatory subunit 1 (PRKAR1A)*	PRKAR1A encodes for a negative regulator of protein kinase A (PKA), a downstream mediator of cAMP signaling. Loss of PKA regulation leads to inappropriate cAMP activity	Germline inactivating mutations of PRKAR1A are present in autosomal dominant Carney complex	GH and prolactin adenomas
Cyclin D1	Cell cycle regulatory protein; promotes G1-S transition	Overexpression	Aggressive adenomas
HRAS	Ras regulates multiple oncogenic pathways including proliferation, cell survival and metabolism	Activating mutation	Pituitary carcinomas
Loss of Function			
MEN1*	MEN1 encodes for menin, a protein with protean roles in tumor suppression, including repression of oncogenic transcription factor JunD, and in histone modification.	Germline inactivating mutations of MEN1 (multiple endocrine neoplasia, type 1)	GH, prolactin, and ACTH adenomas
CDKN1B (p27/KIP1)*	The p27 protein is a negative regulator of the cell cycle	Germline inactivating mutations of CDKN1B (“MEN-1-like” syndrome)	ACTH adenomas
Aryl hydrocarbon receptor interacting protein (AIP)*	Receptor for aryl hydrocarbons and a ligand-activated transcription factor	Germline mutations of AIP cause pituitary adenoma predisposition [PAP] syndrome	GH adenomas (especially in patients younger than 35 years of age)
Retinoblastoma (RB)	Retinoblastoma protein is a negative regulator of the cell cycle (Chapter 7)	Methylation of RB gene promoter	Aggressive adenomas

ACTH, Adrenocorticotrophic hormone; GH, growth hormone.

*Genetic alterations associated with *familial* predisposition to pituitary adenomas.

Figure 24-3 G-protein signaling in endocrine neoplasia. Mutations that lead to G-protein hyperactivity are seen in a variety of endocrine neoplasms, including pituitary, thyroid, and parathyroid adenomas. G proteins (composed of α and $\beta\gamma$ subunits) play a critical role in signal transduction, transmitting signals from cell surface receptors (GHRH, TSH, or PTH receptor) to intracellular effectors (e.g., adenylyl cyclase), which then generate second messengers (cAMP, cyclic adenosine monophosphate) that stimulate cellular responses. GDP, guanosine diphosphate; GTP, guanosine triphosphate; P_i, inorganic phosphate. See Figure 24-1 for other abbreviations.

critical role in signal transduction, transmitting signals from particular *cell surface receptors* (e.g., GHRH receptor) to *intracellular effectors* (e.g., adenylyl cyclase), which then generate *second messengers* (e.g., cyclic adenosine monophosphate, cAMP). These are heterotrimeric proteins, composed of a specific α -subunit that binds guanine nucleotide and interacts with both cell surface receptors and intracellular effectors (Fig. 24-3); the β - and γ -subunits are noncovalently bound to the specific α -subunit. G_s is a stimulatory G protein that has a pivotal role in signal transduction in several endocrine organs, including the pituitary. The α -subunit of G_s ($G_s\alpha$) is encoded by the *GNAS* gene, located on chromosome 20q13.

In the basal state, G_s exists in an inactive state, with guanosine diphosphate (GDP) bound to the guanine nucleotide-binding site of $G_s\alpha$. On interaction with the ligand-bound cell surface receptor, GDP dissociates, and guanosine triphosphate (GTP) binds to $G_s\alpha$, activating the G protein. The activation of $G_s\alpha$ results in the generation of cAMP, which is a potent mitogen for a variety of endocrine cell types (e.g., pituitary somatotrophs and corticotrophs, thyroid follicular cells, parathyroid cells), promoting cellular proliferation and hormone synthesis and secretion. Normally, $G_s\alpha$ activation is *transient* because of an intrinsic GTPase activity in the α -subunit, which hydrolyzes GTP into GDP.

Approximately 40% of somatotroph cell adenomas bear *GNAS* mutations that abrogate the GTPase

activity of $G_s\alpha$, leading to constitutive activation of $G_s\alpha$, persistent generation of cAMP, and unchecked cellular proliferation (Table 24-2). *GNAS* mutations have also been described in a minority of corticotroph adenomas; in contrast, *GNAS* mutations are absent in thyrotroph, lactotroph, and gonadotroph adenomas, because their respective hypothalamic release hormones do not act via cAMP-dependent pathways.

- The overwhelming majority of pituitary adenomas are sporadic in nature, but approximately 5% of cases arise as a result of an inherited genetic defect. Four causative genes have been identified thus far: *MEN1*, *CDKN1B*, *PRKARIA*, and *AIP* (see Table 24-2 for a summary of these aberrations and most commonly associated pituitary tumor subtypes). Of note, somatic mutations of these four genes are rarely encountered in sporadic pituitary adenomas.
- Molecular abnormalities associated with aggressive behavior include aberrations in cell cycle checkpoint proteins, such as overexpression of cyclin D1, mutations of *TP53*, and epigenetic silencing of the retinoblastoma gene (*RB*). In addition, activating mutations of the *HRAS* oncogene are observed in rare *pituitary carcinomas* (Table 24-2).

MORPHOLOGY

The **typical pituitary adenoma** is soft and well-circumscribed. Small adenomas may be confined to the sella turcica, but with expansion they frequently erode the sella turcica and anterior clinoid processes. Larger lesions usually extend superiorly through the diaphragm sella into the suprasellar region, where they often compress the optic chiasm and adjacent structures, such as some of the cranial nerves (Fig. 24-4). In as many as 30% of cases, the adenomas are not grossly encapsulated and infiltrate neighboring tissues such as the cavernous and sphenoid sinuses, dura, and on occasion, the brain itself. Such lesions are termed **invasive adenomas**. Not unexpectedly, macroadenomas are invasive more frequently than smaller tumors. Foci of hemorrhage and necrosis are also more common in these larger adenomas.

Histologically, typical pituitary adenomas are composed of uniform, polygonal cells arrayed in sheets or cords. Supporting connective tissue, or reticulin, is sparse, accounting for the soft, gelatinous consistency of many of these tumors. Mitotic activity is usually sparse. The cytoplasm of the tumor cells may be acidophilic, basophilic, or chromophobic, depending on the type and amount of secretory product within the cells, but it is generally uniform throughout the tumor. **This cellular monomorphism and the absence of a significant reticulin network distinguish pituitary adenomas from nonneoplastic anterior pituitary parenchyma** (Fig. 24-5). The biologic behavior of the adenoma cannot always be reliably predicted from its histologic appearance. A subset of pituitary adenomas demonstrates elevated mitotic activity and nuclear p53 expression, a feature that correlates with the presence of *TP53* mutations. These tumors have a higher propensity for aggressive behavior, including invasion and recurrence, and are termed **atypical adenomas**.

Clinical Course. The signs and symptoms of pituitary adenomas are related to endocrine abnormalities and mass effects. The effects of excessive secretion of anterior

Figure 24-4 Pituitary adenoma. This massive, nonfunctional adenoma has grown far beyond the confines of the sella turcica and has distorted the overlying brain. Nonfunctional adenomas tend to be larger at the time of diagnosis than those that secrete a hormone.

Figure 24-5 Pituitary adenoma. The monomorphism of these cells contrasts markedly with the mixture of cells seen in the normal anterior pituitary. Note also the absence of reticulin network.

pituitary hormones are mentioned later, when the specific types of pituitary adenoma are described. Local mass effects may be produced by any type of pituitary tumor. As already mentioned, these effects include *radiographic abnormalities of the sella turcica*, *visual field abnormalities*, signs and symptoms of *elevated intracranial pressure*, and occasionally *hypopituitarism*. Acute hemorrhage into an adenoma is sometimes associated with *pituitary apoplexy*, as noted earlier.

The following is a discussion of the individual types of tumors.

Lactotroph Adenoma

Prolactin-secreting lactotroph adenomas are the most frequent type of hyperfunctioning pituitary adenoma, accounting for about 30% of all clinically recognized cases. These lesions range from small microadenomas to large, expansile tumors associated with substantial mass effect.

MORPHOLOGY

The overwhelming majority of lactotroph adenomas are comprised of chromophobic cells with juxtannuclear localization of the transcription factor PIT-1; these are known as **sparsely granulated lactotroph adenomas** (Fig. 24-6A). Much rarer are the acidophilic **densely granulated lactotroph adenomas**, characterized by diffuse cytoplasmic PIT-1 expression localization (Fig. 24-6B). Prolactin can be demonstrated within the secretory granules in the cytoplasm of the cells using immunohistochemical stains. Lactotroph adenomas have a propensity to undergo dystrophic calcification, ranging from isolated psammoma bodies to extensive calcification of virtually the entire tumor mass (“pituitary stone”). Prolactin secretion by functioning adenomas is usually efficient (even microadenomas secrete sufficient prolactin to cause hyperprolactinemia) and proportional, in that serum prolactin concentrations tend to correlate with the size of the adenoma.

Figure 24-6 Ultrastructural features of prolactinomas. **A**, Electron micrograph of a sparsely granulated prolactinoma. The tumor cells contain abundant granular endoplasmic reticulum (indicative of active protein synthesis) and small numbers of electron-dense secretory granules. **B**, Electron micrograph of densely granulated growth hormone-secreting adenoma. The tumor cells are filled with numerous large, electron-dense secretory granules. (Courtesy Dr. Eva Horvath, St. Michael's Hospital, Toronto, Ont. Canada.)

Clinical Course. Increased serum levels of prolactin, or *prolactinemia*, cause amenorrhea, galactorrhea, loss of libido, and infertility. The diagnosis of an adenoma is made more readily in women than in men, especially between the ages of 20 and 40 years, presumably because of the sensitivity of menses to disruption by hyperprolactinemia. Lactotroph adenoma underlies almost a quarter of cases of amenorrhea. In contrast, in men and older women, the hormonal manifestations may be subtle, allowing the tumors to reach considerable size (macroadenomas) before being detected clinically.

Hyperprolactinemia may result from causes other than prolactin-secreting pituitary adenomas. Physiologic hyperprolactinemia occurs in pregnancy. Prolactin levels are also elevated by nipple stimulation, as occurs during suckling in lactating women, and as a response to many types of stress. Pathologic hyperprolactinemia can also result from *lactotroph hyperplasia* caused by loss of dopamine-mediated inhibition of prolactin secretion. This may occur with damage of the dopaminergic neurons of the hypothalamus, damage of the pituitary stalk (e.g., due to head trauma), or exposure to drugs that block dopamine receptors on lactotroph cells. Any mass in the suprasellar compartment (e.g., a pituitary adenoma) may disturb the normal inhibitory influence of the hypothalamus on prolactin secretion, resulting in hyperprolactinemia. Therefore, a mild elevation in serum prolactin in a person with a pituitary adenoma does not necessarily indicate a prolactin-secreting tumor. Other causes of hyperprolactinemia include renal failure and hypothyroidism. Lactotroph adenomas are treated by surgery or, more commonly, with bromocriptine, a dopamine receptor agonist that causes the lesions to diminish in size.

Somatotroph Adenomas

Growth hormone (GH)-secreting somatotroph adenomas are the second most common type of functioning pituitary adenoma, and cause gigantism in children and acromegaly in adults. Somatotroph adenomas may be quite large by the time they come to clinical attention because the manifestations of excessive GH may be subtle.

MORPHOLOGY

Histologically, pure somatotroph adenomas are also classified into **densely granulated** and **sparsely granulated subtypes**. Densely granulated adenomas are composed of monomorphic, acidophilic cells that have strong cytoplasmic GH reactivity on immunohistochemistry. In contrast, the sparsely granulated variants are composed of chromophobe cells with considerable nuclear and cytologic pleomorphism and focal, weak staining for GH. Bihormonal **mammomatotroph** adenomas that synthesize both GH and prolactin are being increasingly recognized; morphologically, most bihormonal adenomas resemble the densely granulated pure somatotroph adenomas, but are distinguished by having immunohistochemical reactivity for prolactin as well as GH.

Clinical Course. Persistently elevated levels of GH stimulate the hepatic secretion of insulin-like growth factor 1 (IGF-1), which causes many of the clinical manifestations.

- If a somatotroph adenoma appears in children before the epiphyses have closed, the elevated levels of GH (and IGF-1) result in *gigantism*. This is characterized by a generalized increase in body size with disproportionately long arms and legs.
- If the increased levels of GH are present after closure of the epiphyses, *acromegaly* develops. In this condition, growth is most conspicuous in skin and soft tissues, viscera (thyroid, heart, liver, and adrenals), and the bones of the face, hands, and feet. Bone density may increase (hyperostosis) in both the spine and the hips. Enlargement of the jaw results in its protrusion (prognathism), and broadening of the lower face. The feet and hands are enlarged, and the fingers become thickened and sausage-like. In most instances gigantism is also accompanied by evidence of acromegaly. These changes may develop slowly over decades before being recognized, hence the opportunity for the adenomas to reach substantial size.
- GH excess can also be associated with a variety of other disturbances, including gonadal dysfunction, diabetes mellitus, generalized muscle weakness, hypertension, arthritis, congestive heart failure, and an increased risk of gastrointestinal cancers.

The diagnosis of pituitary GH excess relies on documentation of elevated serum GH and IGF-1 levels. In addition, failure to suppress GH production in response to an oral load of glucose is one of the most sensitive tests for acromegaly. The underlying pituitary adenoma can be either removed surgically or treated via pharmacologic means. The latter includes somatostatin analogs (recall that somatostatin inhibits pituitary GH secretion) or the use of GH receptor antagonists, which prevent hormone binding to target organs such as the liver. When effective control of high GH levels is achieved, the characteristic tissue overgrowth and related symptoms gradually recede, and the metabolic abnormalities improve.

Corticotroph Adenomas

Excess production of ACTH by functioning corticotroph adenomas leads to adrenal hypersecretion of cortisol and the development of hypercortisolism (also known as Cushing syndrome).

MORPHOLOGY

Corticotroph adenomas are usually microadenomas at the time of diagnosis. These tumors are most often basophilic (**densely granulated**) and occasionally chromophobic (**sparsely granulated**). Both variants stain positively with periodic acid-Schiff (PAS) because of the presence of carbohydrate in proopiomelanocortin (POMC), the ACTH precursor molecule; in addition, they demonstrate variable immunoreactivity for POMC and its derivatives, including ACTH and β -endorphin.

Clinical Course. The clinical manifestations of Cushing syndrome are discussed in more detail later with the diseases of the adrenal gland. The syndrome can be caused by a wide variety of conditions in addition to ACTH-producing pituitary tumors. When the hypercortisolism is due to excessive production of ACTH by the pituitary, it is

designated *Cushing disease*. Large destructive pituitary adenomas can develop in patients after surgical removal of the adrenal glands for treatment of Cushing syndrome. This condition, known as *Nelson syndrome*, occurs most often because of a loss of the inhibitory effect of adrenal corticosteroids on a preexisting corticotroph microadenoma. Because the adrenals are absent in persons with this disorder, hypercortisolism does not develop, and patients present with mass effects due to the pituitary tumor, and there can be hyperpigmentation because of the stimulatory effect of other products of the ACTH precursor molecule on melanocytes.

Other Anterior Pituitary Adenomas

Pituitary adenomas may elaborate more than one hormone (e.g., mammosomatotroph adenomas). Other unusual “plurihormonal” adenomas secrete multiple hormones; these tumors are usually aggressive. A few comments are made about several of the less frequent functioning tumors.

- *Gonadotroph (LH-producing and FSH-producing) adenomas* can be difficult to recognize because they secrete hormones inefficiently and variably, and the secretory products usually do not cause a recognizable clinical syndrome (*nonfunctioning adenomas*, see later). Gonadotroph adenomas are most frequently found in middle-aged men and women when they become large enough to cause neurologic symptoms, such as impaired vision, headaches, diplopia, or pituitary apoplexy. Pituitary hormone deficiencies can also be found, most commonly impaired secretion of LH. This causes decreased energy and libido in men (due to reduced testosterone) and amenorrhea in premenopausal women. The neoplastic cells usually demonstrate immunoreactivity for the common gonadotropin α -subunit and the specific β -FSH and β -LH subunits; FSH is usually the predominant secreted hormone. Gonadotroph adenomas usually express steroidogenic factor-1 (SF-1) and GATA-2, transcription factors associated with normal gonadotroph differentiation.
- *Thyrotroph (TSH-producing) adenomas* are uncommon, accounting for approximately 1% of all pituitary adenomas. Thyrotroph adenomas are a rare cause of *hyperthyroidism*.
- *Nonfunctioning pituitary adenomas* are a heterogeneous group that constitutes approximately 25% to 30% of all pituitary tumors. Their lineage can be established by immunohistochemical staining for hormones or by biochemical demonstration of cell type-specific transcription factors. In the past, many such tumors have been called *silent variants* or *null-cell adenomas*. Not surprisingly, nonfunctioning adenomas typically present with symptoms stemming from mass effects. These lesions may also compromise the residual anterior pituitary sufficiently to cause hypopituitarism, which may appear slowly due to gradual enlargement of the adenoma or abruptly because of acute intratumoral hemorrhage (pituitary apoplexy).

Pituitary carcinoma is rare, accounting for less than 1% of pituitary tumors. The presence of craniospinal or systemic metastases is a *sine qua non* of a pituitary carcinoma.

Most pituitary carcinomas are functional, with prolactin and ACTH being the most common secreted products. Metastases usually appear late in the course, following multiple local recurrences.

KEY CONCEPTS

Hyperpituitarism

- The most common cause of hyperpituitarism is an anterior lobe pituitary adenoma.
- Pituitary adenomas can be *macroadenomas* (greater than 1 cm in diameter) or *microadenomas*.
- Functioning adenomas are associated with distinct endocrine signs and symptoms, while nonfunctioning (silent) adenomas typically present with mass effects, including visual disturbances.
- Lactotroph adenomas secrete prolactin and can present with amenorrhea, galactorrhea, loss of libido, and infertility
- Somatotroph adenomas secrete GH and present with gigantism in children and acromegaly in adults, impaired glucose tolerance, and diabetes mellitus.
- Corticotroph adenomas secrete ACTH and present with Cushing syndrome and hyperpigmentation.
- The two distinctive morphologic features of most adenomas are their cellular monomorphism and absence of a reticulin network.

Hypopituitarism

Hypopituitarism refers to decreased secretion of pituitary hormones, which can result from diseases of the hypothalamus or of the pituitary. Hypofunction of the anterior pituitary occurs when approximately 75% of the parenchyma is lost or absent. This may be congenital or the result of a variety of acquired abnormalities that are intrinsic to the pituitary. Hypopituitarism accompanied by evidence of posterior pituitary dysfunction in the form of diabetes insipidus (see later) is almost always of hypothalamic origin.

Most cases of hypopituitarism arise from destructive processes directly involving the anterior pituitary. The causes include the following:

- *Tumors and other mass lesions:* Pituitary adenomas, other benign tumors arising within the sella, primary and metastatic malignancies, and cysts can cause hypopituitarism. Any mass lesion in the sella can cause damage by exerting pressure on adjacent pituitary cells.
- *Traumatic brain injury and subarachnoid hemorrhage* are among the most common causes of pituitary hypofunction.
- *Pituitary surgery or radiation:* Surgical excision of a pituitary adenoma may inadvertently extend to the nonadenomatous pituitary. Radiation of the pituitary, used to prevent regrowth of residual tumor after surgery, can damage the nonadenomatous pituitary.
- *Pituitary apoplexy:* As mentioned earlier, this is caused by a sudden hemorrhage into the pituitary gland, often occurring into a pituitary adenoma. In its most dramatic presentation, apoplexy causes the sudden onset of

excruciating headache, diplopia due to pressure on the oculomotor nerves, and hypopituitarism. In severe cases, it can cause cardiovascular collapse, loss of consciousness, and even sudden death. The combination of mass effects from the hemorrhage and the acute hypopituitarism makes pituitary apoplexy a true neurosurgical emergency.

- *Ischemic necrosis of the pituitary and Sheehan syndrome:* Sheehan syndrome, also known as postpartum necrosis of the anterior pituitary, is the most common form of clinically significant ischemic necrosis of the anterior pituitary. During pregnancy the anterior pituitary enlarges to almost twice its normal size. This physiologic expansion of the gland is not accompanied by an increase in blood supply from the low-pressure venous system; hence, there is relative hypoxia. Any further reduction in blood supply caused by obstetric hemorrhage or shock may precipitate infarction of the anterior lobe. Because the posterior pituitary receives its blood directly from arterial branches, it is much less susceptible to ischemic injury and is therefore usually not affected. Pituitary necrosis may also be encountered in other conditions, such as disseminated intravascular coagulation and (more rarely) sickle cell anemia, elevated intracranial pressure, traumatic injury, and shock of any origin. Whatever the pathogenesis, the ischemic area is resorbed and replaced by a nubbin of fibrous tissue attached to the wall of an empty sella.
- *Rathke cleft cyst:* These cysts, lined by ciliated cuboidal epithelium with occasional goblet cells and anterior pituitary cells, can accumulate proteinaceous fluid and expand, compromising the normal gland.
- *Empty sella syndrome:* Any condition or treatment that destroys part or all of the pituitary gland, such as ablation of the pituitary by surgery or radiation, can result in an *empty sella* and the *empty sella syndrome*. There are two types: (1) In a *primary* empty sella, a defect in the diaphragma sella allows the arachnoid mater and cerebrospinal fluid to herniate into the sella, expanding the sella and compressing the pituitary. Classically, this occurs in obese women with a history of multiple pregnancies. Affected individuals often present with visual field defects and occasionally with endocrine anomalies, such as *hyperprolactinemia*, due to interruption of inhibitory hypothalamic inputs. Sometimes the loss of functioning parenchyma is sufficient to produce hypopituitarism. (2) In *secondary* empty sella, a mass, such as a pituitary adenoma, enlarges the sella and is then either surgically removed or undergoes infarction, leading to loss of pituitary function.
- *Hypothalamic lesions:* As mentioned earlier, hypothalamic lesions can also affect the pituitary by interfering with the delivery of pituitary hormone-releasing factors. In contrast to diseases that involve the pituitary directly, hypothalamic abnormalities can also diminish the secretion of ADH, resulting in diabetes insipidus (discussed later). Hypothalamic lesions that cause hypopituitarism include *tumors*, which may be benign (e.g., craniopharyngioma) or malignant; most of the latter are metastases from tumors such as breast and lung carcinoma. Hypothalamic insufficiency can also appear following irradiation of brain or nasopharyngeal tumors.

- *Inflammatory disorders and infections*, such as sarcoidosis or tuberculous meningitis, can involve the hypothalamus and cause deficiencies of anterior pituitary hormones and diabetes insipidus.
- *Genetic defects:* Congenital deficiency of transcription factors required for normal pituitary function is a rare cause of hypopituitarism. For example, mutation of the pituitary-specific gene *PIT-1* results in combined pituitary hormone deficiency, characterized by deficiencies of GH, prolactin, and TSH.

The clinical manifestations of anterior pituitary hypofunction vary depending on the specific hormones that are lacking.

- Children can develop growth failure (*pituitary dwarfism*) due to growth hormone deficiency.
- Gonadotropin (LH and FSH) deficiency leads to amenorrhea and infertility in women and decreased libido, impotence, and loss of pubic and axillary hair in men.
- TSH and ACTH deficiencies result in symptoms of hypothyroidism and hypoadrenalism, respectively, and are discussed later in the chapter.
- Prolactin deficiency results in failure of postpartum lactation.
- The anterior pituitary is also a rich source of MSH, synthesized from the same precursor molecule that produces ACTH; therefore, one of the manifestations of hypopituitarism includes pallor due to a loss of stimulatory effects of MSH on melanocytes.

Posterior Pituitary Syndromes

The clinically relevant posterior pituitary syndromes involve ADH and include *diabetes insipidus* and *secretion of inappropriately high levels of ADH*.

- ***Diabetes insipidus.* ADH deficiency causes *diabetes insipidus*, a condition characterized by excessive urination (polyuria) due to an inability of the kidney to resorb water properly from the urine.** Diabetes insipidus can occur in a variety of conditions, including head trauma, tumors, inflammatory disorders of the hypothalamus and pituitary, and surgical complications. The condition can also arise spontaneously, in the absence of an identifiable underlying disorder. Diabetes insipidus from ADH deficiency is designated as *central* to differentiate it from *nephrogenic* diabetes insipidus, which is a result of renal tubular unresponsiveness to circulating ADH. The clinical manifestations of these two disorders are similar and include the excretion of large volumes of dilute urine with a lower than normal specific gravity. Serum sodium and osmolality are increased by the excessive renal loss of free water, resulting in thirst and polydipsia. Patients who can drink water generally compensate for the urinary losses, but patients who are obtunded, bedridden, or otherwise limited in their ability to obtain water may develop life-threatening dehydration.
- ***Syndrome of inappropriate ADH (SIADH) secretion.* ADH excess causes resorption of excessive amounts of free water, resulting in hyponatremia.** The most

frequent causes of SIADH are the secretion of ectopic ADH by malignant neoplasms (particularly small-cell carcinoma of the lung), drugs that increase ADH secretion, and a variety of central nervous system disorders, including infections and trauma. The clinical manifestations of SIADH are dominated by hyponatremia, cerebral edema, and resultant neurologic dysfunction. Although total body water is increased, blood volume remains normal, and peripheral edema does not develop.

Hypothalamic Suprasellar Tumors

Neoplasms in this location may induce hypofunction or hyperfunction of the anterior pituitary, diabetes insipidus, or combinations of these manifestations. The most commonly implicated tumors are *gliomas* (sometimes arising in the chiasm; [Chapter 28](#)) and *craniopharyngiomas*. The craniopharyngioma is thought to arise from vestigial remnants of Rathke pouch. These slow-growing tumors account for 1% to 5% of intracranial tumors. A small minority of these lesions occurs within the sella, but most are suprasellar, with or without intrasellar extension. A bimodal age distribution is observed, with one peak in childhood (5 to 15 years) and a second peak in adults 65 years or older. Patients usually come to attention because of headaches and visual disturbances, while children sometimes present with growth retardation due to pituitary hypofunction and GH deficiency. Abnormalities of the *WNT signaling pathway*, including activating mutations of the gene encoding β -catenin, have been reported in craniopharyngiomas.

MORPHOLOGY

Craniopharyngiomas average 3 to 4 cm in diameter; they may be encapsulated and solid, but more commonly they are cystic and sometimes multiloculated. They often encroach on the optic chiasm or cranial nerves, and not infrequently they bulge into the floor of the third ventricle and base of the brain. Two distinct histologic variants are recognized: **adamantinomatous craniopharyngioma** (most often observed in children) and **papillary craniopharyngioma** (most often observed in adults). The adamantinomatous type frequently contains radiologically demonstrable calcifications; the papillary variant calcifies only rarely.

Adamantinomatous craniopharyngioma consists of nests or cords of stratified squamous epithelium embedded in a spongy

Figure 24-7 Adamantinomatous craniopharyngioma, demonstrating characteristic compact, lamellar “wet” keratin (right half of photomicrograph) and cords of squamous epithelium with peripheral palisading on the left. (Courtesy Dr. Charles Eberhart, Department of Pathology, Johns Hopkins University, Baltimore, Md.)

“reticulum” that becomes more prominent in the internal layers. “Palisading” of the squamous epithelium is frequently observed at the periphery. Compact, lamellar keratin formation (“wet keratin”) is a diagnostic feature of this tumor ([Fig. 24-7](#)). As mentioned earlier, **dystrophic calcification** is a frequent finding. Additional features include cyst formation, fibrosis, and chronic inflammation. The cysts of adamantinomatous craniopharyngiomas often contain a cholesterol-rich, thick brownish-yellow fluid that has been compared to “machine oil.” These tumors extend fingerlets of epithelium into adjacent brain, where they elicit a brisk glial reaction.

Papillary craniopharyngiomas contain both solid sheets and papillae lined by well-differentiated squamous epithelium. These tumors usually lack keratin, calcification, and cysts. The squamous cells of the solid sections of the tumor lack the peripheral palisading and do not typically generate a spongy reticulum in the internal layers.

Patients with craniopharyngiomas, especially those less than 5 cm in diameter, have an excellent recurrence-free and overall survival. Larger lesions are more invasive but this does not impact on the prognosis. Malignant transformation of craniopharyngiomas into squamous carcinomas is exceptionally rare and usually occurs after irradiation.

THYROID GLAND

The thyroid gland, usually located below and anterior to the larynx, consists of two bulky lateral lobes connected by a relatively thin isthmus. The thyroid is divided by thin fibrous septae into lobules composed of about 20 to 40 evenly dispersed follicles, lined by a cuboidal to low columnar epithelium, and filled with PAS-positive

thyroglobulin. In response to hypothalamic factors, TSH (*thyrotropin*) is released by thyrotrophs in the anterior pituitary into the circulation. The binding of TSH to its receptor on the thyroid follicular epithelium results in activation of the receptor, allowing it to associate with a G_s protein ([Fig. 24-8](#)). Activation of the G protein stimulates downstream

Figure 24-8 Homeostasis in the hypothalamus-pituitary-thyroid axis and mechanism of action of thyroid hormones. Secretion of thyroid hormones (T_3 and T_4) is controlled by trophic factors secreted by both the hypothalamus and the anterior pituitary. Decreased levels of T_3 and T_4 stimulate the release of thyrotropin-releasing hormone (TRH) from the hypothalamus and thyroid-stimulating hormone (TSH) from the anterior pituitary, causing T_3 and T_4 levels to rise. Elevated T_3 and T_4 levels, in turn, feed back to suppress the secretion of both TRH and TSH. TSH binds to the TSH receptor on the thyroid follicular epithelium, which causes activation of G proteins, and cAMP-mediated synthesis and release of thyroid hormones (T_3 and T_4). In the periphery, T_3 and T_4 interact with the thyroid hormone receptor (TR) to form a hormone-receptor complex that translocates to the nucleus and binds to so-called thyroid response elements (TREs) on target genes to initiate transcription.

events that result in an increase in intracellular cAMP levels, which stimulates thyroid growth and thyroid hormone synthesis and release via cAMP-dependent protein kinases.

Thyroid follicular epithelial cells convert thyroglobulin into *thyroxine* (T_4) and lesser amounts of *triiodothyronine* (T_3). T_4 and T_3 are released into the systemic circulation, where most of these peptides are reversibly bound to circulating plasma proteins, such as thyroxine-binding globulin and transthyretin. The binding proteins act as a buffer that maintains the serum unbound (“free”) T_3 and T_4 concentrations within narrow limits, while ensuring that the hormones are readily available to the tissues. In the periphery, the majority of free T_4 is deiodinated to T_3 ; the latter binds to thyroid hormone nuclear receptors in target cells with tenfold greater affinity than does T_4 and has proportionately greater activity. Binding of thyroid hormone to its nuclear thyroid hormone receptor (TR) results in the assembly of a multiprotein hormone-receptor complex on thyroid hormone response elements (TREs) in target genes, up regulating their transcription (Fig. 24-8). Thyroid

hormone has diverse cellular effects, including the stimulation of carbohydrate and lipid catabolism and protein synthesis in a wide range of cells. The net result is an increase in the basal metabolic rate. In addition, thyroid hormone has a critical role in brain development in the fetus and neonate (see later).

The function of the thyroid gland can be inhibited by a variety of chemical agents, collectively referred to as *goitrogens*. Because they suppress T_3 and T_4 synthesis, the level of TSH increases, and subsequent hyperplastic enlargement of the gland (*goiter*) follows. The antithyroid agent *propylthiouracil* inhibits the oxidation of iodide and thus blocks the production of thyroid hormones; parenthetically, propylthiouracil also inhibits the peripheral deiodination of circulating T_4 into T_3 , thus ameliorating symptoms of thyroid hormone excess (see later). Iodide, when given in large doses to individuals with thyroid hyperfunction, also blocks the release of thyroid hormones by inhibiting the proteolysis of thyroglobulin. Thus, thyroid hormone is synthesized and incorporated into colloid, but it is not released into the blood.

The thyroid gland follicles also contain a population of *parafollicular cells*, or C cells, which synthesize and secrete the hormone *calcitonin*. This hormone promotes the absorption of calcium by the skeletal system and inhibits the resorption of bone by osteoclasts.

Diseases of the thyroid include conditions associated with excessive release of thyroid hormones (hyperthyroidism), thyroid hormone deficiency (hypothyroidism), and mass lesions of the thyroid. We will first consider the clinical consequences of disturbed thyroid function, and then turn to the disorders that generate these problems.

Hyperthyroidism

Thyrotoxicosis is a hypermetabolic state caused by elevated circulating levels of free T_3 and T_4 . Because it is caused most commonly by hyperfunction of the thyroid gland, it is often referred to as *hyperthyroidism*. However, in certain conditions the oversupply is related to either excessive release of preformed thyroid hormone (e.g., in thyroiditis) or to an extrathyroidal source, rather than hyperfunction of the gland (Table 24-3). Thus, strictly speaking, hyperthyroidism is only one (albeit the most common) cause of thyrotoxicosis. The terms *primary* and *secondary hyperthyroidism* are sometimes used to designate hyperthyroidism arising from an intrinsic thyroid abnormality and that arising from processes outside of the thyroid, such as a TSH-secreting pituitary tumor, respectively. With this caveat, we follow the common practice of using the terms *thyrotoxicosis* and *hyperthyroidism* interchangeably. **The three most common causes of thyrotoxicosis are associated with hyperfunction of the gland and include the following:**

- *Diffuse hyperplasia* of the thyroid associated with Graves disease (approximately 85% of cases)
- Hyperfunctional *multinodular goiter*
- Hyperfunctional thyroid *adenoma*

Clinical Course. The clinical manifestations of hyperthyroidism are protean and include changes referable to the

Table 24-3 Disorders Associated with Thyrotoxicosis

Associated with Hyperthyroidism
Primary
Diffuse hyperplasia (Graves disease)
Hyperfunctioning (“toxic”) multinodular goiter
Hyperfunctioning (“toxic”) adenoma
Iodine-induced hyperthyroidism
Neonatal thyrotoxicosis associated with maternal Graves disease
Secondary
TSH-secreting pituitary adenoma (rare)*
Not Associated with Hyperthyroidism
Granulomatous (de Quervain) thyroiditis (<i>painful</i>)
Subacute lymphocytic thyroiditis (<i>painless</i>)
Struma ovarii (ovarian teratoma with ectopic thyroid)
Factitious thyrotoxicosis (exogenous thyroxine intake)

*Associated with increased thyroid-stimulating hormone (TSH); all other causes of thyrotoxicosis associated with decreased TSH.

hypermetabolic state induced by excess thyroid hormone and to overactivity of the *sympathetic nervous system* (i.e., an increase in the β -adrenergic “tone”).

- Excessive levels of thyroid hormone result in an increase in the basal metabolic rate. The skin of thyrotoxic patients tends to be soft, warm, and flushed because of increased blood flow and peripheral vasodilation, adaptations that serve to increase heat loss. Heat intolerance is common. Sweating is increased because of higher levels of calorogenesis. Heightened catabolic metabolism results in weight loss despite increased appetite.
- Cardiac manifestations are among the earliest and most consistent features. Individuals with hyperthyroidism can have elevated cardiac contractility and cardiac output, in response to increased peripheral oxygen requirements. Tachycardia, palpitations, and cardiomegaly are common. Arrhythmias, particularly atrial fibrillation, occur frequently and are more common in older patients. Congestive heart failure may develop, especially in older patients with preexisting cardiac disease. Myocardial changes, such as focal lymphocytic and eosinophilic infiltrates, mild fibrosis, myofibril fatty change, and an increase in size and number of mitochondria, have been described. Some individuals with thyrotoxicosis develop reversible left ventricular dysfunction and “low-output” heart failure, so-called thyrotoxic or hyperthyroid cardiomyopathy.
- Overactivity of the sympathetic nervous system produces tremor, hyperactivity, emotional lability, anxiety, inability to concentrate, and insomnia. Proximal muscle weakness and decreased muscle mass are common (thyroid myopathy). In the gastrointestinal system, sympathetic hyperstimulation of the gut results in hypermotility, diarrhea, and malabsorption.
- Ocular changes often call attention to hyperthyroidism. A wide, staring gaze and lid lag are present because of sympathetic overstimulation of the superior tarsal muscle (also known as Müller’s muscle), which functions alongside the levator palpebrae superioris muscle to raise the upper eyelid (Fig. 24-9). However, true thyroid ophthalmopathy associated with proptosis occurs only in Graves disease (see later).

ophthalmopathy associated with proptosis occurs only in Graves disease (see later).

- The skeletal system is also affected. Thyroid hormone stimulates bone resorption, increasing porosity of cortical bone and reducing the volume of trabecular bone. The net effect is osteoporosis and an increased risk of fractures in patients with chronic hyperthyroidism. Other findings include atrophy of skeletal muscle, with fatty infiltration and focal interstitial lymphocytic infiltrates; minimal liver enlargement due to fatty changes in the hepatocytes; and generalized lymphoid hyperplasia and lymphadenopathy in patients with Graves disease.
- Thyroid storm refers to the abrupt onset of severe hyperthyroidism. This condition occurs most commonly in patients with underlying Graves disease and probably results from an acute elevation in catecholamine levels, as might be encountered during infection, surgery, cessation of antithyroid medication, or any form of stress. Patients are often febrile and present with tachycardia out of proportion to the fever. Thyroid storm is a medical emergency. A significant number of untreated patients die of cardiac arrhythmias.
- Apathetic hyperthyroidism refers to thyrotoxicosis occurring in older adults, in whom advanced age and various co-morbidities may blunt the features of thyroid hormone excess that typically bring younger patients to attention. The diagnosis of thyrotoxicosis in these individuals is often made during laboratory work-up for unexplained weight loss or worsening cardiovascular disease.

A diagnosis of hyperthyroidism is made using both clinical and laboratory findings. The measurement of serum TSH concentration is the most useful single screening test for hyperthyroidism, because its levels are decreased even at the earliest stages, when the disease may still be subclinical. A low TSH value is usually confirmed with measurement of free T_4 , which is predictably increased. In occasional patients, hyperthyroidism results

Figure 24-9 A person with hyperthyroidism. A wide-eyed, staring gaze, caused by overactivity of the sympathetic nervous system, is one of the features of this disorder. In Graves disease, one of the most important causes of hyperthyroidism, accumulation of loose connective tissue behind the eyeballs, also adds to the protuberant appearance of the eyes.

predominantly from increased circulating levels of T_3 (“ T_3 toxicosis”). In these cases, free T_4 levels may be decreased, and direct measurement of serum T_3 may be useful. In rare cases of pituitary-associated (secondary) hyperthyroidism, TSH levels are either normal or raised. Determining TSH levels after the injection of thyrotropin-releasing hormone (TRH stimulation test) is used in the evaluation of cases of suspected hyperthyroidism with equivocal changes in the baseline serum TSH level. A normal rise in TSH after administration of TRH excludes secondary hyperthyroidism. Once the diagnosis of thyrotoxicosis has been confirmed by a combination of TSH assays and free thyroid hormone levels, measurement of radioactive iodine uptake by the thyroid gland can help to determine the etiology. For example, there may be diffusely increased uptake in the whole gland (Graves disease), increased uptake in a solitary nodule (toxic adenoma), or decreased uptake (thyroiditis).

The therapeutic options for hyperthyroidism include several medications, each with a different mechanism of action. Typically, these include a β -blocker to control symptoms induced by increased adrenergic tone, a thionamide to block new hormone synthesis, an iodine solution to block the release of thyroid hormone, and agents that inhibit peripheral conversion of T_4 to T_3 . Radioiodine, which is incorporated into thyroid tissues, resulting in ablation of thyroid function over a period of 6 to 18 weeks, may also be used.

Hypothyroidism

Hypothyroidism is a condition caused by a structural or functional derangement that interferes with the production of thyroid hormone. Hypothyroidism is a fairly common disorder. By some estimates the population prevalence of overt hypothyroidism is 0.3%, while subclinical hypothyroidism can be found in greater than 4%. The prevalence increases with age, and it is nearly tenfold more common in women than in men. It can result from a defect anywhere in the hypothalamic-pituitary-thyroid axis. As in the case of hyperthyroidism, this disorder is divided into *primary* and *secondary* forms, depending on whether the hypothyroidism arises from an intrinsic abnormality in the thyroid itself, or occurs as a result of pituitary and hypothalamic disease (Table 24-4). Primary hypothyroidism accounts for the vast majority of cases, and may be accompanied by an enlargement in the size of the thyroid gland (goiter).

Primary hypothyroidism can be congenital, autoimmune, or iatrogenic.

Congenital hypothyroidism. Worldwide, congenital hypothyroidism is most often the result of **endemic iodine deficiency in the diet** (see later). Other rare forms of congenital hypothyroidism include *inborn errors of thyroid metabolism* (*dysmorphonogenetic goiter*), wherein any one of the multiple steps leading to thyroid hormone synthesis may be defective, such as (1) iodide transport into thyrocytes, (2) “organification” of iodine (binding of iodine to tyrosine residues of the storage protein, thyroglobulin), and (3) iodotyrosine coupling to form hormonally active T_3 and T_4 . In rare instances there may be complete absence of thyroid

Table 24-4 Causes of Hypothyroidism

Primary
Genetic defects in thyroid development (<i>PAX8</i> , <i>FOXE1</i> , TSH receptor mutations) (rare)
Thyroid hormone resistance syndrome (<i>THRB</i> mutations) (rare)
Postablative
Surgery, radioiodine therapy, or external irradiation
Autoimmune hypothyroidism
Hashimoto thyroiditis*
Iodine deficiency*
Drugs (lithium, iodides, <i>p</i> -aminosalicylic acid)*
Congenital biosynthetic defect (dysmorphonogenetic goiter) (rare) *
Secondary (Central)
Pituitary failure (rare)
Hypothalamic failure (rare)

*Associated with enlargement of thyroid (“goitrous hypothyroidism”). Hashimoto thyroiditis and postablative hypothyroidism account for the majority of cases of hypothyroidism in developed countries. *FOXE1*, forkhead box E1; *PAX8*, paired box 8; *THRB*, thyroid hormone receptor β .

parenchyma (*thyroid agenesis*), or the gland may be greatly reduced in size (*thyroid hypoplasia*) due to germline mutations in genes responsible for thyroid development (Table 24-4).

Autoimmune hypothyroidism. Autoimmune hypothyroidism is the most common cause of hypothyroidism in iodine-sufficient areas of the world. The vast majority of cases of autoimmune hypothyroidism are due to Hashimoto thyroiditis. Circulating autoantibodies, including *anti-microsomal*, *antithyroid peroxidase*, and *antithyroglobulin* antibodies, are found in this disorder, and the thyroid is typically enlarged (goitrous). Autoimmune hypothyroidism can occur in isolation or in conjunction with autoimmune polyendocrine syndrome (APS), types 1 and 2 (see discussion in “Adrenal Glands”).

Iatrogenic hypothyroidism. This can be caused by either *surgical or radiation-induced ablation*. A large resection of the gland (total thyroidectomy) for the treatment of hyperthyroidism or a primary neoplasm can lead to hypothyroidism. The gland may also be ablated by radiation, whether in the form of radioiodine administered for the treatment of hyperthyroidism, or exogenous irradiation, such as external radiation therapy to the neck. *Drugs* given intentionally to decrease thyroid secretion (e.g., methimazole and propylthiouracil) can also cause acquired hypothyroidism, as can agents used to treat nonthyroid conditions (e.g., lithium, *p*-aminosalicylic acid).

Secondary (or central) hypothyroidism is caused by deficiencies of TSH or, far more uncommonly, TRH. Any of the causes of hypopituitarism (for example, pituitary tumor, postpartum pituitary necrosis, trauma, and nonpituitary tumors), or of hypothalamic damage from tumors, trauma, radiation therapy, or infiltrative diseases can cause central hypothyroidism.

Cretinism

Cretinism refers to hypothyroidism that develops in infancy or early childhood. The term *cretin* was derived from the French *chrétien*, meaning “Christian” or

“Christlike,” and was applied to these unfortunates because they were considered to be so mentally retarded as to be incapable of sinning. In the past this disorder occurred fairly commonly in regions of the world where dietary iodine deficiency is endemic, such as the Himalayas, inland China, Africa, and other mountainous areas. It is now much less prevalent as a result of the widespread supplementation of foods with iodine. On rare occasions, cretinism may also result from genetic defects that interfere with the biosynthesis of thyroid hormone (dys-hormonogenetic goiter, see earlier).

Clinical features of cretinism include impaired development of the skeletal system and central nervous system, manifested by severe mental retardation, short stature, coarse facial features, a protruding tongue, and umbilical hernia. The severity of the mental impairment seems to be related to the time at which thyroid deficiency occurs in utero. Normally, maternal T₃ and T₄ cross the placenta and are critical for fetal brain development. If there is maternal thyroid deficiency before the development of the fetal thyroid gland, mental retardation is severe. In contrast, maternal thyroid hormone deficiency later in pregnancy, after the fetal thyroid has become functional, does not affect normal brain development.

Myxedema

The term *myxedema* is applied to hypothyroidism developing in the older child or adult. Myxedema was first linked with thyroid dysfunction in 1873 by Sir William Gull in an article addressing the development of a “cretinoid state” in adults. The clinical manifestations vary with the age of onset of the deficiency. Older children show signs and symptoms intermediate between those of the cretin and those of the adult with hypothyroidism. In the adult the condition appears insidiously and may take years before arousing clinical suspicion.

Myxedema is marked by a slowing of physical and mental activity. The initial symptoms include generalized fatigue, apathy, and mental sluggishness, which may mimic depression. Speech and intellectual functions are slowed. Patients with myxedema are listless, cold intolerant, and frequently overweight. Decreased sympathetic activity results in constipation and decreased sweating. The skin is cool and pale because of decreased blood flow. Reduced cardiac output probably contributes to shortness of breath and decreased exercise capacity, two frequent complaints. Thyroid hormones regulate the transcription of several sarcolemmal genes, such as calcium ATPases and the β adrenergic receptor, and lowered expression of these genes results in a decrease in cardiac output. In addition, hypothyroidism promotes an atherogenic profile—an increase in total cholesterol and low-density lipoprotein (LDL) levels—that probably contributes to the increased cardiovascular mortality in this disease. Histologically, there is an accumulation of matrix substances, such as glycosaminoglycans and hyaluronic acid, in skin, subcutaneous tissue, and a number of visceral sites. This results in nonpitting edema, a broadening and coarsening of facial features, enlargement of the tongue, and deepening of the voice.

Laboratory evaluation plays a vital role in the diagnosis of suspected hypothyroidism because of the nonspecific

nature of symptoms. Patients with unexplained increases in body weight or hypercholesterolemia should be assessed for potential hypothyroidism. **Measurement of the serum TSH level is the most sensitive screening test for this disorder.** The TSH level is increased in primary hypothyroidism as a result of a loss of feedback inhibition of TRH and TSH production by the hypothalamus and pituitary, respectively. The TSH level is not increased in persons with hypothyroidism due to primary hypothalamic or pituitary disease. T₄ levels are decreased in individuals with hypothyroidism of any origin.

Thyroiditis

Thyroiditis, or inflammation of the thyroid gland, encompasses a diverse group of disorders characterized by some form of thyroid inflammation.

Although multiple entities exist under the diagnostic umbrella of “thyroiditis,” this discussion focuses on the three most common and clinically significant subtypes: (1) Hashimoto thyroiditis, (2) granulomatous (de Quervain) thyroiditis, and (3) subacute lymphocytic thyroiditis.

Hashimoto Thyroiditis

Hashimoto thyroiditis is an autoimmune disease that results in destruction of the thyroid gland and gradual and progressive thyroid failure. It is the most common cause of hypothyroidism in areas of the world where iodine levels are sufficient. The name is derived from the 1912 report by Hashimoto describing patients with goiter and intense lymphocytic infiltration of the thyroid (*struma lymphomatosa*). It is most prevalent between 45 and 65 years of age and is more common in women than in men, with a female predominance of 10:1 to 20:1. It can also occur in children and is a major cause of nonendemic goiter in the pediatric population.

Pathogenesis. Hashimoto thyroiditis is caused by a breakdown in self-tolerance to thyroid autoantigens. This is exemplified by the presence of circulating autoantibodies against thyroglobulin and thyroid peroxidase in the vast majority of Hashimoto patients. The inciting events have not been elucidated, but possibilities include abnormalities of regulatory T cells (Tregs), or exposure of normally sequestered thyroid antigens (Chapter 6). Similar to other autoimmune diseases, Hashimoto thyroiditis has a strong genetic component. Increased susceptibility to Hashimoto thyroiditis is associated with polymorphisms in immune regulation-associated genes, including *cytotoxic T lymphocyte-associated antigen-4 (CTLA4)* and *protein tyrosine phosphatase-22 (PTPN22)*, both of which code for regulators of T-cell responses. Susceptibility to other autoimmune diseases, such as type 1 diabetes (see later), is also associated with polymorphisms in both *CTLA4* and *PTPN22*.

Induction of thyroid autoimmunity is accompanied by a progressive depletion of thyroid epithelial cells by apoptosis and replacement of the thyroid parenchyma by mononuclear cell infiltration and fibrosis. Multiple immunologic mechanisms may contribute to thyroid cell death, including (Fig. 24-10):

Figure 24-10 Pathogenesis of Hashimoto thyroiditis. Breakdown of peripheral tolerance to thyroid autoantigens, results in progressive autoimmune destruction of thyroid cells by infiltrating cytotoxic T cells, locally released cytokines, or by antibody-dependent cytotoxicity.

- *CD8+ cytotoxic T cell-mediated cell death:* CD8+ cytotoxic T cells may destroy thyroid follicular cells.
- *Cytokine-mediated cell death:* Activation of CD4+ T cells leads to the production of inflammatory cytokines such as interferon- γ in the thyroid gland, with resultant recruitment and activation of macrophages and damage to follicles.
- A less likely mechanism involves binding of antithyroid antibodies (antithyroglobulin, and antithyroid peroxidase antibodies) followed by antibody-dependent cell-mediated cytotoxicity (Chapter 6).

Clinical Course. Hashimoto thyroiditis most often comes to clinical attention as painless enlargement of the thyroid, usually associated with some degree of hypothyroidism, in a middle-aged woman. The enlargement of the gland is usually symmetric and diffuse, but in some cases it may be sufficiently localized to raise the suspicion of a neoplasm. In the usual case, hypothyroidism develops gradually. In some patients, however, it may be preceded by transient thyrotoxicosis caused by disruption of thyroid follicles, leading to release of thyroid hormones (“*hashitoxicosis*”). During this phase, free T_4 and T_3 levels are elevated, TSH is diminished, and radioactive iodine uptake is decreased. As hypothyroidism supervenes, T_4 and T_3 levels fall, accompanied by a compensatory increase in TSH.

Individuals with Hashimoto thyroiditis are at increased risk for developing other autoimmune diseases, both

MORPHOLOGY

The thyroid is often diffusely enlarged, although more localized enlargement may be seen in some cases. The capsule is intact, and the gland is well demarcated from adjacent structures. The cut surface is pale, yellow-tan, firm, and somewhat nodular. There is extensive infiltration of the parenchyma by a **mononuclear inflammatory infiltrate** containing small lymphocytes, plasma cells, and well-developed **germinal centers** (Fig. 24-11). The thyroid follicles are atrophic and are lined in many areas by epithelial cells distinguished by the presence of abundant eosinophilic, granular cytoplasm, termed **Hürthle cells**. This is a metaplastic response of the normally low cuboidal follicular epithelium to ongoing injury. In fine-needle aspiration biopsy samples, the presence of Hürthle cells in conjunction with a heterogeneous population of lymphocytes is characteristic of Hashimoto thyroiditis. In “classic” Hashimoto thyroiditis, interstitial connective tissue is increased and may be abundant. Unlike Reidel thyroiditis (see later), the fibrosis does not extend beyond the capsule of the gland.

Figure 24-11 Hashimoto thyroiditis. The thyroid parenchyma contains a dense lymphocytic infiltrate with germinal centers. Residual thyroid follicles lined by deeply eosinophilic Hürthle cells are also seen.

endocrine (type 1 diabetes, autoimmune adrenalitis) and nonendocrine (systemic lupus erythematosus, myasthenia gravis, and Sjögren syndrome; [Chapter 6](#)). They are also at increased risk for the development of extranodal marginal zone B-cell lymphomas within the thyroid gland ([Chapter 13](#)). The relationship between Hashimoto disease and thyroid epithelial cancers remains controversial, with some morphologic and molecular studies suggesting a predisposition to papillary carcinomas.

Subacute Lymphocytic (Painless) Thyroiditis

Subacute lymphocytic thyroiditis, which is also referred to as *painless thyroiditis*, usually comes to clinical attention because of mild hyperthyroidism, goitrous enlargement of the gland, or both. Although it can occur at any age, it is most often seen in middle-aged adults and is more common in women. A disease process resembling painless thyroiditis can occur during the postpartum period in up to 5% of women (*postpartum thyroiditis*). Painless and postpartum thyroiditides are variants of autoimmune thyroiditis. Most of the patients have circulating antithyroid peroxidase antibodies or a family history of other autoimmune disorders. As many as a third of cases can evolve into overt hypothyroidism over time, and the thyroid histology may resemble Hashimoto thyroiditis.

MORPHOLOGY

Except for possible mild symmetric enlargement, the thyroid appears grossly normal. Microscopic examination reveals lymphocytic infiltration with large germinal centers within the thyroid parenchyma and patchy disruption and collapse of thyroid follicles. Unlike Hashimoto thyroiditis, however, fibrosis and Hürthle cell metaplasia are not prominent.

Clinical Course. Affected individuals may present with a painless goiter, transient overt hyperthyroidism, or both. Some patients transition from hyperthyroidism to hypothyroidism before recovery. As stated, as many as a third of affected individuals eventually progress to overt hypothyroidism over a 10-year period.

Granulomatous Thyroiditis

Granulomatous thyroiditis (also called *De Quervain thyroiditis*) occurs much less frequently than does Hashimoto disease. The disorder is most common between the ages of 40 and 50 and, like other forms of thyroiditis, affects women considerably more often than men (4:1).

Pathogenesis. Granulomatous thyroiditis is believed to be triggered by a viral infection. The majority of patients have a history of an upper respiratory infection just before the onset of thyroiditis. The disease has a seasonal incidence, with occurrences peaking in the summer, and clusters of cases have been reported in association with coxsackievirus, mumps, measles, adenovirus, and other viral infections. Although the pathogenesis of the disease is unclear, one model suggests that it results from a viral infection that leads to exposure to a viral or thyroid antigen secondary to virus-induced host tissue damage. This antigen stimulates cytotoxic T lymphocytes, which then damage

Figure 24-12 Granulomatous thyroiditis. The thyroid parenchyma contains a chronic inflammatory infiltrate with a multinucleate giant cell (*above left*) and a colloid follicle (*bottom right*).

thyroid follicular cells. In contrast to autoimmune thyroid disease, the immune response is virus-initiated and not self-perpetuating, so the process is limited.

MORPHOLOGY

The gland may be unilaterally or bilaterally enlarged and firm, with an intact capsule that may adhere to surrounding structures. On cut section, the involved areas are firm and yellow-white and stand out from the more rubbery, normal brown thyroid substance. Histologic changes are patchy and depend on the stage of the disease. Early in the active inflammatory phase, scattered follicles may be disrupted and replaced by neutrophils forming microabscesses. Later, more characteristic features appear in the form of aggregates of lymphocytes, activated macrophages, and plasma cells associated with collapsed and damaged thyroid follicles. **Multinucleate giant cells** enclose naked pools or fragments of colloid ([Fig. 24-12](#)), hence the designation **granulomatous thyroiditis**. In later stages of the disease a chronic inflammatory infiltrate and fibrosis may replace the foci of injury. Different histologic stages are sometimes found in the same gland, suggesting waves of destruction over a period of time.

Clinical Course. Granulomatous thyroiditis is the most common cause of *thyroid pain*. There is a variable enlargement of the thyroid. Inflammation of the thyroid and hyperthyroidism are transient, usually diminishing in 2 to 6 weeks, even if the patient is not treated. Nearly all patients have high serum T_4 and T_3 levels and low serum TSH levels during this phase. However, unlike in hyperthyroid states such as Graves disease, radioactive iodine uptake is diminished. After recovery, generally in 6 to 8 weeks, normal thyroid function returns.

Other, less common forms of thyroiditis include *Riedel thyroiditis*, a rare disorder characterized by extensive fibrosis involving the thyroid and contiguous neck structures. The presence of a hard and fixed thyroid mass clinically simulates a thyroid carcinoma. It may be associated with fibrosis in other sites in the body, such as the retroperitoneum, and appears to be another manifestation of a

systemic autoimmune IgG4-related disease, which is associated with fibrosis and tissue infiltration by plasma cells producing IgG4 (Chapter 6).

KEY CONCEPTS

Thyroiditis

- Hashimoto thyroiditis is the most common cause of hypothyroidism in regions where dietary iodine levels are sufficient.
- Hashimoto thyroiditis is an *autoimmune* thyroiditis characterized by progressive destruction of thyroid parenchyma, Hürthle cell change, and mononuclear (lymphoplasmacytic) infiltrates, with germinal centers and with or without extensive fibrosis.
- Subacute lymphocytic thyroiditis often occurs after a pregnancy (*postpartum thyroiditis*), typically is painless, and is characterized by lymphocytic inflammation in the thyroid. It is also a type of autoimmune thyroiditis.
- Granulomatous (de Quervain) thyroiditis is a self-limited disease, probably secondary to a viral infection, and is characterized by pain and the presence of a granulomatous inflammation in the thyroid.

Graves Disease

Graves disease is the most common cause of endogenous hyperthyroidism. Graves reported in 1835 his observations of a disease characterized by “violent and long continued palpitations in females” associated with enlargement of the thyroid gland. The disease is characterized by a *triad* of clinical findings:

- *Hyperthyroidism* associated with diffuse enlargement of the gland
- Infiltrative *ophthalmopathy* with resultant exophthalmos
- Localized, infiltrative *dermopathy*, sometimes called *pretibial myxedema*, which is present in a minority of patients

Graves disease has a peak incidence between 20 and 40 years of age. Women are affected as much as 10 times more frequently than men. This disorder is said to affect 1.5% to 2% of women in the United States.

Pathogenesis. Graves disease is an autoimmune disorder characterized by the production of autoantibodies against multiple thyroid proteins, most importantly the TSH receptor. A variety of antibodies that can either stimulate or block the TSH receptor are detected in the circulation. The most common antibody subtype, known as *thyroid-stimulating immunoglobulin* (TSI), is observed in approximately 90% of patients with Graves disease. In contrast to antibodies reactive with thyroglobulin and thyroid peroxidase, TSI is almost never observed in other autoimmune diseases of the thyroid. TSI binds to the TSH receptor and mimics its actions, stimulating adenyl cyclase and increasing the release of thyroid hormones. As stated, some patients also have TSH receptor *blocking antibodies* in the circulation, and in a minority of patients these may lead to hypothyroidism.

Graves disease (hyperthyroidism) and Hashimoto thyroiditis (hypothyroidism) represent two extremes of

autoimmune thyroid disorders, and not surprisingly share many underlying features. For example, as with Hashimoto thyroiditis, genetic factors are important in the etiology of Graves disease. The concordance rate in monozygotic twins is 30% to 40%, compared with less than 5% among dizygotic twins, and like Hashimoto thyroiditis, genetic susceptibility is linked to polymorphisms in immune-function genes like *CTLA4* and *PTPN22* and the HLA-DR3 allele.

Autoimmunity also plays a role in the development of the *infiltrative ophthalmopathy* that is characteristic of Graves disease. In Graves ophthalmopathy, the protrusion of the eyeball (exophthalmos) is associated with increased volume of the retroorbital connective tissues and extraocular muscles, for several reasons. These include (1) marked infiltration of the retroorbital space by mononuclear cells, predominantly T cells; (2) inflammation with edema and swelling of extraocular muscles; (3) accumulation of extracellular matrix components, specifically hydrophilic glycosaminoglycans such as hyaluronic acid and chondroitin sulfate; and (4) increased numbers of adipocytes (fatty infiltration). These changes displace the eyeball forward and can interfere with the function of the extraocular muscles. Studies performed in animal models suggest that orbital preadipocyte fibroblasts, which express the TSH receptor, appear to stimulate the autoimmune reaction. Activated CD4+ helper T cells secrete cytokines that stimulate fibroblast proliferation and synthesis of extracellular matrix proteins (glycosaminoglycans), leading to progressive infiltration of the retroorbital space and ophthalmopathy.

MORPHOLOGY

The thyroid gland is usually symmetrically enlarged due to **diffuse hypertrophy and hyperplasia** of thyroid follicular epithelial cells (Fig. 24-13A). Increases in weight to over 80 gm are not uncommon. On cut section, the parenchyma has a soft, meaty appearance resembling muscle. Histologically, the follicular epithelial cells in untreated cases are tall and more crowded than usual. This crowding often results in the formation of small papillae, which project into the follicular lumen and encroach on the colloid, sometimes filling the follicles (Fig. 24-13B). Such papillae lack fibrovascular cores, in contrast to those of papillary carcinoma (see later). The colloid within the follicular lumen is pale, with scalloped margins. Lymphoid infiltrates, consisting predominantly of T cells, along with scattered B cells and mature plasma cells, are present throughout the interstitium. Germinal centers are common.

Preoperative therapy alters the morphology of the thyroid in Graves disease. Administration of iodine causes involution of the epithelium and the accumulation of colloid by blocking thyroglobulin secretion. Treatment with the antithyroid drug propylthiouracil exaggerates the epithelial hypertrophy and hyperplasia by stimulating TSH secretion.

Changes in extrathyroidal tissue include lymphoid hyperplasia, especially enlargement of the thymus in younger patients. The heart may be hypertrophied, and ischemic changes may be present, particularly in patients with preexisting coronary artery disease. In patients with ophthalmopathy, the tissues of the orbit are edematous because of the presence of hydrophilic

Figure 24-13 Graves disease. **A**, There is diffuse symmetric enlargement of the gland and a beefy deep red parenchyma. Compare with gross photograph of multinodular goiter in Figure 24-15. **B**, Diffusely hyperplastic thyroid in a case of Graves disease. The follicles are lined by tall, columnar epithelium. The crowded, enlarged epithelial cells project into the lumens of the follicles. These cells actively resorb the colloid in the centers of the follicles, resulting in the scalloped appearance of the edges of the colloid. (**A**, Reproduced with permission from Lloyd RV, et al (eds): Atlas of Nontumor Pathology: Endocrine Diseases. Washington, DC, American Registry of Pathology, 2002.)

mucopolysaccharides. In addition, there is infiltration by lymphocytes and fibrosis. Orbital muscles are edematous initially but may undergo fibrosis late in the course of the disease. The dermatopathy, if present, is characterized by thickening of the dermis due to deposition of glycosaminoglycans and lymphocyte infiltration.

Clinical Course. The clinical findings in Graves disease include some changes associated with *thyrotoxicosis* and others associated uniquely with Graves disease, such as *diffuse hyperplasia of the thyroid*, *ophthalmopathy*, and *dermatopathy*. The degree of thyrotoxicosis varies from case to case and is sometimes less conspicuous than other manifestations of the disease. Diffuse enlargement of the thyroid is present in all cases. The *thyroid enlargement* may be accompanied by increased flow of blood through the hyperactive gland, often producing an audible “bruit.” *Sympathetic overactivity* produces a characteristic wide, staring gaze and lid lag. The ophthalmopathy of Graves disease results in abnormal protrusion of the eyeball (*exophthalmos*). The extraocular muscles are often weak. The exophthalmos may persist or progress despite successful treatment of the thyrotoxicosis, sometimes resulting in corneal injury. The infiltrative dermatopathy, or *pretibial myxedema*, is most common in the skin overlying the shins, where it presents as scaly thickening and induration. The basis of such localization is not clear, and it is present only in a minority of patients. Sometimes individuals spontaneously develop thyroid hypofunction. Patients are at increased risk for other autoimmune diseases, such as systemic lupus erythematosus, pernicious anemia, type 1 diabetes, and Addison disease.

Laboratory findings in Graves disease include *elevated free T₄ and T₃ levels* and *depressed TSH levels*. Because of ongoing stimulation of the thyroid follicles by thyroid-stimulating immunoglobulins, radioiodine scans show a diffusely increased uptake of iodine.

Graves disease is treated with β -blockers, which address symptoms related to the increased β -adrenergic tone (e.g., tachycardia, palpitations, tremulousness, and anxiety), and by measures aimed at decreasing thyroid hormone synthesis, such as the administration of thionamides (e.g.,

propylthiouracil), radioiodine ablation, and thyroidectomy. Surgery is used mostly in patients who have large goiters that are compressing surrounding structures.

KEY CONCEPTS

Graves Disease

- Graves disease, the most common cause of endogenous hyperthyroidism, is characterized by the triad of thyrotoxicosis, ophthalmopathy, and dermatopathy.
- Graves disease is an autoimmune disorder caused by activation of thyroid epithelial cells by autoantibodies to the TSH receptor that mimic TSH action (*thyroid-stimulating immunoglobulins*).
- The thyroid in Graves disease is characterized by diffuse hypertrophy and hyperplasia of follicles and lymphoid infiltrates; glycosaminoglycan deposition and lymphoid infiltrates are responsible for the ophthalmopathy and dermatopathy.
- Laboratory features include elevations in serum free T₃ and T₄ and decreased serum TSH.

Diffuse and Multinodular Goiters

Enlargement of the thyroid, or goiter is caused by impaired synthesis of thyroid hormone, which is most often the result of dietary iodine deficiency. Impairment of thyroid hormone synthesis leads to a compensatory rise in the serum TSH level, which, in turn, causes hypertrophy and hyperplasia of thyroid follicular cells and, ultimately, gross enlargement of the thyroid gland. The compensatory increase in functional mass of the gland overcomes the hormone deficiency, ensuring a *euthyroid* metabolic state in most individuals. If the underlying disorder is sufficiently severe (e.g., a congenital biosynthetic defect or endemic iodine deficiency, discussed later), the compensatory responses may be inadequate, resulting in *goitrous hypothyroidism*. The degree of thyroid enlargement is proportional to the level and duration of thyroid hormone deficiency. Goiters can broadly be divided into two types: *diffuse nontoxic* and *multinodular*.

Diffuse Nontoxic (Simple) Goiter

Diffuse nontoxic (simple) goiter causes enlargement of the entire gland without producing nodularity. Because the enlarged follicles are filled with colloid, the term *colloid goiter* has been applied to this condition. This disorder occurs in both an endemic and a sporadic distribution.

- **Endemic goiter** occurs in geographic areas where the soil, water, and food supply contain low levels of iodine. The term endemic is used when goiters are present in more than 10% of the population in a given region. Such conditions are particularly common in mountainous areas of the world, including the Andes and Himalayas, where iodine deficiency is widespread. The lack of iodine leads to decreased synthesis of thyroid hormone and a compensatory increase in TSH, leading to follicular cell hypertrophy and hyperplasia and goitrous enlargement. With increasing dietary iodine supplementation, the frequency and severity of endemic goiter have declined significantly, although as many as 200 million people worldwide continue to be at risk for severe iodine deficiency.

Variations in the prevalence of endemic goiter in regions with similar levels of iodine deficiency point to the existence of other causative influences, particularly dietary substances, referred to as *goitrogens*. The ingestion of substances that interfere with thyroid hormone synthesis at some level, such as vegetables belonging to the Brassicaceae (Cruciferae) family (e.g., cabbage, cauliflower, Brussels sprouts, turnips, and cassava), has been documented to be goitrogenic. Native populations subsisting on cassava root are particularly at risk. Cassava contains a thiocyanate that inhibits iodide transport within the thyroid, worsening any possible concurrent iodine deficiency.

- **Sporadic goiter** occurs less frequently than does endemic goiter. There is a striking female preponderance and a peak incidence at puberty or in young adult life. Sporadic goiter can be caused by several conditions, including the ingestion of substances that interfere with thyroid hormone synthesis. In other instances, goiter may result from hereditary enzymatic defects that interfere with thyroid hormone synthesis, all transmitted as autosomal-recessive conditions (dyshormonogenetic goiter; see earlier). In most cases, however, the cause of sporadic goiter is not apparent.

MORPHOLOGY

Two phases can be identified in the evolution of diffuse nontoxic goiter: the **hyperplastic phase** and the phase of **colloid involution**. In the hyperplastic phase, the thyroid gland is diffusely and symmetrically enlarged, although the increase is usually modest, and the gland rarely exceeds 100 to 150 gm. The follicles are lined by crowded columnar cells, which may pile up and form projections similar to those seen in Graves disease. The accumulation is not uniform throughout the gland, and some follicles are hugely distended, whereas others remain small. If dietary iodine subsequently increases or if the demand for thyroid hormone decreases, the stimulated follicular epithelium involutes to form an enlarged, colloid-rich gland (**colloid**

Figure 24-14 A 52-year-old woman with a huge colloid goiter who developed compressive symptoms. (Reproduced with permission from Lloyd RV, et al (eds): Atlas of Nontumor Pathology: Endocrine Diseases. Washington, DC, American Registry of Pathology, 2002.)

goiter). In these cases the cut surface of the thyroid is usually brown, somewhat glassy, and translucent. Histologically the follicular epithelium is flattened and cuboidal, and colloid is abundant during periods of involution.

Clinical Course. As stated earlier, the vast majority of persons with simple goiters are clinically euthyroid. Therefore, the clinical manifestations are primarily related to *mass effects* from the enlarged thyroid gland (Fig. 24-14). Although serum T₃ and T₄ levels are normal, the serum TSH is usually elevated or at the upper range of normal, as is expected in marginally euthyroid individuals. In children, dyshormonogenetic goiter, caused by a congenital biosynthetic defect, may induce cretinism.

Multinodular Goiter

With time, recurrent episodes of hyperplasia and involution combine to produce a more irregular enlargement of the thyroid, termed *multinodular goiter*. Virtually all longstanding simple goiters convert into multinodular goiters. **Multinodular goiters produce the most extreme thyroid enlargements and are more frequently mistaken for neoplasms than any other form of thyroid disease.** Because they derive from simple goiter, they occur in both sporadic and endemic forms, having the same female-to-male distribution and presumably the same origins but affecting older individuals because they are late complications.

It is believed that multinodular goiters arise because of variations among follicular cells in their response to external stimuli, such as trophic hormones. If some cells in a follicle have a growth advantage, perhaps because of intrinsic genetic abnormalities similar to those that give

Figure 24-15 Multinodular goiter. **A**, Gross morphology demonstrating a coarsely nodular gland, containing areas of fibrosis and cystic change. **B**, Photomicrograph of a hyperplastic nodule, with compressed residual thyroid parenchyma on the periphery. Note absence of a prominent capsule, a distinguishing feature from follicular neoplasms. (**B**, Courtesy Dr. William Westra, Department of Pathology, Johns Hopkins University, Baltimore, Md.)

rise to adenomas, such cells can give rise to clones of proliferating cells. This may result in the formation of a nodule whose continued growth is autonomous, without the external stimulus. Consistent with this model, both polyclonal and monoclonal nodules coexist within the same multinodular goiter, the latter presumably having arisen because of the acquisition of a genetic abnormality favoring growth. Not surprisingly, activating mutations affecting proteins of the TSH-signaling pathway have been identified in a subset of autonomous thyroid nodules (TSH-signaling pathway mutations and their implications are discussed under “Adenomas”). The uneven follicular hyperplasia, generation of new follicles, and accumulation of colloid produce physical stress that may lead to rupture of follicles and vessels followed by hemorrhages, scarring, and sometimes calcifications. With scarring, nodularity appears, which may be accentuated by the preexisting stromal framework of the gland.

MORPHOLOGY

Multinodular goiters are multilobulated, asymmetrically enlarged glands that can reach weights of more than 2000 gm. The pattern of enlargement is quite unpredictable and may involve one lobe far more than the other, producing lateral pressure on midline structures, such as the trachea and esophagus. In other instances the goiter grows behind the sternum and clavicles to produce the so-called **intrathoracic** or **plunging goiter**. Occasionally, most of it is hidden behind the trachea and esophagus; in other instances one nodule may stand out, imparting the clinical appearance of a solitary nodule. On cut section, irregular nodules containing variable amounts of brown, gelatinous colloid are present (Fig. 24-15A). Older lesions have areas of hemorrhage, fibrosis, calcification, and cystic change. The microscopic appearance includes colloid-rich follicles lined by flattened, inactive epithelium and areas of **follicular hyperplasia**, accompanied by degenerative changes related to physical stress. In contrast to follicular neoplasms, a prominent capsule between the hyperplastic nodules and residual compressed thyroid parenchyma is not present (Fig. 24-15B).

Clinical Course. The dominant clinical features of multinodular goiter are those caused by *mass effects*. In addition to the obvious cosmetic effects, goiters may cause airway obstruction, dysphagia, and compression of large vessels

in the neck and upper thorax (*superior vena cava syndrome*). Most patients are euthyroid or have subclinical hyperthyroidism (identified only by reduced TSH levels), but in a substantial minority of patients an autonomous nodule may develop within a long-standing goiter and produce hyperthyroidism (*toxic multinodular goiter*). This condition, known as *Plummer syndrome*, is not accompanied by the infiltrative ophthalmopathy and dermatopathy of Graves disease. It is estimated that clinically apparent autonomous nodules develop in approximately 10% of multinodular goiters over a 10-year follow-up. The incidence of malignancy in long-standing multinodular goiters is low (<5%) but not zero, and concern for malignancy arises in goiters that demonstrate sudden changes in size or symptoms (e.g., hoarseness). Dominant nodules in a multinodular goiter can present as a “solitary thyroid nodule”, mimicking a thyroid neoplasm. A radioiodine scan demonstrates uneven iodine uptake (including the occasional “hot” autonomous nodule) consistent with the diffuse parenchymal involvement, and an admixture of hyperplastic and involuting nodules. A fine-needle aspiration biopsy is helpful and can often, albeit not always, facilitate the distinction of follicular hyperplasia from a thyroid neoplasm (see later).

Neoplasms of the Thyroid

The solitary thyroid nodule is a palpably discrete swelling within an otherwise apparently normal thyroid gland. The estimated incidence of solitary palpable nodules in the adult population of the United States varies between 1% and 10%, but is significantly higher in endemic goitrous regions. Single nodules are about four times more common in women than in men. The incidence of thyroid nodules increases throughout life.

From a clinical standpoint, the major concern in persons who present with thyroid nodules is the possibility of a malignant neoplasm. Fortunately, the overwhelming majority of solitary nodules of the thyroid prove to be localized, nonneoplastic lesions (e.g., a dominant nodule in multinodular goiter, simple cysts, or foci of thyroiditis) or benign neoplasms such as follicular adenoma. In fact, *benign neoplasms outnumber thyroid carcinomas by a ratio of nearly 10:1*. While less than 1% of solitary thyroid nodules are malignant, this still represents about 15,000 new cases

of thyroid carcinoma per year in the United States. Fortunately, most of these cancers are indolent; more than 90% of affected patients are alive 20 years after being diagnosed.

Several clinical criteria provide clues to the nature of a thyroid nodule:

- *Solitary nodules*, in general, are more likely to be neoplastic than are multiple nodules.
- *Nodules in younger patients* are more likely to be neoplastic than are those in older patients.
- *Nodules in males* are more likely to be neoplastic than are those in females.
- A history of *radiation* treatment to the head and neck region is associated with an increased incidence of thyroid malignancy.
- Functional nodules that take up radioactive iodine in imaging studies (*hot nodules*) are much more likely to be benign than malignant.

These associations and statistics, however, are of little comfort to a patient, in whom the timely recognition of a malignancy can be lifesaving. Ultimately, morphologic evaluation of a given thyroid nodule, by fine-needle aspiration and surgical resection, provides the most definitive information about its nature. The following sections consider the major thyroid tumors, including adenoma and carcinoma in its various forms.

Adenomas

Adenomas of the thyroid are typically discrete, solitary masses, derived from follicular epithelium, and hence they are also known as follicular adenomas. Clinically, follicular adenomas can be difficult to distinguish from dominant nodules of follicular hyperplasia or from the less common follicular carcinomas. In general, follicular adenomas are *not* forerunners to carcinomas; nevertheless, shared genetic alterations support the possibility that at least of subset of follicular carcinomas arises in preexisting adenomas (see later). Although the vast majority of adenomas are nonfunctional, a small subset produces thyroid hormones and causes clinically apparent thyrotoxicosis. Hormone production in functional adenomas (“toxic adenomas”) is independent of TSH stimulation.

Pathogenesis. Somatic mutations of the TSH receptor signaling pathway are found in toxic adenomas, as well as in toxic multinodular goiter. Gain-of-function mutations in one of two components of this signaling system—most often the gene encoding the TSH receptor (TSHR) or the α -subunit of G_s (*GNAS*)—cause follicular cells to secrete thyroid hormone independent of TSH stimulation (“thyroid autonomy”). This leads to symptoms of hyperthyroidism and produces a functional “hot” nodule on imaging. Overall, mutations in the TSH receptor signaling pathway are present in slightly over half of toxic thyroid nodules. Notably, *TSHR* and *GNAS* mutations are rare in follicular carcinomas; thus, toxic adenomas and toxic multinodular goiter do not seem to be forerunners of malignancy.

A minority (<20%) of *nonfunctioning* follicular adenomas have mutations of *RAS* or *PIK3CA*, which encodes a subunit of the PI-3 kinase, or bear a *PAX8-PPARG* fusion

Figure 24-16 Follicular adenoma of the thyroid. **A**, A solitary, well-circumscribed nodule is seen. **B**, The photomicrograph shows well-differentiated follicles resembling normal thyroid parenchyma.

gene, genetic alterations that are shared with follicular carcinomas. These are discussed in further detail under “Carcinomas” (see later).

MORPHOLOGY

The typical thyroid adenoma is a solitary, spherical, encapsulated lesion that is demarcated from the surrounding thyroid parenchyma by a well-defined, intact capsule (Fig. 24-16A). **These features are important in making the distinction from multinodular goiters**, which contain multiple nodules even in patients presenting clinically with a solitary dominant nodule. Follicular adenomas average about 3 cm in diameter, but some are much larger (≥ 10 cm in diameter). In freshly resected specimens the adenoma bulges from the cut surface and compresses the adjacent thyroid. The color ranges from gray-white to red-brown, depending on the cellularity of the adenoma and its colloid content. Areas of hemorrhage, fibrosis, calcification, and cystic change, similar to those encountered in multinodular goiters, are common in follicular adenomas, particularly within larger lesions.

Microscopically, the constituent cells often form uniform-appearing follicles that contain colloid (Fig. 24-16B). The follicular growth pattern is usually quite distinct from the adjacent nonneoplastic thyroid. The neoplastic cells show little variation in cell size, cell shape, or nuclear morphology, and mitotic figures are rare. Occasionally the neoplastic cells acquire brightly eosinophilic granular cytoplasm (*oxyphil* or *Hürthle cell change*) (Fig. 24-17). The hallmark of all follicular adenomas is

Figure 24-17 Hürthle cell (oxyphil) adenoma. A high-power view showing that the tumor is composed of cells with abundant eosinophilic cytoplasm and small regular nuclei. (Courtesy Dr. Mary Sunday, Duke University, Durham, N.C.)

the presence of an intact, well-formed capsule encircling the tumor. **Careful evaluation of the integrity of the capsule is therefore critical in distinguishing follicular adenomas from follicular carcinomas**, which demonstrate capsular and/or vascular invasion (see later). Extensive mitotic activity, necrosis, or high cellularity also warrants close inspection to exclude follicular carcinoma and the follicular variant of papillary carcinoma (see later).

Clinical Features. Many follicular adenomas present as unilateral painless masses that are discovered during a routine physical examination. Larger masses may produce local symptoms, such as difficulty in swallowing. Nonfunctioning adenomas take up less radioactive iodine than does normal thyroid parenchyma. On radionuclide scanning, therefore, nonfunctioning adenomas appear as *cold* nodules relative to the adjacent thyroid tissue. However, as many as 10% of cold nodules are malignant. Other techniques used to evaluate suspected adenomas are ultrasonography and fine-needle aspiration biopsy. **Because of the need for evaluating capsular integrity, the definitive diagnosis of adenomas can be made only after careful histologic examination of the resected specimen.** Suspected adenomas of the thyroid are therefore removed surgically to exclude malignancy. Follicular adenomas do not recur or metastasize and have an excellent prognosis.

Carcinomas

Carcinomas of the thyroid are relatively uncommon in the United States, accounting for about 1.5% of all cancers. A female predominance has been noted among patients who develop thyroid carcinoma in the early and middle adult years. In contrast, cases presenting in childhood and late adult life are distributed equally among males and females.

The major subtypes of thyroid carcinoma and their relative frequencies are as follows:

- Papillary carcinoma (>85% of cases)
- Follicular carcinoma (5% to 15% of cases)

- Anaplastic (undifferentiated) carcinoma (<5% of cases)
- Medullary carcinoma (5% of cases)

Most thyroid carcinomas (except medullary carcinomas) are derived from the thyroid follicular epithelium, and of these, the vast majority are well-differentiated lesions. Because of the unique clinical, molecular and biologic features associated with each variant of thyroid carcinoma, these subtypes are described separately. We begin with a discussion of the molecular pathogenesis of all thyroid cancers.

Pathogenesis

Genetic Factors. Distinct genetic events are involved in the pathogenesis of the four major histologic variants of thyroid cancer. As stated, medullary carcinomas do not arise from the follicular epithelium. **Genetic alterations in the three follicular cell-derived malignancies are in growth factor receptor signaling pathways (Fig. 24-18).** You will recall that in normal cells, these pathways are transiently activated by binding of soluble growth factor ligands to the extracellular domain of receptor tyrosine kinases, which results in autophosphorylation of the cytoplasmic domain of the receptor. This in turn sets in motion events that lead to activation of RAS and two downstream signaling arms involving MAP kinase (MAPK) and PI-3 kinase (PI3K). In thyroid carcinomas, as with many cancers (Chapter 7), gain-of-function mutations in components of these pathways lead to their constitutive activation, driving excessive cellular proliferation and increased cell survival.

Figure 24-18 Genetic alterations in follicular cell-derived malignancies of the thyroid gland.

Papillary Carcinomas. Most papillary carcinomas have gain-of-function mutations involving the genes encoding the RET or NTRK1 receptor tyrosine kinases, or in the serine/threonine kinase BRAF, which you will recall lies in the MAPK pathway (Fig. 24-18).

- The RET gene is located on chromosome 10q11, and the receptor tyrosine kinase it encodes is normally not expressed in thyroid follicular cells. In papillary cancers, either a paracentric inversion of chromosome 10 or a reciprocal translocation between chromosomes 10 and 17 places the tyrosine kinase domain of RET under the transcriptional control of genes that are constitutively expressed in the thyroid epithelium. The novel fusion genes that are so formed are known as RET/PTC (RET/papillary thyroid carcinoma) and are present in approximately 20% to 40% of papillary thyroid cancers. There are more than 15 fusion partners of RET, and two—designated as PTC1 and PTC2—are most commonly observed in sporadic papillary cancers. The frequency of RET/PTC rearrangements is significantly higher in papillary cancers arising in the backdrop of radiation exposure. The RET/PTC rearrangements produce genes that encode fusion proteins with constitutive tyrosine kinase activity. Similarly, paracentric inversions or translocations of NTRK1 on chromosome 1q21 are present in 5% to 10% of papillary thyroid cancers. These genetic events also produce constitutively active NTRK1 fusion proteins.
- BRAF encodes an intermediate signaling component in the MAP kinase pathway. One third to one half of papillary thyroid carcinomas harbor a gain-of-function mutation in the BRAF gene, which is most commonly a valine-to-glutamate change in codon 600 (BRAF^{V600E}). The presence of BRAF mutations in papillary carcinomas correlates with adverse prognostic factors like metastatic disease and extrathyroidal extension. As discussed in other chapters, a similar BRAF mutation is found in some other cancers as well, including melanomas, hairy cell leukemia and a subset of colon cancers, suggesting that diverse tumors may share a similar pathway to malignancy.

Because chromosomal rearrangements of the RET or NTRK1 genes and mutations of BRAF have redundant effects on MAP kinase signaling, it is not surprising that they are usually (but not always) mutually exclusive events. The histologic variants of papillary carcinoma demonstrate some unique characteristics vis-à-vis the frequency or nature of BRAF mutation (see later). Of further interest, RET/PTC rearrangements and BRAF point mutations are not observed in follicular adenomas or carcinomas.

Follicular Carcinomas. In contrast to papillary carcinomas, follicular carcinomas are associated with acquired mutations that activate RAS or the PI-3K/AKT arm of the receptor tyrosine kinase signaling pathway. It is evident from Figure 24-18 that activated mutations in RAS would be expected to stimulate both the MAPK and PI3K signaling pathways. Why RAS mutations produce follicular neoplasms, rather than papillary neoplasms, is not understood, a point that highlights our lack of insight into the nuances of intracellular signaling. Approximately one third to

one half of follicular thyroid carcinomas harbor gain-of-function point mutations of RAS or PIK3CA (the gene that encodes PI-3 kinase), PIK3CA amplifications, or loss-of-function mutations of PTEN, a tumor suppressor gene and negative regulator of this pathway (Fig. 24-18). These genetic alterations are almost always mutually exclusive in follicular carcinomas, in line with their functional equivalence. The progressive increase in the prevalence of RAS and PIK3CA mutations from benign follicular adenomas to follicular carcinomas to anaplastic carcinomas (see later) suggests a shared histogenesis and molecular evolution among these follicular tumors.

A unique (2;3)(q13;p25) translocation has been described in one third to one half of follicular carcinomas. This translocation creates a fusion gene composed of portions of PAX8, a paired homeobox gene that is important in thyroid development, and the peroxisome proliferator-activated receptor gene (PPARG), whose gene product is a nuclear hormone receptor implicated in terminal differentiation of cells. Fewer than 10% of follicular adenomas harbor PAX8-PPARG fusion genes, and these have not been documented thus far in other thyroid neoplasms.

Anaplastic (Undifferentiated) Carcinomas. These highly aggressive and lethal tumors can arise de novo, or more commonly, by “dedifferentiation” of a well-differentiated papillary or follicular carcinoma. Molecular alterations present in anaplastic carcinomas include those also seen in well-differentiated carcinomas (e.g., RAS or PIK3CA mutations). Other genetic “hits,” such as inactivation of TP53 or activating mutations of β -catenin, are essentially restricted to anaplastic carcinomas and may contribute to their aggressive behavior.

Medullary Thyroid Carcinomas. Familial medullary thyroid carcinomas occur in multiple endocrine neoplasia type 2 (MEN-2, see later) and are associated with germline RET mutations that lead to constitutive activation of the receptor. RET mutations are also seen in approximately one half of nonfamilial (sporadic) medullary thyroid cancers. Chromosomal rearrangements involving RET, such as the RET/PTC translocations reported in papillary cancers, are not seen in medullary carcinomas.

Environmental Factors. The major risk factor predisposing to thyroid cancer is exposure to ionizing radiation, particularly during the first 2 decades of life. In keeping with this, there was a marked increase in the incidence of papillary carcinomas among children exposed to ionizing radiation after the Chernobyl nuclear disaster in 1986. Deficiency of dietary iodine (and by extension, an association with goiter) is linked with a higher frequency of follicular carcinomas.

Papillary Carcinoma

Papillary carcinomas are the most common form of thyroid cancer, accounting for nearly 85% of primary thyroid malignancies in the United States. They occur throughout life but most often between the ages of 25 and 50, and account for the majority of thyroid carcinomas associated with previous exposure to ionizing radiation. The diagnosis of papillary carcinoma has increased markedly in the last 30 years, partly because of the recognition of follicular variants (see later) that were misclassified in the past.

Figure 24-19 Papillary carcinoma of the thyroid. **A**, The macroscopic appearance of a papillary carcinoma with grossly discernible papillary structures. **B**, This particular example contains well-formed papillae. **C**, High power shows cells with characteristic empty-appearing nuclei, sometimes called “Orphan Annie eye” nucle. **D**, Cells obtained by fine-needle aspiration of a papillary carcinoma. Characteristic intranuclear inclusions are visible in some of the aspirated cells.

MORPHOLOGY

Papillary carcinomas may be solitary or multifocal. Some tumors are well circumscribed and even encapsulated; others infiltrate the adjacent parenchyma and have ill-defined margins. The tumors may contain areas of fibrosis and calcification and are often cystic. The cut surface sometimes reveals papillary foci that point to the diagnosis. The microscopic hallmarks of papillary neoplasms include the following (Fig. 24-19):

- Papillary carcinomas may contain branching **papillae** having a fibrovascular stalk covered by a single to multiple layers of cuboidal epithelial cells. In most neoplasms, the epithelium covering the papillae consists of well-differentiated, uniform, orderly cuboidal cells, but at the other extreme are those with fairly anaplastic epithelium showing considerable variation in cell and nuclear morphology. When present, the papillae of papillary carcinoma differ from those seen in areas of hyperplasia in being more complex and having dense fibrovascular cores.
- The nuclei of papillary carcinoma cells contain finely dispersed chromatin, which imparts an **optically clear** or **empty** appearance, giving rise to the designation **ground-glass** or **Orphan Annie eye nuclei**. In addition, invaginations of the cytoplasm may give the appearance of intranuclear inclusions (“pseudo-inclusions”) or intranuclear grooves. **The diagnosis of papillary carcinoma can be made based on these nuclear features**, even in the absence of papillary architecture.

- Concentrically calcified structures termed **psammoma bodies** are often present, usually within the cores of papillae. These structures are almost never found in follicular and medullary carcinomas, and so, when present in fine-needle aspiration material, they are a strong indication that the lesion is a papillary carcinoma.
- Foci of lymphatic invasion by tumor are often present, but involvement of blood vessels is relatively uncommon, particularly in smaller lesions. Metastases to adjacent cervical lymph nodes occur in up to half of cases.

There are over a dozen histologic variants of papillary carcinoma that can mimic other thyroid lesions or harbor distinct prognostic implications; most are beyond the scope of this book. The most common variant, and the one most liable to misdiagnosis, is the **follicular variant**, which has the characteristic nuclear features of papillary carcinoma and an almost totally follicular architecture. Follicular variant papillary carcinomas can be either encapsulated or poorly circumscribed and infiltrative. The encapsulated follicular variant of papillary carcinoma has a generally favorable prognosis, while the poorly circumscribed and infiltrative lesions need to be treated more aggressively. The genetic alterations in the follicular variant, especially the encapsulated tumors, demonstrate several distinctions from conventional papillary carcinomas, including a lower frequency of *RET/PTC* rearrangements, a lower frequency and different spectrum of *BRAF* mutations, and a significantly higher frequency of *RAS* mutations. When considered in conjunction with their higher propensity for angioinvasion and lower

incidence of lymph node metastases, it has become evident that at least a subset of the encapsulated follicular variant display biological features that are more comparable to minimally invasive follicular carcinomas (see later) than conventional papillary carcinomas.

The **tall-cell variant** has tall columnar cells with intensely eosinophilic cytoplasm lining the papillary structures. These tumors tend to occur in older individuals and have higher frequencies of vascular invasion, extrathyroidal extension, and cervical and distant metastases than conventional papillary thyroid carcinoma. Tall-cell variant papillary carcinomas harbor *BRAF* mutations in most (55% to 100%) cases, and often have *RET/PTC* translocations as well. The occurrence of these two aberrations together may synergistically enhance MAPK signaling, contributing to the aggressive behavior of this variant.

An unusual **diffuse sclerosing variant** of papillary carcinoma occurs in younger individuals, including children. The tumor has a prominent papillary growth pattern intermixed with solid areas containing nests of squamous metaplasia. As the name suggests, there is extensive, diffuse fibrosis throughout the thyroid gland, often associated with a prominent lymphocytic infiltrate, simulating Hashimoto thyroiditis. Lymph node metastases are present in almost all cases. The diffuse sclerosing variant carcinomas lack *BRAF* mutations, but *RET/PTC* translocations are found in approximately half the cases.

Finally, the **papillary microcarcinoma** is defined as an otherwise conventional papillary carcinoma less than 1 cm in size. These lesions most commonly come to attention as an incidental finding in patients undergoing surgery, and may be precursors of typical papillary carcinomas.

Clinical Course. Most conventional papillary carcinomas present as asymptomatic thyroid nodules, but the first manifestation may be a mass in a cervical lymph node. Interestingly, the presence of isolated cervical nodal metastases does not have a significant influence on prognosis, which is generally good. Most carcinomas are single nodules that move freely with the thyroid gland during swallowing and are not distinguishable on examination from benign nodules. Hoarseness, dysphagia, cough, or dyspnea suggests advanced disease. In a minority of patients, hematogenous metastases are present at the time of diagnosis, most commonly in the lung.

A variety of diagnostic tests have been used to help separate benign from malignant thyroid nodules, including radionuclide scanning and fine-needle aspiration. Papillary carcinomas are *cold* masses on scintiscans. Improvements in cytologic analysis have made fine-needle aspiration cytology a reliable test for distinguishing between benign and malignant nodules. The nuclear features are often demonstrated nicely in aspirated specimens.

Papillary thyroid cancers have an excellent prognosis, with a 10-year survival rate in excess of 95%. Between 5% and 20% of patients have local or regional recurrences, and 10% to 15% have distant metastases. The prognosis of someone with papillary thyroid cancers is dependent on several factors including age (in general, being less favorable among patients older than 40 years), the presence of extrathyroidal extension, and presence of distant metastases (stage).

Follicular Carcinoma

Follicular carcinomas account for 5% to 15% of primary thyroid cancers, but are more frequent in areas with dietary iodine deficiency, where they constitute 25% to 40% of thyroid cancers. They are more common in women (3:1) and present more often in older patients than do papillary carcinomas; the peak incidence is between 40 and 60 years of age.

MORPHOLOGY

Follicular carcinomas are single nodules that may be well circumscribed or widely infiltrative (Fig. 24-20A). Sharply demarcated lesions may be exceedingly difficult to distinguish from follicular adenomas by gross examination. Larger lesions may penetrate the capsule and infiltrate well beyond the thyroid capsule into the adjacent neck. They are gray to tan to pink on cut section and may be somewhat translucent due to the presence of large, colloid-filled follicles. Degenerative changes, such as central fibrosis and foci of calcification, are sometimes present.

Figure 24-20 Follicular carcinoma. **A**, Cut surface of a follicular carcinoma with substantial replacement of the lobe of the thyroid. The tumor has a light-tan appearance and contains small foci of hemorrhage. **B**, A few of the glandular lumens contain recognizable colloid.

Figure 24-21 Capsular integrity in follicular neoplasms. In adenomas (**A**), a fibrous capsule, usually thin but occasionally more prominent, circumferentially surrounds the neoplastic follicles and no capsular invasion is seen (*arrows*); compressed normal thyroid parenchyma is usually present external to the capsule (*top of the panel*). In contrast, follicular carcinomas demonstrate capsular invasion (**B**, *arrows*) that may be minimal, as in this case, or widespread. The presence of vascular invasion is another feature of follicular carcinomas.

Microscopically, most follicular carcinomas are composed of fairly uniform cells forming small follicles containing colloid, quite reminiscent of normal thyroid (Fig. 24-20B). In other cases follicular differentiation may be less apparent, and there may be nests or sheets of cells without colloid. Occasional tumors are dominated by cells with abundant granular, eosinophilic cytoplasm (**Hürthle cell or oncocytic variant of follicular carcinoma**). Whatever the pattern, the nuclei lack the features typical of papillary carcinoma, and psammoma bodies are not present. While nuclear features (optically clear nuclei, nuclear grooves) are helpful in distinguishing papillary from follicular neoplasms, **there is no reliable cytologic difference between follicular adenomas and minimally invasive follicular carcinomas**. Making this distinction requires extensive histologic sampling of the tumor-capsule-thyroid interface to exclude capsular and/or vascular invasion (Fig. 24-21). The criterion for vascular invasion is applicable only to capsular vessels and vascular spaces beyond the capsule; the presence of tumor plugs within intra-tumoral blood vessels has little prognostic significance. Unlike in papillary cancers, lymphatic spread is uncommon in follicular cancers.

In contrast to minimally invasive follicular cancers, the diagnosis of carcinoma is obvious in **widely invasive follicular carcinomas**, which infiltrate the thyroid parenchyma and extrathyroidal soft tissues. Histologically, these cancers tend to have a greater proportion of solid or trabecular growth pattern, less evidence of follicular differentiation, and increased mitotic activity.

Clinical Course. Follicular carcinomas present as slowly enlarging painless nodules. Most frequently they are *cold nodules* on scintigrams, although rare, better-differentiated lesions may be hyperfunctional, take up radioactive iodine and appear *warm* on scintiscan. Because follicular carcinomas have little propensity for invading lymphatics, regional lymph nodes are rarely involved, but vascular (hematogenous) dissemination is common, with metastases to bone, lungs, liver, and elsewhere.

The prognosis depends largely on the extent of invasion and stage at presentation. Widely invasive follicular

carcinoma often presents with systemic metastases, and as many as half of affected patients succumb to their disease within 10 years. This is in sharp contrast to minimally invasive follicular carcinomas, which have a 10-year survival rate of greater than 90%. Most follicular carcinomas are treated with total thyroidectomy followed by the administration of radioactive iodine, which can be used to identify metastases and to ablate such lesions. In addition, because any residual follicular carcinoma may respond to TSH stimulation, patients are usually treated with thyroid hormone after surgery to suppress endogenous TSH levels. Serum thyroglobulin levels are used for monitoring tumor recurrence, because this thyroid protein should be barely detectable in a patient who is free of disease.

Anaplastic (Undifferentiated) Carcinoma

Anaplastic carcinomas are undifferentiated tumors of the thyroid follicular epithelium, accounting for less than 5% of thyroid tumors. They are aggressive, with a mortality rate approaching 100%. Patients with anaplastic carcinoma are older than those with other types of thyroid cancer, with a mean age of 65 years. Approximately a quarter of patients with anaplastic thyroid carcinomas have a past history of a well-differentiated thyroid carcinoma, and another quarter harbors a concurrent well-differentiated tumor in the resected specimen.

MORPHOLOGY

Microscopically, these neoplasms are composed of highly anaplastic cells, with variable morphology, including (1) large, pleomorphic **giant** cells, including occasional osteoclast-like multinucleate giant cells; (2) **spindle** cells with a sarcomatous appearance; and (3) **mixed** spindle and giant cells. Foci of papillary or follicular differentiation may be present in some tumors, suggesting an origin from a better-differentiated carcinoma. The neoplastic cells express epithelial markers like cytokeratin, but are usually negative for markers of thyroid differentiation, like thyroglobulin.

Clinical Course. Anaplastic carcinomas usually present as a rapidly enlarging bulky neck mass. In most cases, the disease has already spread beyond the thyroid capsule into adjacent neck structures or has metastasized to the lungs at the time of presentation. Symptoms related to compression and invasion, such as dyspnea, dysphagia, hoarseness, and cough, are common. There are no effective therapies, and the disease is almost uniformly fatal. Although metastases to distant sites are common, in most cases death occurs in less than 1 year as a result of aggressive growth and compromise of vital structures in the neck.

Medullary Carcinoma

Medullary carcinomas of the thyroid are neuroendocrine neoplasms derived from the parafollicular cells, or C cells, of the thyroid, and account for approximately 5% of thyroid neoplasms. Medullary carcinomas, similar to normal C cells, secrete *calcitonin*, the measurement of which plays an important role in the diagnosis and postoperative follow-up of patients. In some instances the tumor cells elaborate other polypeptide hormones, such as serotonin, ACTH, and vasoactive intestinal peptide (VIP). About 70% of tumors arise sporadically. The remainder occurs in the setting of MEN syndrome 2A or 2B or as familial tumors without an associated MEN syndrome (familial medullary thyroid carcinoma, or FMTC; see “[Multiple Endocrine Neoplasia Syndromes](#)”). Recall that *activating point mutations in the RET proto-oncogene* play an important role in the development of both familial and sporadic medullary carcinomas. Cases associated with MEN types 2A or 2B occur in younger patients, and may even arise during the first decade of life. In contrast, sporadic as well as familial medullary carcinomas are lesions of adulthood, with a peak incidence in the 40s and 50s.

MORPHOLOGY

Sporadic medullary thyroid carcinomas present as a solitary nodule (Fig. 24-22A). In contrast, **bilaterality and multicentricity are common in familial cases.** Larger lesions often contain areas of necrosis and hemorrhage and may extend through the capsule of the thyroid. The tumor tissue is firm, pale gray to tan, and infiltrative. There may be foci of hemorrhage and necrosis in the larger lesions.

Microscopically, medullary carcinomas are composed of polygonal to spindle-shaped cells, which may form nests, trabeculae, and even follicles. Small, more anaplastic cells are present in some tumors and may be the predominant cell type. Acellular **amyloid deposits** derived from calcitonin polypeptides are present in the stroma in many cases (Fig. 24-22B). Calcitonin is readily demonstrable within the cytoplasm of the tumor cells as well as in the stromal amyloid by immunohistochemical methods. As with all neuroendocrine tumors, electron microscopy reveals variable numbers of membrane-bound electron-dense granules within the cytoplasm of the neoplastic cells (Fig. 24-23). One of the features of familial medullary cancers is the presence of multicentric **C-cell hyperplasia** in the surrounding thyroid parenchyma, a feature that is usually absent in sporadic lesions, and that is believed to be a precursor lesion in familial cases. Thus, the presence of multiple

Figure 24-22 Medullary carcinoma of thyroid. **A**, These tumors typically show a solid pattern of growth and do not have connective tissue capsules. **B**, Histology demonstrates abundant deposition of amyloid, visible here as homogeneous extracellular material, derived from calcitonin molecules secreted by the neoplastic cells. (**A**, Courtesy Dr. Joseph Corson, Brigham and Women's Hospital, Boston, Mass.)

prominent clusters of C cells scattered throughout the parenchyma should raise the specter of an inherited predisposition, even if a family history is not present.

Clinical Course. Sporadic cases of medullary carcinoma come to medical attention most often as a mass in the neck, sometimes associated with dysphagia or hoarseness. In some instances, the initial manifestations are those of a paraneoplastic syndrome caused by the secretion of a peptide hormone (e.g., diarrhea due to the secretion of VIP, or Cushing syndrome due to ACTH). Notably, hypocalcemia is not a prominent feature, despite the presence of raised calcitonin levels. In addition to circulating calcitonin, secretion of carcinoembryonic antigen by the neoplastic cells is a useful biomarker, especially for presurgical assessment of tumor load and in calcitonin-negative tumors.

Patients with *familial syndromes* may come to attention because of symptoms localized to the thyroid or as a result of endocrine neoplasms in other organs (e.g., adrenal or

Figure 24-23 Electron micrograph of medullary thyroid carcinoma. These cells contain membrane-bound secretory granules that are the sites of storage of calcitonin and other peptides.

parathyroid glands). Medullary carcinomas arising in the context of MEN-2B are generally more aggressive and metastasize more frequently than those occurring in patients with sporadic tumors, MEN-2A, or FMTC. As will be discussed later, asymptomatic MEN-2 patients carrying germline *RET* mutations are offered prophylactic thyroidectomy as early as possible to prevent the otherwise inevitable development of medullary carcinomas, the major risk factor for poor outcome in these individuals. Sometimes the only histologic finding in the resected thyroid of asymptomatic carriers is the presence of C-cell hyperplasia or small (<1 cm) “micromedullary” carcinomas. Several small-molecule inhibitors of RET tyrosine kinase have recently been developed, and are being tested in individuals with medullary carcinomas.

KEY CONCEPTS

Thyroid Neoplasms

- Most thyroid neoplasms manifest as *solitary thyroid nodules*; only 1% of all thyroid nodules are neoplastic.
- *Follicular adenomas* are the most common benign neoplasms, while papillary carcinoma is the most common malignancy.
- Multiple genetic pathways are involved in *thyroid carcinogenesis*. Some of the genetic abnormalities that are fairly unique to thyroid cancers include *PAX8/PPARG* fusion

genes or mutations that activate RAS or PI-3K (in follicular carcinomas), chromosomal rearrangements involving the *RET* oncogene or mutations in *BRAF* (in papillary carcinomas), and mutations of *RET* (in medullary carcinomas).

- *Follicular adenomas and carcinomas* both are composed of well-differentiated follicular epithelial cells; the latter are distinguished by evidence of capsular and/or vascular invasion.
- *Papillary carcinomas* are recognized based on nuclear features (ground-glass nuclei, pseudoinclusions) even in the absence of papillae. Psammoma bodies are a characteristic feature of papillary cancers; these neoplasms often metastasize by way of lymphatics, but the prognosis is excellent.
- *Anaplastic carcinomas* are thought to arise by dedifferentiation of more differentiated neoplasms. They are highly aggressive, uniformly lethal cancers.
- *Medullary cancers* are neoplasms arising from the parafollicular C cells and can occur in either sporadic (70%) or familial (30%) settings. Multicentricity and C cell hyperplasia are features of familial cases. Amyloid deposits are a characteristic histologic finding.

Congenital Anomalies

Thyroglossal duct cyst is the most common clinically significant congenital anomaly of the thyroid. A sinus tract may persist as a vestige of the tubular development of the thyroid gland. Parts of this tube may be obliterated, leaving small segments to form cysts. These occur at any age and might not become evident until adult life. Mucinous, clear secretions may collect within the cysts to form either spherical masses or fusiform swellings, rarely over 2 to 3 cm in diameter, that present in the midline of the neck anterior to the trachea. Segments of the duct and cysts that occur high in the neck are lined by stratified squamous epithelium resembling the covering of the posterior portion of the tongue in the region of the foramen cecum. Anomalies that occur in the lower neck more proximal to the thyroid gland are lined by epithelium resembling the thyroidal acinar epithelium. Characteristically, subjacent to the lining epithelium, there is an intense lymphocytic infiltrate. Superimposed infection may convert these lesions into abscess cavities, and rarely, they give rise to cancers.

PARATHYROID GLANDS

The four parathyroid glands are composed of two cell types: chief cells and oxyphil cells. Chief cells predominate; they are polygonal, 12 to 20 μm in diameter, and have central, round, uniform nuclei and light to dark pink cytoplasm. Sometimes these cells take on a *water-clear* appearance due to the presence of large amounts of cytoplasmic glycogen. In addition, they have secretory granules containing *parathyroid hormone (PTH)*. *Oxyphil cells* and transitional oxyphils are found throughout the normal parathyroid, either singly or in small clusters. They

are slightly larger than the chief cells, have acidophilic cytoplasm, and are tightly packed with mitochondria. Glycogen granules are also present in these cells, but secretory granules are sparse or absent. In early infancy and childhood, the parathyroid glands are composed almost entirely of solid sheets of chief cells. The amount of stromal fat increases up to age 25, reaching a maximum of approximately 30% of the gland, and then plateaus.

The function of the parathyroid glands is to regulate calcium homeostasis. The activity of the parathyroid

glands is controlled by the level of free (ionized) calcium in the bloodstream. Normally, decreased levels of free calcium stimulate the synthesis and secretion of PTH. The metabolic functions of PTH that regulate serum calcium levels are several. Specifically, PTH:

- Increases the renal tubular reabsorption of calcium, thereby conserving free calcium
- Increases the conversion of vitamin D to its active dihydroxy form in the kidneys
- Increases urinary phosphate excretion, thereby lowering serum phosphate levels
- Augments gastrointestinal calcium absorption

The net result of these activities is to elevate the level of free calcium, which, in turn, inhibits further PTH secretion in a classic feedback loop. Similar to the other endocrine organs, abnormalities of the parathyroid glands include both hyperfunction and hypofunction. Tumors of the parathyroid glands, in contrast to thyroid tumors, usually come to attention because of excessive secretion of PTH rather than mass effects.

Hyperparathyroidism

Hyperparathyroidism is caused by elevated parathyroid hormone and is classified into primary, secondary, and least commonly, tertiary types.

- *Primary hyperparathyroidism*: an autonomous overproduction of parathyroid hormone (PTH), usually resulting from an adenoma or hyperplasia of parathyroid tissue
- *Secondary hyperparathyroidism*: compensatory hypersecretion of PTH in response to prolonged hypocalcemia, most commonly from chronic renal failure
- *Tertiary hyperparathyroidism*: persistent hypersecretion of PTH even after the cause of prolonged hypocalcemia is corrected, for example after renal transplant

Primary Hyperparathyroidism

Primary hyperparathyroidism is one of the most common endocrine disorders, and it is an important cause of hypercalcemia. The frequency of the various parathyroid lesions underlying the hyperfunction is as follows:

- Adenoma: 85% to 95%
- Primary hyperplasia (diffuse or nodular): 5% to 10%
- Parathyroid carcinoma: ~1%

Primary hyperparathyroidism is usually a disease of adults and is more common in women than in men by a ratio of nearly 4:1. The annual incidence is now estimated to be about 25 cases per 100,000 in the United States and Europe; as many as 80% of patients with this condition are identified in the outpatient setting, when hypercalcemia is discovered incidentally on a serum electrolyte panel. Most cases occur in the 50s or later in life.

The most common cause of primary hyperparathyroidism is a solitary parathyroid adenoma arising sporadically (Fig. 24-24). Most, if not all, sporadic parathyroid

Figure 24-24 Parathyroid adenoma imaging. Technetium-^{99m}-sestamibi radionuclide scan demonstrates an area of increased uptake corresponding to the left inferior parathyroid gland (arrow), which contained a parathyroid adenoma. Preoperative scintigraphy is useful in localizing and distinguishing adenomas from parathyroid hyperplasia, where more than one gland would demonstrate increased uptake.

adenomas are monoclonal, consistent with their being neoplasms. As with nodules in goitrous thyroids, sporadic parathyroid “hyperplasia” is also monoclonal in many instances, particularly when associated with a persistent stimulus for parathyroid growth (refractory secondary or tertiary parathyroidism; see later), suggesting that these lesions lie in the gray zone between reactive hyperplasias and neoplasia. There are two molecular defects that have an established role in the development of sporadic adenomas:

- *Cyclin D1 gene inversions leading to overexpression of cyclin D1*, a major regulator of the cell cycle. A pericentromeric inversion on chromosome 11 results in relocation of the *cyclin D1* gene (normally on 11q), so that it is positioned adjacent to the 5′-flanking region of the *PTH* gene (on 11p). As a consequence of these changes, a regulatory element from the *PTH* gene 5′-flanking sequence directs overexpression of cyclin D1 protein, causing the cells to proliferate. Between 10% and 20% of adenomas have this clonal rearrangement. In addition, cyclin D1 is overexpressed in approximately 40% of parathyroid adenomas, suggesting that mechanisms other than *cyclin D1* gene inversion can lead to its overexpression.
- *MEN1 mutations*: Approximately 20% to 30% of sporadic parathyroid tumors have mutations in both copies of the *MEN1* gene, a tumor suppressor gene on chromosome 11q13. Germline mutations of *MEN1* are also found in patients with familial parathyroid adenomas (see later). The spectrum of *MEN1* mutations in sporadic tumors is virtually identical to that in familial parathyroid adenomas.

Familial syndromes are a distant second to sporadic adenomas as causes of primary hyperparathyroidism. The genetic syndromes associated with *familial parathyroid adenomas* include Multiple Endocrine Neoplasia, types 1 and 2, caused by germline mutations of *MEN1* and *RET*, respectively (both are discussed in further detail later), and familial hypocalciuric hypercalcemia, a rare autosomal-dominant disorder caused by loss-of-function mutations in

the parathyroid *calcium-sensing receptor gene (CASR)*, which results in decreased sensitivity to extracellular calcium.

MORPHOLOGY

The morphologic changes seen in primary hyperparathyroidism include those in the parathyroid glands as well as those in other organs affected by elevated levels of PTH and calcium. Parathyroid **adenomas** are almost always solitary and, similar to the normal parathyroid glands, may lie in close proximity to the thyroid gland or in an ectopic site (e.g., the mediastinum). The typical parathyroid adenoma averages 0.5 to 5 gm and consists of a well-circumscribed, soft, tan to reddish-brown nodule invested by a delicate capsule. In contrast to primary hyperplasia, the glands outside the adenoma are usually normal in size or somewhat shrunken because of feedback inhibition by elevated levels of serum calcium. Microscopically, parathyroid adenomas are mostly composed of uniform, polygonal chief cells with small, centrally placed nuclei (Fig. 24-25). At least a few nests of larger oxyphil cells are present as well; uncommonly, adenomas are composed entirely of this cell type (**oxyphil adenomas**). These may resemble Hürthle cell tumors in the thyroid. A rim of compressed, nonneoplastic parathyroid tissue, generally separated by a fibrous capsule, is often visible at the edge of the adenoma. Mitotic figures are rare, but it is not uncommon to find bizarre and pleomorphic nuclei even

Figure 24-25 Parathyroid adenoma. **A**, Solitary chief cell parathyroid adenoma (low-power photomicrograph) revealing clear delineation from the residual gland below. **B**, High-power detail of a chief cell parathyroid adenoma. There is some slight variation in nuclear size but no anaplasia and some slight tendency to follicular formation.

within adenomas (so-called **endocrine atypia**); this is not a criterion for malignancy. In contrast to the normal parathyroid parenchyma, adipose tissue is inconspicuous.

Primary hyperplasia may occur sporadically or as a component of MEN syndrome. Although classically all four glands are involved, there is frequently asymmetry with apparent sparing of one or two glands, making the distinction between hyperplasia and adenoma difficult. The combined weight of all glands rarely exceeds 1 gm and is often less. Microscopically, the most common pattern seen is that of chief cell hyperplasia, which may involve the glands in a diffuse or multinodular pattern. Less commonly, the constituent cells contain abundant water-clear cells ("water-clear cell hyperplasia"). In many instances there are islands of oxyphils, and poorly developed, delicate fibrous strands may envelop the nodules. As in the case of adenomas, stromal fat is inconspicuous within hyperplastic glands.

Parathyroid carcinomas may be circumscribed lesions that are difficult to distinguish from adenomas, or they may be clearly invasive neoplasms. These tumors enlarge one parathyroid gland and consist of gray-white, irregular masses that sometimes exceed 10 gm in weight. The cells are usually uniform and resemble normal parathyroid cells, and are arrayed in nodular or trabecular patterns. The mass is usually enclosed by a dense, fibrous capsule. **Diagnosis of carcinoma based on cytologic detail is unreliable, and invasion of surrounding tissues and metastasis are the only reliable criteria.** Local recurrence occurs in one third of cases, and more distant dissemination occurs in another third.

Morphologic changes of hyperparathyroidism in the skeletal system (Chapter 26) and the urinary tract deserve special mention. Symptomatic, untreated primary hyperparathyroidism manifests with three interrelated skeletal abnormalities: osteoporosis, brown tumors and osteitis fibrosa cystica. The osteoporosis results in decreased bone mass, with preferential involvement of the phalanges, vertebrae and proximal femur. For unknown reasons, the increased osteoclast activity in hyperparathyroidism affects cortical bone (subperiosteal and endosteal surfaces) more severely than medullary bone. In medullary bone, osteoclasts tunnel into and dissect centrally along the length of the trabeculae, creating the appearance of railroad tracks and producing what is known as dissecting osteitis (Fig. 24-26). The marrow spaces around the affected surfaces are replaced by fibrovascular tissue. The correlative radiographic finding is a decrease in bone density or osteoporosis.

The bone loss predisposes to microfractures and secondary hemorrhages that elicit an influx of macrophages and an ingrowth of reparative fibrous tissue, creating a mass of reactive tissue, known as a **brown tumor** (Fig. 26-16, Chapter 26). The brown color is the result of the vascularity, hemorrhage, and hemosiderin deposition, and it is not uncommon for the lesions to undergo cystic degeneration. The combination of increased osteoclast activity, peritrabecular fibrosis, and cystic brown tumors is the hallmark of severe hyperparathyroidism and is known as **generalized osteitis fibrosa cystica (von Recklinghausen disease of bone)**. Osteitis fibrosa cystica is now rarely encountered because hyperparathyroidism is usually diagnosed on routine blood tests and treated at an early, asymptomatic stage (see later).

PTH-induced hypercalcemia favors formation of **urinary tract stones** (nephrolithiasis) as well as calcification of the renal interstitium and tubules (nephrocalcinosis). Metastatic

Figure 24-26 Hyperparathyroidism with osteoclasts boring into the center of the trabeculum (dissecting osteitis). (Photomicrograph reproduced from Horvai A: Bone and Soft Tissue Pathology: A Volume in the High Yield Pathology Series, Elsevier, Philadelphia, 2012.)

calcification secondary to hypercalcemia may also be seen in other sites, including the stomach, lungs, myocardium, and blood vessels.

Clinical Course. Primary hyperparathyroidism may be (1) asymptomatic and identified on routine blood chemistry profile, or (2) associated with the classic clinical manifestations of primary hyperparathyroidism.

Asymptomatic Hyperparathyroidism. Because serum calcium levels are routinely assessed, most patients with primary hyperparathyroidism are diagnosed incidentally, on the basis of clinically silent hypercalcemia. In fact, primary hyperparathyroidism is the most common cause of *asymptomatic* hypercalcemia. Hence, many of the classic manifestations, particularly those referable to bone and renal disease, are now seen infrequently in clinical practice. Among other causes of hypercalcemia (Table 24-5), *malignancy* stands out as the most frequent cause of *symptomatic* hypercalcemia in adults, and must be excluded by appropriate clinical and laboratory investigations. As discussed in Chapter 7, hypercalcemia can occur both with solid tumors, such as lung, breast, head and neck, and renal cancers, and with hematologic malignancies, notably

multiple myeloma. The most common mechanism (in ~80% of cases) through which osteolytic tumors induce hypercalcemia is by secretion of PTH-related peptide (PTHrP), whose functions are similar to PTH in inducing osteoclastic bone resorption and hypercalcemia; the remaining 20% induce hypercalcemia through metastases to the bone and subsequent cytokine-induced bone resorption. In individuals with primary hyperparathyroidism, serum PTH levels are inappropriately elevated for the level of serum calcium, whereas PTH levels are low to undetectable in hypercalcemia caused by nonparathyroid diseases (Table 24-5). Radioimmunoassays specific for PTH and PTHrP are available and can be useful in distinguishing primary hyperparathyroidism and malignancy-associated hypercalcemia. Other laboratory alterations referable to PTH excess include hypophosphatemia and increased urinary excretion of both calcium and phosphate. Secondary renal disease may lead to phosphate retention with normalization of serum phosphate levels.

Symptomatic Primary Hyperparathyroidism. The signs and symptoms of hyperparathyroidism reflect the combined effects of increased PTH secretion and hypercalcemia. Primary hyperparathyroidism is associated with “painful bones, renal stones, abdominal groans, and psychic moans.” The constellation of symptoms includes:

- *Bone disease* and bone pain secondary to fractures of bones weakened by osteoporosis or osteitis fibrosa cystica.
- *Nephrolithiasis* (renal stones) in 20% of newly diagnosed patients, with attendant pain and obstructive uropathy. Chronic renal insufficiency and abnormalities in renal function lead to polyuria and secondary polydipsia.
- Gastrointestinal disturbances, including constipation, nausea, peptic ulcers, pancreatitis, and gallstones.
- Central nervous system alterations, including depression, lethargy, and eventually seizures.
- Neuromuscular abnormalities, including weakness and fatigue.
- Cardiac manifestations, including aortic or mitral valve calcifications (or both).

The abnormalities most directly related to hyperparathyroidism are nephrolithiasis and bone disease, whereas those attributable to hypercalcemia include fatigue, weakness, pancreatitis, metastatic calcifications, and constipation.

Secondary Hyperparathyroidism

Secondary hyperparathyroidism is caused by any condition that gives rise to chronic hypocalcemia, which in turn leads to compensatory overactivity of the parathyroid glands. Renal failure is by far the most common cause of secondary hyperparathyroidism, although several other diseases, including inadequate dietary intake of calcium, steatorrhea, and vitamin D deficiency, may also cause this disorder. The mechanisms by which chronic renal failure induces secondary hyperparathyroidism are complex and not fully understood. Chronic renal insufficiency is associated with decreased phosphate excretion, which in turn results in hyperphosphatemia. The elevated serum phosphate levels directly depress serum calcium levels and

Table 24-5 Causes of Hypercalcemia

Raised [PTH]	Decreased [PTH]
Hyperparathyroidism	Hypercalcemia of malignancy*
Primary (adenoma > hyperplasia)*	Vitamin D toxicity
Secondary†	Immobilization
Tertiary†	Thiazide diuretics
Familial hypocalciuric hypercalcemia	Granulomatous disease (sarcoidosis)

[PTH], Parathyroid hormone concentration.

*Primary hyperparathyroidism is the most common cause of hypercalcemia overall. Malignancy is the most common cause of *symptomatic* hypercalcemia. Primary hyperparathyroidism and malignancy account for nearly 90% of cases of hypercalcemia.

†Secondary and tertiary hyperparathyroidism are most commonly associated with progressive renal failure.

thereby stimulate parathyroid gland activity. In addition, loss of renal substance reduces the availability of α -1-hydroxylase necessary for the synthesis of the active form of vitamin D, which in turn reduces intestinal absorption of calcium (Chapter 9). Because vitamin D has suppressive effects on parathyroid growth and PTH secretion, its relative deficiency compounds the hyperparathyroidism in renal failure.

MORPHOLOGY

The **parathyroid glands in secondary hyperparathyroidism are hyperplastic**. As in primary hyperparathyroidism, the degree of glandular enlargement is not necessarily symmetric. Microscopically, the hyperplastic glands contain an increased number of chief cells, or cells with more abundant, clear cytoplasm (so-called water-clear cells) in a diffuse or multinodular distribution. Fat cells are decreased in number. **Metastatic calcification** may be seen in many tissues, including lungs, heart, stomach, and blood vessels.

Clinical Course. The clinical features of secondary hyperparathyroidism are usually dominated by the inciting chronic renal failure. Secondary hyperparathyroidism *per se* is usually not as severe or as prolonged as primary hyperparathyroidism, hence the skeletal abnormalities (referred to as *renal osteodystrophy*) tend to be milder. Control of the hyperparathyroidism allows the bony changes to regress significantly or disappear completely. The vascular calcification associated with secondary hyperparathyroidism may occasionally result in significant ischemic damage to skin and other organs, a process sometimes referred to as *calciophylaxis*. Patients with secondary hyperparathyroidism often respond to dietary vitamin D supplementation, as well as phosphate binders, which decrease the prevailing hyperphosphatemia.

In a minority of patients, parathyroid activity may become autonomous and excessive, with resultant hypercalcemia, a process that is sometimes termed *tertiary hyperparathyroidism*. Parathyroidectomy may be necessary to control the hyperparathyroidism in such patients.

KEY CONCEPTS

Hyperparathyroidism

- Primary hyperparathyroidism is the most common cause of asymptomatic hypercalcemia.
- In a majority of cases, primary hyperparathyroidism is caused by a sporadic parathyroid adenoma and, less commonly, by parathyroid hyperplasia.
- Parathyroid adenomas are solitary, while hyperplasia typically is a multiglandular process.
- Skeletal manifestations of hyperparathyroidism include bone resorption, *osteitis fibrosa cystica*, and *brown tumors*. Renal changes include nephrolithiasis (stones) and nephrocalcinosis.
- The clinical manifestations of hyperparathyroidism can be summarized as “painful bones, renal stones, abdominal groans, and psychic moans.”

- Secondary hyperparathyroidism most often is caused by renal failure, which lowers serum calcium levels, resulting in reactive hyperplasia of parathyroid glands.
- Malignancies are the most important cause of symptomatic hypercalcemia, which results from osteolytic metastases or release of PTH-related protein from nonparathyroid tumors.

Hypoparathyroidism

Hypoparathyroidism is far less common than is hyperparathyroidism. Acquired hypoparathyroidism is almost always an inadvertent consequence of surgery; in addition, there are several genetic causes of hypoparathyroidism.

- *Surgically induced hypoparathyroidism* occurs with inadvertent removal of all the parathyroid glands during thyroidectomy, excision of the parathyroid glands in the mistaken belief that they are lymph nodes during radical neck dissection for some form of malignant disease, or removal of too large a proportion of parathyroid tissue in the treatment of primary hyperparathyroidism.
- *Autoimmune hypoparathyroidism* is often associated with chronic mucocutaneous candidiasis and primary adrenal insufficiency; this syndrome is known as autoimmune polyendocrine syndrome type 1 (APS1) and is caused by mutations in the *autoimmune regulator (AIRE)* gene. The syndrome typically presents in childhood with the onset of candidiasis, followed several years later by hypoparathyroidism and then adrenal insufficiency during adolescence. APS1 is discussed further under “Adrenal Glands.”
- *Autosomal-dominant hypoparathyroidism* is caused by gain-of-function mutations in the *calcium-sensing receptor (CASR)* gene. Inappropriate CASR activity due to heightened calcium sensing suppresses PTH, resulting in *hypocalcemia* and *hypercalciuria*. Recall that loss-of-function CASR mutations are a rare cause of familial parathyroid adenomas.
- *Familial isolated hypoparathyroidism (FIH)* is a rare condition with either autosomal dominant or autosomal recessive patterns of inheritance. Autosomal-dominant FIH is caused by a mutation in the gene encoding PTH precursor peptide, which impairs its processing to the mature hormone. Autosomal-recessive FIH is caused by loss-of-function mutations in the transcription factor gene *glial cells missing-2 (GCM2)*, which is essential for development of the parathyroid.
- *Congenital absence* of parathyroid glands can occur in conjunction with other malformations, such as thymic aplasia and cardiovascular defects, or as a component of the 22q11 deletion syndrome. As discussed in Chapter 6, when thymic defects are present, the condition is called *DiGeorge syndrome*.

Clinical Features. The major clinical manifestations of hypoparathyroidism are related to the severity and chronicity of the hypocalcemia.

- The hallmark of hypocalcemia is *tetany*, which is characterized by *neuromuscular irritability*, resulting from

decreased serum calcium levels. The symptoms range from circumoral numbness or paresthesias (tingling) of the distal extremities and carpopedal spasm, to life-threatening laryngospasm and generalized seizures. The classic findings on physical examination are *Chvostek sign* and *Trousseau sign*. Chvostek sign is elicited in subclinical disease by tapping along the course of the facial nerve, which induces contractions of the muscles of the eye, mouth, or nose. Trousseau sign refers to carpal spasms produced by occlusion of the circulation to the forearm and hand with a blood pressure cuff for several minutes.

- *Mental status changes* include emotional instability, anxiety and depression, confusional states, hallucinations, and frank psychosis.
- *Intracranial manifestations* include calcifications of the basal ganglia, parkinsonian-like movement disorders, and increased intracranial pressure with resultant papilledema. The paradoxical association of hypocalcemia with calcifications may be because of an increase in phosphate levels, resulting in tissue deposits with calcium that exists in local extracellular milieu.
- *Ocular disease* takes the form of calcification of the lens and cataract formation.

- *Cardiovascular manifestations* include a conduction defect that produces a characteristic prolongation of the QT interval in the electrocardiogram.
- *Dental abnormalities* occur when hypocalcemia is present during early development. These findings are highly characteristic of hypoparathyroidism and include dental hypoplasia, failure of eruption, defective enamel and root formation, and abraded carious teeth.

Pseudohypoparathyroidism

In this condition, hypoparathyroidism occurs because of end-organ resistance to the actions of PTH. Indeed, serum PTH levels are normal or elevated. In one form of pseudohypoparathyroidism, there is end-organ resistance to TSH and FSH/LH as well as PTH. All of these hormones signal via G-protein-coupled receptors, and the disorder results from genetic defects in components of this pathway that are shared across endocrine tissues. PTH resistance is the most obvious clinical manifestation. It presents as hypocalcemia, hyperphosphatemia, and elevated circulating PTH. TSH resistance is generally mild, while LH/FSH resistance manifests as hypergonadotropic hypogonadism in females.

THE ENDOCRINE PANCREAS

The endocrine pancreas consists of about 1 million clusters of cells, the *islets of Langerhans*, which contain four major and two minor cell types. The four main types are β , α , δ , and PP (pancreatic polypeptide) cells. They can be differentiated by the ultrastructural characteristics of their granules, and by their hormone content (Fig. 24-27). The β cells produce *insulin*, which regulates glucose utilization in tissues and reduces blood glucose levels, as will be detailed in the discussion of diabetes. α cells secrete *glucagon*, which stimulates glycogenolysis in the liver and thus increases blood sugar. δ cells secrete *somatostatin*, which suppresses both insulin and glucagon release. PP cells secrete *pancreatic polypeptide*, which exerts several gastrointestinal effects, such as stimulation of secretion of gastric and intestinal enzymes and inhibition of intestinal motility. These cells not only are present in islets but also are scattered in the exocrine pancreas. The two rare cell types are *D1 cells* and *enterochromaffin cells*. D1 cells elaborate vasoactive intestinal polypeptide (*VIP*), a hormone that induces glycogenolysis and hyperglycemia; it also stimulates gastrointestinal fluid secretion and causes secretory diarrhea. *Enterochromaffin cells* synthesize *serotonin* and are the source of pancreatic tumors that cause the carcinoid syndrome (Chapter 19).

The following discussion focuses on the two main disorders of islet cells: diabetes mellitus and pancreatic endocrine tumors.

Diabetes Mellitus

Diabetes mellitus is a group of metabolic disorders sharing the common feature of hyperglycemia. Hyperglycemia

in diabetes results from defects in insulin secretion, insulin action, or, most commonly, both. The chronic hyperglycemia and attendant metabolic dysregulation may be associated with secondary damage in multiple organ systems, especially the kidneys, eyes, nerves, and blood vessels. **In the United States, diabetes is the leading cause of end-stage renal disease, adult-onset blindness and non-traumatic lower extremity amputations resulting from atherosclerosis of the arteries.**

Diabetes and related disorders of glucose metabolism are extremely common. According to the American Diabetes Association, diabetes affects more than 25 million children and adults, or more than 8% of the population, in the United States, nearly a third of whom are currently unaware that they have hyperglycemia. Approximately 1.9 million new cases of adult diabetes are diagnosed each year in the United States. Furthermore, a staggering 79 million adults in this country have impaired glucose tolerance or “prediabetes,” which is defined as elevated blood sugar that does not reach the criterion accepted for an outright diagnosis of diabetes (see later), and individuals with prediabetes are at high risk for developing frank diabetes. Compared to non-Hispanic whites, Native Americans, African Americans, and Hispanics are 1.5 to 2 times more likely to develop diabetes in their lifetimes. The World Health Organization estimates that as many as 346 million people suffer from diabetes worldwide, with India and China being the largest contributors to the world’s diabetic load. Increasingly sedentary life styles and poor eating habits have contributed to the simultaneous escalation of diabetes and obesity, which some have called the *diabesity epidemic*. Sadly, obesity and diabetes have now extended even to

Figure 24-27 Hormone production in pancreatic islet cells. Immunoperoxidase staining shows a dark reaction product for insulin in β cells (A), glucagon in α cells (B), and somatostatin in δ cells (C). D, Electron micrograph of a β cell shows the characteristic membrane-bound granules, each containing a dense, often rectangular core and distinct halo. E, Portions of an α cell (left) and a δ cell (right) also show granules, but with closely apported membranes. The α -cell granule shows a dense, round center. (Electron micrographs courtesy Dr. Arthur Like, University of Massachusetts Medical School, Worcester, Mass.)

children who subsist on “junk” food and lack adequate exercise.

The mortality rate from diabetes varies across countries, with middle- and low-income nations accounting for almost 80% of diabetes-related deaths and nearly double the mortality rates observed in developed nations. Nonetheless, diabetes continues to be one of the top 10 “killers” in the United States. The total yearly costs related to diabetes in the United States are estimated to be an astounding 174 billion dollars, including \$116 billion in direct medical costs and the additional \$58 billion in indirect costs such as disability, work loss, and premature mortality.

Diagnosis

Blood glucose is normally maintained in a very narrow range of 70 to 120 mg/dL. According to the ADA and WHO, **diagnostic criteria for diabetes include:**

1. A fasting plasma glucose ≥ 126 mg/dL,
2. A random plasma glucose ≥ 200 mg/dL (in a patient with classic hyperglycemic signs, as discussed later),
3. 2-hour plasma glucose ≥ 200 mg/dL during an oral glucose tolerance test (OGTT) with a loading dose of 75 gm, and

4. A glycated hemoglobin (Hb_{A1C}) level $\geq 6.5\%$ (glycated hemoglobin is further discussed under chronic complications of diabetes)

All tests, except the random blood glucose test in a patient with classic hyperglycemic signs, need to be repeated and confirmed on a separate day. If there is discordance between two assays (e.g., fasting glucose and Hb_{A1C} level), then the result with greater degree of abnormality is considered the “readout.” Of note, many acute stresses, such as severe infections, burns or trauma, can lead to transient hyperglycemia due to secretion of hormones like catecholamines and cortisol that oppose the action of insulin. The diagnosis of diabetes requires persistence of hyperglycemia following resolution of the acute illness.

Impaired glucose tolerance (prediabetes) is defined as:

1. A fasting plasma glucose between 100 and 125 mg/dL (“impaired fasting glucose”),
2. 2-hour plasma glucose between 140 and 199 mg/dL following a 75-gm glucose OGTT, and/or
3. A glycated hemoglobin (Hb_{A1C}) level between 5.7% and 6.4%

As many as one-fourth of individuals with impaired glucose tolerance will develop overt diabetes over 5 years,

with additional factors such as obesity and family history compounding the risk. In addition, individuals with pre-diabetes also harbor a significant risk for cardiovascular complications.

Classification

Although all forms of diabetes mellitus share hyperglycemia as a common feature, the underlying abnormalities involved in the development of hyperglycemia vary widely. The previous classification schemes of diabetes mellitus were based on the age at onset of the disease or on the mode of therapy; in contrast, the current etiologic classification reflects our greater understanding of the pathogenesis of each variant (Table 24-6). The vast majority of cases of diabetes fall into one of two broad classes:

- **Type 1 diabetes is an autoimmune disease characterized by pancreatic β cell destruction and an absolute deficiency of insulin.** It accounts for approximately 5% to 10% of all cases, and is the most common subtype diagnosed in patients younger than 20 years of age.
- **Type 2 diabetes is caused by a combination of peripheral resistance to insulin action and an inadequate secretory response by the pancreatic β cells (“relative insulin deficiency”).** Approximately 90% to 95% of diabetic patients have type 2 diabetes, and the vast majority of such individuals are overweight. Although classically considered “adult-onset,” the prevalence of type 2 diabetes in children and adolescents has been increasing at an alarming pace due to the increasing rates of obesity in these age groups. One piece of encouraging news is that the incidence of obesity in the U.S. in children ages 2-5 years fell by over 40% during the period of 2004 to 2012, a tipping of the scales that may signal a reversal of a troubling trend.

The important similarities and differences between types 1 and 2 diabetes are summarized in Table 24-7.

A variety of monogenic and secondary causes are responsible for the remaining cases (discussed later). It should be stressed that while the major types of diabetes have different pathogenic mechanisms, the long-term complications affecting the kidneys, eyes, nerves, and blood vessels are the same, as are the principal causes of morbidity and death. The pathogenesis of the two major types is discussed separately. We will first briefly review normal insulin secretion and the mechanism of insulin action since these are critical to understanding the pathogenesis of diabetes.

Glucose Homeostasis

Normal glucose homeostasis is tightly regulated by three interrelated processes: glucose production in the liver; glucose uptake and utilization by peripheral tissues, chiefly skeletal muscle; and actions of insulin and counterregulatory hormones, including glucagon, on glucose uptake and metabolism.

Insulin and glucagon have opposing regulatory effects on glucose homeostasis. During fasting states, low insulin and high glucagon levels facilitate hepatic gluconeogenesis and glycogenolysis (glycogen breakdown) while decreasing glycogen synthesis, thereby preventing hypoglycemia.

Table 24-6 Classification of Diabetes Mellitus

Type 1 diabetes (β-cell destruction, usually leading to absolute insulin deficiency)
Immune-mediated Idiopathic
Type 2 diabetes (combination of insulin resistance and β-cell dysfunction)
Genetic defects of β-cell function
Maturity-onset diabetes of the young (MODY), caused by mutations in: Hepatocyte nuclear factor 4 α (<i>HNF4A</i>), MODY1 Glucokinase (<i>GCK</i>), MODY2 Hepatocyte nuclear factor 1 α (<i>HNF1A</i>), MODY3 Pancreatic and duodenal homeobox 1 (<i>PDX1</i>), MODY4 Hepatocyte nuclear factor 1 β (<i>HNF1B</i>), MODY5 Neurogenic differentiation factor 1 (<i>NEUROD1</i>), MODY6 Neonatal diabetes (activating mutations in <i>KCNJ11</i> and <i>ABCC8</i> , encoding Kir6.2 and SUR1, respectively) Maternally inherited diabetes and deafness (MIDD) due to mitochondrial DNA mutations (m.3243A→G) Defects in proinsulin conversion Insulin gene mutations
Genetic defects in insulin action
Type A insulin resistance Lipoatrophic diabetes
Exocrine pancreatic defects
Chronic pancreatitis Pancreatectomy/trauma Neoplasia Cystic fibrosis Hemochromatosis Fibrocaltolous pancreatopathy
Endocrinopathies
Acromegaly Cushing syndrome Hyperthyroidism Pheochromocytoma Glucagonoma
Infections
Cytomegalovirus Coxsackie B virus Congenital rubella
Drugs
Glucocorticoids Thyroid hormone Interferon- α Protease inhibitors β -adrenergic agonists Thiazides Nicotinic acid Phenytoin (Dilantin) Vacor

Down syndrome Klinefelter syndrome Turner syndrome Prader-Willi syndrome
Gestational diabetes mellitus

American Diabetes Association: Position statement from the American Diabetes Association on the diagnosis and classification of diabetes mellitus. *Diabetes Care* 31 (Suppl. 1): S55-S60, 2008.

Table 24-7 Type 1 Versus Type 2 Diabetes Mellitus

Type 1 Diabetes Mellitus	Type 2 Diabetes Mellitus
Clinical	
Onset: usually childhood and adolescence	Onset: usually adult; increasing incidence in childhood and adolescence
Normal weight or weight loss preceding diagnosis	Vast majority are obese (80%)
Progressive decrease in insulin levels	Increased blood insulin (early); normal or moderate decrease in insulin (late)
Circulating islet autoantibodies (anti-insulin, anti-GAD, anti-ICA512)	No islet autoantibodies
Diabetic ketoacidosis in absence of insulin therapy	Nonketotic hyperosmolar coma more common
Genetics	
Major linkage to MHC class II genes; also linked to polymorphisms in <i>CTLA4</i> and <i>PTPN22</i> , and insulin gene VNTRs	No HLA linkage; linkage to candidate diabetogenic and obesity-related genes (<i>TCF7L2</i> , <i>PPARG</i> , <i>FTO</i> , etc.)
Pathogenesis	
Dysfunction in T cell selection and regulation leading to breakdown in self-tolerance to islet autoantigens	Insulin resistance in peripheral tissues, failure of compensation by β -cells
	Multiple obesity-associated factors (circulating nonesterified fatty acids, inflammatory mediators, adipocytokines) linked to pathogenesis of insulin resistance
Pathology	
Insulinitis (inflammatory infiltrate of T cells and macrophages)	No insulinitis; amyloid deposition in islets
β -cell depletion, islet atrophy	Mild β -cell depletion
HLA, Human leukocyte antigen; MHC, major histocompatibility complex; VNTRs, variable number of tandem repeats.	

Thus, fasting plasma glucose levels are determined primarily by hepatic glucose output. Following a meal, insulin levels rise and glucagon levels fall in response to the large glucose load. Insulin promotes glucose uptake and utilization in tissues (discussed later). The skeletal muscle is the major insulin-responsive site for postprandial glucose utilization, and is critical for preventing hyperglycemia and maintaining glucose homeostasis.

Regulation of Insulin Release

Insulin is produced in the β cells of the pancreatic islets (Fig. 24-27) as a precursor protein and is proteolytically cleaved in the Golgi complex to generate the mature hormone and a peptide byproduct, *C-peptide*. Both insulin and *C-peptide* are then stored in secretory granules and secreted in equimolar quantities after physiologic stimulation; thus, *C-peptide* levels serve as a surrogate for β -cell function, decreasing with loss of β -cell mass in type 1 diabetes, or increasing with insulin resistance-associated hyperinsulinemia.

The most important stimulus for insulin synthesis and release is glucose itself. An increase in blood glucose levels results in glucose uptake into pancreatic β cells, facilitated by an insulin-independent glucose-transporter, GLUT-2 (Fig. 24-28). β cells express an ATP-sensitive K^+

channel on the membrane, which comprises two subunits: an ATP-sensitive K^+ channel and the sulfonylurea receptor, the latter being the binding site for oral hypoglycemic agents (sulfonylureas), one of the several classes of drugs used in the treatment of diabetes (see later). Metabolism of glucose generates ATP, which inhibits the activity of the ATP-sensitive K^+ channel, leading to membrane depolarization and the influx of Ca^{2+} . The resultant increase in intracellular Ca^{2+} stimulates secretion of insulin, presumably from stored hormone within the β -cell granules. This is the phase of *immediate release of insulin*. If the secretory stimulus persists, a delayed and protracted response follows that involves *active synthesis of insulin*.

Oral intake of food leads to secretion of multiple hormones that play a role in glucose homeostasis and satiety. Of these, the most important class of hormones responsible for promoting insulin secretion from pancreatic β cells following feeding is the incretins. Two incretins have been identified: *glucose-dependent insulinotropic polypeptide (GIP)*, secreted by enteroendocrine “K cells” in the proximal small bowel, and *glucagon-like peptide-1 (GLP-1)*, secreted by “L cells” in the distal ileum and colon. The elevation in GIP and GLP-1 levels following oral food intake is known as the “incretin effect.” In addition to increased insulin secretion from β cells, these hormones also reduce glucagon secretion and delay gastric emptying, which promotes satiety. Once released, circulating GIP and GLP-1 are degraded in circulation by a class of enzymes known as dipeptidyl peptidase (DPPs), especially DPP-4. The “incretin effect” is significantly blunted in patients with type 2 diabetes, and efforts to restore incretin function can lead to improved glycemic control and loss of weight (through restoration of satiety). These observations have resulted in the development of two new classes of drugs for patients with type 2 diabetes: *GLP-1 receptor agonists*, which are synthetic GLP-1 mimetics that bind to, and activate the GLP-1 receptor on islet and extrapancreatic sites, and DPP-4 inhibitors, which enhance levels of endogenous incretins by delaying their degradation.

Figure 24-28 Insulin synthesis and secretion. The influx of glucose into β cells through the GLUT-2 receptors initiates a cascade of signaling events that culminates in Ca^{2+} -induced release of stored insulin (see text for details).

Figure 24-29 Metabolic actions of insulin in striated muscle, adipose tissue, and liver.

Insulin Action and Insulin Signaling Pathways

Insulin is the most potent anabolic hormone known, with multiple synthetic and growth-promoting effects (Fig. 24-29). The principal metabolic function of insulin is to increase the rate of glucose transport into certain cells in the body, thus increasing a major source of energy as well as metabolic intermediates that are used in the biosynthesis of cellular building blocks such as lipids, nucleotides, and amino acids. These cells are the *striated muscle cells* (including myocardial cells) and, to a lesser extent, *adipocytes*, which together represent about two thirds of the entire body weight. Glucose uptake in other peripheral tissues, most notably the brain, is insulin independent. In muscle cells, glucose is then either stored as glycogen or oxidized to generate ATP. In adipose tissue, glucose is primarily stored as lipid. Besides promoting lipid synthesis, insulin also inhibits lipid degradation in adipocytes. Similarly, insulin promotes amino acid uptake and protein synthesis, while inhibiting protein degradation. Thus, the anabolic effects of insulin are attributable to increased synthesis and reduced degradation of glycogen, lipids, and proteins. In addition, insulin has several *mitogenic* functions, including initiation of DNA synthesis in certain cells and stimulation of their growth and differentiation.

The molecular basis of insulin signaling is complex; the more pertinent mediators are summarized in Fig. 24-30. The *insulin receptor* is a tetrameric protein composed of two α - and two β -subunits. The β -subunit cytosolic domain possesses tyrosine kinase activity. Insulin binding to the α -subunit extracellular domain activates the β -subunit tyrosine kinase, resulting in autophosphorylation of the receptor and the phosphorylation (activation) of several intracellular substrate proteins, such as the family of insulin receptor substrates (IRS), which includes IRS1-IRS4 and GAB1. The substrate proteins, in turn, activate multiple

downstream signaling cascades, including the PI3K and the MAP kinase pathways, which mediate the metabolic and mitogenic activities of insulin on the cell. Insulin signaling also facilitates the trafficking and docking of vesicles containing the insulin-sensitive glucose transporter protein GLUT-4 to the plasma membrane, which promotes glucose uptake. This process is mediated by AKT, the principal effector of the PI3K pathway, but also independently by the cytoplasmic protein CBL, which is a direct phosphorylation target of the insulin receptor.

Pathogenesis of Type 1 Diabetes Mellitus

Type 1 diabetes is an autoimmune disease in which islet destruction is caused primarily by immune effector cells reacting against endogenous β -cell antigens. Type 1 diabetes most commonly develops in childhood, becomes manifest at puberty, and progresses with age. Because the disease can develop at any age, including late adulthood, the previously used appellation “juvenile diabetes” is now considered inaccurate. Similarly, the older moniker “insulin-dependent diabetes mellitus” has been excluded from the current classification of diabetes because all forms of diabetes may be treated with insulin. Nevertheless, most patients with type 1 diabetes require insulin for survival; without insulin they develop serious metabolic complications such as ketoacidosis and coma.

Figure 24-30 Insulin action on a target cell. The metabolic actions of insulin include promoting glycogen synthesis by activating glycogen synthase, and enhancing protein synthesis and lipogenesis while inhibiting lipolysis (see text). Dashed arrows represent intermediate proteins and binding partners that are not shown in this overview diagram.

As with most autoimmune diseases, the pathogenesis of type 1 diabetes involves an interplay of genetic and environmental factors.

Genetic Susceptibility

Epidemiologic studies, such as those demonstrating higher concordance rates for disease in monozygotic vs dizygotic twins, have convincingly established a genetic basis for type 1 diabetes. More recently, genome-wide association studies have identified multiple genetic susceptibility loci for type 1 diabetes, as well as for type 2 diabetes (see later). More than 30 susceptibility loci for type 1 diabetes are now known. **Of these, the most important locus is the HLA gene cluster on chromosome 6p21, which according to some estimates contributes as much as 50% of the genetic susceptibility to type 1 diabetes.** Ninety percent to 95% of Caucasians with this disease have either an HLA-DR3 or HLA-DR4 haplotype, in contrast to about 40% of normal subjects; moreover, 40% to 50% of patients with type 1 diabetes are combined DR3/DR4 heterozygotes, in contrast to 5% of normal subjects. Individuals who have either DR3 or DR4 concurrently with a DQ8 haplotype (which corresponds to *DQA1*0301-DQB1*0302* alleles) demonstrate one of the highest inherited risks for type 1 diabetes in sibling studies. Predictably, the polymorphisms in the HLA molecules are located in or adjacent to the peptide-binding pockets, consistent with the notion that disease-associated alleles code for molecules that have the capacity to display particular antigens. However, as discussed in [Chapter 6](#), it is still not known if these HLA-disease associations reflect the ability of specific HLA molecules to present self islet antigens or if they are related to the role of HLA molecules in T-cell selection and tolerance.

Several *non-HLA* genes also confer susceptibility to type 1 diabetes. The first disease-associated non-MHC gene to be identified was *insulin*, with variable number of tandem repeats (VNTRs) in the promoter region being associated with disease susceptibility. The mechanism underlying this association is unknown. It is possible that these polymorphisms influence the level of expression of insulin in the thymus, thus affecting the negative selection of insulin-reactive T cells ([Chapter 6](#)). The association between polymorphisms in *CTLA4* and *PTPN22* and autoimmune thyroiditis was mentioned earlier; not surprisingly, these genes have also been linked with susceptibility to type 1 diabetes. The relationship of type 1 diabetes to altered T-cell selection and regulation is also underscored by the striking prevalence of this disease in individuals with rare germline defects in genes that code for immune regulators, such as *AIRE*, mutations of which cause autoimmune polyendocrinopathy syndrome, type 1 (APS, type 1) (see [Adrenal Gland](#) later).

Environmental Factors

As in other autoimmune diseases, genetic susceptibility contributes to only a part of diabetes risk, and environmental factors must play a role. The nature of these environmental influences remains an enigma. Although antecedent *viral infections* have been suggested as triggers for development of the disease, neither the type of virus nor how it promotes islet-specific autoimmunity is established. Some studies suggest that viruses might share epitopes with islet antigens, and the immune response to the virus results in

Figure 24-31 Stages in the development of type 1 diabetes mellitus. The stages are listed from left to right, and hypothetical β -cell mass is plotted against age. (From Eisenbarth GE: Type 1 diabetes: a chronic autoimmune disease. *N Engl J Med* 314:1360, 1986. Copyright © 1986, Massachusetts Medical Society. All rights reserved.)

cross-reactivity and destruction of islet tissues, a phenomenon known as *molecular mimicry*. On the other hand, infections are also known to be protective against type 1 diabetes.

Mechanisms of β Cell Destruction

Although the clinical onset of type 1 diabetes is often abrupt, there is a lengthy lag period between initiation of the autoimmune process and the appearance of disease, during which there is progressive loss of insulin reserves ([Fig. 24-31](#)). The classic manifestations of the disease (hyperglycemia and ketosis) occur late in its course, after more than 90% of the β cells have been destroyed.

The fundamental immune abnormality in type 1 diabetes is a failure of self-tolerance in T cells specific for islet antigens. This failure of tolerance may be a result of some combination of defective clonal deletion of self-reactive T cells in the thymus, as well as defects in the functions of regulatory T cells or resistance of effector T cells to suppression by regulatory cells. Thus, autoreactive T cells not only survive but are poised to respond to self-antigens. The initial activation of these cells is thought to occur in the peripancreatic lymph nodes, perhaps in response to antigens that are released from damaged islets. The activated T cells then traffic to the pancreas, where they cause β -cell injury. Multiple T-cell populations have been implicated in this damage, including T_H1 cells (which may secrete cytokines, including IFN- γ and TNF, that injure β cells), and CD8+ CTLs (which kill β cells directly). The islet autoantigens that are the targets of immune attack may include insulin, the β cell enzyme glutamic acid decarboxylase (GAD), and islet cell autoantigen 512 (ICA512).

A role for antibodies in type 1 diabetes is suspected because of the observation that autoantibodies against islet antigens are found in the vast majority of patients with type 1 diabetes, as well as in asymptomatic family members at risk for progression to overt disease; in fact, the presence of islet cell antibodies is used as a predictive marker for the disease. However, it is not clear if the autoantibodies cause injury or are merely produced as a consequence of islet injury.

Pathogenesis of Type 2 Diabetes Mellitus

Type 2 diabetes is a complex disease that involves an interplay of genetic and environmental factors and a pro-inflammatory state. Unlike type 1 diabetes, there is no evidence of an autoimmune basis.

Genetic Factors

Genetic susceptibility contributes to the pathogenesis, as evidenced by the disease concordance rate of greater than 90% in monozygotic twins. Furthermore, first-degree relatives have 5- to 10-fold higher risk of developing type 2 diabetes than those without a family history, when matched for age and weight. Genome-wide association studies (GWAS) performed over the last decade have identified at least 30 loci that individually confer a minimal to modest increase in the lifetime risk for type 2 diabetes. The detailed description of these susceptibility loci is beyond the scope of this chapter, although many of the polymorphisms identified are in genes associated with *insulin secretion*. Elucidating the biochemical mechanisms through which these and other linked genes contribute to diabetes pathogenesis is a work in progress.

Environmental Factors

The most important environmental risk factor for type 2 diabetes is obesity, particularly central or visceral obesity. Greater than 80% of individuals with type 2 diabetes are obese, and the incidence of diabetes worldwide has risen in proportion to obesity. Obesity contributes to the cardinal metabolic abnormalities of diabetes (see later) and to insulin resistance early in disease. In fact, even modest weight loss through dietary modifications can reduce insulin resistance and improve glucose tolerance. A sedentary lifestyle (typified by lack of exercise) is another risk factor for diabetes, independent of obesity. Weight loss and exercise usually have additive effects on improving insulin sensitivity and are often the first non-pharmacological measures attempted in patients with milder type 2 diabetes.

Metabolic Defects in Diabetes

The two cardinal metabolic defects that characterize type 2 diabetes are:

- Decreased response of peripheral tissues, especially skeletal muscle, adipose tissue, and liver, to insulin (**insulin resistance**)
- Inadequate insulin secretion in the face of insulin resistance and hyperglycemia (**β -cell dysfunction**)

Insulin resistance predates the development of hyperglycemia and is usually accompanied by compensatory β -cell hyperfunction and hyperinsulinemia in the early

Figure 24-32 Development of type 2 diabetes. Insulin resistance associated with obesity is induced by adipokines, free fatty acids, and chronic inflammation in adipose tissue. Pancreatic β cells compensate for insulin resistance by hypersecretion of insulin. However, at some point, β -cell compensation is followed by β -cell failure, and diabetes ensues. (Reproduced with permission from Kasuga M: Insulin resistance and pancreatic β -cell failure. *J Clin Invest* 116:1756, 2006.)

stages of the evolution of diabetes (Fig. 24-32). Over time, the inability of β cells to adapt to increasing secretory needs for maintaining a euglycemic state results in chronic hyperglycemia and the resulting long-standing complications of diabetes.

Insulin Resistance

Insulin resistance is the failure of target tissues to respond normally to insulin. The liver, skeletal muscle and adipose tissue are the major tissues where insulin resistance manifests in abnormal glucose tolerance. Insulin resistance results in:

- Failure to inhibit endogenous glucose production (gluconeogenesis) in the liver, which contributes to high fasting blood glucose levels
- Failure of glucose uptake and glycogen synthesis to occur in skeletal muscle following a meal, which contributes to high post-prandial blood glucose level
- Failure to inhibit lipoprotein lipase in adipose tissue, leading to excess circulating free fatty acids (FFAs), which in turn, amplify the state of insulin resistance

A variety of functional defects have been reported in the insulin signaling pathway in states of insulin resistance. For example, reduced tyrosine phosphorylation of the insulin receptor and IRS proteins is observed in peripheral tissues, which compromises insulin signaling and reduces the level of the glucose transporter GLUT-4 on the cell

surface (Fig. 24-30). In fact, one of the mechanisms by which exercise can improve insulin sensitivity is through increased translocation of GLUT-4 to the surface of skeletal muscle cells.

Obesity and Insulin Resistance. Multiple factors contribute to insulin resistance, of which obesity is probably the most important. The risk for diabetes increases as the body mass index (a measure of body fat content) increases. It is not only the absolute amount but also the distribution of body fat that has an effect on insulin sensitivity: central obesity (abdominal fat) is more likely to be linked with insulin resistance than are peripheral (gluteal/subcutaneous) fat depots.

Obesity can adversely impact insulin sensitivity in numerous ways (Fig. 24-32):

- **Free fatty acids (FFAs).** Cross-sectional studies have demonstrated an inverse correlation between fasting plasma FFAs and insulin sensitivity. Central adipose tissue is more “lipolytic” than peripheral sites, which might explain the particularly deleterious consequences of this pattern of fat distribution. Excess FFAs overwhelm the intracellular fatty acid oxidation pathways, leading to accumulation of cytoplasmic intermediates like diacylglycerol (DAG). These “toxic” intermediates can attenuate signaling through the insulin receptor pathway. In liver cells, insulin normally inhibits gluconeogenesis by blocking the activity of phosphoenolpyruvate carboxykinase, the first enzymatic step in this process. Attenuated insulin signaling allows phosphoenolpyruvate carboxykinase to “ramp up” gluconeogenesis. Excess FFAs also compete with glucose for substrate oxidation, leading to feedback inhibition of glycolytic enzymes, thereby further exacerbating the existing glucose imbalance.
- **Adipokines.** You will recall that adipose tissue is not merely a passive storage depot for fat but is a functional endocrine organ that releases hormones in response to changes in metabolic status (Chapter 9). A variety of proteins secreted into the systemic circulation by adipose tissue have been identified, and these are collectively termed *adipokines* (or adipose cytokines). Some of these promote hyperglycemia, and other adipokines (such as leptin and adiponectin) decrease blood glucose, in part by increasing insulin sensitivity in peripheral tissues. Adiponectin levels are reduced in obesity, thus contributing to insulin resistance.
- **Inflammation:** Over the past several years, inflammation has emerged as an important factor in the pathogenesis of type 2 diabetes. It is now known that an inflammatory milieu—mediated not by an autoimmune process such as type 1 diabetes but rather by proinflammatory cytokines that are secreted in response to excess nutrients such as free fatty acid (FFAs) and glucose—results in both insulin resistance and β -cell dysfunction. Excess FFAs within macrophages and β cells can activate the inflammasome, a multiprotein cytoplasmic complex that leads to secretion of the cytokine interleukin IL-1 β (Chapter 3). IL-1 β , in turn, mediates the secretion of additional pro-inflammatory cytokines from macrophages, islet cells, and other cells. IL-1 and other cytokines are released into the circulation and act on the

major sites of insulin action to promote insulin resistance. Thus, excess FFAs can impede insulin signaling directly within peripheral tissues, as well as indirectly through the release of pro-inflammatory cytokines.

β -Cell Dysfunction

While insulin resistance by itself can lead to impaired glucose tolerance, **β -cell dysfunction is virtually a requirement for the development of overt diabetes.** In contrast to the severe genetic defects in β -cell function that occur in monogenic forms of diabetes (see later), β -cell function actually increases early in the disease process in most patients with “sporadic” type 2 diabetes, mainly as a compensatory measure to counter insulin resistance and maintain euglycemia. Eventually, however, β cells seemingly exhaust their capacity to adapt to the long-term demands of peripheral insulin resistance, and the hyperinsulinemic state gives way to a state of relative insulin deficiency.

Several mechanisms have been implicated in promoting β -cell dysfunction in type 2 diabetes, including:

- Excess free fatty acids that compromise β cell function and attenuate insulin release (“*lipotoxicity*”)
- The impact of chronic hyperglycemia (“*glucotoxicity*”)
- An abnormal “*incretin effect*,” leading to reduced secretion of GIP and GLP-1, hormones that promote insulin release (see earlier)
- Amyloid deposition within islets. This is a characteristic finding in individuals with long-standing type 2 diabetes, being present in more than 90% of diabetic islets examined, but it is unclear whether it is a cause or an effect of β -cell “burnout.”
- Finally, the impact of genetics cannot be discounted, as many of the polymorphisms associated with an increased lifetime risk for type 2 diabetes occur in genes that control insulin secretion (see earlier).

Monogenic Forms of Diabetes

Although genetically defined causes of diabetes are uncommon, they have been intensively studied in the hope of gaining insights into the disease. As Table 24-6 illustrates, monogenic forms of diabetes are classified separately from types 1 and 2. These forms of diabetes result from either a primary defect in β -cell function or a defect in insulin receptor signaling (described later).

Genetic Defects in β -Cell Function. Approximately 1% to 2% of patients with diabetes harbor a primary defect in β -cell function that occurs without β -cell loss, affecting either β -cell mass and/or insulin production. This form of monogenic diabetes is caused by a heterogeneous group of genetic defects. The largest subgroup of patients in this category was traditionally designated as having “maturity-onset diabetes of the young” (MODY) because of its superficial resemblance to type 2 diabetes and its occurrence in younger patients. MODY can result from germline loss-of-function mutations in one of six genes (Table 24-6), of which mutations of *glucokinase* (*GCK*) are the most common. Glucokinase is a rate limiting step in oxidative glucose metabolism, which in turn, is coupled to insulin secretion within islet β cells (Fig. 24-28). Other rare genetic causes for primary defects in β cell function include mutations of

genes that code for the two subunits of the ATP-sensitive K⁺-channel, defects in mitochondrial DNA (which can impede ATP synthesis), and mutations of the insulin gene itself.

Genetic Defects that Impair Tissue Response to Insulin.

Rare *insulin receptor mutations* that affect receptor synthesis, insulin binding, or receptor tyrosine kinase activity can cause severe insulin resistance, accompanied by hyperinsulinemia and diabetes (type A insulin resistance). Such patients often show a velvety hyperpigmentation of the skin, known as *acanthosis nigricans*. Females with type A insulin resistance frequently have polycystic ovaries and elevated androgen levels. *Lipoatrophic diabetes*, as the name suggests, is hyperglycemia accompanied by loss of adipose tissue, the latter occurring selectively in the subcutaneous fat. This rare group of genetic disorders has in common insulin resistance, diabetes, hypertriglyceridemia, *acanthosis nigricans*, and abnormal fat deposition in the liver (hepatic steatosis). Multiple subtypes of lipoatrophic diabetes, each ascribed to a different causal mutation, have been reported.

Diabetes and Pregnancy

Pregnancy can be complicated by diabetes in one of two settings: when women with preexisting diabetes become pregnant (“pregestational” or overt diabetes), or women who were previously euglycemic develop impaired glucose tolerance and diabetes for the first time during pregnancy (“gestational” diabetes). Approximately 5% of pregnancies occurring in the United States are complicated by hyperglycemia, and the incidence of both pregestational and gestational diabetes is rising in parallel with the rising incidence of obesity and diabetes in the general population. Pregnancy is a “diabetogenic” state in which the prevailing hormonal milieu favors a state of insulin resistance. In a previously euglycemic woman who is otherwise susceptible due to concurrent genetic and environmental factors, the consequence may be gestational diabetes. Women with pregestational diabetes (where hyperglycemia is already present in the periconception period) have an increased risk of *stillbirth* and *congenital malformations* in the fetus. Poorly controlled diabetes that arises later in pregnancy, regardless of prior history, can lead to excessive birth weight in the newborn (*macrosomia*), as well as long-term sequelae for the child exposed to a diabetic environment in utero, including obesity and diabetes later in life. Gestational diabetes typically resolves following delivery; however, the majority of women with this condition will develop overt diabetes over the next 10 to 20 years.

Clinical Features of Diabetes

It is difficult to sketch with brevity the diverse clinical presentations of diabetes mellitus. We will discuss the most common initial presentation or mode of diagnosis for each of the two major subtypes, followed by a discussion of acute, and then chronic (long-term) complications of diabetes.

Type 1 diabetes was formerly thought to occur primarily in persons younger than age 18 but is now known to occur at any age. In the initial 1 or 2 years following the

onset of overt type 1 diabetes, the exogenous insulin requirements may be minimal because of ongoing endogenous insulin secretion (referred to as the *honeymoon period*). Thereafter, any residual β -cell reserve is exhausted and insulin requirements increase dramatically. Although β -cell destruction is a prolonged process, the transition from impaired glucose tolerance to overt diabetes may be abrupt and is often brought on by an event, such as infection, that is also associated with increased insulin requirements.

In contrast to type 1 diabetes, patients with **type 2 diabetes** are typically older than 40 years and frequently obese. However, with the increase in obesity and sedentary lifestyle in this society, type 2 diabetes is being seen in children and adolescents with increasing frequency. In some cases, medical attention is sought because of unexplained fatigue, dizziness, or blurred vision. **Most frequently, however, the diagnosis of type 2 diabetes is made after routine blood testing in asymptomatic persons.** In fact, in light of the large number of asymptomatic individuals with undiagnosed hyperglycemia in the United States, routine glucose testing is recommended for everyone older than 45 years of age.

The Classic Triad of Diabetes

The onset of type 1 diabetes is usually marked by the triad of polyuria, polydipsia, polyphagia, and, when severe, diabetic ketoacidosis, all resulting from metabolic derangements. Because insulin is a major anabolic hormone, its deficiency results in a *catabolic* state that affects not only glucose metabolism but also fat and protein metabolism. Unopposed secretion of counterregulatory hormones (glucagon, growth hormone, epinephrine) also plays a role in these metabolic derangements. The assimilation of glucose into muscle and adipose tissue is sharply diminished or abolished. Not only does storage of glycogen in liver and muscle cease, but also reserves are depleted by glycogenolysis. The resultant hyperglycemia exceeds the renal threshold for reabsorption, and glycosuria ensues. The glycosuria induces an osmotic diuresis and thus *polyuria*, causing a profound loss of water and electrolytes (Fig. 24-33). The obligatory renal water loss combined with the hyperosmolarity resulting from the increased levels of glucose in the blood tends to deplete intracellular water, triggering the osmoreceptors of the thirst centers of the brain. In this manner, intense thirst (*polydipsia*) appears. With a deficiency of insulin the scales swing from insulin-promoted anabolism to catabolism of proteins and fats. Proteolysis follows, releasing gluconeogenic amino acids that are removed by the liver and used as building blocks for glucose. The catabolism of proteins and fats tends to induce a negative energy balance, which in turn leads to increasing appetite (*polyphagia*), thus completing the classic triad of diabetes: polyuria, polydipsia, and polyphagia. Despite the increased appetite, catabolic effects prevail, resulting in weight loss and muscle weakness. The combination of polyphagia and weight loss is paradoxical and should always raise the suspicion of diabetes.

Acute Metabolic Complications of Diabetes

Diabetic ketoacidosis is a severe acute metabolic complication of type 1 diabetes, but may also occur in type 2 diabetes, though not as commonly and not to as marked an

Figure 24-33 Sequence of metabolic derangements underlying the clinical manifestations of diabetes. An absolute insulin deficiency leads to a catabolic state, culminating in ketoacidosis and severe volume depletion. These cause sufficient central nervous system compromise to lead to coma and eventual death if left untreated.

extent. The most common precipitating factor is a failure to take insulin, although other stressors such as intercurrent infections, illness, trauma and certain drugs might also lead to this complication. Many of these factors are associated with the release of the catecholamine *epinephrine*, which blocks any residual insulin action and stimulates the secretion of glucagon. The insulin deficiency coupled with glucagon excess decreases peripheral utilization of glucose while increasing gluconeogenesis, severely exacerbating hyperglycemia (the plasma glucose levels are usually in the range of 250 to 600 mg/dL). The hyperglycemia causes an osmotic diuresis and dehydration characteristic of the ketoacidotic state.

The second major effect of insulin deficiency is activation of the ketogenic machinery. Insulin deficiency stimulates lipoprotein lipase, with resultant breakdown of adipose stores and an increase in levels of free fatty acids. When these free

fatty acids reach the liver, they are esterified to fatty acyl coenzyme A. Oxidation of fatty acyl coenzyme A molecules within the hepatic mitochondria produces *ketone bodies* (acetoacetic acid and β -hydroxybutyric acid). The rate at which ketone bodies are formed may exceed the rate at which acetoacetic acid and β -hydroxybutyric acid can be utilized by peripheral tissues, leading to *ketonemia* and *ketonuria*. If the urinary excretion of ketones is compromised by dehydration, the result is a systemic *metabolic ketoacidosis*. Release of ketogenic amino acids by protein catabolism aggravates the ketotic state.

The clinical manifestations of diabetic ketoacidosis include fatigue, nausea and vomiting, severe abdominal pain, a characteristic fruity odor, and deep, labored breathing (also known as *Kussmaul breathing*). Persistence of the ketotic state eventually leads to depression in cerebral consciousness and coma. Reversal of ketoacidosis requires

administration of insulin, correction of metabolic acidosis, and treatment of the underlying precipitating factors such as infection.

In contrast to type 1 diabetes, the frequency of ketoacidosis is significantly lower in type 2 diabetes, presumably because of higher portal vein insulin levels in these patients, which prevents unrestricted hepatic fatty acid oxidation and keeps the formation of ketone bodies in check. Instead, **type 2 diabetics may develop a condition known as hyperosmolar hyperosmotic syndrome (HHS)** due to severe dehydration resulting from sustained osmotic diuresis (particularly in patients who do not drink enough water to compensate for urinary losses from chronic hyperglycemia). Typically, the patient is an older diabetic who is disabled by a stroke or an infection and is unable to maintain adequate water intake. Furthermore, the absence of ketoacidosis and its symptoms (nausea, vomiting, Kussmaul breathing) delays the seeking of medical attention until severe dehydration and impairment of mental status occur. The hyperglycemia is usually more severe than in diabetic ketoacidosis, in the range of 600 to 1200 mg/dL.

Ironically, the most common acute metabolic complication in either type of diabetes is hypoglycemia, usually as a result of having missed a meal, excessive physical exertion, an excess insulin administration, or during the phase of dose finding for antidiabetic agents. The signs and symptoms of hypoglycemia include dizziness, confusion, sweating, palpitations, and tachycardia; if hypoglycemia persists, loss of consciousness may occur. Reversal of hypoglycemia through oral or intravenous glucose intake prevents the onset of permanent neurological damage.

Chronic Complications of Diabetes

The morbidity associated with longstanding diabetes of either type is due to damage induced in large- and medium-sized muscular arteries (diabetic macrovascular disease) and in small vessels (diabetic microvascular disease) by chronic hyperglycemia. Macrovascular disease causes accelerated atherosclerosis among diabetics, resulting in increased risk of myocardial infarction, stroke, and lower extremity ischemia. The effects of microvascular disease are most profound in the retina, kidneys, and peripheral nerves, resulting in *diabetic retinopathy, nephropathy, and neuropathy*, respectively (see later).

Pathogenesis of Chronic Complications. Persistent hyperglycemia (“glucotoxicity”) seems to be responsible for the long term complications of diabetes. Much of the evidence supporting a role for glycemic control in ameliorating the long-term complications of diabetes has come from large randomized trials. The assessment of glycemic control in these trials has been based on the percentage of *glycated hemoglobin*, also known as Hb_{A1C} , which is formed by non-enzymatic covalent addition of glucose moieties to hemoglobin in red cells. Unlike blood glucose levels, Hb_{A1C} provides a measure of glycemic control over the lifespan of a red cell (120 days) and is affected little by day-to-day variations. *It is recommended that Hb_{A1C} be maintained below 7% in diabetic patients.* It is important to stress that hyperglycemia is not the only factor responsible for the long-term complications of diabetes, and that other underlying

abnormalities, such as insulin resistance, and co-morbidities like obesity, also play an important role.

At least four distinct mechanisms have been implicated in the deleterious effects of persistent hyperglycemia on peripheral tissues, although the primacy of any one over the others is unclear. **In each of the proposed mechanisms, increased glucose flux through various intracellular metabolic pathways is thought to generate harmful precursors that contribute to end organ damage.**

Formation of Advanced Glycation End Products. *Advanced glycation end products (AGEs)* are formed as a result of nonenzymatic reactions between intracellular glucose-derived dicarbonyl precursors (glyoxal, methylglyoxal, and 3-deoxyglucosone) with the amino groups of both intracellular and extracellular proteins. The natural rate of AGE formation is greatly accelerated in the presence of hyperglycemia. AGEs bind to a specific receptor (RAGE) that is expressed on inflammatory cells (macrophages and T cells), endothelium, and vascular smooth muscle. The detrimental effects of the AGE-RAGE signaling axis within the vascular compartment include:

- Release of *cytokines and growth factors*, including *transforming growth factor β (TGF β)*, which leads to deposition of excess basement membrane material, and *vascular endothelial growth factor (VEGF)*, implicated in diabetic retinopathy (see later)
- Generation of *reactive oxygen species (ROS)* in endothelial cells
- Increased *procoagulant activity* on endothelial cells and macrophages
- Enhanced *proliferation of vascular smooth muscle cells* and *synthesis of extracellular matrix*

Not surprisingly, endothelium specific overexpression of RAGE in diabetic mice accelerates large vessel injury and microangiopathy, while RAGE-null mice show attenuation of these features. Antagonists of RAGE have emerged as a therapeutic strategy in diabetes and are being tested in clinical trials.

In addition to receptor-mediated effects, AGEs can directly cross-link extracellular matrix proteins. Cross-linking of collagen type I molecules in large vessels decreases their elasticity, which may predispose these vessels to shear stress and endothelial injury ([Chapter 11](#)). Similarly, AGE-induced cross-linking of type IV collagen in basement membrane decreases endothelial cell adhesion and increases extravasation of fluid. Proteins cross-linked by AGEs are resistant to proteolytic digestion. Thus, cross-linking decreases protein removal while enhancing protein deposition. AGE-modified matrix components also trap nonglycated plasma or interstitial proteins. In large vessels, trapping of LDL, for example, retards its efflux from the vessel wall and enhances the deposition of cholesterol in the intima, thus accelerating atherogenesis ([Chapter 11](#)). In capillaries, including those of renal glomeruli, plasma proteins such as albumin bind to the glycated basement membrane, accounting in part for the basement membrane thickening that is characteristic of diabetic microangiopathy.

Activation of Protein Kinase C. Calcium-dependent activation of intracellular protein kinase C (PKC) and the

second messenger diacyl glycerol (DAG) is an important signal transduction pathway. Intracellular hyperglycemia stimulates the *de novo* synthesis of DAG from glycolytic intermediates, and hence causes excessive PKC activation. The downstream effects of PKC activation are numerous, including production of VEGF, TGF- β , and the procoagulant protein plasminogen activator inhibitor-1 (PAI-1) (Chapter 4) by the vascular endothelium.

It should be evident that some effects of AGEs and activated PKC are overlapping, and both likely contribute to diabetic microangiopathy.

Oxidative Stress and Disturbances in Polyol Pathways. Even in some tissues that do not require insulin for glucose transport (e.g., nerves, lenses, kidneys, blood vessels), persistent hyperglycemia in the extracellular milieu leads to an increase in intracellular glucose. This excess glucose is metabolized by the enzyme *aldose reductase* to sorbitol, a polyol, and eventually to fructose, in a reaction that uses NADPH (the reduced form of nicotinamide dinucleotide phosphate) as a cofactor. NADPH is also required by the enzyme glutathione reductase in a reaction that regenerates reduced glutathione (GSH). GSH is one of the important antioxidant mechanisms in the cell (Chapter 2), and any reduction in GSH increases cellular susceptibility

to ROS (“oxidative stress”). In the face of sustained hyperglycemia, progressive depletion of intracellular NADPH by aldol reductase compromises GSH regeneration, increasing cellular susceptibility to oxidative stress. Sorbitol accumulation in the lens contributes to cataract formation.

Hexosamine Pathways and Generation of Fructose-6-Phosphate. Finally, it is postulated that hyperglycemia-induced flux through the hexosamine pathway increases intracellular levels of *fructose-6-phosphate*, which is a substrate for glycosylation of proteins, leading to generation of excess proteoglycans. These glycosylation changes are accompanied by abnormal expression of TGF β or PAI-1, which further exacerbate the end-organ damage.

Morphology and Clinical Features of Chronic Complications of Diabetes

The important morphologic changes are related to the many late systemic complications of diabetes. As previously discussed, these changes are seen in both type 1 and type 2 diabetes (Fig. 24-34). We will first discuss the morphologic changes and then describe the clinical manifestations resulting from the altered morphology.

Figure 24-34 Long-term complications of diabetes.

Figure 24-35 **A**, Insulinitis, shown here from a rat (BB) model of autoimmune diabetes, also seen in type 1 human diabetes. **B**, Amyloidosis of a pancreatic islet in type 2 diabetes. (**A**, Courtesy Dr. Arthur Like, University of Massachusetts, Worcester, Mass.)

MORPHOLOGY

Pancreas

Lesions in the pancreas are inconstant and rarely of diagnostic value. Distinctive changes are more commonly associated with type 1 than with type 2 diabetes. One or more of the following alterations may be present:

- **Reduction in the number and size of islets.** This is most often seen in type 1 diabetes, particularly with rapidly advancing disease. Most of the islets are small and inconspicuous.
- **Leukocytic infiltrates in the islets** (insulinitis) are principally composed of T lymphocytes, and are also seen in animal models of autoimmune diabetes (Fig. 24-35A). Lymphocytic infiltrates may be present in type 1 diabetics at the time of clinical presentation. The distribution of insulinitis may be strikingly uneven in infants who fail to survive the immediate postnatal period.
- **In type 2 diabetes there may be a subtle reduction in islet cell mass,** demonstrated only by special morphometric studies.
- **Amyloid deposition within islets in type 2 diabetes** begins in and around capillaries and between cells. At advanced stages, the islets may be virtually obliterated (Fig. 24-35B); fibrosis may also be observed. Similar lesions may be found in older nondiabetics, apparently as part of normal aging.
- **An increase in the number and size of islets** is especially characteristic of nondiabetic newborns of diabetic mothers. Presumably, fetal islets undergo hyperplasia in response to the maternal hyperglycemia.

Diabetic Macrovascular Disease

Diabetes exacts a heavy toll on the vascular system. **Endothelial dysfunction** (Chapter 11), which predisposes to atherosclerosis and other cardiovascular morbidities, is widespread in diabetes, as a consequence of the deleterious effects of persistent hyperglycemia and insulin resistance on the vascular compartment. The hallmark of diabetic macrovascular disease is **accelerated atherosclerosis** involving the aorta and large- and medium-sized arteries. Except for its greater severity and earlier

age at onset, atherosclerosis in diabetics is indistinguishable from that in nondiabetics (Chapter 11). **Myocardial infarction, caused by atherosclerosis of the coronary arteries, is the most common cause of death in diabetics. Gangrene of the lower extremities,** as a result of advanced vascular disease, is about 100 times more common in diabetics than in the general population. The larger renal arteries are also subject to severe atherosclerosis, but the most damaging effect of diabetes on the kidneys is exerted at the level of the glomeruli and the microcirculation. This is discussed later.

Hyaline arteriosclerosis, the vascular lesion associated with hypertension (Chapters 11 and 20), is both more prevalent and more severe in diabetics than in nondiabetics, but it is not specific for diabetes and may be seen in older nondiabetics without hypertension. It takes the form of an amorphous, hyaline thickening of the wall of the arterioles, which causes narrowing of the lumen (Fig. 24-36). Not surprisingly, in diabetics it is related not only to the duration of the disease but also to the level of blood pressure.

Figure 24-36 Severe renal hyaline arteriosclerosis. Note a markedly thickened, tortuous afferent arteriole. The amorphous nature of the thickened vascular wall is evident. (PAS stain). (Courtesy M.A. Venkatachalam, MD, Department of Pathology, University of Texas Health Science Center at San Antonio, Texas.)

Diabetic Microangiopathy

One of the most consistent morphologic features of diabetes is **diffuse thickening of basement membranes**. The thickening is most evident in the capillaries of the skin, skeletal muscle, retina, renal glomeruli, and renal medulla. However, it may also be seen in such nonvascular structures as renal tubules, the Bowman capsule, peripheral nerves, and placenta. It should be noted that despite the increase in the thickness of basement membranes, **diabetic capillaries are more leaky than normal to plasma proteins. The microangiopathy underlies the development of diabetic nephropathy, retinopathy, and some forms of neuropathy.** An indistinguishable microangiopathy can be found in aged nondiabetic patients but rarely to the extent seen in patients with long-standing diabetes.

Diabetic Nephropathy

The kidneys are prime targets of diabetes. Renal failure is second only to myocardial infarction as a cause of death from this disease. **Three lesions are encountered: (1) glomerular lesions; (2) renal vascular lesions, principally arteriosclerosis; and (3) pyelonephritis, including necrotizing papillitis.**

The most important glomerular lesions are capillary basement membrane thickening, diffuse mesangial sclerosis, and nodular glomerulosclerosis.

Capillary Basement Membrane Thickening. Widespread thickening of the glomerular capillary basement membrane (GBM) occurs in virtually all cases of diabetic nephropathy and is part and parcel of the diabetic microangiopathy. Pure capillary basement membrane thickening can be detected only by electron microscopy (Fig. 24-37). Careful morphometric studies demonstrate that this thickening begins as early as 2 years after the onset of type 1 diabetes and by 5 years amounts to about a 30% increase. The thickening continues progressively and usually concurrently with mesangial widening. Simultaneously, there is thickening of the tubular basement membranes (Fig. 24-38).

Diffuse Mesangial Sclerosis. This lesion consists of **diffuse increase in mesangial matrix**. There can be mild proliferation

Figure 24-37 Electron micrograph of a renal glomerulus showing markedly thickened glomerular basement membrane (B) in a diabetic. L, glomerular capillary lumen; U, urinary space. (Courtesy Dr. Michael Kashgarian, Department of Pathology, Yale University School of Medicine, New Haven, Conn.)

Figure 24-38 Renal cortex showing thickening of tubular basement membranes in a diabetic patient (PAS stain).

of mesangial cells early in the disease process, but cell proliferation is not a prominent part of this injury. The mesangial increase is typically associated with the overall thickening of the GBM. The matrix depositions are PAS-positive (Fig. 24-39). As the disease progresses, the expansion of mesangial areas can extend to nodular configurations. The progressive expansion of the mesangium has been shown to correlate well with measures of deteriorating renal function such as increasing proteinuria.

Nodular Glomerulosclerosis. This is also known as **intercapillary glomerulosclerosis or Kimmelstiel-Wilson disease**. The glomerular lesions take the form of ovoid or spherical, often laminated, nodules of matrix situated in the periphery of the glomerulus. The nodules are PAS-positive. They lie within the mesangial core of the glomerular lobules and can be surrounded by patent peripheral capillary loops (Fig. 24-39) or loops that are markedly dilated. The nodules often show features of mesangiolysis with fraying of the mesangial/capillary lumen interface and disruption of sites at which the capillaries are anchored into the mesangial stalks. The latter may produce capillary microaneurysms as the untethered capillaries distend outward due to force imparted by intracapillary blood pressure and flow. Usually, not all the lobules in individual glomeruli are

Figure 24-39 Diffuse and nodular diabetic glomerulosclerosis (PAS stain). Note the diffuse increase in mesangial matrix and characteristic acellular PAS-positive nodules.

Figure 24-40 Nephrosclerosis in a patient with long-standing diabetes. The kidney has been bisected to demonstrate both diffuse granular transformation of the surface (*left*) and marked thinning of the cortical tissue (*right*). Additional features include some irregular depressions, the result of pyelonephritis, and an incidental cortical cyst (*far right*).

involved by nodular lesions, but even uninvolved lobules and glomeruli show striking diffuse mesangial sclerosis. As the disease advances, the individual nodules enlarge and may eventually compress and engulf capillaries, obliterating the glomerular tuft. These nodular lesions are frequently accompanied by prominent accumulations of hyaline material in capillary loops (“**fibrin caps**”) or adherent to Bowman capsules (“**capsular drops**”). Both afferent and efferent glomerular hilar arterioles show hyalinosis. As a consequence of the glomerular and arteriolar lesions, the kidney suffers from ischemia, develops tubular atrophy and interstitial fibrosis, and usually undergoes overall contraction in size (Fig. 24-40). Approximately 15% to 30% of individuals with long-term diabetes develop nodular glomerulosclerosis, and in most instances it is associated with renal failure.

Renal atherosclerosis and arteriosclerosis constitute part of the macrovascular disease in diabetics. The kidney is one of the most frequently and severely affected organs; however, the changes in the arteries and arterioles are similar to those found in other tissues. Hyaline arteriosclerosis affects not only the afferent but also the efferent arteriole. Such efferent arteriosclerosis is rarely, if ever, encountered in individuals who do not have diabetes.

Pyelonephritis is an acute or chronic inflammation of the kidneys that usually begins in the interstitial tissue and then spreads to affect the tubules. Both the acute and chronic forms of this disease are more common in diabetics than in the general population, and, once affected, diabetics tend to have more severe involvement. One special pattern of acute pyelonephritis, **necrotizing papillitis** (or papillary necrosis), is much more prevalent in diabetics than in nondiabetics.

Diabetic Ocular Complications

The eye is profoundly affected by diabetes mellitus. The architecture and microanatomy of the eye are discussed in Chapter 29.

Diabetes-induced hyperglycemia leads to acquired opacification of the lens, a condition known as *cataract*.

Long-standing diabetes is also associated with increased intraocular pressure (**glaucoma**) (see later), and resulting damage to the optic nerve.

The most profound histopathologic changes of diabetes are seen in the retina. The retinal vasculopathy of diabetes mellitus can be classified into *background* (preproliferative) *diabetic retinopathy* and *proliferative diabetic retinopathy* (Chapter 29).

Diabetic Neuropathy

The prevalence of peripheral neuropathy in individuals with diabetes depends on the duration of the disease; up to 50% of diabetics overall have peripheral neuropathy clinically, and up to 80% of those who have had the disease for more than 15 years. This is discussed further in Chapter 27.

Clinical Manifestations of Chronic Diabetes

Table 24-7 summarizes some of the pertinent clinical, genetic, and histopathologic features that distinguish type 1 and type 2 diabetes. **In both types it is the long-term effects of diabetes, more than the acute metabolic complications, that are responsible for the overwhelming majority of the morbidity and mortality.** In most instances these complications appear approximately 15 to 20 years after the onset of hyperglycemia. The severity of chronic complications is related to both the degree and the duration of hyperglycemia, as evidenced by the attenuation of end-organ damage by effective glycemic control in prospective studies.

- **Macrovascular complications such as myocardial infarction, renal vascular insufficiency, and cerebrovascular accidents are the most common causes of mortality in long-standing diabetes.** Diabetics have a two to four times greater incidence of coronary artery disease, and a fourfold higher risk of dying from cardiovascular complications than nondiabetics. An elevated risk for cardiovascular disease is even observed in prediabetics. Significantly, myocardial infarction is almost as common in diabetic women as in diabetic men. In contrast, myocardial infarction is uncommon in nondiabetic women of reproductive age. Diabetes is often accompanied by underlying conditions that favor the development of adverse cardiovascular events. For example, *hypertension* is found in approximately 75% of individuals with type 2 diabetes and potentiates the effects of hyperglycemia and insulin resistance on endothelial dysfunction and atherosclerosis. Another cardiovascular risk frequently seen in diabetics is *dyslipidemia*, which includes both increased triglycerides and LDL levels and decreased levels of the “protective” lipoprotein, high-density lipoprotein (Chapter 11). Insulin resistance is believed to contribute to “diabetic dyslipidemia” by favoring the hepatic production of atherogenic lipoproteins and by suppressing the uptake of circulating lipids in peripheral tissues. Finally, diabetics have elevated levels of PAI-1, which is an inhibitor of fibrinolysis and therefore acts as a procoagulant in the formation of atherosclerotic plaques.

- **Diabetic nephropathy is a leading cause of end-stage renal disease in the United States.** Approximately 30% to 40% of all diabetics develop clinical evidence of nephropathy, but a considerably smaller fraction of patients with type 2 diabetes progress to end-stage renal disease. However, because of the much greater prevalence of type 2 diabetes, these patients constitute slightly over half the diabetic patients starting dialysis each year.

The frequency of diabetic nephropathy is greatly influenced by the genetic makeup of the population in question; for example, Native Americans, Hispanics, and African Americans have a greater risk of developing end-stage renal disease than do non-Hispanic whites with type 2 diabetes. The earliest manifestation of diabetic nephropathy is the appearance of low amounts of albumin in the urine (>30 mg/day, but <300 mg/day), that is, *microalbuminuria*. Notably, microalbuminuria is also a marker for greatly increased cardiovascular morbidity and mortality for persons with either type 1 or type 2 diabetes. Therefore, all patients with microalbuminuria should be screened for macrovascular disease, and aggressive intervention should be undertaken to reduce cardiovascular risk factors. Without specific interventions, approximately 80% of type 1 diabetics and 20% to 40% of type 2 diabetics will develop *overt nephropathy with macroalbuminuria* (>300 mg of urinary albumin per day) over 10 to 15 years, usually accompanied by the appearance of hypertension. The progression from overt nephropathy to end-stage renal disease is highly variable, but by 20 years, more than 75% of type 1 diabetics and approximately 20% of type 2 diabetics with overt nephropathy will develop end-stage renal disease, requiring dialysis or renal transplantation.

- **Visual impairment, sometimes even total blindness, is one of the more feared consequences of long-standing diabetes.** Approximately 60% to 80% of patients develop some form of *diabetic retinopathy* approximately 15 to 20 years after diagnosis. The fundamental lesion of retinopathy—neovascularization—is attributable to hypoxia-induced overexpression of VEGF in the retina. Current treatment for this condition includes administration of antiangiogenic agents. As stated earlier, diabetics also have an increased propensity for *glaucoma* and *cataract formation*, both of which contribute to visual impairment in diabetes.
- **Diabetic neuropathy** can elicit a variety of clinical syndromes, afflicting the central nervous system, peripheral sensorimotor nerves, and the autonomic nervous system. **The most frequent pattern of involvement is a distal symmetric polyneuropathy of the lower extremities that affects both motor and sensory function.** Over time the upper extremities may be involved as well, thus approximating a “glove and stocking” pattern of polyneuropathy. Other forms include *autonomic neuropathy*, which produces disturbances in bowel and bladder function and sometimes erectile dysfunction, and *diabetic mononeuropathy*, which may manifest as sudden footdrop, wristdrop, or isolated cranial nerve palsies.
- **Diabetics are plagued by enhanced susceptibility to infections of the skin and to tuberculosis, pneumonia,**

and pyelonephritis. Such infections cause the deaths of about 5% of diabetics. In an individual with diabetic neuropathy, a trivial infection in a toe may be the first event in a long succession of complications (gangrene, bacteremia, pneumonia) that may ultimately lead to death. The basis of enhanced susceptibility is multifactorial, and includes decreased neutrophil functions (chemotaxis, adherence to the endothelium, phagocytosis, and microbicidal activity), and impaired cytokine production by macrophages. The vascular compromise also reduces delivery of circulating cells and molecules that are required for host defense.

The staggering numbers and the societal and economic impact of diabetes have already been discussed. For the most part, diabetes remains a lifelong diagnosis, although pancreatic islet cell transplantation has the potential to ameliorate type 1 diabetes for many patients. For some individuals with type 2 diabetes, dietary modifications, exercise and weight loss regimens can reduce insulin resistance and hyperglycemia at least early in the disease. However, all patients will ultimately require some form of therapeutic intervention to maintain glycemic control.

KEY CONCEPTS

Diabetes Mellitus: Pathogenesis and Long-Term Complications

- Type 1 diabetes is an *autoimmune disease* characterized by progressive destruction of islet β cells, leading to absolute insulin deficiency. The fundamental immune abnormality in type 1 diabetes is a failure of self-tolerance in T cells, and circulating autoantibodies to islet cell antigens (including insulin) often are detected in affected patients.
- Type 2 diabetes has no autoimmune basis; instead, features central to its pathogenesis are *insulin resistance* and *β -cell dysfunction*, resulting in relative insulin deficiency.
- **Obesity** has an important relationship with insulin resistance (and hence type 2 diabetes), mediated through multiple factors including excess free fatty acids, cytokines released from adipose tissues (adipocytokines), and inflammation.
- Monogenic forms of diabetes are uncommon and are caused by single-gene defects that result in primary β -cell dysfunction (e.g., *glucokinase* mutation) or lead to abnormalities of insulin-insulin receptor signaling (e.g., insulin receptor gene mutations).
- The long-term complications of diabetes are similar in both types and involve four potential mechanisms resulting from sustained hyperglycemia: formation of advanced glycation end products (AGEs), activation of protein kinase C (PKC), disturbances in the polyol pathways leading to oxidative stress, and overload of the hexosamine pathway.
- Long term complications of diabetes include both large vessel disease (*macroangiopathy*), such as atherosclerosis, ischemic heart disease and lower extremity ischemia, as well as small vessel disease (*microangiopathy*), the latter manifesting mainly as retinopathy, nephropathy and neuropathy.

Pancreatic Neuroendocrine Tumors

The preferred term for tumors of the pancreatic islet cells (“islet cell tumors”) is *pancreatic neuroendocrine tumors* or *PanNETs*. They are rare in comparison with tumors of the exocrine pancreas, accounting for only 2% of all pancreatic neoplasms. PanNETs can occur anywhere along the length of the pancreas, embedded in the substance of the pancreas or arising in the immediate peripancreatic tissues. They resemble their counterparts, carcinoid tumors, found elsewhere in the alimentary tract (Chapter 17). These tumors may be single or multiple and benign or malignant. Pancreatic endocrine neoplasms often elaborate pancreatic hormones, or may be nonfunctional.

Like other endocrine neoplasms, it is difficult to predict the behavior of a pancreatic endocrine neoplasm based on their light microscopic appearance. Unequivocal criteria for malignancy include metastases, vascular invasion, and local infiltration. The functional status of the tumor has some impact on prognosis, in that approximately 90% of insulin producing tumors are benign, while 60% to 90% of other functioning and nonfunctioning pancreatic endocrine neoplasms are malignant. Fortunately, insulinomas are the most common subtype of pancreatic endocrine neoplasms.

The genome of sporadic PanNETs recently has been sequenced, with identification of recurrent somatic alterations in three major genes or pathways:

- *MEN1*, which causes familial MEN syndrome, type 1, also is mutated in a number of sporadic neuroendocrine tumors
- Loss-of-function mutations in tumor suppressor genes such *PTEN* and *TSC2* (Chapter 7), which result in activation of the oncogenic mammalian TOR (mTOR) signaling pathway.
- Inactivating mutations in two genes, *alpha-thalassemia/mental retardation syndrome, X-linked (ATRX)* and death-domain associated protein (*DAXX*), which have multiple cellular functions, including telomere maintenance. Of note, nearly half of PanNETs have a somatic mutation in either *ATRX* or *DAXX*, but not both, suggesting that the encoded proteins function in a critical common pathway.

The three most common and distinctive clinical syndromes associated with functional pancreatic endocrine neoplasms are (1) *hyperinsulinism*, (2) *hypergastrinemia and the Zollinger-Ellison syndrome*, and (3) *multiple endocrine neoplasia (MEN)* (described in detail later).

Hyperinsulinism (Insulinoma)

β -cell tumors (insulinomas) are the most common of pancreatic endocrine neoplasms, and may produce sufficient insulin to induce clinically significant hypoglycemia. The characteristic clinical picture is dominated by hypoglycemic episodes, which occur if the blood glucose level falls below 50 mg/dL of serum. The clinical manifestations include confusion, stupor, and loss of consciousness. These episodes are precipitated by fasting or exercise and are promptly relieved by feeding or parenteral administration of glucose.

MORPHOLOGY

Insulinomas are most often found within the pancreas and are generally benign. Most are solitary, although multiple tumors may be encountered. *Bona fide* carcinomas, making up only about 10% of cases, are diagnosed on the basis of local invasion and distant metastases. On rare occasions an insulinoma may arise in ectopic pancreatic tissue. In such cases, electron microscopy reveals the distinctive granules of β -cells (Fig. 24-27).

Solitary tumors are usually small (often < 2 cm in diameter), encapsulated, pale to red-brown nodules located anywhere in the pancreas. Histologically, these benign tumors look remarkably like giant islets, with preservation of the regular cords of monotonous cells and their orientation to the vasculature. Not even the malignant lesions present much evidence of anaplasia, and they may be deceptively encapsulated. **Deposition of amyloid** is a characteristic feature of many insulinomas (Fig. 24-41).

Hyperinsulinism may also be caused by **focal or diffuse hyperplasia of the islets**. This change is found occasionally in adults but is far more commonly encountered as congenital hyperinsulinism with hypoglycemia in neonates and infants. Several clinical scenarios may result in islet hyperplasia (previously known as *nesidioblastosis*), including maternal diabetes, Beckwith-Wiedemann syndrome (Chapter 10), and rare mutations in the β -cell K^+ -channel protein or sulfonylurea receptor. In maternal diabetes, the fetal islets respond to hyperglycemia by increasing their size and number. In the postnatal period, these hyperactive islets may be responsible for serious episodes of hypoglycemia. This phenomenon is usually transient.

Clinical Features. While up to 80% of islet cell tumors demonstrate excessive insulin secretion, the hypoglycemia is mild in all but about 20%, and many cases never become clinically symptomatic. The critical laboratory findings in insulinomas are high circulating levels of insulin and a high insulin-to-glucose ratio. Surgical removal of the tumor is usually followed by prompt reversal of the hypoglycemia.

It is important to note that there are many other causes of hypoglycemia besides insulinomas. The differential diagnosis of this metabolic abnormality includes such conditions as abnormal insulin sensitivity, diffuse liver disease, inherited glycogenoses, and ectopic production of insulin by certain retroperitoneal fibromas and fibrosarcomas. Depending on the clinical circumstances, hypoglycemia induced by self-injection of insulin should also be considered.

Zollinger-Ellison Syndrome (Gastrinomas)

Marked hypersecretion of gastrin usually has its origin in gastrin-producing tumors (*gastrinomas*), which are just as likely to arise in the duodenum and peripancreatic soft tissues as in the pancreas (so-called gastrinoma triangle). There has been lack of agreement regarding the cell of origin of these tumors, although it seems likely that endocrine cells of either the gut or the pancreas could be the source. Zollinger and Ellison first called attention to the **association of pancreatic islet cell lesions, hypersecretion of gastric acid and severe peptic ulceration**, which are present in 90% to 95% of patients.

Figure 24-41 Pancreatic endocrine neoplasm (“islet cell tumor”). The neoplastic cells are monotonous and demonstrate minimal pleomorphism or mitotic activity. There is abundant amyloid deposition, characteristic of an insulinoma. Clinically, the patient had episodic hypoglycemia.

MORPHOLOGY

More than half of gastrin-producing tumors are locally invasive or have already metastasized at the time of diagnosis. In approximately 25% of patients, gastrinomas arise in conjunction with other endocrine tumors, as part of the MEN-1 syndrome (see later); MEN-1-associated gastrinomas are frequently multifocal, while sporadic gastrinomas are usually single. As with insulin-secreting tumors of the pancreas, gastrin-producing tumors are histologically bland and rarely show marked anaplasia.

In the Zollinger-Ellison syndrome, hypergastrinemia gives rise to extreme gastric acid secretion, which in turn causes **peptic ulceration** (Chapter 17). The duodenal and gastric ulcers are often multiple; although they are identical to those found in the general population, they are often unresponsive to therapy. In addition, ulcers may occur in unusual locations such as the jejunum; **when intractable jejunal ulcers are found, Zollinger-Ellison syndrome should be considered.**

Clinical Features. More than 50% of the patients have diarrhea; in 30%, it is the presenting symptom. Treatment

of Zollinger-Ellison syndrome involves control of gastric acid secretion by use of H^+K^+ -ATPase inhibitors and excision of the neoplasm. Total resection of the neoplasm, when possible, eliminates the syndrome. Patients with hepatic metastases have a shortened life expectancy, with progressive tumor growth leading to liver failure usually within 10 years.

Other Rare Pancreatic Endocrine Neoplasms

α -cell tumors (glucagonomas) are associated with increased serum levels of glucagon and a syndrome consisting of mild diabetes mellitus, a characteristic skin rash (necrolytic migratory erythema), and anemia. They occur most frequently in perimenopausal and postmenopausal women and are characterized by extremely high plasma glucagon levels.

δ -cell tumors (somatostatinomas) are associated with diabetes mellitus, cholelithiasis, steatorrhea, and hypochlorhydria. They are exceedingly difficult to localize preoperatively. High plasma somatostatin levels are required for diagnosis.

VIPoma (watery diarrhea, hypokalemia, achlorhydria, or WDHA syndrome) induces a characteristic syndrome that is caused by release of vasoactive intestinal peptide (VIP) from the tumor. Some of these tumors are locally invasive and metastatic. A VIP assay should be performed on all patients with severe secretory diarrhea. Neural crest tumors, such as neuroblastomas, ganglioneuroblastoma, and ganglioneuromas (Chapter 10) and pheochromocytomas (see later) can also be associated with the VIPoma syndrome.

Pancreatic carcinoid tumors producing serotonin and an atypical carcinoid syndrome are exceedingly rare. *Pancreatic polypeptide-secreting endocrine tumors* present as mass lesions as even high plasma levels of this hormone fail to cause symptoms.

Some pancreatic and extra-pancreatic endocrine tumors produce two or more hormones. In addition to insulin, glucagon, and gastrin, pancreatic endocrine tumors may produce ACTH, MSH, ADH, serotonin, and norepinephrine. These *multihormonal tumors* are to be distinguished from the MEN syndromes (discussed later), in which a multiplicity of hormones is produced by tumors in several different glands.

ADRENAL GLANDS

Adrenal Cortex

The *adrenal glands* are paired endocrine organs consisting of a cortex and a medulla, which differ in their development, structure, and function. In essence the cortex and medulla are two glands packaged as one structure. The adrenal cortex has three zones. Beneath the capsule is the narrow layer of zona glomerulosa. An equally narrow zona reticularis abuts the medulla. Intervening is the broad zona fasciculata, which makes up about 75% of the total cortex. The *adrenal cortex* synthesizes three different types of steroids: (1) *glucocorticoids* (principally cortisol), which are

synthesized primarily in the zona fasciculata and to a lesser degree in the zona reticularis; (2) *mineralocorticoids*, the most important being aldosterone, which is generated in the zona glomerulosa; and (3) *sex steroids* (estrogens and androgens), which are produced largely in the zona reticularis. The *adrenal medulla* is composed of chromaffin cells, which synthesize and secrete *catecholamines*, mainly epinephrine. Catecholamines have many effects that allow rapid adaptations to changes in the environment.

Diseases of the adrenal cortex can be conveniently divided into those associated with hyperfunction and those associated with hypofunction.

Adrenocortical Hyperfunction (Hyperadrenalism)

The syndromes of adrenal hyperfunction are caused by overproduction of the three major hormones of the adrenal cortex (1) *Cushing syndrome*, characterized by an excess of cortisol; (2) *hyperaldosteronism* as a result of excessive aldosterone; and (3) *adrenogenital or virilizing syndromes* caused by an excess of androgens. The clinical features of these syndromes overlap somewhat because of the overlapping functions of some of the adrenal steroids.

Hypercortisolism (Cushing Syndrome)

Pathogenesis. This disorder is caused by conditions that produce elevated glucocorticoid levels. Cushing syndrome can be broadly divided into *exogenous* and *endogenous* causes. The vast majority of cases of Cushing syndrome are the result of the administration of exogenous glucocorticoids (“iatrogenic” Cushing syndrome). The endogenous causes can, in turn, be divided into those that are *ACTH dependent* and those that are *ACTH independent* (Table 24-8).

ACTH-secreting pituitary adenomas account for approximately 70% of cases of endogenous hypercortisolism. In recognition of Harvey Cushing, the neurosurgeon who first published the full description of this syndrome, the pituitary form is referred to as *Cushing disease*. The disorder affects women about four times more frequently than men and occurs most frequently in young adults. In the vast majority of cases it is caused by an *ACTH-producing pituitary microadenoma*. In some cases there is an underlying macroadenoma and rarely there is *corticotroph cell hyperplasia* without a discrete adenoma. Corticotroph cell hyperplasia may be primary or arise

secondarily from excessive stimulation of ACTH release by a hypothalamic corticotrophin-releasing hormone (CRH)-producing tumor. The adrenal glands in individuals with Cushing disease are characterized by variable degrees of nodular cortical hyperplasia (discussed later), caused by the elevated levels of ACTH. The cortical hyperplasia, in turn, is responsible for hypercortisolism.

Secretion of ectopic ACTH by nonpituitary tumors accounts for about 10% of ACTH-dependent Cushing syndrome. In many instances the responsible tumor is a *small-cell carcinoma of the lung*, although other neoplasms, including carcinoids, medullary carcinomas of the thyroid, and islet cell tumors, have been associated with the syndrome. In addition to tumors that elaborate ectopic ACTH, occasionally a neuroendocrine neoplasm may produce ectopic corticotrophin releasing hormone (CRH), which, in turn, causes ACTH secretion and hypercortisolism. As in the pituitary variant, the adrenal glands undergo bilateral cortical hyperplasia, but the rapid downhill course of patients with these cancers often limits the extent of the adrenal enlargement. This variant of Cushing syndrome is more common in men and usually occurs in the 40s and 50s.

Primary adrenal neoplasms, such as adrenal adenoma (~10%) and carcinoma (~5%) are the most common underlying causes for ACTH-independent Cushing syndrome. The biochemical *sine qua non* of ACTH-independent Cushing syndrome is elevated serum levels of cortisol with low levels of ACTH. Cortical carcinomas tend to produce more marked hypercortisolism than adenomas or hyperplasias. In instances of a unilateral neoplasm, the uninvolved adrenal cortex and the cortex in the opposite gland undergo atrophy because of suppression of ACTH secretion.

The overwhelming majority of hyperplastic adrenals are ACTH dependent, and *primary cortical hyperplasia* (i.e., ACTH-independent hyperplasia) is uncommon. In *macronodular hyperplasia* the nodules are usually greater than 3 mm in diameter. Macronodular hyperplasia is typically a sporadic (nonsyndromic) condition observed in adults. It is now known that, although the condition is ACTH independent, it is not entirely “autonomous.” Specifically, cortisol production is regulated by non-ACTH circulating hormones, because of ectopic overexpression of their corresponding receptors in the adrenocortical cells. Such non-ACTH hormones include gastric inhibitory peptide, LH and ADH; their receptors are overexpressed on hyperplastic adrenal cortical cells. The mechanism by which these receptors for non-ACTH hormones are overexpressed in adrenocortical tissues is not known. A subset of macronodular hyperplasia arises in the setting of McCune-Albright syndrome (Chapter 26), characterized by somatic mutations that activate *GNAS*, which encodes a stimulatory $G_s\alpha$. This $G_s\alpha$ mutation causes hyperplasia by increasing intracellular levels of cAMP, which you will recall is an important second messenger in many endocrine cell types. Given this, it is not surprising that mutations in several other proteins that are involved in cAMP signaling, such as the regulatory subunit of cAMP-dependent protein kinase (encoded by the *PRKARIA* gene) and a phosphodiesterase (an enzyme that breaks down cAMP, encoded by the *PDE11A* gene), are also associated with primary cortical hyperplasia.

Table 24-8 Endogenous Causes of Cushing Syndrome

Cause	Relative Frequency (%)	Ratio of Females to Males
ACTH-Dependent		
Cushing disease (pituitary adenoma; rarely CRH)	70	3.5:1
Ectopic corticotropin syndrome (ACTH)	10	1:1
ACTH-Independent		
Adrenal adenoma	10	4:1
Adrenal carcinoma	5	1:1
Macronodular hyperplasia (ectopic expression of hormone receptors, including GIPR, LHR, vasopressin and serotonin receptors)	<2	1:1
Primary pigmented nodular adrenal disease (<i>PRKARIA</i> and <i>PDE11</i> mutations)	<2	1:1
McCune-Albright syndrome (<i>GNAS</i> mutations)	<2	1:1

ACTH, Adrenocorticotrophic hormone; GIPR, gastric inhibitory polypeptide receptor; LHR, luteinizing hormone receptor; *PRKARIA*, protein kinase A regulatory subunit 1 α ; *PDE11*, phosphodiesterase 11A.

Note: These etiologies are responsible for endogenous Cushing syndrome. The most common overall cause of Cushing syndrome is exogenous glucocorticoid administration (iatrogenic Cushing syndrome).

Adapted with permission from Newell-Price J, et al: Cushing syndrome. *Lancet* 367:1605-1616, 2006.

MORPHOLOGY

The main lesions of Cushing syndrome are found in the pituitary and adrenal glands. The **pituitary** shows changes regardless of the cause. The most common alteration, resulting from high levels of endogenous or exogenous glucocorticoids, is termed **Crooke hyaline change**. In this condition the normal granular, basophilic cytoplasm of the ACTH-producing cells in the anterior pituitary becomes homogeneous and paler. This alteration is the result of the accumulation of intermediate keratin filaments in the cytoplasm.

Depending on the cause of the hypercortisolism the **adrenals** show one of the following abnormalities: (1) cortical atrophy, (2) diffuse hyperplasia, (3) macronodular or micronodular hyperplasia, and (4) an adenoma or carcinoma. In patients in whom the syndrome results from exogenous glucocorticoids, suppression of endogenous ACTH results in bilateral **cortical atrophy**, due to a lack of stimulation of the zona fasciculata and reticularis by ACTH. The zona glomerulosa is of normal thickness in such cases, because this portion of the cortex functions independently of ACTH. In contrast, in cases of endogenous hypercortisolism, the adrenals either are hyperplastic or contain a cortical neoplasm. **Diffuse hyperplasia** is found in individuals with ACTH-dependent Cushing syndrome (Fig. 24-42). Both glands are enlarged, either subtly or markedly, weighing up to 30 gm. The adrenal cortex is diffusely thickened and variably nodular, although the latter is not as pronounced as seen in cases of ACTH-independent nodular hyperplasia. Microscopically, the hyperplastic cortex demonstrates an expanded “lipid-poor” zona reticularis, comprising compact, eosinophilic cells, surrounded by an outer zone of vacuolated “lipid-rich” cells, resembling those seen in the zona fasciculata. Any nodules present are usually composed of vacuolated “lipid-rich” cells, which account for the yellow color of diffusely hyperplastic glands. In contrast, in **macronodular hyperplasia** the adrenals are almost entirely replaced by prominent nodules of varying sizes (≤ 3 cm), which contain an admixture of lipid-poor and lipid-rich cells. Unlike diffuse hyperplasia, the areas between the macroscopic nodules also demonstrate evidence of microscopic nodularity. **Micronodular hyperplasia** is composed of 1- to 3-mm darkly pigmented (brown to black) micronodules, with atrophic intervening areas (Fig. 24-43). The pigment is believed to be lipofuscin, a wear-and-tear pigment (Chapter 2).

Primary adrenocortical neoplasms causing Cushing syndrome may be malignant or benign. Functional adenomas or carcinomas of the adrenal cortex as the source of cortisol are

Figure 24-42 Diffuse hyperplasia of the adrenal contrasted with normal adrenal gland. In cross-section the adrenal cortex is yellow and thickened, and a subtle nodularity is seen (contrast with Fig. 24-46). Both adrenal glands were diffusely hyperplastic in this patient with ACTH-dependent Cushing syndrome.

not morphologically distinct from nonfunctioning adrenal neoplasms (described later). Both the benign and the malignant lesions are more common in women in their 30s to 50s. Adrenocortical **adenomas** are yellow tumors surrounded by thin or well-developed capsules, and most weigh less than 30 gm. Microscopically, they are composed of cells that are similar to those encountered in the normal zona fasciculata. The **carcinomas** associated with Cushing syndrome, by contrast, tend to be larger than the adenomas. These tumors (detailed later) are unencapsulated masses frequently exceeding 200 to 300 gm in weight that have all of the anaplastic characteristics of cancer. With functioning tumors, both benign and malignant, the adjacent adrenal cortex and that of the contralateral adrenal gland are atrophic, as a result of suppression of endogenous ACTH by high cortisol levels.

Figure 24-43 **A**, Micronodular adrenocortical hyperplasia with prominent pigmented nodules in the adrenal gland. **B**, On histologic examination the nodules are composed of cells containing lipofuscin pigment, seen in the right part of the field. Table 24-9 Clinical Features of Cushing Syndrome

Feature	Percent
Obesity or weight gain	95%*
Facial plethora	90%
Rounded face	90%
Decreased libido	90%
Thin skin	85%
Decrease in linear growth in children	70-80%
Menstrual irregularity	80%
Hypertension	75%
Hirsutism	75%
Depression/emotional lability	70%
Easy bruising	65%
Glucose intolerance	60%
Weakness	60%
Osteopenia or fracture	50%
Nephrolithiasis	50%

*100% in children.

Adapted from Newell-Price J, et al: Cushing syndrome. *Lancet* 367:1605-1616, 2006.

Clinical Course. Cushing syndrome develops slowly and can be quite subtle in its early manifestations. Early stages of the disorder may present with hypertension and weight gain (Table 24-9). With time the more characteristic central pattern of adipose tissue deposition becomes apparent in the form of truncal obesity, moon facies, and accumulation of fat in the posterior neck and back (*buffalo hump*). Hypercortisolism causes selective atrophy of fast-twitch (type 2) myofibers, resulting in decreased muscle mass and proximal limb weakness. Glucocorticoids induce gluconeogenesis and inhibit the uptake of glucose by cells, with resultant *hyperglycemia*, *glucosuria* and *polydipsia* (*secondary diabetes*). The catabolic effects cause loss of collagen and resorption of bones. Consequently the *skin is thin, fragile, and easily bruised*; wound healing is poor; and cutaneous striae are particularly common in the abdominal area (Fig. 24-44). Bone resorption results in the development of *osteoporosis*, with consequent backache and increased susceptibility to fractures. Persons with Cushing syndrome are at increased risk for a variety of infections, because glucocorticoids suppress the immune response. Additional manifestations include several *mental disturbances*, including mood swings, depression, and frank psychosis, as well as *hirsutism* and *menstrual abnormalities*.

The laboratory diagnosis of Cushing syndrome is based on the following: (1) the 24-hour urine free-cortisol concentration, which is increased, and (2) loss of normal diurnal pattern of cortisol secretion. Determining the cause of Cushing syndrome depends on the serum ACTH and measurement of urinary steroid excretion after administration of dexamethasone (dexamethasone suppression test). The results of these tests fall into three general patterns:

- In pituitary Cushing syndrome, the most common form, ACTH levels are elevated and cannot be suppressed by the administration of a low dose of dexamethasone. Hence, there is no reduction in urinary excretion of 17-hydroxycorticosteroids. After higher doses of injected dexamethasone, however, the pituitary responds by

reducing ACTH secretion, which is reflected by suppression of urinary steroid secretion.

- Ectopic ACTH secretion results in an elevated level of ACTH, but its secretion is completely insensitive to low or high doses of exogenous dexamethasone.
- When Cushing syndrome is caused by an adrenal tumor, the ACTH level is quite low because of feedback inhibition of the pituitary. As with ectopic ACTH secretion, both low-dose and high-dose dexamethasone fail to suppress cortisol excretion.

KEY CONCEPTS

Hypercortisolism (Cushing Syndrome)

- The most common cause of hypercortisolism is exogenous administration of steroids.
- Endogenous hypercortisolism most often is secondary to an ACTH-producing pituitary microadenoma (*Cushing disease*), followed by primary adrenal neoplasms (*ACTH-independent hypercortisolism*) and paraneoplastic ACTH production by tumors (e.g., small cell lung cancer).
- The morphologic features in the adrenal vary from bilateral cortical atrophy (in exogenous steroid-induced disease), to bilateral diffuse or nodular hyperplasia (most common finding in endogenous Cushing syndrome), to an adrenocortical neoplasm.

Primary Hyperaldosteronism

Hyperaldosteronism is the generic term for a group of closely related conditions characterized by chronic excess aldosterone secretion. Hyperaldosteronism may be primary, or it

Figure 24-44 A patient with Cushing syndrome demonstrating central obesity, "moon facies," and abdominal striae. (Reproduced with permission from Lloyd RV, et al (eds): *Atlas of Nontumor Pathology: Endocrine Diseases*. Washington, DC, American Registry of Pathology, 2002.)

Figure 24-45 The major causes of primary hyperaldosteronism and its principal effects on the kidney.

may be secondary to an extra-adrenal cause. *Primary hyperaldosteronism* stems from an autonomous overproduction of aldosterone, with resultant suppression of the renin-angiotensin system and *decreased plasma renin activity*. **Blood pressure elevation is the most common manifestation of primary hyperaldosteronism**, which is caused by one of three mechanisms (Fig. 24-45):

- *Bilateral idiopathic hyperaldosteronism (IHA)*, characterized by bilateral nodular hyperplasia of the adrenal glands, is the most common underlying cause of primary hyperaldosteronism, accounting for about 60% of cases. Individuals with idiopathic hyperaldosteronism tend to be older and to have less severe hypertension than those presenting with adrenal neoplasms. The pathogenesis of idiopathic hyperaldosteronism remains unclear, although recent studies suggest that a subset of patients with familial idiopathic hyperaldosteronism harbor germline mutations of *KCNJ5*, encoding a potassium channel.
- *Adrenocortical neoplasm*, either an aldosterone-producing adenoma (the most common cause) or, rarely, an adrenocortical carcinoma. In approximately 35% of cases, primary hyperaldosteronism is caused by a solitary aldosterone-secreting adenoma, a condition referred to as *Conn syndrome*. This syndrome occurs most frequently in adult middle life and is more common in women than in men (2:1). Multiple adenomas may be present in an occasional patient. Somatic mutations of *KCNJ5* are also present in a subset of aldosterone-secreting adenomas.
- *Glucocorticoid-remediable hyperaldosteronism* is an uncommon cause of primary familial hyperaldosteronism. In

some families, it stems from a rearrangement involving chromosome 8 that places *CYP11B2* (the gene that encodes *aldosterone synthase*) under the control of the ACTH responsive *CYP11B1* gene promoter. ACTH thus stimulates the production of aldosterone synthase, the enzyme that is responsible for the last step in aldosterone synthesis. Because in this unusual circumstance aldosterone production is under the control of ACTH, it is suppressible by dexamethasone.

In *secondary hyperaldosteronism*, in contrast, aldosterone release occurs in response to activation of the renin-angiotensin system (Chapter 11). It is characterized by *increased levels of plasma renin* and is encountered in conditions such as the following:

- Decreased renal perfusion (arteriolar nephrosclerosis, renal artery stenosis)
- Arterial hypovolemia and edema (congestive heart failure, cirrhosis, nephrotic syndrome)
- Pregnancy (due to estrogen-induced increases in plasma renin substrate)

MORPHOLOGY

Aldosterone-producing adenomas are almost always solitary, small (<2 cm in diameter), well-circumscribed lesions, more often found on the left than on the right. They tend to occur in the 30s and 40s, and in women more often than in men. They are often buried within the gland and do not produce visible enlargement, a point to be remembered in interpreting sonographic or scanning images. They are bright yellow on cut section and, surprisingly, are composed of lipid-laden cortical cells that more closely resemble fasciculata cells than glomerulosa cells (the normal source of aldosterone). In general, the cells tend to be uniform in size and shape; occasionally, there is modest nuclear and cellular pleomorphism (see Fig. 24-51). A characteristic feature of aldosterone-producing adenomas is the presence of eosinophilic, laminated cytoplasmic inclusions, known as **spironolactone bodies**, found after treatment with the antihypertensive drug spironolactone. In contrast to cortical adenomas associated with Cushing syndrome, those associated with hyperaldosteronism do not usually suppress ACTH secretion. Therefore, the adjacent adrenal cortex and that of the contralateral gland are not atrophic.

Bilateral idiopathic hyperplasia is marked by diffuse and focal hyperplasia of cells resembling those of the normal zona glomerulosa. The hyperplasia is often wedge-shaped, extending from the periphery toward the center of the gland. The enlargement may be subtle, and as a rule an adrenocortical adenoma must be carefully excluded as the cause for hyperaldosteronism.

Clinical Course. The most important clinical consequence of hyperaldosteronism is hypertension. With an estimated prevalence rate of 5% to 10% among nonselected hypertensive patients, primary hyperaldosteronism may be the most common cause of secondary hypertension (i.e., hypertension secondary to an identifiable cause). The prevalence of hyperaldosteronism increases with the severity of hypertension, reaching nearly 20% in patients who are classified as having treatment-resistant hypertension.

Through its effects on the renal mineralocorticoid receptor, aldosterone promotes sodium reabsorption, which secondarily increases the reabsorption of water, expanding the extracellular fluid volume and elevating cardiac output.

The long-term effects of hyperaldosteronism-induced hypertension are cardiovascular compromise (e.g., left ventricular hypertrophy and reduced diastolic volumes) and an increase in the prevalence of adverse events such as stroke and myocardial infarction. *Hypokalemia* was considered a mandatory feature of primary hyperaldosteronism, but increasing numbers of normokalemic patients are now diagnosed. Hypokalemia results from renal potassium wasting and, when present, can cause a variety of neuromuscular manifestations, including weakness, paresthesias, visual disturbances, and occasionally frank tetany.

The diagnosis of primary hyperaldosteronism is confirmed by elevated ratios of plasma aldosterone concentration to plasma renin activity; if this screening test is positive, a confirmatory *aldosterone suppression test* must be performed, because many unrelated causes can alter the plasma aldosterone and renin ratios.

In primary hyperaldosteronism, the therapy varies according to cause. Adenomas are amenable to surgical excision. In contrast, surgical intervention is not very

beneficial in patients with primary hyperaldosteronism due to bilateral hyperplasia, which often occurs in children and young adults. These patients are best managed medically with an aldosterone antagonist such as spironolactone. The treatment of secondary hyperaldosteronism rests on correcting the underlying cause stimulating the renin-angiotensin system.

Adrenogenital Syndromes

Disorders of sexual differentiation, such as *virilization* or *feminization*, can be caused by primary gonadal disorders (Chapter 22) and several primary adrenal disorders. The adrenal cortex secretes two compounds—dehydroepiandrosterone and androstenedione—that can be converted to testosterone in peripheral tissues. Unlike gonadal androgens, ACTH regulates adrenal androgen formation (Fig. 24-46); thus, excess secretion can occur either as a “pure” syndrome or as a component of Cushing disease. The adrenal causes of androgen excess include *adrenocortical neoplasms* and a group of disorders that have been designated *congenital adrenal hyperplasia (CAH)*.

Adrenocortical neoplasms associated with virilization are more likely to be *androgen-secreting adrenal carcinomas* than adenomas. Such tumors are often also associated with hypercortisolism (“mixed syndrome”). They are

Figure 24-46 Consequences of C-21 hydroxylase deficiency. 21-Hydroxylase deficiency impairs the synthesis of both cortisol and aldosterone at different steps (shown as “Block” in the biosynthesis pathway). The resultant decrease in feedback inhibition (*dashed line*) causes increased secretion of ACTH, resulting ultimately in adrenal hyperplasia and increased synthesis of testosterone. The sites of action of 11-, 17-, and 21-hydroxylase are shown by the numbers in circles.

morphologically identical to other cortical neoplasms and will be discussed later.

Congenital adrenal hyperplasia stems from several autosomal-recessive, inherited metabolic errors, each characterized by a deficiency or total lack of a particular enzyme involved in the biosynthesis of cortical steroids, particularly cortisol (Fig. 24-46). Steroid precursors that build behind the defective step in the pathway are channeled into other pathways, resulting in increased production of androgens, which accounts for virilization. Simultaneously, the deficiency of cortisol leads to increased secretion of ACTH, culminating in adrenal hyperplasia. Certain enzyme defects may also impair aldosterone secretion, adding *salt wasting* to the virilizing syndrome. Other enzyme deficiencies may be incompatible with life or, in rare instances, may involve only the aldosterone pathway without involving cortisol synthesis.

21-hydroxylase deficiency (caused by mutations of *CYP21A2*) is by far the most common, accounting for over 90% of cases. [Figure 24-46](#) illustrates normal adrenal steroidogenesis and the consequences of 21-hydroxylase deficiency, which may range from a total lack to a mild loss, depending on the nature of the *CYP21A2* mutation. Three distinctive syndromes have been described: (1) salt-wasting (“classic”) adrenogenitalism, (2) simple virilizing adrenogenitalism, and (3) “nonclassic” adrenogenitalism.

- The *salt-wasting syndrome* results from an inability to convert progesterone into deoxycorticosterone because of a total lack of the hydroxylase. Thus, there is virtually no synthesis of mineralocorticoids, and concomitantly, there is a block in the conversion of hydroxyprogesterone into deoxycortisol resulting in deficient cortisol synthesis. This pattern usually comes to light soon after birth, because in utero the electrolytes and fluids can be maintained by the maternal kidneys. There is *salt wasting*, *hyponatremia*, and *hyperkalemia*, which induce acidosis, *hypotension*, cardiovascular collapse, and possibly death. The concomitant block in cortisol synthesis and excess production of androgens, however, lead to virilization, which is easily recognized in the female at birth or in utero. Males with this disorder are generally unrecognized at birth but come to clinical attention 5 to 15 days later because of some salt-losing crisis.
- *Simple virilizing adrenogenital syndrome without salt wasting* (presenting as genital ambiguity) occurs in approximately a third of patients with 21-hydroxylase deficiency. These patients generate sufficient mineralocorticoid to prevent a salt-wasting “crisis.” However, the lowered glucocorticoid level fails to cause feedback inhibition of ACTH secretion. Thus, the level of testosterone is increased, with resultant progressive virilization.
- *Nonclassic or late-onset adrenal virilism* is significantly more common than the classic patterns already described. There is only a partial deficiency in 21-hydroxylase function, which accounts for the later onset. Individuals with this syndrome may be virtually asymptomatic or have mild manifestations, such as hirsutism, acne, and menstrual irregularities. Nonclassic CAH cannot be diagnosed on routine newborn screening, and the diagnosis is usually rendered by demonstration of biosynthetic defects in steroidogenesis.

MORPHOLOGY

In all cases of CAH the adrenals are bilaterally hyperplastic, sometimes increasing to 10 to 15 times their normal weights because of the sustained elevation in ACTH. The adrenal cortex is thickened and nodular, and on cut section the widened cortex appears brown, because of total depletion of all lipid. The proliferating cells are mostly compact, eosinophilic, lipid-depleted cells, intermixed with lipid-laden clear cells. Hyperplasia of corticotroph (ACTH-producing) cells is present in the anterior pituitary in most persons with CAH.

Clinical Course. The clinical features of these disorders are determined by the specific enzyme deficiency and include abnormalities related to *androgen excess*, with or without *aldosterone* and *glucocorticoid deficiency*. CAH affects not only adrenal cortical enzymes but also products synthesized in the medulla. High levels of intra-adrenal glucocorticoids are required to facilitate medullary catecholamine (epinephrine and norepinephrine) synthesis. In patients with severe salt-wasting 21-hydroxylase deficiency, a combination of low cortisol levels and developmental defects of the medulla (*adrenomedullary dysplasia*) profoundly affects catecholamine secretion, further predisposing these individuals to hypotension and circulatory collapse.

Depending on the nature and severity of the enzymatic defect, the onset of clinical symptoms may occur in the perinatal period, later childhood, or, less commonly, adulthood. For example, in 21-hydroxylase deficiency excessive androgenic activity causes signs of masculinization in females, ranging from clitoral hypertrophy and pseudohermaphroditism in infants, to oligomenorrhea, hirsutism, and acne in postpubertal females. In males, androgen excess is associated with enlargement of the external genitalia and other evidence of precocious puberty in prepubertal patients and oligospermia in older males.

CAH should be suspected in any neonate with ambiguous genitalia. Severe enzyme deficiency in infancy can be a life-threatening condition with vomiting, dehydration, and salt wasting. Individuals with CAH are treated with exogenous glucocorticoids, which, in addition to providing adequate levels of glucocorticoids, also suppress ACTH levels and thus decrease the excessive synthesis of the steroid hormones responsible for many of the clinical abnormalities. Mineralocorticoid supplementation is required in the salt-wasting variants of CAH. With the availability of routine neonatal metabolic screens for CAH and the feasibility of molecular testing for antenatal detection of 21-hydroxylase mutations, the outcome for even the most severe variants has improved significantly.

KEY CONCEPTS

Adrenogenital Syndromes

- The adrenal cortex can secrete excess androgens in either of two settings: adrenocortical neoplasms (usually *virilizing carcinomas*) or congenital adrenal hyperplasia (CAH).
- CAH consists of a group of autosomal recessive disorders characterized by defects in steroid biosynthesis, usually

cortisol; the most common subtype is caused by deficiency of the enzyme 21-hydroxylase.

- Reduction in cortisol production causes a compensatory increase in ACTH secretion, which in turn stimulates androgen production. Androgens have virilizing effects, including masculinization in females (ambiguous genitalia, oligomenorrhea, hirsutism), precocious puberty in males, and in some instances, salt (sodium) wasting and hypotension.
- Bilateral hyperplasia of the adrenal cortex is characteristic, and a subset of 21-hydroxylase-deficient patients also demonstrates *adrenomedullary dysplasia*.

Adrenocortical Insufficiency

Adrenocortical insufficiency, or hypofunction, may be caused by either primary adrenal disease (primary hypoadrenalism) or decreased stimulation of the adrenals due to a deficiency of ACTH (secondary hypoadrenalism) (Table 24-10). The patterns of adrenocortical insufficiency can be considered under the following headings: (1) primary *acute* adrenocortical insufficiency (adrenal crisis), (2) primary *chronic* adrenocortical insufficiency (*Addison disease*), and (3) secondary adrenocortical insufficiency.

Primary Acute Adrenocortical Insufficiency

Acute adrenal cortical insufficiency occurs in a variety of clinical settings.

Table 24-10 Adrenocortical Insufficiency

Primary Insufficiency
Loss of Cortical Cells
Congenital adrenal <i>hypoplasia</i>
X-linked adrenal hypoplasia (<i>DAX1</i> gene on Xp21)
"Miniature"-type adrenal hypoplasia (unknown cause)
Adrenoleukodystrophy (<i>ALD</i> gene on Xq28)
Autoimmune adrenal insufficiency
Autoimmune polyendocrinopathy syndrome type 1 (<i>AIRE1</i> gene on 21q22)
Autoimmune polyendocrinopathy syndrome type 2 (polygenic)
Isolated autoimmune adrenalitis (polygenic)
Infection
Acquired immune deficiency syndrome
Tuberculosis
Fungi
Acute hemorrhagic necrosis (<i>Waterhouse-Friderichsen syndrome</i>)
Amyloidosis, sarcoidosis, hemochromatosis
Metastatic carcinoma
Metabolic Failure in Hormone Production
Congenital adrenal <i>hyperplasia</i> (cortisol and aldosterone deficiency with virilization)
Drug- and steroid-induced inhibition of ACTH or cortical cell function
Secondary Insufficiency
Hypothalamic Pituitary Disease
Neoplasm, inflammation (sarcoidosis, tuberculosis, pyogens, fungi)
Hypothalamic Pituitary Suppression
Long-term steroid administration
Steroid-producing neoplasms
ACTH, Adrenocorticotropic hormone.

Figure 24-47 Diffuse purpuric rash in a patient with Waterhouse-Friderichsen syndrome. (Reproduced with permission from C. Vincentelli et al, *Am J Emerg Med*. 27:751, 2009).

- As a *crisis* in individuals with chronic adrenocortical insufficiency precipitated by any form of stress that requires an immediate increase in steroid output from glands incapable of responding
- In patients maintained on exogenous corticosteroids, in whom *rapid withdrawal of steroids* or failure to increase steroid doses in response to an acute stress may precipitate an adrenal crisis, because of the inability of the atrophic adrenals to produce glucocorticoid hormones
- As a result of *massive adrenal hemorrhage*, which damages the adrenal cortex sufficiently to cause acute adrenocortical insufficiency—as occurs in newborns following prolonged and difficult delivery with considerable trauma and hypoxia. It also occurs in some patients maintained on anticoagulant therapy, in postsurgical patients who develop disseminated intravascular coagulation and consequent hemorrhagic infarction of the adrenals, and as a complication of disseminated bacterial infection; in this last setting, it is called *Waterhouse-Friderichsen syndrome*.

Waterhouse-Friderichsen Syndrome

This uncommon but catastrophic syndrome is characterized by the following:

- Overwhelming bacterial infection, classically *Neisseria meningitidis* septicemia but occasionally caused by other highly virulent organisms, such as *Pseudomonas* species, pneumococci, *Haemophilus influenzae*, or even staphylococci
- Rapidly progressive hypotension leading to shock
- Disseminated intravascular coagulation associated with widespread purpura, particularly of the skin (Fig. 24-47)

Figure 24-48 Waterhouse-Friderichsen syndrome. At autopsy, the adrenals were grossly hemorrhagic and shrunken; microscopically, little residual cortical architecture is discernible.

- Rapidly developing adrenocortical insufficiency associated with massive bilateral adrenal hemorrhage

Waterhouse-Friderichsen syndrome can occur at any age but is more common in children. The basis for the adrenal hemorrhage is uncertain but could be due to direct bacterial seeding of small vessels in the adrenal, the development of disseminated intravascular coagulation, or endothelial dysfunction caused by microbial products and inflammatory mediators. Whatever the basis, the adrenals are converted to sacs of clotted blood, which obscures virtually all of the underlying detail. Histologic examination reveals that the hemorrhage starts within the medulla near thin-walled venous sinusoids, then suffuses peripherally into the cortex, often leaving islands of recognizable cortical cells (Fig. 24-48). Prompt recognition and appropriate therapy must be instituted immediately, or death follows within hours to a few days.

Primary Chronic Adrenocortical Insufficiency (Addison Disease)

In an article published in 1855, Thomas Addison described a group of patients suffering from a constellation of symptoms, including “general languor and debility, remarkable feebleness of the heart’s action, and a peculiar change in the color of the skin” associated with disease of the “suprarenal capsules” or, in more modern parlance, the adrenal glands. Addison disease, or chronic adrenocortical insufficiency, is an uncommon disorder resulting from progressive destruction of the adrenal cortex. In general, clinical manifestations of adrenocortical insufficiency do not appear until at least 90% of the adrenal cortex has been compromised. The causes of chronic adrenocortical insufficiency are listed in Table 24-10. Although all races and both sexes may be affected, certain causes of Addison disease (e.g., autoimmune adrenalitis) are much more common in whites and in women.

Pathogenesis. A large number of diseases may affect the adrenal cortex, including lymphomas, amyloidosis,

sarcoidosis, hemochromatosis, fungal infections, and adrenal hemorrhage, but more than 90% of all cases are attributable to one of four disorders: autoimmune adrenalitis, tuberculosis, AIDS, or metastatic cancers.

- *Autoimmune adrenalitis* accounts for 60% to 70% of cases; it is by far the most common cause of primary adrenal insufficiency in developed countries. As the name implies, there is autoimmune destruction of steroidogenic cells. Autoantibodies to several key steroidogenic enzymes (21-hydroxylase, 17-hydroxylase) have been detected in these patients. Autoimmune adrenalitis can occur in one of two clinical settings:
 - *Autoimmune polyendocrine syndrome type 1 (APS1)*, also known as autoimmune polyendocrinopathy, candidiasis, and ectodermal dystrophy (APECED), is characterized by chronic mucocutaneous candidiasis and abnormalities of skin, dental enamel, and nails (ectodermal dystrophy) in association with a combination of organ-specific autoimmune disorders (autoimmune adrenalitis, autoimmune hypoparathyroidism, idiopathic hypogonadism, pernicious anemia) that result in immune destruction of target organs. APS1 is caused by mutations in the autoimmune regulator (*AIRE*) gene on chromosome 21q22. *AIRE* is expressed primarily in the thymus, where it functions as a transcription factor that promotes the expression of many peripheral tissue antigens. Self-reactive T cells that recognize these antigens are eliminated (Chapter 6). In the absence of *AIRE* function, central T-cell tolerance to peripheral tissue antigens is compromised, promoting autoimmunity. Individuals with APS1 develop autoantibodies against IL-17 and IL-22, which are the principal effector cytokines secreted by T_H17 T-cells (Chapter 6). Because these two T_H17 -derived cytokines are crucial for defense against fungal infections, it is not surprising that patients develop chronic mucocutaneous candidiasis.
 - *Autoimmune polyendocrine syndrome type 2 (APS2)* usually starts in early adulthood and presents as a combination of adrenal insufficiency and autoimmune thyroiditis or type 1 diabetes. Unlike in APS1, mucocutaneous candidiasis, ectodermal dysplasia, and autoimmune hypoparathyroidism do not develop.
- *Infections*, particularly tuberculosis and those produced by fungi, may also cause primary chronic adrenocortical insufficiency. *Tuberculous adrenalitis*, which once accounted for as much as 90% of cases of Addison disease, has become less common with the development of antituberculous agents. With the resurgence of tuberculosis in most urban centers and the persistence of the disease in developing countries, however, this cause of adrenal insufficiency must be kept in mind. When present, tuberculous adrenalitis is usually associated with active infection in other sites, particularly in the lungs and genitourinary tract. Among fungi, disseminated infections caused by *Histoplasma capsulatum* and *Coccidioides immitis* may result in chronic adrenocortical insufficiency. AIDS sufferers are at risk for developing adrenal insufficiency from several infectious (cytomegalovirus, *Mycobacterium*

avium-intracellulare) and noninfectious (Kaposi sarcoma) complications.

- **Metastatic neoplasms** involving the adrenals are another cause of adrenal insufficiency. The adrenals are a fairly common site for metastases in patients with disseminated carcinomas. Although adrenal function is preserved in most such patients, the metastatic tumors occasionally destroy enough adrenal cortex to produce a degree of adrenal insufficiency. Carcinomas of the lung and breast are the source of a majority of metastases, although many other neoplasms, including gastrointestinal carcinomas, malignant melanoma, and hematopoietic neoplasms, may also metastasize to the adrenals.
- **Genetic causes of adrenal insufficiency** include congenital adrenal hypoplasia (*adrenal hypoplasia congenita*) and *adrenoleukodystrophy*. Adrenoleukodystrophy is described in [Chapter 28](#). Congenital adrenal hypoplasia is a rare X-linked disease caused by mutations in a gene that encodes a transcription factor implicated in adrenal development.

MORPHOLOGY

The anatomic changes in the adrenal glands depend on the underlying disease. **Primary autoimmune adrenalitis** is characterized by irregularly shrunken glands, which may be difficult to identify within the suprarenal adipose tissue. Histologically the cortex contains only scattered residual cortical cells in a collapsed network of connective tissue. A variable lymphoid infiltrate is present in the cortex and may extend into the adjacent medulla, although the medulla is otherwise preserved ([Fig. 24-49](#)). In cases of **tuberculous and fungal disease** the adrenal architecture is effaced by a granulomatous inflammatory reaction identical to that encountered in other sites of infection. When hypoadrenalism is caused by **metastatic carcinoma**, the adrenals are enlarged and the normal architecture is obscured by the infiltrating neoplasm.

Clinical Course. Addison disease begins insidiously and does not come to attention until the levels of circulating glucocorticoids and mineralocorticoids are significantly decreased. The initial manifestations include *progressive weakness and easy fatigability*, which may be dismissed as nonspecific complaints. *Gastrointestinal* disturbances are

Figure 24-49 Autoimmune adrenalitis. In addition to loss of all but a subcapsular rim of cortical cells, there is an extensive mononuclear cell infiltrate.

common and include anorexia, nausea, vomiting, weight loss, and diarrhea. In individuals with primary adrenal disease, *hyperpigmentation* of the skin, particularly of sun-exposed areas and at pressure points, such as the neck, elbows, knees, and knuckles, is quite characteristic. This is caused by elevated levels of pro-opiomelanocortin (POMC), which is derived from the anterior pituitary and is a precursor of both ACTH and melanocyte stimulating hormone (MSH). By contrast, hyperpigmentation is not seen in persons with adrenocortical insufficiency caused by primary pituitary or hypothalamic disease. Decreased mineralocorticoid activity in persons with primary adrenal insufficiency results in potassium retention and sodium loss, with consequent *hyperkalemia*, *hyponatremia*, *volume depletion*, and *hypotension*. Hypoglycemia may occasionally occur as a result of glucocorticoid deficiency and impaired gluconeogenesis. Stresses such as infections, trauma, or surgical procedures in such patients can precipitate an acute adrenal crisis, manifested by intractable vomiting, abdominal pain, hypotension, coma, and vascular collapse. Death occurs rapidly unless corticosteroid therapy begins immediately.

KEY CONCEPTS

Adrenocortical Insufficiency (Hypoadrenalism)

- Primary adrenocortical insufficiency can be acute (Waterhouse-Friderichsen syndrome) or chronic (Addison disease)
- Chronic adrenal insufficiency in the developed world most often is secondary to *autoimmune adrenalitis*, which occurs in the context of one of two autoimmune polyendocrine syndromes: APS1 (caused by mutations in the *AIRE* gene) or APS2. APS1 is characterized by autoimmune attack against multiple endocrine organs and autoantibodies against IL-17.
- Tuberculosis and infections due to opportunistic pathogens associated with the human immunodeficiency virus and tumors metastatic to the adrenals are the other important causes of chronic hypoadrenalism.
- Patients typically present with fatigue, weakness, and gastrointestinal disturbances. Primary adrenocortical insufficiency also is characterized by high ACTH levels with associated skin pigmentation.

Secondary Adrenocortical Insufficiency

Any disorder of the hypothalamus and pituitary, such as metastatic cancer, infection, infarction, or irradiation, that reduces the output of ACTH leads to a syndrome of hypoadrenalism that has many similarities to Addison disease. Analogously, prolonged administration of exogenous glucocorticoids suppresses the output of ACTH and adrenal function. With secondary disease the hyperpigmentation of primary Addison disease is lacking, because levels of melanocyte-stimulating hormone are not elevated. The manifestations also differ in that secondary hypoadrenalism is characterized by deficient cortisol and androgen output but normal or near-normal aldosterone synthesis. Thus, in adrenal insufficiency secondary to pituitary malfunction, marked hyponatremia and hyperkalemia are not seen.

ACTH deficiency can occur alone, but in some instances, it is only one component of panhypopituitarism, associated with multiple trophic hormone deficiencies. Secondary disease can be differentiated from Addison disease by demonstration of low levels of plasma ACTH in the former. In patients with primary disease the destruction of the adrenal cortex reduces the response to exogenously administered ACTH, whereas in those with secondary hypofunction there is a prompt rise in plasma cortisol levels.

MORPHOLOGY

In cases of hypoadrenalism secondary to hypothalamic or pituitary disease (**secondary hypoadrenalism**), depending on the severity of ACTH deficiency, the adrenals may be moderately to markedly decreased in size. The small, flattened glands usually retain their yellow color as a result of a small amount of residual lipid. The cortex may be reduced to a thin ribbon composed largely of zona glomerulosa. The medulla is unaffected.

Adrenocortical Neoplasms

It should be evident from the preceding sections that functional adrenal neoplasms may be responsible for any of the various forms of hyperadrenalism. Adenomas and carcinomas are about equally common in adults; in children, carcinomas predominate. While most cortical neoplasms are sporadic, two familial cancer syndromes are associated with a predisposition for developing adrenocortical carcinomas: Li-Fraumeni syndrome, in patients who harbor germline *TP53* mutations (Chapter 7), and Beckwith-Wiedemann syndrome, a disorder of epigenetic imprinting (Chapter 10).

Functional adenomas are most commonly associated with hyperaldosteronism and Cushing syndrome, whereas a virilizing neoplasm is more likely to be a carcinoma. However, not all adrenocortical neoplasms elaborate steroid hormones. *Functional and nonfunctional adrenocortical neoplasms cannot be distinguished on the basis of morphologic features.* Determination of functionality is based on clinical evaluation, and measurement of hormones or hormone metabolites in the blood.

MORPHOLOGY

Most **adrenocortical adenomas** are clinically silent and are usually incidental findings at autopsy or during abdominal imaging for an unrelated cause (see the discussion of adrenal “incidentalomas” later). The typical cortical adenoma is a well-circumscribed, nodular lesion up to 2.5 cm in diameter that expands the adrenal (Fig. 24-50). In contrast to functional adenomas, which are associated with atrophy of the adjacent cortex, the cortex adjacent to nonfunctional adenomas is normal. On cut surface, adenomas are usually yellow to yellow-brown because of the presence of lipid.

Microscopically, adenomas are composed of cells similar to those populating the normal adrenal cortex. The nuclei tend to be small, although some degree of pleomorphism may be encountered even in benign lesions (“endocrine atypia”). The cytoplasm of the neoplastic cells ranges from eosinophilic to vacuolated, depending on their lipid content (Fig. 24-51). Mitotic activity is generally inconspicuous.

Figure 24-50 Adrenal cortical adenoma. The adenoma is distinguished from nodular hyperplasia by its solitary, circumscribed nature. The functional status of an adrenal cortical adenoma cannot be predicted from its gross or microscopic appearance.

Adrenocortical carcinomas are rare neoplasms that can occur at any age, including childhood. They are more likely to be functional than adenomas and are often associated with virilism or other clinical manifestations of hyperadrenalism. In most cases adrenocortical carcinomas are large, invasive lesions, many exceeding 20 cm in diameter, which efface the native adrenal gland (Fig. 24-52). The less common, smaller, and better-circumscribed lesions may be difficult to distinguish from an adenoma. On cut surface, adrenocortical carcinomas are typically variegated, poorly demarcated lesions containing areas of necrosis, hemorrhage, and cystic change. Adrenal cancers have a strong tendency to invade the adrenal vein, vena cava, and lymphatics. Metastases to regional and periaortic nodes are common, as is distant hematogenous spread to

Figure 24-51 Histologic features of an adrenal cortical adenoma. The neoplastic cells are vacuolated because of the presence of intracytoplasmic lipid. There is mild nuclear pleomorphism. Mitotic activity and necrosis are not seen.

Figure 24-52 Adrenal carcinoma. The hemorrhagic and necrotic tumor dwarfs the kidney and compresses the upper pole.

the lungs and other viscera. The median patient survival is about 2 years.

Microscopically, adrenocortical carcinomas may be composed of well-differentiated cells, resembling those seen in cortical adenomas, or bizarre, monstrous giant cells (Fig. 24-53), which may be difficult to distinguish from those of an undifferentiated carcinoma metastatic to the adrenal. Between these extremes are found cancers with moderate degrees of anaplasia, some composed predominantly of spindle cells. Carcinomas, particularly those of bronchogenic origin, may metastasize to the adrenals, and may be difficult to differentiate from primary cortical carcinomas. Of note, metastases to the adrenal cortex are significantly more common than primary adrenocortical carcinomas.

Other Adrenal Lesions

Adrenal cysts are relatively uncommon; however, with the use of sophisticated abdominal imaging techniques, the frequency of detection of these lesions is increasing. Larger cysts may produce an abdominal mass and flank pain. Both cortical and medullary neoplasms may undergo necrosis

and cystic degeneration and may present as “nonfunctional cysts.”

Adrenal myelolipomas are unusual benign lesions composed of mature fat and hematopoietic cells. Although most of these lesions represent incidental findings, occasional myelolipomas may reach massive proportions. Histologically, mature adipocytes are admixed with aggregates of hematopoietic cells belonging to all three lineages. Foci of myelolipomatous change may be seen in cortical tumors and in adrenals with cortical hyperplasia.

The term *adrenal incidentaloma* is a half-facetious moniker that has crept into the medical lexicon as advancements in medical imaging have led to the incidental discovery of adrenal masses in asymptomatic individuals or in individuals in whom the presenting complaint is not directly related to the adrenal gland. The estimated population prevalence of “incidentalomas” discovered by imaging is approximately 4%, with an age-dependent increase in prevalence. Fortunately, the vast majority of adrenal incidentalomas are small nonsecreting cortical adenomas of no clinical importance.

Adrenal Medulla

The adrenal medulla is developmentally, functionally, and structurally distinct from the adrenal cortex. It is composed of specialized neural crest (neuroendocrine) cells, termed *chromaffin* cells, and their supporting (sustentacular) cells. The adrenal medulla is the major source of catecholamines (epinephrine, norepinephrine) in the body. Neuroendocrine cells similar to chromaffin cells are widely dispersed in an extra-adrenal system of clusters and nodules that, together with the adrenal medulla, make up the *paraganglion system*. These extra-adrenal paraganglia are closely associated with the autonomic nervous system and can be divided into three groups based on their anatomic distribution: (1) branchiomeric, (2) intravagal, and (3) aortic sympathetic. The branchiomeric and intravagal paraganglia associated with the parasympathetic system are located close to the major arteries and cranial nerves of the head and neck and include the carotid bodies (Chapter 16). The intravagal

paraganglia, as the term implies, are distributed along the vagus nerve. The aorticosympathetic chain is found in association with segmental ganglia of the sympathetic system and therefore is distributed mainly alongside of the abdominal aorta. The organs of Zuckerkandl, close to the aortic bifurcation, belong to this group.

The most important diseases of the adrenal medulla are neoplasms, which include neoplasms of chromaffin cells (*pheochromocytomas*) and neuronal neoplasms (*neuroblastic tumors*). Neuroblastomas and other neuroblastic tumors are discussed in [Chapter 10](#).

Pheochromocytoma

Pheochromocytomas are neoplasms composed of chromaffin cells, which synthesize and release catecholamines and in some instances peptide hormones. It is important to recognize these tumors because they are a rare cause of surgically correctable hypertension. Traditionally, the features of pheochromocytomas have been summarized by the “rule of 10s”.

- *Ten percent of pheochromocytomas are extra-adrenal, occurring in sites such as the organs of Zuckerkandl and the carotid body. Pheochromocytomas that develop in extra-adrenal paraganglia are designated paragangliomas and are discussed in Chapter 16.*
- *Ten percent of sporadic adrenal pheochromocytomas are bilateral; this figure may rise to as high as 50% in cases that are associated with familial tumor syndromes (see later).*
- *Ten percent of adrenal pheochromocytomas are biologically malignant, defined by the presence of metastatic disease. Malignancy is more common (20% to 40%) in extra-adrenal paragangliomas, and in tumors arising in the setting of certain germline mutations (see later).*
- *Ten percent of adrenal pheochromocytomas are not associated with hypertension. Of the 90% that present with hypertension, approximately two thirds have “paroxysmal” episodes associated with sudden rise in blood pressure and palpitations, which can, on occasion, be fatal.*

One “traditional” 10% rule that has now been modified pertains to familial cases. It is now recognized that *as many as 25% of individuals with pheochromocytomas and paragangliomas harbor a germline mutation in one one of at least six known genes (Table 24-11)*. Patients with germline mutations are typically younger at presentation than those with sporadic tumors and more often harbor bilateral disease. The affected genes fall into two broad classes, those that enhance growth factor receptor pathway signaling (e.g., *RET*, *NF1*), and those that increase the activity of the transcription factor HIF-1 α . You will recall that the VHL gene encodes a tumor suppressor protein that is needed for the oxygen-dependent degradation of HIF-1 α and is mutated in patients with von Hippel-Lindau (VHL) syndrome, which is associated with a number of tumors, including pheochromocytoma. Other familial cases of pheochromocytoma are associated with germline mutations in genes encoding components of the succinate dehydrogenase complex (*SDHB*, *SDHC*, and *SDHD*). This complex is involved in mitochondrial electron transport and oxygen sensing, and it is believed that these mutations also lead to upregulation of HIF-1 α , which appears to be a key oncogenic driver in this type of tumor.

MORPHOLOGY

Pheochromocytomas range from small, circumscribed lesions confined to the adrenal ([Fig. 24-54](#)) to large hemorrhagic masses weighing kilograms. The average weight of a pheochromocytoma is 100 gm, but weights from just over 1 gm to almost 4000 gm have been reported. The larger tumors are well demarcated by either connective tissue or compressed cortical or medullary tissue. Richly vascularized fibrous trabeculae within the tumor produce a lobular pattern. In many tumors, remnants of the adrenal gland can be seen, stretched over the surface or attached at one pole. On section, the cut surfaces of smaller pheochromocytomas are yellow-tan. Larger lesions tend to be hemorrhagic, necrotic, and cystic and typically efface the adrenal gland. Incubation of fresh tissue with a potassium dichromate solution turns the tumor a dark brown color

Figure 24-54 Pheochromocytoma. The tumor is enclosed within an attenuated cortex and demonstrates areas of hemorrhage. The comma-shaped residual adrenal is seen below. (Courtesy Dr. Jerrold R. Turner, Department of Pathology, University of Chicago Hospitals, Chicago, Ill.)

due to oxidation of stored catecholamines, thus the term **chromaffin**.

The histologic pattern in pheochromocytoma is quite variable. The tumors are composed of clusters of polygonal to spindle-shaped chromaffin cells or chief cells that are surrounded by supporting sustentacular cells, creating small nests or alveoli (**zellballen**) that are supplied by a rich vascular network (Fig. 24-55). Uncommonly, the dominant cell type is a spindle or small cell; various patterns can be found in any one tumor. The cytoplasm has a finely granular appearance, best demonstrated with silver stains, due to the presence of granules containing catecholamines. The nuclei are usually round to ovoid, with a stippled “salt and pepper” chromatin that is characteristic of

Figure 24-55 Pheochromocytoma demonstrating characteristic nests of cells (“zellballen”) with abundant cytoplasm. Granules containing catecholamine are not visible in this preparation. It is not uncommon to find bizarre cells even in pheochromocytomas that are biologically benign. (Courtesy Dr. Jerrold R. Turner, Department of Pathology, University of Chicago Hospitals, Chicago, Ill.)

Figure 24-56 Electron micrograph of pheochromocytoma. This tumor contains membrane-bound secretory granules in which catecholamines are stored (30,000 \times).

neuroendocrine tumors. Electron microscopy reveals variable numbers of membrane-bound, electron-dense secretory granules (Fig. 24-56). Immunoreactivity for neuroendocrine markers (chromogranin and synaptophysin) is seen in the chief cells, while the peripheral sustentacular cells stain with antibodies against S-100, a calcium-binding protein expressed by a variety of mesenchymal cell types.

Determining malignancy in pheochromocytomas can be vexing. **There is no histologic feature that reliably predicts clinical behavior.** Several histologic features, such as numbers of mitoses, confluent tumor necrosis, and spindle cell morphology, have been associated with an aggressive behavior and increased risk of metastasis, but are not entirely reliable. Tumors with “benign” histologic features may metastasize, while bizarrely pleomorphic tumors may remain confined to the adrenal gland. In fact, cellular and nuclear pleomorphism, including the presence of giant cells, and mitotic figures are often seen in benign pheochromocytomas, while cellular monotony is paradoxically associated with an aggressive behavior. Even capsular and vascular invasion may be encountered in benign lesions. **Therefore, the definitive diagnosis of malignancy in pheochromocytomas is based exclusively on the presence of metastases.** These may involve regional lymph nodes as well as more distant sites, including liver, lung, and bone.

Clinical Course. The dominant clinical manifestation of pheochromocytoma is *hypertension*, observed in 90% of patients. Approximately two thirds of patients with hypertension demonstrate *paroxysmal episodes*, which are described as an abrupt, precipitous elevation in blood pressure, associated with tachycardia, palpitations, headache, sweating, tremor, and a sense of apprehension. These episodes may also be associated with pain in the abdomen or chest, nausea, and vomiting. *Isolated* paroxysmal episodes of hypertension occur in fewer than half of patients; more commonly, patients demonstrate chronic, sustained elevation in blood pressure punctuated by the aforementioned paroxysms. The paroxysms may be precipitated by emotional stress, exercise, changes in posture, and palpation in the region of the tumor; patients with urinary bladder paragangliomas occasionally precipitate a

paroxysm during micturition. The elevations of blood pressure are induced by the sudden release of catecholamines that may acutely precipitate congestive heart failure, pulmonary edema, myocardial infarction, ventricular fibrillation, and cerebrovascular accidents.

The cardiac complications have been attributed to what has been called *catecholamine cardiomyopathy*, or catecholamine-induced myocardial instability and ventricular arrhythmias. Nonspecific myocardial changes, such as focal necrosis, mononuclear infiltrates, and interstitial fibrosis, have been attributed either to ischemic damage secondary to catecholamine-induced constriction of myocardial blood vessels or to direct catecholamine toxicity. In

some cases pheochromocytomas secrete other hormones, such as ACTH and somatostatin, and may therefore be associated with clinical features related to the secretion of these or other peptide hormones. The laboratory diagnosis of pheochromocytoma is based on the demonstration of increased urinary excretion of free catecholamines and their metabolites, such as vanillylmandelic acid and metanephrines.

Isolated benign tumors are treated with surgical excision, after preoperative and intraoperative medication of patients with adrenergic-blocking agents to prevent a hypertensive crisis. Multifocal lesions require long-term medical treatment for hypertension.

MULTIPLE ENDOCRINE NEOPLASIA SYNDROMES

The MEN syndromes are a group of inherited diseases resulting in proliferative lesions (hyperplasia, adenomas, and carcinomas) of multiple endocrine organs. Like other inherited cancer disorders (Chapter 7), endocrine tumors arising in the context of MEN syndromes have certain distinct features that contrast with their sporadic counterparts.

- Tumors occur at a younger age than sporadic tumors.
- They arise in multiple endocrine organs, either synchronously (at the same time) or metachronously (at different times).
- Even in one organ, the tumors are often multifocal.
- The tumors are usually preceded by an asymptomatic stage of hyperplasia involving the cell of origin. For example, individuals with MEN-2 almost universally demonstrate C-cell hyperplasia in the thyroid parenchyma adjacent to medullary thyroid carcinomas.
- These tumors are usually more aggressive and recur in a higher proportion of cases than do similar sporadic endocrine tumors.

Multiple Endocrine Neoplasia, Type I

MEN-1, or *Wermer syndrome*, is a rare heritable disorder with a prevalence of about 2 per 100,000. MEN-1 is characterized by abnormalities involving the parathyroid, pancreas, and pituitary glands; thus the mnemonic device, the 3Ps:

- **Parathyroid:** Primary hyperparathyroidism is the most common manifestation of MEN-1 (80% to 95% of patients) and is the initial manifestation of the disorder in most patients, appearing in almost all patients by age 40 to 50. Parathyroid abnormalities include both hyperplasia and adenomas.
- **Pancreas:** Endocrine tumors of the pancreas are a leading cause of morbidity and mortality in persons with MEN-1. These tumors are usually aggressive and often present with metastatic disease. It is not uncommon to find multiple “microadenomas” scattered throughout the pancreas in conjunction with one or two dominant lesions. MEN-1-associated pancreatic endocrine tumors are often functional; however, because pancreatic polypeptide is the most commonly secreted product, many

tumors fail to produce an endocrine hypersecretion syndrome. Among those that do, Zollinger-Ellison syndrome (associated with gastrinomas) and hypoglycemia and neurologic manifestations (associated with insulinomas) are most common.

- **Pituitary:** The most frequent anterior pituitary tumor encountered in MEN-1 is a prolactinoma; some patients develop acromegaly from somatotrophin-secreting tumors.
- It is now recognized that the spectrum of this disease extends beyond the 3Ps. The duodenum is the most common site of gastrinomas in individuals with MEN-1 (far in excess of the frequency of pancreatic gastrinomas), and synchronous duodenal and pancreatic tumors may be present in the same individual. In addition, carcinoid tumors, thyroid and adrenocortical adenomas, and lipomas are more frequent than in the general population.

MEN-1 syndrome is caused by germline mutations in the *MEN1* tumor suppressor gene, which encodes a protein called **menin**. Menin is a component of several different transcription factor complexes, which (depending on the specific binding partner) may either promote or inhibit tumorigenesis. This dichotomy in menin function is best exemplified in the interactions of menin with two oncogenic transcription factors—JunD and the mixed-lineage leukemia (MLL) protein. When menin partners with JunD, it blocks transcriptional activation by JunD; in fact, loss of this tumor suppressor interaction is believed to contribute to the multiple endocrine neoplasia observed in the setting of MEN1 inactivating mutations. On the contrary, the association of wild-type menin with MLL leads to the formation of a tumor promoting transcriptional complex in a subset of leukemias (Chapter 13).

The dominant clinical manifestations of MEN-1 usually result from the peptide hormones that are overproduced and include such abnormalities as recurrent hypoglycemia due to insulinomas, intractable peptic ulcers in persons with Zollinger-Ellison syndrome, nephrolithiasis caused by PTH-induced hypercalcemia, or symptoms of prolactin excess from a pituitary tumor. As expected, malignant behavior by one or more of the endocrine tumors arising in these patients is often the proximate cause of death.

Multiple Endocrine Neoplasia, Type 2

MEN-2 is subclassified into three distinct syndromes: MEN-2A, MEN-2B, and familial medullary thyroid cancer.

- *MEN-2A*, or *Sipple syndrome*, is characterized by *pheochromocytoma*, *medullary carcinoma of the thyroid*, and *parathyroid hyperplasia* (Table 24-11). Medullary carcinomas of the thyroid occur in almost 100% of patients. They are usually multifocal and are virtually always associated with foci of C-cell hyperplasia in the adjacent thyroid. The medullary carcinomas may elaborate calcitonin and other active products and are usually clinically aggressive. Among individuals with MEN-2A, 40% to 50% have pheochromocytomas, which are often bilateral and may arise in extra-adrenal sites. Parathyroid hyperplasia and evidence of hypercalcemia or renal stones occur in 10% to 20% of patients. **MEN-2A is clinically and genetically distinct from MEN-1 and is caused by germline gain-of-function mutations in the RET proto-oncogene on chromosome 10q11.2.** As was noted earlier, the *RET* proto-oncogene encodes a receptor tyrosine kinase that binds *glial-derived neurotrophic factor* (GDNF) and other ligands in the GDNF family and transmits growth and differentiation signals (Chapter 7). *Loss-of-function* mutations in *RET* result in intestinal aganglionosis and Hirschsprung disease (Chapter 17). In contrast, in MEN-2A (as well as in MEN-2B), germline mutations constitutively activate the *RET* receptor.
- *MEN-2B* has significant clinical overlap with MEN-2A. Patients develop medullary thyroid carcinomas, which are usually multifocal and more aggressive than in MEN-2A, and pheochromocytomas. However, unlike in MEN-2A, primary hyperparathyroidism is not present.

In addition, MEN-2B is accompanied by *neuromas* or *ganglioneuromas* involving the skin, oral mucosa, eyes, respiratory tract, and gastrointestinal tract, and a *marfanoid habitus*, with long axial skeletal features and hyperextensible joints (Table 24-11). A germline mutation leading to a single amino acid change in *RET*, distinct from the mutations that are seen in MEN-2A, seems to be responsible for virtually all cases of MEN-2B. This point substitution affects a critical region of the tyrosine kinase domain of the protein and leads to constitutive activation of *RET* in the absence of ligand. Of note, approximately a third of sporadic medullary thyroid carcinomas harbor the identical mutation, and these cases are associated with aggressive disease and an adverse prognosis.

- *Familial medullary thyroid cancer* is a variant of MEN-2A, in which there is a strong predisposition to medullary thyroid cancer but not the other clinical manifestations of MEN-2A or MEN-2B. A substantial majority of cases of medullary thyroid cancer are sporadic, but as many as 20% may be familial. Familial medullary thyroid cancers develop at an older age than those occurring in the full-blown MEN-2 syndrome and follow a more indolent course.

In contrast to MEN-1, in which the long-term benefit of early diagnosis by genetic screening is not well established, diagnosis via screening of at-risk family members in MEN-2A kindred is important because medullary thyroid carcinoma is a life-threatening disease that can be prevented by early thyroidectomy. Now, routine genetic testing identifies *RET* mutation carriers earlier and more reliably in MEN-2 kindreds; all individuals carrying germline *RET* mutations are advised to undergo prophylactic thyroidectomy to prevent the inevitable development of medullary carcinomas.

PINEAL GLAND

The rarity of clinically significant lesions (virtually only tumors) justifies brevity in the consideration of the pineal gland. It is a minute, pinecone-shaped organ (hence its name), weighing 100 to 180 mg and lying between the superior colliculi at the base of the brain. It is composed of a loose, neuroglial stroma enclosing nests of epithelial-appearing *pineocytes*, cells with photosensory and neuroendocrine functions (hence the designation of the pineal gland as the “third eye”). Silver impregnation stains reveal that these cells have long, slender processes reminiscent of primitive neuronal precursors intermixed with the processes of astrocytic cells. The principal secretory product of the pineal gland is melatonin, which is involved in the control of circadian rhythms, including the sleep-wake cycle; hence the popular use of melatonin for the treatment of jet lag.

All tumors involving the pineal are rare; most (50% to 70%) arise from sequestered embryonic germ cells (Chapter 28). They most commonly take the form of so-called *germinomas*, resembling testicular seminoma (Chapter 21) or ovarian dysgerminoma (Chapter 22). Other lines of germ cell differentiation include embryonal carcinomas;

choriocarcinomas; mixtures of germinoma, embryonal carcinoma, and choriocarcinoma; and, uncommonly, typical teratomas (usually benign). Whether to characterize these germ cell neoplasms as pinealomas is debated, but most “pinealophiles” favor restricting the term *pinealoma* to neoplasms arising from the pineocytes.

Pinealomas

These neoplasms are divided into two categories, pineoblastomas and pineocytomas, based on their level of differentiation, which, in turn, correlates with their aggressiveness. These tumors are rare, and are described in specialized texts.

The Skin: More Than a Mechanical Barrier

More than a century and a half ago, the noted pathologist Rudolph Virchow described the skin as a mere protective covering for more delicate and functionally sophisticated internal viscera. Then, and for most of the time that followed, the skin was viewed as a necessary but rather uninteresting barrier to fluid loss and mechanical injury. Over the last several decades, however, the skin has come to be appreciated as a surprisingly complicated organ—the largest in the body—in which precisely regulated cellular and molecular interactions govern many essential processes.

Although the human integument may appear drab compared with the skin and pelage of other members of the animal kingdom, it is extraordinarily vibrant with regard to the diversity of functions that it carries out. Chief among these is its role as one of the first lines of defense against

potentially harmful infectious and physical agents. However, the skin is also a highly sophisticated sensory organ, and even has important endocrine roles, particularly the synthesis of vitamin D (Chapter 9), which is “powered” by sun exposure. It is composed of several cell types and structures that function interdependently and cooperatively (Fig. 25-1).

- *Squamous epithelial cells (keratinocytes)* are normally “glued” tightly together by cell junctions known as desmosomes and produce abundant amounts of keratin protein, both of which serve to create a tough, durable physical barrier. In addition, keratinocytes secrete soluble molecules such as cytokines and defensins that augment and regulate cutaneous immune responses (described later).
- *Melanocytes* within the epidermis are responsible for the production of melanin, a brown pigment that absorbs and protects against potentially injurious ultraviolet (UV) radiation in sunlight.

Figure 25-1 *Left*, The skin is composed of an epidermal layer (e) from which specialized adnexa (hair follicles, h; sweat glands, g; and sebaceous glands, s) descend into the underlying dermis (d). *Inset*, This projection of the epidermal layer (e) and underlying superficial dermis demonstrates the progressive upward maturation of basal cells (b) into cornified squamous epithelial cells of the stratum corneum (sc). Melanin-containing dendritic melanocytes (m) (and rare Merkel cells containing neurosecretory granules) and mid-epidermal dendritic Langerhans cells (lc) are also present. The underlying dermis contains small vessels (v), fibroblasts (f), perivascular mast cells (mc), and dendrocytes (dc), which participate in dermal immune responses and repair.

- **Dendritic cells.** Skin serves as one of the first lines of defense against microorganisms and is constantly exposed to microbial and nonmicrobial antigens, which are processed by intraepidermal dendritic cells known as *Langerhans cells*. Langerhans cells secrete factors that augment innate immune responses, and migrate from the skin to regional lymph nodes where they present their antigenic cargoes to T lymphocytes, thereby stimulating the adaptive immune system. Specialized *dendrocytes*, another type of dendritic cell found within the dermis, perform similar functions.
- **Lymphocytes.** Following their stimulation by dendritic cells in regional lymph nodes, T cells expressing an adhesion molecule called cutaneous lymphocyte-associated antigen (CLA) and chemokine receptors such as CCR4 and CCR10 leave the lymph node and home back to the dermis, a process that is directed in part by chemokines secreted by activated keratinocytes. The infiltrating T cells usually include helper (CD4+), cytotoxic (CD8+), and regulatory (Treg) T cells (Chapter 6). Cytokines produced by these T cells mediate the microscopic patterns and clinical expressions of cutaneous inflammatory and infectious diseases. In addition, small numbers of B cells are found in the dermis that can participate in humoral responses to antigens encountered in the skin.
- Like the gut (Chapter 17), there is increasing appreciation that the skin is a large and complex ecosystem that

provides niches for a broad spectrum of organisms, including bacteria, fungi, viruses, and mites. These organisms have evolved symbiotic relationships with their human hosts and appear to contribute to health in a number of ways. By occupying skin niches, the normal “zoo” of skin organisms prevents colonization of the skin by other potentially harmful organisms. In addition, the skin fauna primes and “educates” the cutaneous immune system in a manner that is believed to enhance immune responses to potential pathogens. This story is just in its infancy, and it is likely that the role of the skin microbiome in health and disease will continue to expand in the coming years.

- **Afferent nerve fibers** and a diverse set of associated specialized structures referred to as *neural end organs* are responsible for physical sensations that run that gamut from pleasurable to painful, including touch, vibration, itchiness, cold, and heat. In addition, *autonomic efferent nerve fibers* regulate adnexal components such as sweat glands and effector pili muscles (see later) and can also influence the function of innate and adaptive immune cells in the dermis. Another cell type found in skin that remains cloaked in mystery is the *Merkel cell*; these cells are located in epithelial basal cell layer and may have neuroendocrine or mechanoreceptor functions.
- **Adnexal components.** *Sweat glands* guard against deleterious variations in body temperature, and *hair follicles*, in addition to manufacturing hair shafts, have protected

Table 25-1 Nomenclature of Skin Lesions

Macroscopic Lesions	Definition
Excoriation	Traumatic lesion breaking the epidermis and causing a raw linear area (i.e., deep scratch); often self-induced
Lichenification	Thickened, rough skin (similar to a lichen on a rock); usually the result of repeated rubbing
Macule, Patch	Circumscribed, flat lesion distinguished from surrounding skin by color. Macules are 5 mm in diameter or less, patches are greater than 5 mm.
Onycholysis	Separation of nail plate from nail bed
Papule, Nodule	Elevated dome-shaped or flat-topped lesion. Papules are 5 mm or less across, while nodules are greater than 5 mm in size.
Plaque	Elevated flat-topped lesion, usually greater than 5 mm across (may be caused by coalescent papules)
Pustule	Discrete, pus-filled, raised lesion
Scale	Dry, horny, platelike excrescence; usually the result of imperfect cornification
Vesicle, Bulla, Blister	Fluid-filled raised lesion 5 mm or less across (vesicle) or greater than 5 mm across (bulla). Blister is the common term for either.
Wheal	Itchy, transient, elevated lesion with variable blanching and erythema formed as the result of dermal edema
Microscopic Lesions	Definition
Acanthosis	Diffuse epidermal hyperplasia
Dyskeratosis	Abnormal, premature keratinization within cells below the stratum granulosum
Erosion	Discontinuity of the skin showing incomplete loss of the epidermis
Exocytosis	Infiltration of the epidermis by inflammatory cells
Hydropic swelling (ballooning)	Intracellular edema of keratinocytes, often seen in viral infections
Hypergranulosis	Hyperplasia of the stratum granulosum, often due to intense rubbing
Hyperkeratosis	Thickening of the stratum corneum, often associated with a qualitative abnormality of the keratin
Lentiginous	A linear pattern of melanocyte proliferation within the epidermal basal cell layer
Papillomatosis	Surface elevation caused by hyperplasia and enlargement of contiguous dermal papillae
Parakeratosis	Keratinization with retained nuclei in the stratum corneum. On mucous membranes, parakeratosis is normal.
Spongiosis	Intercellular edema of the epidermis
Ulceration	Discontinuity of the skin showing complete loss of the epidermis revealing dermis or subcutis
Vacuolization	Formation of vacuoles within or adjacent to cells; often refers to basal cell-basement membrane zone area

niches harboring epithelial stem cells capable of regenerating superficial epithelial skin structures, which may be disrupted by trauma, burns, and other types of injuries.

Imbalances in factors affecting the delicate homeostasis that exists among skin cells may result in conditions as diverse as wrinkles and hair loss, blisters and rashes, and life-threatening cancers and disorders of immune regulation. For example, long-term exposure to sunlight fosters premature cutaneous aging, blunts immunologic responses to environmental antigens, and favors the development of a variety of premalignant and malignant cutaneous neoplasms. Ingested agents, such as therapeutic drugs, can cause an enormous number of rashes or exanthems. Systemic disorders, such as diabetes mellitus, amyloidosis, and lupus erythematosus, may also have important manifestations in the skin.

Skin conditions are very common, affecting about one third of the United States population each year. Since skin is uniquely accessible to visual examination, for the experienced observer it can yield numerous insights into the functional state of the body (if not the very soul of a patient). Close attention to the appearance and distribution of skin lesions is critical, as these characteristics are essential in formulating diagnoses and in understanding pathogenesis. To underscore this point, special emphasis is placed on the gross appearance of skin lesions under each specific entity.

Thousands of diseases affect the skin. Only those that are common or that illustrate important pathologic mechanisms are described here. Dermatologists and dermatopathologists have developed a set of terms to describe the gross and microscopic appearance of skin lesions that every student must be familiar with in order to be fluent in dermatopathology; the most important of these terms and definitions are given in [Table 25-1](#).

Disorders of Pigmentation and Melanocytes

Focal or widespread loss of normal protective pigmentation can make individuals extraordinarily vulnerable to the harmful effects of sunlight (as in albinism). Changes in preexisting skin pigmentation may signify important primary skin disorders (e.g., malignant transformation of a mole) or point to the existence of an underlying systemic disorder (e.g., Addison disease, [Chapter 24](#)).

Freckle (Ephelis)

Freckles are the most common pigmented lesions of childhood in lightly pigmented individuals. It is unclear whether freckles result from a focal abnormality in pigment production in a discrete field of melanocytes, enhanced melanin transfer to adjacent basal keratinocytes, or some

Table 25-2 Representative Variant Forms of Melanocytic Nevi

Nevus Variant	Diagnostic Architectural Features	Cytologic Features	Clinical Significance
Congenital nevus	Deep dermal and sometimes subcutaneous growth around adnexa, neurovascular bundles, and blood vessel walls	Identical to ordinary acquired nevi	Present at birth; large variants have increased melanoma risk
Blue nevus	Non-nested dermal infiltration, often with associated fibrosis	Highly dendritic, heavily pigmented nevus cells	Black-blue nodule; often confused with melanoma clinically
Spindle and epithelioid cell nevus (Spitz nevus)	Fascicular growth	Large, plump cells with pink-blue cytoplasm; fusiform cells	Common in children; red-pink nodule; often confused with hemangioma clinically
Halo nevus	Lymphocytic infiltration surrounding nevus cells	Identical to ordinary acquired nevi	Host immune response against nevus cells and surrounding normal melanocytes
Dysplastic nevus	Coalescent intraepidermal nests	Cytologic atypia	Potential marker or precursor of melanoma

combination thereof. The *café au lait* spots seen in neurofibromatosis (Chapter 27) are similar to freckles histologically, but differ in that they are larger, arise independently of sun exposure, and contain aggregated melanosomes (macromelanosomes), which can be seen within the cytoplasm of melanocytes in electron micrographs.

MORPHOLOGY

Freckles are generally small (1 to several mm in diameter), tan-red or light brown macules that appear after sun exposure. Once present, freckles fade and darken in a cyclic fashion during winter and summer, respectively. This is not because of changes in the number of melanocytes, but in the degree of pigmentation. Hyperpigmentation of freckles results from increased amounts of melanin pigment within basal keratinocytes. Associated melanocytes may be slightly enlarged but are normal in density.

Lentigo

The term lentigo (plural, lentiginos) refers to a common benign localized hyperplasia of melanocytes occurring at all ages, but often initiated in infancy and childhood. There is no sex or racial predilection, and the cause and pathogenesis are unknown.

MORPHOLOGY

Lentiginos may involve mucous membranes as well as the skin and consist of small (5 to 10 mm across), oval, tan-brown macules or patches. Unlike freckles, lentiginos do not darken when exposed to sunlight. The essential histologic feature is **linear (nonnested) melanocytic hyperplasia** restricted to the cell layer immediately above the basement membrane that produces a hyperpigmented basal cell layer. So characteristic is this pattern that the term *lentiginous* is used to describe similar cellular proliferations within the basal cell layer in melanocytic tumors, such as in lentiginous nevi and in certain melanomas (termed *acral lentiginous melanomas*). Elongation and thinning of the rete ridges are also commonly seen in a lentigo.

Melanocytic Nevus (Pigmented Nevus, Mole)

Melanocytic nevi (known colloquially as moles) are common benign neoplasms caused in most cases by

acquired activating mutations in components of the Ras signaling pathway. Most of us have at least a few “moles” and probably regard them as mundane and uninteresting. However, in truth moles (or melanocytic nevi) are diverse, dynamic, and biologically fascinating neoplasms. There are numerous subtypes of melanocytic nevi that are distinguished based on their clinical and histologic features; Table 25-2 provides a summary of salient features of some commonly encountered forms. Acquired melanocytic nevi are the most common type and are found in virtually all individuals.

Pathogenesis. Proof that nevi are neoplasms comes from studies showing that many have acquired mutations that lead to constitutive activation of NRAS or the serine/threonine kinase BRAF, which lies immediately downstream of RAS (described in Chapter 7 and later under Melanoma). Given that RAS signals have potent transforming activity and are thought to have key roles in many full-blown cancers, it is reasonable to ask why nevi only rarely give rise to melanomas. One answer appears to lie in the phenomenon referred to as oncogene-induced senescence. Expression of either activated RAS or BRAF in normal human melanocytes causes only a limited period of proliferation that is followed by a permanent growth arrest mediated by the accumulation of p16/INK4a, a potent inhibitor of several cyclin-dependent kinases, including CDK4 and CDK6 (Chapter 7). This protective response is disrupted in melanoma and some precursor lesions that give rise to melanoma.

MORPHOLOGY

Common acquired melanocytic nevi are tan to brown, uniformly pigmented, small (usually less than 6 mm across), relatively flat macules or elevated papules with well-defined, rounded borders (Figs. 25-2A and 25-3A). They may become more prominent during pregnancy, indicating a degree of hormone sensitivity. Melanocytic nevi are thought to progress through a series of morphologic changes over time. The earliest lesions are believed to be **junctional nevi**, which consist of aggregates or nests of round cells that grow along the dermoepidermal junction (Fig. 25-2B). Nuclei of nevus cells are uniform and rounded in contour, contain inconspicuous nucleoli, and show little or no mitotic activity. Eventually, most junctional nevi grow into the underlying dermis as nests or cords of cells to form **compound nevi** (Fig. 25-3B). In older lesions the epidermal nests may be lost entirely to form pure **intradermal nevi**.

Figure 25-2 Melanocytic nevus, junctional type. **A**, Grossly, lesions are small, relatively flat, symmetric, and uniform. **B**, On histologic examination, junctional nevi are characterized by rounded nests of nevus cells originating at the tips of rete ridges along the dermoepidermal junction.

Figure 25-3 Melanocytic nevus, compound type. In contrast to the junctional nevus, the compound nevus (**A**) is raised and dome-shaped. The symmetry and uniform pigment distribution suggest a benign process. Histologically (**B**), compound nevi combine the features of junctional nevi (intraepidermal nevus cell nests) with nests and cords of dermal nevus cells.

Clinically, compound and dermal nevi are often more elevated than junctional nevi.

Progressive growth of nevus cells from the dermoepidermal junction into the underlying dermis is accompanied by morphologic changes that are taken to be a reflection of oncogene-induced senescence (Fig. 25-4). Whereas superficial nevus cells are larger, tend to produce melanin, and grow in nests, deeper nevus cells are smaller, produce little or no pigment, and appear as cords and single cells. At the deepest extent of the lesions, these cells often acquire fusiform contours and grow in fascicles resembling neural tissue (neurotization; Fig. 25-4E). This striking metamorphosis correlates with enzymatic changes (progressive loss of tyrosinase activity and acquisition of cholinesterase activity) in deeper, nonpigmented “nervelike” nevus cells. **These changes are helpful in distinguishing benign nevi from melanomas, which lack such features.**

Although melanocytic nevi are common, their clinical and histologic diversity necessitates thorough knowledge of their appearance and natural evolution, lest they be confused with other skin conditions, most notably melanoma. The biologic importance of some nevi, however, resides in their possible transformation to melanoma or as markers of increased risk for melanoma (as described below).

Dysplastic Nevi

Dysplastic nevi are important because they may be direct precursors of melanoma and when multiple in number are a marker of an increased risk for melanoma. The association of melanocytic nevi with melanoma was

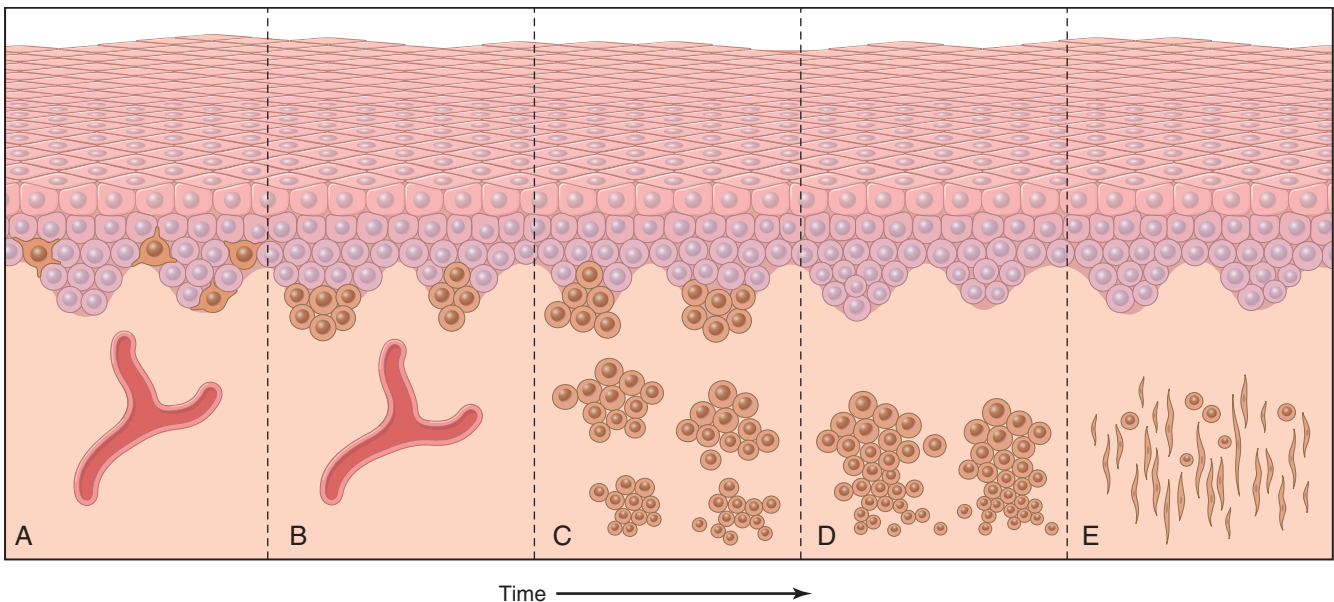

Figure 25-4 Maturation sequence of nondysplastic melanocytic nevi. **A**, Normal skin shows only scattered dendritic melanocytes within the epidermal basal cell layer. **B**, Junctional nevus. **C**, Compound nevus. **D**, Dermal nevus. **E**, Dermal nevus with neurotization, a change that is also referred to as maturation. Nevi may exist at any stage in this sequence for variable periods of time, although many are believed to progress through this sequence.

made almost 200 years ago, but a potential precursor of melanoma was not identified until 1978 when Clark and colleagues described the lesions that are now referred to as *dysplastic nevi*. Several lines of evidence support the concept that some dysplastic nevi are precursors of melanoma. One of the most compelling pieces of evidence involves studies of families affected by *dysplastic nevus syndrome*, an autosomal dominant disorder in which a tendency to develop multiple dysplastic nevi and melanoma are co-inherited. The probability that a person with dysplastic nevus syndrome will develop melanoma is over 50% by age 60, and at-risk individuals sometimes develop several melanomas at multiple sites. Even more directly, apparent transformation of dysplastic nevi to melanoma has been documented histologically.

Although dysplastic nevi can give rise to melanoma, the vast majority of such lesions are clinically stable and never progress. Conversely, not all melanomas in individuals with dysplastic nevus syndrome arise from dysplastic nevi, suggesting that these lesions may be best viewed as indicators of increased melanoma risk. Indeed, melanoma may arise in individuals completely lacking in dysplastic nevi. Dysplastic nevi may also occur as isolated lesions in otherwise normal individuals, in which case the risk of malignant transformation is very low.

Pathogenesis. Clark and associates have proposed stages in the development of dysplastic nevi and their eventual progression to melanoma (Fig. 25-5), presumably through stepwise acquisition of mutations or epigenetic changes. Indeed, like conventional nevi, dysplastic nevi also fre-

quently have acquired activating mutations in the *NRAS* and *BRAF* genes. What then distinguishes dysplastic nevi from typical melanocytic nevi? An important clue comes from individuals with dysplastic nevus syndrome. Such individuals often have inherited loss of function mutations in *CDKN2A*. As discussed further under melanoma, *CDKN2A* encodes several proteins including p16/INK4a (described in more detail under melanoma), which you will recall is a negative regulator of cyclin-dependent kinase 4 (CDK4) and cyclin-dependent kinase 6. Other affected families have mutations in *CDK4* that make the CDK4 protein resistant to inhibition by p16/INK4a. Thus, it appears that RAS or BRAF activation and increased CDK4 activity contributes to the development of dysplastic nevi. However, not all patients with germline mutations in *CDKN2A* or *CDK4* have dysplastic nevi, and not all familial dysplastic nevi are associated with mutations in these genes. As a result it is suspected that additional genes influence whether dysplastic nevi occur in a particular individual; the identities of these modifier genes, as well as the other genes that are responsible for the syndrome, are being sought. One possible suspect is germline mutations that increase the expression of *TERT*, the gene that encodes the catalytic subunit of telomerase (described later under Melanoma).

MORPHOLOGY

Dysplastic nevi are **larger than most acquired nevi (often greater than 5 mm across)** and may number in the

Figure 25-5 Potential steps of tumor progression in dysplastic nevi. **A**, Lentiginous melanocytic hyperplasia. **B**, Lentiginous junctional nevus. **C**, Lentiginous compound nevus with abnormal architectural and cytologic features (dysplastic nevus). **D**, Early melanoma, or melanoma in radial growth phase (large dark cells in epidermis). **E**, Advanced melanoma (vertical growth phase) with malignant spread into the dermis and vessels. The risk of malignant transformation of any single dysplastic nevus is small, but appears to be higher than that of typical nevi.

Figure 25-6 Dysplastic nevus. **A**, Numerous atypical nevi on the back. **B**, One such lesion (*inset A*) has a compound nevus component (*left*) and an asymmetric junctional nevus component (*right*). The former corresponds to the more pigmented and raised central zone and the latter to the less pigmented, flat peripheral rim of the lesion shown in **A**. **C**, An important feature is the presence of cytologic atypia (irregularly shaped, dark-staining nuclei). The dermis underlying the atypical cells characteristically shows linear, or lamellar, fibrosis.

hundreds in those with the dysplastic nevus syndrome (Fig. 25-6A). They are flat macules, slightly raised plaques with a “pebbly” surface, or target-like lesions with a darker raised center and irregular flat periphery. They can be recognized by their size, variability in pigmentation (variegation), and irregular borders. Most seem to be acquired rather than congenital. Unlike ordinary moles, dysplastic nevi occur on both sun-exposed and protected body surfaces.

Microscopically, dysplastic nevi usually involve both the epidermis and the dermis and exhibit architectural and cytologic atypia (Fig. 25-6A, B). **Nevus cell nests within the epidermis may be enlarged and often fuse or coalesce with adjacent nests.** As part of this process, single nevus cells begin to replace the normal basal cell layer along the dermo-epidermal junction, producing **lentiginous hyperplasia**. Cytologic atypia takes the form of nuclear enlargement, irregular, often angulated, nuclear contours, and hyperchromasia (Fig. 25-6C). Associated alterations in the superficial dermis include lymphocytic infiltrates (usually sparse); release of melanin from dead nevus cells into the dermis (**melanin incontinence**), where it is phagocytosed by dermal macrophages; and a peculiar **linear fibrosis** surrounding the epidermal rete ridges that are involved by the nevus. The diagnosis is based on this constellation of features, rather than any single finding.

Melanoma

Melanoma is the most deadly of all skin cancers and is strongly linked to acquired mutations caused by exposure to UV radiation in sunlight. Melanoma is a relatively common neoplasm that can be cured if it is detected and treated when it is in its earliest stages. The great preponderance of melanoma arises in the skin; other sites of origin include the oral and anogenital mucosal surfaces (i.e., oropharynx, gastrointestinal and genitourinary tracts), esophagus, meninges, and the uvea of the eye (Chapter 29). The following comments apply to cutaneous melanomas.

Today, as a result of increased public awareness of the signs of cutaneous melanoma, most are cured surgically.

Nevertheless, the reported incidence of melanoma is increasing; more than 76,000 cases and more than 9,700 deaths are expected in the United States in 2014.

Pathogenesis. About 10% to 15% of melanomas are inherited as an autosomal dominant trait with variable penetrance; as mentioned when discussing dysplastic nevi, some of these familial cases are associated with germline mutations affecting the genes that regulate cell-cycle progression or telomerase (described later). The overwhelming majority of melanoma is sporadic and is related to a single predisposing environmental factor: ultraviolet radiation (UVR) damage from sun exposure. UVR is associated strongly with DNA damage. Consistent with a pathogenic role in this disease, sequencing of melanoma genomes has demonstrated a very high rate of point mutations that bear the signature of the damaging effects of UV radiation on DNA. In line with this molecular evidence, melanomas most commonly arise on sun-exposed surfaces, particularly the upper back in men and the back and legs in women, and lightly pigmented individuals are at higher risk than are darkly pigmented individuals. Other inherited genetic variants linked to a modestly increased risk of melanoma in fair-skinned populations act by diminishing melanin production in skin, thus presumably increasing the amount of damage that sun-exposure wreaks on melanocytes.

Nevertheless, the relationship between sun exposure and melanoma is not as straightforward as with other skin cancers (discussed later). Some studies suggest that periodic severe sunburns early in life are the most important risk factor. Furthermore, since melanomas sometimes occur in dark-skinned individuals and at body sites that are not sun-exposed, sunlight is not always an essential predisposing factor, and other environmental factors may also contribute to risk.

The most frequent “driver” mutations in melanoma affect cell cycle control, pro-growth pathways, and telomerase. Some of the more common mutations are as follows:

- *Mutations that disrupt cell cycle control genes.* The *CDKN2A* gene is mutated in approximately 40% of pedigrees with

Figure 25-7 Pathways important in melanoma. Growth factors activate signaling circuits involving receptor tyrosine kinases (e.g., KIT), RAS, and two key downstream pathways that include the serine/threonine kinase BRAF and the phospholipid kinase PI3K. Proteins indicated by asterisks are mutated in melanoma. Components of these pathways that are being targeted by drugs are indicated.

autosomal dominant familial melanoma. *CDKN2A* is a complex locus that encodes three different tumor suppressors, p15/INK4b, p16/INK4a, and p14/ARF. Of these, loss of p16/INK4a is clearly implicated in human melanoma, and experimental evidence also supports a role for loss of p14/ARF. As already mentioned, p16/INK4a inhibits cyclin-dependent kinase 4 (CDK4) and cyclin-dependent kinase 6 (CDK6), thus reinforcing the ability of the RB tumor suppressor to block cells in the G₁ phase of the cell cycle. By contrast, p14/ARF enhances the activity of the p53 tumor suppressor by inhibiting MDM2, an oncoprotein that stimulates p53 degradation. *CDKN2A* is mutated in approximately 10% of sporadic melanomas, and these mutations uniformly abolish the production of p16/INK4a and more variably affect p14/ARF. However, it is suspected that these mutations are the tip of the “oncogenic iceberg” with respect to molecular lesions affecting the G₁ checkpoint. For example, 30% to 70% of melanomas show loss of p16/INK4a expression though varied mechanisms, and other familial and sporadic melanomas have mutations in CDK4 that prevent its inhibition by p16/INK4a. The net effect of all of these alterations is the same; increased melano-

cytic proliferation due to loss of cell-cycle control and escape from oncogene-induced cellular senescence.

- *Mutations that activate pro-growth signaling pathways.* A second common group of molecular lesions in sporadic melanoma leads to aberrant increases in RAS and PI3K/AKT signaling (Fig. 25-7), which you will recall promote cell growth and survival (Chapter 7). Activating mutations in BRAF, a serine/threonine kinase that is downstream of RAS, are seen in 40% to 50% of melanomas, while activating mutations in NRAS occur in an additional 15% to 20% of tumors. Melanomas with BRAF mutations also often show loss of the PTEN tumor suppressor, leading to heightened activation of the PI3K/AKT pathway. For reasons that are unclear, melanomas arising in non-sun exposed cutaneous sites rarely have mutations in BRAF or NRAS and are more likely to have activating mutations in the receptor tyrosine kinase KIT, which sits upstream of both RAS and PI3K/AKT. PTEN is also silenced in 20% of melanomas arising at in non-sun exposed sites. Other melanomas have loss-of-function mutations in the tumor suppressor neurofibromin 1 (NF1), a negative regulator of RAS, which

represents yet another mechanism of unleashing RAS signaling.

- *Mutations that activate telomerase.* Reactivation of telomerase, the enzyme activity that preserves telomeres and protects cells from senescence, has long been known to be important in cancer (Chapter 7), but how this occurs has been mysterious. Recently, sequencing of sporadic melanomas identified mutations in the promoter of *TERT*, the gene that encodes the catalytic subunit of telomerase, in roughly 70% of tumors, making *TERT* the most commonly mutated gene yet identified in this cancer. As might be anticipated, the mutations increase *TERT* expression, suggesting that they act as an antidote to senescence. The *TERT* promoter mutations create new binding sites for Ets family transcription factors, which are known to be up-regulated by BRAF signaling, providing a mechanistic link between these two oncogenic events. These findings strongly

suggest that mutations that turn on telomerase have a key role in the development of most melanomas.

MORPHOLOGY

Unlike benign nevi, melanomas show striking **variations in color**, appearing in shades of black, brown, red, dark blue, and gray (Fig. 25-8A). On occasion, zones of white or flesh-colored hypopigmentation also appear, sometimes due to focal regression of the tumor. **The borders of melanomas are irregular and often notched**, unlike the smooth, round, and uniform borders of melanocytic nevi.

Central to understanding the progression of melanoma is the concept of radial and vertical growth phases. **Radial growth** describes the horizontal spread of melanoma within the epidermis and superficial dermis (Fig. 25-8B). During this initial stage

Figure 25-8 Melanoma. **A**, Typical lesions are irregular in contour and pigmentation. Macular areas correlate with the radial growth phase, while raised areas correspond to nodular aggregates of malignant cells in vertical growth phase. **B**, Radial growth phase, showing irregular nested and single-cell growth of melanoma cells within the epidermis and an underlying inflammatory response within the dermis. **C**, Vertical growth phase, demonstrating nodular aggregates of infiltrating cells. **D**, High-power view of melanoma cells. The *inset* shows a sentinel lymph node with a tiny cluster of melanoma cells (*arrow*) staining for the melanocytic marker HMB-45. Even small numbers of malignant cells in a draining lymph node may confer a worse prognosis.

the tumor cells seem to lack the capacity to metastasize. Tumors in radial growth phase fall into several clinicopathologic classes, including: **lentigo maligna**, usually presenting as an indolent lesion on the face of older men that may remain in the radial growth phase for several decades; **superficial spreading**, the most common type of melanoma, usually involving sun-exposed skin; and **acral/mucosal lentiginous melanoma** that is unrelated to sun exposure.

After a variable (and unpredictable) period of time, melanoma shifts from the radial phase to a **vertical growth phase**, during which the tumor cells invade downward into the deeper dermal layers as an expansile mass (Fig. 25-8C). **The vertical growth phase is often heralded by the appearance of a nodule and correlates with the emergence of a tumor subclone with metastatic potential.** Unlike melanocytic nevi, “neurotization” is absent from the deep invasive portion of melanoma. The probability of metastasis in such lesions correlates with the depth of invasion, which by convention is the distance from the superficial epidermal granular cell layer to the deepest intradermal tumor cells; this measurement is known as the **Breslow thickness**. Other histologic features that correlate with outcome include the number of mitoses and the presence of ulceration; these and other prognostic factors are discussed later.

Individual melanoma cells are usually considerably larger than normal melanocytes or cells found in melanocytic nevi. They have large nuclei with irregular contours, chromatin that is characteristically clumped at the periphery of the nuclear membrane, and prominent red (eosinophilic) nucleoli (Fig. 25-8D). The appearance of the tumor cells is similar in the radial and vertical phases of growth. While most nevi and melanomas are easily distinguished based on their appearance, a tiny fraction of “atypical” lesions fall in a histologic gray zone and have been termed melanocytic tumors of uncertain malignant potential; such lesions require complete excision and close clinical follow-up.

Prognostic Factors. Once a melanoma is excised, a number of clinical and pathologic features are used to gauge the probability of metastatic spread and prognosis. One model used to predict outcome is based on the following variables: (1) tumor depth (the Breslow thickness); (2) number of mitoses; (3) evidence of tumor regression (presumably due to the host immune response); (4) ulceration of overlying skin; (5) the presence and number of tumor infiltrating lymphocytes; (6) gender; and (7) location (central body or extremity). Determinants of a more favorable prognosis in this model include thinner tumor depth, no or very few mitoses (< 1 per mm²), a brisk tumor infiltrating lymphocyte response, absence of regression, and lack of ulceration. Since most melanomas initially metastasize to regional lymph nodes, additional prognostic information may be obtained by performing a sentinel lymph node biopsy; as in breast cancer (Chapter 23), this involves the identification, removal, and careful examination of the lymph node (or nodes) that is the initial site of drainage of intratumoral lymphatic vessels. Microscopic involvement of a sentinel node by even a small number of melanoma cells (micrometastases) confers a worse prognosis (Fig. 25-7D, inset). The degree of involvement and the total number of lymph nodes involved correlate well with overall survival.

Clinical Features. The most important warning signs, sometimes called the ABCDEs of melanoma, are (1) **asymmetry**; (2) **irregular borders**; and (3) **variegated color**, (4) **increasing diameter**, and (5) **evolution or change over time, especially if rapid**. Because locally advanced melanomas often metastasize, early recognition and complete excision are critical. Melanoma of the skin is usually asymptomatic, although itching or pain may be early manifestations. The majority of lesions are greater than 10 mm in diameter at diagnosis. The most consistent clinical signs are changes in the color, size, or shape of a pigmented lesion. Other features of pigmented lesions that should raise concern are a diameter greater than 6 mm, any change in appearance, and new onset of itching or pain.

Molecular insights into the pathogenesis of melanoma have spawned attempts to treat this cancer with drugs that target the RAS and PI3K/AKT pathways (Fig. 25-8). Such approaches are urgently needed, as metastatic melanoma is resistant to both conventional chemotherapy and radiation treatment. Ultimately, it is likely that these types of targeted therapies will be used in combinations tailored to fit the oncogenic molecular lesions found in individual tumors. This idea is based on the observation that a high fraction of tumors with BRAF mutations respond to BRAF inhibitors, whereas tumors belonging to other molecular subtypes do not.

More recently, recognition that melanoma is inherently immunogenic has spawned interest in therapies such as anti-CTLA4 blocking antibodies or, even more promising, anti-PD1 blocking antibodies that enhance host recognition of melanoma-specific antigens. Such treatments have produced encouraging results in early clinical trials. This clinical paradigm of taking the brakes off the immune system is one that may be applicable to other cancers as well (Chapter 7). Ultimately, it may be that such agents will be used in combination with targeted therapies such as BRAF antagonists.

KEY CONCEPTS

Melanocytic Lesions, Benign and Malignant

- Most *melanocytic nevi* have activating mutations in *BRAF* or less often *NRAS*, but the vast majority never undergo malignant transformation
- Most sporadic *dysplastic nevi* are best regarded as markers of melanoma risk rather than premalignant lesions. They are characterized by architectural and cytologic atypia and are associated with germline mutations in genes encoding cell cycle regulators (p16/INK4a, CDK4) and telomerase.
- *Melanoma* is a highly aggressive malignancy linked to sun exposure; risk of spread is predicted by a number of tumor characteristics, particularly the vertical thickness of excised tumors
- Melanoma is associated with mutations in cell cycle regulators (p16/INK4a, CDK4), pro-growth signaling factors (growth factor receptors [e.g., KIT], RAS, BRAF), and telomerase
- Melanoma often incites a host immune response and sometimes shows dramatic responses to antibody therapies that enhance T-cell immunity

Benign Epithelial Tumors

Benign cutaneous epithelial neoplasms are common tumors that are derived from the keratinizing stratified squamous epithelium of the epidermis and hair follicles and the ductular epithelium of cutaneous glands. They often recapitulate the structures from which they arise. Their appearance sometime raises a concern of malignancy, particularly when they are pigmented or inflamed, and biopsy is frequently required to establish a definitive diagnosis. In very rare instances they are a telltale sign of syndromes associated with potentially life-threatening visceral malignancies, such as multiple trichilemmomas in Cowden syndrome or multiple sebaceous neoplasms in Muir-Torre syndrome. Diagnosis of epithelial tumors in these instances may facilitate recognition of the underlying syndrome and implementation of appropriate clinical interventions.

Seborrheic Keratoses

These common epidermal tumors occur most frequently in middle-aged or older individuals. They arise spontaneously and are particularly numerous on the trunk, although the extremities, head, and neck may also be involved. In people of color, multiple small lesions on the face are termed *dermatosis papulosa nigra*.

Pathogenesis. Activating mutations in the fibroblast growth factor receptor-3 (FGFR3), a receptor tyrosine kinase, are found in many sporadic seborrheic keratoses and are thought to drive the growth of the tumor. Seborrheic keratoses may suddenly appear in large numbers as part of a paraneoplastic syndrome (*Leser-Trélat sign*), possibly due to stimulation of keratinocytes by transforming growth factor- α produced by tumor cells, most commonly carcinomas of the gastrointestinal tract.

MORPHOLOGY

Seborrheic keratoses characteristically appear as round, flat, coinlike, waxy plaques that vary in diameter from millimeters to several centimeters (Fig. 25-9, *inset*). They are uniformly tan to dark brown and usually have a velvety to granular surface. Inspection with a hand lens usually reveals small, round, pore-like ostia impacted with keratin, a feature helpful in differentiating these pigmented lesions from melanomas.

On histologic examination, these neoplasms are exophytic and sharply demarcated from the adjacent epidermis. They are composed of sheets of small cells that most resemble basal cells of the normal epidermis (Fig. 25-9). Variable melanin pigmentation is present within these basaloid cells, accounting for the brown coloration. Exuberant keratin production (hyperkeratosis) occurs at the surface, and small keratin-filled cysts (horn cysts) and invaginations of keratin into the main mass (invagination cysts) are characteristic features. If irritated and inflamed, seborrheic keratoses develop whirling foci of squamous differentiation resembling eddy currents in a stream.

Acanthosis Nigricans

Acanthosis nigricans may be an important cutaneous sign of several underlying benign and malignant condi-

Figure 25-9 Seborrheic keratosis. A well-demarcated coinlike pigmented lesion containing dark keratin-filled surface plugs (*inset*) is composed of benign basaloid cells associated with prominent keratin-filled “horn” cysts, some of which communicate with the surface (pseudohorn cysts).

tions. It is a condition marked by thickened, hyperpigmented skin with a “velvet-like” texture that most commonly appears in the flexural areas (axillae, skin folds of the neck, groin, and anogenital regions). It is divided into two types based on the underlying condition.

- In 80% of cases, acanthosis nigricans is associated with benign conditions and develops gradually, usually during childhood or puberty. It may occur (1) as an autosomal dominant trait with variable penetrance, (2) in association with obesity or endocrine abnormalities (particularly with pituitary or pineal tumors and diabetes), and (3) as part of several rare congenital syndromes. The most common associations are with obesity and diabetes.
- In the remaining cases, acanthosis nigricans arises in association with cancers, most commonly *gastrointestinal adenocarcinomas*, usually in middle-aged and older individuals. In this setting, acanthosis nigricans is best viewed as a paraneoplastic phenomenon that is likely caused by growth factors released from tumors.

Pathogenesis. The unifying feature in all types of acanthosis nigricans is a disturbance that leads to increased growth factor receptor signaling in the skin. The familial form is associated with germline activating mutations in the receptor tyrosine kinase FGFR3, the same receptor that is frequently mutated in seborrheic keratoses. Depending on the mutation, acanthosis may be an isolated finding or be seen together with skeletal deformities, including achondroplasia and thanatophoric dysplasia. Why in some cases FGFR3 mutation gives rise to seborrheic keratosis and in others acanthosis nigricans is not clear. In those with type 2 diabetes, hyperinsulinemia is believed to provoke increased stimulation of insulin-like growth factor receptor-1 (IGF1R), another receptor tyrosine kinase that activates the same signaling pathways as FGFR3. Factors responsible for paraneoplastic acanthosis nigricans are uncertain; some cases have been linked to high levels of transforming growth factor- α (TGF- α), which may result in excessive activation of epidermal growth factor receptor (EGFR), yet another receptor tyrosine kinase, in the skin.

MORPHOLOGY

All forms of acanthosis nigricans have similar histologic features. The epidermis and underlying enlarged dermal papillae undulate sharply to form numerous repeating peaks and valleys. Variable hyperplasia may be seen, along with hyperkeratosis and slight basal cell layer hyperpigmentation (but no melanocytic hyperplasia).

Fibroepithelial Polyp

The fibroepithelial polyp has many names (acrochordon, squamous papilloma, skin tag) and is one of the most common cutaneous lesions. It usually comes to attention in middle-aged and older individuals on the neck, trunk, face, and intertriginous areas. Rarely, fibroepithelial polyps and tumors of perifollicular mesenchyme (specialized fibroblasts associated with the hair bulb) are seen together in *Birt-Hogg-Dubé syndrome*, but the vast majority of polyps are sporadic.

MORPHOLOGY

Fibroepithelial polyps are soft, flesh-colored, bag-like tumors that are often attached to the surrounding skin by a slender stalk. On histologic examination these tumors consist of fibrovascular cores covered by benign squamous epithelium. It is not uncommon for the polyps to undergo ischemic necrosis due to torsion, which may cause pain and precipitate their removal.

Fibroepithelial polyps are usually inconsequential, but can occasionally be associated with diabetes, obesity, and intestinal polyposis. Of interest, like melanocytic nevi and hemangiomas, they often become more numerous or prominent during pregnancy, presumably related to hormonal stimulation.

Epithelial or Follicular Inclusion Cyst (Wen)

Epithelial cysts are common lesions formed by the invagination and cystic expansion of the epidermis or, perhaps more commonly, a hair follicle. The lay term, *wen*, derives from the Anglo-Saxon *wenn*, meaning a lump or tumor. When large they may be subject to traumatic rupture, which can spill keratin into the dermis and lead to an extensive and often painful granulomatous inflammatory response.

Adnexal (Appendage) Tumors

There are literally hundreds of neoplasms arising from or showing differentiation toward cutaneous appendages. Their significance varies according to type and clinical context.

- Some are entirely benign, but may be confused with cutaneous cancers such as basal cell carcinoma.
- Other appendage tumors are associated with mendelian patterns of inheritance and occur as multiple disfiguring lesions.

- In some instances, these lesions warn of a predisposition for internal malignancy; such is the relationship between multiple *trichilemmomas* and *Cowden syndrome*, a disorder caused by germline loss of function mutations in the tumor suppressor gene *PTEN* that is associated with an increased risk of endometrial cancer, breast cancer, and many other tumors.

Appendage tumors are often nondescript, flesh-colored solitary or multiple papules and nodules. Some have a predisposition to occur on specific body surfaces. Selected examples are provided here to illustrate neoplasms of hair follicles and sebaceous, eccrine, and apocrine glands.

- *Eccrine poroma* occurs predominantly on the palms and soles where sweat glands are numerous.
- *Cylindroma*, an appendage tumor with ductal (apocrine or eccrine) differentiation, usually occurs on the forehead and scalp (Fig. 25-10A), where coalescence of nodules with time may produce a hatlike growth, hence the name *turban tumor*. These lesions may be dominantly inherited; in such cases they appear early in life and are associated with inactivating mutations in the tumor suppressor gene *CYLD*, which encodes a deubiquitinating enzyme that negatively regulates the oncogenic transcription factor NF- κ B and other factors that contribute to cell cycle progression. In addition to familial cylindromatosis, germline mutations in *CYLD* are associated with two other genetic syndromes marked by the occurrence of multiple adnexal tumors, multiple *familial trichoepithelioma* (a follicular tumor) and *Brooke-Spiegler syndrome* (associated with both trichoepithelioma and cylindroma).
- *Syringomas*, lesions with eccrine differentiation, usually occur as multiple, small, tan papules in the vicinity of the lower eyelids.
- *Sebaceous adenomas* can be associated with internal malignancy in the *Muir-Torre syndrome*, a subset of the hereditary nonpolyposis colorectal carcinoma syndrome (Chapter 17) associated with germline deficits in DNA mismatch repair proteins.
- *Pilomatricomas*, showing follicular differentiation, are associated with activating mutations in *CTNNB1*, the gene encoding β -catenin. Mutations in this gene are seen in numerous neoplasms but are of interest here since Wnt signaling through β -catenin is critical for early hair development and regulates hair growth and maintenance.
- Adnexal tumors can also show primarily apocrine differentiation; these usually arise in body areas where apocrine glands are most prevalent, such as the axilla and scalp. Some skin adnexal tumors may arise from multipotent cutaneous stem cells, which are believed to reside in a specialized niche associated with hair follicles.

MORPHOLOGY

The **cylindroma** is composed of islands of cells resembling those of the normal epidermal or adnexal basal cell layer (basaloid cells). These islands fit together like pieces of a jigsaw puzzle within a fibrous dermal matrix (Fig. 25-10B).

Figure 25-10 Cylindroma and trichoepithelioma. **A**, Multiple cylindromas (papules) on the forehead are composed (**B**) of islands of basaloid cells containing occasional ducts that fit together like pieces of a jigsaw puzzle. **C**, Perinasal papules and small nodules of trichoepithelioma are composed (**D**) of buds of basaloid cells that resemble primitive hair follicles.

Trichoepithelioma is a proliferation of basaloid cells that forms primitive structures resembling hair follicles (Fig. 25-10C, D). **Sebaceous adenoma** shows a lobular proliferation of sebocytes with increased peripheral basaloid cells and more mature sebocytes in the central portion, characterized by frothy or bubbly cytoplasm due to lipid vesicle content (Fig. 25-11A). **Pilomatrixomas** are composed of basaloid cells that show

trichilemmal or hairlike differentiation similar to that seen in the germinal portion of the normal hair bulb in the anagen growth phase (Fig. 25-11B). **Apocrine carcinoma** shows ductal differentiation with prominent decapitation secretion similar to that seen in the normal apocrine gland (Fig. 25-11C). The infiltrative growth pattern is a hint of malignancy in this otherwise well-differentiated tumor.

Figure 25-11 Diverse adnexal tumors. **A**, Sebaceous adenoma; *inset* demonstrates sebaceous differentiation. **B**, Pilomatrixoma; *inset* shows hair matrix differentiation to anucleate "ghost cells." **C**, Apocrine carcinoma (well-differentiated); *inset* shows apocrine differentiation and luminal secretions produced by "decapitation" of the lining cells.

Although most appendage tumors are benign, malignant variants do exist. Apocrine tumors are unusual in that malignant forms seem to be more common than benign forms. *Sebaceous carcinoma* arises from the meibomian glands of the eyelid and may follow an aggressive course replete with systemic metastases. *Eccrine* and *apocrine carcinomas* can be confused with metastatic adenocarcinoma because of their tendency to form gland-like structures.

Premalignant and Malignant Epidermal Tumors

Actinic Keratosis

Actinic keratoses; as the name implies, usually occur in sun-damaged skin and exhibit hyperkeratosis. As expected, they occur with particularly high incidence in lightly pigmented individuals. Exposure to ionizing radiation, industrial hydrocarbons, and arsenicals may induce similar lesions. These lesions may show progressively worsening dysplastic changes that culminate in cutaneous squamous cell carcinoma, and are analogous in this regard to the precursor lesions that give rise to squamous carcinomas of the uterine cervix (Chapter 22).

MORPHOLOGY

Actinic keratoses are usually less than 1 cm in diameter. They are typically tan-brown, red, or skin-colored and have a rough, sandpaper-like consistency. Some lesions produce so much keratin that a “cutaneous horn” develops (Fig. 25-12A), which

in extreme cases may become so prominent that they resemble the actual horns of animals! Sun-exposed sites (face, arms, dorsum of hands) are most frequently affected. The lips may also develop similar lesions (termed **actinic cheilitis**).

Cytologic atypia is seen in the lowermost layers of the epidermis and may be associated with hyperplasia of basal cells (Fig. 25-12B) or, alternatively, with atrophy that results in thinning of the epidermis. The atypical basal cells usually have pink or reddish cytoplasm due to dyskeratosis. Intercellular bridges are present, in contrast to basal cell carcinoma, in which they are not visible. The superficial dermis contains thickened, blue-gray elastic fibers (**elastosis**), a probable result of abnormal elastic fiber synthesis by sun-damaged fibroblasts. The stratum corneum is thickened, and unlike normal skin, the cells in this layer often retain their nuclei (**parakeratosis**).

Whether all actinic keratoses progress to skin cancer (usually squamous cell carcinoma) if given enough time is conjectural. Lesions may regress or remain stable during a normal life span, but enough do become malignant that local eradication is warranted. This can usually be accomplished by gentle curettage, freezing, or topical application of chemotherapeutic agents. Of interest, topical administration of imiquimod, a drug that activates Toll-like receptors (TLRs), eradicates up to 50% of lesions, a rate considerably higher than the spontaneous regression rate of approximately 5%. By stimulating TLR signaling, imiquimod activates cutaneous innate immune cells, which may recognize and eradicate precancerous lesions. Direct proapoptotic effects of the imiquimod on lesional keratinocytes have also been proposed, but these are poorly understood at present.

Figure 25-12 Actinic keratosis. **A**, Excessive keratotic scale in this lesion has produced a “cutaneous horn.” **B**, Basal cell layer atypia (dysplasia) is associated with marked hyperkeratosis and parakeratosis. **C**, Progression to full-thickness nuclear atypia, with or without the presence of superficial epidermal maturation, heralds the development of squamous cell carcinoma in situ.

Squamous Cell Carcinoma

Squamous cell carcinoma is the second most common tumor arising on sun-exposed sites in older people, exceeded only by basal cell carcinoma. Except for lesions on the lower legs, these tumors have a higher incidence in men than in women. Invasive squamous cell carcinomas are usually discovered while they are small and resectable. Less than 5% of these tumors metastasize to regional nodes; these lesions are generally deeply invasive and involve the subcutis.

Pathogenesis. The most important cause of cutaneous squamous cell carcinoma is DNA damage induced by exposure to UV light. Tumor incidence is proportional to the degree of lifetime sun exposure. A second common association is with immunosuppression, most notably chronic immunosuppression as a result of chemotherapy or organ transplantation. Immunosuppression may contribute to carcinogenesis by reducing host surveillance and increasing the susceptibility of keratinocytes to infection and transformation by oncogenic viruses, particularly human papilloma virus (HPV) subtypes 5 and 8. These same HPVs have been implicated in tumors arising in patients with a rare autosomal recessive condition, *epidermodysplasia verruciformis*, which is marked by a high susceptibility to cutaneous squamous cell carcinomas. In addition to its damaging effect on DNA, sunlight, through uncertain mechanisms, seems to cause a transient defect in cutaneous innate immunity that may diminish immune-mediated elimination of sun-damaged cells. Other risk factors for squamous cell carcinoma include industrial carcinogens (tars and oils), chronic ulcers and draining osteomyelitis, old burn scars, ingestion of arsenicals, ionizing radiation, and (in the oral cavity) tobacco and betel nut chewing.

Most studies on the genetics of squamous cell carcinoma have focused on acquired defects in sporadic tumors and their precursors (actinic keratoses), and the relationships between these defects and sun-exposure. The incidence of *TP53* mutations in actinic keratoses found in Caucasians is high, suggesting that p53 dysfunction is an early event in the development of tumors induced by sunlight. Normally, DNA damaged by UV light is sensed by checkpoint kinases such as ATM and ATR, which send out signals that up-regulate the expression and stability of p53. p53 in turn arrests cells in the G_1 phase of the cell cycle and promotes either “high-fidelity” DNA repair or the elimination by apoptosis of cells that are damaged beyond repair (Chapter 7). When these protective functions of p53 are lost, DNA damage induced by UV light is more likely to be “repaired” by error-prone mechanisms, creating mutations that are passed down to daughter cells. Of note, the mutations that are seen in *TP53* often occur at pyrimidine dimers, indicating that they, too, stem from damage caused by UV light. A similar story underlies the remarkable susceptibility of patients with *xeroderma pigmentosum* to squamous cell carcinoma. This disorder is caused by inherited mutations in genes in the nucleotide excision repair pathway, which is required for accurate repair of pyrimidine dimers; when this pathway is defective, error-prone repair pathways take over, leading to the rapid accumulation of mutations and eventual carcinogenesis.

As with all other forms of cancer, cutaneous squamous cell carcinoma stems from multiple driver mutations. In addition to defects in p53, mutations that increase RAS signaling and decrease Notch signaling are common and are also likely to contribute to the transformation process.

MORPHOLOGY

Squamous cell carcinomas that have not invaded through the basement membrane of the dermoepidermal junction (termed in situ carcinoma) appear as sharply defined, red, scaling plaques. More advanced, invasive lesions are nodular, show variable keratin production (appreciated grossly as hyperkeratotic scale), and may ulcerate (Fig. 25-13A).

Unlike actinic keratoses, in squamous cell carcinoma in situ, cells with atypical (enlarged and hyperchromatic) nuclei involve all levels of the epidermis (Fig. 25-12C). Invasive squamous cell carcinoma (Fig. 25-13B, C) shows variable degrees of differentiation, ranging from tumors composed of polygonal cells arranged in orderly lobules and having numerous large areas of keratinization, to neoplasms consisting of highly anaplastic cells that exhibit only abortive, single-cell keratinization (dyskeratosis). The latter tumors may be so poorly differentiated that immunohistochemical stains for keratins are needed to confirm the diagnosis.

Basal Cell Carcinoma

Basal cell carcinoma is a distinctive locally aggressive cutaneous tumor that is associated with mutations that activate the Hedgehog pathway signaling. Basal cell carcinoma is the most common invasive cancer in humans, numbering nearly 1 million cases per year in the United States. These are slow-growing tumors that rarely metastasize. The vast majority is recognized at an early stage and is cured by local excision. However, a small number of tumors (<0.5%) are locally aggressive and potentially disfiguring, or exceedingly rarely may metastasize to distant sites. They occur at sun-exposed sites in lightly pigmented elderly adults. As with squamous cell carcinoma, the incidence of basal cell carcinoma is increased in the setting of immunosuppression and in disorders of DNA repair, such as *xeroderma pigmentosum* (Chapter 7).

Pathogenesis. Most basal cell carcinomas have mutations that lead to unbridled Hedgehog signaling. As is often the case in biology and medicine, study of a rare genetic syndrome associated with a high risk of a common disease (basal cell carcinoma) has led to the elucidation of pathogenic mechanisms of general importance. The syndrome in question, *nevroid basal cell carcinoma syndrome* (NBCCS; also known as *basal cell nevus* or *Gorlin syndrome*), is an autosomal dominant disorder characterized by the development of multiple basal cell carcinomas, often before age 20, accompanied by various other tumors (especially medulloblastomas and ovarian fibromas), odontogenic keratocysts, pits of the palms and soles, and certain developmental abnormalities. NBCCS is one of a number of cancer syndromes associated with skin manifestations (Table 25-3). The gene associated with NBCCS is *PTCH*, a tumor suppressor that is the human homologue of the *Drosophila* developmental gene *patched*. Individuals with

Figure 25-13 Invasive squamous cell carcinoma. **A**, Lesions are often nodular and ulcerated, as seen in this scalp tumor. **B**, Tongues of atypical squamous epithelium have transgressed the basement membrane and invaded deeply into the dermis. **C**, Invasive tumor cells show enlarged nuclei with angulated contours and prominent nucleoli.

NBCCS are born with a germline loss of function mutation in one *PTCH* allele; the second normal allele is inactivated in tumors by a mutation acquired by chance or due to exposure to mutagens (particularly UV light).

PTCH protein is a receptor for *sonic hedgehog* (*SHH*), a component of the Hedgehog signaling pathway, which determines polarity during embryonic development and also regulates hair follicle formation and hair growth. In the “off” state, PTCH exists in a complex with another transmembrane protein called SMO (for “smoothened”). Binding of SHH to PTCH releases SMO, which in turn

activates the transcription factor GLI1 (Fig. 25-14), thus turning on the expression of genes that support tumor cell growth and survival. Mice engineered to have excessive GLI1 activation are prone to development of skin tumors resembling basal cell carcinomas. Similarly, in NBCCS the loss of PTCH function causes constitutive activation of SMO and GLI1, leading to the development of basal cell carcinoma.

Mutations that activate Hedgehog signaling are also prevalent in sporadic basal cell carcinomas. Loss of function *PTCH* mutations are common, and about one third

Table 25-3 Survey of Familial Cancer Syndromes with Cutaneous Manifestations

Disease	Inheritance	Chromosomal Location	Gene/Protein	Normal Function/Manifestation of Loss
Ataxia-telangiectasia	AR	11q22.3	<i>ATM/ATM</i>	DNA repair after radiation injury/neurologic and vascular lesions
Nevoid basal cell carcinoma syndrome	AD	9q22	<i>PTCH/PTCH</i>	Developmental patterning gene/multiple basal cell carcinomas; medulloblastoma, jaw cysts
Cowden syndrome	AD	10q23	<i>PTEN/PTEN</i>	Lipid phosphatase/benign follicular appendage tumors (trichilemmomas); internal adenocarcinoma (often breast or endometrial)
Familial melanoma syndrome	AD	9p21	<i>CDKN2/p16/INK4</i> <i>CDKN2/p14/ARF</i>	Inhibits CDK4/6 phosphorylation of RB, promoting cell cycle arrest/melanoma; pancreatic carcinoma Binds MDM2, promoting p53 function/melanoma; pancreatic carcinoma
Muir-Torre syndrome	AD	2p22 3p21	<i>MSH2/MSH2</i> <i>MLH1/MLH1</i>	Involved in DNA mismatch repair/sebaceous neoplasia; internal malignancy (colon and others)
Neurofibromatosis I	AD	17q11	<i>NF1/neurofibromin</i>	Negatively regulates RAS signaling/neurofibromas
Neurofibromatosis II	AD	22q12	<i>NF2/merlin</i>	Integrates cytoskeletal signaling/neurofibromas and acoustic neuromas
Tuberous sclerosis	AD	9q34 16p13	<i>TSC1/hamartin</i> <i>TSC2/tuberin</i>	Work together in a complex that negatively regulates mTOR/angiofibromas/mental retardation
Xeroderma pigmentosum	AR	9q22 and others	<i>XPA/XPA</i> and others	Nucleotide excision repair/melanoma and nonmelanoma skin cancers

AD, Autosomal dominant; AR, autosomal recessive.

From Tsai KY, Tsao H: The genetics of skin cancer. *Am J Med Genet C Semin Med Genet* 131C:82, 2004.

Figure 25-14 Normal and oncogenic hedgehog signaling. *Left*, Normally, PTCH and SMO form a receptor complex that can bind sonic hedgehog (SHH). In the absence of SHH, PTCH blocks SMO activity. When SHH binds PTCH, SMO is released to trigger a signal transduction cascade that leads to activation of GLI1 and other transcription factors. *Right*, Mutations in *PTCH*, and less often in *SMO*, allow SMO to signal without SHH binding and produce constitutive activation of GLI1. GLI signaling is a characteristic feature of sporadic basal cell carcinomas and tumors associated with the nevoid basal cell carcinoma (Gorlin) syndrome.

of these mutations consist of C→T transitions that are considered hallmarks of UV damage. Other tumors have activating mutations in *SMO*. This insight has paved the way for the development of small molecule inhibitors of the Hedgehog pathway, which produce excellent clinical responses in patients with locally aggressive or metastatic basal cell carcinoma.

MORPHOLOGY

Basal cell carcinomas usually present as **pearly papules** containing prominent dilated subepidermal blood vessels (**telangiectasias**) (Fig. 25-15A). Some tumors contain melanin and superficially resemble melanocytic nevi or melanomas. Advanced lesions may ulcerate, and extensive local invasion of bone or facial sinuses may occur after many years of neglect or in unusually aggressive tumors, explaining the archaic designation **rodent ulcers**. One common and important variant, the superficial basal cell carcinoma, presents as an erythematous, occasionally pigmented plaque that may resemble early forms of melanoma.

Histologically, the tumor cells resemble those in the normal basal cell layer of the epidermis. They arise from the epidermis or follicular epithelium and do not occur on mucosal surfaces. Two patterns are seen: **multifocal growths** originating from the epidermis and sometimes extending over several square centimeters or more of skin surface (multifocal superficial

type) and **nodular lesions** growing downward deeply into the dermis as cords and islands of variably basophilic cells with hyperchromatic nuclei, embedded in a mucinous matrix, and often surrounded by many fibroblasts and lymphocytes (Fig. 25-15B). The cells at the periphery of the tumor cell islands tend to be arranged radially with their long axes in parallel alignment (**palisading**). In sections, the stroma retracts away from the carcinoma (Fig. 25-15C), creating clefts or separation artifacts that assist in differentiating basal cell carcinomas from certain appendage tumors that are also characterized by proliferation of basaloid cells, such as trichoepithelioma.

KEY CONCEPTS

Malignant Epidermal Tumors

- The incidence of both basal cell and squamous cell carcinoma is strongly correlated with increasing lifetime sun exposure.
- Cutaneous squamous cell carcinoma can progress from actinic keratoses but also arises from chemical exposure, at thermal burn sites, or in association with HPV infection in the setting of immunosuppression.
- Cutaneous squamous cell carcinoma has potential for metastasis but is much less aggressive than squamous cell carcinoma at mucosal sites.

Figure 25-15 Basal cell carcinoma. Pearly, telangiectatic nodules (A) are composed of nests of uniform basaloid cells within the dermis (B) that are often separated from the adjacent stroma by thin clefts (C), an artifact of sectioning.

- Basal cell carcinoma, the most common malignancy worldwide, is a locally aggressive tumor associated with mutations that activate Hedgehog signaling. Metastasis is very rare.

Tumors of the Dermis

The dermis contains a variety of elements such as smooth muscle, pericytes, fibroblasts, neural tissue, and endothelium. Neoplasms comprised of cells resembling all of these elements occur in the skin, but most also involve other soft tissues and viscera and are discussed elsewhere, or are too rare to merit mention. This section discusses two dermal neoplasms—one benign, one malignant—that arise primarily in the skin.

Benign Fibrous Histiocytoma (Dermatofibroma)

Benign fibrous histiocytoma refers to a heterogeneous family of morphologically and histogenetically related benign dermal neoplasms of uncertain lineage. These tumors are usually seen in adults and often occur on the legs of young and middle-aged women. Lesions are asymptomatic or tender and may increase and decrease slightly in size over time. Their biologic behavior is indolent.

The cause of fibrous histiocytomas remains a mystery. Many cases have a history of antecedent trauma, suggesting an abnormal response to injury and inflammation, perhaps analogous to the deposition of increased amounts of altered collagen in a hypertrophic scar or keloid. These common yet curious tumors appear to be composed at least partially of factor XIIIa-positive dermal dendritic cells.

MORPHOLOGY

These neoplasms appear as firm, tan to brown papules (Fig. 25-16A). Most are less than 1 cm in diameter, but actively growing lesions may reach several centimeters in diameter; with time they often become flattened.

The most common form of fibrous histiocytoma is referred to as a **dermatofibroma**. These tumors consist of benign, spindle-shaped cells that are usually arranged in a well-defined, nonencapsulated mass within the mid-dermis (Fig. 25-16B, C). Extension of these cells into the subcutaneous fat is sometimes observed. Many cases demonstrate a peculiar form of overlying epidermal hyperplasia, characterized by downward elongation of hyperpigmented rete ridges (**pseudoepitheliomatous hyperplasia**). Numerous histologic variants are noted, such as more cellular forms or tumors with pools of extravascular blood and hemosiderin (aneurysmal).

Dermatofibrosarcoma Protuberans

Dermatofibrosarcoma protuberans is best regarded as a well-differentiated, primary fibrosarcoma of the skin. These tumors are slow growing, and although they are locally aggressive and can recur, they rarely metastasize.

Pathogenesis. The molecular hallmark of dermatofibrosarcoma protuberans is a translocation involving the genes encoding collagen 1A1 (*COL1A1*) and platelet-derived growth factor- β (*PDGFB*). The resulting rearrangement juxtaposes the *COL1A1* promoter sequences and the coding region of *PDGFB* and leads to overexpression and increased secretion of PDGF β , which drives tumor cell growth through an autocrine loop. While the primary mode of treatment is wide local excision, rare cases that are

Figure 25-16 Benign fibrous histiocytoma (dermatofibroma). This firm, tan papule on the leg (**A**) contains a circumscribed dermal proliferation of benign-appearing spindle cells (**B**). Note the characteristic overlying epidermal hyperplasia (**B**) and the tendency of fibroblasts to surround individual collagen bundles (**C**).

unresectable due to their location or because of metastatic spread can be treated with inhibitors of the PDGF β receptor tyrosine kinase. Included in this class of drugs is imatinib mesylate, which first came to fame for its efficacy in treatment of chronic myeloid leukemia (CML). As in CML patients, withdrawal of the drug is followed by regrowth of the tumor, so use of this agent is lifelong.

characteristic “honeycomb” pattern, is frequently seen (Fig. 25-17B, C). These tumors may extend down into the subcutis and thus require wide excision to prevent local recurrence.

MORPHOLOGY

Dermatofibrosarcoma protuberans usually appears as a “protuberant” nodule, most often on the trunk, within a firm (indurated) plaque that may sometimes ulcerate (Fig. 27-17A). These neoplasms are composed of closely packed fibroblasts arranged radially, reminiscent of blades of a pinwheel, a pattern referred to as **storiform**. Mitoses are rare. In contrast to dermatofibroma, the overlying epidermis is generally thinned. Deep extension from the dermis into subcutaneous fat, producing a

Tumors of Cellular Migrants to the Skin

Aside from tumors that arise directly from epidermal and dermal cells, several proliferative disorders of the skin involve cells whose progenitors arise elsewhere and then specifically home to the cutaneous microenvironment.

Mycosis Fungoides (Cutaneous T-Cell Lymphoma)

Cutaneous T-cell lymphoma (CTCL) spans a spectrum of lymphoproliferative disorders affecting the skin (Chapter 13), many with distinctive presentations. This section

Figure 25-17 Dermatofibrosarcoma protuberans. **A**, The tumor consists of a flesh-colored fibrotic nodule on sectioning. **B**, The lesion often infiltrates the subcutis in a manner reminiscent of “Swiss cheese” to aficionados. **C**, A characteristic storiform (swirling) alignment of the spindled cells is apparent.

focuses on *mycosis fungoides*, a lymphoma of skin-homing CD4+ T helper cells that presents in the skin. In most affected individuals, the disease remains localized to the skin for many years, but it may eventually evolve into a systemic lymphoma. This tumor may occur at any age, but most commonly afflicts persons older than age 40.

Lesions of *mycosis fungoides* usually involve truncal areas and include scaly, red-brown *patches*; raised, scaling *plaques* that may even be confused with psoriasis; and fungating *nodules*. Prognosis is related to the percentage of body surface involved and progression from patch to plaque to nodular forms. Eczema-like lesions typify early stages of disease when obvious visceral or nodal spread has not occurred. Raised, indurated, irregularly outlined, erythematous plaques may then supervene. Development of multiple, large red-brown nodules correlates with systemic spread. Sometimes plaques and nodules ulcerate (Fig. 25-18A). Ultimately, lesions may affect numerous body surfaces, including the trunk, extremities, face, and scalp. In some individuals, seeding of the blood by malignant T cells is accompanied by diffuse erythema and scaling of the entire body surface (erythroderma), a condition known as *Sézary syndrome* (Chapter 13).

The proliferating cells in CTCL are clonal populations of CD4-positive T helper cells that home to the skin due to expression of cutaneous lymphocyte antigen. The neoplastic cells have clonal T-cell receptor gene rearrangements and sometimes express aberrant combinations of T-cell surface antigens. Topical therapy with steroids or UV light is often used for early skin lesions, whereas more aggressive systemic chemotherapy is indicated for advanced disease.

MORPHOLOGY

The histologic hallmark of CTCL of the *mycosis fungoides* type is the presence of the **Sézary-Lutzner cells**, which characteristically form bandlike aggregates within the superficial dermis (Fig. 25-18B) and invade the epidermis as single cells and small clusters (**Pautrier microabscesses**). These cells have markedly infolded nuclear membranes, imparting a hyperconvoluted or cerebriform contour. Although patches and plaques show pronounced epidermal infiltration by Sézary-Lutzner cells

(epidermotropism), in more advanced nodular lesions the malignant T cells often lose this epidermotropic tendency, grow deeply into the dermis, and eventually spread systemically.

Mastocytosis

The term *mastocytosis* encompasses a spectrum of rare disorders characterized by increased numbers of mast cells in the skin and, in some instances, in other organs as well. A cutaneous form of the disease that affects predominantly children and accounts for more than 50% of all cases is termed *urticaria pigmentosa*. The cutaneous lesions are usually multiple, although solitary mastocytomas may also occur in very young children. About 10% of individuals with mast cell disease have systemic disease, with mast cell infiltration of many organs. These individuals are often adults, and unlike localized cutaneous disease, the prognosis may be poor.

Many of the signs and symptoms of mastocytosis are due to the effects of histamine, heparin, and other substances released when mast cells degranulate. *Darier sign* refers to a localized area of dermal edema and erythema (wheal) that occurs when lesional skin is rubbed. *Dermatographism* refers to an area of dermal edema resembling a hive that occurs as a result of localized stroking of apparently normal skin with a pointed instrument. In systemic disease, all of the following may be seen: pruritus and flushing, variously triggered by certain foods, temperature changes, alcohol, and certain drugs (morphine, codeine, aspirin); watery nasal discharge (rhinorrhea); rarely, gastrointestinal or nasal bleeding, possibly due to the anticoagulant effects of heparin; and bone pain, which may be caused by mast cell infiltration or by pathologic fractures stemming from osteoporosis. Osteoporosis is caused by excessive histamine release in the marrow microenvironment and can be a clue to the diagnosis, particularly in premenopausal women and in men.

Pathogenesis. Many cases of mastocytosis have acquired activating point mutations in the KIT receptor tyrosine kinase. The resulting increase in KIT signaling drives mast cell growth and survival. This insight has led to trials of KIT kinase inhibitors in patients with disseminated disease.

Figure 25-18 Cutaneous T-cell lymphoma. **A**, Several erythematous plaques with scaling and ulceration are evident. **B**, Microscopically, there is an infiltrate of atypical lymphocytes that accumulates beneath and invades the epidermis.

Figure 25-19 Mastocytosis. **A**, Solitary mastocytoma in a 1-year-old child. **B**, By histology, numerous ovoid cells with uniform, centrally located nuclei are observed in the dermis. **C**, Giemsa staining reveals purple “metachromatic” granules within the cytoplasm of the mast cells.

MORPHOLOGY

The pathologic findings are highly variable. In **urticaria pigmentosa**, lesions are multiple and widely distributed, consisting of round to oval, red-brown, nonscaling papules and small plaques. Solitary **mastocytoma** presents as a pink to tan-brown nodule that may be pruritic or show blister formation (Fig. 25-19A). The histologic picture in urticaria pigmentosa or solitary mastocytoma varies from a subtle increase in the numbers of spindle-shaped and stellate mast cells around superficial dermal blood vessels, to large numbers of tightly packed, round to oval mast cells in the upper to mid-dermis (Fig. 25-19B). Fibrosis, edema, and small numbers of eosinophils may also be present. Mast cells may be difficult to differentiate from lymphocytes in routine, hematoxylin and eosin–stained sections, and special metachromatic stains (toluidine blue or Giemsa) must be used to visualize their granules (Fig. 25-19C). Even with these stains, extensive degranulation may result in failure to recognize these cells by light microscopy, but their identity can be readily confirmed with immunohistochemical stains for mast cell markers, such as mast cell tryptase and KIT.

categories include *ichthyosis vulgaris* (autosomal dominant or acquired), *congenital ichthyosiform erythroderma* (autosomal recessive), *lamellar ichthyosis* (autosomal recessive), and *X-linked ichthyosis*. Most ichthyoses become apparent either at or around the time of birth. Acquired (noninherited) variants also exist; one such variant, *ichthyosis vulgaris*, may be associated with lymphoid and visceral malignancies.

Pathogenesis. The primary abnormality in some forms of ichthyosis is defective desquamation, leading to retention of abnormally formed scale. For example, X-linked ichthyosis is caused by a deficiency of steroid sulfatase, an enzyme helps to remove proadhesive cholesterol sulfate from intercellular spaces. In its absence cholesterol sulfate accumulates, resulting in persistent cell-to-cell

Disorders of Epidermal Maturation

Ichthyosis

Of the numerous disorders that impair epidermal maturation, ichthyosis is perhaps one of the most striking. The term is derived from the Greek root *ichthy*, meaning “fishy,” and accordingly, this group of inherited disorders is associated with chronic, excessive keratin buildup (hyperkeratosis) that results clinically in fishlike scales (Fig. 25-20A). The clinical types of ichthyosis vary according to the mode of inheritance, histology, and clinical features; the primary

Figure 25-20 Ichthyosis. Note prominent fishlike scales (**A**) and compacted, thickened stratum corneum (**B**).

adhesion within the stratum corneum and a failure of desquamation.

MORPHOLOGY

All forms of ichthyosis exhibit a buildup of compacted stratum corneum that is associated with loss of the normal basket-weave pattern (Fig. 25-20B). There is generally little or no inflammation. Variations in the thickness of the epidermis and the stratum granulosum and the gross appearance and distribution of lesions are used to subclassify these disorders.

Acute Inflammatory Dermatoses

Literally thousands of inflammatory dermatoses have been described. In general, acute lesions last from days to weeks and are characterized by inflammatory infiltrates (usually composed of lymphocytes and macrophages rather than neutrophils), edema, and variable degrees of epidermal, vascular, or subcutaneous injury. Chronic lesions, on the other hand, persist for months to years and are often associated with changes in epidermal growth (atrophy or hyperplasia) or dermal fibrosis. The lesions discussed here are examples of the more commonly encountered acute dermatoses.

Urticaria

Urticaria (hives) is a common disorder of the skin characterized by localized mast cell degranulation and resultant dermal microvascular hyperpermeability. This combination of effects produces pruritic edematous plaques called *wheals*. Angioedema is closely related to urticaria and is characterized by edema of the deeper dermis and the subcutaneous fat.

Urticaria most often occurs between ages 20 and 40, but all age groups are susceptible. Individual lesions develop and fade within hours (usually less than 24 hours), and episodes may last for days or persist for months. Sites of predilection for urticarial eruptions include any area exposed to pressure, such as the trunk, distal extremities, and ears. Persistent episodes of urticaria may herald an

underlying disease (e.g., collagen vascular disorders, Hodgkin lymphoma), but in the majority of cases no underlying cause is identified.

Pathogenesis. Urticaria is most commonly the result of antigen-induced release of vasoactive mediators from mast cells but there are other less common causes as well.

- *Mast cell-dependent, IgE-dependent.* Urticaria of this type follows exposure to many different antigens (pollens, foods, drugs, insect venom), and is an example of a localized immediate hypersensitivity (type I) reaction triggered by the binding of antigen to IgE antibodies that are attached to mast cells through Fc receptors (Chapter 6).
- *Mast cell-dependent, IgE-independent.* This subset results from substances that directly incite the degranulation of mast cells, such as opiates, certain antibiotics, curare, and radiographic contrast media.
- *Mast cell-independent, IgE-independent.* These forms of urticaria are triggered by local factors that increase vascular permeability. One form is initiated by exposure to chemicals or drugs, such as aspirin, that inhibit cyclooxygenase and arachidonic acid production. The precise mechanism of aspirin-induced urticaria is unknown. A second form is *hereditary angioneurotic edema* (Chapter 6), caused by an inherited deficiency of C1 inhibitor that results in excessive activation of the early components of the complement system and production of vasoactive mediators.

MORPHOLOGY

Lesions vary from small, pruritic papules to large edematous plaques (Fig. 25-21A). Individual lesions may coalesce to form annular, linear, or arciform configurations. The histologic features of urticaria may be very subtle. There is usually a sparse superficial perivascular infiltrate consisting of mononuclear cells and rare neutrophils. Eosinophils may also be present. Collagen bundles are more widely spaced than in normal skin, a result of superficial dermal edema (Fig. 25-21B). Superficial lymphatic channels are dilated due to increased absorption of edema fluid. There are no changes in the epidermis.

Figure 25-21 Urticaria. **A**, Erythematous, edematous, often circular plaques are characteristic. **B**, Histologically, there is superficial dermal edema, manifested by spaces between collagen bundles, and dilated lymphatic and blood-filled vascular spaces; the epithelium is normal.

Acute Eczematous Dermatitis

The Greek word *eczema*, meaning “to boil over,” vividly describes the appearance of acute eczematous dermatitis one of the most common skin disorders. Based on initiating factors, eczematous dermatitis can be subdivided into the following categories: (1) allergic contact dermatitis, (2) atopic dermatitis, (3) drug-related eczematous dermatitis, (4) photoeczematous dermatitis, and (5) primary irritant dermatitis.

The causes of eczema are sometimes broadly separated into “inside” and “outside” types: disease resulting from external application of an antigen (e.g., poison ivy) or a reaction to an internal circulating antigen (which may be derived from ingested food or a drug). Treatment involves a search for offending substances that can be removed from the environment. Topical steroids nonspecifically block the inflammatory response. While such treatments are only palliative and do not cure, they are nevertheless helpful in interrupting acute exacerbations of eczema that can become self-perpetuating if unchecked.

Pathogenesis. Eczematous dermatitis typically results from T cell-mediated inflammatory reactions (type IV hypersensitivity). This has been well studied in dermatitis triggered by contact antigens (e.g., uroshiol from poison ivy). It is believed that reactive chemicals introduced at the epidermal surface modify self proteins, acting as “haptens”, and these proteins become neoantigens. The antigens are

taken up by Langerhans cells, which then migrate by way of dermal lymphatics to draining lymph nodes. Here the antigens are presented to naive CD4⁺ T cells, which are activated and develop into effector and memory cells (Chapter 6). On antigen reexposure, memory T cells expressing homing molecules such as common lymphocyte antigen and particular chemokine receptors migrate to skin sites of antigen localization. Here they release the cytokines and chemokines that recruit the numerous inflammatory cells characteristic of eczema. This process occurs within 24 hours and accounts for the initial erythema and pruritus that characterize cutaneous delayed hypersensitivity in the acute, spongiotic phase.

Langerhans cells within the epidermis play a central role in contact dermatitis, and understandably factors that affect Langerhans cell function impact the inflammatory reaction. Chronic exposure to UV light is injurious to epidermal Langerhans cells and can prevent sensitization to contact antigens, although UV light can also alter antigens and generate forms that are more likely to induce sensitivity reactions.

MORPHOLOGY

All types of eczematous dermatitis are characterized by red, papulovesicular, oozing, and crusted lesions that, if persistent, develop reactive **acanthosis** and **hyperkeratosis** that produce raised scaling plaques (Fig. 25-22). A striking example of

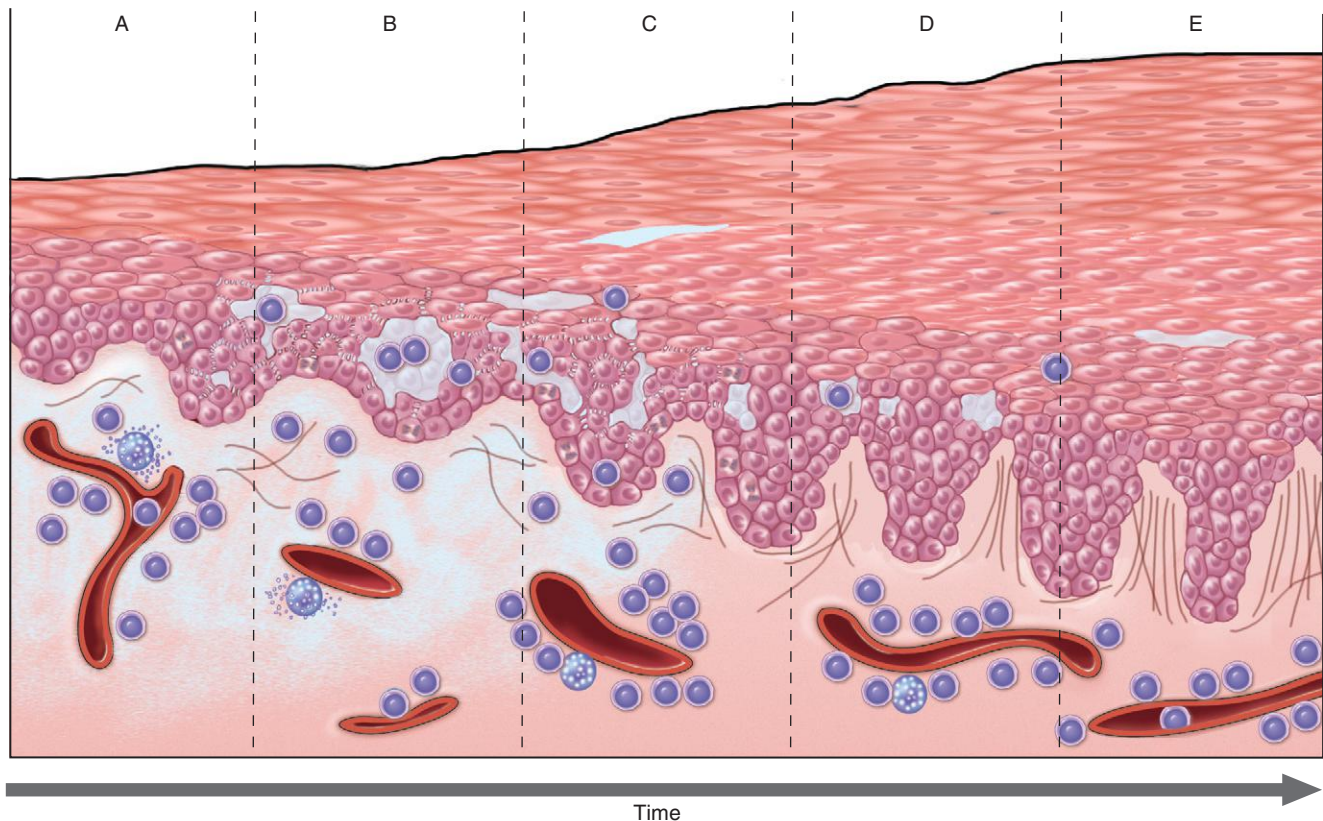

Figure 25-22 Stages of eczema development. **A**, Initial dermal edema and perivascular infiltration by inflammatory cells is followed within 24 to 48 hours by **(B)** epidermal spongiosis and microvesicle formation. **C**, Abnormal scale, including parakeratosis, along with progressive acanthosis **(D)** and hyperkeratosis **(E)** appear as the lesion becomes chronic.

Figure 25-23 Eczematous dermatitis. **A**, Acute allergic contact dermatitis due to antigen exposure (in this case, laundry detergent in clothing) marked by numerous vesicular lesions on erythematous skin. **B**, Edema within the epidermis creates small fluid-filled intraepidermal vesicles.

eczema is an acute contact reaction to topical antigens such as urushiol in poison ivy/oak (*Rhus toxicodendron*), characterized by pruritic, edematous, oozing plaques, often containing small and large blisters (vesicles and bullae) (Fig. 25-23A). Such lesions are prone to bacterial superinfection, which produces a yellow crust (impetiginization). With time, persistent lesions become less “wet” (fail to ooze or form vesicles) and become progressively (hyperkeratotic and acanthotic). **Spongiosis** characterizes acute eczematous dermatitis, hence the histologic synonym spongiotic dermatitis. Unlike urticaria, in which edema is restricted to the superficial dermis, edema seeps into the intercellular spaces of the epidermis, splaying apart keratinocytes, particularly in the stratum spinosum. Mechanical shearing of intercellular attachment sites (desmosomes) and cell membranes by progressive accumulation of intercellular fluid may result in the formation of intraepidermal vesicles (Fig. 25-23B).

During the earliest stages of eczematous dermatitis, there is a superficial, perivascular, lymphocytic infiltrate associated with papillary dermal edema and mast cell degranulation. The pattern and composition of this infiltrate may provide clues to the underlying cause. For example, eczema resulting from certain ingested drugs is marked by a lymphocytic infiltrate, often containing eosinophils, around deep as well as superficial dermal vessels. By contrast, eczematous dermatitis resulting from contact antigens tends to produce a mononuclear inflammatory reaction that preferentially affects the superficial dermal layer.

Erythema Multiforme

Erythema multiforme is an uncommon self-limited hypersensitivity reaction to certain infections and drugs. It affects individuals of any age and is associated with the following conditions: (1) infections such as herpes simplex, mycoplasmal infections, histoplasmosis, coccidioidomycosis, typhoid, and leprosy, among others; (2) exposure to certain drugs (sulfonamides, penicillin, barbiturates, salicylates, hydantoin, and antimalarials); (3) cancer (carcinomas and lymphomas); and (4) collagen vascular diseases (lupus erythematosus, dermatomyositis, and polyarteritis nodosa).

Pathogenesis. Erythema multiforme is characterized by **keratinocyte injury mediated by skin-homing CD8+ cytotoxic T lymphocytes**. This mechanism of injury is shared with a number of other conditions, including acute graft-versus-host disease, skin allograft rejection, and fixed drug eruptions. In erythema multiforme, CD8+ cytotoxic T cells are more prominent in the central portion of the lesions, while CD4+ helper T cell and Langerhans cells are more prevalent in the peripheral portions. The epidermal antigens that are recognized by the infiltrating T cells in erythema multiforme remain unknown.

MORPHOLOGY

Affected individuals present with a diverse array of lesions (hence the term multiforme), including macules, papules, vesicles, bullae, and characteristic targetoid (target-like) lesions (Fig. 25-24A). The lesions may occur in a variety of distributions. Cases that are limited in extent often show symmetric involvement of the extremities. A febrile form associated with extensive involvement of the skin is called **Stevens-Johnson syndrome**, which is often (but not exclusively) seen in children. In Stevens-Johnson syndrome, lesions involve not only the skin but also the lips and oral mucosa, conjunctiva, urethra, and genital and perianal areas. Secondary infection of involved areas due to loss of skin integrity may result in life-threatening sepsis. Another variant termed **toxic epidermal necrolysis** is characterized by diffuse necrosis and sloughing of cutaneous and mucosal epithelial surfaces. The widespread epidermal damage produces a clinical picture similar to that seen in patients with extensive burns.

On histologic examination, the “targetoid” lesions show a superficial perivascular, lymphocytic infiltrate associated with dermal edema and accumulation of lymphocytes along the dermoepidermal junction, where they are intimately associated with degenerating and necrotic keratinocytes, a pattern termed **interface dermatitis** (Fig. 25-24B). With time there is upward migration of lymphocytes into the epidermis. Discrete and confluent zones of epidermal necrosis occur with concomitant blister formation. Epidermal sloughing leads to shallow erosions.

Figure 25-24 Erythema multiforme. **A**, The target-like lesions consist of a central blister or zone of epidermal necrosis surrounded by macular erythema. **B**, An early lesion shows lymphocytes accumulating along the dermoepidermal junction where basal keratinocytes have begun to become vacuolated (arrow). With time, necrotic/apoptotic keratinocytes appear in the overlying epithelium (double arrow).

Chronic Inflammatory Dermatoses

This category includes inflammatory skin disorders that persist for many months to years. The skin surface in some chronic inflammatory dermatoses is roughened as a result of excessive or abnormal scale formation and shedding. However, not all scaling lesions are inflammatory; witness the hereditary ichthyoses, described earlier, with extensive scale due to defects in desquamation.

Psoriasis

Psoriasis is a chronic inflammatory dermatosis that appears to have an autoimmune basis. It is a common disorder, affecting as many as 1% to 2% of people in the United States. Persons of all ages may develop the disease. Approximately 15% of the patients with psoriasis have associated arthritis. Psoriatic arthritis may be mild or may produce severe deformities resembling the joint changes seen in rheumatoid arthritis. It can affect any joint in the body and may be symmetrical or affect one side only. In addition, psoriasis may also be associated with myopathy, enteropathy, and AIDS.

Pathogenesis. Psoriasis results from interactions of genetic and environmental factors. As in the case of many autoimmune diseases it is linked to genes within the HLA locus. There is a strong association with HLA-C, particularly with the *HLA-Cw*0602* allele. About two thirds of affected individuals carry this allele, and homozygotes for *HLA-Cw*0602* have a 2.5-fold higher risk for developing psoriasis than do heterozygotes. Conversely, only about 10% of *HLA-Cw*0602* heterozygotes develop psoriasis, indicating that other factors interact with this MHC molecule to cause disease susceptibility. The culprit antigens remain elusive, but it appears that sensitized populations of CD4+ T_H1 and T_H17 cells and activated CD8+ cytotoxic effector T cells enter the skin and accumulate in the epidermis. These T cells may create an abnormal microenvironment by stimulating the secretion of cytokines and growth factors that induce keratinocyte proliferation, resulting in the charac-

teristic lesions. The interactions between CD4+ T cells, CD8+ T cells, dendritic cells, and keratinocytes give rise to a cytokine “soup” dominated by T_H1-type and T_H17-type cytokines such as IL-12, interferon- γ , tumor necrosis factor (TNF), and IL-17. The importance of these factors is highlighted by the generally excellent clinical responses that are observed in patients treated with therapies that block TNF function. Lymphocytes also produce growth factors for keratinocytes that may contribute to epidermal thickening. Psoriatic lesions can be induced in susceptible individuals by local trauma, a process known as the *Koebner phenomenon*, presumably because trauma sets in motion a local inflammatory response that becomes self-perpetuating.

MORPHOLOGY

Psoriasis most frequently affects the skin of the elbows, knees, scalp, lumbosacral areas, intergluteal cleft, and glans penis. The typical lesion is a well-demarcated, **pink to salmon-colored plaque covered by loosely adherent silver-white scale** (Fig. 25-25A). Variations exist, with some lesions occurring in annular, linear, gyrate, or serpiginous configurations. Psoriasis is one cause of total body erythema and scaling known as erythroderma. **Nail changes** occur in 30% of cases of psoriasis and consist of yellow-brown discoloration (often likened to an oil slick), with pitting, dimpling, separation of the nail plate from the underlying bed (onycholysis), thickening, and crumbling.

Established lesions of psoriasis have a characteristic histologic picture. Increased epidermal cell proliferation results in marked epidermal thickening (acanthosis), with regular downward elongation of the rete ridges sometimes described as appearing like test tubes in a rack (Fig. 25-25B). Mitotic figures are easily identified well above the basal cell layer, where mitotic activity is confined in normal skin. **The stratum granulosum is thinned or absent, and extensive overlying parakeratotic scale is seen.** Typical of psoriatic plaques is thinning of the portion of the epidermal cell layer that overlies the tips of dermal papillae (suprapapillary plates) and dilated, tortuous blood vessels within these papillae. This constellation of changes results in abnormal proximity of vessels within the dermal papillae to the overlying parakeratotic scale, and accounts for

Figure 25-25 Psoriasis. **A**, Early lesions may be dominated by inflammation, marked by the presence of small pustules and erythema (*left*). Established chronic lesions are erythematous and covered by a characteristic silver-white scale (*right*). **B**, Microscopically there is epidermal hyperplasia, parakeratotic scale, and accumulation of neutrophils within the superficial epidermis.

the characteristic clinical phenomenon of multiple, minute, bleeding points when the scale is lifted from the plaque (**Auspitz sign**). Neutrophils form small aggregates within slightly spongiotic foci of the superficial epidermis (**spongiform pustules**) and within the parakeratotic stratum corneum (**Munro microabscesses**). In pustular psoriasis, larger abscess-like accumulations of neutrophils are present directly beneath the stratum corneum.

Seborrheic Dermatitis

Seborrheic dermatitis is a chronic inflammatory dermatosis that is even more common than psoriasis, affecting up to 5 % of the general population. It classically involves regions with a high density of sebaceous glands, such as the scalp, forehead (especially the glabella), external auditory canal, retroauricular area, nasolabial folds, and the presternal area. Despite this association and its name, however, seborrheic dermatitis is associated with inflammation of the epidermis and is not a disease of the sebaceous glands per se.

Pathogenesis. The precise etiology of seborrheic dermatitis is unknown. Increased sebum production, often in response to androgens, is one possible contributory factor. Involvement of sebum is supported by clinical observations of patients with Parkinson disease, who typically show increased sebum production secondary to dopamine deficiency and have a markedly increased incidence of seborrheic dermatitis. Once treated with levodopa, the oiliness of the skin decreases and the seborrheic dermatitis improves. However, other conditions associated with increased sebum production such as acne (discussed later) are not associated with seborrheic dermatitis, and sebum production is probably best viewed as being necessary but not sufficient to cause the disorder. Other work has suggested a relationship with colonization of the skin by certain fungal species of the genus *Malassezia*, but there is no definitive evidence of a cause and effect relationship. A severe form of seborrheic dermatitis that is difficult to treat is seen in many HIV-infected individuals with low CD4

counts; as with other forms of the disorder, its etiology is also unknown.

MORPHOLOGY

The individual lesions are macules and papules on an erythematous-yellow, often greasy base, typically in association with extensive scaling and crusting. Fissures may also be present, particularly behind the ears. Dandruff is the common clinical expression of seborrheic dermatitis of the scalp. Microscopically, seborrheic dermatitis shares features with both spongiotic dermatitis and psoriasis, with earlier lesions being more spongiotic and later ones more acanthotic. Typically, mounds of parakeratosis containing neutrophils and serum are present at the ostia of hair follicles (so-called **follicular lipping**). A superficial perivascular inflammatory infiltrate generally consists of an admixture of lymphocytes and neutrophils. With human immunodeficiency virus infection, apoptotic keratinocytes and plasma cells may also be present.

Lichen Planus

“Pruritic, purple, polygonal, planar, papules, and plaques” are the tongue-twisting **“six Ps”** of lichen planus, a disorder of skin and mucosa. Lichen planus is usually self-limited, most commonly resolving spontaneously 1 to 2 years after onset. Resolution often leaves a residuum of postinflammatory hyperpigmentation. Oral lesions, however, may persist for years. Squamous cell carcinoma has been noted to occur in chronic mucosal and paramucosal lesions of lichen planus, and could be an example of carcinogenesis in the setting of a chronic inflammatory process. As in psoriasis, the Koebner phenomenon may be seen in lichen planus.

Pathogenesis. The pathogenesis of lichen planus is not known. It is plausible that expression of altered antigens in basal epidermal cells or the dermoepidermal junction elicit a cell-mediated cytotoxic (CD8+) T cell response. In support of this notion, T-lymphocyte infiltrates and hyperplasia of Langerhans cells are characteristic features of this disorder.

Figure 25-26 Lichen planus. **A**, This flat-topped pink-purple, polygonal papule has a white lacelike pattern of lines that are referred to as Wickham striae. **B**, There is a bandlike infiltrate of lymphocytes at the dermoepidermal junction, hyperkeratosis, and pointed rete ridges (sawtoothing), the latter as a result of chronic basal cell layer injury.

MORPHOLOGY

Cutaneous lesions consist of itchy, violaceous, flat-topped papules that may coalesce focally to form plaques (Fig. 25-26A). These papules are often highlighted by white dots or lines called **Wickham striae**, which are created by areas of hypergranulosis. In darkly pigmented individuals, lesions may acquire a dark-brown color due to release of melanin into the dermis as the basal cell layer is destroyed. Lesions are usually multiple and symmetrically distributed, particularly on the extremities and often about the wrists and elbows. The glans penis is another common site of involvement. In 70% of cases, oral lesions are present as white, reticulated, or netlike areas involving the mucosa.

Lichen planus is characterized histologically by a dense, continuous infiltrate of lymphocytes along the dermoepidermal junction, a prototypic example of **interface dermatitis** (Fig. 25-26B). The lymphocytes are intimately associated with basal keratinocytes, which show degeneration, necrosis, and a resemblance in size and contour to more mature cells of the stratum spinosum (squamatization). As a consequence of this destructive lymphocytic infiltrate, the dermoepidermal interface takes on an angulated zigzag contour (sawtoothing). Anucleate, necrotic basal cells may become incorporated into the inflamed papillary dermis, where they are referred to as **colloid** or **Civatte bodies**. Though characteristic of lichen planus, these bodies may be detected in any chronic dermatitis in which basal keratinocytes are destroyed. Although the lesions bear some similarities to those in erythema multiforme, lichen planus shows changes of chronicity, namely, epidermal hyperplasia (or rarely atrophy) and thickening of the granular cell layer and stratum corneum (hypergranulosis and hyperkeratosis, respectively).

KEY CONCEPTS

Inflammatory Dermatoses

- Many specific inflammatory dermatoses exist, which can be mediated by IgE antibodies (urticaria) or antigen-specific T cells (eczema, erythema multiforme, and psoriasis)

- These disorders are diagnosed based on the distribution and gross appearance of skin lesions and the microscopic patterns of inflammation (e.g., interface dermatitis in lichen planus and erythema multiforme)

Blistering (Bullous) Diseases

Although vesicles and bullae (blisters) occur in several unrelated conditions such as herpesvirus infection, spongiotic dermatitis, erythema multiforme, and thermal burns, there exists a group of disorders in which blisters are the primary and most distinctive features. These *bullous diseases*, as they are called, produce dramatic lesions and in some instances are fatal if untreated. Blisters in the various disorders occur at different levels within the skin (Fig. 25-27); histologic assessment is essential for accurate diagnosis and provides insight into the pathogenic mechanisms. Knowledge of the structure of desmosomes and hemidesmosomes (described in Chapter 1), which you will recall provide the skin with mechanical stability, is helpful in understanding these diseases, as they are often caused by acquired or inherited defects in proteins that make up or bind to these structures (Fig. 25-28).

Inflammatory Blistering Disorders

Pemphigus

Pemphigus is a blistering disorder caused by autoantibodies that result in the dissolution of intercellular attachments within the epidermis and mucosal epithelium. The pathobiology of blistering disorders provides important insights into the molecular underpinnings of keratinocyte adhesion. The majority of individuals who develop pemphigus are in the fourth to sixth decades of life, and men and women are affected equally. There are multiple variants: (1) pemphigus vulgaris, (2) pemphigus vegetans, (3) pemphigus foliaceus, (4) pemphigus erythematosus, and (5) paraneoplastic pemphigus. These disorders are usually benign, but in extreme cases can be fatal without treatment.

Figure 25-27 Schematic representation of different types of blisters. **A**, In subcorneal blisters, the stratum corneum forms the roof of the bulla (as in pemphigus foliaceus). **B**, In a suprabasilar blister, a portion of the epidermis, including the stratum corneum, forms the roof (as in pemphigus vulgaris). **C**, In a subepidermal blister, the entire epidermis separates from the dermis (as in bullous pemphigoid).

- *Pemphigus vulgaris*, by far the most common type (accounting for more than 80% of cases worldwide), involves the mucosa and skin, especially on the scalp, face, axilla, groin, trunk, and points of pressure. It may present as oral ulcers that may persist for months before skin involvement appears. Primary lesions are superficial vesicles and bullae that rupture easily, leaving shallow erosions covered with dried serum and crust (Fig. 25-29A).
- *Pemphigus vegetans* is a rare form that usually presents not with blisters but with large, moist, verrucous (wart-like), vegetating plaques studded with pustules on the groin, axillae, and flexural surfaces.
- *Pemphigus foliaceus* is a more benign form that is endemic in Brazil (where it is called *fogo selvagem*) and occurs sporadically in other geographic regions. Sites of predilection are the scalp, face, chest, and back, and the mucous membranes are only rarely affected. Bullae are so superficial that they mainly present as areas of erythema and crusting; these represent superficial erosions at sites of previous blister rupture (Fig. 25-30A).
- *Pemphigus erythematosus* is considered to be a localized, less severe form of pemphigus foliaceus that may selectively involve the malar area of the face in a lupus erythematosus-like fashion.

Figure 25-28 Keratinocyte adhesion molecules and blistering inflammatory disorders. Knowledge of the proteins composing desmosomes and hemidesmosomes is key to understanding blistering disorders. Desmogleins 1 and 3 (Dsg1, Dsg3) are functionally interchangeable components of desmosomes, but have different distributions within the epidermis (left panel). The major structural proteins of desmosomes and hemidesmosomes are shown at right. In pemphigus vulgaris autoantibodies against Dsg1 and Dsg3 cause blisters in the deep suprabasal epidermis, whereas in pemphigus foliaceus the autoantibodies are against Dsg1 alone, leading to superficial, subcorneal blisters. In bullous pemphigoid autoantibodies bind BPAG2, a component of the hemidesmosomes, leading to blister formation at the level of the lamina lucida of the basement membrane. Dermatitis herpetiformis is caused by IgA autoantibodies to the fibrils that anchor hemidesmosomes to the dermis.

Figure 25-29 Pemphigus vulgaris. **A**, Eroded plaques are formed following the rupture of confluent, thin-roofed bullae, here affecting axillary skin. **B**, Suprabasal acantholysis results in an intraepidermal blister in which dyscohesive (acantholytic) epidermal cells are present (*inset*). **C**, Ulcerated blisters in the oral mucosa are also common, as seen here on the lip.

- *Paraneoplastic pemphigus* occurs in association with various malignancies, most commonly non-Hodgkin lymphoma.

Pathogenesis. All forms of pemphigus are autoimmune diseases caused by IgG autoantibodies against desmogleins that disrupt intercellular adhesions and result in the formation of blisters. By direct immunofluorescence, lesions show a characteristic net-like pattern of intercellular IgG deposits. IgG is usually seen at all levels of the epithelium in pemphigus vulgaris, but tends to be more superficial in pemphigus foliaceus (Fig. 25-31). The distribution of desmoglein 1 and 3 in the epidermis and the presence of autoantibodies to one or both proteins appear to explain the position and severity of the blisters (Fig. 25-28). The antibodies cause these lesions primarily by disrupting the intercellular adhesive function of the desmosomes; they may also act indirectly by activating intercellular proteases. Paraneoplastic pemphigus arises

most often in the setting of lymphoid neoplasms, and is also caused by autoantibodies that recognize desmogleins or other proteins involved in intercellular adhesion.

MORPHOLOGY

The common histologic denominator in all forms of pemphigus is **acantholysis**, the dissolution or lysis of the intercellular bridges that connect squamous epithelial cells. Acantholytic cells dissociate from one another, lose their polyhedral shape and become rounded. In pemphigus vulgaris and pemphigus vegetans, acantholysis selectively involves the cells immediately above the basal cell layer. In the vegetans variant, there is also overlying epidermal hyperplasia. An immediately **suprabasal acantholytic blister** is characteristic of pemphigus vulgaris (Fig. 25-29B). The single layer of intact basal cells that forms the blister base has been likened to a row of tombstones. In pemphigus foliaceus, blisters form by similar mechanisms but,

Figure 25-30 Pemphigus foliaceus. **A**, The delicate superficial (subcorneal) blisters are much less erosive than those seen in pemphigus vulgaris. **B**, Subcorneal separation of the epithelium is seen.

Figure 25-31 Direct immunofluorescence staining for immunoglobulin of epidermis involved by pemphigus. **A**, In pemphigus vulgaris there is deposition of immunoglobulin along the plasma membranes of keratinocytes in a reticular or fishnet-like pattern accompanied by suprabasilar loss of cell-to-cell adhesion (acantholysis). **B**, In pemphigus foliaceus the immunoglobulin deposits and acantholysis are more superficial.

unlike pemphigus vulgaris, are found in the superficial epidermis at the level of the stratum granulosum (Fig. 25-30B). Variable superficial dermal infiltration by lymphocytes, macrophages, and eosinophils accompanies each type of pemphigus.

The mainstay of treatment in all forms of pemphigus is immunosuppressive agents, which decrease the titers of the pathogenic antibodies.

Bullous Pemphigoid

Generally affecting elderly individuals, bullous pemphigoid shows a wide range of clinical presentations. Sites of involvement include the inner aspects of the thighs, flexor surfaces of the forearms, axillae, groin, and lower abdomen.

Figure 25-32 Bullous pemphigoid. **A**, Bullae consist of tense subepidermal blisters that usually fail to rupture, as their roof consists of the full epidermal thickness. Ulcers form when the blisters are rupture. **B**, An intact sub-basilar blister associated with eosinophils, lymphocytes and occasional neutrophils.

Oral lesions are present in 10% to 15% of affected individuals, usually appearing after the cutaneous lesions. Some patients may present with urticarial plaques associated with severe pruritus.

Pathogenesis. Bullous pemphigoid is caused by autoantibodies that bind to proteins that are required for adherence of basal keratinocytes to the basement membrane. Most antibody deposition occurs in a continuous linear pattern at the dermoepidermal junction (Fig. 25-33A), which contains specialized structures called hemidesmosomes that link basal keratinocytes to the underlying basement membrane (Fig. 25-33B). The so-called bullous pemphigoid antigens (BPAGs) are components of hemidesmosomes (Fig. 25-29). Antibodies against one such component called BPAG2 are proven to cause blistering. Pathogenic autoantibodies also activate complement, leading to the recruitment of neutrophils and eosinophils, inflammation, and disruption of epidermal attachments.

MORPHOLOGY

The lesions are tense bullae filled with clear fluid involving erythematous or normal-appearing skin (Fig. 25-32A). The bullae are usually less than 2 cm in diameter but occasionally may reach 4 to 8 cm in diameter. They do not rupture easily, unlike the blisters seen in pemphigus, and heal without scarring unless they become infected secondarily. The separation of bullous pemphigoid from pemphigus is based on the identification of **subepidermal, nonacantholytic** blisters. Early lesions show a superficial and sometimes deep perivascular infiltrate of lymphocytes and variable numbers of eosinophils, occasional neutrophils, superficial dermal edema, and associated basal cell layer vacuolization (Fig. 25-32B). Eosinophils showing degranulation are typically detected directly beneath the epidermal basal cell layer. The vacuolated basal cell layer eventually lifts away, allowing space for a fluid-filled blister to form.

Dermatitis Herpetiformis

Dermatitis herpetiformis is a rare disorder characterized by urticaria and grouped vesicles. The disease affects predominantly males, most often in the third and fourth

Figure 25-33 **A**, Linear deposition of complement along the dermoepidermal junction in bullous pemphigoid. **B**, Electron micrograph showing the ultrastructural features of the dermoepidermal junction. The bullous pemphigoid antigen (BPAG) is located in the basal portion of basal keratinocytes in association with hemidesmosomes (HD), which attach the epidermis to the lamina lucida (LL) of the basement membrane. AF, Anchoring fibrils; LD, lamina densa. (See also Fig. 25-31.)

decades of life. In some cases it occurs in association with intestinal celiac disease and responds to a gluten-free diet (Chapter 17). The plaques and vesicles are extremely pruritic.

Pathogenesis. The association of dermatitis herpetiformis with celiac disease provides a clue to its pathogenesis. Genetically predisposed individuals develop IgA antibodies to dietary gluten (derived from the wheat protein *gliadin*). The antibodies cross-react with reticulin, a component of the anchoring fibrils that tether the epidermal basement membrane to the superficial dermis. The resultant injury and inflammation produce a subepidermal blister. In some people with dermatitis herpetiformis and gluten-sensitive enteropathy, both disorders respond to a gluten-free diet.

MORPHOLOGY

The lesions are bilateral, symmetric and grouped, involving preferentially the extensor surfaces, elbows, knees, upper back, and buttocks (Fig. 25-34C). Fibrin and neutrophils accumulate selectively at the **tips of dermal papillae**, forming small microabscesses (Fig. 25-34A). The basal cells overlying these microabscesses show vacuolization and focal dermoepidermal separation that ultimately coalesce to form a true **subepidermal blister**. By direct immunofluorescence, dermatitis herpetiformis shows discontinuous, **granular deposits of IgA** that selectively localize in the tips of dermal papillae (Fig. 25-34B).

Noninflammatory Blistering Disorders

Epidermolysis Bullosa and Porphyria

Some disorders characterized by vesicles and bullae are mediated by inherited or in some cases acquired defects involving structural proteins that maintain the normal organization of the skin. Two such disorders are epidermolysis bullosa and porphyria.

Epidermolysis Bullosa. Epidermolysis bullosa is a blanket term for a group of disorders caused by inherited defects in structural proteins that lend mechanical stability to the skin. The common feature is a proclivity to form blisters at sites of pressure, rubbing, or trauma, at or soon after birth. The histologic changes in all forms are so subtle that electron microscopy may be required to differentiate among the various types.

- In the *simplex type*, defects of the basal cell layer of the epidermis almost always result from mutations in the genes encoding keratin 14 or keratin 5. These two proteins normally pair with one another to make a functional keratin fiber, thus explaining the similar phenotype resulting from mutations in either gene. The mutated proteins have a dominant negative activity, and as a result the disorder shows an autosomal dominant mode of inheritance. This is the most common type of epidermolysis bullosa, encompassing 75% to 85% of cases.
- In the *junctional type*, blisters occur in otherwise histologically normal skin at precisely the level of the lamina lucida (Figs. 25-35 and 25-28). Most cases are caused by autosomal recessive defects in one of the subunits of laminin, a multicomponent protein located in the lamina lucida that binds to both hemidesmosomes and anchoring filaments. Some of the remaining cases are caused by mutations in BPAG2, the same protein that is targeted by autoantibodies in bullous pemphigoid.
- In the scarring *dystrophic types*, blisters develop beneath the lamina densa in association with rudimentary or defective anchoring fibrils. Dystrophic epidermolysis bullosa usually results from mutations in the *COL7A1* gene, which encodes type VII collagen (Chapter 3), a major component of the basement membrane anchoring fibrils. Depending on the mutation, the disorder may follow an autosomal dominant or autosomal recessive mode of inheritance.
- *Mixed types*, marked by defects at several levels, are also recognized.

Porphyria. *Porphyria* refers to a group of uncommon inborn or acquired disturbances of porphyrin metabolism.

Figure 25-34 Dermatitis herpetiformis. **A**, Lesions consist of intact and eroded (usually scratched) erythematous blisters, often grouped (seen here on elbows and arms). **B**, Selective deposition of IgA autoantibody at the tips of dermal papillae is characteristic. **C**, The blisters are associated with the accumulation of neutrophils (microabscesses) at the tips of dermal papillae. (**B**, Courtesy Dr. Victor G. Prieto, Houston, Texas.)

Porphyrias are pigments that are normally present in hemoglobin, myoglobin, and cytochromes. The classification of porphyrias is based on both clinical and biochemical features. The five major types are (1) congenital erythropoietic porphyria, (2) erythrohepatic protoporphyria, (3) acute intermittent porphyria, (4) porphyria cutanea tarda, and (5) mixed porphyria. Cutaneous manifestations consist of urticaria and vesicles associated with scarring that are exacerbated by exposure to sunlight. The vesicles are subepidermal in location and the adjacent dermis contains vessels with walls that are thickened by glassy deposits of serum proteins, including immunoglobulins (Fig. 25-36). The pathogenesis of these alterations is not understood.

KEY CONCEPTS

Blistering Disorders

- Blistering disorders are classified based on the level of epidermal separation.
- These disorders are often caused by autoantibodies specific for epithelial or basement membrane proteins that lead to unmooring of keratinocytes (acantholysis).
- Pemphigus is associated with IgG autoantibodies to various intercellular desmogleins, resulting in bullae that are either subcorneal (pemphigus foliaceus) or suprabasilar (pemphigus vulgaris).
- Bullous pemphigoid is associated with IgG autoantibodies to basement membrane proteins and produces a subepidermal blister.
- Dermatitis herpetiformis is associated with IgA autoantibodies to fibrils that bind the epidermal basement membrane to the dermis, and also produces subepidermal blisters.
- None inflammatory blistering disorders include inherited defects in proteins that stabilize the epidermis (e.g., epidermolysis bullosa) and inherited defects in porphyrin synthesis (the porphyrias) that lead to sun-induced skin damage through uncertain mechanisms.

Disorders of Epidermal Appendages

Acne Vulgaris

Virtually universal in the middle to late teenage years, acne vulgaris affects both males and females, although males tend to have more severe disease. Acne is seen in all races but is usually milder in people of Asian descent. It may be induced or exacerbated by drugs (corticosteroids, adrenocorticotrophic hormone, testosterone, gonadotropins, contraceptives, trimethadione, iodides, and bromides), occupational exposures (cutting oils, chlorinated hydrocarbons, and coal tars), and conditions that favor occlusion of

Figure 25-35 Epidermolysis bullosa. **A**, Junctional epidermolysis bullosa showing typical erosions in flexural creases. **B**, A subepidermal blister at the level of the lamina lucida. There is no associated inflammation.

sebaceous glands, such as heavy clothing, cosmetics, and tropical climates. Some families seem to be particularly prone to acne, suggesting a hereditary component.

Acne is divided into noninflammatory and inflammatory types, although both types may coexist. Noninflammatory acne may take the form of open and closed comedones.

- *Open comedones* are small follicular papules containing a central black keratin plug. This color is the result of oxidation of melanin pigment (not dirt).
- *Closed comedones* are follicular papules without a visible central plug. Because the keratin plug is trapped beneath the epidermal surface, these lesions are potential sources of follicular rupture and inflammation.

Figure 25-36 Porphyria. A noninflammatory blister at the dermoepidermal junction; note the seemingly rigid dermal papillae at the base that contain abnormal superficial vessels.

Pathogenesis. The pathogenesis of acne is incompletely understood and is likely multifactorial. At least four factors contribute to its development: (1) keratinization of the lower portion of the follicular infundibulum and development of a keratin plug that blocks outflow of sebum to the skin surface, (2) hypertrophy of sebaceous glands during puberty under the influence of androgens, (3) lipase-synthesizing bacteria (*Propionibacterium acnes*) colonizing the upper and midportion of the hair follicle, converting lipids within sebum to proinflammatory fatty acids, and (4) secondary inflammation of the involved follicle. Androgens, which increase sebum production, were first implicated in times past when it was noted that young castrated males generally did not develop the condition (a questionable tradeoff). Elimination of *P. acnes* is the rationale for administration of antibiotics to individuals with inflammatory acne. The synthetic vitamin A derivative 13-*cis*-retinoic acid (isotretinoin) brings about remarkable improvement in some cases of severe acne through its strong antisebaceous action.

MORPHOLOGY

Inflammatory acne is marked by erythematous papules, nodules, and pustules (Fig. 25-37A). Severe variants (e.g., **acne conglobata**) result in sinus tract formation and dermal scarring. Depending on the stage of the disease, open or closed comedones, papules, pustules, or deep inflammatory nodules may develop. **Open comedones** have large, patulous orifices, whereas those of **closed comedones** are identifiable only microscopically (Fig. 25-37B, C). Variable infiltrates of lymphocytes and macrophages are present in and around affected follicles, and extensive acute inflammation accompanies follicular rupture. Dermal abscesses may form in association with rupture (Fig. 25-37B) and lead to scarring.

Rosacea

Rosacea is a common disease of middle age and beyond, affecting up to 3% of the US population, with a predilection for females. Four stages are recognized: (1) flushing episodes (pre-rosacea), (2) persistent erythema and

Figure 25-37 Acne. **A**, Inflammatory acne associated with erythematous papules and pustules. **B**, A hair shaft pierces the follicular epithelium, eliciting inflammation and fibrosis. **C**, An open comedone.

telangiectasia, (3) pustules and papules, and (4) rhinophyma—permanent thickening of the nasal skin by confluent erythematous papules and prominent follicles.

Pathogenesis. Individuals with rosacea have high cutaneous levels of the antimicrobial peptide cathelicidin, an important mediator of the cutaneous innate immune response. *The cathelicidin peptides present are qualitatively distinct from those seen in individuals without rosacea as a result of alternative processing by proteases such as kallikrein 5 (also known as stratum corneum tryptic enzyme).* Injection of cathelicidin peptides from patients into mice induces some of the cutaneous changes seen in rosacea, including inflammation and vascular dilation. In addition, it has been noted that activation of Toll-like receptor 2 (TLR2) up-regulates kallikrein 5 expression in keratinocytes, suggesting that factors that stimulate TLR2 are involved. Several microbial triggers have been proposed, but none are proven.

MORPHOLOGY

Rosacea is characterized by a nonspecific perifollicular infiltrate composed of lymphocytes surrounded by dermal edema and telangiectasia. In the pustular phase neutrophils may colonize the follicles, and follicular rupture may cause a granulomatous dermal response. The development of rhinophyma is associated with hypertrophy of sebaceous glands and follicular plugging by keratotic debris.

Panniculitis

Erythema Nodosum and Erythema Induratum

Panniculitis is an inflammatory reaction in the subcutaneous adipose tissue that may preferentially affect (1) the lobules of fat, or (2) the connective tissue that separates fat into lobules. Panniculitis often involves the lower legs. *Erythema nodosum* is the most common form and usually has a subacute presentation. A second somewhat distinctive form, *erythema induratum*, also merits brief discussion.

- *Erythema nodosum* presents as poorly defined, exquisitely tender, erythematous plaques and nodules that may be more readily palpated than seen. Its occurrence is often associated with infections (β -hemolytic streptococcal infection, tuberculosis and, less commonly, coccidioidomycosis, histoplasmosis, and leprosy), drug administration (sulfonamides, oral contraceptives), sarcoidosis, inflammatory bowel disease, and certain malignant neoplasms, but many times a cause cannot be identified. Fever and malaise may accompany the cutaneous signs. It is considered to be caused by a delayed hypersensitivity reaction to microbial or drug related antigens. In some cases immune complexes have been implicated but in many cases the pathogenesis remains mysterious. Over the course of weeks, lesions usually flatten and become bruiselike, leaving no residual clinical scars, while new lesions develop. Biopsy of a deep wedge of tissue to generously sample the subcutis is usually required for histologic diagnosis.
- *Erythema induratum* is an uncommon type of panniculitis that affects primarily adolescents and menopausal women. Although the cause is not known, most observers regard this as a primary vasculitis of deep vessels supplying the fat lobules of the subcutis; the associated vascular compromise leads to fat necrosis and inflammation. *Erythema induratum* presents as an erythematous, slightly tender nodule that usually goes on to ulcerate. Originally considered a hypersensitivity response to tuberculosis, *erythema induratum* today most commonly occurs without an associated underlying disease.

MORPHOLOGY

The histopathology of **erythema nodosum** is distinctive. In early lesions, the connective tissue septae are widened by edema, fibrin exudation, and neutrophilic infiltration. Later, infiltration by lymphocytes, histiocytes, multinucleated giant cells, and occasional eosinophils is associated with septal fibrosis. Vasculitis is not present. In **erythema induratum**, on the other hand, granulomatous inflammation and zones of caseous necrosis involve the fat lobule. Early lesions show necrotizing vasculitis affecting small- to medium-sized arteries and veins in the deep dermis and subcutis.

Many other types of panniculitis have also been described, a few of which merit brief mention.

- *Weber-Christian disease (relapsing febrile nodular panniculitis)* is a rare form of lobular, nonvasculitic panniculitis seen in children and adults. It is marked by crops of erythematous plaques or nodules, predominantly on the lower extremities, created by deep-seated foci of inflammation containing aggregates of foamy macrophages admixed with lymphocytes, neutrophils, and giant cells.
- *Factitial panniculitis* is a form of secondary panniculitis caused by self-inflicted trauma or injection of foreign or toxic substances.
- Rare types of *T-cell lymphoma* home to fat lobules, producing fat necrosis and superimposed inflammation that mimics panniculitis.
- *Lupus erythematosus* may occasionally cause inflammation of the subcutis and an associated panniculitis.

Infection

The skin frequently succumbs to the attack of microorganisms, parasites, and insects. We have already discussed the possible role of bacteria in the pathogenesis of common acne, and the dermatoses resulting from viruses are too numerous to list. In the setting of the immunocompromised individual, ordinarily trivial cutaneous infections may become life threatening. Many disorders, such as herpes simplex and herpes zoster, the viral exanthems, deep fungal infections, and immune reactions in skin provoked by infectious agents, are discussed in [Chapter 8](#). Here we cover a representative sampling of common infections whose primary clinical manifestations are in the skin.

Verrucae (Warts)

Verrucae are squamoproliferative disorders caused by human papillomaviruses. They are common lesions of children and adolescents, although they may be encountered at any age. Transmission of disease usually involves direct contact between individuals or autoinoculation. Verrucae are generally self-limited, regressing spontaneously within 6 months to 2 years.

Pathogenesis. More than 150 types of papillomavirus have been identified, many of them capable of producing warts in humans. The clinical variants of warts are often associated with distinct HPV subtypes. For example, anogenital warts are caused predominantly by HPV types 6 and 11. HPV type 16 has been associated with in situ squamous cell carcinoma of the genitalia and with *bowenoid papulosis* (genital lesions of young adults with the histologic appearance of carcinoma in situ, but which usually regress spontaneously; see also [Chapter 21](#)). The relationship of HPV subtypes 5 and 8 to squamous cell carcinomas, particularly in individuals affected by the rare condition epidermodysplasia verruciformis, was mentioned earlier. These patients develop multiple flat warts that contain HPV genomes, some of which progress to carcinoma. Viral typing can be accomplished by either in situ hybridization ([Fig. 25-38D](#)) or polymerase chain reaction.

You will recall that HPVs that are associated with a high risk of cancer produce E6 proteins that abolish p53 function ([Chapter 7](#)). By contrast, HPV subtypes 5 and 8 produce variant E6 proteins that do not affect p53, probably explaining why these forms of HPV have low oncogenic potential. Some recent studies suggest that the E6 proteins of low-risk HPVs interfere with Notch signaling, which is known to be required for the normal maturation of keratinocytes, and this effect may contribute to the epidermal hyperplasia that characterizes warts.

MORPHOLOGY

The classification of verrucae is based largely on appearance and location. **Verruca vulgaris** is the most common type of wart. The lesions of verruca vulgaris occur anywhere but most frequently on the hands, particularly on the dorsal surfaces and periungual areas, where they appear as gray-white to tan, flat to convex, 0.1- to 1-cm papules with a rough, pebble-like surface ([Fig. 25-38A](#)). **Verruca plana**, or **flat wart**, is common on the face or the dorsal surfaces of the hands. The warts are slightly elevated, flat, smooth, tan papules that are generally smaller than verruca vulgaris. **Verruca plantaris** and **verruca palmaris** occur on the soles and palms, respectively. Rough, scaly lesions may reach 1 to 2 cm in diameter, coalesce, and be confused with ordinary calluses. **Condyloma acuminatum (venereal wart)** occurs on the penis, female genitalia, urethra, perianal areas, and rectum. Venereal warts appear as soft, tan, cauliflower-like masses that occasionally reach many centimeters in diameter.

Histologic features common to verrucae include epidermal hyperplasia that is often undulant in character, termed **verrucous or papillomatous epidermal hyperplasia** ([Fig. 25-38B](#)); and cytoplasmic vacuolization (koilocytosis) involving the more superficial epidermal layers, producing haloes of pallor surrounding infected nuclei. Electron microscopy of these zones reveals numerous HPV virions within nuclei. Infected cells may also demonstrate prominent and apparently condensed keratohyaline granules and jagged eosinophilic intracytoplasmic keratin aggregates as a result of viral cytopathic effects ([Fig. 25-38C](#)). These cellular alterations are not as prominent in condylomas; hence, their diagnosis is based primarily on hyperplastic papillary architecture containing wedge-shaped zones of koilocytosis.

Molluscum Contagiosum

Molluscum contagiosum is a common, self-limited viral disease of the skin caused by a poxvirus. The virus is characteristically brick shaped, has a dumbbell-shaped DNA core, and measures 300 nm in maximal dimension, and thus represents the largest pathogenic poxvirus in humans and one of the largest viruses in nature. Infection is usually spread by direct contact, particularly among children and young adults.

MORPHOLOGY

Multiple lesions may occur on the skin and mucous membranes, with a predilection for the trunk and anogenital areas. Individual lesions are firm, often pruritic, pink to skin-colored

Figure 25-38 Verruca vulgaris. **A**, Multiple papules with rough pebble-like surfaces. Low power (**B**) and high power (**C**) lesions showing papillomatous epidermal hyperplasia and cytopathic alterations, including nuclear pallor and prominent keratohyaline granules. **D**, In situ hybridization demonstrating HPV DNA within epidermal cells.

umbilicated papules, generally ranging in diameter from 0.2 cm to 0.4 cm. Rarely, “giant” forms occur measuring up to 2 cm in diameter. A curd-like material can be expressed from the central umbilication. Smearing this material onto a glass slide and staining with Giemsa often shows diagnostic molluscum bodies.

On microscopic examination, lesions show cuplike verrucous epidermal hyperplasia. The diagnostically specific structure is the **molluscum body**, which occurs as a large (up to 35 μm), ellipsoid, homogeneous, cytoplasmic inclusion in cells of the stratum granulosum and the stratum corneum (Fig. 25-39). In the hematoxylin and eosin stain, these inclusions are eosinophilic in the blue-purple stratum granulosum and acquire a pale blue hue in the red stratum corneum. Numerous virions are present within molluscum bodies.

Figure 25-39 Molluscum contagiosum. A focus of verrucous epidermal hyperplasia contains numerous cells with ellipsoid cytoplasmic inclusions (molluscum bodies) within the stratum granulosum and stratum corneum.

Impetigo

Impetigo is a common superficial bacterial infection of skin. It is highly contagious and is frequently seen in otherwise healthy children as well as occasionally in adults in poor health. The infection usually involves exposed skin, particularly that of the face and hands. Two forms exist,

classically referred to as *impetigo contagiosa* and *impetigo bullosa*; they differ from each other simply by the size of the pustules. Over the past decade a remarkable shift in etiology has been observed. Whereas in the past impetigo contagiosa was almost exclusively caused by group A β -hemolytic streptococci and impetigo bullosa by *Staphylococcus aureus*, both are now usually caused by *Staphylococcus aureus*.

Pathogenesis. Bacterial species in the epidermis evoke an innate immune response that causes epidermal injury, leading to local serous exudate and formation of a scale crust (scab). The pathogenesis of blister formation in impetigo is related to bacterial production of a toxin that specifically cleaves desmoglein 1, the protein responsible for cell-to-cell adhesion within the uppermost epidermal layers. Recall that in pemphigus foliaceus, which has a similar plane of blister formation, desmoglein 1 is compromised not by a toxin but by an autoantibody (Fig. 25-28). Because there is virtually no involvement of the dermis, once the bacteria are eliminated the lesions heal without scarring.

MORPHOLOGY

Impetigo presents as an erythematous macule, but multiple small pustules rapidly supervene. As pustules break, shallow erosions form, covered with drying serum, giving the characteristic appearance of **honey-colored crust**. If the crust is not removed, new lesions form about the periphery and extensive epidermal damage may ensue. A bullous form of impetigo mainly occurs in children.

The characteristic microscopic feature of impetigo is **accumulation of neutrophils beneath the stratum corneum**, often producing a subcorneal pustule containing serum proteins and inflammatory cells. Special stains reveal the presence of bacteria in these foci. Nonspecific, reactive epidermal alterations and superficial dermal inflammation accompany these findings. Rupture of pustules releases serum, neutrophils, and cellular debris, which layer out and dry to form the characteristic crust.

Superficial Fungal Infections

As opposed to deep fungal infections of the skin, where the dermis or subcutis is primarily involved, superficial fungal infections of the skin are confined to the stratum corneum, and are caused primarily by dermatophytes. These organisms grow in the soil and on animals and produce a number of diverse lesions with characteristic distributions, as follows:

- *Tinea capitis* usually occurs in children and is only rarely seen in infants and adults. It is a dermatophytosis of the scalp characterized by asymptomatic, often hairless patches of skin associated with mild erythema, crust formation, and scaling.
- *Tinea barbae* is a dermatophyte infection of the beard area that affects adult men; it is a relatively uncommon disorder.
- *Tinea corporis*, on the other hand, is a common superficial fungal infection of the body surface that affects persons of all ages, but particularly children. Predisposing factors include excessive heat and humidity, exposure to infected animals, and chronic dermatophytosis of the feet or nails. The most common type of tinea corporis is an expanding, round, slightly erythematous plaque with an elevated scaling border (Fig. 25-40A).
- *Tinea cruris* occurs most frequently in the inguinal areas of obese men during warm weather. Heat, friction, and maceration all predispose to its development. The infection usually first appears on the upper inner thighs as moist, red patches with raised scaly borders.
- *Tinea pedis* (athlete's foot) affects 30% to 40% of the population at some time in their lives. There is diffuse erythema and scaling, often initially localized to the web spaces. Most of the inflammatory reaction, however, appears to be the result of bacterial superinfection and is not directly related to the primary dermatophytosis. Spread to (or primary infection of the nails) is referred to as *onychomycosis*. This produces discoloration, thickening, and deformity of the nail plate.
- *Tinea versicolor* usually occurs on the upper trunk and is highly distinctive in appearance. Caused by *Malassezia furfur* (a yeast, not a dermatophyte), the lesions consist

Figure 25-40 Tinea. **A**, Characteristic plaque of tinea corporis. **B**, Routine histology shows a mild eczematous (spongiotic) dermatitis and focal neutrophilic abscesses. A periodic acid-Schiff stain (inset) reveals deep red hyphae within the stratum corneum.

of groups of macules of varied size and color with a fine peripheral scale.

MORPHOLOGY

The histologic features of dermatophytoses are variable, depending on the properties of the organism, the host response, and the degree of bacterial superinfection. There may be mild eczematous dermatitis associated with intraepidermal neutrophils (Fig. 25-40B). Due to cell walls rich in mucopolysaccharides, fungi stain bright pink to red with periodic acid-Schiff stain. They are found in the anucleate cornified layer of lesional skin, hair, or nails (Fig. 25-40B, inset). Culture of material scraped from these areas usually permits the identification of the offending species.

BONE

Basic Structure and Function of Bone

The adult human skeleton is composed of 206 bones and accounts for approximately 12% of body weight. The functions of bone include mechanical support, transmission of forces generated by muscles, protection of viscera, mineral homeostasis, and providing a niche for production of blood cells. The constituents of bone include an extracellular matrix and specialized cells responsible for production and maintenance of the matrix.

Matrix

Bone matrix is the extracellular component of bone. It is composed of an organic component known as osteoid (35%) and a mineral component (65%). Osteoid is made up of predominantly type I collagen with smaller amounts of glycosaminoglycans and other proteins, which are grouped according to function in Table 26-1. Of these, only osteopontin (also called osteocalcin) is unique to bone. It is produced by osteoblasts and plays a role in bone formation and mineralization and in calcium homeostasis. It is measurable in the serum and serves as a sensitive and specific marker for osteoblast activity. Several cytokines and growth factors also control bone cell proliferation, maturation, and metabolism, thereby playing a crucial role in translating mechanical and metabolic signals into local bone cell activity and eventual skeletal adaptation.

The unique feature of bone matrix, its hardness, is imparted by the inorganic moiety hydroxyapatite [$\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$], which also serves as a repository for 99% of the body's calcium and 85% of its phosphorus. The bone matrix is synthesized in one of two histologic forms, woven or lamellar (Fig. 26-1). Woven bone is produced rapidly, such as during fetal development or fracture repair, but the haphazard arrangement of collagen fibers imparts less structural integrity than the parallel collagen fibers in slowly produced lamellar bone. In an adult, the presence of woven bone is always abnormal, but it is not

specific for any particular bone disease since it can be found in a variety of pathologic settings (discussed later). A cross-section of a typical long bone shows a dense outer cortex and a central medulla composed of bony trabeculae separated by marrow.

Cells

The cellular component of mature bone consists of bone synthesizing osteoblasts, osteocytes, and bone-resorbing osteoclasts.

- **Osteoblasts**, located on the surface of the matrix, synthesize, transport and assemble the matrix and regulate its mineralization (Fig. 26-2A). The synthesis of matrix is tightly regulated by hormonal and local mediators as described in detail later. Over time, osteoblasts may become inactive, indicated by a decrease in cytoplasm. Some inactive cells remain on the surface of

Figure 26-1 Woven bone (A) is more cellular and disorganized than lamellar bone (B).

Figure 26-2 **A**, Active osteoblasts synthesizing bone matrix. The surrounding spindle cells represent osteoprogenitor cells. **B**, Two osteoclasts resorbing bone.

trabecula. Alternatively, they may become embedded within the matrix (osteocytes).

- **Osteocytes** are interconnected by an intricate network of dendritic cytoplasmic processes through tunnels known as canaliculi. Osteocytes help to control calcium and phosphate levels in the microenvironment, and detect mechanical forces and translate them into biologic activity—a process called mechanotransduction.
- **Osteoclasts** are specialized multinucleated macrophages derived from circulating monocytes that are responsible for bone resorption (Fig. 26-2B). By means of cell surface integrins, osteoclasts attach to bone matrix and create a sealed extracellular trench (resorption pit). Secretion of acid and neutral proteases (predominantly matrix metalloproteases, [MMPs]) into the pit results in dissolution of the inorganic and organic components of bone.

Development

During embryogenesis, most bones develop from a cartilage mold by the process of endochondral ossification. The cartilage mold (*anlagen*) is synthesized by mesenchymal precursor cells. At approximately 8 weeks' gestation, a putative mononuclear cell known as the chondroblast

removes the central portion of the mold creating the medullary canal. Simultaneously, at midshaft (*diaphysis*), osteoblasts begin to deposit the cortex beneath the nascent periosteum. The resulting *primary center of ossification* produces radial growth of bone. At each longitudinal end (*epiphysis*), endochondral ossification proceeds in a centrifugal fashion (*secondary center of ossification*). Eventually, a plate of the cartilage anlage becomes entrapped between the two expanding centers of ossification forming the *physis* or *growth plate* (Fig. 26-3). The chondrocytes within the growth plate undergo sequential proliferation, hypertrophy and apoptosis. In the region of apoptosis the matrix mineralizes and is invaded by capillaries, providing the nutrients for osteoblasts to be activated and synthesize osteoid. Although the calcified cartilage matrix is resorbed, remnant struts persist and act as scaffolding for the deposition of bone on their surfaces. These structures are known as *primary spongiosa* and are the first bony trabeculae (Fig. 26-3). The above process progressively deposits new bone at the bottom of the growth plate resulting in longitudinal bone growth.

Intramembranous ossification, by contrast, is responsible for the development of flat bones. Bones of the cranium, for example, are formed by osteoblasts directly from a fibrous layer of tissue that is derived from mesenchyme, without a cartilage anlagen. Because bone is made only by osteoblasts, the enlargement of bones is achieved by the deposition of new bone on a preexisting surface. This mechanism of appositional growth is instrumental in bone development and modeling.

The development of bone is controlled by a number of local and systemic factors:

- Growth hormone (GH) is secreted by the anterior pituitary. It acts on resting chondrocytes to induce and maintain proliferation.

Figure 26-3 Active growth plate with ongoing endochondral ossification. 1, Reserve zone. 2, Zone of proliferation. 3, Zone of hypertrophy. 4, Zone of mineralization. 5, Primary spongiosa.

- Thyroid hormone (T3) is secreted by the thyroid gland, and acts on proliferating chondrocytes to induce hypertrophy.
- Indian hedgehog (Ihh) is a locally secreted regulator, made by prehypertrophic chondrocytes, that coordinates chondrocyte proliferation and differentiation and osteoblasts proliferation.
- Parathyroid hormone related protein (PTHrP) is a local factor, expressed by perichondrial stromal cells and early proliferating chondrocytes, that activates the PTH receptor and maintains proliferation of chondrocytes.
- Wnt is a family of secreted factors that are expressed at highest levels in the proliferating zone and bind to the receptors Frizzled and LRP5/6 to activate β -catenin signaling. They can promote both proliferation and maturation of chondrocytes.
- SOX9 is a transcription factor expressed by proliferating but not hypertrophic chondrocytes that is essential for differentiation of precursor cells into chondrocytes.
- RUNX2 is a transcription factor involved in chondrocyte and osteoblast differentiation. It is expressed in early hypertrophic chondrocytes and immature mesenchymal cells and controls terminal chondrocyte and osteoblast differentiation, respectively.
- Fibroblast growth factors (FGFs) are secreted by a variety of mesenchymal cells. FGF (most notably FGF3) acts on hypertrophic chondrocytes to inhibit proliferation and promote differentiation.
- Bone morphogenic proteins (BMPs) are members of the TGF- β family. They are expressed at various stages of chondrocyte development in the growth plate and have diverse effects on chondrocyte proliferation and hypertrophy.

Homeostasis and Remodeling

The adult skeleton appears static but is actually constantly turning over in a tightly regulated process known as remodeling. Approximately 10% of the skeleton is replaced annually. This process can repair microdamage or change the shape of bones in response to structural and mechanical demands. Remodeling takes place at a microscopic locus known as the bone (or basic) multicellular unit (BMU), which consists of a unit of coupled osteoblast and osteoclast activity on the bone surface. An orderly sequence of osteoclast attachment, resorption, osteoblast attachment and proliferation and, finally, matrix synthesis proceeds at the BMU.

The events at the bone multicellular unit are regulated by cell-cell interactions and cytokines. The control mechanisms are not known completely, but several signaling pathways of particular importance have emerged (Fig. 26-4). One such pathway involves three factors: (1) the transmembrane receptor RANK (receptor activator for NF- κ B), which is expressed on osteoclast precursors; (2) RANK ligand, (RANKL) which is expressed on osteoblasts and marrow stromal cells; and (3) osteoprotegerin (OPG), a secreted “decoy” receptor made by osteoblasts and several other types of cells that can bind RANKL and thus prevent its interaction with RANK. When stimulated by RANKL, RANK signaling activates the transcription factor

Figure 26-4 Paracrine molecular mechanisms that regulate osteoclast formation and function. Osteoclasts are derived from the same mononuclear cells that differentiate into macrophages. Osteoblast/stromal cell membrane-associated RANKL binds to its receptor RANK located on the cell surface of osteoclast precursors. This interaction in the background of macrophage colony-stimulating factor (M-CSF) causes the precursor cells to produce functional osteoclasts. Stromal cells also secrete osteoprotegerin (OPG), which acts as a “decoy” receptor for RANKL, preventing it from binding the RANK receptor on osteoclast precursors. Consequently, OPG prevents bone resorption by inhibiting osteoclast differentiation.

NF- κ B, which is essential for the generation and survival of osteoclasts. A second important pathway involves monocyte colony stimulating factor (M-CSF) produced by osteoblasts. Activation of the M-CSF receptor on osteoclast precursors stimulates a tyrosine kinase cascade that is also crucial for the generation of osteoclasts. Also notable is the WNT/ β -catenin pathway. WNT proteins produced by osteoprogenitor cells bind to the LRP5 and LRP6 receptors on osteoblasts and thereby trigger the activation of β -catenin and the production of OPG (Fig. 26-5). Conversely, sclerostin, which is produced by osteocytes, inhibits the WNT/ β -catenin pathway. The importance of these pathways is proven by rare but informative germline mutations in the *OPG*, *RANK*, *RANKL*, and *LRP5* genes, which cause severe disturbances of bone metabolism (described later).

The balance between net bone formation and resorption is modulated by the signals that connect to the RANK and WNT signaling pathways. For example, because OPG and RANKL oppose one another, either bone resorption or bone formation can be favored by tipping the RANK-to-OPG ratio. Systemic factors that affect this balance include hormones (parathyroid hormone, estrogen, testosterone,

Figure 26-5 Bone cells and their interrelated activities. Hormones, cytokines, growth factors, and signal-transducing molecules are instrumental in their formation and maturation, and allow communication between osteoblasts and osteoclasts. Bone resorption and formation in remodeling are coupled processes that are controlled by systemic factors and local cytokines, some of which are deposited in the bone matrix. BMP, bone morphogenetic protein; LRP5/6, LDL receptor related proteins 5 and 6.

and glucocorticoids), vitamin D, inflammatory cytokines (e.g., IL-1), and growth factors (e.g., bone morphogenetic factors). Each of the above presumably acts by altering the levels of RANK/NF- κ B and WNT/ β -catenin signaling in osteoblasts. The mechanisms are complex, but parathyroid hormone, IL-1 and glucocorticoids promote osteoclast differentiation and bone turnover. In contrast, bone morphogenetic proteins and sex hormones generally block osteoclast differentiation or activity by favoring OPG expression.

Another level of control involves paracrine crosstalk between osteoblasts and osteoclasts. Breakdown of matrix by osteoclasts liberates and activates matrix proteins, growth factors, cytokines, and enzymes (e.g., collagenase), including some that stimulate osteoblasts. Thus, as bone is broken down to its elemental units, substances are released into the microenvironment that initiate its renewal (Fig. 26-5).

Peak bone mass is achieved in early adulthood after the cessation of skeletal growth. This set point is determined by a variety of factors, including polymorphisms in the receptors for vitamin D and LRP5/6, nutrition, physical activity, age, and hormonal status. Beginning in the fourth decade, however resorption exceeds formation, so there is a steady decline in skeletal mass.

Developmental Disorders of Bone and Cartilage

Developmental abnormalities of the skeleton are frequently the result of inherited mutations and first become manifest

during the earliest stages of bone formation. In contrast, acquired diseases are usually detected in adulthood. The complexity of the skeleton's growth, development, maintenance, and relationships with other organ systems makes it unusually vulnerable to adverse influences. The spectrum of disorders of bone development is broad and the classification system is not standardized. Here we will categorize the major diseases according to their perceived pathogenesis.

Developmental anomalies can result from localized problems in the migration and condensation of mesenchyme (dysostosis) or global disorganization of bone and/or cartilage (dysplasia). Dysostoses are usually limited to defined embryologic structures and may occur in isolation or as part of more complex syndromes. They result from defects in the formation of the mesenchymal condensations and their differentiation into the cartilage anlage. The most common forms include complete absence of a bone or entire digit (*aplasia*), extra bones or digits (*supernumerary digit*), and abnormal fusion of bones (e.g., *syndactyly*, *craniosynostosis*). Genetic alterations that affect transcription factors, especially those encoded by the homeobox genes, cytokines and cytokine receptors, are especially common among the dysostoses. In contrast, dysplasias arise from mutations in genes that control development or remodeling of the entire skeleton. It is important to note that the term dysplasia in this context simply implies abnormal growth rather than a premalignant lesion as used in the context of neoplasia (Chapter 7).

More than 350 skeletal dysostoses and dysplasias, most extremely rare, have been recognized. The classification has evolved from purely clinical and radiographic

Table 26-2 Diseases of the Skeleton with Identified Genetic Defects

Disorder	Gene Symbol	Affected Molecule	Clinical Phenotype
Defects in transcription factors producing abnormalities in mesenchymal condensation and related cell differentiation			
Brachydactyly types D and E	<i>HOXD13</i>	Transcription factor	Short, broad terminal phalanges of first digits
Camptomelic dysplasia	<i>SOX9</i>	Transcription factor	Sex reversal, abnormal skeletal development
Cleidocranial dysplasia	<i>RUNX2</i>	Transcription factor	Abnormal clavicles, Wormian bones, supernumerary teeth
Holt-Oram syndrome	<i>TBX5</i>	Transcription factor	Congenital abnormalities, forelimb anomalies
Nail-patella syndrome	<i>LMX1B</i>	Transcription factor	Hypoplastic nails, hypoplastic or aplastic patellas, dislocated radial head, progressive nephropathy
Waardenburg syndrome types 1 and 3	<i>PAX3</i>	Transcription factor	Hearing loss, abnormal pigmentation, craniofacial abnormalities
Defects in hormones and signal transduction proteins producing abnormal proliferation or maturation of osteoblasts, osteoclasts or chondrocytes			
Achondroplasia	<i>FGFR3</i>	Receptor	Short stature, rhizomelic shortening of limbs, frontal bossing, midface deficiency
Hypochondroplasia	<i>FGFR3</i>	Receptor	Disproportionately short stature, micromelia, relative macrocephaly
Osteopetrosis, autosomal dominant	<i>LRP5</i>	Receptor	Increased bone density, hearing loss, skeletal fragility
Osteopetrosis, infantile form	<i>RANKL</i>	Receptor ligand	Increased bone density
Osteoporosis-pseudoglioma syndrome	<i>LRP5</i>	Receptor	Congenital or infant-onset loss of vision, skeletal fragility
Thanatophoric dysplasia	<i>FGFR3</i>	Receptor	Severe limb shortening and bowing, frontal bossing, depressed nasal bridge
Defects in extracellular structural proteins			
Achondrogenesis type 2	<i>COL2A1</i>	Type II collagen	Short trunk
Metaphyseal dysplasia, Schmid type	<i>COL10A1</i>	Type X collagen	Mildly short stature
Osteogenesis imperfecta types 1-4	<i>COL1A1, COL1A2</i>	Type I collagen	Bone fragility
Defects in metabolic enzymes and transporters			
Osteopetrosis with renal tubular acidosis	<i>CA2</i>	Carbonic anhydrase	Increased bone density, fragility, renal tubular acidosis
Osteopetrosis, late onset type 2	<i>CLCN7</i>	Chloride channel	Increased bone density, fragility

Modified from Mundlos S, Olsen BR: Heritable diseases of the skeleton. descriptions to one that also includes recently identified genetic defects. Table 26-2 lists some of the better characterized developmental abnormalities based on the nature of the genetic defect. The relationships between genes and phenotypes illustrate that various point mutations in a single gene (e.g., *COL2A1*) can result in different phenotypes while mutations in diverse genes (e.g., *LRP5*, *RANKL*) can give rise to similar clinical phenotypes.

Defects in Nuclear Proteins and Transcription Factors

Defects in nuclear proteins and transcription factors, especially homeobox proteins, cause disorganized mesenchymal condensation and abnormal differentiation of osteoblasts and chondrocytes. These defects manifest as abnormally developed bones.

- *Brachydactyly types D and E*, caused by mutation in the homeobox *HOXD13* gene, produces shortening of the terminal phalanges of the thumb and big toe.
- Loss-of-function mutations in the *RUNX2* gene result in *cleidocranial dysplasia*, an autosomal dominant disorder characterized by patent fontanelles, delayed closure of cranial sutures, Wormian bones (extra bones that occur within a cranial suture), delayed eruption of secondary teeth, primitive clavicles, and short height.

Defects in Hormones and Signal Transduction Proteins

Achondroplasia is the most common skeletal dysplasia and a major cause of dwarfism. It is an autosomal dominant disorder resulting in retarded cartilage growth. Affected individuals have shortened proximal extremities, a trunk of relatively normal length, and an enlarged head with bulging forehead and conspicuous depression of the root of the nose. The skeletal abnormalities are usually not associated with changes in longevity, intelligence, or reproductive status. It is caused by gain-of-function mutations in the FGF receptor 3 (*FGFR3*). Normally, FGF-mediated activation of *FGFR3* inhibits endochondral growth. Constitutive activation of *FGFR3* exaggerates this effect, suppressing growth. Approximately 90% of cases stem from new mutations, almost all of which occur in the paternal allele.

Thanatophoric dysplasia is the most common lethal form of dwarfism, affecting about 1 in every 20,000 live births. Affected individuals have micromelic shortening of the limbs, frontal bossing, relative macrocephaly, a small chest cavity, and a bell-shaped abdomen. The underdeveloped thoracic cavity leads to respiratory insufficiency, and these individuals frequently die at birth or soon after. The histologic changes in the growth plate show diminished proliferation of chondrocytes and disorganization

Table 26-3 Subtypes of Osteogenesis Imperfecta

Subtype	Collagen Defect	Inheritance	Major Clinical Features	Prognosis
I	Decreased synthesis of pro- α 1(1) chain Abnormal pro- α 1(1) or pro- α 2(1) chains	Autosomal dominant	Postnatal fractures, blue sclera Normal stature Skeletal fragility Dentinogenesis imperfecta Hearing impairment Joint laxity Blue sclerae	Compatible with survival
II	Abnormally short pro- α 1(1) chain Unstable triple helix Abnormal or insufficient pro- α 2(1)	Most autosomal recessive Some autosomal dominant New mutations	Death in utero or within days of birth Skeletal deformity with excessive fragility and multiple fractures Blue sclera	Perinatal lethal
III	Altered structure of pro-peptides of pro- α 2(1) Impaired formation of triple helix	Autosomal dominant (75%) Autosomal recessive (25%)	Compatible with survival Growth retardation Multiple fractures Progressive kyphoscoliosis Blue sclera at birth that become white Hearing impairment Dentinogenesis imperfecta	Progressive, deforming
IV	Short pro- α 2(1) chain Unstable triple helix	Autosomal dominant	Postnatal fractures, normal sclerae Moderate skeletal fragility Short stature Sometimes dentinogenesis imperfecta	Compatible with survival

OI, Osteogenesis imperfecta.

in the zone of proliferation. It is also caused by gain-of-function mutations in *FGFR3* that differ from those in achondroplasia.

Abnormal bone density can result from mutations in genes that regulate osteoclast differentiation or osteoclast function. Such mutations can cause either osteoporosis (too little bone) or osteopetrosis (too much), which are described in more detail in separate sections. Interestingly, specific mutations in the gene for the receptor *LPR5* can manifest as either osteoporosis or osteopetrosis in adults, depending on the gene defect. One infantile form of osteopetrosis is associated with mutation of *RANKL*, resulting in decreased or absent osteoclasts. In animals, osteopetrosis can also be caused by mutations in *M-CSF* and *OPG*, which (as already discussed) regulate osteoclast formation and function.

Defects in Extracellular Structural Proteins

The interaction of the organic components of bone matrix is complex and a focus of intense scientific investigation. The importance of the structural bone proteins is exemplified by the diseases associated with deranged metabolism of the major bone and cartilage collagens (types I, II, IX, X, and XI). Their clinical manifestations are highly variable, ranging from lethal disease to premature osteoarthritis.

Type I Collagen Diseases (Osteogenesis Imperfecta)

Osteogenesis imperfecta (OI), or brittle bone disease, is a phenotypically diverse disorder caused by deficiencies in the synthesis of type I collagen. It is the most common inherited disorder of connective tissue. OI principally affects bone, but also impacts other tissues rich in type I collagen (joints, eyes, ears, skin, and teeth). It usually results from autosomal dominant mutations (more than 800 have been identified) in the genes that encode the α 1 and α 2 chains of type I collagen. Many of these mutations

lead to replacement of a glycine residue with another amino acid in the triple-helical domain, resulting in defective assembly of higher order collagen polypeptides. Collagen synthesis and extracellular transport require triple helix formation, and these defects not only cause the misfolding of the mutated collagen polypeptides, but also interfere with the proper assembly of wild type collagen chains (a dominant negative loss of function activity).

The fundamental abnormality in OI is too little bone, resulting in extreme skeletal fragility. Other findings include blue sclerae caused by decreased collagen content, making the sclera translucent and allowing partial visualization of the underlying choroid; hearing loss related to both a sensorineural deficit and impeded conduction due to abnormalities in the bones of the middle and inner ear; and dental imperfections (small, misshapen, and blue-yellow teeth) secondary to a deficiency in dentin.

Osteogenesis imperfecta can be separated into four major clinical subtypes that vary widely in severity (Table 26-3). The severity of the disease is based on the location of the mutation within the protein. Mutations resulting in decreased synthesis of qualitatively normal collagen are associated with mild skeletal abnormalities. More severe or lethal phenotypes have abnormal polypeptide chains that cannot be arranged in a triple helix. The type 2 variant is at one end of the spectrum and is uniformly fatal in utero or during the perinatal period. It is characterized by extraordinary bone fragility with multiple intrauterine fractures (Fig. 26-6). In contrast, individuals with the type 1 form have a normal life span but experience childhood fractures that decrease in frequency following puberty.

Diseases Associated with Mutations of Types II, IX, X, and XI Collagen

Types II, IX, X, and XI collagens are important structural components of hyaline cartilage. Although uncommon, mutations in the genes encoding these proteins produce an

Figure 26-6 Skeletal radiograph of a fetus with lethal type 2 osteogenesis imperfecta. Note the numerous fractures of virtually all bones, resulting in accordion-like shortening of the limbs.

array of disorders of varying severity (Table 26-2). In the severe disorders, the type II collagen molecules are not secreted by the chondrocytes, and insufficient bone formation occurs. In the milder disorders there is reduced synthesis of normal type II collagen.

Defects in Metabolic Pathways (Enzymes, Ion Channels, and Transporters)

Osteopetrosis

Osteopetrosis, also known as marble bone disease and Albers-Schönberg disease, refers to a group of rare genetic diseases that are characterized by reduced bone resorption and diffuse symmetric skeletal sclerosis due to impaired formation or function of osteoclasts. The term *osteopetrosis* reflects the stone-like quality of the bones. However, the bones are abnormally brittle and fracture easily, like a piece of chalk. Osteopetrosis is classified into variants based on both the mode of inheritance and the severity of clinical findings.

Pathogenesis. Most of the mutations underlying osteopetrosis interfere with the process of acidification of the

osteoclast resorption pit, which is required for the dissolution of the calcium hydroxyapatite within the matrix. Examples include autosomal recessive defects in the gene for the enzyme carbonic anhydrase 2 (CA2). CA2 is required by osteoclasts and renal tubular cells to generate protons from carbon dioxide and water. The absence of CA2 prevents osteoclasts from acidifying the resorption pit and solubilizing hydroxyapatite, and also blocks the acidification of urine by the renal tubular cells. Other forms of the disease are caused by mutations in *CLCN7*, which encodes a proton pump located on the surface of osteoclasts.

MORPHOLOGY

Due to deficient osteoclast activity, bones involved by osteopetrosis lack a medullary canal, and the ends of long bones are bulbous (Erlenmeyer flask deformity) and misshapen (Fig. 26-7). The neural foramina are small and compress exiting nerves. The primary spongiosa, which is normally removed during growth, persists and fills the medullary cavity, leaving no room for the hematopoietic marrow and preventing the formation of mature trabeculae (Fig. 26-8). Deposited bone is not remodeled and tends to be woven in architecture. Depending on the underlying genetic defect, the number of osteoclasts may be normal, increased, or decreased.

Figure 26-7 Radiograph of the upper extremity in an individual with osteopetrosis. The bones are diffusely sclerotic, and the distal metaphyses of the ulna and radius are poorly formed.

Figure 26-8 Section of proximal tibial diaphysis from a fetus with osteopetrosis. The cortex (1) is present, but the medullary cavity (2) is filled with primary spongiosa, which replaces the hematopoietic elements.

Clinical Features. Severe infantile osteopetrosis is autosomal recessive and usually becomes evident in utero or soon after birth. Fracture, anemia, and hydrocephaly are often seen, resulting in postpartum mortality. Affected individuals who survive into their infancy have cranial nerve defects (optic atrophy, deafness, and facial paralysis) and repeated—often fatal—infections because of leukopenia, despite extensive extramedullary hematopoiesis that can lead to prominent hepatosplenomegaly. The mild autosomal dominant form may not be detected until adolescence or adulthood, when it is discovered on x-ray studies performed because of repeated fractures. These individuals may also have mild cranial nerve deficits and anemia.

Osteopetrosis was the first genetic disease treated with hematopoietic stem cell transplantation, which is effective because osteoclasts are derived from hematopoietic precursors. The normal osteoclasts produced from donor stem cells reverse many of the skeletal abnormalities.

Diseases Associated with Defects in Degradation of Macromolecules

Mucopolysaccharidoses

The mucopolysaccharidoses, discussed in [Chapter 5](#), are a group of lysosomal storage diseases that are caused by deficiencies in the enzymes that degrade dermatan sulfate, heparan sulfate, and keratan sulfate. The affected enzymes are mainly acid hydrolases. Mesenchymal cells, especially chondrocytes, normally degrade extracellular matrix mucopolysaccharides. In these diseases, mucopolysaccharides accumulate inside the chondrocytes, causing apoptotic death of the cells, and also in the extracellular space, resulting in structural defects in articular cartilage. Consequently, many of the skeletal manifestations of the mucopolysaccharidoses result from abnormalities in hyaline cartilage, including the cartilage anlage, growth plates, costal cartilages, and articular surfaces. Affected individuals are frequently of short stature and have chest wall abnormalities, and malformed bones.

KEY CONCEPTS

Developmental Disorders of Bone and Cartilage

Abnormalities in a single bone or a localized group of bones are called **dysostoses** and arise from defects in the migration and condensation of mesenchyme. They manifest as absent, supernumerary or abnormally fused bones. Global disorganization of bone and/or cartilage is called a **dysplasia**. Developmental abnormalities can be categorized by the associated genetic defect.

- **Transcription factors:** Homeobox genes, such as *HOXD13*, are frequently mutated in some cases of brachydactyly syndromes.
- **Hormones and signal transduction molecules:** *FGFR3* mutations are responsible for achondroplasia and thanatophoric dysplasia, both of which manifest as dwarfism.
- **Structural proteins:** Mutations in the genes for type I collagen underlie most types of osteogenesis imperfecta (brittle bone disease), characterized by defective bone formation and skeletal fragility.
- **Metabolic enzymes and transporters:** Mutations in *CA2* result in osteopetrosis (marble bone disease, in which bones are hard but brittle) and renal tubular acidosis.

Acquired Disorders of Bone and Cartilage

Osteopenia and Osteoporosis

The term osteopenia refers to decreased bone mass, and osteoporosis is defined as osteopenia that is severe enough to significantly increase the risk of fracture. Radiographically, osteoporosis is considered bone mass at least 2.5 standard deviations below mean peak bone mass in young adults and osteopenia as 1 to 2.5 standard deviations below the mean. Alternatively, the presence of an atraumatic or vertebral compression fracture signifies osteoporosis. The disorder may be localized to a certain bone or region, as in disuse osteoporosis of a limb, or may involve the entire skeleton, as a manifestation of a metabolic bone disease. Generalized osteoporosis, in turn, may be primary or secondary to a large variety of conditions ([Table 26-4](#)).

The most common forms of osteoporosis are the senile and postmenopausal types. An estimated one million Americans experience a fracture related to osteoporosis each year, at a cost of more than 14 billion dollars. Effective treatment and prevention are imperative. The following discussion relates largely to these dominant forms of osteoporosis.

Pathogenesis. Peak bone mass is achieved during young adulthood. Its magnitude is determined largely by hereditary factors, especially polymorphisms in the genes that influence bone metabolism (discussed later). Physical activity, muscle strength, diet, and hormonal state also make important contributions. Once maximal skeletal mass is attained, a small deficit in bone formation accrues with every resorption and formation cycle of each bone

Pulmonary disease

metabolic unit. Accordingly, age-related bone loss, which may average 0.7% per year, is a normal and predictable biologic phenomenon. Both sexes are affected equally and whites more so than blacks. Gender and racial differences in peak bone mass may partially explain why certain populations are prone to develop this disorder. Although much remains unknown, discoveries in the molecular biology of bone formation and resorption have provided new insights into the pathogenesis of osteoporosis (Fig. 26-9):

- **Age-related changes** in bone cells and matrix have a strong impact on bone metabolism. Osteoblasts from older individuals have reduced proliferative and biosynthetic potential when compared with osteoblasts from younger individuals. Also, the cellular response to growth factors bound to the extracellular matrix becomes attenuated in older individuals. The net result is a diminished capacity to make bone. This form of osteoporosis, known as *senile osteoporosis*, is categorized as a *low-turnover variant*.
- **Reduced physical activity** increases the rate of bone loss in experimental animals and humans, because mechanical forces stimulate normal bone remodeling. Bone loss in an immobilized or paralyzed extremity, the reduction of skeletal mass in astronauts in a zero gravity environment for prolonged periods, and the higher bone density in athletes exemplify the role of physical activity in preventing bone loss. The type of exercise is

important, as load magnitude influences bone density more than the number of load cycles. Because muscle contraction is the dominant source of skeletal loading, resistance exercises such as weight training are more effective stimuli for increasing bone mass than repetitive endurance activities such as bicycling. The decreased physical activity that is associated with normal aging contributes to senile osteoporosis.

- **Genetic factors.** Single gene defects (e.g., *LRP5*, discussed above) account for only a small fraction of cases. Polymorphisms in other genes may account for the variation in peak bone density within a population. In genome-wide association studies, the top associated genes include *RANKL*, *OPG*, and *RANK*, all of which encode key regulators of osteoclasts. Also associated are the HLA locus (perhaps reflecting the effects of inflammation on calcium metabolism) and the estrogen receptor gene (discussed later). Some studies have also implicated genetic variants of the vitamin D receptor and genes involved in Wnt signaling as risk factors.
- **Calcium nutritional state** contributes to peak bone mass. Adolescent girls (more than boys) tend to have insufficient calcium intake in the diet. This calcium deficiency occurs during a period of rapid bone growth, restricting the peak bone mass ultimately achieved. Thus, these individuals are at greater risk of developing osteoporosis. Calcium deficiency, increased PTH concentrations, and reduced levels of vitamin D may also have a role in the development of senile osteoporosis.
- **Hormonal influences.** Postmenopausal osteoporosis is characterized by an acceleration of bone loss. In the decade after menopause, yearly reductions in bone mass may reach up to 2% of cortical bone and 9% of cancellous bone. Women may lose as much as 35% of their cortical bone and 50% of their cancellous bone by 30 to 40 years after menopause. It is thus no surprise that post-menopausal women suffer osteoporotic fractures more commonly than men of the same age. *Estrogen deficiency* plays the major role in this phenomenon and close to 40% of postmenopausal women are affected by

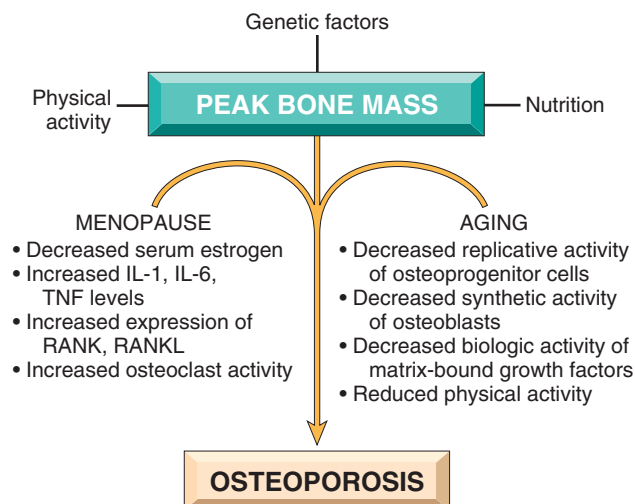

**Figure 26-9** Pathophysiology of postmenopausal and senile osteoporosis (see text).

Figure 26-10 Osteoporotic vertebral body (*right*) shortened by compression fractures compared with a normal vertebral body (*left*). Note that the osteoporotic vertebra has a characteristic loss of horizontal trabeculae and thickened vertical trabeculae.

osteoporosis. Decreased estrogen levels after menopause actually increase *both* bone resorption and formation but the latter does not keep up with the former, leading to **high-turnover** osteoporosis. The decreased estrogen appears to increase secretion of inflammatory cytokines by blood monocytes and bone marrow cells. These cytokines stimulate osteoclast recruitment and activity by increasing the levels of RANKL, diminishing the expression of OPG, decreasing osteoclast proliferation and preventing osteoclast apoptosis. Cytokines such as IL-6, TNF- α , and IL-1 have also been implicated in postmenopausal osteoporosis, either independently or as downstream mediators of estrogen signaling.

MORPHOLOGY

The hallmark of osteoporosis is histologically normal bone that is decreased in quantity. The entire skeleton is affected in postmenopausal and senile osteoporosis (Fig. 26-10), but certain bones tend to be more severely impacted. In postmenopausal osteoporosis the increase in osteoclast activity affects mainly bones or portions of bones that have increased surface area, such as the cancellous compartment of vertebral bodies. The trabecular plates become perforated, thinned, and lose their interconnections (Fig. 26-11), leading to progressive microfractures and eventual vertebral collapse. In senile osteoporosis the cortex is thinned by subperiosteal and endosteal resorption and the Haversian systems are widened. In severe cases the Haversian systems are so enlarged that the cortex mimics cancellous bone.

Clinical Course. The clinical manifestations of osteoporosis depend on which bones are involved. Vertebral fractures that frequently occur in the thoracic and lumbar regions are painful, and, when multiple, can cause significant loss of height and various deformities, including lumbar lordosis and kyphoscoliosis. Complications of fractures of the femoral neck, pelvis, or spine, such as pulmonary embolism and pneumonia, are frequent and result in 40,000 to 50,000 deaths per year.

Osteoporosis cannot be reliably detected in plain radiographs until 30% to 40% of the bone mass is lost, and measurement of blood levels of calcium, phosphorus, and alkaline phosphatase are not diagnostic. Osteoporosis is thus a difficult condition to screen for in asymptomatic people. The best estimates of bone loss, aside from biopsy

(which is rarely performed), are specialized radiographic imaging techniques, such as dual-energy x-ray absorptiometry and quantitative computed tomography, both of which measure bone density.

The prevention and treatment of senile and postmenopausal osteoporosis includes exercise, appropriate calcium and vitamin D intake, and pharmacologic agents, most commonly bisphosphonates, which reduce osteoclast activity and induce apoptosis. Although menopausal hormone therapy has been used to prevent fracture, complications, particularly deep venous thrombosis and stroke, have prompted search for more selective estrogen receptor modulators. Denosumab, an anti-RANKL antibody, has shown promise in treating some forms of postmenopausal osteoporosis. Other novel investigational therapeutic approaches include anti-sclerostin antibodies and cathepsin K inhibitors.

Paget Disease (Osteitis Deformans)

Paget disease is a disorder of increased, but disordered and structurally unsound, bone mass. This unique skeletal disease can be divided into three sequential phases: (1) an initial osteolytic stage, (2) a mixed osteoclastic-osteoblastic stage, which ends with a predominance of osteoblastic activity and evolves ultimately into (3) a final burned-out quiescent osteosclerotic stage (Fig. 26-12).

Paget disease usually begins in late adulthood (average age at diagnosis, 70 years) and becomes progressively more common thereafter. An intriguing aspect is the striking geographic variation in its prevalence. Paget disease is relatively common in whites in England, France, Austria, regions of Germany, Australia, New Zealand, and the United States. In contrast, the disease is rare in the native populations of Scandinavia, China, Japan, and Africa. The exact incidence is hard to determine because many affected individuals are asymptomatic; it is estimated that 1% of the US population older than age 40 is affected and the prevalence in England is 2.5% for men and 1.6% for women 55 years or older. Recent surveys show that there has been a decrease in new cases in some countries over the past 25 to 30 years.

Figure 26-11 In advanced osteoporosis, both the trabecular bone of the medulla (*bottom*) and the cortical bone (*top*) are markedly thinned.

Figure 26-12 Diagrammatic representation of Paget disease of bone demonstrating the three phases in the evolution of the disease.

Pathogenesis. The cause of Paget disease remains uncertain, and current evidence suggests both genetic and environmental factors contribute. Forty percent to 50% of cases of familial Paget disease, and 5% to 10% of sporadic cases, harbor mutations in the *SQSTM1* gene. The net effect of these mutations is to increase the activity of NF- κ B, which as already discussed increases osteoclast activity. Activating mutations in *RANK* and inactivating mutations in *OPG* account for some cases of juvenile Paget disease. Cell culture studies have shown modulation of vitamin D sensitivity and IL-6 secretion by virally infected osteoclasts. These results suggest that chronic infection of osteoclast precursors by measles or other RNA viruses may play a role in the disease. The geographic distribution is also consistent with some environmental influence.

MORPHOLOGY

Paget disease shows remarkable histologic variation over time and from site to site. **The hallmark is a mosaic pattern of lamellar bone, seen in the sclerotic phase.** This jigsaw puzzle-like appearance is produced by unusually **prominent cement lines**, which join haphazardly oriented units of lamellar bone (Fig. 26-13). The findings during the other phases are less specific. In the initial lytic phase there are waves of osteoclastic activity and numerous resorption pits. The osteoclasts are abnormally large and have many more than the normal 10 to 12 nuclei; sometimes 100 nuclei are present. Osteoclasts persist in the mixed phase, but now many of the bone surfaces are lined by prominent osteoblasts. The marrow adjacent to the bone-forming surface is replaced by loose connective tissue that contains osteoprogenitor cells and numerous blood vessels. The newly formed bone may be woven or lamellar, but eventually all of it is remodeled into lamellar bone. As the mosaic pattern unfolds and the cell activity decreases, the periosteal fibrovascular tissue recedes and is replaced by normal marrow. In the end, the bone is composed of coarsely thickened trabeculae and cortices that are soft and porous and lack structural stability. These aspects make the bone vulnerable to deformation under stress; consequently, it fractures easily.

Clinical Course. Clinical findings are extremely variable and depend on the extent and site of the disease. Most cases are asymptomatic and are discovered as an incidental radiographic finding. Paget disease is *monostotic* in about 15% of cases and *polyostotic* in the remainder. The axial skeleton or proximal femur is involved in up to 80% of cases. Pain localized to the affected bone is common. It is caused by microfractures or by bone overgrowth that compresses spinal and cranial nerve roots. Enlargement of the craniofacial skeleton may produce *leontiasis ossea* (lion face) and a cranium so heavy that is difficult for the person to hold the head erect. The weakened Pagetic bone may lead to invagination of the skull base (*platybasia*) and compression of the posterior fossa. Weight bearing causes anterior bowing of the femurs and tibiae and distorts the femoral

Figure 26-13 Mosaic pattern of lamellar bone pathognomonic of Paget disease.

Figure 26-14 Severe Paget disease. The tibia is bowed and the affected portion is enlarged, sclerotic, and exhibits irregular thickening of both the cortical and cancellous bone.

heads, resulting in the development of severe *secondary osteoarthritis*. *Chalk stick-type fractures* are another frequent complication and usually occur in the long bones of the lower extremities. Compression fractures of the spine result in spinal cord injury and the development of kyphosis. The hypervascularity of Pagetic bone warms the overlying skin, and in severe polyostotic disease the increased blood flow acts like an arteriovenous shunt, leading to high-output heart failure or exacerbation of underlying cardiac disease.

A variety of tumor and tumor-like conditions develop in Pagetic bone. The benign lesions include giant cell tumor, giant cell reparative granuloma, and extra-osseous masses of hematopoietic tissue. The most dreaded complication is sarcoma, which occurs in less than 1% of all individuals with Paget disease, and in 5% to 10% of those with severe polyostotic disease. The sarcomas are usually osteosarcoma or fibrosarcoma, and they arise in Paget lesions in the long bones, pelvis, skull, and spine.

The diagnosis can frequently be made from the radiographic findings. Pagetic bone is typically enlarged with thick, coarsened cortices and cancellous bone (Fig. 26-14). Active disease has a wedge-shaped lytic leading edge that may progress along the length of the bone at a rate of 1 cm per year. Many affected individuals have elevated serum alkaline phosphatase levels but normal serum calcium and phosphorus.

In the absence of malignant transformation, Paget disease is usually not a serious or life-threatening disease. Most affected individuals have mild symptoms that are

readily suppressed by treatment with calcitonin and bisphosphonates.

Rickets and Osteomalacia

Both rickets and osteomalacia are manifestations of vitamin D deficiency or its abnormal metabolism (and are detailed in Chapter 9). The fundamental defect is an impairment of mineralization and a resultant accumulation of unmineralized matrix. This contrasts with osteoporosis, in which the mineral content of the bone is normal and the total bone mass is decreased. *Rickets* refers to the disorder in children, in whom it interferes with the deposition of bone in the growth plates. *Osteomalacia* is the adult counterpart, in which bone formed during remodeling is undermineralized, resulting in predisposition to fractures.

Hyperparathyroidism

As discussed in Chapter 24, parathyroid hormone (PTH) plays a central role in calcium homeostasis through the following effects:

- Osteoclast activation, increasing bone resorption and calcium mobilization. PTH mediates the effect indirectly by increased RANKL expression on osteoblasts.
- Increased resorption of calcium by the renal tubules
- Increased urinary excretion of phosphates
- Increased synthesis of active vitamin D, 1,25(OH)₂-D, by the kidneys, which in turn enhances calcium absorption from the gut and mobilizes bone calcium by inducing RANKL on osteoblasts

The net result of the actions of PTH is an elevation in serum calcium, which, under normal circumstances, inhibits further PTH production. However, excessive or inappropriate levels of PTH can result from autonomous parathyroid secretion (*primary hyperparathyroidism*) or can occur in the setting of underlying renal disease (*secondary hyperparathyroidism*) (see also Chapter 24).

In either setting, **hyperparathyroidism leads to significant skeletal changes related to unabated osteoclast activity.** The entire skeleton is affected, although some sites can be more severely affected than others. PTH is directly responsible for the bone changes seen in primary hyperparathyroidism, but additional alterations contribute to the development of bone disease in secondary hyperparathyroidism. In chronic renal insufficiency there is inadequate 1,25-(OH)₂-D synthesis, which ultimately affects gastrointestinal calcium absorption. The hyperphosphatemia of renal failure also suppresses renal α 1-hydroxylase, further impairing vitamin D synthesis; additional influences include metabolic acidosis and aluminum deposition in bone. As bone mass decreases, affected patients are increasingly susceptible to fractures, bone deformation, and joint problems. Fortunately, a reduction in PTH levels to normal can completely reverse the bone changes.

MORPHOLOGY

Symptomatic, untreated primary hyperparathyroidism manifests with three interrelated skeletal abnormalities: **osteoporosis**, **brown tumors** and **osteitis fibrosa cystica**. Osteoporosis is

Figure 26-15 Hyperparathyroidism with osteoclasts boring into the center of the trabeculum (dissecting osteitis).

generalized, but is most severe in the phalanges, vertebrae and proximal femur. The increased osteoclast activity in hyperparathyroidism is most prominent in cortical bone (subperiosteal and endosteal surfaces) but medullary bone is not spared. Indeed, osteoclasts may tunnel into and dissect centrally along the length of the trabeculae, creating the appearance of railroad tracks and producing what is known as **dissecting osteitis** (Fig. 26-15). The marrow spaces around the affected surfaces are replaced by fibrovascular tissue. The correlative radiographic finding is a decrease in bone density or osteoporosis.

The bone loss predisposes to microfractures and secondary hemorrhages that elicit an influx of macrophages and an ingrowth of reparative fibrous tissue, creating a mass of reactive tissue, known as a **brown tumor** (Fig. 26-16). The brown color is the result of the vascularity, hemorrhage, and hemosiderin deposition, and it is not uncommon for the lesions to undergo cystic degeneration. The combination of increased bone cell activity, peritrabecular fibrosis, and cystic brown tumors is the hallmark of severe hyperparathyroidism and is known as **generalized osteitis fibrosa cystica (von Recklinghausen disease of bone)**.

Figure 26-16 Resected rib, harboring an expansile brown tumor adjacent to the costal cartilage.

Osteitis fibrosa cystica is now rarely encountered because hyperparathyroidism is usually diagnosed on routine blood tests and treated at an early stage. Secondary hyperparathyroidism is usually not as severe or as prolonged as primary hyperparathyroidism, hence the skeletal abnormalities tend to be milder. Control of hyperparathyroidism allows the bony changes to regress or disappear completely.

Renal Osteodystrophy

The term **renal osteodystrophy** describes collectively the skeletal changes that occur in chronic renal disease, including those associated with dialysis. The manifestations are not unique, but include many of the entities described above including (1) osteopenia/osteoporosis (2) osteomalacia, (3) secondary hyperparathyroidism, and (4) growth retardation. As advances in medical technology have prolonged the lives of individuals with renal disease, its impact on skeletal homeostasis has assumed greater clinical importance. The various histologic bone changes in individuals with end-stage renal failure can be divided into three major types of disorders:

- **High-turnover osteodystrophy** is characterized by increased bone resorption and bone formation, with the former predominating.
- **Low-turnover or aplastic disease** is manifested by adynamic bone (little osteoclastic and osteoblastic activity) and, less commonly, osteomalacia.
- **Mixed pattern of disease** with areas of high turnover and low turnover.

Pathogenesis. Kidney disease causes skeletal abnormalities through three mechanisms (Fig. 26-17).

- **Tubular dysfunction.** The major tubular disease that affects the skeleton is renal tubular acidosis. The associated low pH dissolves hydroxyapatite, resulting in demineralization of the matrix and osteomalacia.
- **Generalized renal failure,** affecting glomerular and tubular function, leads to reduced phosphate excretion, chronic hyperphosphatemia, hypocalcemia and, ultimately **secondary hyperparathyroidism**. The resulting metabolic state is not completely analogous to primary

Figure 26-17 Mechanisms of renal osteodystrophy involves electrolyte levels and endocrine signaling between bone and kidney.

hyperparathyroidism in that bone volume, turnover, and mineralization can vary independently.

- **Decreased production of secreted factors.** The kidney converts vitamin D to its active form (1,25-OH₂-vitamin D₃) and secretes the proteins BMP-7 and Klotho. Decreased vitamin D₃ results in hypocalcemia and contributes to secondary hyperparathyroidism. A hormonal feedback loop between kidney and bone that regulates calcium and phosphate homeostasis involves secreted BMP-7 and FGF-23 and the membrane protein Klotho. BMP-7, produced by renal tubular cells, induces osteoblast differentiation and proliferation, whereas FGF-23, made by osteocytes, acts on the kidney to regulate phosphate homeostasis and vitamin D production, which are dependent on production of membrane-bound Klotho in the kidney. The mechanism of action of Klotho is not understood. The levels of these signals change in chronic renal failure, interrupting the steady state and resulting in osteopenia and osteomalacia.

Other factors, such as aluminum from dialysis, oral phosphate binders, iron deposition, and diabetes mellitus may indirectly contribute to bone disease in the setting of renal failure.

KEY CONCEPTS

Acquired Disorders of Bone and Cartilage

- **Osteopenia** and **osteoporosis** represent histologically normal bone that is decreased in quantity, but osteoporosis is sufficiently severe to significantly increase risk of fracture. The disease is very common with marked morbidity and mortality from fractures. Multiple factors including peak bone mass, age, activity, genetics, nutrition and hormonal influences contribute to its pathogenesis.
- **Paget disease** is a disorder of locally increased but disordered bone. Typically asymptomatic, it is usually discovered incidentally. A mosaic pattern of mineralization is the histologic hallmark at the late stage of the disease. Genetic and possibly viral infectious etiologies have been proposed.
- **Osteomalacia** is characterized by bone that is insufficiently mineralized. In the developing skeleton, the manifestations are characterized by a condition known as rickets.
- **Hyperparathyroidism** arises from either autonomous or compensatory hypersecretion of PTH and can lead to **osteoporosis**, **brown tumors**, and **osteitis fibrosa cystica**. However, in developed countries, where early diagnosis is the norm, these manifestations are rarely seen.
- **Renal osteodystrophy** represents the constellation of bone abnormalities (osteopenia, osteomalacia, hyperparathyroidism, and growth retardation) from chronic renal failure. The mechanisms are complex but stem from decreased tubular, glomerular, and hormonal functions of the kidney.

Fractures

A fracture is defined as loss of bone integrity due to mechanical injury and/or diminished bone strength.

Fractures are some of the most common pathologic conditions affecting bone. The following qualifiers describe fracture types and affect treatment:

- **Simple:** the overlying skin is intact.
- **Compound:** the bone communicates with the skin surface.
- **Comminuted:** the bone is fragmented.
- **Displaced:** the ends of the bone at the fracture site are not aligned.
- **Stress:** a slowly developing fracture that follows a period of increased physical activity in which the bone is subjected to repetitive loads
- **“Greenstick”:** extending only partially through the bone, common in infants when bones are soft
- **Pathologic:** involving bone weakened by an underlying disease process, such as a tumor

Healing of Fractures

Bone has a remarkable capacity for repair. This process involves regulated expression of a multitude of genes and can be separated into overlapping stages with particular molecular, biochemical, histologic, and biomechanical features.

Immediately after fracture, rupture of blood vessels results in a hematoma, which fills the fracture gap and surrounds the area of bone injury. The clotted blood provides a fibrin mesh, sealing off the fracture site and at the same time creates a framework for the influx of inflammatory cells and ingrowth of fibroblasts and new capillaries. Simultaneously, degranulated platelets and migrating inflammatory cells release PDGF, TGF-β, FGF, and other factors, which activate osteoprogenitor cells in the periosteum, medullary cavity, and surrounding soft tissues and stimulate osteoclastic and osteoblastic activity. Thus, by the end of the first week, the major changes are organization of the hematoma, matrix production in adjacent tissues, and remodeling of the fractured ends of the bone. This fusiform and predominantly uncalcified tissue—called *soft tissue callus* or *procallus*—provides some anchorage between the ends of the fractured bones but not structural rigidity for weight bearing.

After approximately 2 weeks, the soft tissue callus is transformed into a *bony callus*. The activated osteoprogenitor cells deposit subperiosteal trabeculae of **woven bone** that are oriented perpendicular to the cortical axis and within the medullary cavity. In some cases, the activated mesenchymal cells in the soft tissues and bone surrounding the fracture line also differentiate into chondrocytes that make fibrocartilage and hyaline cartilage. The bony callus reaches its maximal girth at the end of the second or third week and helps to stabilize the fracture site. The newly formed cartilage along the fracture line undergoes endochondral ossification, forming a contiguous network of bone with newly deposited bone trabeculae in the medulla and beneath the periosteum. In this fashion, the fractured ends are bridged, and as it mineralizes, the stiffness and strength of the callus increases to the point that controlled weight bearing is tolerated (Fig. 26-18).

In the early stages of callus formation, an excess of fibrous tissue, cartilage, and woven bone is produced. As the callus matures and is subjected to weight-bearing

Figure 26-18 A, Recent fracture of the fibula. **B**, Marked callus formation 6 weeks later. (Courtesy Dr. Barbara Weissman, Brigham and Women's Hospital, Boston, Mass.)

forces, the portions that are not physically stressed are resorbed. In this manner the callus is reduced in size and the shape and outline of the fractured bone are reestablished as *lamellar bone*. The healing process is complete with restoration of the medullary cavity.

The sequence of events in the healing of a fracture can be easily impeded or even blocked. For example, displaced and comminuted fractures frequently result in some deformity. Inadequate immobilization permits movement of the callus and prevents its normal formation, resulting in *delayed union* or *nonunion*. If a nonunion persists, the malformed callus undergoes cystic degeneration, and the luminal surface can actually become lined by synovial-like cells, creating a false joint or *pseudoarthrosis*. A serious obstacle to healing is infection of the fracture site, which is especially common in open fractures. Malnutrition and skeletal dysplasia also hinder fracture healing. In children and young adults, near perfect union is the norm. In older adults, fractures often occur in the background of other bone disorders (e.g., osteoporosis and osteomalacia). In such settings, surgical immobilization is often needed for adequate repair.

Osteonecrosis (Avascular Necrosis)

Infarction of bone and marrow is a relatively common event that can occur in the medullary cavity or involve both the medulla and cortex. Most cases of bone necrosis stem from fractures or corticosteroid administration. A diverse set of other conditions also predispose to osteonecrosis (Table 26-5). All are believed to lead to vascular insufficiency through mechanical injury to blood vessels, thromboembolism, external pressure on vessels, or venous occlusion.

MORPHOLOGY

Regardless of etiology, medullary infarcts are geographic and involve the trabecular bone and marrow. The cortex is usually not affected because of its collateral blood flow. In subchondral infarcts, a triangular or wedge-shaped segment of tissue that has the subchondral bone plate as its base undergoes necrosis. The overlying articular cartilage remains viable, as it can access nutrients that are present in synovial fluid. Microscopically, dead bone is recognized by empty lacunae surrounded by necrotic adipocytes that frequently rupture. The released fatty acids bind calcium and form insoluble calcium soaps that may persist for life. In the healing response, osteoclasts resorb the necrotic trabeculae. Trabeculae that remain act as scaffolding for the deposition of new bone in a process known as creeping substitution. In subchondral infarcts the pace of this substitution is too slow to be effective, so there is collapse of the necrotic bone and distortion, fracture, and even sloughing of the articular cartilage (Fig. 26-19).

Table 26-5 Conditions Associated with Osteonecrosis

Trauma
Tumors

Figure 26-19 Femoral head with a subchondral, wedge-shaped pale yellow area of osteonecrosis. The space between the overlying articular cartilage and bone is caused by trabecular compression fractures without repair.

Clinical Course. The symptoms depend on the location and extent of infarction. Typically, subchondral infarcts cause pain that is initially associated only with activity but then becomes constant as secondary changes supervene. Subchondral infarcts often collapse and may lead to severe, secondary osteoarthritis. In contrast, medullary infarcts are usually small and clinically silent except when they occur in the setting of Gaucher disease, dysbarism (e.g., the “bends”, Chapter 4), and sickle cell anemia. More than 10% of the 500,000 joint replacements performed annually in the United States are for treatment of complications of osteonecrosis.

Osteomyelitis

Osteomyelitis denotes inflammation of bone and marrow, virtually always secondary to infection. Osteomyelitis may be a complication of any systemic infection but frequently manifests as a primary solitary focus of disease. All types of organisms, including viruses, parasites, fungi, and bacteria, can produce osteomyelitis, but infections caused by certain pyogenic bacteria and mycobacteria are the most common. Currently in the United States, exotic infections in immigrants from developing countries and opportunistic infections in immunosuppressed individuals have made the diagnosis and treatment of osteomyelitis challenging.

Pyogenic Osteomyelitis

Pyogenic osteomyelitis is almost always caused by bacterial infections. Organisms may reach the bone by (1) hematogenous spread, (2) extension from a contiguous site, and (3) direct implantation. In otherwise healthy children, most osteomyelitis is hematogenous in origin and develops in the long bones. The initiating bacteremia may stem from seemingly trivial mucosal injuries, such as may occur during defecation or vigorous chewing of hard foods, or from minor infections of the skin. In adults, however, osteomyelitis more often occurs as a complication of open fractures, surgical procedures, and diabetic infections of the feet.

Staphylococcus aureus is responsible for 80% to 90% of the cases of culture-positive pyogenic osteomyelitis. These

organisms express cell wall proteins that bind to bone matrix components such as collagen, which facilitates adherence of the bacteria to bone. *Escherichia coli*, *Pseudomonas*, and *Klebsiella* are more frequently isolated from individuals with genitourinary tract infections or who are intravenous drug abusers. Mixed bacterial infections are seen in the setting of direct spread or inoculation of organisms during surgery or into open fractures. In the neonatal period, *Haemophilus influenzae* and group B streptococci are frequent pathogens, and individuals with sickle cell disease are predisposed to *Salmonella* infection. In almost 50% of suspected cases, no organisms can be isolated.

The location of the bone infections is influenced by the osseous vascular circulation, which varies with age. In the neonate the metaphyseal vessels penetrate the growth plate, resulting in frequent infection of the metaphysis, epiphysis, or both. In children, localization of microorganisms in the metaphysis is typical. After growth plate closure, the metaphyseal vessels reunite with their epiphyseal counterparts and provide a route for the bacteria to seed the epiphyses and subchondral regions, which are common sites of infection in the adult.

MORPHOLOGY

Changes associated with osteomyelitis depend on the stage (acute, subacute, or chronic) and location of the infection. In the acute phase, bacteria proliferate and induce a neutrophilic inflammatory reaction. Necrosis of bone cells and marrow ensues within the first 48 hours. The bacteria and inflammation spread longitudinally and may percolate throughout the Haversian systems to reach the periosteum. In children the periosteum is loosely attached to the cortex. Thus, a sizable subperiosteal abscesses may form that can dissect for long distances along the bone surface. Lifting of the periosteum further impairs the blood supply to the affected region, contributing to the necrosis. The dead bone is known as a **sequestrum**. Rupture of the periosteum leads to a soft tissue abscess which can channel to the skin as a draining sinus. Sometimes the sequestrum crumbles, releasing fragments that pass through the sinus tract.

In infants, but uncommonly in adults, epiphyseal infection spreads through the articular surface or along capsular and tendoligamentous insertions into a joint, producing septic or suppurative arthritis, which can cause destruction of the articular cartilage and permanent disability. An analogous process involves the vertebrae, in which the infection destroys the hyaline cartilage end plate and intervertebral disc and spreads into adjacent vertebrae.

After the first week, chronic inflammatory cells release cytokines that stimulates osteoclastic bone resorption, ingrowth of fibrous tissue, and the deposition of reactive bone at the periphery. The newly deposited bone can form a shell of living tissue, known as an **involucrum**, around the segment of devitalized infected bone (Fig. 26-20). Several morphologic variants of osteomyelitis have eponyms. **Brodie abscess** is a small intraosseous abscess that frequently involves the cortex and is walled off by reactive bone. **Sclerosing osteomyelitis of Garré** typically develops in the jaw and is associated with extensive new bone formation that obscures much of the underlying osseous structure.

Figure 26-20 Resected femur in a person with draining osteomyelitis. The drainage tract in the subperiosteal shell of viable new bone (involucrum) reveals the inner native necrotic cortex (sequestrum).

Clinical Course. Hematogenous osteomyelitis sometimes manifests as an acute systemic illness with malaise, fever, chills, leukocytosis, and marked-to-intense throbbing pain over the affected region. In other instances, the presentation is subtle, with only unexplained fever (most often in infants) or localized pain (most often in adults). The diagnosis is strongly suggested by the characteristic radiographic findings of a lytic focus of bone destruction surrounded by a zone of sclerosis. In some untreated cases blood cultures are positive, but biopsy and bone cultures are required to identify the pathogen in most instances. The combination of antibiotics and surgical drainage is usually curative.

In 5% to 25% of cases, acute osteomyelitis fails to resolve and persists as chronic infection. Chronic infections may develop when there is delay in diagnosis, extensive bone necrosis, inadequate antibiotic therapy or surgical debridement, or weakened host defenses. The course of chronic infections may be punctuated by acute flare-ups; these are usually spontaneous and may occur after years of dormancy. Other complications of chronic osteomyelitis include pathologic fracture, secondary amyloidosis, endocarditis, sepsis, and development of squamous cell carcinoma in the draining sinus tracts and sarcoma in the infected bone.

Mycobacterial Osteomyelitis

Mycobacterial osteomyelitis, historically a problem in developing countries, has increased in incidence in the developed world due to immigration patterns and immunocompromised patients. Overall, approximately 1% to 3% of individuals with pulmonary or extrapulmonary tuberculosis have osseous infection.

The organisms are usually blood borne and originate from a focus of active visceral disease during the initial stages of primary infection. Direct extension (e.g., from a pulmonary focus into a rib or from tracheobronchial nodes into adjacent vertebrae) or spread via the circulation

may also occur. The bone infection may persist for years before being recognized. Typically, affected individuals present with localized pain, low-grade fevers, chills, and weight loss. Infection is usually solitary except in immunocompromised individuals. The histologic findings, namely caseous necrosis and granulomas, are typical of tuberculosis elsewhere (Chapter 8). Mycobacterial osteomyelitis tends to be more destructive and resistant to control than pyogenic osteomyelitis.

Tuberculous spondylitis (Pott disease) is particularly destructive. The spine is involved in 40% of cases of mycobacterial osteomyelitis. The infection breaks through intervertebral discs to affect multiple vertebrae and extends into the soft tissues. Destruction of discs and vertebrae frequently results in permanent compression fractures that produce scoliosis or kyphosis and neurologic deficits secondary to spinal cord and nerve compression. Other complications of tuberculous osteomyelitis include tuberculous arthritis, sinus tract formation, psoas abscess, and amyloidosis.

Skeletal Syphilis

Syphilis (*Treponema pallidum*) and yaws (*Treponema pertenue*) can involve bone. Currently, syphilis is experiencing resurgence; however, bone involvement remains infrequent because the disease is usually diagnosed and treated before this complication develops.

In congenital syphilis, the bone lesions appear about the fifth month of gestation and are fully developed at birth. The spirochetes tend to localize in areas of active enchondral ossification (osteochondritis) and in the periosteum (periostitis). The syphilitic *saber shin* is produced by massive reactive periosteal bone deposition on the medial and anterior surfaces of the tibia. In acquired syphilis, bone disease may begin early in the tertiary stage, usually 2 to 5 years after the initial infection. The bones most frequently involved are those of the nose, palate, skull, and extremities, especially the long tubular bones such as the tibia.

MORPHOLOGY

Syphilitic bone infection is characterized by edematous granulation tissue containing numerous plasma cells and necrotic bone. The spirochetes can be demonstrated in the inflammatory tissue with silver histochemical stains or immunohistochemistry. Typical gummas may also form in both congenital and acquired syphilis (Chapter 8).

Bone Tumors and Tumor-Like Lesions

The rarity of primary bone tumors and the often disfiguring surgery required to treat a malignancy make this group of disorders especially challenging. Although metastases and hematopoietic tumors far outnumber primary bone neoplasms, about 2400 new cases of bone sarcoma are diagnosed annually, accounting for less than 1% of all bone disease in the United States. While not very common, bone sarcomas are lethal in 50% of cases. Therapy aims to optimize survival while maintaining the function of affected

Table 26-6 Classification of Major Primary Tumors Involving Bones

Category and fraction (%)	Behavior	Tumor type	Common locations	Age (yr)	Morphology
Hematopoietic (20)	Malignant	Myeloma Lymphoma	Vertebrae, pelvis	50-60	Malignant plasma cells or lymphocytes replacing marrow space
Cartilage forming (30)	Benign	Osteochondroma	Metaphysis of long bones	10-30	Bony excrescence with cartilage cap
		Chondroma	Small bones of hands and feet	30-50	Circumscribed hyaline cartilage nodule in medulla
		Chondroblastoma	Epiphysis of long bones	10-20	Circumscribed, pericellular calcification
	Malignant	Chondromyxoid fibroma Chondrosarcoma (conventional)	Tibia, pelvis Pelvis, shoulder	20-30 40-60	Collagenous to myxoid matrix, stellate cells Extends from medulla through cortex into soft tissue, chondrocytes with increased cellularity and atypia
Bone forming (26)	Benign	Osteoid osteoma	Metaphysis of long bones	10-20	Cortical, interlacing microtrabeculae of woven bone
		Osteoblastoma	Vertebral column	10-20	Posterior elements of vertebra, histology similar to osteoid osteoma
Unknown origin (15)	Benign	Osteosarcoma	Metaphysis of distal femur, proximal tibia	10-20	Extends from medulla to lift periosteum, malignant cells producing woven bone
		Giant cell tumor	Epiphysis of long bones	20-40	Destroys medulla and cortex, sheets of osteoclasts
	Malignant	Aneurysmal bone cyst	Proximal tibia, distal femur, vertebra	10-20	Vertebral body, hemorrhagic spaces separated by cellular, fibrous septae
		Ewing sarcoma Adamantinoma	Diaphysis of long bones Tibia	10-20 30-40	Sheets of primitive small round cells Cortical, fibrous, bone matrix with epithelial islands
Notochordal (4)	Malignant	Chordoma	Clivus, sacrum	30-60	Destroys medulla and cortex, foamy cells in myxoid matrix

body parts. Most bone neoplasms develop during the first several decades of life and have a propensity for the long bones of the extremities. The occurrence in certain age groups and predilection for particular anatomic sites provides important diagnostic clues about specific types of tumors. For example, osteosarcoma peaks during adolescence and most frequently involves the knee whereas chondrosarcoma affects older adults and involves the pelvis and proximal extremities.

Bone tumors may present in a number of ways. The more common benign lesions are often asymptomatic incidental findings. Many tumors, however, produce pain or a slow-growing mass. In some circumstances the first hint of a tumor's presence is a pathologic fracture. Radiographic imaging studies have an important role in diagnosing these lesions. In addition to providing the exact location and extent of the tumor, imaging studies can detect features that narrow the diagnostic possibilities. Ultimately, in almost all instances biopsy is necessary for definitive diagnosis.

When possible, bone tumors are classified according to the normal cell or matrix they produce. Lesions that do not have normal tissue counterparts are grouped according to their clinicopathologic features (Table 26-6). **Benign tumors greatly outnumber their malignant counterparts** and occur with greatest frequency within the first three decades of life, whereas in older adults, a bone tumor is likely to be malignant. Excluding neoplasms originating from hematopoietic cells (myeloma, lymphoma, and leukemia), osteosarcoma is the most common primary cancer of bone, followed by chondrosarcoma and Ewing sarcoma.

Insults that induce chronic injury and inflammation, such as bone infarcts, chronic osteomyelitis, Paget disease, radiation, and metal prostheses, increase the risk of bone neoplasia, possibly because proliferation associated with

chronic inflammation and repair set the stage for acquisition of oncogenic mutations. As we will describe, some of the causative mutations involve classic oncogenes and tumor suppressors that are implicated in many other tumors, whereas others involve genes that are specifically involved in bone development and are mutated only in bone tumors.

Bone-Forming Tumors

Tumors in this category all produce unmineralized osteoid or mineralized woven bone.

Osteoid Osteoma and Osteoblastoma

Osteoid osteoma and osteoblastoma are benign bone-producing tumors that have identical histologic features but differ in size, sites of origin, and symptoms. Osteoid osteomas are, by definition less than 2 cm in diameter, and usually occur in young men in their teens and 20s. These tumors can arise in any bone but have a predilection for the appendicular skeleton. About 50% of cases involve the femur or tibia, wherein they typically arise in the cortex and less frequently within the medullary cavity. Usually, there is a thick rind of reactive cortical bone that may be the only clue radiographically. Despite the small size, they present with severe nocturnal pain that is relieved by aspirin and other non-steroidal anti-inflammatory agents. The pain is probably caused by prostaglandin E₂ (PGE₂) produced by the proliferating osteoblasts. Osteoblastoma is larger than 2 cm and involves the posterior spine (laminae and pedicles) more frequently; the pain is unresponsive to aspirin, and the tumor usually does not induce a marked bony reaction. Osteoid osteoma is frequently treated by radiofrequency ablation, whereas osteoblastoma is usually curetted or excised en bloc. Malignant transformation is rare.

Figure 26-21 Osteoid osteoma composed of haphazardly interconnecting trabeculae of woven bone that are rimmed by prominent osteoblasts. The intertrabecular spaces are filled by vascularized loose connective tissue.

MORPHOLOGY

Osteoid osteoma and osteoblastoma are round-to-oval masses of hemorrhagic gritty tan tissue. They are well circumscribed and composed of randomly interconnecting trabeculae of woven bone that are prominently rimmed by a single layer of osteoblasts (Fig. 26-21). The stroma surrounding the neoplastic bone consists of loose connective tissue that contains many dilated and congested capillaries. The relatively small size, well-defined margins, and benign cytologic features of the neoplastic osteoblasts help distinguish these tumors from osteosarcoma. Osteoid osteomas elicit the formation of a tremendous amount of reactive bone, which encircles the lesion. The actual neoplasm (known as the nidus) manifests radiographically as a small round lucency that may be centrally mineralized (Fig. 26-22).

Osteosarcoma

Osteosarcoma is a malignant tumor in which the cancerous cells produce osteoid matrix or mineralized bone. It is the most common primary malignant tumor of bone,

Figure 26-22 Specimen radiograph of intracortical osteoid osteoma. The round radiolucency with central mineralization represents the lesion and is surrounded by abundant reactive bone that has massively thickened the cortex.

exclusive of myeloma and lymphoma, and accounts for approximately 20% of primary bone cancers. Osteosarcoma occurs in all age groups but has a bimodal age distribution; 75% occur in persons younger than 20 years of age. The smaller second peak occurs in older adults, who frequently suffer from conditions known to predispose to osteosarcoma—Paget disease, bone infarcts, and prior radiation. Overall, men are more commonly affected than women (1.6:1). Any bone can be involved. The tumors usually arise in the metaphyseal region of the long bones of the extremities, and almost 50% occur about the knee (i.e., distal femur or proximal tibia).

Osteosarcomas typically present as painful, progressively enlarging masses. Sometimes a sudden fracture of the bone is the first symptom. Radiographs usually show a large destructive, mixed lytic and blastic mass with infiltrative margins (Fig. 26-23). The tumor frequently breaks through the cortex and lifts the periosteum, resulting in reactive periosteal bone formation. The triangular shadow between the cortex and raised ends of periosteum, known radiographically as *Codman triangle*, is indicative of an aggressive tumor. It is characteristic but not diagnostic of osteosarcoma.

Pathogenesis. Approximately 70% of osteosarcomas have acquired genetic abnormalities such as complex structural and numerical chromosomal aberrations. Molecular studies have shown that these tumors usually have mutations in

Figure 26-23 Distal femoral osteosarcoma with prominent bone formation extending into the soft tissues. The periosteum, which has been lifted, has laid down a proximal triangular shell of reactive bone known as a Codman triangle (arrow).

well-known tumor suppressors and oncogenes, including the following:

- *RB*, which you will recall is a critical negative regulator of the cell cycle. Patients with germline mutations in *RB* have a 1000-fold increased risk of osteosarcoma and *RB* mutations are present in up to 70% of sporadic osteosarcomas.
- *TP53*, a gene whose product functions as the guardian of genomic integrity by promoting DNA repair and apoptosis of irreversibly damaged cells (Chapter 7): Patients with Li-Fraumeni syndrome, who have germline *TP53* gene mutations, have greatly elevated incidence of this tumor, and abnormalities that interfere with p53 function are common in sporadic tumors.
- *INK4a* is inactivated in many osteosarcomas. You will recall that this gene encodes two tumor suppressors, p16 (a negative regulator of cyclin-dependent kinases) and p14 (which augments p53 function).
- *MDM2* and *CDK4*, which are cell cycle regulators that inhibit into p53 and *RB* function, respectively, are overexpressed in many low-grade osteosarcomas, often through chromosomal amplification of region 12q13-q15.

It is also noteworthy that osteosarcomas peak in incidence around the time of the adolescent growth spurt and occur most frequently in the region of the growth plate in bones with the fastest growth. The increased proliferation at these sites may predispose to mutations that drive osteosarcoma development.

MORPHOLOGY

Several subtypes of osteosarcoma are recognized and are grouped according to:

- Site of origin (intramedullary, intracortical, or surface)
- Histologic grade (low, high)
- Primary (underlying bone is unremarkable) or secondary to preexisting disorders (benign tumors, Paget disease, bone infarcts, previous radiation)
- Histologic features (osteoblastic, chondroblastic, fibroblastic, telangiectatic, small cell, and giant cell)

The most common subtype arises in the metaphysis of long bones and is primary, intramedullary, osteoblastic, and high grade.

Osteosarcomas are bulky tumors that are gritty, gray-white, and often contain areas of hemorrhage and cystic degeneration (Fig. 26-24). The tumors frequently destroy the surrounding cortices and produce soft tissue masses. They spread extensively in the medullary canal, infiltrating and replacing hematopoietic marrow. Infrequently, they penetrate the epiphyseal plate or enter the joint. When joint invasion occurs, the tumor grows into it along tendoligamentous structures or through the attachment site of the joint capsule.

The tumor cells vary in size and shape and frequently have large hyperchromatic nuclei. Bizarre tumor giant cells are common, as are mitoses, some of them abnormal (e.g. tripolar). Vascular invasion is usually conspicuous, and some tumors also exhibit extensive necrosis. **The formation of bone by the tumor cells is diagnostic** (Fig. 26-25). The neoplastic bone usually has a fine, lace-like architecture but also may be

Figure 26-24 Osteosarcoma of the proximal tibia. The tan-white tumor fills most of the medullary cavity of the metaphysis and proximal diaphysis. It has infiltrated through the cortex, lifted the periosteum, and formed soft tissue masses on both sides of the bone.

deposited in broad sheets or as primitive trabeculae. In addition to bone, tumor cells may produce cartilage or fibrous tissue, but these are not required for diagnosis. When malignant cartilage is abundant, the tumor is called **chondroblastic osteosarcoma**.

Clinical Course. Osteosarcoma is treated with a multimodality approach that includes neoadjuvant chemotherapy, which is given under the assumption that all patients have occult metastases at the time of diagnosis, followed by surgery. The prognosis of osteosarcoma has improved substantially since the advent of chemotherapy, with 5-year survival rates reaching 60% to 70% in patients without overt metastases at initial diagnosis. These aggressive neoplasms spread hematogenously to the lungs. At the time of diagnosis, approximately 10% to 20% of affected individuals have demonstrable pulmonary metastases; of

Figure 26-25 Fine, lacelike pattern of neoplastic bone produced by anaplastic malignant tumor cells in an osteosarcoma. Note the abnormal mitotic figures (arrow).

those who die of the neoplasm, 90% have metastases to the lungs, bones, brain, and elsewhere. Unfortunately, the outcome for patients with metastases, recurrent disease or secondary osteosarcoma is still poor (<20% 5-year survival rate).

Cartilage-Forming Tumors

Although osteosarcoma is the most common primary malignant tumor of the bones, cartilage tumors account for the majority of primary bone tumors (both benign and malignant). They are characterized by the formation of hyaline or myxoid cartilage; fibrocartilage and elastic cartilage are rare components. As in most types of bone tumors, benign cartilage tumors are much more common than malignant ones.

Osteochondroma

Osteochondroma, also known as an *exostosis*, is a benign cartilage-capped tumor that is attached to the underlying skeleton by a bony stalk. It is the most common benign bone tumor; about 85% are solitary. The remainder is seen as part of the *multiple hereditary exostosis syndrome*, which is an autosomal dominant hereditary disease. Solitary osteochondromas are usually first diagnosed in late adolescence and early adulthood, but multiple osteochondromas become apparent during childhood. Men are affected three times more often than women. Osteochondromas develop only in bones of endochondral origin and arise from the metaphysis near the growth plate of long tubular bones, especially near the knee. Occasionally, they develop from bones of the pelvis, scapula, and ribs, and in these sites they are frequently sessile and have short stalks. Osteochondromas present as slow-growing masses, which can be painful if they impinge on a nerve or if the stalk is fractured. In many cases they are detected incidentally. In

multiple hereditary exostosis the underlying bones may be bowed and shortened, reflecting an associated disturbance in epiphyseal growth.

Pathogenesis. Hereditary exostoses are associated with germline loss-of-function mutations in either the *EXT1* or the *EXT2* gene and subsequent loss of the remaining wild type allele in chondrocytes of the growth plate. Reduced expression of *EXT1* or *EXT2* has also been observed in sporadic osteochondromas. These genes encode enzymes that synthesize heparan sulfate glycosaminoglycans. The reduced or abnormal glycosaminoglycans may prevent normal diffusion of the factor Indian hedgehog (*Ihh*), a local regulator of cartilage growth, thereby disrupting chondrocyte differentiation and local skeletal development.

MORPHOLOGY

Osteochondromas are sessile or pedunculated, and range in size from 1 to 20 cm. The cap is composed of benign hyaline cartilage varying in thickness (Fig. 26-26) and is covered peripherally by perichondrium. The cartilage has the appearance of disorganized growth plate and undergoes enchondral ossification, with the newly made bone forming the inner portion of the head and stalk. The cortex of the stalk merges with the cortex of the host bone, so that the medullary cavity of the osteochondroma and bone from which it arises are in continuity.

Clinical Course. Osteochondromas usually stop growing at the time of growth plate closure (Fig. 26-27). Symptomatic tumors are cured by simple excision. Rarely in sporadic cases, but more commonly in those with multiple hereditary exostosis (5% to 20%), osteochondromas progress to chondrosarcoma.

Figure 26-26 Osteochondroma. **A**, Radiograph of an osteochondroma arising from the distal femur (arrow). **B**, The cartilage cap has the histologic appearance of disorganized growth plate-like cartilage.

Figure 26-27 The development of an osteochondroma, beginning with an outgrowth from the epiphyseal cartilage.

Chondromas

Chondromas are benign tumors of hyaline cartilage that usually occur in bones of enchondral origin. They can arise within the medullary cavity, where they are known as *enchondromas*, or on the surface of bone, where they are called *juxtacortical chondromas*. Enchondromas are the most common of the intraosseous cartilage tumors and are usually diagnosed in individuals 20 to 50 years of age. Typically, they appear as solitary metaphyseal lesions of tubular bones of the hands and feet. The radiographic features consist of circumscribed lucencies with central irregular calcifications, a sclerotic rim and an intact cortex (Fig. 26-28). *Ollier disease* and *Maffucci syndrome* are nonhereditary disorders characterized by multiple enchondromas. *Maffucci syndrome* is, in addition, distinguished by presence of spindle cell hemangiomas.

Most enchondromas of large bones are asymptomatic and are detected incidentally. Occasionally, they are

painful and cause pathologic fracture. The tumors in enchondromatosis may be numerous and large, producing severe deformities.

Pathogenesis. Heterozygous mutations in the *IDH1* and *IDH2* genes have been identified in the chondrocytes of syndromic and solitary enchondromas. Patients with enchondroma syndromes are mosaics, harboring IDH mutations in only a subset of otherwise normal cells throughout their bodies. Similarly, IDH mutations are found in only a subset of tumor cells in both syndromic and sporadic enchondromas. This unusual situation may be explained by the functional consequences of the IDH1 and IDH2 mutations. Both cause the encoded proteins, two isoforms of the enzyme isocitrate dehydrogenase, to acquire a new enzymatic activity that leads to the synthesis of 2-hydroxyglutarate. You will recall from Chapter 7 that this so-called “oncometabolite” interferes with regulation of DNA methylation. It is hypothesized that the 2-hydroxyglutarate produced by the subset of IDH-mutated cells in enchondromas diffuses into neighboring cells with normal IDH genes, thereby causing oncogenic epigenetic changes in genetically normal neighbors (transformation by association).

Figure 26-28 Enchondroma of the proximal phalanx. The radiolucent nodule of cartilage with central calcification is juxtacortical but does not penetrate the cortex.

MORPHOLOGY

Enchondromas are usually smaller than 3 cm and are gray-blue and translucent. They are composed of well-circumscribed nodules of hyaline cartilage containing cytologically benign chondrocytes (Fig. 26-29). The peripheral portion of the nodules may undergo enchondral ossification, and the center can calcify and infarct. The enchondromas in Ollier disease and Maffucci syndrome are sometimes more cellular than sporadic enchondromas and exhibit cytologic atypia, making them more difficult to distinguish from chondrosarcomas.

Clinical Course. The growth potential of chondromas is limited. Treatment depends on the clinical situation and is usually observation or curettage. Solitary chondromas rarely undergo sarcomatous transformation, but those associated with enchondromatosis do so more frequently. Individuals with Maffucci syndrome are also at risk of developing other types of malignancies, including ovarian carcinomas and brain gliomas.

Figure 26-29 Enchondroma composed of a nodule of hyaline cartilage encased by a thin layer of reactive bone.

Chondrosarcoma

Chondrosarcomas are malignant tumors that produce cartilage. They are subclassified histologically as *conventional* (hyaline cartilage producing), *clear cell*, *dedifferentiated*, and *mesenchymal* variants. Conventional tumors are further subdivided by site as *central* (intramedullary) and *peripheral* (juxtacortical). Conventional central tumors constitute about 90% of chondrosarcomas. Chondrosarcoma is about half as common as osteosarcoma and is the second most common malignant matrix-producing tumor of bone. Individuals with chondrosarcoma are usually in their 40s or older. The clear cell and especially the mesenchymal variants occur in younger patients, in their teens or 20s. These tumors affect men twice as frequently as women. Chondrosarcomas commonly arise in the axial skeleton, especially the pelvis, shoulder, and ribs. Unlike benign enchondroma, the distal extremities are rarely involved. On imaging, the calcified matrix appears as foci of flocculent densities. A slow-growing, low-grade tumor causes reactive thickening of the cortex, whereas a more aggressive high-grade neoplasm destroys the cortex and forms a soft tissue mass. The clear cell variant is unique in that it originates in the epiphyses of long tubular bones. About 15%

of conventional chondrosarcomas are secondary, arising from a preexisting enchondroma or osteochondroma.

Although chondrosarcomas are genetically heterogeneous, a few reproducible abnormalities have been identified. Chondrosarcomas arising in multiple osteochondroma syndrome exhibit mutations in the *EXT* genes, and both chondromatosis-related and sporadic chondrosarcomas may have *IDH1* and *IDH2* mutations. Silencing of the *CDKN2A* tumor suppressor gene by DNA methylation is also relatively common in sporadic tumors.

MORPHOLOGY

Conventional chondrosarcomas are large bulky tumors made up of nodules of glistening gray-white, translucent cartilage but matrix is often gelatinous or myxoid (Fig. 26-30A). The myxoid matrix can ooze from the cut surface. Spotty calcifications are typically present, and central necrosis may create cystic spaces. The tumor spreads through the cortex into surrounding muscle or fat. Histologically, the cartilage infiltrates the marrow space and surrounds pre-existing bony trabeculae. The tumors vary in cellularity, cytologic atypia, and mitotic activity and are assigned a grade from 1 to 3. Grade 1 tumors have relatively low cellularity, and the chondrocytes have plump vesicular nuclei with small nucleoli. By contrast, grade 3 chondrosarcomas are characterized by high cellularity, extreme pleomorphism with bizarre tumor giant cells, and mitoses (Fig. 26-30B).

Dedifferentiated chondrosarcoma is defined as a low-grade chondrosarcoma with a second, high-grade component that does not produce cartilage. **Clear cell chondrosarcoma** contains sheets of large, malignant chondrocytes that have abundant clear cytoplasm, numerous osteoclast-type giant cells, and intralesional reactive bone formation, which often causes confusion with osteosarcoma. **Mesenchymal chondrosarcoma** is composed of islands of well-differentiated hyaline cartilage surrounded by sheets of small round cells, which can mimic Ewing sarcoma.

Clinical Course. Chondrosarcomas usually present as painful, progressively enlarging masses. There is a direct correlation between the grade and the biologic behavior of the tumor. Fortunately, most conventional chondrosarcomas are grade 1 tumors with 5-year survival rates of 80% to 90% (versus 43% for grade 3 tumors). Grade 1

Figure 26-30 Chondrosarcoma. **A**, Nodules of hyaline and myxoid cartilage permeating throughout the medullary cavity, growing through the cortex, and forming a relatively well-circumscribed soft tissue mass. **B**, Anaplastic chondrocytes amid hyaline cartilage matrix in a grade 3 chondrosarcoma.

chondrosarcomas rarely metastasize, whereas 70% of grade 3 tumors spread hematogenously, especially to the lungs. The treatment of conventional chondrosarcoma is wide surgical excision. The mesenchymal and dedifferentiated tumors are also excised and additionally treated with chemotherapy because of their more aggressive clinical course.

Tumors of Unknown Origin

Ewing Sarcoma Family Tumors

Ewing sarcoma is a malignant bone tumor characterized by primitive round cells without obvious differentiation. Recently, Ewing sarcoma and **primitive neuroectodermal tumor** (PNET) have been unified into a single category: the **Ewing sarcoma family tumors** (ESFT) based on shared clinical, morphologic, biochemical and molecular features (discussed later). Although PNET demonstrates more neuroectodermal differentiation than Ewing sarcoma, the distinction is not clinically significant.

Ewing sarcoma family tumors account for approximately 6% to 10% of primary malignant bone tumors and follow osteosarcoma as the second most common group of bone sarcomas in children. Of all bone sarcomas, ESFT have the youngest average age at presentation, since approximately 80% are younger than 20 years. Boys are affected slightly more frequently than girls, and there is a striking predilection for whites; blacks and Asians are rarely afflicted. ESFT usually arise in the diaphysis of long tubular bones, especially the femur and the flat bones of the pelvis. They present as painful enlarging masses, and the affected site is frequently tender, warm, and swollen. Some affected individuals have systemic findings that mimic infection, including fever, elevated sedimentation rate, anemia, and leukocytosis. Plain radiographs show a destructive lytic tumor with permeative margins that extends into the surrounding soft tissues. The characteristic periosteal reaction produces layers of reactive bone deposited in an *onion-skin* fashion.

Pathogenesis. Most ESFT contain a (11;22) (q24;q12) translocation generating in-frame fusion of the *EWS* gene on chromosome 22 to the *FLI1* gene. Variant translocations fuse *EWS* to other members of the ETS transcription factor family. The exact fusion sites vary between tumors, leading to different downstream effects. How *EWS* fusion proteins contribute to transformation remains unsettled; effects on transcription, RNA splicing, and the cell cycle machinery have all been proposed. Similarly, the cell of origin still remains to be identified; the leading candidates are mesenchymal stem cells and primitive neuroectodermal cells.

MORPHOLOGY

Arising in the medullary cavity, Ewing sarcoma usually invades the cortex, periosteum, and soft tissue. The tumor is soft, tan-white, and frequently contains areas of hemorrhage and necrosis. It is composed of sheets of uniform small, round cells that are slightly larger and more cohesive than lymphocytes (Fig. 26-31). They have scant cytoplasm, which may appear clear because it is rich in glycogen. The presence of Homer-Wright rosettes (round groupings of cells with a central fibrillary core) indicate a greater degree of neuroectodermal differentiation.

Figure 26-31 Ewing sarcoma composed of sheets of small round cells with small amounts of clear cytoplasm.

Although the tumor contains fibrous septae, there is generally little stroma. Geographic necrosis may be prominent, and there are relatively few mitotic figures in relation to the dense cellularity of the tumor.

Clinical Course. ESFT are aggressive malignancies treated with neoadjuvant chemotherapy followed by surgical excision with or without irradiation. The advent of effective chemotherapy has achieved 5-year survival of 75% and long-term cure in 50%. The amount of chemotherapy-induced necrosis is an important prognostic finding.

Giant Cell Tumor

Giant cell tumor is so named because the histology is dominated by multinucleated osteoclast-type giant cells, giving rise to the synonym **osteoclastoma**. It is a relatively uncommon benign, but locally aggressive, neoplasm. It usually arises in individuals in their 20s to 40s.

Pathogenesis. Current evidence suggests that the neoplastic cells of giant cell tumor are primitive osteoblast precursors but they represent only a minority of the tumor cells. The bulk of the tumor consists of non-neoplastic osteoclasts and their precursors. The neoplastic cells express high levels of RANKL, which promotes the proliferation of osteoclast precursors and their differentiation into mature osteoclasts via RANK expressed by these cells. However, the feedback between osteoblasts and osteoclasts that normally regulates this process during bone remodeling is absent. What results is a localized but highly destructive resorption of bone matrix by reactive osteoclasts.

Giant cell tumors arise in the epiphysis but may extend into the metaphysis. The majority arise around the knee (distal femur and proximal tibia), but virtually any bone can be involved. The typical location of these tumors near joints frequently causes arthritis-like symptoms. Occasionally, they present with pathologic fractures. Most are solitary; however, multicentric tumors do occur, especially in the distal extremities.

MORPHOLOGY

Giant cell tumors often destroy the overlying cortex, producing a bulging soft tissue mass delineated by a thin shell of reactive

Figure 26-32 Giant cell tumor of the proximal fibula is predominantly lytic, expansile with destruction of the cortex. A pathologic fracture is also present.

bone (Fig. 26-32). These are large, red-brown masses that frequently undergo cystic degeneration. Histologically, the tumor consists of sheets of uniform oval mononuclear cells and numerous osteoclast-type giant cells with 100 or more nuclei (Fig. 26-33). The nuclei of the mononuclear cells and the osteoclasts are similar, ovoid with prominent nucleoli. Thus, the neoplastic population of osteoblast precursors is difficult to identify on routine histology. Necrosis and mitotic activity may be prominent. Although reactive bone, especially at the periphery of a lesion, may be present, the tumor cells do not synthesize bone or cartilage.

Clinical Course. Giant cell tumors are typically treated with curettage, but 40% to 60% recur locally. Up to 4% of tumors metastasize to the lungs, but these sometimes spontaneously regress and they are seldom fatal. Recently, the

Figure 26-33 Benign giant cell tumor illustrating an abundance of multinucleated giant cells with background mononuclear stromal cells.

RANKL inhibitor, denosumab has shown promise as an adjuvant therapy in giant cell tumor.

Aneurysmal Bone Cyst

Aneurysmal bone cyst (ABC) is a tumor characterized by multiloculated blood-filled cystic spaces. Interestingly, radiographic and histologic findings typical of ABC can also be seen as a secondary reaction to other primary bone tumors. Primary ABC affects all age groups but generally occurs during the first 2 decades of life and has no sex predilection. It most frequently develops in the metaphysis of long bones and the posterior elements of vertebral bodies. The most common signs and symptoms are pain and swelling. When an ABC involves the vertebrae, it can compress nerves and cause neurologic symptoms. Rarely, pathologic fractures occur. Secondary ABC can be present in the setting of a number of primary neoplasms, especially giant cell tumor and chondroblastoma.

Radiographically, ABC is usually an eccentric, expansile lesion with well-defined margins (Fig. 26-34A). Most lesions are completely lytic and often contain a thin shell of reactive bone at the periphery. Computed tomography and magnetic resonance imaging may demonstrate internal septa and characteristic fluid-fluid levels (Fig. 26-34B).

Pathogenesis. The spindle cells of ABC frequently demonstrate rearrangements of chromosome 17p13 resulting in fusion of the coding region of *USP6* to the promoters of genes that are highly expressed in osteoblasts, leading to *USP6* overexpression. *USP6* encodes an ubiquitin specific protease that regulates the activity of the transcription factor NFκB. Increased NFκB activity appears to upregulate genes such as matrix metalloproteases that lead to cystic resorption of bone. Secondary ABCs do not have *USP6* rearrangements and appear to be triggered by epigenetic mechanisms.

MORPHOLOGY

Aneurysmal bone cyst consists of multiple blood-filled cystic spaces separated by thin, tan-white septa (Fig. 26-35). The septa are composed of plump uniform fibroblasts, multinucleated osteoclast-like giant cells, and reactive woven bone. The bone is lined by osteoblasts, and its deposition typically follows the contours of the fibrous septa. Approximately one third of cases contain an unusual densely calcified matrix called “blue bone.” Necrosis is uncommon unless a pathologic fracture is present.

Clinical Course. The treatment of aneurysmal bone cyst is surgical, usually curettage or, in certain situations, en bloc resection. The recurrence rate is low, and spontaneous regression may occur following incomplete removal.

Lesions Simulating Primary Neoplasms

Fibrous Cortical Defect and Nonossifying Fibroma

Fibrous cortical defects (also known as **metaphyseal fibrous defects**) are extremely common, present in 30% to 50% of children older than 2 years. The vast majority arise eccentrically in the metaphysis of the distal femur and proximal tibia, and almost half are bilateral or multiple. Often they are small, about 0.5 cm in diameter. Those that

Figure 26-34 **A**, Coronal computed axial tomography scan showing eccentric aneurysmal bone cyst of tibia. The soft tissue component is delineated by a thin rim of reactive subperiosteal bone. **B**, Axial magnetic resonance image demonstrating characteristic fluid-fluid levels.

grow to 5 or 6 cm in size are classified as **nonossifying fibromas**; these are usually not detected until adolescence or adulthood.

MORPHOLOGY

Both fibrous cortical defect and nonossifying fibroma produce sharply demarcated radiolucencies with a long axis of a bone parallel to the cortex, surrounded by a thin rim of sclerosis (Fig. 26-36). They consist of gray to yellow-brown cellular lesions containing fibroblasts and macrophages. The cytologically bland fibroblasts are frequently arranged in a storiform (pinwheel) pattern, and the macrophages may take the form of clustered cells with foamy cytoplasm or multinucleated giant cells with foamy cytoplasm or multinucleated giant cells (Fig. 26-37). Hemosiderin is commonly present.

Figure 26-35 Aneurysmal bone cyst with blood-filled cystic space surrounded by a fibrous wall containing proliferating fibroblasts, reactive woven bone, and osteoclast-type giant cells.

Fibrous cortical defects are asymptomatic and are detected incidentally on radiographic studies. The findings are sufficiently specific on plain radiography that biopsy is rarely necessary. Most fibrous cortical defects have limited growth potential and undergo spontaneous resolution within several years, being replaced by normal cortical bone. The few that progressively enlarge into nonossifying fibromas may present with pathologic fracture or require biopsy and curettage to exclude other types of tumors.

Figure 26-36 Nonossifying fibroma of the distal tibial metaphysis producing an eccentric lobulated radiolucency surrounded by a sclerotic margin.

Figure 26-37 Storiform pattern created by benign spindle cells with scattered osteoclast-type giant cells characteristic of a fibrous cortical defect and nonossifying fibroma.

Fibrous Dysplasia

Fibrous dysplasia is a benign tumor that has been likened to a localized developmental arrest; all of the components of normal bone are present, but they do not differentiate into mature structures. The lesions arise during skeletal development, and appear in several distinctive but sometimes overlapping clinical patterns:

- Monostotic: involvement of a single bone
- Polyostotic: involvement of multiple bones
- *Mazabraud syndrome*: fibrous dysplasia (usually polyostotic) and soft tissue myxomas
- *McCune-Albright syndrome*: polyostotic disease, associated with café-au-lait skin pigmentations and endocrine abnormalities, especially precocious puberty.

Pathogenesis. All of the above manifestations result from a somatic gain-of-function mutation during development in *GNAS1*, the gene that is also mutated in pituitary adenomas (Chapter 24). The mutations produce a constitutively active G_s -protein that promotes cellular proliferation. The extent of phenotype depends on (1) the stage of embryogenesis when the mutation is acquired and (2) the fate of the cell harboring the mutation. At one extreme, a mutation during embryogenesis produces the *McCune-Albright syndrome* while a mutation in an osteoblast precursor, during or after formation of the skeleton, results in monostotic fibrous dysplasia. The skeletal manifestations arise from G_s -cAMP mediated interruption of normal osteoblast differentiation from precursors.

MORPHOLOGY

The lesions of fibrous dysplasia are well circumscribed, intramedullary, and vary greatly in size. Larger lesions expand and distort the bone. The lesional tissue is tan-white and gritty and is composed of curvilinear trabeculae of woven bone surrounded by a moderately cellular fibroblastic proliferation. The curvilinear shapes of the trabeculae mimic Chinese characters, and the bone lacks prominent osteoblastic rimming (Fig. 26-38). Nodules of hyaline cartilage with the appearance of disorganized growth plate are also present in approximately 20% of cases. Cystic degeneration, hemorrhage, and foamy macrophages are other common findings.

Clinical Course. Monostotic fibrous dysplasia occurs equally in boys and girls, usually in early adolescence, and often stops enlarging at the time of growth plate closure. The femur, tibia, ribs, jawbones, calvarium, and humerus are most commonly affected. The lesion is frequently asymptomatic and usually discovered incidentally but it may cause pain, fracture, and discrepancies in limb length. The lesion is readily recognized radiologically by its typical ground-glass appearance and well-defined margination. Symptomatic lesions are cured by curettage.

Polyostotic fibrous dysplasia manifests at a slightly earlier age than the monostotic type and may continue to cause problems into adulthood. The bones affected, in descending order of frequency, are the femur, skull, tibia, humerus, ribs, fibula, radius, ulna, mandible, and vertebrae. Craniofacial involvement is present in 50% of those who have a moderate number of bones affected and in 100% of those with extensive skeletal disease. Polyostotic disease has a propensity to involve the shoulder and pelvic girdles, resulting in severe, progressive disease including crippling deformities and fractures. Patients may require multiple corrective orthopedic surgical procedures. Bisphosphonates can be used to reduce the severity of the bone pain. A rare complication, usually in the setting of polyostotic involvement, is malignant transformation of a lesion into a sarcoma.

Mazabraud syndrome presents with skeletal features of polyostotic fibrous dysplasia with multiple skeletal deformities identified in childhood. The intramuscular myxomas present in adulthood often in the same anatomic region as existing fibrous dysplasia. Although benign, these tumors can cause local compression symptoms or further deformity to a limb but are cured by surgical excision.

The most common clinical presentation of *McCune-Albright syndrome* is precocious sexual development, which occurs most often in girls. The syndrome can include other endocrinopathies such as hyperthyroidism, pituitary adenomas that secrete growth hormone, and primary adrenal hyperplasia. The bone lesions are often unilateral, and the skin pigmentation is usually limited to the same side of the body. The cutaneous macules are classically large; dark to

Figure 26-38 Fibrous dysplasia composed of curvilinear trabeculae of woven bone that lack conspicuous osteoblastic rimming and arise in a background of fibrous tissue.

café-au-lait in color; have irregular serpiginous borders; and are found primarily on the neck, chest, back, shoulder, and pelvic region. The skeletal manifestations are managed as for other polyostotic fibrous dysplasia while the endocrinopathies are treated medically, for example with aromatase inhibitors for precocious puberty.

Metastatic Tumors

Metastatic tumors are the most common form of skeletal malignancy, greatly outnumbering primary bone cancers. The pathways of spread include (1) direct extension, (2) lymphatic or hematogenous dissemination, and (3) intrasplinal seeding (via the Batson plexus of veins). Any cancer can spread to bone, but in adults more than 75% of skeletal metastases originate from cancers of the prostate, breast, kidney, and lung. In children, metastases to bone originate from neuroblastoma, Wilms tumor, osteosarcoma, Ewing sarcoma, and rhabdomyosarcoma.

Skeletal metastases are typically multifocal. However, carcinomas of the kidney and thyroid may present with solitary lesions. Most metastases involve the axial skeleton (vertebral column, pelvis, ribs, skull, and sternum). The red marrow in these areas, with its rich capillary network and slow blood flow, facilitates implantation and growth of the tumor cells. Metastases to the small bones of the hands and feet are uncommon and usually originate from cancers of the lung, kidney, or colon.

The radiographic appearance of metastases may be purely *lytic* (bone destroying), purely *blastic* (bone forming), or *mixed* lytic and blastic. Furthermore, some cancers are associated with predominantly one pattern or the other. For example, prostatic adenocarcinoma is predominantly blastic whereas carcinomas of the kidney, lung, and gastrointestinal tract and malignant melanoma produce lytic lesions. Bidirectional interactions between metastatic cancer cells and native bone cells account for the changes that manifest in the bone matrix. Tumor cells do not directly resorb bone in lytic lesions. Rather, they secrete substances such as prostaglandins, cytokines, and PTHrP that upregulate RANKL on osteoblasts and stromal cells thereby stimulating osteoclast activity. At the same time, tumor cell growth is supported by the release of matrix-bound growth

factors (e.g., TGF- β , IGF-1, and FGF) as bone is resorbed. Sclerotic metastases may be produced by tumor cells secreting WNT proteins that stimulate osteoblastic bone formation.

The presence of bone metastases unfortunately carries a dim prognosis since it indicates wide dissemination of the cancer. Treatment strategies aim at managing symptoms and limiting further spread. Therapeutic options include systemic chemotherapy, localized radiation and bisphosphonates. Surgery may be necessary to stabilize pathologic fractures.

KEY CONCEPTS

Bone Tumors and Tumor-Like Lesions

Primary bone tumors are classified according to the normal cell or matrix they produce. The remainder is grouped according to clinicopathologic features. Most primary bone tumors are benign. Metastases, especially adenocarcinomas, are more common than primary bone neoplasms.

Major categories of primary bone tumors include:

- **Bone forming:** Osteoblastoma and osteoid osteoma consist of benign osteoblasts that synthesize osteoid. Osteosarcoma is a tumor of malignant osteoblasts, predominantly involving adolescents with an aggressive clinical course.
- **Cartilage forming:** Osteochondroma is a polypoid exostosis with a cartilage cap. Sporadic and syndromic forms arise from mutations in the *EXT* genes. Chondromas are benign intramedullary tumors producing hyaline cartilage, usually arising in the digits. Chondrosarcomas are malignant tumors of cartilage, involving the axial skeleton in adults.
- **Ewing sarcoma family of tumors** consists of aggressive malignant small round cell tumors most often associated with t(11;22).
- **Fibrous cortical defect** and **fibrous dysplasia** are unusual examples of disorders caused by gain-of-function mutations that occur during development

JOINTS

Joints allow movement while providing mechanical stability. They are classified as *solid (nonsynovial)* and *cavitated (synovial)*. The solid joints, also known as *synarthroses*, provide structural integrity and allow only minimal movement. They lack a joint space and are grouped according to the type of connective tissue (fibrous tissue or cartilage) that bridges the ends of the bones. Fibrous synarthroses include the cranial sutures and the bonds between roots of teeth and the jawbones. Cartilaginous synarthroses (synchondroses) are represented by the symphyses (manubriosternalis and pubic). Synovial joints, in contrast, have a joint space that allows for a wide range of motion. Situated between the ends of bones formed via enchondral ossification, they are strengthened by a dense fibrous capsule reinforced by ligaments and muscles. The boundary of the joint space consists of the synovial membrane, which is firmly anchored to the underlying capsule and does not cover

the articular surface. Its contour is smooth except near the osseous insertion, where it is thrown into numerous villous folds. Synovial membranes are lined by two types of cells that are arranged one to four layers deep. Type A synoviocytes are specialized macrophages with phagocytic activity. Type B synoviocytes are similar to fibroblasts and synthesize hyaluronic acid and various proteins. The synovial lining lacks a basement membrane, which allows for efficient exchange of nutrients, wastes, and gases between blood and synovial fluid. Synovial fluid is a plasma filtrate containing hyaluronic acid that acts as a viscous lubricant and provides nutrition for the articular hyaline cartilage.

Hyaline cartilage is a unique connective tissue ideally suited to serve as an elastic shock absorber and wear-resistant surface. It lacks a blood supply and does not have lymphatic drainage or innervation. Hyaline cartilage is

composed of water (70%), type II collagen (10%), proteoglycans (8%), and chondrocytes. The collagen fibers enable the cartilage to resist tensile stresses and transmit vertical loads. The water and proteoglycans give hyaline cartilage its resistance to compression and have an important role in limiting friction. The chondrocytes synthesize the matrix as well as enzymatically digest it, with the half-life of the different components ranging from weeks (proteoglycans) to years (type II collagen). Chondrocytes secrete degradative enzymes in inactive forms and enrich the matrix with enzyme inhibitors. Diseases that destroy articular cartilage do so by activating the catabolic enzymes and decreasing the production of inhibitors, thereby accelerating the rate of matrix breakdown. Cytokines such as IL-1 and TNF trigger the degradative process; their sources include chondrocytes, synoviocytes, fibroblasts, and inflammatory cells. Destruction of articular cartilage by indigenous cells is an important mechanism in many joint diseases.

Osteoarthritis

Osteoarthritis, also called degenerative joint disease, is characterized by degeneration of cartilage that results in structural and functional failure of synovial joints. It is the most common type of joint disease. Annual costs from lost productivity and treatment of osteoarthritis in the United States are estimated to be more than 65 billion dollars. Although the term osteoarthritis implies an inflammatory disease, it is considered to be an intrinsic disease of cartilage in which chondrocytes respond to biochemical and mechanical stresses resulting in breakdown of the matrix.

In most instances osteoarthritis appears insidiously, without apparent initiating cause, as an aging phenomenon (*idiopathic* or *primary osteoarthritis*). In these cases the disease is usually oligoarticular (affects few joints) but may be generalized. In about 5% of cases, osteoarthritis appears in younger individuals with some predisposing condition, such as joint deformity, a previous joint injury, or an underlying systemic disease such as diabetes, ochronosis, hemochromatosis, or marked obesity that places joints at risk. In these settings the disease is called *secondary osteoarthritis*. Gender has some influence on distribution. The knees and hands are more commonly affected in women and the hips in men.

Pathogenesis. The lesions of osteoarthritis (OA) stem from degeneration of the articular cartilage and its disordered repair. The articular cartilage contributes to the virtually frictionless movement of the joint while providing resistance to tension and compression, from type II collagen and proteoglycans, respectively, both synthesized by chondrocytes. Although historically OA was considered an inevitable process of wear and tear, this is an oversimplification, as the disease actually involves complex pathologic changes in chondrocytes and matrix.

The changes to chondrocytes can be divided into three phases: (1) chondrocyte injury, related to genetic and biochemical factors; (2) early OA, in which chondrocytes proliferate and secrete inflammatory mediators, collagens, proteoglycans, and proteases, which act together to remodel the cartilaginous matrix and initiate secondary

inflammatory changes in the synovium and subchondral bone; and (3) late OA, in which repetitive injury and chronic inflammation lead to chondrocyte drop out, marked loss of cartilage, and extensive subchondral bone changes.

Virtually every extracellular component of articular cartilage is affected in OA. Collagen type II is degraded by matrix metalloproteinases. Although chondrocytes continuously synthesize and secrete proteoglycans during disease progression, degradation ultimately exceeds synthesis, and the composition of proteoglycans changes. Inflammatory cells are sparse, but cytokines and diffusible factors associated with other inflammatory conditions, particularly TGF- β (which induces matrix metalloproteinases), TNF, prostaglandins and nitric oxide, have been implicated in osteoarthritis.

Environmental and genetic influences contribute to the pathogenesis of OA. The major environmental factors relate to aging and biomechanical stress. The association with aging is strong; the prevalence of OA increases exponentially beyond the age of 50, and about 40% of people older than 70 are affected. Studies of families and twins have suggested that the risk of OA is the sum of multiple genes, each with a small effect. Candidate gene studies and genome-wide association studies show that OA is genetically heterogeneous.

MORPHOLOGY

In the early stages of osteoarthritis, the chondrocytes proliferate, forming clusters (so-called cloning). Concurrently, the water content of the matrix increases and the concentration of proteoglycans decreases. The normally horizontally arranged collagen type II fibers in the superficial zone are cleaved, yielding fissures and clefts at the articular surface (Fig. 26-39A). This manifests as a granular soft articular surface. Eventually, chondrocytes die and full-thickness portions of the cartilage are sloughed. The dislodged pieces of cartilage and subchondral bone tumble into the joint, forming loose bodies (joint mice). The exposed subchondral bone plate becomes the new articular surface, and friction with the opposing surface smooths and burnishes the exposed bone, giving it the appearance of polished ivory (bone eburnation) (Fig. 26-39B). There is rebuttoning and sclerosis of the underlying cancellous bone. Small fractures through the articulating bone are common, and the fracture gaps allow synovial fluid to be forced into the subchondral regions in a one-way, ball valve-like mechanism. The loculated fluid collection increases in size, forming fibrous-walled cysts. Mushroom-shaped osteophytes (bony outgrowths) develop at the margins of the articular surface and are capped by fibrocartilage and hyaline cartilage that gradually ossify. The synovium is usually only mildly congested and fibrotic, and may have scattered chronic inflammatory cells.

Clinical Course. Osteoarthritis is an insidious disease. Patients with primary disease are usually asymptomatic until they are in their 50s. If a young person has significant manifestations of osteoarthritis, a search for some underlying cause should be made. Characteristic symptoms include deep, achy pain that worsens with use, morning stiffness, crepitus, and limitation of range of movement. Impingement on spinal foramina by osteophytes results in cervical and lumbar nerve root compression and radicular pain, muscle

spasms, muscle atrophy, and neurologic deficits. Typically, only one or a few joints are involved except in the uncommon generalized variant. The joints commonly involved include the hips (Fig. 26-40), knees, lower lumbar and cervical vertebrae, proximal and distal interphalangeal joints of the fingers, first carpometacarpal joints, and first tarsometatarsal joints. *Heberden nodes*, prominent osteophytes at the distal interphalangeal joints, are common in women (but not men). The wrists, elbows, and shoulders are usually spared. With time, joint deformity can occur, but unlike rheumatoid arthritis (discussed next), fusion does not take place (Fig. 26-41). The level of disease severity detected radiographically, however, does not correlate well with pain and disability. There are still no satisfactory means of preventing primary osteoarthritis, and there are

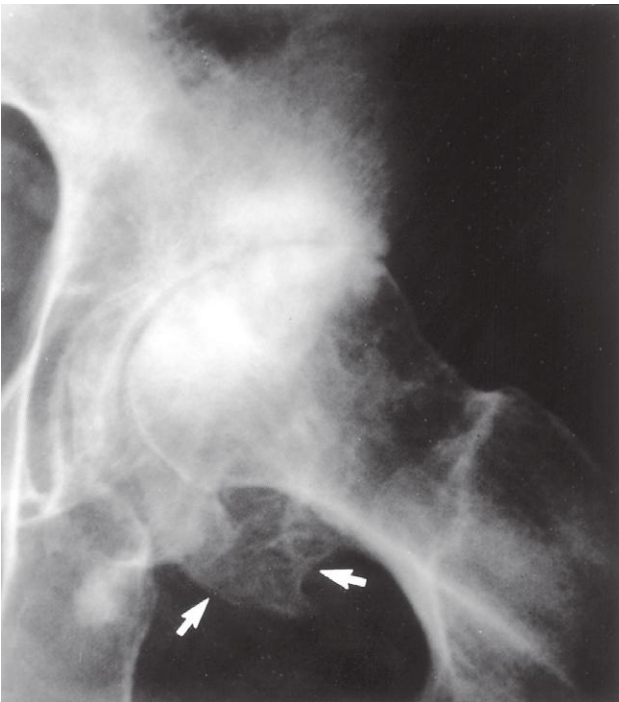

Figure 26-40 Severe osteoarthritis of the hip. The joint space is narrowed, and there is subchondral sclerosis with scattered oval radiolucent cysts and peripheral osteophyte lipping (arrows).

no effective methods of halting its progression. Therapy includes management of pain, activity modification and, for severe cases, arthroplasty.

Rheumatoid Arthritis

Rheumatoid arthritis (RA) is a chronic inflammatory disorder of autoimmune origin that may affect many tissues and organs but principally attacks the joints, producing a nonsuppurative proliferative and inflammatory synovitis. RA often progresses to destruction of the articular cartilage and ankylosis of the joints. Extraarticular lesions may involve skin, heart, blood vessels and lungs and, therefore, the clinical manifestations can resemble other systemic autoimmune disorders such as systemic lupus erythematosus or scleroderma. The prevalence in the United States is approximately 1%. The disease peaks in the second to fourth decades and is three times more common in women than men.

Pathogenesis. As in other autoimmune diseases, genetic predisposition and environmental factors contribute to the development, progression, and chronicity of the disease. The pathologic changes are mediated by antibodies against self-antigens and cytokine-mediated inflammation, predominantly secreted by CD4⁺ T-cells (Fig. 26-42).

CD4⁺ T helper (T_H) cells may initiate the autoimmune response in RA by reacting with an arthritogenic agent, perhaps microbial or a self-antigen. The T cells produce cytokines that stimulate other inflammatory cells to effect tissue injury. Although a large number of cytokines can be isolated from inflamed joints, the most important ones include:

- IFN- γ from T_H1 cells activates macrophages and resident synovial cells.
- IL-17 from T_H17 cells recruits neutrophils and monocytes.
- TNF and IL-1 from macrophages stimulates resident synovial cells to secrete proteases that destroy hyaline cartilage.
- RANKL expressed on activated T cells stimulates bone resorption.

Figure 26-41 Comparison of the morphologic features of rheumatoid arthritis and osteoarthritis.

Of these, TNF has been most firmly implicated in the pathogenesis of RA and TNF antagonists have proved to be remarkable effective therapies for the disease (see later).

The synovium of RA contains germinal centers with secondary follicles and abundant plasma cells which produce antibodies, some of which are against

self-antigens. Many of the autoantibodies produced in lymphoid organs and in the synovium are specific for *citrullinated peptides* (CCPs) in which arginine residues are post-translationally converted to citrulline. In RA, antigen-antibody complexes containing citrullinated fibrinogen, type II collagen, α -enolase and vimentin deposit in the joints. Antibodies against these peptides are diagnostic markers for the disease and may mediate joint injury. Evidence suggests that the raised levels of anti-CCP antibodies in combination with a T-cell response to the citrullinated proteins contribute to the disease becoming chronic. Additionally, about 80% of patients have serum IgM or IgA autoantibodies that bind to the F_c portions of their own IgG. These autoantibodies are called *rheumatoid factor* and may also deposit in joints as immune complexes although they are not uniformly present in all patients with RA and can be found in patients without the disease, so the link to pathogenesis is questionable.

It is estimated that 50% of the risk of developing RA is related to inherited genetic susceptibility. Specific *HLA-DRB1* alleles are linked to rheumatoid arthritis, and these alleles share a common sequence of amino acids in a polymorphic region of the β chain, which is designated the *shared epitope*. The shared epitope is located in the antigen-binding cleft of the DR molecule. This location is presumably the specific binding site of the arthritogen(s) that initiates the inflammatory synovitis. Linkage and genome wide association studies have also implicated the *PTPN22* gene. *PTPN22* encodes a protein tyrosine phosphatase that is postulated to inhibit T-cell activation.

The environmental arthritogen whose antigens initiate RA by activating T or B cells remains uncertain. CCPs are produced during inflammation, so insults such as infection and smoking may promote citrullination of self-proteins, creating new epitopes that trigger autoimmune reactions. The robust immune reaction to these autoantigens suggests that they may be important arthritogenic agents.

Figure 26-42 Major processes involved in the pathogenesis of rheumatoid arthritis.

Figure 26-43 Rheumatoid arthritis. **A**, Schematic view of the joint lesion. **B**, Low magnification reveals marked synovial hypertrophy with formation of villi. **C**, At higher magnification, subsynovial tissue containing a dense lymphoid aggregate. (**A**, Modified from Feldmann M: Development of anti-TNF therapy for rheumatoid arthritis. *Nat Rev Immunol* 2:364, 2002.)

MORPHOLOGY

Joints. RA typically manifests as a symmetric arthritis principally affecting the small joints of the hand and feet. The synovium becomes grossly edematous, thickened, and hyperplastic, transforming its smooth contour to one covered by delicate and bulbous villi (Fig. 26-43A, B). The characteristic histologic features include (1) **synovial cell hyperplasia** and proliferation; (2) **dense inflammatory infiltrates** (frequently forming lymphoid follicles) of CD4+ helper T cells, B cells, plasma cells, dendritic cells, and macrophages (Fig. 26-43C); (3) increased vascularity due to angiogenesis; (4) fibrinopurulent exudate on the synovial and joint surfaces; (5) osteoclastic activity in underlying bone, allowing the synovium to penetrate into the bone and cause periarticular erosions and subchondral cysts. Together, the above changes produce a **pannus**: a mass of edematous synovium, inflammatory cells, granulation tissue, and fibroblasts that grows over the articular cartilage and causes its erosion. In time, after the cartilage has been destroyed, the pannus bridges the apposing bones to form a **fibrous ankylosis**, which eventually ossifies and results in fusion of the bones, called **bony ankylosis** (Fig. 26-41).

Skin. **Rheumatoid subcutaneous nodules** are the most common cutaneous lesions. They occur in approximately 25% of affected individuals, usually those with severe disease, and arise in regions of the skin that are subjected to pressure, including the ulnar aspect of the forearm, elbows, occiput, and lumbosacral area. Less commonly they form in the lungs, spleen, pericardium, myocardium, heart valves, aorta, and other viscera. Rheumatoid nodules are firm, nontender, and round to oval, and in the skin arise in the subcutaneous tissue. Microscopically they resemble necrotizing granulomas with a central zone of fibrinoid necrosis surrounded by a prominent rim activated macrophages and numerous lymphocytes and plasma cells (Fig. 26-44).

Blood Vessels. Affected individuals with severe erosive disease, rheumatoid nodules, and high titers of rheumatoid factor are at risk of developing **vasculitis** (Chapter 11). The acute necrotizing vasculitis involves small and large arteries. It

may involve the pleura, pericardium or lung evolving into chronic fibrosing processes. Frequently, segments of small arteries such as vasa nervorum and the digital arteries are obstructed by an obliterating endarteritis resulting in peripheral neuropathy, ulcers, and gangrene. Leukocytoclastic vasculitis produces purpura, cutaneous ulcers, and nail bed infarction. Ocular changes such as uveitis and keratoconjunctivitis (similar to Sjögren syndrome, Chapter 6) may be prominent.

Clinical Course. In about half of patients, RA may begin slowly and insidiously with malaise, fatigue, and generalized musculoskeletal pain, likely mediated by IL-1 and TNF. After several weeks to months the joints become involved. The pattern of joint involvement varies, but it is generally symmetrical and the small joints are affected before the larger ones. Symptoms usually develop in the hands (metacarpophalangeal and proximal interphalangeal joints) and feet, followed by the wrists, ankles, elbows,

Figure 26-44 Rheumatoid nodule composed of central necrosis rimmed by palisaded histiocytes.

and knees. Uncommonly the upper spine is involved, but the lumbosacral region and hips are usually spared.

Involved joints are swollen, warm, painful, and particularly stiff when rising in the morning or following inactivity. The typical patient has progressive joint enlargement, decreased range of motion evolving to complete ankylosis, with the greatest damage occurring in the first 4 or 5 years. Approximately 20% of affected individuals enjoy periods of partial or complete remission, but the symptoms inevitably return and involve previously unaffected joints. A minority of individuals (10%) have an acute onset over several days with severe symptoms and polyarticular involvement.

Inflammation in the tendons, ligaments, and occasionally the adjacent skeletal muscle frequently accompanies the arthritis and produces the characteristic radial deviation of the wrist, ulnar deviation of the fingers and flexion-hyperextension of the fingers (swan-neck deformity, boutonnière deformity). The end result is a joint that has no stability and minimal or no range of motion. Large synovial cysts, like the *Baker cyst* in the posterior knee, may develop as the increased intra-articular pressure causes herniation of the synovium. Radiographic hallmarks are joint effusions and juxta-articular osteopenia with erosions and narrowing of the joint space and loss of articular cartilage (Fig. 26-45).

The presence of multisystem involvement must be distinguished from other forms of chronic arthritis (lupus, scleroderma, Lyme disease). The diagnosis of RA is supported by (1) characteristic radiographic findings, (2) sterile, turbid synovial fluid with decreased viscosity, poor mucin clot formation, and inclusion-bearing neutrophils, and (3) the combination of rheumatoid factor and anti-CCP antibody (80% of patients).

The treatment of rheumatoid arthritis is aimed at relieving the pain and inflammation, and slowing or arresting the relentless joint destruction. Therapies include corticosteroids, synthetic and biologic disease-modifying drugs such as methotrexate, and, most notably, antagonists of TNF. Such drugs prevent or slow joint destruction, which is the greatest source of disability, and have altered the natural history of the disease for the better. However, anti-TNF agents are not curative, and patients must be maintained on TNF antagonists to avoid disease flares. Other biologic agents that interfere with T and B lymphocyte responses are also approved therapies.

Long-term complications include *systemic amyloidosis* (Chapter 6) in 5% to 10% of patients and infection with opportunistic organisms in patients who receive long-term anti-TNF or other immunosuppressive agents.

Juvenile Idiopathic Arthritis

Juvenile idiopathic arthritis (JIA) is a heterogeneous group of disorders of unknown cause that present with arthritis before age 16 and persist for at least 6 weeks. The prevalence is 30,000 to 50,000 in the United States. Compared to RA, in JIA (1) oligoarthritis is more common, (2) systemic disease is more frequent, (3) large joints are affected more often than small joints, (4) rheumatoid nodules and rheumatoid factor are usually absent, and (5) antinuclear antibody (ANA) seropositivity is common. The pathogenesis is unknown but similar to adult RA; risk

Figure 26-45 Rheumatoid arthritis of the hand. Characteristic features include diffuse osteopenia, marked loss of the joint spaces of the carpal, metacarpal, phalangeal, and interphalangeal joints, periarticular bony erosions, and ulnar drift of the fingers.

factors include *HLA* and *PTPN22* variants. Also like adult RA, damage in JIA appears to be caused by T_H1 and T_H17 cells and the mediators IL-1, IL-17, TNF, and IFN- γ .

Attempts at subclassification of JIA are based on clinical (e.g., oligoarticular, systemic) and laboratory (ANA, rheumatoid factor titers) variables. Some of these subgroups (e.g., systemic, polyarticular rheumatoid factor positive; enthesitis-related, which refers to involvement of sites of ligament and cartilage insertion into bone; oligoarticular) seem to represent defined entities while others (e.g., polyarticular rheumatoid factor negative; psoriatic) remain heterogeneous. Treatment consists of similar regimens as adult RA with some success using an IL-6 receptor antibody in the systemic form. Long-term prognosis of JIA is very variable. Although many affected individuals may have chronic disease, only about 10% develop serious functional disability.

Seronegative Spondyloarthropathies

The spondyloarthropathies are also a heterogeneous group of disorders that are unified by the following features:

- Pathologic changes in the ligamentous attachments rather than synovium

- Involvement of sacroiliac joints, with or without other joints
- Absence of rheumatoid factor
- Association with HLA-B27

The manifestations are immune mediated and are triggered by a T-cell response presumably directed against an undefined antigen, likely infectious, that may cross-react with native molecules of the musculoskeletal system.

Ankylosing Spondylitis

Ankylosing spondylitis causes destruction of articular cartilage and bony ankylosis, especially of the sacroiliac and apophyseal joints (between tuberosities and processes). It is also known as *rheumatoid spondylitis* and *Marie-Strümpell disease*. Disease involving the sacroiliac joints and vertebrae becomes symptomatic in the second and third decades of life as lower back pain and spinal immobility. Involvement of peripheral joints, such as the hips, knees, and shoulders, occurs in at least one third of affected individuals. Approximately 90% of patients are HLA-B27 positive; associations have also been found with the IL-23 receptor gene.

Reactive Arthritis

Reactive arthritis is defined by a triad of arthritis, nongonococcal urethritis or cervicitis, and conjunctivitis. Most affected individuals are men in their 20s or 30s, and more than 80% are HLA-B27 positive. This form of arthritis also affects individuals infected with the human immunodeficiency virus (HIV). The disease is probably caused by an autoimmune reaction initiated by prior infection of the genitourinary system (*Chlamydia*) or the gastrointestinal tract (*Shigella*, *Salmonella*, *Yersinia*, *Campylobacter*).

Arthritic symptoms develop within several weeks of the inciting bout of urethritis or diarrhea. Joint stiffness and low back pain are common early symptoms. The ankles, knees, and feet are affected most often, frequently in an asymmetric pattern. Synovitis of a digital tendon sheath produces the sausage finger or toe, and ossification of tendoligamentous insertion sites leads to calcaneal spurs and bony outgrowths. Patients with severe chronic disease have involvement of the spine that is indistinguishable from ankylosing spondylitis. Extraarticular involvement manifests as inflammatory balanitis, conjunctivitis, cardiac conduction abnormalities, and aortic regurgitation. The episodes of arthritis usually wax and wane over several weeks to 6 months. Almost 50% of affected individuals have recurrent arthritis, tendonitis and lumbosacral pain.

Enteritis Associated Arthritis

Enteritis-associated arthritis is caused by gastrointestinal infection by *Yersinia*, *Salmonella*, *Shigella*, and *Campylobacter*, among others. The outer cell membranes of these organisms have lipopolysaccharides as a major component, and they stimulate a range of immunological responses. The arthritis appears abruptly and tends to involve the knees and ankles but sometimes also the wrists, fingers, and toes. Unlike reactive arthritis, it lasts for about

a year, then generally clears and only rarely is accompanied by ankylosing spondylitis.

Psoriatic Arthritis

Psoriatic arthritis is a chronic inflammatory arthropathy associated with psoriasis that affects peripheral and axial joints and entheses (ligaments and tendons). Susceptibility to the disease is genetically determined and related to HLA-B27 and HLA-Cw6 alleles. Symptoms manifest between the ages of 30 and 50. It develops in more than 10% of the psoriatic population, usually concurrently or following the onset of skin disease. Although the sacroiliac joints are involved in 20% of patients, this is predominantly a peripheral arthritis of the hands and feet. The distal interphalangeal joints of the hands and feet are first affected in an asymmetric distribution in more than 50% of patients, producing the characteristic “pencil in cup” deformity (unlike RA, which you will recall typically involves the proximal interphalangeal joints). Histologically, psoriatic arthritis is similar to rheumatoid arthritis. Psoriatic arthritis, however, is usually not as severe, remissions are more frequent, and joint destruction is less frequent.

Infectious Arthritis

Microorganisms of all types can seed joints during hematogenous dissemination. Articular structures can also become infected by direct inoculation or from contiguous spread from a soft tissue abscess or focus of osteomyelitis. Infectious arthritis is potentially serious, because it can cause rapid joint destruction leading to permanent deformities.

Suppurative Arthritis

Bacterial infections that cause acute suppurative arthritis usually enter the joints from distant sites by hematogenous spread. In neonates there is an increased incidence of contiguous spread from underlying epiphyseal osteomyelitis. *H. influenza* arthritis predominates in children younger than 2 years of age, *S. aureus* is the main causative agent in older children and adults, and gonococcus is prevalent during late adolescence and young adulthood. Individuals with sickle cell disease are prone to infection with *Salmonella* at any age. These joint infections affect the sexes equally except for gonococcal arthritis, which is seen mainly in sexually active women. Individuals with deficiencies of components of the complement membrane attack complex (C5, C6, and C7) are susceptible to disseminated gonococcal infections and hence arthritis. Other predisposing conditions include immune deficiencies (congenital and acquired), debilitating illness, joint trauma, chronic arthritis of any cause, and intravenous drug abuse.

The classic presentation is the sudden development of an acutely painful and swollen joint that has a restricted range of motion. Systemic findings of fever, leukocytosis, and elevated sedimentation rate are common. In disseminated gonococcal infection the symptoms are more subacute. In 90% of nongonococcal cases, the infection involves only a single joint, most commonly the knee followed in

frequency by the hip, shoulder, elbow, wrist, and sternoclavicular joints. The axial joints are more often involved in drug users. Joint aspiration is diagnostic if it yields purulent fluid in which the causal agent can be identified. Prompt recognition and effective antimicrobial therapy can prevent joint destruction.

Mycobacterial Arthritis

Mycobacterial arthritis is a chronic progressive monoarticular infection caused by *M. tuberculosis*, which occurs in all age groups, especially adults. It usually develops as a complication of adjoining osteomyelitis or after hematogenous dissemination from a visceral (usually pulmonary) site of infection. Onset is insidious and causes gradual progressive pain. Systemic symptoms may or may not be present. Mycobacterial seeding of the joint induces the formation of confluent granulomas with central caseous necrosis. The affected synovium may grow as a pannus over the articular cartilage and erode the bone along the joint margins. Chronic disease results in fibrous ankylosis and obliteration of the joint space. The weight-bearing joints are usually affected, especially the hips, knees, and ankles in descending order of frequency.

Lyme Arthritis

Lyme arthritis is caused by infection with the spirochete *Borrelia burgdorferi*, which is transmitted by deer ticks of the *Ixodes ricinus* complex. It is the leading arthropod borne disease in the United States. In its classic form, Lyme disease progressively involves multiple organ systems, as outlined in Chapter 8. The initial infection of the skin is followed within several days or weeks by dissemination of the organism to other sites, especially the joints.

Approximately 60% to 80% of untreated individuals with the disease develop arthritis during the late stage. The arthritis primarily involves large joints, especially the knees, shoulders, elbows, and ankles in descending order of frequency. Usually one or two joints are affected at a time, and the attacks last for a few weeks to months, migrating to new sites. Spirochetes can only be identified in about 25% of joints with arthritis but the diagnosis can be confirmed by serologic testing for anti-*Borrelia* antibodies. The majority of individuals respond to antibiotic therapy.

A chronic arthritis that is antibiotic refractory develops in approximately 10% of affected individuals. In many of these patients, *Borrelia* cannot be detected in the joint fluid even by PCR. It has been proposed that cellular (especially T_H1) and humoral responses to *Borrelia* outer surface protein A may initiate an autoimmune arthritis, but this is not proven.

Infected synovium exhibits a chronic synovitis marked by synoviocyte hyperplasia, fibrin deposition, mononuclear cell infiltrates (especially CD4+ T cells), and onion-skin thickening of arterial walls. The morphology in severe cases can closely resemble that of rheumatoid arthritis.

Viral Arthritis

Arthritis can occur in the setting of a variety of viral infections, including alphavirus, parvovirus B19, rubella, Epstein-Barr virus, and hepatitis B and C viruses. The

manifestations of the arthritis range from acute to subacute symptoms. The joint symptoms may be caused by direct infection of the joint by the virus, as seen in rubella and some alphavirus infections, or by an autoimmune reaction generated by the infection, as is seen in other forms of reactive or post-infectious arthritides. A variety of rheumatic conditions, including reactive arthritis, psoriatic arthritis, and septic arthritis, may develop in individuals infected with HIV. The pathogenesis of some of these forms of HIV-associated chronic arthritis is probably autoimmune. Antiretroviral therapies for HIV have reduced the severity of HIV-associated arthritis.

Crystal-Induced Arthritis

Articular crystal deposits are associated with a variety of acute and chronic joint disorders. Endogenous crystals shown to be pathogenic include monosodium urate (*gout*), calcium pyrophosphate dehydrate (*pseudogout*), and basic calcium phosphate. Exogenous crystals, such as corticosteroid ester crystals and talcum, and the biomaterials polyethylene and methyl methacrylate, may also induce joint disease. Silicone, polyethylene, and methyl methacrylate are used in prosthetic joints, and their debris that accumulates with long use and wear may result in local arthritis and failure of the prosthesis. Endogenous and exogenous crystals produce disease by triggering a cytokine-mediated cascade that destroys cartilage.

Gout

Gout is marked by transient attacks of acute arthritis initiated by crystallization of monosodium urate within and around joints. Gout can be divided into primary and secondary forms (Table 26-7), both sharing the common feature of hyperuricemia. In the primary form (90% of cases), gout is the major manifestation of the disease and the cause is usually unknown. In secondary gout (10% of cases), uric acid is increased because of a known underlying disease that usually dominates the clinical picture.

Table 26-7 Classification of Gout

Clinical Category	Uric Acid Production	Uric Acid Excretion
Primary Gout (90%)		
Unknown enzyme defects (85%-90%)	↑ (majority)	Normal
	↑↑ (minority)	↑
	Normal	↓
Known enzyme defects (e.g., partial HGPRT deficiency)	↑	Normal
Secondary Gout (10%)		
Increased nucleic acid turnover (e.g., leukemia)	↑↑	↑
Chronic renal disease	Normal	↓
Congenital (e.g., Lesch-Nyhan syndrome HGPRT deficiency)	↑↑	↑

HGPRT, Hypoxanthine guanine phosphoribosyl transferase.

Pathogenesis. Hyperuricemia (plasma urate level above 6.8 mg/dL) is necessary, but not sufficient, for the development of gout. Elevated uric acid can result from overproduction or reduced excretion or both (Table 26-7). Uric acid metabolism can be summarized as follows:

- **Synthesis:** Uric acid is the end product of purine catabolism. Increased urate synthesis typically reflects some abnormality in purine production. The synthesis of purine nucleotides, in turn, involves two interlinked pathways. In the *de novo* pathway, purine nucleotides are synthesized from nonpurine precursors, and in salvage pathways they are synthesized from free purine bases from dietary intake and catabolism of purine nucleotides.
- **Excretion:** Uric acid is filtered from the circulation by the glomerulus and virtually completely resorbed by the proximal tubule of the kidney. A small fraction of the resorbed uric acid is secreted by the distal nephron and excreted in the urine.

Hyperuricemia can result from either overproduction or reduced excretion. The vast majority of *primary gout* is caused by increased uric acid biosynthesis for unknown reasons. A small minority of patients have overproduction because of identifiable enzymatic defects. For example, partial deficiency of hypoxanthine guanine phosphoribosyl transferase (HGPRT) interrupts the salvage pathway, so purine metabolites cannot be salvaged and are, instead, degraded into uric acid. Complete absence of HGPRT also results in hyperuricemia, but the significant neurologic manifestations of this condition (*Lesch-Nyhan syndrome*) dominate the clinical picture so it is classified as *secondary gout*. Secondary gout can also be caused by increased production (e.g., rapid cell lysis during chemotherapy for leukemia) or decreased excretion (chronic renal disease).

The inflammation in gout is triggered by precipitation of monosodium urate (MSU) crystals into the joints, which result in the production of cytokines that recruit leukocytes (Fig. 26-46). Macrophages phagocytose the MSU and the intracellular sensor, the inflammasome (Chapter 3), recognizes the crystals. The inflammasome activates caspase-1, which is involved in the production of some biologically active cytokines, most notably IL-1. IL-1 is proinflammatory, and promotes accumulation of neutrophils and macrophages in the joint. These cells, in turn, release other cytokines, free radicals, proteases and arachidonic acid metabolites, all of which recruit more leukocytes and damage the joint. Urate crystals may also activate the complement system, leading to the generation of chemotactic complement byproducts. These cascades trigger an acute arthritis, which typically remits spontaneously in days to weeks.

The solubility of MSU in a joint is modulated by temperature and the chemical composition of the fluid. Synovial fluid is inherently a poorer solvent for monosodium urate than plasma. The lower temperature of the peripheral joints also favors precipitation. Crystallization is dependent on the presence of nucleating agents such as insoluble collagen fibers, chondroitin sulfate, proteoglycans and cartilage fragments.

Figure 26-46 Pathogenesis of acute gouty arthritis. LTB₄, Leukotriene B₄; IL-1 β , interleukin 1 β .

Hyperuricemia does not necessarily lead to gouty arthritis. Many factors contribute to the conversion of asymptomatic hyperuricemia into primary gout, including the following:

- Age of the individual and duration of the hyperuricemia. Gout usually appears after 20 to 30 years of hyperuricemia.
- Genetic predisposition. In addition to the well-defined X-linked abnormalities of HGPRT, primary gout follows multifactorial inheritance and runs in families. Polymorphisms in genes involved in urate transport and homeostasis (URAT1 and GLUT9) are also associated with gout.
- Heavy alcohol consumption
- Obesity
- Drugs (e.g., thiazides) that reduce excretion of urate
- Lead toxicity (so-called saturnine gout)

Repeated attacks of acute arthritis lead eventually to chronic tophaceous arthritis and the formation of tophi in the inflamed synovial membranes and periarticular tissue. Severe damage to the cartilage develops and the function of the joints is compromised.

MORPHOLOGY

The distinctive morphologic changes in gout are (1) acute arthritis, (2) chronic tophaceous arthritis, (3) tophi in various sites, and (4) gouty nephropathy.

Acute arthritis is characterized by a dense neutrophilic infiltrate that permeates the synovium and synovial fluid. MSU crystals are frequently found in the cytoplasm of the neutrophils and are arranged in small clusters in the synovium. They are long, slender, and needle-shaped, and are negatively birefringent. The synovium is edematous and congested, and also contains scattered lymphocytes, plasma cells, and macrophages. When the episode of crystallization abates and the crystals are resorbed, the acute attack remits.

Chronic tophaceous arthritis evolves from the repetitive precipitation of urate crystals during acute attacks. The MSU encrusts the articular surface and forms visible deposits in the synovium (Fig. 26-47A). The synovium becomes hyperplastic, fibrotic, and thickened by inflammatory cells and forms a pannus that destroys the underlying cartilage and lead to juxta-articular bone erosions. In severe cases, fibrous or bony ankylosis ensues, resulting in loss of joint function.

Tophi are the pathognomonic hallmark of gout. They are formed by large aggregations of urate crystals surrounded by an intense inflammatory reaction of foreign body giant cells. (Fig. 26-47B,C). Tophi may appear in the articular cartilage, ligaments, tendons, and bursae. Less frequently they may occur in soft tissues (earlobes, fingertips) or kidneys. Superficial tophi can ulcerate through the overlying skin.

Gouty nephropathy (Chapter 20) refers to the renal complications caused by MSU crystals or tophi in the renal medullary interstitium or tubules. Complications include uric acid nephrolithiasis and pyelonephritis, particularly when the urates induce urinary obstruction.

Clinical Course. Gout is more common in men and after the age of 30. Patients with obesity, metabolic syndrome, excess alcohol intake and renal failure are at increased risk.

Four clinical stages are recognized:

- *Asymptomatic hyperuricemia* appears around puberty in males and after menopause in females.
- *Acute arthritis* presents after several years as sudden onset of excruciating joint pain associated with localized hyperemia, warmth. Constitutional symptoms are uncommon except for occasional mild fever. Most first attacks are monoarticular; 50% occur in the first metatarsophalangeal joint. Eventually, about 90% of affected individuals experience acute attacks in the following locations (in descending order of frequency): insteps, ankles, heels, knees, wrists, fingers, and elbows. Untreated, acute gouty arthritis may last for hours to weeks, but gradually there is complete resolution.
- *Asymptomatic intercritical period:* Resolution of the acute arthritis leads to a symptom free interval. Although some patients never have another attack, most experience a second acute episode within months to a few years. In the absence of appropriate therapy, the attacks recur at shorter intervals and frequently become polyarticular.
- *Chronic tophaceous gout* develops on average about 12 years after the initial acute attack and the appearance of

Figure 26-47 Gout. **A**, Amputated great toe with white tophi involving the joint and soft tissues. **B**, Gouty tophus—an aggregate of dissolved urate crystals is surrounded by reactive fibroblasts, mononuclear inflammatory cells, and giant cells. **C**, Urate crystals are needle shaped and negatively birefringent under polarized light.

chronic tophaceous arthritis. At this stage, radiographs show characteristic juxta-articular bone erosion caused by osteoclastic bone resorption and loss of the joint space. Progression leads to severe crippling disease.

Renal manifestations sometimes appear in the form of renal colic associated with the passage of gravel and stones and may proceed to chronic gouty nephropathy. About 20% of those with chronic gout die of renal failure.

Numerous drugs are available to abort or prevent acute attacks of arthritis and mobilize tophaceous deposits. Their use is important, because many aspects of the disease are related to the duration and severity of the hyperuricemia. Generally, gout does not materially shorten the life span, but it may impair the quality of life.

Calcium Pyrophosphate Crystal Deposition Disease (Pseudo-Gout)

Calcium pyrophosphate crystal deposition disease (CPPD), also known as *pseudo-gout* and *chondrocalcinosis*, usually occurs in individuals older than 50 years of age and becomes more common with increasing age, rising to a prevalence of 30% to 60% in those 85 years or older. The sexes and races are equally affected. CPPD is divided into sporadic (idiopathic), hereditary, and secondary types. In an autosomal dominant variant the crystals develop relatively early in life and are associated with severe osteoarthritis. The disease is caused by germline mutations in the pyrophosphate transport channel. The secondary form is associated with various disorders, including previous joint damage, hyperparathyroidism, hemochromatosis, hypomagnesemia, hypothyroidism, ochronosis, and diabetes.

Pathophysiology. The basis for crystal formation is not known but studies suggest that articular cartilage proteoglycans, which normally inhibit mineralization, are degraded allowing crystallization around chondrocytes. As in gout, inflammation is caused by activation of the inflammasome in macrophages (Fig. 26-46).

MORPHOLOGY

The crystals first develop in the articular cartilage, menisci, and intervertebral discs, and as the deposits enlarge they may rupture and seed the joint. The crystals form chalky, white friable deposits, which are seen histologically in stained preparations as oval blue-purple aggregates (Fig. 26-48A). Individual crystals are rhomboid, 0.5 to 5 μm in greatest dimension (Fig. 26-48B) and are positively birefringent. Inflammation, if present, is usually milder than in gout.

CPPD is frequently asymptomatic. However, it may produce acute, subacute, or chronic arthritis that can be confused with osteoarthritis or rheumatoid arthritis. The joint involvement may last from several days to weeks and may be monoarticular or polyarticular; the knees, followed by the wrists, elbows, shoulders, and ankles, are most commonly affected. Ultimately, approximately 50% of affected individuals experience significant joint damage. Therapy is supportive. There is no known treatment that prevents or slows crystal formation.

KEY CONCEPTS

Arthritis

- **Osteoarthritis (degenerative joint disease)**, the most common disease of joints, is a degenerative process of articular cartilage in which matrix breakdown exceeds synthesis. Inflammation is minimal and typically second-

Figure 26-48 Pseudogout. **A**, Deposits are present in cartilage and consist of amorphous basophilic material. **B**, Smear preparation of calcium pyrophosphate crystals.

ary. Local production of inflammatory cytokines may contribute to the progression of joint degeneration.

- **Rheumatoid arthritis (RA)** is a chronic autoimmune inflammatory disease that affects mainly small joints, but can be systemic. RA is caused by a cellular and humoral immune response against self-antigens, particularly citrullinated proteins. TNF plays a central role and antagonists against TNF are of clinical benefit.
- **Seronegative spondyloarthropathies** are a heterogeneous group of likely autoimmune arthritides that preferentially involve the sacroiliac and vertebral joints and are associated with HLA-B27.
- **Suppurative arthritis** describes direct infection of a joint space by bacterial organisms.
- **Lyme disease** is a systemic infection by *Borrelia burgdorferi* which manifests, in part, as an infectious arthritis, possibly with an autoimmune component in chronic stages.
- **Gout and pseudogout** result from inflammatory responses triggered by precipitation of urate or calcium pyrophosphate, respectively.

Joint Tumors and Tumor-Like Conditions

Reactive tumor-like lesions, such as ganglions, synovial cysts, and osteochondral loose bodies commonly involve joints and tendon sheaths. They usually result from trauma or degenerative processes and are much more common than neoplasms. Primary neoplasms are rare, usually benign and tend to recapitulate the cells and tissue types (synovial membrane, fat, blood vessels, fibrous tissue, and cartilage) native to joints and related structures. Malignant tumors are rare; these are discussed later with soft tissue tumors.

Ganglion and Synovial Cysts

A *ganglion* is a small (1 to 1.5 cm) cyst that is almost always located near a joint capsule or tendon sheath. A common location is around the joints of the wrist, where it appears as a firm, fluctuant, pea-sized translucent nodule. It arises as a result of cystic or myxoid degeneration of connective tissue; hence the cyst wall lacks a cell lining. The lesion may be multilocular and enlarges through coalescence of adjacent areas of myxoid change. The fluid that fills the cyst is similar to synovial fluid; however, there is no communication with the joint space. Despite the name, the lesion is unrelated to ganglia of the nervous system.

Herniation of synovium through a joint capsule or massive enlargement of a bursa may produce a *synovial cyst*. A well-recognized example is the synovial cyst that forms in the popliteal space in the setting of rheumatoid arthritis (*Baker cyst*). The synovial lining may be hyperplastic and contain inflammatory cells and fibrin.

Tenosynovial Giant Cell Tumor

Tenosynovial giant cell tumor is the term for several closely related benign neoplasms that develop in the synovial lining of joints, tendon sheaths, and bursae. Clinical variants of tenosynovial giant cell tumor include the *diffuse type* (previously known as *pigmented villonodular synovitis*), and the *localized type* (also known as *giant cell tumor of tendon*

sheath). Whereas the diffuse form tends to involve large joints, the localized type usually occurs as a discrete nodule attached to a tendon sheath, commonly in the hand. Both variants usually are diagnosed in the 20s to 40s and affect the sexes equally.

Pathogenesis. These tumors harbor a reciprocal somatic chromosomal translocation, $t(1;2)(p13;q37)$, resulting in fusion of the type VI collagen α -3 promoter upstream of the coding sequence of the monocyte colony-stimulating factor (M-CSF) gene. As a result, the tumor cells overexpress M-CSF, which, through autocrine and paracrine effects, stimulates proliferation of macrophages, in a manner similar to giant cell tumor of bone (described previously).

MORPHOLOGY

Tenosynovial giant cell tumors are red-brown to orange-yellow. In diffuse tumors the normally smooth joint synovium is converted into a tangled mat by red-brown folds, finger-like projections, and nodules (Fig. 26-49A). In contrast, localized tumors are well circumscribed. The neoplastic cells, which account for only 2% to 16% of the cells in the mass, are polygonal, moderately sized, and resemble synoviocytes (Fig. 26-49B). In the diffuse variant they spread along the surface and infiltrate the subsynovial issue. In nodular tumors, the cells grow in a solid aggregate that may be attached to the synovium by a pedicle. Both variants are heavily infiltrated by macrophages, and may contain hemosiderin or foamy lipid. Scattered multinucleated giant cells and patchy fibrosis are commonly present.

Clinical Features. Diffuse tenosynovial giant cell tumor presents in the knee in 80% of cases, followed in frequency by the hip, ankle, and calcaneocuboid joints. Affected individuals typically complain of pain, locking, and recurrent swelling similar to monoarticular arthritis. Tumor progression limits the range of movement of the joint and causes it to become stiff and firm. Sometimes a palpable mass is appreciated. Aggressive tumors erode into adjacent bones and soft tissues, causing confusion with other types of

Figure 26-49 Tenosynovial giant cell tumor, diffuse type. **A**, Excised synovium with fronds and nodules typical of pigmented villonodular synovitis (arrow). **B**, Sheets of proliferating cells in tenosynovial giant cell tumor bulging the synovial lining.

neoplasms. In contrast, the localized variant manifests as a solitary, slow-growing, painless mass that frequently involves the tendon sheaths along the wrists and fingers; it is the most common mesenchymal neoplasm of the hand.

Cortical erosion of adjacent bone occurs in approximately 15% of cases. Both types are amenable to surgical excision, but recurrence is common. Clinical trials using antagonists of M-CSF signaling have produced encouraging responses.

SOFT TISSUE

In terms of clinical and pathologic entities, soft tissue refers to non-epithelial tissue excluding the skeleton, joints, central nervous system, hematopoietic and lymphoid tissues. Although nonneoplastic conditions can involve soft tissue, they are seldom confined to this compartment so the area of soft tissue pathology is restricted to neoplasms. With the exception of skeletal muscle neoplasms, benign soft tissue tumors outnumber their malignant counterparts, the sarcomas, by 100 fold. In the United States, the incidence of soft tissue sarcomas is approximately 12,000 per year, which is less than 1% of all cancers. Sarcomas, however, cause 2% of all cancer mortality, reflecting their aggressive behavior. Most soft tissue tumors arise in the extremities, especially the thigh. Approximately 15% arise in children but the incidence increases with age.

Pathogenesis. The majority of sarcomas are sporadic and have no known predisposing cause. A small minority of soft tissue neoplasms are associated with germline mutations in tumor suppressor genes (neurofibromatosis 1, Gardner syndrome, Li-Fraumeni syndrome, Osler-Weber Rendu syndrome). A few tumors can be linked to known environmental exposures such as radiation, burns or toxins.

Unlike tumors such as colonic carcinoma that usually arises from easily recognized precursor lesions, the origin of sarcomas is unknown. The best guess is that the tumors arise from pluripotent mesenchymal stem cells, which acquire somatic “driver” mutations in oncogenes and tumor suppressor genes. Despite heterogeneous mechanisms of tumorigenesis among sarcomas, some generalizations can be made based on their karyotypic complexity:

- Simple karyotype (15% to 20%): Like many leukemias and lymphomas, sarcomas are often euploid tumors

with a single, or limited number, of chromosomal changes (Table 26-8) that occur early in tumorigenesis and are specific enough to serve as diagnostic markers. Tumors with these features most commonly arise in younger patients and tend to have a monomorphic appearance microscopically. Examples include the Ewing sarcoma, described earlier, and synovial sarcoma. In some cases, the oncogenic effect of these rearrangements is reasonably well understood, but in other cases it remains unknown (Table 26-8).

- Complex karyotype (80% to 85%): These tumors are usually aneuploid or polyploid and demonstrate multiple, severe chromosomal gains and losses, none of which are recurrent, a feature that probably speaks to an underlying abnormality producing genomic instability. Examples include leiomyosarcomas and undifferentiated sarcomas. Such tumors are more common in adults and tend to be morphologically pleomorphic.

Classification of soft tissue tumors continues to evolve as new molecular genetic abnormalities are identified. Clinically, soft tissue tumors range from benign, self-limited lesions that require minimal treatment to intermediate grade, locally aggressive tumors with minimal metastatic risk to highly aggressive malignancies with significant metastatic risk and mortality. The term *sarcoma* is applied somewhat inconsistently such that some, but not all, locally aggressive tumors fall into this category. Tumors with significant metastatic potential are, of course, considered sarcomas. Pathologic classification integrates morphology (e.g., muscle differentiation), immunohistochemistry and molecular diagnostics (Table 26-9). In addition to accurate diagnosis, grade (degree of differentiation)

Table 26-8 Chromosomal Abnormalities in Soft tissue Tumors

Tumor	Cytogenetic Abnormality	Gene fusion	Proposed function
Ewing sarcoma family tumors	t(11;22)(q24;q12) t(21;22)(q22;q12)	<i>EWS-FLI1</i> <i>EWS-ERG</i>	Disordered protein with multiple functions, including aberrant transcription, cell cycle regulation, RNA splicing and telomerase
Extraskeletal myxoid chondrosarcoma	t(9;22)(q22;q12)	<i>EWS-CHN</i>	
Desmoplastic small round-cell tumor	t(11;22)(p13;q12)	<i>EWS-WT1</i>	
Clear-cell sarcoma	t(12;22)(q13;q12)	<i>EWS-ATF1</i>	
Liposarcoma—myxoid and round-cell type	t(12;16)(q13;p11)	<i>FUS-DDIT3</i>	Arrests adipocytic differentiation
Synovial sarcoma	t(x;18)(p11;q11)	<i>SS18-SSX1</i> <i>SS18-SSX2</i> <i>SS18-SSX4</i>	Chimeric transcription factors, interrupts cell cycle control
Rhabdomyosarcoma—alveolar type	t(2;13)(q35;q14) t(1;13)(p36;q14)	<i>PAX3-FOXO1</i> <i>PAX7-FOXO1</i>	Chimeric transcription factors, disrupt skeletal muscle differentiation
Dermatofibrosarcoma protuberans	t(17;22)(q22;q15)	<i>COL1A1-PDGFB</i>	Promoter driven overexpression of PDGF- β , autocrine stimulation
Alveolar soft-part sarcoma	t(X;17)(p11.2;q25)	<i>TFE3-ASPL</i>	unknown
Infantile fibrosarcoma	t(12;15)(p13;q23)	<i>ETV6-NTRK3</i>	Chimeric tyrosine kinase leads to constitutively active Ras/MAPK pathway
Nodular fasciitis	t(22;17)	<i>MYH9-USP6</i>	Unknown

Table 26-9 Soft Tissue Tumors

Category	Behavior	Tumor Type	Common Locations	Age (yr)	Morphology
Adipose	Benign	Lipoma	Superficial extremity, trunk	40-60	Mature adipose tissue
	Malignant	Well-differentiated liposarcoma	Deep extremity, retroperitoneum	50-60	Adipose tissue with scattered atypical spindle cells
		Myxoid liposarcoma	Thigh, leg	30s	Myxoid matrix, "chicken wire" vessels, round cells, lipoblasts
Fibrous	Benign	Nodular fasciitis	Arm, forearm	20-30	Tissue culture growth, extravasated erythrocytes,
		Deep fibromatosis	Abdominal wall	30-40	Dense collagen, long, unidirectional fascicles
Skeletal muscle	Benign	Rhabdomyoma	Head and neck	0-60	Polygonal rhabdomyoblasts, "spider" cells
	Malignant	Alveolar rhabdomyosarcoma	Extremities, sinuses	5-15	Uniform round discohesive cells between septae
		Embryonal rhabdomyosarcoma	Genitourinary tract	1-5	Primitive spindle cells, "strap" cells
Smooth muscle	Benign	Leiomyoma	Extremity	20s	Uniform, plump eosinophilic cells in fascicles
	Malignant	Leiomyosarcoma	Thigh, retroperitoneum	40-60	Pleomorphic eosinophilic cells
Vascular	Benign	Hemangioma	Head and neck	0-10	Circumscribed mass of capillary or venous channels
	Malignant	Angiosarcoma	Skin, deep lower extremity	50-80	Infiltrating capillary channels
Nerve sheath	Benign	Schwannoma	Head and neck	20-50	Encapsulated, fibrillar stroma, nuclear palisading
		Neurofibroma	Wide, cutaneous, subcutis	10-20+	Myxoid, ropy collagen, loose fascicles, mast cells
	Malignant	Malignant peripheral nerve sheath tumor	Extremities, shoulder girdle	20-50	Tight fascicles, atypia, mitotic activity, necrosis
Uncertain histotype	Benign	Solitary fibrous tumor	Pelvis, pleura	20-70	Branching ectatic vessels,
	Malignant	Synovial sarcoma	Thigh, leg	15-40	Tight fascicles of uniform basophilic spindle cells, Pseudoglandular structures
		Undifferentiated pleomorphic sarcoma	Thigh	40-70	High grade anaplastic polygonal, round or spindle cells
		Alveolar soft part sarcoma	Trunk, extremities	15-35	Bizarre nuclei, atypical mitoses, necrosis
		Clear cell sarcoma	Tendons, extremities	20-40	Multiple nodules of eosinophilic round cells, septae
					Sheets of pale or clear spindle cells, wreath-like giant cells

and stage (size and depth) are important prognostic indicators.

With this as a primer, we will next consider representative or especially illustrative soft tissue tumors.

Tumors of Adipose Tissue

Lipoma

Lipoma, a benign tumor of fat, is the most common soft tissue tumor of adulthood. These tumors are subclassified according to morphologic and/or characteristic molecular features as conventional lipoma, fibrolipoma, angiolipoma, spindle cell lipoma and myelolipoma.

MORPHOLOGY

The conventional lipoma, the most common subtype, is a well-encapsulated mass of mature adipocytes. It usually arises in the subcutis of the proximal extremities and trunk, most frequently during middle adulthood. Infrequently, lipomas are large, intramuscular, and poorly circumscribed.

Lipomas are soft, mobile, and painless (except angiolipoma) and are usually cured by simple excision.

Liposarcoma

Liposarcoma is one of the most common sarcomas of adulthood. It occurs mainly in people in their 50s to 60s in the deep soft tissues of the proximal extremities and in the retroperitoneum. Amplification of 12q13-q15 and t(12;16) are characteristic of well-differentiated and myxoid liposarcomas, respectively. One of the key genes in the amplified region of chromosome 12q is *MDM2*, which you will recall encodes a potent inhibitor of p53. Pleomorphic liposarcomas contain complex karyotypes without reproducible genetic abnormalities.

MORPHOLOGY

Liposarcomas are histologically divided into three morphologic subtypes:

- Well-differentiated liposarcoma contains adipocytes with scattered atypical spindle cells (Fig. 26-50A).
- Myxoid liposarcoma contains abundant basophilic extracellular matrix, arborizing capillaries and primitive cells at various stages of adipocyte differentiation reminiscent of fetal fat (Fig. 26-50B).
- Pleomorphic liposarcoma consists of sheets of anaplastic cells, bizarre nuclei and variable amounts of immature adipocytes (lipoblasts).

Figure 26-50 Liposarcoma. **A**, the well-differentiated subtype consists of mature adipocytes and scattered spindle cells with hyperchromatic nuclei. **B**, Myxoid liposarcoma with abundant ground substance and a rich capillary network in which are scattered immature adipocytes and more primitive round to stellate cells.

All types of liposarcoma recur locally and often repeatedly unless adequately excised. The well-differentiated variant is relatively indolent, the myxoid/round cell type is intermediate in its malignant behavior, while the pleomorphic variant usually is aggressive and frequently metastasizes.

Fibrous Tumors

Nodular Fasciitis

Nodular fasciitis is a self-limited fibroblastic and myofibroblastic proliferation that typically occurs in young adults in the upper extremity. A history of trauma is present in approximately 25% of cases and the tumors grow rapidly over a period of several weeks or months, typically no larger than 5 cm. Whereas nodular fasciitis was historically considered a reactive inflammatory lesion, identification of *t(17;22)* that produces a *MYH9-USP6* fusion gene indicates that it is a clonal, but self-limited, proliferation. It appears that the proliferating cells lack some key hallmark of cancer, perhaps the ability to avoid senescence. Intriguingly, ABC (discussed earlier), another tumor that sits in a gray zone between reactive and neoplastic proliferations, also contains *USP6* fusion genes. Nodular fasciitis typically spontaneously regresses and if excised, it rarely recurs.

MORPHOLOGY

Nodular fasciitis arises in the deep dermis, subcutis, or muscle. Grossly the lesion is less than 5 cm, circumscribed, or slightly infiltrative. The lesion is richly cellular and contains plump, immature-appearing fibroblasts and myofibroblasts arranged randomly or in short fascicles reminiscent of tissue culture fibroblasts (Fig. 26-51). A gradient of maturation (zonation) from cellular, loose, and myxoid to organized and fibrous is typical. The cells vary in size and shape (spindle to stellate) and have conspicuous nucleoli; mitotic figures are abundant. Lymphocytes and extravasated red blood cells are common but neutrophils are unusual.

Fibromatoses

Superficial Fibromatosis

Superficial fibromatosis is an infiltrative fibroblastic proliferation that can cause local deformity but has an innocuous clinical course. All forms of superficial fibromatosis affect males more frequently than females. They are characterized by nodular or poorly defined broad fascicles of fibroblasts in long, sweeping fascicles, surrounded by abundant dense collagen. Several clinical subtypes have been identified:

- **Palmar (*Dupuytren contracture*):** Irregular or nodular thickening of the palmar fascia either unilaterally or bilaterally (50%). Over a span of years, attachment to the overlying skin causes puckering and dimpling. At the same time a slowly progressive flexion contracture develops that mainly affects the fourth and fifth fingers of the hand.

Figure 26-51 Nodular fasciitis with plump, randomly oriented spindle cells surrounded by myxoid stroma. Note the mitotic activity (arrowheads) and extravasated red blood cells.

- **Plantar:** Common in young patients, unilateral and without contractures.
- **Penile (Peyronie disease):** Palpable induration or mass on the dorsolateral aspect of the penis. Eventually, it may cause abnormal curvature of the shaft, constriction of the urethra, or both.

In about 20% to 25% of cases, the palmar and plantar fibromatoses stabilize and do not progress, in some instances resolving spontaneously. Some recur after excision, particularly the plantar variant.

Deep Fibromatosis (Desmoid Tumors)

Deep fibromatoses are large, infiltrative masses that frequently recur but do not metastasize. They are most frequent in the teens to 30s, predominantly in women. Abdominal fibromatosis generally arises in the musculoaponeurotic structures of the anterior abdominal wall but tumors can arise in the limb girdles or the mesentery. Deep fibromatoses contain mutations in the *APC* or β -catenin genes, both of which lead to increased Wnt signaling. The majority of tumors are sporadic, but individuals with familial adenomatous polyposis (Gardner syndrome, Chapter 17) who have germline *APC* mutations are predisposed to deep fibromatosis.

MORPHOLOGY

Fibromatoses are gray-white, firm, poorly demarcated masses varying from 1 to 15 cm in greatest diameter. They are rubbery and tough, and have marked infiltration of surrounding muscle, nerve and fat. Cytologically bland fibroblasts arranged in broad sweeping fascicles amid dense collagen are the characteristic histologic pattern (Fig. 26-52). The histology resembles scar.

In addition to possibly being disfiguring or disabling, deep-seated fibromatosis is occasionally painful. Because of the extensively infiltrative nature, complete excision is often difficult. Recent efforts have concentrated on medical therapy with cyclooxygenase 2 inhibitors, tyrosine kinase inhibitors, or hormonal blockade (tamoxifen).

Skeletal Muscle Tumors

Skeletal muscle neoplasms, in contrast to other mesenchymal histotypes, are almost all malignant. The benign variant, rhabdomyoma, is frequent in individuals with tuberous sclerosis and is discussed in Chapter 28.

Rhabdomyosarcoma

Rhabdomyosarcoma is a malignant mesenchymal tumor with skeletal muscle differentiation. Three subtypes are recognized: *alveolar* (20%), *embryonal* (60%) and *pleomorphic* (20%). Rhabdomyosarcoma (alveolar and embryonal) is the most common soft tissue sarcoma of childhood and adolescence, usually appearing before age 20. Pleomorphic rhabdomyosarcoma is seen predominantly in adults. The pediatric forms often arise in the sinuses, head and neck and genitourinary tract, locations that do not normally contain much skeletal muscle, underscoring the notion

Figure 26-52 Fibromatosis infiltrating between skeletal muscle cells.

that arcomas do not arise from mature, terminally differentiated muscle cells. The embryonal and pleomorphic subtypes are genetically heterogeneous. Alveolar rhabdomyosarcoma frequently contains fusions of the *FOXO1* gene to either the *PAX3* or the *PAX7* gene, rearrangements marked by the presence of (2;13) or (1;13) translocations, respectively. *PAX3* is a transcription factor that initiates skeletal muscle differentiation, and it appears that the chimeric *PAX3-FOXO1* fusion protein interferes with the gene expression program that drives differentiation, a mechanism similar to many of the transcription factor fusion proteins that are found in various forms of acute leukemia.

MORPHOLOGY

Embryonal rhabdomyosarcoma presents as soft gray infiltrative mass. The tumor cells mimic skeletal muscle at various stages of embryogenesis and consist of sheets of both primitive round and spindled cells in a myxoid stroma (Fig. 26-53A). Rhabdomyoblasts with visible cross-striations may be present.

Sarcoma botryoides, described in Chapter 22, is a variant of embryonal rhabdomyosarcoma that develops in the walls of hollow, mucosal-lined structures, such as the nasopharynx, common bile duct, bladder, and vagina. Where the tumors abut the mucosa of an organ, they form a submucosal zone of hypercellularity called the **cambium layer**.

Alveolar rhabdomyosarcoma is traversed by a network of fibrous septae that divide the cells into clusters or aggregates, creating a crude resemblance to pulmonary alveoli. Those in the center of the aggregates are discohesive, while those at the periphery adhere to the septae. The tumor cells are uniform round, with little cytoplasm—cross striations are not a common feature (Fig. 26-53B).

Pleomorphic rhabdomyosarcoma is characterized by numerous large, sometimes multinucleated, bizarre eosinophilic tumor cells and can resemble other pleomorphic sarcomas histologically. Immunohistochemistry (e.g., myogenin) is usually necessary to confirm rhabdomyoblastic differentiation.

Rhabdomyosarcomas are aggressive neoplasms that are usually treated with surgery and chemotherapy, with or without radiation therapy. The histologic type and location of the tumor influence survival. The botryoid variant of embryonal rhabdomyosarcoma has the best prognosis, while the pleomorphic subtype is often fatal.

Figure 26-53 Rhabdomyosarcoma. **A**, Embryonal subtype composed of malignant cells ranging from primitive and round to densely eosinophilic with skeletal muscle differentiation. **B**, Alveolar rhabdomyosarcoma with numerous spaces lined by discohesive, uniform round tumor cells.

Smooth Muscle Tumors

Leiomyoma

Leiomyoma, a benign tumor of smooth muscle, often arises in the uterus; in fact, uterine leiomyomas are the most common neoplasm in women (Chapter 22). They develop in 77% of women and, depending on their number, size, and location, may cause a variety of symptoms including infertility. Leiomyomas may also arise from the erector pili muscles (*pilar leiomyomas*) found in the skin, nipples, scrotum, and labia and rarely in the deep soft tissues and the muscularis of the gut. Pilar leiomyomas may be multiple and painful. The phenotype of multiple cutaneous leiomyomas may be transmitted as an autosomal dominant trait that is also associated with uterine leiomyomas and renal cell carcinoma—*hereditary leiomyomatosis and renal cell cancer syndrome*. This disorder is associated with a germline loss-of-function mutation in the fumarate hydratase gene located on chromosome 1q42.3. Fumarate hydratase is an enzyme that participates in the Krebs cycle, and this association thus constitutes another intriguing example of the link between metabolic abnormalities and certain forms of neoplasia.

Soft tissue leiomyomas are usually 1 to 2 cm and are composed of fascicles of densely eosinophilic spindle cells that tend to intersect each other at right angles. The tumor cells have blunt-ended, elongated nuclei and show minimal atypia and few mitotic figures. Solitary lesions are easily cured. However, multiple tumors may be so numerous that complete surgical removal is impractical.

Leiomyosarcoma

Leiomyosarcoma accounts for 10% to 20% of soft tissue sarcomas. They occur in adults and afflict women more frequently than men. Most develop in the deep soft tissues of the extremities and retroperitoneum. A particularly deadly form arises from the great vessels, especially the inferior vena cava. Leiomyosarcomas have complex genotypes that stem from underlying defects that lead to profound genomic instability.

MORPHOLOGY

Leiomyosarcomas present as painless firm masses. Retroperitoneal tumors may be large and bulky and cause abdominal symptoms. They consist of eosinophilic spindle cells with blunt-ended, hyperchromatic nuclei arranged in interweaving fascicles. Ultrastructurally, the tumor cells contain bundles of thin filaments with dense bodies and pinocytotic vesicles, and individual cells are surrounded by basal lamina. Immunohistochemically, they stain with antibodies to smooth muscle actin and desmin.

Treatment depends on tumor size, location, and grade. Superficial or cutaneous leiomyosarcomas are usually small and have a good prognosis, whereas those of the retroperitoneum are large, cannot be entirely excised, and cause death by both local extension and metastatic spread, especially to the lungs.

Tumors of Uncertain Origin

Although many soft tissue tumors can be assigned to recognizable histological types, a large proportion of tumors do not recapitulate any known mesenchymal lineage. This group includes examples with simple and complex karyotypes; one of each type is described later.

Synovial Sarcoma

Synovial sarcoma was so-named because the first described cases arose in the soft tissues near the knee joint and a morphologic relationship to synovium was postulated. However, this name is a misnomer, as these tumors can present in locations (chest wall, head and neck) that lack synovium and their morphologic features are inconsistent with an origin from synoviocytes. Synovial sarcomas account for approximately 10% of all soft tissue sarcomas and rank as the fourth most common sarcoma. Most occur in people in their 20s to 40s. Patients usually present with a deep-seated mass that has been present for several years. Most synovial sarcomas show a characteristic chromosomal translocation $t(x;18)(p11;q11)$ producing *SS18-SSX1*,

Figure 26-54 Synovial sarcoma revealing the classic biphasic spindle cell and glandlike histologic appearance.

-SSX2, or -SSX4 fusion genes that encode chimeric transcription factors.

MORPHOLOGY

Synovial sarcomas are morphologically monophasic or biphasic. Monophasic synovial sarcoma consists of uniform spindle cells with scant cytoplasm and dense chromatin growing in short, tightly packed fascicles. Many tumors historically classified as fibrosarcoma likely would be classified as synovial sarcoma today. The tumors may calcify. The biphasic type contains, in addition to the spindle cell component above, gland-like structures composed of cuboidal to columnar epithelioid cells (Fig. 26-54). Immunohistochemistry is helpful in identifying these tumors, since the tumor cells, especially in the biphasic type, are positive for epithelial markers (e.g., keratins), differentiating them from most other sarcomas.

Synovial sarcomas are treated aggressively with limb-sparing surgery and frequently chemotherapy. The 5-year survival varies from 25% to 62%, related to stage and patient age. Common sites of metastases are the lung and occasionally the regional lymph nodes.

Undifferentiated Pleomorphic Sarcoma

Undifferentiated pleomorphic sarcoma (UPS) includes malignant mesenchymal tumors with high-grade, pleomorphic cells that cannot be classified into another category by a combination of histomorphology, immunophenotype, ultrastructure or molecular genetics. Despite advances in molecular characterization of sarcomas, UPS represents the largest category of adult sarcomas. Most arise in the deep soft tissues of the extremity, especially the thigh of middle aged or older adults. The diagnosis of *malignant fibrous histiocytoma* (MFH), sometimes used interchangeably with UPS, has fallen out of usage because (1) the category included both undifferentiated tumors and others that were reclassified with immunohistochemistry or molecular methods, and (2) no consensus exists for the morphologic definition of fibrohistiocytic. Not surprisingly, reproducible genetic changes are not typical of UPS. Most tumors

are aneuploid with multiple structural and numerical chromosomal changes.

MORPHOLOGY

UPS are usually large, grey-white fleshy masses and can grow quite large (10 to 20 cm) depending on the anatomic compartment. Necrosis and hemorrhage are common. They consist of sheets of large, anaplastic spindled to polygonal cells with hyperchromatic irregular, sometimes bizarre nuclei (Fig. 26-55). Mitotic figures, including atypical non-symmetric forms, are abundant as is coagulative necrosis. By definition, tumor cells lack differentiation along recognized lineages.

UPS are aggressive malignancies that are treated with surgery and adjuvant chemotherapy and/or radiation. The prognosis is generally poor, with metastases arising in 30% to 50% of cases.

KEY CONCEPTS

Soft Tissue Tumors

- The category of soft tissue neoplasia describes tumors that do not fall into categories of epithelial, skeletal, central nervous system, hematopoietic or lymphoid tissues. A sarcoma is a malignant mesenchymal tumor.
- Although all soft tissue tumors probably arise from pluripotent mesenchymal stem cells, rather than mature cells, tumors can be classified into:
 - Tumors that recapitulate a mature mesenchymal tissue (e.g., skeletal muscle) can be further subdivided into benign and malignant forms.
 - Tumors composed of cells for which there is no normal counterpart (e.g., synovial sarcoma, undifferentiated pleomorphic sarcoma)
- Sarcomas with simple karyotypes demonstrate reproducible, chromosomal and molecular abnormalities which contribute to pathogenesis and are sufficiently specific to have diagnostic utility.
- Most adult sarcomas have complex karyotypes, tend to be pleomorphic and genetically heterogeneous with a poor prognosis.

Neuromuscular diseases are a complex group of disorders with numerous inherited and acquired causes that typically present with weakness, muscle pain, or sensory deficits. They can be grouped according to anatomy, the tempo of the disease course, and pathogenesis. Physicians keep all these characteristics in mind when evaluating a patient. This chapter uses an anatomical approach, grouping neuromuscular disorders into those that preferentially affect the peripheral nerves, the neuromuscular junction, or the skeletal muscles. A discussion of neoplasms that arise from peripheral nerves ends the chapter. Conditions that can produce similar clinical presentations but are caused by disorders of the central nervous system are discussed in [Chapter 28](#).

Diseases of Peripheral Nerves

The two main components of peripheral nerves are axons and myelin sheaths made by Schwann cells. Injuries to either of these components may result in a peripheral neuropathy. Before discussing the pathology of these

disorders, a brief review of peripheral nerve structure and function is in order. *Somatic motor function* is carried out by the motor unit, which consists of (1) a lower motor neuron located in the anterior horn of the spinal cord or in the brainstem; (2) an axon that travels to a target muscle as part of a nerve; (3) the neuromuscular junctions; and (4) multiple innervated myofibers (muscle fibers). *Somatic sensory function* depends on (1) the distal nerve endings, which may contain specialized structures that serve to register specific sensory modalities; (2) an axon that travels as part of a peripheral nerve to the dorsal root ganglia; and (3) a proximal axon segment that synapses on neurons in the spinal cord or the brainstem. *Autonomic nerve fibers* outnumber somatic fibers in the peripheral nervous system, but signs and symptoms related to their involvement are generally not prominent features of peripheral neuropathies, with a few important exceptions (e.g., in some cases of diabetic neuropathy, discussed later).

Specific sensations (pain, temperature, touch) and motor signals are each conveyed by axons that can be distinguished based on their diameter. Axonal diameters are in turn correlated with the thickness of their myelin sheaths

Figure 27-1 Relationship between lipid bilayers and associated proteins in myelin within internodes. Myelin basic protein (MBP) is an intracellular protein that has a role in myelin compaction. Mutant forms of myelin protein zero (MPZ), peripheral myelin protein 22 (PMP22), and periaxin (PRX) cause some forms of Charcot-Marie-Tooth disease, a hereditary demyelinating neuropathy.

and with their conduction speeds. Thin unmyelinated fibers mediate autonomic functions as well as pain and temperature sensation and have the slowest conduction speeds. Large diameter axons with thick myelin sheaths transmit light touch and motor signals and have fast conduction speeds. In the case of myelinated axons, individual Schwann cells make exactly one myelin sheath that wraps around a single axon to create a myelinated segment called an *internode*. Internodes are separated by unmyelinated gaps referred to as *nodes of Ranvier*, which are uniformly spaced along the length of the axon. A number of specialized proteins are essential for normal assembly and function of myelin within internodes (Fig. 27-1). Unmyelinated axons are also intimately associated with Schwann cells but in a different arrangement in which one cell surrounds segments of multiple axons.

Most peripheral nerves carry out both motor and sensory functions and thus contain axons of varying diameter and myelin thickness. The axons are bundled together by three major connective tissue components: the *epineurium*, which encloses the entire nerve; the *perineurium*, a multilayered concentric connective tissue sheath that groups subsets of axons into fascicles; and the *endoneurium*, which surrounds individual nerve fibers.

General Types of Peripheral Nerve Injury

Axonal Neuropathies

Axons are the primary target of the damage in this large group of peripheral neuropathies (Fig. 27-2). The morphologic hallmarks of axonal neuropathies can be produced experimentally by cutting a peripheral nerve, which results in a prototypical pattern of injury described as *Wallerian degeneration*. Portions of axons that are distal to the point of transection are disconnected from the central neuron

and degenerate. Within a day of injury, the distal axons begin to fragment and the associated myelin sheaths unravel (Fig. 27-3) and disintegrate into spherical structures (*myelin ovoids*). Macrophages are recruited and they participate in the removal of axonal and myelin debris. Regeneration starts at the site of transection with the formation of a growth cone and the outgrowth of new branches from the stump of the proximal axon. Schwann cells and their associated basement membranes guide the sprouting axons, which grow at about 1 mm per day, toward their distal target. Continuous pruning of the sprouting axons removes misguided branches. The Schwann cells create new myelin sheaths around the regenerating axons, but these myelin internodes tend to be thinner and shorter than in the original ones. The repair process is successful only if the two transected ends remain closely approximated. A failure of the outgrowing axons to find their distal target can produce a “pseudotumor” termed *traumatic neuroma* – a nonneoplastic haphazard whorled proliferation of axonal processes and associated Schwann cells that results in a painful nodule (Fig. 27-4).

The changes observed following experimental nerve transections only partially resemble those seen in various axonal neuropathies. One key difference is that in these disease states (unlike nerve transection) damage occurs over an extended period of time. As a result, degenerating and regenerating axons co-exist in a single biopsy. With time, damage tends to outpace repair, resulting in progressive loss of axons. Consequently, the electrophysiologic hallmark of axonal neuropathies is a reduction in signal strength owing to the dropout of axons from affected peripheral nerves.

Demyelinating Neuropathies

In these disorders, Schwann cells with their myelin sheaths are the primary targets of damage (Fig. 27-2),

Figure 27-2 Patterns of peripheral nerve damage. **A**, In normal motor units, type I and type II myofibers are arranged in a “checkerboard” distribution, and the internodes along the motor axons are uniform in thickness and length. **B**, Acute axonal injury (*left axon*) results in degeneration of the distal axon and its associated myelin sheath, with atrophy of denervated myofibers. In contrast, acute demyelinating disease (*right axon*) produces random segmental degeneration of individual myelin internodes, while sparing the axons. **C**, Regeneration of axons after injury (*left axon*) allows reinnervation of myofibers. The regenerated axon is myelinated by proliferating Schwann cells, but the new internodes are shorter and the myelin sheaths are thinner than the original ones. Remission of demyelinating disease (*right axon*) allows remyelination to take place, but the new internodes also are shorter and have thinner myelin sheaths than flanking normal undamaged internodes. See [Table 27-1](#) and [Fig. 27-7](#) for comparison.

Figure 27-3 Electron micrographs illustrating features of axonal degeneration. **A**, Degenerating myelin with loosened myelin layers is seen in the degenerating axon in the lower left corner, to be contrasted with a normal myelin sheath with tightly packed myelin and intact axon in the upper right corner. **B**, In addition to an unraveling myelin sheath, several cells contain lipid droplets (seen as vacuoles) derived from degenerating myelin.

Figure 27-4 Trichrome-stained section of a traumatic neuroma showing the transition from normal nerve containing a parallel arrangement of axons (upper left corner) to a haphazard swirl of red stained axons associated with admixture of Schwann cells and blue-staining connective tissue.

whereas axons are relatively preserved. This definition is similar to that of demyelinating diseases that affect the central nervous system (Chapter 28). Individual myelin sheaths degenerate in a seemingly random pattern, resulting in discontinuous damage of myelin segments. In response to this damage, Schwann cells or Schwann cell precursors proliferate and initiate repair through the formation of new myelin sheaths, but these again tend to be shorter and thinner than the original ones. The electrophysiologic hallmark of these disorders is slowed nerve conduction velocity, reflective of the loss of myelin.

Neuronopathies

Neuronopathies result from destruction of neurons, leading to secondary degeneration of axonal processes. Infections like herpes zoster and toxins like platinum compounds are examples of insults that may lead to neuronopathies. Because the damage is at the level of the neuronal cell body, peripheral nerve dysfunction caused by neuronopathies is equally likely to affect proximal and distal parts of the body (unlike peripheral axonopathies which preferentially affect the distal extremities).

Anatomic Patterns of Peripheral Neuropathies

Peripheral neuropathies can be separated into several groups according to the anatomic distribution of involvement and the associated neurological deficits. This approach can be helpful clinically, since each pattern has a different set of potential underlying causes. These anatomic patterns of injury are as follows:

- *Mononeuropathies* affect a single nerve and result in deficits in a restricted distribution dictated by normal anatomy. Trauma, entrapment, and infections are common causes of mononeuropathy.

- *Polyneuropathies* are characterized by involvement of multiple nerves, usually in a symmetric fashion. In most cases axons are affected in a length dependent fashion leading to deficits that start in the feet and ascend with disease progression. The hands often start to show involvement by the time deficits extend to the level of the knee, resulting in a characteristic “stocking and glove” distribution of sensory deficits.
- *Mononeuritis multiplex* describes a disease process that damages several nerves in a haphazard fashion. An affected patient might have a right wrist drop from involvement of the right radial nerve and a left foot drop from peroneal nerve damage. Vasculitis is a common cause of this pattern of injury.
- *Polyradiculoneuropathies* affect nerve roots as well as peripheral nerves, leading to diffuse symmetric symptoms in proximal and distal parts of the body.

Specific Peripheral Neuropathies

Many different types of disease processes can damage peripheral nerves, including inflammatory diseases, infections, metabolic changes, toxic injury, trauma, (para)neoplastic disease, and inherited gene defects.

Inflammatory Neuropathies

Guillain-Barré Syndrome (Acute Inflammatory Demyelinating Polyneuropathy)

Guillain-Barré syndrome is a demyelinating peripheral neuropathy that may lead to life-threatening respiratory paralysis. The overall annual incidence is approximately one case per 100,000 persons. The disease is characterized clinically by weakness beginning in the distal limbs that rapidly advances to affect proximal muscle function (“ascending paralysis”). Histologic features are inflammation and demyelination of spinal nerve roots and peripheral nerves (radiculoneuropathy).

Pathogenesis. In most cases, Guillain-Barré syndrome is thought to be an acute-onset *immune-mediated demyelinating neuropathy*. Approximately two thirds of cases are preceded by an acute, influenza-like illness from which the affected individual has recovered by the time the neuropathy becomes symptomatic. Infections with *Campylobacter jejuni*, cytomegalovirus, Epstein-Barr virus, and *Mycoplasma pneumoniae*, or prior vaccination, have significant epidemiologic associations with Guillain-Barré syndrome. No infectious agent has been demonstrated in affected nerves, and an immunologic reaction is favored as the underlying cause. A similar inflammatory disease of peripheral nerves can be reproduced in experimental animals by immunization with a peripheral nerve myelin protein. A T-cell-mediated immune response ensues, accompanied by segmental demyelination induced by activated macrophages. Transfer of these T cells to a naive animal results in comparable lesions. Moreover, lymphocytes from individuals with Guillain-Barré syndrome have been shown to produce demyelination in tissue cultures of myelinated nerve fibers. Circulating antibodies that cross-react with components of peripheral nerves may also play a role.

MORPHOLOGY

The dominant histopathologic finding is **inflammation of peripheral nerves**, manifested as perivenular and endoneurial infiltration by lymphocytes, macrophages, and a few plasma cells. Segmental demyelination affecting peripheral nerves is the most prominent lesion, but damage to axons is also seen, particularly when the disease is severe. Electron microscopy has identified an early effect on myelin sheaths. The cytoplasmic processes of macrophages penetrate the basement membrane of Schwann cells, particularly in the vicinity of the nodes of Ranvier, and extend between the myelin lamellae, stripping the myelin sheath from the axon. Ultimately, the remnants of the myelin sheath are engulfed by the macrophages. Inflammation and demyelination can be widespread in the peripheral nervous system but are typically most prominent proximally, close to the nerve roots.

Clinical Features. The clinical picture is dominated by ascending paralysis and areflexia. Deep tendon reflexes disappear early in the process. Sensory involvement, including loss of pain sensation, is often present but is usually not a prominent feature. Nerve conduction velocities are slowed because of multifocal destruction of myelin segments in many axons within a nerve. Cerebrospinal fluid (CSF) protein levels are elevated due to inflammation and altered permeability of the microcirculation within the spinal roots as they traverse the subarachnoid space. Inflammatory cells, on the other hand, remain confined to the roots, therefore, there is little or no CSF pleocytosis. Many patients spend weeks in hospital intensive-care units before recovering normal function. With improved supportive respiratory care, cardiovascular monitoring, and prophylaxis against deep venous thrombosis, the mortality rate has fallen. Plasmapheresis and intravenous immunoglobulin appear to be beneficial, apparently because these remove pathogenic antibodies and suppress immune function, respectively. However, 2% to 5% of affected patients still die of respiratory paralysis, autonomic instability, cardiac arrest, or related complications, and up to 20% of hospitalized survivors suffer long-term disability.

Chronic Inflammatory Demyelinating Poly(radiculo)neuropathy

This is the most common chronic acquired inflammatory peripheral neuropathy, characterized by symmetrical mixed sensorimotor polyneuropathy that persists for 2 months or more. By definition, signs and symptoms must be present for at least 2 months but often the disease evolves over years, usually with relapses and remissions. While typically there is a symmetric, mixed sensorimotor polyneuropathy, some patients may present with predominantly sensory or motor impairment. Clinical remissions can often be achieved with immunosuppressive therapies, such as glucocorticoids, intravenous immunoglobulin, plasmapheresis, and biologic agents directed against T cells or B cells. The time course and the response to steroids distinguish chronic inflammatory demyelinating polyradiculoneuropathy from Guillain-Barré syndrome.

Pathogenesis. T cells as well as humoral factors are implicated in the inflammatory process. Molecules expressed at

Figure 27-5 Onion bulb neuropathy. Compared with the normal ultrastructure of axons in a nerve (**A**), an “onion bulb” (**B**) is composed of a thinly myelinated axon (arrow) surrounded by multiple concentrically arranged Schwann cells. *Inset*, Light-microscopic appearance of an onion bulb neuropathy, characterized by “onion bulbs” surrounding axons. (**B**, Courtesy G. Richard Dickersin, MD, from *Diagnostic Electron Microscopy: A Text Atlas*. New York, Igaku-Shoin Medical Publishers, 2000, p 984.)

the Schwann cell-axon junction and in noncompact areas of myelin appear to be the target of the immune response. Complement-fixing IgG and IgM can be found on the myelin sheath, and the deposition of these opsonins leads to recruitment of macrophages that strip myelin from axons. Sural nerve biopsies show evidence of recurrent demyelination and remyelination associated with proliferation of Schwann cells. When excessive, this proliferation leads to the formation of so-called *onion-bulbs* – structures in which multiple layers of Schwann cells wrap around an axon like the layers of an onion (Fig. 27-5).

Neuropathy Associated with Systemic Autoimmune Diseases

Systemic autoimmune diseases like rheumatoid arthritis, Sjögren syndrome, or systemic lupus erythematosus (SLE) can be associated with peripheral neuropathies that often take the form of distal sensory or sensorimotor polyneuropathies. These neuropathies are distinct from vasculitic peripheral neuropathies, which can arise as secondary manifestations of these same diseases.

Neuropathy Associated with Vasculitis

Vasculitis is a noninfectious inflammation of blood vessels that can involve and damage peripheral nerves. About one third of patients with vasculitis have peripheral nerve involvement, and neuropathy may be the presenting feature. Vasculitis often presents as mononeuritis multiplex, but mononeuritis and polyneuropathy are also encountered.

Peripheral nerves involved by vasculitis typically show patchy axonal degeneration and loss, with some fascicles being more severely affected than others. Perivascular inflammatory infiltrates are often present. Identification of blood vessels with characteristic forms of acute or chronic damage (Chapter 11) helps establish the diagnosis.

Infectious Neuropathies

Many infectious processes affect peripheral nerves. Among these, leprosy, diphtheria, and varicella-zoster cause relatively specific pathologic changes in nerves that are the

point of focus here. Each of these disorders is also discussed in more detail in [Chapter 8](#).

Leprosy (Hansen Disease)

Peripheral nerves are involved in both lepromatous and tuberculoid leprosy (discussed in [Chapter 8](#)).

- In *lepromatous leprosy*, Schwann cells are invaded by *Mycobacterium leprae*, which proliferate and eventually infect other cells. There is evidence of segmental demyelination and remyelination and loss of both myelinated and unmyelinated axons. As the infection advances, endoneurial fibrosis and multilayered thickening of the perineurial sheaths occur. Affected individuals develop a symmetric polyneuropathy that is most severe in the relatively cool distal extremities and in the face because lower temperatures favor mycobacterial growth. The infection prominently involves pain fibers, and the resulting loss of sensation contributes to injury, since the patient is rendered unaware of injurious stimuli and damaged tissues. Thus, large traumatic ulcers may develop.
- *Tuberculoid leprosy* is characterized by an active cell-mediated immune response to *M. leprae* that is usually manifest as dermal nodules containing granulomatous inflammation. The inflammation injures cutaneous nerves in the vicinity; axons, Schwann cells, and myelin are lost, and there is fibrosis of the perineurium and endoneurium. In tuberculoid leprosy, affected individuals have much more localized nerve involvement.

Lyme Disease

Lyme disease causes various neurologic manifestations in the second and third stage of the disease. These include polyradiculoneuropathy and unilateral or bilateral facial nerve palsies.

HIV/AIDS

Patients infected with human immunodeficiency virus (HIV) develop several patterns of peripheral neuropathy that are poorly understood, but all appear to be related in some way to immune dysregulation. Early stage HIV infection can be associated with mononeuritis multiplex and demyelinating disorders that may resemble Guillain-Barré syndrome or chronic inflammatory demyelinating polyradiculoneuropathy. More commonly, later stages of HIV infection are associated with a distal sensory neuropathy that is often painful.

Diphtheria

Diphtheria is most commonly found in the developing world and is a continuing medical problem because of incomplete immunization or waning immunity in adults. *Peripheral nerve dysfunction results from the effects of the diphtheria exotoxin*. It produces an acute peripheral neuropathy associated with prominent bulbar and respiratory muscle dysfunction, which can lead to death or long-term disability. The mechanism of action of diphtheria toxin is described in [Chapter 8](#).

Varicella-Zoster Virus

Varicella-zoster is one of the most common viral infections of the peripheral nervous system. Following chickenpox, a latent infection persists within neurons of sensory

ganglia. If the virus is reactivated, sometimes many years later, it may be transported along the sensory nerves to the skin. Here it infects keratinocytes, leading to a *painful, vesicular skin eruption (shingles) in a distribution that follows sensory dermatomes*. Most common is the involvement of thoracic or trigeminal nerve dermatomes. The factors underlying reactivation of the virus are not fully understood, but decreased cell-mediated immunity is suspected to play a role. In a small proportion of patients, weakness is also apparent in the same distributions. Affected ganglia show neuronal death, usually accompanied by abundant mononuclear inflammatory cell infiltrates; focal necrosis and hemorrhage may also be found. Peripheral nerves show degeneration of the axons that belong to the dead sensory neurons. Focal destruction of the large motor neurons of the anterior horns or cranial nerve motor nuclei may be seen at the corresponding levels. Intranuclear inclusions generally are not found in the peripheral nervous system.

Metabolic, Hormonal, and Nutritional Neuropathies

Diabetes

Diabetes is the most common cause of peripheral neuropathy. The prevalence of this complication depends on the duration of the disease; up to 50% of patients with diabetes overall and up to 80% of those who have had the disease for more than 15 years have clinical evidence of peripheral neuropathy. Patients with type 1 and type 2 diabetes are affected ([Chapter 24](#)). Several distinct clinicopathologic patterns of diabetes-related peripheral neuropathy are recognized (described later), but the most common by far is an ascending distal symmetric sensorimotor polyneuropathy.

Pathogenesis. The mechanism of diabetic neuropathy is complex and not completely resolved; both metabolic and secondary vascular changes are believed to contribute to the damage of neurons and Schwann cells. Hyperglycemia causes the nonenzymatic glycosylation of proteins, lipids, and nucleic acids. The resulting advanced glycosylation end products (AGEs) may interfere with normal protein function and activate inflammatory signaling through the receptor for AGE. Excess glucose within cells is reduced to sorbitol, a process that depletes NADPH and increases intracellular osmolality. These and other metabolic disturbances may predispose peripheral nerves to injury by reactive oxygen species. In addition, the vascular injuries that occur in chronic diabetes due to hyperlipidemia and other metabolic alterations may cause ischemic damage of the nerves.

MORPHOLOGY

In individuals with a **distal symmetric sensorimotor neuropathy**, the predominant pathologic finding is an axonal neuropathy. Nerve biopsies show reduced numbers of axons. Variable degrees of ongoing axonal damage, marked by degenerating myelin sheaths and regenerative axonal clusters, may be present. Endoneurial arterioles show thickening, hyalinization, and intense periodic acid–Schiff positivity of their walls and extensive reduplication of basement membranes ([Fig. 27-6](#)).

Figure 27-6 Diabetic neuropathy with marked loss of myelinated fibers, a thinly myelinated fiber (*arrowheads*), and thickening of endoneurial vessel wall (*arrow*).

Clinical Features. *Distal symmetric diabetic polyneuropathy* typically presents with sensory symptoms, like numbness, loss of pain sensation, difficulty with balance, and paresthesias or dysesthesias. Paresthesias or dysesthesias are so called “positive” symptoms—painful sensations that result from abnormal discharges of damaged nerves. Neuropathy leads to considerable morbidity, in particular an increased susceptibility to foot and ankle fractures and chronic skin ulcers, which may eventually lead to amputations.

Another manifestation is *dysfunction of the autonomic nervous system*; this affects 20% to 40% of individuals with diabetes mellitus, nearly always in association with a distal sensorimotor neuropathy. Diabetic autonomic neuropathy has protean manifestations, including postural hypotension, incomplete emptying of the bladder (resulting in recurrent infections), and sexual dysfunction. Some affected individuals, especially older adults with a long history of diabetes, develop a peripheral neuropathy that manifests with asymmetric presentations, including *mononeuropathy*, *cranial neuropathy* and *radiculoplexus neuropathy*. The latter is a devastatingly painful acute disorder that presents in the distribution of the brachial or lumbosacral nerve plexus. It is often monophasic and can improve over several months. These asymmetric manifestations may be caused by microvascular disease.

Other Metabolic, Hormonal, and Nutritional Neuropathies

A diverse group of metabolic, hormonal, and nutritional disorders are associated with peripheral neuropathy, including the following:

- **Uremic neuropathy.** Most individuals with renal failure have a peripheral neuropathy. Typically this is a distal, symmetric neuropathy that may be asymptomatic or may be associated with muscle cramps, distal dysesthesias, and diminished deep tendon reflexes. In these patients axonal degeneration is the primary event; occasionally there is secondary demyelination. Regeneration and recovery are common after dialysis.
- **Thyroid dysfunction.** Hypothyroidism can lead to compression mononeuropathies such as carpal tunnel

syndrome or cause a distal symmetric predominantly sensory polyneuropathy. In rare cases, hyperthyroidism is associated with a neuropathy resembling Guillain-Barré syndrome.

- **Vitamin B₁₂ (cyanocobalamin) deficiency** classically results in subacute combined degeneration with damage to long tracts in the spinal cord (**Chapter 28**), and also peripheral nerves.
- **Deficiencies of vitamin B₁ (thiamine), vitamin B₆ (pyridoxine), folate, vitamin E, copper, and zinc** have all been associated with peripheral neuropathy.

Toxic Neuropathies

Peripheral neuropathies may appear after *exposure to industrial or environmental chemicals, biologic toxins, or therapeutic drugs*. Important causes of toxic peripheral nerve damage include alcohol (independent of associated nutritional deficiencies), heavy metals (lead, mercury, arsenic, and thallium), and organic solvents. Various medications can cause toxic nerve damage, but the most notorious are chemotherapeutic agents. These include vinca alkaloids and taxanes, microtubule inhibitors that interfere with axonal transport, and cisplatin, which may cause a neuronopathy.

Neuropathies Associated with Malignancy

Neuropathies associated with cancers may stem from local effects, complications of therapy, paraneoplastic effects, or (in the case of B-cell tumors) tumor-derived immunoglobulins.

- **Direct infiltration or compression of peripheral nerves** by tumor is a common cause of mononeuropathy and may be a presenting symptom of cancer. These neuropathies include *brachial plexopathy* from neoplasms of the apex of the lung, *obturator palsy* from pelvic malignant neoplasms, and *cranial nerve palsies* from intracranial tumors or tumors of the base of the skull. A *polyradiculopathy* involving the lower extremity may develop when the cauda equina is involved by meningeal carcinomatosis.
- In addition to complications of chemotherapy (discussed earlier), damage to nerves in cancer patients may be caused by *radiation, poor nutrition and infection*.
- **Paraneoplastic neuropathies.** These can occur at any time during the patient’s course, but often precede the diagnosis of the underlying tumor. *Sensorimotor neuronopathy is the most common paraneoplastic form*, but a chronic inflammatory demyelinating polyradiculoneuropathy-like picture, plexopathy, and autonomic neuropathy may also be seen. Paraneoplastic sensorimotor neuronopathy is most commonly associated with small cell lung cancer. Antibodies that recognize proteins expressed by cancer cells and normal neurons (for example anti-Hu antibodies) are often present, but the damage appears to be mediated by a CD8+ cytotoxic T-cell attack on dorsal root ganglion cells. Sensory symptoms usually start distally in an asymmetric and multifocal pattern. Other patients with so-called anti-CV2 autoantibodies (which recognize CRMP5, an intracellular signaling protein) tend to present with a mixed axonal and demyelinating sensorimotor neuropathy.

- *Neuropathies associated with monoclonal gammopathies.* Neoplastic B cells may secrete monoclonal immunoglobulins or immunoglobulin fragments (so-called paraproteins) that damage nerves. For example, tumors that secrete IgM immunoglobulin may be associated with a demyelinating peripheral neuropathy. In most cases, the pathogenic IgM paraprotein is thought to bind directly to myelin-associated antigens such as myelin associated glycoprotein (MAG). Deposition of IgM can be seen ultrastructurally between the membrane layers of the myelin sheath. IgG or IgA paraproteins may also be associated with peripheral neuropathy. One distinctive presentation is *POEMS syndrome* (polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, and skin changes), in which patients often develop a demyelinating neuropathy associated with deposition of paraprotein between noncompacted myelin lamellae. Finally, excess immunoglobulin light chain may deposit as amyloid (Chapter 6), which can lead to peripheral neuropathy due to vascular insufficiency or a direct toxic effects.

Neuropathies Caused by Physical Forces

Peripheral nerves are commonly injured by trauma or entrapment. *Lacerations* result from cutting injuries and from sharp fragments of fractured bone, both of which may sever a nerve. *Avulsion* of a nerve may occur when tension is applied, often to one of the limbs. *Compression neuropathy (entrapment neuropathy)* occurs when a peripheral nerve is chronically subjected to increased pressure, often within an anatomic compartment. *Carpal tunnel syndrome*, the most common entrapment neuropathy, results from compression of the median nerve at the level of the wrist within the compartment delimited by the transverse carpal ligament. Women are more commonly affected than men, and the problem is frequently bilateral. The disorder may be observed in association with many conditions including tissue edema, pregnancy, inflammatory arthritis, hypothyroidism, amyloidosis (especially that related to β_2 -microglobulin deposition in individuals on renal dialysis), acromegaly, diabetes mellitus, and excessive repetitive motions of the wrist. Symptoms are limited to dysfunction of the median nerve and typically include numbness and paresthesias of the tips of the thumb and first two digits. Other nerves prone to compression neuropathies include the ulnar nerve at the level of the elbow, the peroneal nerve at the level of the knee, and the radial nerve in the upper arm; the latter occurs from sleeping with the arm in an awkward position (“Saturday night palsy”). Another form of compression neuropathy is found in the foot, affecting the interdigital nerve at intermetatarsal sites. This problem, which occurs more often in women than in men, leads to foot pain (metatarsalgia) and is associated with a histologic lesion called a *Morton neuroma*, which is marked by perineural fibrosis.

Inherited Peripheral Neuropathies

Inherited peripheral neuropathies are a group of genetically diverse disorders with overlapping clinical phenotypes that often present in adults. Even with delayed onset, the possibility of an inherited neuropathy has to be considered in the differential diagnosis for any patient that

presents with a peripheral neuropathy. The major types of inherited peripheral neuropathies include (1) hereditary motor and sensory neuropathies, also known as *Charcot-Marie-Tooth (CMT) disease*, (2) hereditary motor neuropathies, (3) hereditary sensory neuropathies, with or without autonomic neuropathy, and (4) other inherited conditions causing neuropathy, including familial amyloidosis and inherited metabolic diseases.

Historically, these diseases were classified based on their inheritance pattern and clinical features. Now there is a continuously growing list of genetic defects that are linked to these. The complexity of the genetics of inherited neuropathies is no doubt a reflection of the complicated homeostatic mechanisms that sustain normal peripheral nerve function. There is no simple unifying concept tying all the implicated genes together, but subsets of involved genes can be clustered into the following functionally related groups:

- Genes encoding myelin-associated proteins (Fig. 27-1)
- Genes encoding growth factors and growth factor receptors
- Genes encoding proteins that regulate mitochondrial function
- Genes encoding proteins that are involved in vesicle and axonal transport
- Genes encoding heat shock proteins, which may prevent protein aggregation
- Genes encoding proteins that are involved in cell membrane structure or function

Many areas of the classification are muddy, and genotype/phenotype relationships are not always clear-cut. For example, mutations in the *HSPB1* gene, which encodes the heat shock protein HSP27, may be associated with a clinical picture resembling CMT disease or a hereditary motor neuron disorder. Below, some of the more common and distinctive types of inherited peripheral neuropathies are described in brief.

Hereditary motor and sensory neuropathies/ Charcot-Marie-Tooth (CMT) disease

These are by far the most common inherited peripheral neuropathies, affecting up to 1 in 2500 people. The initial description of these disorders, based on clinical features, was deceptively simple—an inherited disease associated with distal muscle atrophy, sensory loss, and foot deformities. It is now appreciated that this clinical phenotype encompasses mutations in more than 50 different genes, some with relatively distinctive clinical features. Current systems classify hereditary motor and sensory neuropathies based on the mode of inheritance and the pattern of injury (e.g., axonal, demyelinating, or mixed). Demyelinating forms of CMT are associated with morphologic features of demyelination and remyelination including Schwann cell hyperplasia and onion bulb formation, which may be so severe that the involved nerve is palpably enlarged. Listed are a few more common variants:

- CMT1 encompasses a group of autosomal dominant disorders that collectively are the most common subtype of hereditary motor and sensory neuropathy. CMT1A accounts for some 55% of genetically defined CMT cases and 37% of all CMT disease. It is caused by a duplication

of a region on chromosome 17 that includes the peripheral myelin protein 22 (*PMP22*) gene. The disease usually presents in the second decade of life as a slowly progressive distal demyelinating motor and sensory neuropathy. CMT1B is caused by mutations in the myelin protein zero gene and accounts for about 9% of genetically defined cases of CMT.

- CMTX encompasses X-linked forms of CMT disease. CMT1X is the most common of these, accounting for 15% of genetically defined cases of CMT. It is linked to mutations in the *GJB1* gene, which encodes connexin32, a gap junction component that is expressed in Schwann cells.
- CMT2 includes autosomal dominant neuropathies associated with axonal rather than demyelinating injury. CMT2A is the most common subtype, accounting for 4% of all CMT disease. It is caused by mutations in the *MFN2* gene, which is required for normal mitochondrial fusion. The phenotype is typically severe, with disease onset in early childhood.

Hereditary sensory neuropathies with or without autonomic neuropathy

This is a diverse group of diseases marked by loss of sensation and variable autonomic disturbances. Loss of pain and temperature sensation is the most common symptom. The inability to sense pain leads to traumatic injury to affected portions of the body. These are typically axonal neuropathies.

Hereditary neuropathy with pressure palsy

This disorder is caused by deletion of the gene encoding *PMP22* (the same gene that is duplicated in CMT1A). It is marked by transient motor and sensory mononeuropathies that are triggered by compression of individual nerves at sites that are prone to entrapment (e.g., the carpal tunnel or the fibular head). Symptoms related to the neuropathy usually resolve within days or weeks, but in some patients the disease eventually progresses to a chronic neuropathy. Swollen, bulbous myelin sheaths at the end of internodes (referred to as *tomaculi*, Latin for a type of sausage) are a characteristic morphologic feature that can be appreciated on special teased fiber preparations of affected nerves.

Familial amyloid polyneuropathies

These are hereditary disorders characterized by amyloid deposition within peripheral nerves. Most are caused by germ line mutations of the transthyretin gene. The mutated transthyretin protein, which is normally involved in serum binding and transport of thyroid hormone, is prone to deposit as amyloid fibrils in a number of tissues, including peripheral nerve (Chapter 6). The clinical presentation is similar to that of hereditary sensory and autonomic neuropathies.

Peripheral neuropathy accompanying inherited metabolic disorders

Several hereditary metabolic disorders are accompanied by peripheral neuropathy during the course of the disease. These include leukodystrophies such as adrenoleukodystrophy (Chapter 28), porphyria (Chapter 25), and Refsum disease, a disorder caused by deficiency of a peroxisomal enzyme.

KEY CONCEPTS

Peripheral Neuropathies

- Anatomic patterns include mononeuropathy, mononeuritis multiplex, polyneuropathy, and polyradiculoneuropathy.
- Damage may occur primarily in Schwann cells (demyelinating neuropathy), axons (axonal neuropathy), or central neurons (neuronopathy); mixed patterns of injury occur.
- Inflammatory disease, infections, metabolic changes, toxic injury, trauma, paraneoplastic disorders, and inherited gene defects can all cause peripheral neuropathy.
- Diabetes mellitus is the most common cause of peripheral neuropathy, which most often presents as a distal symmetric neuropathy.
- Guillain-Barré syndrome and chronic inflammatory demyelinating polyradiculoneuropathy are the major acute and chronic acquired demyelinating peripheral neuropathies.
- Inherited peripheral neuropathies are genetically and phenotypically diverse disorders that often present in adulthood and may be marked by sensory, motor, or autonomic dysfunction, alone or in combination.

Diseases of the Neuromuscular Junction

The neuromuscular junction is a complex specialized structure located at the interface of motor nerve axons and skeletal muscle that serves to control muscle contraction. Neuromuscular junctions are found midway along the length of myofibers. Here, the distal ends of peripheral motor nerves branch into small processes that terminate in bulbous synaptic boutons. Upon depolarization, these presynaptic nerve terminals release acetylcholine (ACh) into the synaptic cleft, the space separating the nerve endings from the myofiber membrane (referred to as the *sarcolemma*). The postsynaptic sarcolemma is characterized by complex infoldings and exhibits distinct specializations with localized clustering of acetylcholine receptors (AChR). These receptors are responsible for the initiation of signals leading to muscle contraction.

Regardless of cause, disorders that impair the function of neuromuscular junctions tend to present with painless weakness. Autoantibodies that inhibit key neuromuscular junction proteins are the most common cause of disrupted neuromuscular transmission, as found in myasthenia gravis (literally, *grave weakness*). Understandably, inherited defects in specialized neuromuscular junction proteins are also associated with myasthenic syndromes. Disorders caused by toxins that alter neuromuscular transmission are rarely encountered, but had an important role historically in elucidating how the neuromuscular junction functions.

Antibody-Mediated Diseases of the Neuromuscular Junction

Myasthenia Gravis

Myasthenia gravis is an autoimmune disease that is usually associated with autoantibodies directed against acetylcholine receptors. It has a prevalence of 150 to 200 per million and shows a bimodal age distribution. The

female-to-male ratio is 2:1 in the young adults, but in older adults there is a male predominance.

Pathogenesis. About 85% of patients have autoantibodies against postsynaptic acetylcholine receptors, while most of the remaining patients have antibodies against the sarcolemmal protein *muscle-specific receptor tyrosine kinase*. These autoantibodies appear to be pathogenic, as the disease can be passively transferred to animals with serum from affected individuals, and therapeutic maneuvers that decrease autoantibody levels are associated with a reduction in symptoms.

The mechanism of action of the various autoantibodies appears to differ. Anti-acetylcholine receptor antibodies are thought to lead to the aggregation and degradation of the receptors, and also to damage of the postsynaptic membrane through complement fixation. As a result, postsynaptic membranes show alterations in morphology and are depleted of acetylcholine receptors. This limits the ability of myofibers to respond to acetylcholine. Autoantibodies directed against muscle-specific receptor tyrosine kinase do not fix complement. Instead, these antibodies seem to interfere with the trafficking and clustering of acetylcholine receptor within the sarcolemmal membrane, the net effect again being decreased acetylcholine receptor function.

There is a strong association between pathogenic anti-acetylcholine receptor autoantibodies and thymic abnormalities. Approximately 10% of patients with myasthenia gravis have a *thymoma*, a tumor of thymic epithelial cells (Chapter 13). An additional 30% of patients (and particularly those who are young) have a different thymic abnormality called *thymic hyperplasia*. This peculiar condition is marked by the appearance of B-cell follicles in the thymus. The thymus normally contains small numbers of myoid cells, stromal cells that express skeletal muscle antigens. It is hypothesized that both thymoma and thymic hyperplasia disrupt normal thymic function in a manner that promotes autoimmunity against acetylcholine receptors expressed on thymic myoid cells. In contrast, thymic abnormalities are usually absent in cases of myasthenia gravis that occur in older patients or that are not associated with anti-acetylcholine receptor autoantibodies; the basis for the development of autoantibodies in such cases is unknown.

Clinical Features. Patients with anti-acetylcholine receptor antibodies typically present with fluctuating weakness that worsens with exertion and often over the course of the day. *Diplopia* and *ptosis* due to involvement of extraocular muscles are common and distinguish myasthenia gravis from myopathies, in which involvement of extraocular muscles is unusual. In some patients, symptoms are confined to ocular muscles, while others develop generalized weakness that can be so severe as to require mechanical ventilation. Cases with antibodies against muscle-specific receptor tyrosine kinase differ from typical cases by exhibiting more focal muscle involvement (neck, shoulder, facial, respiratory, and bulbar muscles).

Diagnosis is based on clinical history, physical findings, the identification of autoantibodies, and electrophysiologic studies. The latter reveal a decrement in muscle response with repeated stimulation, a characteristic of this

disorder. Overall mortality has dropped from over 30% in the 1950s to less than 5% with current therapies. Acetylcholinesterase inhibitors that increase the half-life of acetylcholine are the first line of treatment. Other treatments, such as plasmapheresis and immunosuppressive drugs (e.g., glucocorticoids, cyclosporine, rituximab), can bring symptoms under control by decreasing autoantibody titers. Thymectomy is often effective in patients with thymoma, but is of uncertain benefit in those with thymic hyperplasia or lacking thymic abnormalities.

Lambert-Eaton Myasthenic Syndrome

Lambert-Eaton myasthenic syndrome is an autoimmune disorder caused by antibodies that block acetylcholine release by inhibiting a presynaptic calcium channel. In contrast to myasthenia gravis, rapid repetitive stimulation increases muscle response. Muscle strength is augmented after a few seconds of muscle activity. Patients typically present with weakness of their extremities. In about half of cases there is an underlying malignancy, most often neuroendocrine carcinoma of the lung. Symptoms may precede the diagnosis of cancer, sometimes by years. It is thought that the stimulus for autoantibody formation in paraneoplastic cases may be the expression of the same calcium channel in the neoplastic cells. Patients without cancer often have other autoimmune diseases, such as vitiligo or thyroid disease. Treatment consists of drugs that increase acetylcholine release by depolarizing synaptic membranes and immunosuppressive agents, such as those used to treat myasthenia gravis.

Congenital Myasthenic Syndromes

Rare disorders falling into this group most commonly have an autosomal recessive mode of inheritance and are marked by varying degrees of muscle weakness. Causative mutations have been identified in genes encoding several different presynaptic, synaptic, or postsynaptic proteins. The most common of these are loss-of-function mutations in the gene encoding the ϵ -subunit of the acetylcholine receptor. Another group of mutations affect proteins that are important in normal clustering of acetylcholine receptors on postsynaptic membranes. Many patients with congenital myasthenic syndromes present in the perinatal period with poor muscle tone, external eye muscle weakness, and breathing difficulties, but others have milder forms of the disease and may not come to clinical attention until adolescence or adulthood. The clinical presentation, response to drugs such as acetylcholinesterase inhibitors, and prognosis depend largely on the underlying mutation.

Disorders Caused by Toxins

Botulism is caused by exposure to a neurotoxin (popularly known as *Botox*) that is produced by the anaerobic Gram-positive organism *Clostridium botulinum*. Botox acts by blocking the release of acetylcholine from presynaptic neurons (Chapter 8). *Curare* is a common name for related muscle relaxants that block acetylcholine receptors, resulting in flaccid paralysis. It was initially discovered and used as poison on arrow tips by indigenous people in the Amazon rain forest. At one time it was used as a muscle relaxant during certain forms of surgery, but has now been

supplanted by other related drugs with a similar mechanism of action.

KEY CONCEPTS

Diseases of the Neuromuscular Junction

- Disorders of neuromuscular junctions present with painless weakness.
- Myasthenia gravis and Lambert-Eaton myasthenic syndrome, the most common forms, are both immune mediated, being caused by antibodies to postsynaptic acetylcholine receptors and presynaptic calcium channels, respectively.
- Myasthenia gravis** is often associated with thymic hyperplasia or thymoma, frequently involves ocular muscles, and is marked by fluctuating weakness that worsens with exertion.
- Lambert-Eaton** myasthenic presents with weakness in the extremities that improves with repetitive stimulation and is often a paraneoplastic disorder associated with lung cancer.
- Genetic defects in neuromuscular junction proteins give rise to **congenital myasthenic syndromes**.
- Bacterial toxins** such as Botox can block neuromuscular transmission by blocking the release of acetylcholine from presynaptic neurons.

Diseases of Skeletal Muscle

Skeletal muscle has unique structural, cellular, and molecular characteristics and accordingly unique patterns of injury and repair. During embryogenesis, skeletal muscle develops through the fusion of mononucleated precursor cells (myoblasts) into multinucleated myotubes. These subsequently mature into myofibers (muscle fibers) of varying length that contain thousands of nuclei. In adult tissues, these myofibers are arranged in fascicles, each associated with a small pool of tissue stem cells referred to as satellite cells, which can contribute to muscle regeneration following injury (outlined later). Myofibers are of two main types, type I and type II (Table 27-1), which are admixed in a checkerboard pattern in normal skeletal muscle. Fiber type is determined by signals received from innervating motor neurons and, as a result, all fibers that are part of a motor unit are of the same type.

Skeletal Muscle Atrophy

Skeletal muscle atrophy is a common feature of many disorders. Loss of innervation, disuse, cachexia, old age, and primary myopathies can all produce muscle atrophy and, if the atrophy is severe, loss of muscle mass. Certain patterns of atrophy are suggestive of specific underlying etiologies:

- Clusters or groups of atrophic fibers are seen in neurogenic disease (Fig. 27-7).
- Perifascicular atrophy is seen in dermatomyositis (see later).
- Type II fiber atrophy with sparing of type I fibers is seen with prolonged corticosteroid therapy or disuse.

Table 27-1 Muscle fiber types

	Type I	Type II
Action	Sustained force	Fast movement
Activity type	Aerobic exercise	Anaerobic exercise
Power produced	Low	High
Resistance to fatigue	High	Low
Lipid content	High	Low
Glycogen content	Low	High
Energy metabolism	Low glycolytic capacity, high oxidative capacity	High glycolytic capacity, low oxidative capacity
Mitochondrial density	High	Low
Enzyme activity	NADH-TR, dark staining ATPase at pH 4.3, dark staining ATPase at pH 9.4, light staining	NADH-TR, light staining ATPase at pH 4.3, light staining ATPase at pH 9.4, dark staining
Myosin heavy chain gene expressed	<i>MYH7</i>	<i>MYH2, MYH4, MYH1</i>
Color	Red (high myoglobin content)	Pale red / tan (low myoglobin content)
Prototype	Soleus (pigeon)	Pectoral (pigeon)

ATPase, Adenosine triphosphatase; NADH-TR, nicotinamide adenine dinucleotide, reduced form, tetrazolium reductase.

Neurogenic and Myopathic Changes in Skeletal Muscle

Disorders impacting skeletal muscle may do so by damaging myofibers directly (myopathic injury) or by disrupting muscle innervation (neurogenic injury). Neurogenic injuries lead to *fiber type grouping* and *grouped atrophy* (Fig. 27-7), both of which stem from the disruption of muscle innervation. The key to understanding these abnormalities is to recognize that muscle fiber type is determined by the innervating motor neuron and can switch if the innervating motor neuron changes from one type to the other. Following denervation, myofibers undergo atrophy, often assuming a flattened, angulated shape. Reinnervation restores fiber size and shape, but may make a denervated myofiber part of a different motor unit and that may lead to a switch in fiber type. In the face of ongoing axonal or neuronal damage and drop out, residual motor axons may innervate increasingly larger numbers of myofibers, leading to enlargement of motor units, each comprised of a single type of muscle fiber (fiber type grouping). These large motor units are also susceptible to grouped atrophy if the innervating axon is damaged.

In contrast, most primary myopathic processes are associated with a distinct set of morphologic changes that include the following:

- Segmental myofiber degeneration and regeneration** is seen when only part of a myofiber undergoes necrosis. Degeneration is associated with release of cytoplasmic enzymes into the blood such as creatine kinase, making these useful markers of muscle damage. The sarcomeres and other components of the damaged myofiber segment are removed by macrophages in a process termed *myophagocytosis*. This sets the stage for

Figure 27-7 **A**, This diagrammatic representation of four normal motor units shows a normal checkerboard type admixture of light and dark stained fibers of opposite type. **B**, Damage to innervating axons leads to loss of trophic input and atrophy of myofibers. **C**, Reinnervation of myofibers can lead to a switch in fiber type and segregation of fibers of like type. As illustrated here, reinnervation is also often associated with an increase in motor unit size, with more myofibers innervated by an individual axon. **D**, Normal muscle has a checkerboard type distribution of type I (light) and type II (dark) fibers on this ATPase reaction (pH9.4) corresponding to findings in **A**. **E**, Clustered flattened “angulated” atrophic fibers (*group atrophy*) are a typical finding associated with disrupted innervation. **F**, With ongoing denervation and reinnervation, large clusters of fibers appear that all share the same fiber type (*type grouping*).

regeneration. Fusion of activated satellite cells to damaged myofibers is an important step for regeneration. Eventually, new sarcomeres are generated and the continuity of the original myofiber is restored. *Regenerating myofibers* are rich in RNA and therefore blue (basophilic) in hematoxylin and eosin stained sections. They have enlarged nuclei with prominent nucleoli that are often randomly distributed in the cytoplasm, instead of being in their normal subsarcolemmal location. Depending on the nature of the primary insult, atrophic myofibers may also be seen. Regeneration can restore muscle to normal following an acute, transient injury, but in chronic disease states regeneration often fails to keep pace with damage. In this setting, muscles often show endomysial fibrosis (collagen deposition), dropout of myofibers, and fatty replacement.

- *Myofiber hypertrophy* can be seen as a physiologic adaptation to exercise or in association with certain chronic myopathic conditions.
- *Cytoplasmic inclusions* in the form of vacuoles, aggregates of proteins, or clustered organelles are characteristic of several primary forms of myopathy.

Inflammatory Myopathies

Historically, polymyositis, dermatomyositis, and inclusion body myositis have been considered the three main primary

inflammatory myopathies; however, inclusion body myositis is an enigmatic condition (discussed later) in which the role of inflammation is uncertain. In contrast, polymyositis and dermatomyositis show typical features of autoimmune inflammatory diseases, including associations with certain autoantibodies, particular HLA-DR genotypes, and other autoimmune disorders. In addition to prototypical presentations, there are overlapping forms and cases that defy precise classification. Other immune-mediated disorders, such as systemic lupus erythematosus, systemic sclerosis, and sarcoidosis (Chapter 6), as well as certain infectious agents (Chapter 8), can also cause myositis and are discussed elsewhere.

Dermatomyositis

Dermatomyositis is a systemic autoimmune disease that typically presents with proximal muscle weakness and skin changes.

Pathogenesis. Dermatomyositis is an immunologic disease in which damage to small blood vessels contributes to muscle injury. The vasculopathic changes can be seen as *telangiectasias* (dilated capillary loops) in the nail folds, eyelids, and gums, and as dropout of capillary vessels in skeletal muscle. Biopsies of muscle and skin may show deposition of the complement membrane attack complex (C5b-9) within capillary beds in both tissues. An inflammatory signature enriched for genes that are upregulated by type I interferons is seen in muscle and in leukocytes. The prominence of this signature appears to correlate with disease activity. Various autoantibodies are often detected by serologic studies, and B lymphocytes as well as plasma cells are part of the inflammatory infiltrate that is seen in muscles. Certain autoantibodies tend to be associated with specific clinical features:

- *Anti-Mi2 antibodies* (directed against a helicase implicated in nucleosome remodeling) show a strong association with prominent Gottron papules and heliotrope rash (described later).
- *Anti-Jo1 antibodies* (directed against the enzyme histidyl t-RNA synthetase) are associated with interstitial lung disease, nonerosive arthritis, and a skin rash described as “mechanic’s hands.”
- *Anti-P155/P140 antibodies* (directed against several transcriptional regulators) are associated with paraneoplastic and juvenile cases of dermatomyositis.

A direct link between these autoantibodies and disease pathogenesis has not yet been established.

MORPHOLOGY

Muscle biopsies of affected patients show infiltrates of mononuclear inflammatory cells that tend to be most pronounced in the perimysial connective tissue and around blood vessels. Sometimes there is a distinctive pattern in which myofiber atrophy is accentuated at the edges of the fascicles—**perifascicular atrophy** (Fig. 27-8B). Segmental fiber necrosis and regeneration may also be seen. Immunohistochemical

Figure 27-8 A, Dermatomyositis. Note the heliotrope rash affecting the eyelids. **B**, Dermatomyositis. The histologic appearance of muscle shows perifascicular atrophy of muscle fibers and inflammation. (Courtesy Dr. Dennis Burns, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas.)

studies may identify an infiltrate rich in CD4+ T-helper cells and the deposition of C5b-9 in capillary vessels. Electron microscopic studies may show tubuloreticular endothelial cell inclusions, a feature of a number of inflammatory disorders that are linked to a type I interferon response.

Clinical Features. Muscle weakness is slow in onset, symmetric, and often accompanied by myalgias. It typically affects the proximal muscles first. As a result, tasks such as getting up from a chair and climbing steps become increasingly difficult. Fine movements controlled by distal muscles are affected only late in the disease. Associated myopathic changes on electrophysiologic studies and elevation in serum creatine kinase levels are reflective of muscle damage. Various rashes are described in dermatomyositis, but the most characteristic ones are a lilac colored discoloration of the upper eyelids (*heliotrope rash*) associated with periorbital edema (Fig. 27-8A) and a scaling erythematous eruption or dusky red patches over the knuckles, elbows, and knees (*Gottron papules*). *Dysphagia* resulting from involvement of oropharyngeal and esophageal muscles occurs in one third of the affected individuals, and another 10% of patients have *interstitial lung disease*, which can sometimes be rapidly progressive and lead to death. Cardiac involvement is common, but rarely leads to cardiac failure.

Juvenile and adult forms are recognized. The average age of onset of juvenile dermatomyositis is 7 years, whereas adult cases tend to present from the fourth to sixth decade of life. Dermatomyositis is the most common inflammatory myopathy in children. Compared to adult disease, childhood disease is more likely to be associated with calcinosis and lipodystrophy and less likely to be associated with myositis-specific antibodies, cardiac involvement, interstitial lung

disease, or an underlying malignancy. As might be expected based on these differences, the overall prognosis is better in children than in adults. From 15% to 24% of adult patients have an associated malignancy, and in such patients dermatomyositis may be viewed as a paraneoplastic disorder.

Polymyositis

Polymyositis is an adult-onset inflammatory myopathy that shares myalgia and weakness with dermatomyositis but lacks its distinctive cutaneous features and is therefore to some degree a diagnosis of exclusion. As in dermatomyositis, patients typically develop symmetric proximal muscle involvement, and there may be inflammatory involvement of the heart and the lungs, as well as similar autoantibodies.

Pathogenesis. The pathogenesis of polymyositis is uncertain, but it is believed to have an immunologic basis. CD8-positive cytotoxic T cells are a prominent part of the inflammatory infiltrate in affected muscle, and it is hypothesized that these cells are the mediators of tissue damage. Unlike dermatomyositis, vascular injury is not believed to have a major role in polymyositis.

MORPHOLOGY

Mononuclear inflammatory cell infiltrates are present, but in contrast to dermatomyositis, these are usually endomysial in location. Sometimes myofibers with otherwise normal morphology appear to be invaded by mononuclear inflammatory cells. Degenerating necrotic, regenerating, and atrophic myofibers are typically found in a random or patchy distribution. The perifascicular pattern of atrophy that is characteristic of dermatomyositis is absent.

Inclusion Body Myositis

Inclusion body myositis is a disease of late adulthood that typically affects patients older than 50 years and is the most common inflammatory myopathy in patients older than age 65 years. Most affected individuals present with slowly progressive muscle weakness that tends to be most severe in the quadriceps and the distal upper extremity muscles. Dysphagia from esophageal and pharyngeal muscle involvement is not uncommon. Laboratory studies usually show modestly elevated creatine kinase levels; most myositis-associated autoantibodies are absent, although an antibody to cN1A has recently been described.

MORPHOLOGY

Inclusion body myositis has a number of features that are similar to those found in polymyositis, including:

- Patchy often endomysial mononuclear inflammatory cell infiltrates rich in CD8+ T-cells
- Increased sarcolemmal expression of MHC class I antigens
- Focal invasion of normal appearing myofibers by inflammatory cells
- Admixed degenerating and regenerating myofibers

Other associated changes, however, are more typical or even specific for inclusion body myositis, as follows:

- Abnormal cytoplasmic inclusions described as “rimmed vacuoles” (Fig. 27-9)
- Tubulofilamentous inclusions in myofibers, seen by electron microscopy
- Cytoplasmic inclusions containing proteins typically associated with neurodegenerative diseases, like beta-amyloid, TDP-43, and ubiquitin
- Endomysial fibrosis and fatty replacement, reflective of a chronic disease course

Whether inclusion body myositis is indeed an inflammatory condition or a degenerative process with secondary inflammatory changes remains an unresolved question. It has certain features in common with polymyositis, as discussed earlier. On the other hand, it shares some features with neurodegenerative diseases, such as the presence of abnormal protein aggregates. Furthermore, there are several familial inclusion body myopathies that are also associated with chronic myopathic changes and rimmed vacuoles. These typically lack any associated inflammation—hence the designation *inclusion body “myopathy”* rather than *“myositis.”*

Treatment of Inflammatory Myopathies

The prognosis for patients with dermatomyositis and polymyositis was poor before the use of corticosteroids, with mortality rates as high as 50% or more. Corticosteroids remain the first-line of treatment for polymyositis and dermatomyositis. Immunosuppressive drugs are used in steroid-resistant disease or as steroid-sparing agents and include azathioprine and methotrexate. Intravenous immunoglobulin (IVIG), cyclophosphamide, cyclosporine, and rituximab (an antibody that targets B cells) are third-line

Figure 27-9 Inclusion body myositis, showing myofibers containing rimmed vacuoles—inclusions with reddish granular rimming (arrows). Modified Gomori trichrome stain.

therapies. Inclusion body myositis usually responds poorly to steroids or immunosuppressive therapies, another feature that argues against an inflammatory or immune origin for this disorder.

Toxic Myopathies

Toxic myopathies can be caused by prescription or recreational drugs, or by certain hormonal imbalances. Among prescription drugs, *statins* are among the leading culprits. Statins are cholesterol-lowering drugs that are widely used to reduce the risks of acute ischemic cardiac events and stroke. *Myopathy is the most common complication of statins* (e.g., atorvastatin, simvastatin, pravastatin). It occurs in approximately 1.5% of users, and is unrelated to dose, cumulative dose, or statin subtype. Genetic variants that influence statin metabolism, on the other hand, may help identify those who are at risk.

Chloroquine and *hydroxychloroquine* were originally used as antimalarial agents and are currently given as long-term therapy to some patients with systemic autoimmune diseases. These drugs interfere with normal lysosomal function and can cause a drug-induced lysosomal storage myopathy that presents with slowly progressive muscle weakness. The muscle tissue shows myopathic changes including vacuolation that predominantly affects type I fibers. Ultrastructural studies identify aggregates of whorled, lamellar membranous structures, including curvilinear bodies that mimic those seen in ceroid lipofuscinoses (Chapter 28).

ICU myopathy or *myosin deficient myopathy* is a neuromuscular disorder seen in patients during the course of treatment for critical illness (usually in an intensive care unit) especially with corticosteroid therapy. There may be relatively selective degradation of sarcomeric myosin thick

filaments, producing profound weakness that can complicate the clinical course (e.g., by interfering with the weaning of a patient from a mechanical respirator).

Thyroid dysfunction can lead to several types of myopathy. *Thyrotoxic myopathy* presents most commonly as an acute or chronic proximal muscle weakness that may precede other signs of hyperthyroidism. Such patients may also present with *exophthalmic ophthalmoplegia*, characterized by swelling of the eyelids, edema of the conjunctiva, and diplopia. *Hypothyroidism* can cause cramping or aching of muscles, and decreased movement. Reflexes may be slowed. Findings in skeletal muscle include fiber atrophy, an increased number of abnormally localized nuclei, glycogen aggregates, and (occasionally) deposition of mucopolysaccharides in connective tissue.

Alcohol can also be myopathic. Most notably, binge drinking may produce an acute toxic syndrome of rhabdomyolysis, myoglobinuria, and renal failure. The affected individual may complain of acute myalgias that are generalized or confined to a single muscle group.

Inherited Diseases of Skeletal Muscle

Inherited mutations are responsible for a diverse collection of disorders marked by defects in skeletal muscle.

In some of these disorders, skeletal muscle is the main site of disease, but in others multiple organs are involved. Of the other organs involved, the heart is of particular

importance, since cardiac involvement is common and often life-limiting.

Historically, inherited myopathies have been subdivided into several broad categories based on inheritance pattern, anatomic pattern of muscle involvement, onset age, clinical course, and underlying pathogenesis.

Congenital myopathies (Table 27-2) typically present in infancy with muscle defects that tend to be static or to even improve over time. They are often associated with distinct structural abnormalities of the muscle.

Muscular dystrophies are characterized by progressive muscle damage that typically comes to attention after infancy. Exceptions to this rule are the *congenital muscular dystrophies*; these tend to present in infancy and are often associated with developmental abnormalities of the CNS as well as progressive muscle damage. These include two important groups:

- *Conditions with defects in extracellular matrix surrounding myofibers.* These are exemplified by Ullrich congenital muscular dystrophy (UCMD) and merosin deficiency. In the former the causative mutations involve one of three collagen VI alpha genes; in the case of merosin deficiency, the gene encoding merosin is disrupted. UCMD is characterized by hypotonia, proximal contractures and distal hyperextensibility. A morphologic hallmark is mismatched expression of normally co-localized matrix proteins perlecan and collagen VI.

Table 27-2 Congenital myopathies

Disease and Inheritance	Gene and Locus	Clinical Findings	Pathologic Findings
Central-core disease; autosomal dominant	Ryanodine receptor-1 (<i>RYR1</i>) gene; 19q13.1	Early-onset hypotonia and weakness; “floppy infant”; associated skeletal abnormalities like scoliosis, hip dislocation, or foot deformities; some RYR1 mutations cause central core disease, some malignant hyperthermia, and some both	Cytoplasmic cores represent demarcated central zones in which the normal arrangement of sarcomeres is disrupted and mitochondria are decreased in number
Nemaline myopathy (NEM)	AD NEM1— α -tropomyosin 3 (<i>TPM3</i>) gene; 1q22–q23 AR NEM2—nebulin (<i>NEB</i>) gene; 2q22 AR NEM3— α -actin-1 (<i>ACTA1</i>) gene; 1q42 AR NEM4—tropomyosin-2 (<i>TPM2</i>) gene; 19p13.2–p13.1 AR NEM5—troponin T1 (<i>TNNI3</i>) gene; 19q13.4 AR NEM7—cofilin-2 (<i>CFL2</i>) gene; 14q12	Childhood weakness; some with more severe weakness, hypotonia at birth (“floppy infant”)	Aggregates of spindle-shaped particles (<i>nemaline rods</i>); occur predominantly in type 1 fibers; derived from Z-band material (α -actinin) and best seen on modified Gomori stain or by electron microscopy
Centronuclear myopathy	XL—myotubularin (<i>MTM1</i>) gene; Xq28 AD—dynammin-2 (and others) <i>DNM2</i> gene; 19p13.2 AR—amphiphysin-2 (<i>BIN1</i>) gene; 2q14)	Severe congenital hypotonia, “floppy infant” and poor prognosis in X-linked form (“myotubular myopathy”) Childhood onset or young adult onset with other variants with weakness and hypotonia	Many fibers contain nuclei in the geometric center of the myofiber; central nuclei are more common in type 1 fibers, which are small in diameter, but can occur in both fiber types
Congenital fiber type disproportion	Selenoprotein 1 (<i>SEPN1</i>) gene; 1p36.11 Alpha-actin-1 (<i>ACTA1</i>) gene; 1q42.13 Tropomyosin 3 (<i>TPM3</i>) gene; 1q21.3	Hypotonia, weakness, failure to thrive, facial and resp. weakness, contractures Wide phenotypic spectrum Mutations in <i>SEPN1</i> are also associated with protein aggregate myopathy and rigid spine muscular dystrophy; mutations in <i>ACTA1</i> are also associated with nemaline myopathy and protein aggregate myopathy; mutations in <i>TPM3</i> are also associated with nemaline myopathy	Predominance and atrophy of type I fibers (not specific)

AD, Autosomal dominant; AR, autosomal recessive; XL, X-linked.

- *Conditions with abnormalities in receptors for extracellular matrix.* In this group are diseases that disrupt the post-translational modification of alpha-dystroglycan (Fig. 27-10) by O-linked glycosylation. Mutations of alpha-dystroglycan itself result in fetal demise but defects in its post-translational modification result in milder forms of dystroglycan deficiency. Alpha-dystroglycan expression is important for CNS and eye development. Severe cases exhibit features of congenital muscular dystrophy as well as developmental defects of the CNS and eyes that cause seizures, mental retardation and blindness. Milder forms may only cause skeletal muscle disease. Some of these mutations are also linked to a presentation described as limb girdle muscular dystrophy (see below).

The following section focuses on the most common and best understood forms of inherited myopathies.

Muscular Dystrophies

Muscular dystrophies include several inherited disorders of skeletal muscle that have in common progressive muscle damage that typically manifests itself between childhood and adulthood. As mentioned earlier, with the exception of congenital muscular dystrophies, these diseases do not present in infancy. While our focus is on X-linked muscular dystrophies, other forms in which the

Figure 27-10 Relationship between the cell membrane (sarcolemma) and the sarcolemmal associated proteins. Dystrophin, an intracellular protein, forms an interface between the cytoskeletal proteins and a group of transmembrane proteins, the dystroglycans and the sarcoglycans. These transmembrane proteins have interactions with the extracellular matrix, including the laminin proteins. Dystrophin also interacts with dystrobrevin and the syntrophins, which form a link with neuronal type nitric oxide synthetase (nNOS) and caveolin. Mutations in dystrophin are associated with the X-linked muscular dystrophies; mutations in caveolin and the sarcoglycan proteins with the limb-girdle muscular dystrophies, which can be autosomal dominant or recessive disorders; and mutations in the α_2 -laminin (merosin) with autosomal recessive congenital muscular dystrophy.

disease pathogenesis is reasonably well understood are also briefly discussed.

X-Linked Muscular Dystrophy with Dystrophin Mutation/ Duchenne and Becker Muscular Dystrophy

The most common muscular dystrophies are X-linked and stem from mutations that disrupt the function of a large structural protein called dystrophin. As a result, these diseases are sometimes referred to as *dystrophinopathies*. The most common early onset form is referred to as *Duchenne muscular dystrophy*. It has an incidence of 1 per 3500 live male births and has a severe progressive phenotype. Becker muscular dystrophy is a second relatively common dystrophinopathy that is characterized by later disease onset and a milder phenotype. Other rare dystrophinopathies may present with isolated cardiomyopathy, asymptomatic elevations of creatine kinase levels, or exercise intolerance because of myalgias and cramps. As with many X-linked diseases, female carriers of dystrophin mutations may be mildly symptomatic due to unfavorable X-chromosome inactivation.

Pathogenesis. Duchenne and Becker muscular dystrophy are caused by loss-of-function mutations in the **dystrophin gene on the X chromosome**. Dystrophin is one of the largest human genes, spanning 2.3 million base pairs and composed of 79 exons. The encoded protein, dystrophin, is a key component of the dystrophin glycoprotein complex (DGC) (Fig. 27-10). This complex spans the plasma membrane and serves as a link between the cytoskeleton inside the myofiber and the basement membrane outside of the cell. The amino terminus of dystrophin binds actin filaments in the cytoplasm of myofibers, while the carboxy terminus binds β -dystroglycan, one of the transmembrane proteins of the DGC. By doing so, dystrophin is thought to provide mechanical stability to the myofiber and its cell membrane during muscle contraction. Defects in the complex may lead to small membrane tears that permit influx of calcium, triggering events that result in myofiber degeneration. In addition to its mechanical function, dystrophin may have a role in signaling pathways; for example, its carboxy terminus interacts with nitric oxide synthase, which generates NO.

Identification and characterization of specific dystrophin mutations has provided an explanation for some of the phenotypic variation in patients with dystrophinopathies. Duchenne muscular dystrophy is typically associated with deletions or frame shift mutations that result in total absence of dystrophin. In contrast, the mutations in Becker muscular dystrophy typically permit the synthesis of a truncated version of dystrophin, which presumably retains some function.

MORPHOLOGY

The changes in Duchenne and Becker muscular dystrophy are similar, but differ in degree. Both are marked by chronic muscle damage that outpaces the capacity for repair (Fig. 27-11). Muscle biopsies in young boys show ongoing damage in the form of **segmental myofiber degeneration and regeneration** associated with an admixture of **atrophic myofibers**. The fascicular architecture is preserved at this stage of the disease,

Figure 27-11 Duchenne muscular dystrophy. Histologic images of muscle biopsy specimens from two brothers. **A** and **B**, Specimens from a 3-year-old boy. **C**, Specimen from his 9-year old brother. As seen in **A**, at a younger age fascicular muscle architecture is maintained, but myofibers show variation in size. Additionally, there is a cluster of basophilic regenerating myofibers (*left side*) and slight endomysial fibrosis, seen as focal pink-staining connective tissue between myofibers. In **B**, immunohistochemical staining shows complete absence of membrane-associated dystrophin, seen as a brown stain in normal muscle (*inset*). In **C**, the biopsy from the older brother illustrates disease progression, which is marked by extensive variation in myofiber size, fatty replacement, and endomysial fibrosis.

and there is usually no inflammation except for the presence of myophagocytosis. As the disease progresses, muscle tissue is replaced by collagen and fat cells (“**fatty replacement**” or “fatty infiltration”). The remaining myofibers at this point in the course show prominent variation in size, from small atrophic fibers to large hypertrophied fibers. This remodeling distorts the fascicular architecture of the muscle, which becomes markedly abnormal over time. **Immunohistochemical studies for dystrophin show absence of the normal sarcolemmal staining pattern in Duchenne muscular dystrophin and reduced staining in Becker muscular dystrophy.**

Clinical Features. Boys with Duchenne muscular dystrophy are normal at birth. Very early motor milestones are met, but walking is often delayed. The first indications of muscle weakness are clumsiness and inability to keep up with peers. Weakness begins in the pelvic girdle muscles and then extends to the shoulder girdle. Enlargement of the muscles of the lower leg associated with weakness, termed *pseudohypertrophy*, is often present. The mean age of wheel chair dependence is around 9.5 years. Patients develop joint contractures, scoliosis, worsening respiratory reserve, and sleep hypoventilation.

Dystrophin is also expressed in the heart and the central nervous system, hence both are affected. Dystrophin deficiency in cardiac muscle often leads to the development of cardiomyopathy and arrhythmias, particularly in older patients. Cognitive impairment, presumably due to a functional role for dystrophin in the brain, is also common and sometimes produces frank mental retardation. Despite supportive care, the mean age of death for patients with Duchenne muscular dystrophy is 25 to 30 years of age, with most patients succumbing to respiratory insufficiency,

pulmonary infection, or heart failure. In contrast, Becker muscular dystrophy presents in later childhood, adolescence or adult life. Its course is more slowly progressive often with a near normal life expectancy.

The diagnosis is based on the history, physical exam, and laboratory studies. Serum creatine kinase is markedly elevated during the first decade of life due to ongoing muscle damage, and then falls as the disease progresses and muscle mass is lost. The presence of a dystrophin mutation can be confirmed by genetic studies.

Treatment of patients with dystrophinopathies is challenging. Current treatment consists primarily of supportive care. Definitive therapy requires restoration of dystrophin levels in skeletal and cardiac muscle fibers. Work in this area is emboldened by the recognition that expression of some dystrophin protein (as in patients with Becker muscular dystrophy) is sufficient to substantially ameliorate the disease phenotype. One approach involves the expression of antisense RNAs that alter RNA splicing so as to cause “skipping” of exons containing deleterious mutations, thus permitting the expression of a truncated, but partially functional, dystrophin protein. A second strategy is exploring the use of drugs that promote ribosomal “read-through” of stop codons, another ploy that may enable the expression of some dystrophin protein. Both of these approaches are mutation-specific and thus need to be tailored to individual patients. Gene therapy (introduction of a normal dystrophin gene) is being investigated, but gene delivery to skeletal muscle cells remains a daunting hurdle.

Myotonic Dystrophy

Myotonic dystrophy is an autosomal dominant multisystem disorder associated with skeletal muscle weakness,

cataracts, endocrinopathy, and cardiomyopathy. It affects about 1 in 10,000 individuals. Myotonia, a sustained involuntary contraction of muscles, is a key feature of the disease. Some patients present with “congenital myotonia,” marked by severe manifestations in infancy.

Pathogenesis. The disease is caused by expansions of CTG triplet repeats in the 3′-noncoding region of the myotonic dystrophy protein kinase (*DMPK*) gene, but precisely how this genetic aberration produces the disease phenotype is unknown. The correlation between the length of expansion and disease severity is variable compared to some other triplet repeat expansion disorders like Huntington disease (Chapter 28). Experimental studies suggest that the skeletal muscle phenotype stems from a “toxic” gain-of-function caused by the triplet repeat expansion. Specifically, the expanded CUG-repeats in the *DMPK* mRNA transcript appear to bind and sequester a protein called *muscleblind-like-1*, which has an important role in RNA splicing. This inhibits muscleblind-like-1 function, leading to missplicing of other RNA transcripts, including the transcript for a chloride channel called *CLC1*. It is believed that the resulting deficiency of *CLC1* is responsible for the characteristic myotonia. In support of this scenario, one rare form of congenital myotonia is caused by germ line loss-of-function mutations in *CLC1*, indicating that *CLC1* is required for normal muscle relaxation.

Emery-Dreifuss Muscular Dystrophy

Emery-Dreifuss muscular dystrophy (EMD) is caused by mutations in genes that encode nuclear lamina proteins. Clinically, it is marked by a triad consisting of slowly progressive humeroperoneal weakness, cardiomyopathy associated with conduction defects, and early contractures of the Achilles tendon, spine, and elbows. The X-linked form (EMD1) and the autosomal form (EMD2) are caused by mutations in the genes encoding emerin and lamin A/C, respectively, both of which localize to the inner face of the nuclear membrane. It is hypothesized that these proteins help maintain the shape and mechanical stability of the nucleus during muscle contraction. They may also influence gene expression by affecting chromatin organization in the nucleus. How defects in these proteins produce the observed phenotypes is unknown.

Fascioscapulohumeral Dystrophy

Fascioscapulohumeral dystrophy is associated with a characteristic pattern of muscle involvement that includes prominent weakness of facial muscles and muscles of the shoulder girdle. It is an autosomal dominant disease affecting about 1 in 20,000 individuals.

Pathogenesis. The pathogenesis of fascioscapulohumeral dystrophy is complex and only partly understood. It is established that the disease involves overexpression of a gene called *DUX4* that is located in a region of subtelomeric repeats on the long arm of chromosome 4. What remains unclear is the mechanism and consequences of *DUX4* overexpression. Some individuals with fascioscapulohumeral dystrophy inherit an abnormally small number of subtelomeric repeats. Each repeat carries a copy of the *DUX4* gene, and it appears that deletion of flanking repeats causes changes in chromatin that “derepress” the

remaining copies of *DUX4* thus leading to its overexpression. However, the reduction in repeats by itself is not sufficient to produce the disease; instead, the disease is confined to those who also inherit certain single nucleotide polymorphisms (SNPs) at positions immediately 3′ of the *DUX4* coding sequence. Only when the SNPs and the repeat contractions are both present is *DUX4* expressed at high enough levels to be pathogenic. Other individuals have a normal number of repeats and possibly have other mechanisms of *DUX4* overexpression. *DUX4* encodes a transcription factor, suggesting that the disease ultimately results from the overexpression of *DUX4* target genes.

Limb-Girdle Muscular Dystrophy

Limb-girdle muscular dystrophies are a heterogeneous group of at least six autosomal dominant and 15 autosomal recessive entities. Their overall incidence is 1 in 25,000 to 50,000 individuals. **As indicated by the name, all forms are characterized by muscle weakness that preferentially involves proximal muscle groups.** Both the age of onset and the disease severity are highly variable. The causative mutations involve genes that participate in diverse cellular functions, making it difficult to discern a unifying mechanism of disease pathogenesis. Based on current knowledge, the implicated genes can be grouped according to function as follows:

- Genes encoding structural components (sarcoglycans) of the dystrophin glycoprotein complex
- Genes encoding enzymes that are responsible for glycosylation of α -dystroglycan, a component of the dystrophin glycoprotein complex
- Genes encoding proteins that associate with the Z-disks of sarcomeres
- Genes encoding proteins involved in vesicle trafficking and cell signaling
- Genes that seemingly stand alone, such as those encoding the protease calpain 3 and lamin A/C (which is also mutated in some patients with Emery-Dreifuss muscular dystrophy)

Diseases of Lipid or Glycogen Metabolism

Many inborn errors of lipid or glycogen metabolism affect skeletal muscle. These disorders tend to produce one of two general patterns of muscle dysfunction. In some, patients become symptomatic only with exercise or fasting, which may produce severe muscle cramping and pain, or even extensive muscle necrosis (*rhabdomyolysis*). Other disorders of this type result in slowly progressive muscle damage, without episodic manifestations. Listed below are some examples in this group of muscle diseases:

- *Carnitine palmitoyltransferase II deficiency* is the most common disorder of lipid metabolism to cause episodic muscle damage with exercise or fasting. The defect in this disorder impairs the transport of free fatty acids into mitochondria.
- *Myophosphorylase deficiency (McArdle disease)* is one of the more common glycogen storage diseases affecting skeletal muscle; it also results in episodic muscle damage with exercise.
- *Acid maltase deficiency* results in impaired lysosomal conversion of glycogen to glucose, causing glycogen to

accumulate within lysosomes. Severe deficiency results in the generalized glycogenosis of infancy, *Pompe disease* (Chapter 5). Milder deficiency can cause a progressive adult onset myopathy that preferentially involves the respiratory and truncal muscles. Enzyme replacement therapy is now being used to treat affected patients.

Mitochondrial Myopathies

Mitochondrial diseases are complex systemic conditions that can involve many organ systems, including skeletal muscle. The genetics of these disorders are varied and unusually complex (discussed later), but many of the causative mutations appear to impair the ability of mitochondria to generate ATP. As a result, these diseases tend to affect skeletal muscles and other tissues rich in cell types with high ATP requirements, particularly cardiac muscle cells and neurons.

Skeletal muscle involvement can manifest as weakness, elevations in serum creatine kinase levels, or rhabdomyolysis. Although the anatomic pattern of muscle weakness is variable, involvement of extraocular eye muscles is common and can be a clue to the diagnosis. Indeed, *chronic progressive external ophthalmoplegia* is a common feature of mitochondrial disorders, and may occur as an isolated phenomenon or a part of a multisystem syndrome. The reason that extraocular eye muscles are particularly sensitive to mitochondrial disease is uncertain, but it may be that these muscles have exceptionally high requirements for ATP. In line with this idea, extraocular eye muscles have the most mitochondria per mass of any of the body's muscles.

Mitochondrial proteins and tRNAs may be encoded by either the nuclear genome or the mitochondrial genome (mtDNA). While mutations in nuclear mitochondrial genes follow Mendelian inheritance patterns, mutations in mtDNA are maternally inherited, since all of the mitochondria in the embryo are contributed by the oocyte (Chapter 5). In addition, unlike nuclear DNA, which is present in only two copies and is evenly distributed from a mother cell to daughter cells during cell division, each cell contains thousands of mtDNA copies, which are distributed in a random fashion to daughter cells at the time of cell division. It is believed that disease results only when a certain threshold of mutated mtDNA copies is exceeded within a substantial fraction of "at-risk" cells (e.g., skeletal muscle cells) in a tissue.

MORPHOLOGY

The most consistent pathologic change in skeletal muscle is abnormal aggregates of mitochondria that are seen preferentially in the subsarcolemmal area of affected myofibers, producing an appearance that is referred to as "ragged red fibers" (Fig. 27-12). By electron microscopy, morphologically abnormal mitochondria are seen. Loss of particular mitochondrial enzyme activities characterizes some mitochondrial diseases and may be appreciated by histochemical staining for cytochrome oxidase. Some mitochondrial diseases lack morphologic changes and can only be diagnosed through enzymatic assays or genetic analyses.

Clinical Features. Due to the complexity of mitochondrial genetics, genotype/phenotype relationships in

Figure 27-12 **A**, Ragged red fiber with increased reddish granular subsarcolemmal staining reflective of abnormal aggregation of mitochondria. **B**, Electron micrograph showing morphologically abnormal mitochondria with concentric membranous rings (so-called "phonograph records") and rhomboid paracrystalline inclusions (lower left side).

mitochondrial disorders are not straightforward. For example, a single point mutation in the mitochondrial leucine tRNA gene may produce isolated chronic progressive external ophthalmoplegia in one patient and a much more severe phenotype, *mitochondrial encephalomyopathy with lactic acidosis and stroke-like episodes*, in a second. Similarly, deletions in mtDNA may lead to either isolated ophthalmoplegia or to *Kearns-Sayre syndrome*, characterized by ophthalmoplegia, pigmentary degeneration of the retina, and complete heart block. *Myoclonic epilepsy with ragged red fibers* and *Leber hereditary optic neuropathy* are other examples of mitochondrial disease caused by point mutations in mtDNA. Many mitochondrial disorders, such as subacute necrotizing encephalopathy (*Leigh syndrome*), are remarkably heterogeneous genetically and may be caused by mutations in either mtDNA or the nuclear genome. In the case of Leigh syndrome, at last count causative mutations have been identified in more than 30 different genes, the common feature being that all of the affected genes encode proteins with essential roles in mitochondrial metabolism.

Spinal Muscular Atrophy and the Differential Diagnosis of a Hypotonic Infant

Spinal muscular atrophy is a neuropathic disorder in which loss of motor neurons leads to muscle weakness and atrophy. Infants with neurologic or neuromuscular disease may present with generalized hypotonia ("floppy infant"). The differential diagnosis of infantile hypotonia includes primary diseases of skeletal muscle (e.g., congenital myasthenic syndrome, congenital myotonia, congenital myopathies, and congenital muscular dystrophies),

Figure 27-13 Spinal muscular atrophy with only rare hypertrophied myofibers admixed with numerous atrophic rounded myofibers. The larger fibers are those that are innervated and have undergone compensatory hypertrophy.

abnormalities of the brain (e.g. encephalopathy), and neuropathies, of which spinal muscular atrophy is a prototypic example.

Spinal muscular atrophy is an autosomal recessive disorder with an incidence of 1 in 6,000 births, and is caused by loss-of-function mutations in the *SMN1* (survival of motor neuron-1) gene. The function of the gene is uncertain—the encoded protein may have a role in RNA splicing—but *SMN1* deficiency has a dramatic effect on motor neuron survival, sometimes leading to loss of motor neurons in utero. The resulting denervation of skeletal muscle may lead to characteristic morphologic changes consisting of large zones of severely atrophic myofibers mixed with scattered normal sized or hypertrophied myofibers, found individually or in small groups (Fig. 27-13). These normal or hypertrophied fibers are those that retain innervation from remaining motor neurons.

Ion Channel Myopathies (Channelopathies)

Channelopathies are a group of inherited diseases caused by mutations affecting the function of ion channel proteins. Most channelopathies are autosomal dominant disorders with variable penetrance. Depending on the channel that is affected, clinical manifestations may include epilepsy, migraine, movement disorders with cerebellar dysfunction, peripheral nerve disease, and muscle disease.

Different ion channel myopathies may cause decreased or increased excitability resulting in hypotonia or hypertonia. Disorders associated with hypotonia can be further sub-classified based on whether symptomatic patients have elevated, depressed, or normal serum potassium levels and are called *hyperkalemic*, *hypokalemic*, and *normokalemic periodic paralysis*, respectively. Examples of mutated gene products that are associated with muscle dysfunction are the following:

- **KCNJ2**—Mutations affecting this potassium channel cause *Andersen-Twail syndrome*, an autosomal disorder associated with periodic paralysis, heart arrhythmias, and skeletal abnormalities.
- **SCN4A**—Mutations affecting this sodium channel cause several autosomal disorders with presentations ranging from myotonia to periodic paralysis.
- **CACNA1S**—Missense mutations in this protein, a subunit of a muscle calcium channel, are the most common cause of *hypokalemic paralysis*.

- **CLC1**—Mutations affecting this chloride channel cause *myotonia congenita*. As already discussed, *CLC1* expression is decreased in *myotonic dystrophy*.
- **RYR1**—Mutations in the *RYR1* gene disrupt the function of the ryanodine receptor, which regulates calcium release from the sarcoplasmic reticulum. *RYR1* mutations are linked to a congenital myopathy (central core disease) and to *malignant hyperthermia*. The latter is characterized by a hypermetabolic state (tachycardia, tachypnea, muscle spasms, and later hyperpyrexia) that can be triggered by anesthetics, most commonly halogenated inhalational agents and succinylcholine. Upon exposure to anesthetic, the mutated receptor allows increased efflux of calcium from the sarcoplasmic reticulum, leading to tetany and excessive heat production.

KEY CONCEPTS

Disorders of Skeletal Muscle

- Altered muscle function may stem from neurogenic or primary myopathic processes.
- Myopathic processes are often marked by degeneration and regeneration of myofibers.
- The three main inflammatory myopathies are polymyositis, dermatomyositis, and inclusion body myositis.
 - **Inclusion body myositis** is a chronic progressive disease of older patients associated with rimmed vacuoles.
 - **Dermatomyositis** occurs in children and adults, the latter frequently as a paraneoplastic disorder. Immune damage to small blood vessels and perifascicular atrophy are common features.
 - **Polymyositis** is an adult onset myopathy caused by CD8+ T cells.
- **Muscular dystrophies** and **congenital myopathies** result from mutations that disrupt the function of proteins that are important for various aspects of muscle development, function, and regeneration. Some of these diseases present in infancy, others in adulthood. They may be relentlessly progressive or cause relatively static deficits.
- Myopathy can result from toxic injury or be the result of metabolic diseases including those of lipid metabolism, glycogen metabolism, and mitochondria.

Peripheral Nerve Sheath Tumors

A number of benign and malignant neoplasms are grouped together as peripheral nerve sheath tumors. *The vast majority of these are composed of cells that show evidence of Schwann cell differentiation.* These include the three common types, schwannoma, neurofibroma, and malignant peripheral nerve sheath tumor (MPNST). Other rare tumors arising from nerves may show evidence of perineurial cell differentiation. There is an abrupt transition between myelination by oligodendrocytes (central myelin) and myelination by Schwann cells (peripheral myelin) that occurs as nerves extend out from the substance of the brain. Thus, peripheral nerve tumors sometimes arise within the dura as well as along the distal course of peripheral nerves.

Peripheral nerve sheath tumors have several unique features. One is their association with relatively common familial tumor syndromes, including neurofibromatosis type 1 (NF1), neurofibromatosis type 2 (NF2), and schwannomatosis. Furthermore MPNSTs seen in the context of NF1 are thought to arise through malignant transformation of preexisting benign plexiform neurofibromas. Although malignant transformation of a preexisting benign lesion is a common origin for certain carcinomas (e.g., colon cancer), it is unusual in soft tissue tumors. Tumors with skeletal muscle differentiation are discussed in [Chapter 26](#).

Schwannomas

These are benign tumors that exhibit Schwann cell differentiation and often arise directly from peripheral nerves. Schwannomas are a component of NF2, and even sporadic schwannomas are commonly associated with inactivating mutations in the *NF2* gene on chromosome 22. Loss of expression of the *NF2* gene product, *merlin*, is a consistent finding in all schwannomas. Merlin normally restricts the cell-surface expression of growth factor receptors, such as EGFR, through interactions involving the actin cytoskeleton; in its absence, cells hyperproliferate in response to growth factors.

MORPHOLOGY

Schwannomas are well-circumscribed, encapsulated masses that abut the associated nerve without invading it, a feature that simplifies surgical excision. Grossly, these tumors form firm, gray masses. Microscopically, they are comprised of an admixture of dense and loose areas referred to as **Antoni A** and **Antoni B** areas, respectively ([Fig. 27-14A](#)). The dense eosinophilic Antoni A areas often contain spindle cells arranged into cellular intersecting fascicles. Palisading of nuclei is common and “nuclear-free zones” that lie between the regions of nuclear palisading are termed **Verocay bodies** ([Fig. 27-14B](#)). In the loose, hypocellular **Antoni B** areas the spindle cells are spread apart by a prominent myxoid extracellular matrix that may be associated with microcyst formation. Schwann cells are characterized by the presence of a spindled elongated nucleus with a wavy or buckled shape. Electron microscopy shows basement membrane deposits encasing single cells and collagen fibers. Because the lesion displaces the nerve of origin as it grows, silver stains or immunostains for neurofilament proteins demonstrate that axons are largely excluded from the tumor, although they may become entrapped in the capsule. The Schwann cell origin of these tumors is borne out by their uniform immunoreactivity for S-100. A variety of degenerative changes may be found in schwannomas, including nuclear pleomorphism, xanthomatous change, vascular hyalinization, cystic change, necrosis and mitotic activity. Some large mitotically active Schwannomas lacking Antoni B areas may mimic a sarcoma. Schwannomas may recur locally if incompletely resected, but malignant transformation is extremely rare (in contrast to plexiform neurofibromas, discussed later).

Clinical Features. Most Schwannomas cause symptoms by local compression of the involved nerve or adjacent structures (e.g., brainstem or spinal cord). Within the cranial vault, most schwannomas occur at the cerebellopontine

angle, where they are attached to the vestibular branch of the eighth nerve. Affected individuals often present with tinnitus and hearing loss; the tumor is commonly referred to as an *acoustic neuroma*—a double misnomer, since the tumor neither arises from the acoustic portion of the nerve nor is it a neuroma. Elsewhere within the dura, sensory nerves are preferentially involved, including branches of the trigeminal nerve and dorsal roots. When extradural, schwannomas can arise in association with large nerve trunks or as soft tissue lesions without an identifiable associated nerve. Surgical removal is curative.

Neurofibromas

Neurofibromas are benign nerve sheath tumors that are more heterogeneous in composition than schwannomas. *The neoplastic Schwann cells are admixed with perineurial-like cells, fibroblasts, mast cells, and CD34+ spindle cells.* Neurofibromas may be either sporadic or NF1-associated. Different types of neurofibroma can be distinguished depending on their growth pattern.

- *Superficial cutaneous neurofibromas* often present as pedunculated nodules that can be seen isolated (if sporadic) or multiple (if NF1-associated).
- *Diffuse neurofibromas* often present as a large plaque-like elevation of skin and are typically NF1-associated.
- *Plexiform neurofibromas* can be found in deep or superficial locations in association with nerve roots or large nerves and are uniformly NF1-associated.

Pathogenesis. Only the Schwann cells in neurofibromas show complete loss of the *NF1* gene product, neurofibromin, indicating that these are the neoplastic cells. You will recall from Chapter 7 that neurofibromin is a tumor suppressor that inhibits RAS activity by stimulating the activity of a GTPase (RAS is active only when bound to GTP). Haploinsufficiency for the *NF1* gene in other associated cells may also contribute to the growth of NF1-associated tumors. For example, there is evidence that NF1-haploinsufficient mast cells are hypersensitive to KIT ligand produced by Schwann cells and in response secrete factors that stimulate Schwann cell growth. This form of tumor/stromal cell cross-talk may be targetable with inhibitors of the KIT receptor tyrosine kinase. Other studies suggest that plexiform neurofibromas and dermal neurofibromas arise from different neural crest derived precursor cells. With rare exceptions, transformation to MPNST is only seen in plexiform neurofibromas. The overall incidence of MPNST in NF1 patients is about 5% to 10%, but patients with large numbers of plexiform neurofibromas and large deletions in the *NF1* gene are at higher risk.

MORPHOLOGY

Localized cutaneous neurofibroma. These are small, well-delineated but unencapsulated nodular lesions that arise in the dermis and subcutaneous fat. They have relatively low cellularity and contain bland Schwann cells admixed with stromal cells such as mast cells, perineurial cells, CD34+ spindle cells, and fibroblasts. Adnexal structures are sometimes entrapped at the edges of the lesion. The stroma of these tumors contains loose collagen.

Figure 27-14 Schwannoma and plexiform neurofibroma. **A** and **B**, Schwannoma. As seen in **A**, schwannomas often contain dense eosinophilic Antoni A areas (*left*) and loose, pale Antoni B areas (*right*), as well as hyalinized blood vessels (*right*). **B**, Antoni A area with the tumor cell nuclei aligned in palisading rows leaving anuclear zones and resulting in the formation of structures termed *Verocay bodies*. **C** and **D**, Plexiform neurofibroma. **C**, Multiple nerve fascicles are expanded by infiltrating tumor cells. **D**, At high power bland spindle cells are admixed with wavy collagen bundles resembling carrot shavings.

Diffuse neurofibroma. This tumor has morphologic features similar to those seen in localized cutaneous neurofibromas, but exhibits a distinctly different growth pattern. The tumor diffusely infiltrates the dermis and subcutaneous connective tissue, entrapping fat and appendage structures and producing a plaque-like appearance. Some of these neurofibromas can grow to large sizes. Focal collections of cells mimicking the appearance of Meissner corpuscles (so-called **pseudo-Meissner corpuscles** or **tactile-like bodies**) are an associated feature.

Plexiform neurofibroma. These tumors grow within and expand nerve fascicles (Fig. 27-14C), entrapping associated axons. The external perineurial layer of the nerve is preserved, giving individual nodules an encapsulated appearance. The expanded, ropy thickening of multiple nerve fascicles results in what is sometimes referred to as a “bag of worms” appearance. The tumor has cellular composition similar to that of other neurofibromas. The extracellular matrix varies from loose and myxoid to more collagenous and fibrous. Often the collagen is seen in bundles likened to “shredded carrot” (Fig. 27-14D).

Malignant Peripheral Nerve Sheath Tumors (MPNST)

Most MPNSTs (approximately 85%) are high-grade tumors, but low-grade variants are recognized. About half arise in NF1 patients and are assumed to result from malignant transformation of a plexiform neurofibroma. Sporadic cases may arise *de novo*. Most are associated with larger peripheral nerves in the chest, abdomen, pelvis, neck or limb-girdle. MPNSTs exhibit complex chromosomal aberrations, including chromosome gains, losses, and rearrangements. The molecular alterations driving malignant transformation of a neurofibroma to MPNST are still poorly understood.

MORPHOLOGY

The lesions are poorly defined tumor masses that frequently infiltrate along the axis of the parent nerve and invade adjacent soft tissues. A wide range of histologic appearance can be encountered. Typical cases show a fasciculated arrangement

of spindle cells. At low power the tumor often appears “marbled” due to variations in cellularity. Mitoses, necrosis, and nuclear anaplasia are common. An interesting phenomenon observed in MPNST is described as “divergent differentiation.” This term refers to the presence of focal areas that exhibit other lines of differentiation, including glandular, cartilaginous, osseous, or rhabdomyoblastic morphology. A tumor exhibiting the latter is referred to as **Triton tumor**. Due to the poorly differentiated nature of MPNST, the distinction from an undifferentiated sarcoma may not be straightforward. Helpful clues include a diagnosis of NF1 in the affected patient and a clearly demonstrated anatomic relationship to a nerve or to a preexisting neurofibroma.

Neurofibromatosis Type 1 and Type 2

Neurofibromatosis Type 1

This is a common autosomal dominant disorder with a frequency of 1 in 3000. It is a systemic disease associated with nonneoplastic manifestations and with a variety of tumors, including neurofibromas of all types, malignant peripheral nerve sheath tumors, gliomas of the optic nerve, other glial tumors and hamartomatous lesions, and pheochromocytomas. Other features include mental retardation or seizures, skeletal defects pigmented nodules of the iris (*Lisch nodules*), and cutaneous hyperpigmented macules (*café au lait spots*). The disease is caused by loss-of-function mutations in the *NF1* gene, located at 17q11.2, which encodes the tumor suppressor neurofibromin. The neoplastic cells in NF1-related tumors lack neurofibromin due to biallelic defects in the *NF1* gene. As has been mentioned earlier, NF-1 protein has GTPase activity that restrains RAS function. In the absence of NF-1, RAS remains trapped in its active state.

The disease has a high penetrance but variable expressivity. Some patients exhibit only subtle features, while others show disease that is restricted to certain parts of the body, a distribution that is attributable to mosaicism. An unfortunate subset has severe disease. Large chromosomal deletions that span *NF1* and extend to involve adjacent genes tend to be associated with more severe phenotypes.

Neurofibromatosis Type 2

This is an autosomal dominant disorder resulting in a range of tumors, most commonly bilateral eighth-nerve schwannomas and multiple meningiomas. Gliomas, typically ependymomas of the spinal cord, also occur in these patients. Many individuals with NF2 also have nonneoplastic lesions, which include nodular ingrowth of Schwann cells into the spinal cord (schwannosis), meningioangiomatosis (a proliferation of meningeal cells and blood vessels that grows into the brain), and glial hamartia (microscopic nodular collections of glial cells at abnormal locations, often in the superficial and deep layers of cerebral cortex). This disorder is much less common than NF1, having a frequency of 1 in 40,000 to 50,000. Certain other rare familial syndromes are also associated with multiple schwannomas, such as schwannomatosis and Carney complex.

The *NF2* gene is located on chromosome 22q12, and is also commonly mutated in sporadic meningiomas and schwannomas. The *NF2* gene product, merlin, is a cytoskeletal protein that appears to regulate membrane receptor signaling. Its tumor suppressive function may be related to a role in contact inhibition of cell growth. There is some correlation between the type of mutation and clinical symptoms, with nonsense and frameshift mutations causing more severe phenotypes than missense mutations.

KEY CONCEPTS

Peripheral Nerve Sheath Tumors

- The three common peripheral nerve sheath tumors—Schwannoma, neurofibroma, and malignant peripheral nerve sheath tumor—all likely arise from cells of Schwann cell lineage.
- Schwannomas are encapsulated benign tumors that can be associated with NF2.
- Neurofibromas are benign peripheral nerve sheath tumors sometimes associated with NF1 that can be subtyped as localized cutaneous, diffuse, or plexiform.
- Malignant peripheral nerve sheath tumors can be de novo sporadic neoplasms or NF1-associated tumors arising through malignant transformation of a (plexiform) neurofibroma.

The principal functional unit of the central nervous system (CNS) is the neuron. Of all the cells in the body, neurons have the unique ability to receive and transmit information. Neurons of different types and in different locations have distinct properties, including functional roles, distribution of their connections, neurotransmitters used, metabolic requirements, and levels of electrical activity at a given moment. A set of neurons, not necessarily clustered together in a region of the brain, may thus show *selective vulnerability* to various insults because it shares one or more of these properties. Since different regions of the brain participate in different functions, the pattern of clinical signs and symptoms that follow injury depend as much on the region of brain involved as on the pathologic process. Mature neurons are incapable of cell division, so destruction of even a small number of neurons essential for a specific function may leave the individual with a neurologic deficit. Neural progenitor populations are present in certain regions of the brain and have been shown to respond to injury by generating new neurons. For this reason, there is continuing interest in whether expansion of endogenous progenitors or delivery of exogenously derived progenitor cells might be a useful therapeutic approach for repair after injury or in the setting of degenerative diseases.

In addition to neurons the CNS contains other cells, such as *astrocytes* and *oligodendrocytes*, which make up the *glia*. The components of the CNS are affected by a number of unique neurologic disorders and also respond to common insults (e.g., ischemia, infection) in a manner that is distinct from other tissues. We start our discussion of diseases of the CNS with an overview of the patterns of injury of different cells and the reactions of these cells to various insults.

Cellular Pathology of the Central Nervous System

Neurons and glia of the CNS undergo a range of functional and morphologic changes in the setting of injury. Understanding these patterns can be informative about the mechanism of cellular injury and type of disease.

Reactions of Neurons to Injury

Neuronal injury may be an acute process, often a consequence of depletion of oxygen or glucose or trauma, or a slower process, often associated with accumulation of abnormal protein aggregates, as occurs in degenerative disorders of the brain. Neurons require a continuous

supply of oxygen and glucose to meet metabolic needs. This satisfies essential physiologic and anatomic requirements of the cells, including maintaining membrane gradients that are essential for action potentials, and supporting the extensive cytoplasmic dendritic arborization of neurons and of axons, which may extend over great distances from the cell body (up to a meter in adults). As most mature neurons are maintained for the life span of an individual, protein turnover and quality have to be carefully regulated to ensure cellular integrity. Not surprisingly, many neurologic diseases result from the injurious effects of accumulated misfolded proteins (*proteinopathies*) (see discussion of protein misfolding and the unfolded protein response in [Chapter 2](#)).

MORPHOLOGY

Acute neuronal injury (“red neurons”) refers to a spectrum of changes that accompany acute CNS hypoxia/ischemia or other acute insults and reflect the earliest morphologic markers of neuronal cell death (see [Fig. 28-13B](#)). “Red neurons” are evident by about 12 to 24 hours after an irreversible hypoxic/ischemic insult. The morphologic features consist of shrinkage of the cell body, pyknosis of the nucleus, disappearance of the nucleolus, and loss of Nissl substance, with intense eosinophilia of the cytoplasm.

Subacute and chronic neuronal injury (“degeneration”) refers to neuronal death occurring as a result of a progressive disease of some duration, as is seen in certain slowly evolving neurodegenerative diseases such as amyotrophic lateral sclerosis and Alzheimer disease. The characteristic histologic feature is cell loss, often selectively involving functionally related groups of neurons, and reactive gliosis. At an early stage, the cell loss is difficult to detect; the associated reactive glial changes are often the best indicator of neuronal injury. For many of these diseases, there is evidence that cell loss occurs via apoptotic death.

Axonal reaction is a change observed in the cell body during regeneration of the axon; it is best seen in anterior horn cells of the spinal cord when motor axons are cut or seriously damaged. There is increased protein synthesis associated with axonal sprouting. This is reflected in enlargement and rounding up of the cell body, peripheral displacement of the nucleus, enlargement of the nucleolus, and dispersion of Nissl substance from the center to the periphery of the cell (central chromatolysis).

Neuronal damage may be associated with a wide range of subcellular alterations in the neuronal organelles and cytoskeleton. **Neuronal inclusions** may occur as a manifestation of aging, when there are intracytoplasmic accumulations of

complex lipids (lipofuscin), proteins, or carbohydrates. Abnormal cytoplasmic deposition of complex lipids and other substances also occurs in genetically determined disorders of metabolism in which substrates or intermediates accumulate (Chapter 5). Viral infection can lead to abnormal intranuclear inclusions, as seen in herpetic infection (Cowdry body), cytoplasmic inclusions, as seen in rabies (Negri body), or both nucleus and cytoplasm as in cytomegalovirus infection.

Some degenerative diseases of the CNS are associated with neuronal intracytoplasmic inclusions, such as neurofibrillary tangles of Alzheimer disease and Lewy bodies of Parkinson disease; others cause abnormal vacuolization of the perikaryon and neuronal cell processes in the neuropil (Creutzfeldt-Jakob disease).

Reactions of Astrocytes to Injury

Gliosis is the most important histopathologic indicator of CNS injury, regardless of etiology, and is characterized by both hypertrophy and hyperplasia of astrocytes. The astrocyte derives its name from its star-shaped appearance. These cells have multipolar, branching cytoplasmic processes that emanate from the cell body and contain glial fibrillary acidic protein (GFAP), a cell type-specific intermediate filament (Fig. 28-1). Astrocytes act as metabolic buffers and detoxifiers within the brain. Additionally, through the foot processes, which surround capillaries or extend to the subpial and subependymal zones, they contribute to barrier functions controlling the flow of macromolecules between the blood, the cerebrospinal fluid (CSF), and the brain. In gliosis, the nuclei of astrocytes, which are typically round to oval (10 μm wide) with evenly dispersed, pale chromatin, enlarge, become vesicular, and develop prominent nucleoli. The previously scant cytoplasm expands to a bright pink, somewhat irregular swath

Figure 28-1 Astrocytes and their processes. Immunohistochemical staining for glial fibrillary acidic protein reveals astrocytic perinuclear cytoplasm and well-developed processes (brown).

around an eccentric nucleus, from which emerge numerous stout, ramifying processes; these cells are called *gemistocytic astrocytes*.

Acute cell injury, as occurs in hypoxia, hypoglycemia, and toxic injuries, is manifested by cellular swelling, as in other cells (Chapter 2). The *Alzheimer type II astrocyte* (unrelated to Alzheimer disease but first described by the same individual) is a gray matter cell with a large (two to three times normal) nucleus, pale-staining central chromatin, an intranuclear glycogen droplet, and a prominent nuclear membrane and nucleolus. This type of change is mainly seen in individuals with long-standing hyperammonemia due to chronic liver disease, Wilson disease, or hereditary metabolic disorders of the urea cycle.

Other types of cell injury lead to the formation of cytoplasmic inclusion bodies. *Rosenthal fibers* are thick, elongated, brightly eosinophilic, irregular structures that occur within astrocytic processes, and contain two heat-shock proteins (αB -crystallin and hsp27) as well as ubiquitin. Rosenthal fibers are typically found in regions of long-standing gliosis; they are also characteristic of one type of glial tumor, pilocytic astrocytoma. In *Alexander disease*, a leukodystrophy associated with mutations in the gene encoding GFAP, abundant Rosenthal fibers are found in periventricular, perivascular, and subpial locations. More commonly seen are *corpora amylacea*, or polyglucosan bodies. These are round, faintly basophilic, periodic acid-Schiff (PAS)-positive, concentrically lamellated structures of 5 to 50 μm in diameter that are located wherever there are astrocytic end processes, especially in the subpial and perivascular zones. They consist primarily of glycosaminoglycan polymers, as well as heat-shock proteins and ubiquitin. They occur in increasing numbers with advancing age and are thought to represent a degenerative change in the astrocyte. The *Lafora bodies* that are seen in the cytoplasm of neurons (as well as hepatocytes, myocytes, and other cells) in myoclonic epilepsy (Lafora body myoclonus with epilepsy) have a similar structure and biochemical composition.

Reactions of Microglia to Injury

Microglia are mesoderm-derived phagocytic cells that serve as the resident macrophages of the CNS. They share many surface markers with peripheral monocytes/macrophages (e.g., CR3 and CD68). They respond to injury by (1) proliferating; (2) developing elongated nuclei (*rod cells*), as in neurosyphilis; (3) forming aggregates around small foci of tissue necrosis (*microglial nodules*); or (4) congregating around cell bodies of dying neurons (*neuronophagia*). In addition to resident microglia, blood-derived macrophages may also be present in inflammatory foci.

Reactions of Other Glial Cells to Injury

Oligodendrocytes are cells that wrap their cytoplasmic processes around axons and form myelin. Each oligodendrocyte myelinates numerous internodes on multiple axons, in contrast to the myelinating Schwann cell in peripheral nerve, which has a one-to-one correspondence between cells and internodes. Injury or apoptosis of oligodendroglial cells is a feature of acquired demyelinating disorders and leukodystrophies. Oligodendroglial nuclei

may harbor viral inclusions in progressive multifocal leukoencephalopathy. *Glial cytoplasmic inclusions*, primarily composed of α -synuclein, are found in oligodendrocytes in multiple system atrophy (MSA).

Ependymal cells, the ciliated columnar epithelial cells lining the ventricles, do not have specific patterns of reaction. When there is inflammation or marked dilation of the ventricular system, disruption of the ependymal lining is paired with proliferation of subependymal astrocytes to produce small irregularities on the ventricular surfaces (*ependymal granulations*). Certain infectious agents, particularly CMV, may produce extensive ependymal injury, with viral inclusions in ependymal cells. However, neither oligodendrocytes nor ependymal cells mediate significant responses to most forms of injury in the CNS.

KEY CONCEPTS

Cellular Pathology of the Central Nervous System

- Each cellular component of the nervous system has a distinct set of patterns of response to injury.
- Neuronal injury commonly results in cell death, either by apoptosis or necrosis. Loss of neurons that is difficult to detect without formal quantification may still contribute to dysfunction.
- Astrocytes show morphologic changes including hypertrophy of the cytoplasm, accumulation of intermediate filament protein (GFAP), and hyperplasia.
- Microglia, the resident monocyte-lineage population of the CNS, proliferate and accumulate in response to injury.

Cerebral Edema, Hydrocephalus, and Raised Intracranial Pressure and Herniation

The brain and the spinal cord are encased and protected by the rigid skull and the bony spinal canal. The pressure within the cranial cavity may rise in one of three commonly observed clinical settings: generalized brain edema, increased CSF volume (hydrocephalus), and focally expanding mass lesions. Depending on the degree and rapidity of the pressure increase and the nature of the underlying lesion, the consequences range from subtle neurologic deficits to death.

Cerebral Edema

Cerebral edema (more precisely, brain parenchymal edema) is the result of increased fluid leakage from blood vessels or injury to various cells of the CNS. There are two main pathways of edema formation in the brain.

- *Vasogenic edema* is an increase in extracellular fluid caused by blood-brain barrier disruption and increased vascular permeability, allowing fluid to shift from the intravascular compartment to the intercellular spaces of

the brain. The paucity of lymphatics greatly impairs the resorption of excess extracellular fluid. Vasogenic edema may be either localized (e.g., adjacent to inflammation or neoplasms) or generalized, as can follow ischemic injury.

- *Cytotoxic edema* is an increase in intracellular fluid secondary to neuronal, glial, or endothelial cell membrane injury, as might be encountered in someone with a generalized hypoxic/ischemic insult or with a metabolic derangement that prevents maintenance of the normal membrane ionic gradient.

In practice, conditions associated with generalized edema often have elements of both vasogenic and cytotoxic edema. In generalized edema, the gyri are flattened, the intervening sulci are narrowed, and the ventricular cavities are compressed. As the brain expands, herniation may occur.

Interstitial edema (hydrocephalic edema) occurs especially around the lateral ventricles when an increase in intravascular pressure causes an abnormal flow of fluid from the intraventricular CSF across the ependymal lining to the periventricular white matter.

Hydrocephalus

Hydrocephalus is the accumulation of excessive CSF within the ventricular system (Fig. 28-2). The choroid plexus within the ventricular system produces CSF, which normally circulates through the ventricular system and enters the cisterna magna at the base of the brain stem through the foramina of Luschka and Magendie. Subarachnoid CSF bathes the superior cerebral convexities and is absorbed by the arachnoid granulations. Most cases of hydrocephalus are a consequence of impaired flow and resorption of CSF; overproduction is a rare cause that can accompany tumors of the choroid plexus. An increased volume of CSF within the ventricles expands them and can elevate the intracranial pressure.

When hydrocephalus develops in infancy before closure of the cranial sutures, there is enlargement of the head,

Figure 28-2 Hydrocephalus. Dilated lateral ventricles seen in a coronal section through the midline.

manifested by an increase in head circumference. Hydrocephalus developing after this period, in contrast, is associated with expansion of the ventricles and increased intracranial pressure, without a change in head circumference. If the ventricular system is obstructed and does not communicate with the subarachnoid space, as may occur because of a mass in the third ventricle, it is called *noncommunicating, or obstructive, hydrocephalus*. In *communicating hydrocephalus*, the ventricular system is in communication with the subarachnoid space, and there is enlargement of the entire ventricular system. The term *hydrocephalus ex vacuo* refers to a compensatory increase in ventricular volume secondary to a loss of brain parenchyma.

Raised Intracranial Pressure and Herniation

Herniation is the displacement of brain tissue past rigid dural folds (the falx and tentorium) or through openings in the skull because of increased intracranial pressure. As the volume of the brain increases, CSF is displaced and the vasculature is compressed, leading to increasing pressure within the cranial cavity. When the increase is beyond the limit permitted by compression of veins and displacement of CSF, tissue herniates between compartments across the pressure gradient. Herniation is mostly associated with mass effect, either diffuse (generalized brain edema) or focal (tumors, abscesses, or hemorrhages). Elevated intracranial pressure may also reduce perfusion of the brain, further exacerbating cerebral edema. If the expansion is sufficiently severe, herniation may occur in multiple anatomic locations (Fig. 28-3).

- *Subfalcine (cingulate) herniation* occurs when unilateral or asymmetric expansion of a cerebral hemisphere

Figure 28-3 Major herniation syndromes of the brain: subfalcine, transtentorial, and tonsillar.

Figure 28-4 Duret hemorrhage involving the brainstem at the junction of the pons and midbrain.

displaces the cingulate gyrus under the falx. This may lead to compression of the anterior cerebral artery and its branches.

- *Transtentorial (uncinate, mesial temporal) herniation* occurs when the medial aspect of the temporal lobe is compressed against the free margin of the tentorium. With increasing displacement of the temporal lobe, the third cranial nerve is compromised, resulting in pupillary dilation and impairment of ocular movements on the side of the lesion. The posterior cerebral artery may also be compressed, resulting in ischemic injury to the territory supplied by that vessel, including the primary visual cortex. When the extent of herniation is large enough the contralateral cerebral peduncle may be compressed, resulting in hemiparesis ipsilateral to the side of the herniation; the compression in the peduncle in this setting is known as the *Kernohan notch*. Progression of transtentorial herniation is often accompanied by secondary hemorrhagic lesions in the midbrain and pons, termed *Duret hemorrhages* (Fig. 28-4). These linear or flame-shaped lesions usually occur in the midline and paramedian regions and are believed to be due to distortion or tearing of penetrating veins and arteries supplying the upper brainstem.
- *Tonsillar herniation* refers to displacement of the cerebellar tonsils through the foramen magnum. This pattern of herniation is life-threatening because it causes brainstem compression and compromises vital respiratory and cardiac centers in the medulla.

KEY CONCEPTS

Cerebral Edema, Hydrocephalus, and Raised Intracranial Pressure and Herniation

- Cerebral edema is the accumulation of excess fluid within the brain parenchyma. Hydrocephalus is an increase in CSF volume within all or part of the ventricular system.

- Increases in the volume of intracranial contents (as a result of increased CSF volume, edema, hemorrhage, or tumor) raise the pressure inside the fixed capacity of the skull.
- Increases in pressure may result in decreased perfusion (leading to ischemia). The increased pressure may also result in displacement of tissue past the edges of dural partitions inside the skull or through openings in the skull (herniations).

Malformations and Developmental Disorders

Although the pathogenesis and etiology of many CNS malformations remain unknown, both genetic and environmental influences appear to be involved. Newer genetic methods, including whole exome and whole genome sequencing, have begun to uncover a range of alterations that may cause many of these malformations. The causal relationship between the genetic alterations and the pathogenesis of the malformations is the subject of active research. Besides genetic factors, many toxic compounds and infectious agents also have teratogenic effects and may cause brain malformations.

Neural Tube Defects

Failure of a portion of the neural tube to close, or reopening of a region of the tube after successful closure, may lead to malformations involving some combination of neural tissue, meninges, and overlying bone or soft tissues. Collectively, neural tube defects account for most CNS malformations, with the most common neural tube defects involving the spinal cord.

- *Spinal dysraphism* or *spina bifida* may be an asymptomatic bony defect (*spina bifida occulta*) or a severe malformation with a flattened, disorganized segment of spinal cord, associated with an overlying meningeal outpouching.
- *Myelomeningocele* (or *meningomyelocele*) refers to extension of CNS tissue through a defect in the vertebral column; the term *meningocele* applies when there is only a meningeal extrusion. Myelomeningoceles occur most commonly in the lumbosacral region. Affected individuals have motor and sensory deficits in the lower extremities as well as disturbances of bowel and bladder control. These are often complicated by superimposed infection that extends into the cord from the thin, overlying skin.
- *Encephalocele* refers to a diverticulum of malformed brain tissue extending through a defect in the cranium. It most often occurs in the posterior fossa, although comparable extensions of brain occur through the cribriform plate in the anterior fossa (sometimes misleadingly referred to as a “nasal glioma”).

The frequency of neural tube defects varies widely among different ethnic groups. Evidence for a genetic basis includes the high concordance rate among monozygotic twins. The overall recurrence rate for a neural tube defect in subsequent pregnancies has been estimated at 4% to 5%.

Folate deficiency during the first several weeks of gestation is a well established risk factor; differences in rates of neural tube defects between populations can be attributed in part to polymorphisms in enzymes involved in folic acid metabolism. Folate supplementation can lower the risk of neural tube defects, but because neural tube closure is normally complete by day 28 of embryonic development (before most pregnancies are recognized), it must be given to women throughout their reproductive years to be fully effective. Precisely how folate deficiency increases the risk is uncertain; defects in the timing of DNA synthesis and effects on DNA methylation (an important epigenetic mode of gene regulation) are suspected.

Anencephaly is a malformation of the anterior end of the neural tube, with absence of most of the brain and calvarium. Forebrain development is disrupted at approximately 28 days of gestation, and all that remains in its place is the *area cerebrovasculosa*, a flattened remnant of disorganized brain tissue with admixed ependyma, choroid plexus, and meningotheelial cells. The posterior fossa structures may be spared, depending on the extent of the skull deficit; descending tracts associated with disrupted structures are, as expected, absent.

Forebrain Anomalies

Abnormalities in the generation and migration of neurons result in malformations of the forebrain that may be focal or involve entire structures. The pool of proliferating precursor cells in the developing brain lies adjacent to the ventricular system. Overall neuronal number is determined by the fraction of proliferating cells that undergo transition into migrating cells with each cell cycle. Early on, most cell divisions yield two more progenitor cells, while as development progresses there are more asymmetric divisions yielding both a progenitor cell and a cell directed to the developing cortex. If excess cells exit the proliferating pool too early, then the overall generation of neurons is reduced; if too few exit during early rounds of division, then the geometric expansion of the proliferating population results in an overproduction of neurons. The migration of neurons from the germinal matrix zone to the cerebral cortex follows two paths: a radial migration for neuronal progenitor cells destined to become excitatory neurons and a tangential migration course for those which will become inhibitory interneurons. The signaling that governs radial migration is better understood than the corresponding mechanisms for tangential migration. For radial migration, a secreted protein (reelin) signals to migrating neuroblasts through a surface receptor; the ability of these cells to respond appropriately is dependent on cytoskeletal proteins that propel the migrating neuroblasts.

A range of malformation patterns have been defined, initially by focusing on the region of the brain that is involved and what changes are present. With genetic advances, it has become clear that many of these patterns can be caused by mutations in several genes that are required for proper cerebral development. Changes may be seen from the surface of the brain, with either too few or too many gyri, in the organization of the brain into normal lobes, in the structure of the cerebral cortex or in the distribution of neurons within the brain.

Figure 28-5 Lissencephaly. The absence of cortical gyri defines this abnormality, seen here in the brain from a full-term infant.

- The volume of brain may be abnormally large (*megalencephaly*) or abnormally small (*microencephaly*). Microencephaly, by far the more common of the two, is typically accompanied by a small head circumference. It can be associated with a number of conditions, including chromosome abnormalities, fetal alcohol syndrome, and human immunodeficiency virus 1 (HIV-1) infection acquired in utero. It is postulated that the underlying anomaly is a reduction in the number of neurons that reach the neocortex and this leads to a simplification of the gyral folding, a model supported by experimental results in mouse models.
- *Lissencephaly* is a malformation characterized by reduction in the number of gyri, which in the extreme case may show no gyral pattern (*agyria*) (Fig. 28-5). Two general patterns are observed, a smooth surfaced form (type 1), and a rough or cobblestoned surfaced form (type 2). In general, type 1 forms are associated with mutations that disrupt the signaling for migration and the cytoskeletal “motor” proteins that drive migration of neuroblasts. In contrast, type 2 lissencephaly is most commonly associated with genetic alterations that disrupt the “stop signal” for migration. This signal depends on a set of specifically glycosylated proteins, and mutations in the enzymes that place the sugars onto the proteins are the most common causes of this form of lissencephaly.
- *Polymicrogyria* is characterized by small, unusually numerous, irregularly formed cerebral convolutions. The gray matter is composed of four layers (or fewer), with entrapment of apparent meningeal tissue at points of fusion that would otherwise be the cortical surface. Polymicrogyria can be induced by localized tissue injury toward the end of neuronal migration, although genetically determined forms, which are typically bilateral and symmetric, are also recognized.
- *Neuronal heterotopias* are a group of migrational disorders that are commonly associated with epilepsy. They are defined by the presence of collections of neurons in inappropriate locations along the pathway of migration. As might be expected, one location in which heterotopias can be found is along the ventricular surface—as though the cells never managed to leave their place of birth. Periventricular heterotopias can be caused by mutations in the gene encoding filamin A, an actin-binding protein responsible for assembly of complex meshworks of filaments. This gene is on the X chromosome, and the mutant allele causes male lethality; in females the process of X inactivation separates neurons into those with a normal allele (in the correct location) and those with the mutant allele (in the heterotopia). Another microtubule-associated protein, doublecortin (DCX), is also encoded by a gene on the X chromosome; mutations in this gene result in lissencephaly in males and in subcortical band heterotopias in females. These heterotopias may consist of discrete nodules of neurons sitting in the subcortical white matter or complete ribbons that parody the overlying cortex.
- *Holoprosencephaly* is a spectrum of malformations characterized by incomplete separation of the cerebral hemispheres across the midline. Severe forms manifest midline facial abnormalities, including cyclopia; less severe variants (*arrhinencephaly*) show absence of the olfactory cranial nerves and related structures. Intrauterine diagnosis of severe forms by ultrasound examination is now possible. Holoprosencephaly is associated with trisomy 13 as well as other genetic syndromes. Mutations in genes that encode components of the sonic hedgehog signaling pathway may result in holoprosencephaly.
- *Agenesis of the corpus callosum*, a relatively common malformation, refers to the absence of the white matter bundles that carry cortical projections from one hemisphere to the other (Fig. 28-6). Radiologic imaging studies show misshapen lateral ventricles (“bat-wing” deformity); on coronal whole-mount sections of the brain, bundles of anteroposteriorly oriented white

Figure 28-6 Agenesis of the corpus callosum. The midsagittal view of the left hemisphere shows the lack of a corpus callosum and cingulate gyrus above the third ventricle.

matter can be demonstrated. Agenesis of the corpus callosum is commonly associated with mental retardation but may occur in clinically normal individuals. It can be present in isolation or associated with a wide range of other malformations.

Posterior Fossa Anomalies

A distinct set of malformations primarily affect the brainstem and the cerebellum, which often show dramatic changes in size and shape. These may be accompanied by morphologic changes in other regions of the brain.

- **Arnold-Chiari malformation** (Chiari type II malformation) consists of a small posterior fossa, a misshapen midline cerebellum with downward extension of vermis through the foramen magnum (Fig. 28-7), and, almost invariably, hydrocephalus and a lumbar myelomeningocele. Other associated changes may include caudal displacement of the medulla, malformation of the tectum, aqueductal stenosis, cerebral heterotopias, and hydromyelia (see later).
- **Chiari type I malformation** is a less severe disorder in which low-lying cerebellar tonsils extend down into the vertebral canal. This may be a silent abnormality or may become symptomatic because of impaired CSF flow and medullary compression; if present, these symptoms can usually be corrected by neurosurgical intervention.
- **Dandy-Walker malformation** is characterized by an enlarged posterior fossa. The cerebellar vermis is absent or present only in rudimentary form in its anterior portion. In its place is a large midline cyst that is lined by ependyma and is contiguous with leptomeninges on its outer surface. This cyst represents the expanded, roofless fourth ventricle in the absence of a normally formed vermis. Dysplasias of brainstem nuclei are commonly found in association with Dandy-Walker malformation.

Figure 28-7 Arnold-Chiari malformation. Midsagittal section showing small posterior fossa contents, downward displacement of the cerebellar vermis, and deformity of the medulla (arrows indicate the approximate level of the foramen magnum).

- **Joubert syndrome**, and its related disorders, share hypoplasia of the cerebellar vermis with apparent elongation of the superior cerebellar peduncles and an altered shape of the brainstem; together these changes give rise to the ‘molar tooth sign’ on imaging. This group of malformations has been found to be caused by diverse mutations affecting genes that encode components of the primary (non-motile) cilium.

Syringomyelia and Hydromyelia

These are disorders characterized by expansion of the ependyma-lined central canal of the cord (*hydromyelia*) or by the formation of a fluid-filled cleft-like cavity in the inner portion of the cord (*syringomyelia*, *syrinx*) that may extend into the brainstem (*syringobulbia*).

Syringomyelia may be associated with the Chiari malformations; it may also occur in association with intraspinal tumors or following traumatic injury. In general, the histologic appearance is similar in all these conditions, with destruction of the adjacent gray and white matter, surrounded by a dense feltwork of reactive gliosis. The disease generally becomes manifest in the second or third decade of life. The distinctive symptoms and signs of a syrinx are the isolated loss of pain and temperature sensation in the upper extremities because of the predilection for early involvement of the crossing anterior spinal commissural fibers of the spinal cord.

KEY CONCEPTS

Malformations and Developmental Disorders

- Malformations may be associated with single gene mutations, larger scale genetic alterations, or exogenous factors.
- Overall, the earlier in development a malformation occurs, the more severe the morphologic and functional phenotype.
- Neural tube defects are associated with failure to close or inappropriate reopening of the developing neural tube; these range from incidental findings to severe manifestations.
- Cortical development depends on proper orchestration of progenitor cell proliferation in the germinal matrix and migration of progenitors upwards into the developing cortex. Disruption of these processes can alter the size, shape, and organization of the brain.
- Malformations involving the posterior fossa are typically distinct from those which affect the cerebral hemispheres.

Perinatal Brain Injury

Brain injury occurring in the perinatal period is an important cause of childhood-onset neurologic disability. Injuries that occur early in gestation may destroy brain tissue without eliciting the reactive changes observed in adult brain and, therefore, may be difficult to distinguish from malformations.

The term *cerebral palsy* refers to a nonprogressive neurologic motor deficit characterized by combinations of

Figure 28-8 Multicystic leukoencephalopathy. Numerous cystic spaces representing the consequences of widespread ischemic injury are present.

spasticity, dystonia, ataxia/athetosis, and paresis, attributable to insults occurring during the prenatal and perinatal periods. Signs and symptoms may not be apparent at birth and only declare themselves later, as development proceeds. Postmortem examinations of children with cerebral palsy have shown a wide range of neuropathologic findings, including destructive lesions traced to remote events that may have caused hemorrhage and infarction.

In premature infants there is an increased risk of *intraparenchymal hemorrhage* within the germinal matrix, often near the junction between the developing thalamus and caudate nucleus. Hemorrhages may remain localized or extend into the ventricular system and thence to the subarachnoid space, sometimes leading to hydrocephalus.

Infarcts may occur in the supratentorial periventricular white matter (*periventricular leukomalacia*), especially in premature infants. These take the form of chalky yellow plaques consisting of discrete regions of white matter necrosis and calcification. When both gray and white matter are involved by extensive ischemic damage, large destructive cystic lesions develop throughout the hemispheres; this condition is termed *multicystic encephalopathy* (Fig. 28-8).

In perinatal ischemic lesions of the cerebral cortex, the depths of sulci bear the brunt of injury and result in thinned-out, gliotic gyri (*ulegyria*). The basal ganglia and thalamus may also suffer ischemic injury, with patchy neuronal loss and reactive gliosis. Later, aberrant and irregular myelination gives rise to a marble-like appearance of the deep nuclei (*status marmoratus*). Because the lesions are in the caudate, putamen, and thalamus, movement disorders such as choreoathetosis are common clinical sequelae.

Trauma

The anatomic location of the lesion and the limited capacity of the brain for functional repair are major determinants of the consequences of CNS trauma. Injury of several cubic

centimeters of brain parenchyma may be clinically silent (if in the frontal lobe), severely disabling (if in the spinal cord), or fatal (if in the brainstem).

The physical forces associated with head injury may result in skull fractures, parenchymal injury, and vascular injury; all three can coexist. The magnitude and distribution of a traumatic brain lesions depend on the shape of the object causing the trauma, the force of impact, and whether the head is in motion at the time of injury. A blow to the head may be *penetrating* or *blunt*; it may cause either an *open* or a *closed injury*.

Skull Fractures

A fracture in which bone is displaced into the cranial cavity by a distance greater than the thickness of the bone is called a *displaced skull fracture*. The thickness of the cranial bones varies; therefore, their resistance to fracture differs greatly. Also, the relative incidence of fractures among skull bones is related to the pattern of falls. When an individual falls while awake, such as might occur when stepping off a ladder, the site of impact is often the occipital portion of the skull; in contrast, a fall that follows loss of consciousness, as might follow a syncopal attack, commonly results in a frontal impact. Symptoms referable to the lower cranial nerves or the cervicomedullary region, and the presence of orbital or mastoid hematomas distant from the point of impact, raise the suspicion of a basal skull fracture, which typically follows impact to the occiput or sides of the head. CSF discharge from the nose or ear and infection (meningitis) may follow. The kinetic energy that causes a fracture is dissipated at a fused suture; fractures that cross sutures are termed *diastatic*. With multiple points of impact or repeated blows to the head, the fracture lines of subsequent injuries do not extend across fracture lines of prior injury.

Parenchymal Injuries

Concussion

Concussion is a clinical syndrome of altered consciousness secondary to head injury typically brought about by a change in the momentum of the head (when a moving head is suddenly arrested by impact on a rigid surface). The characteristic neurologic picture includes instantaneous onset of transient neurologic dysfunction, including loss of consciousness, temporary respiratory arrest, and loss of reflexes. Although neurologic recovery is complete, amnesia for the event often persists. The pathogenesis of the sudden disruption of neurologic function is unknown; it probably involves dysregulation of the reticular activating system in the brainstem. Post-concussive neuropsychiatric syndromes, typically associated with repetitive injuries, are well recognized and there is increasing evidence that significant cognitive impairment can emerge along with distinct pathologic findings termed chronic traumatic encephalopathy (discussed later).

Direct Parenchymal Injury

Contusions and *lacerations* are brain injuries caused by transmission of kinetic energy to the brain. A contusion is analogous to the familiar bruise caused by blunt trauma, while a laceration is an injury caused by penetration of an

object and tearing of tissue. As with any other organ, a blow to the surface of the brain, transmitted through the skull, leads to rapid tissue displacement, disruption of vascular channels, and subsequent hemorrhage, tissue injury, and edema (Fig. 28-9). Hemorrhage can extend into the subarachnoid space from these lesions. The crests of gyri are most susceptible, since this is where the direct force is greatest. The most common locations for contusions correspond to the most frequent sites of direct impact and to regions of the brain that overlie a rough and irregular inner skull surface, such as the frontal lobes along the orbital ridges and the temporal lobes. Contusions are less frequent over the occipital lobes, brainstem, and cerebellum unless these sites are adjacent to a skull fracture (*fracture contusions*).

A person who suffers a blow to the head may develop a contusion at the point of contact (a *coup* injury) or a contusion on the brain surface diametrically opposite to it (a *contrecoup* injury). Since their macroscopic and microscopic appearance is indistinguishable, the distinction between them is based on identification of the point of impact. In general, if the head is immobile at the time of trauma, only a coup injury is found. If the head is mobile, both coup and contrecoup lesions may be found. Whereas the coup lesion is caused by the contact between brain and skull at the site of impact, the contrecoup contusion is thought to develop when the brain strikes the opposite inner surface of the skull after sudden deceleration.

Sudden impacts that result in violent posterior or lateral hyperextension of the neck (as occurs when a pedestrian is struck from the rear by a vehicle) may avulse the pons from the medulla or the medulla from the cervical cord, causing instant death.

MORPHOLOGY

When seen on cross-section, contusions are wedge shaped, with the broad base lying along the surface at the point of impact (Fig. 28-9B). The appearance of contusions is similar regardless of the source of the trauma. In the earliest stages, there is edema and hemorrhage, which is often pericapillary. During the next few hours, the extravasation of blood extends throughout the involved tissue, across the width of the cerebral cortex, and into the white matter and subarachnoid space. Morphologic evidence of neuronal injury (pyknosis of the nucleus, eosinophilia of the cytoplasm, and disintegration of the cell) takes about 24 hours to appear, although functional deficits may occur earlier. Axonal swellings develop in the vicinity of damaged neurons or at great distances away. The inflammatory response to the injured tissue follows its usual course, with the appearance of neutrophils followed by macrophages. Old traumatic lesions on the surface of the brain have a characteristic gross appearance. They are depressed, retracted, yellowish brown patches involving the crests of gyri, most commonly those that are located at the sites of contrecoup injuries (inferior frontal cortex, temporal and occipital poles). The term **plaque jaune** is applied to these lesions (Fig. 28-9C), which can become epileptic foci. More extensive hemorrhagic regions of brain trauma give rise to larger cavitated lesions, which can resemble remote infarcts. In old contusions, gliosis and residual hemosiderin-laden macrophages predominate.

Figure 28-9 **A**, Multiple contusions involving the inferior surfaces of frontal lobes, anterior temporal lobes, and cerebellum. **B**, Acute contusions are present in both temporal lobes, with areas of hemorrhage and tissue disruption (arrows). **C**, Remote contusions are present on the inferior frontal surface of this brain, with a yellow color (associated with the term *plaque jaune*).

Diffuse Axonal Injury

Although it is most often affected, the surface of the brain is not the only region damaged by traumatic injuries. Also affected may be the deep white matter regions (the corpus callosum, paraventricular, and hippocampal areas in the supratentorial compartment), cerebral peduncles, brachium conjunctivum, superior colliculi, and deep reticular formation in the brainstem. The microscopic findings include axonal swelling, indicative of *diffuse axonal injury*, and focal hemorrhagic lesions. As many as 50% of individuals who develop coma shortly after trauma, even without cerebral contusions, are believed to have diffuse axonal injury. Axons are injured by the direct action of mechanical forces, with subsequent alterations in axoplasmic flow. Comparable mechanical disruption of axons can result from angular acceleration alone, which can cause diffuse axonal injury even in the absence of impact.

MORPHOLOGY

Diffuse axonal injury is characterized by widespread, often asymmetric axonal swellings that appear within hours of the injury and may persist for much longer. The swelling is best demonstrated with silver impregnation techniques or with immunoperoxidase stains for axonally transported proteins, such as amyloid precursor protein and α -synuclein. Later, increased numbers of microglia areas are seen in damaged areas of the cerebral cortex, and subsequently there is degeneration of the involved fiber tracts.

Traumatic Vascular Injury

Vascular injury is a frequent component of CNS trauma. It results from direct trauma and disruption of the vessel wall, and leads to hemorrhage in different anatomic sites (Table 28-1). Depending on the position of the ruptured vessel, hemorrhage may occur in the *epidural*, *subdural*, *subarachnoid*, and *intraparenchymal* compartments, sometimes in combination (Fig. 28-10). Both epidural and subdural hemorrhages rarely occur outside of the setting of trauma; in some settings such as coagulopathy or significant cerebral atrophy, subdural hemorrhages can follow even minor trauma. A traumatic tear of the carotid artery where it

Figure 28-10 Epidural hematoma (*left*) in which rupture of a meningeal artery, usually associated with a skull fracture, leads to accumulation of arterial blood between the dura and the skull. In a subdural hematoma (*right*), damage to bridging veins between the brain and the superior sagittal sinus leads to the accumulation of blood between the dura and the arachnoid.

traverses the carotid sinus may lead to the formation of an arteriovenous fistula.

Epidural Hematoma

Normally the dura is fused with the periosteum on the internal surface of the skull. Dural arteries, most importantly the middle meningeal artery, are vulnerable to injury, particularly with temporal skull fractures in which the fracture lines cross the course of the vessel. In children, in whom the skull is deformable, a temporary displacement of the skull bones leading to laceration of a vessel can occur in the absence of a skull fracture.

Once a vessel has been torn, the extravasation of blood under arterial pressure can cause the dura to separate from the inner surface of the skull (Fig. 28-11). The expanding hematoma has a smooth inner contour that compresses the brain surface. When blood accumulates slowly patients may be lucid for several hours before the onset of neurologic signs. An epidural hematoma may expand rapidly and is a neurosurgical emergency requiring prompt drainage.

Table 28-1 Patterns of Vascular Injury in the Central Nervous System

Location	Etiology	Additional Features
Epidural space	Trauma	Usually associated with a skull fracture (in adults); rapidly evolving neurologic symptoms, requiring intervention
Subdural space	Trauma	Level of trauma may be mild; slowly evolving neurologic symptoms, often with a delay from the time of injury
Subarachnoid space	Vascular abnormalities (Arteriovenous malformation or aneurysm)	Sudden onset of severe headache, often with rapid neurologic deterioration; secondary injury may emerge, associated with vasospasm
	Trauma	Typically associated with underlying contusions
Intraparenchymal	Trauma (contusions)	Selective involvement of the crests of gyri, where the brain may contact the inner surface of the skull (frontal and temporal tips, orbitofrontal surface)
	Hemorrhagic conversion of an ischemic infarction	Usually petechial hemorrhages in an area of previously ischemic brain, usually following the cortical ribbon
	Cerebral amyloid angiopathy	“Lobar” hemorrhage, involving cerebral cortex, often with extension into the subarachnoid space
	Hypertension	Centered in the deep white matter, thalamus, basal ganglia, or brainstem; may extend into the ventricular system
	Tumors (primary or metastatic)	Associated with high grade gliomas or certain metastases (melanoma, choriocarcinoma, renal cell carcinoma)

Figure 28-11 Epidural hematoma covering a portion of the dura. Also present are multiple small contusions in the temporal lobe. (Courtesy the late Dr. Raymond D. Adams, Massachusetts General Hospital, Boston, Mass.)

Subdural Hematoma

It is traditionally believed that between the inner surface of the dura mater and the outer arachnoid layer of the leptomeninges lies the subdural space. In reality, the dura is composed of two layers, an external collagenous and an inner border cell layer with scant fibroblasts, and abundant extracellular space devoid of collagen. When bleeding occurs these two layers separate and create the “subdural space” in which blood accumulates. Bridging veins travel from the convexities of the cerebral hemispheres through the subarachnoid space and the subdural space to empty into the superior sagittal sinus. Similar anatomic relationships exist with other dural sinuses. These vessels are particularly prone to tearing along their course through the dural layers and are the source of bleeding in most cases of subdural hematoma. The brain is suspended in CSF, but the venous sinuses are fixed relative to the dura, so the displacement of the brain that occurs in trauma can tear the veins at the point where they penetrate the dura. In older individuals with brain atrophy, the bridging veins are stretched, hence the increased rate of subdural hematomas in these patients, even after relatively minor head trauma. Infants are also particularly susceptible to subdural hematomas because their bridging veins are thin-walled.

MORPHOLOGY

Grossly, **acute subdural hematomas** appear as a collection of freshly clotted blood along the brain surface, without extension into the depths of sulci (Fig. 28-12). The underlying brain is flattened and the subarachnoid space is often clear. Usually, venous bleeding is self-limited and the resulting hematoma is broken down and organized over time. This most often occurs in the following sequence:

- Lysis of the clot (about 1 week)
- Growth of fibroblasts from the dural surface into the hematoma (2 weeks)

- Early development of hyalinized connective tissue (1 to 3 months)

Typically, the organized hematoma is firmly attached by ingrowing fibrous tissue to the inner surface of the dura and is free of the underlying arachnoid, which does not contribute to healing. The lesion can eventually retract as the granulation tissue matures until only a thin layer of reactive connective tissue remains (“subdural membranes”). In other cases, however, multiple recurrent episodes of bleeding occur (**chronic subdural hematomas**), presumably from the thin-walled vessels of the granulation tissue. The risk of repeat bleeding is greatest in the first few months after the initial hemorrhage.

Clinical Features. Symptomatic subdural hematomas most often manifest within 48 hours of injury. They are most common over the lateral aspects of the cerebral hemispheres and are bilateral in about 10% of cases. Neurologic signs commonly observed are attributable to the pressure exerted on the adjacent brain. There may be focal signs, but often the clinical manifestations are nonlocalizing and include headache and confusion. Slowly progressive neurologic deterioration is typical, but acute decompensation may occur. The treatment of subdural hematomas is to remove the blood and associated organizing tissue.

Sequelae of Brain Trauma

A broad range of neurologic syndromes may become manifest months or years after brain trauma of any cause.

Figure 28-12 A, Large organizing subdural hematoma attached to the dura. **B**, Coronal section of the brain showing compression of the hemisphere underlying the subdural hematoma shown in **A**.

These have gained increasing notice in the context of litigation involving issues of compensation for those in the civilian work force, professional athletes and the military services.

- *Posttraumatic hydrocephalus* is largely due to obstruction of CSF resorption from hemorrhage into the subarachnoid spaces.
- *Chronic traumatic encephalopathy* (CTE, previously referred to as “dementia pugilistica”) is a dementing illness that develops after repeated head trauma. Affected brains are typically atrophic, with enlarged ventricles, and show accumulation of tau-containing neurofibrillary tangles in a characteristic pattern involving superficial frontal and temporal lobe cortex. Although concussion is thought of as having no structural consequences, it is clear that repeated events are antecedents to CTE. It remains uncertain if the most critical factors that determine if encephalopathy will develop are the number, frequency or severity of events, or some combination of these.
- Other important sequelae of brain trauma include post-traumatic epilepsy, risk of infection, and psychiatric disorders.

Spinal Cord Injury

The spinal cord is vulnerable to trauma from its skeletal encasement. Most injuries that damage the cord are associated with the transient or permanent displacement of the vertebral column. The level of cord injury determines the extent of the neurologic manifestations: lesions involving the thoracic vertebrae or below can lead to paraplegia; cervical lesions result in quadriplegia; those above C4 can, in addition, lead to respiratory compromise from paralysis of the diaphragm. Damage at the region of impact to descending and ascending white matter tracts isolates the distal spinal cord from the rest of the brain. This interruption, paired with the localized gray matter damage at the level of the impact, is the principal cause of neurologic deficits.

MORPHOLOGY

The histologic features of traumatic injury of the spinal cord are similar to those found at other sites in the CNS. At the level of injury the acute phase consists of hemorrhage, necrosis, and axonal swelling in the surrounding white matter. The lesion tapers above and below the level of injury. In time central areas of neuronal destruction becomes cystic and gliotic; cord sections above and below the lesion show secondary ascending and descending wallerian degeneration, respectively, involving the long white-matter tracts affected at the site of trauma.

KEY CONCEPTS

Perinatal Brain Injury

- Timing of injury is critical, with earlier events resulting in greater damage and deficits.

- Cerebral palsy is the term describing non-progressive deficits associated with injury during the prenatal and perinatal periods.

Trauma

- Physical injury to the brain can occur when the inside of the skull comes into forceful contact with the brain.
- In blunt trauma, if the head is mobile there may be brain injury both at the original point of contact (coup injury) and on the opposite side of the brain (contrecoup injury) owing to impacts with the skull.
- Parenchymal injuries take the form of contusions, with hemorrhage extending into the subarachnoid space.
- Rapid displacement of the head and brain can tear axons (diffuse axonal injury), often causing immediate severe, irreversible neurologic deficits.
- Traumatic tearing of blood vessels leads to epidural or subdural hematoma.

Cerebrovascular Disease

Cerebrovascular disease—*injury to the brain as a consequence of altered blood flow—can be grouped into ischemic and hemorrhagic etiologies.* “Stroke” is the clinical designation that applies to all these conditions, particularly when symptoms begin acutely. Cerebrovascular disease is the third leading cause of death (after heart disease and cancer) in the United States, and the most prevalent cause of morbidity and mortality from neurologic disease. From the standpoint of pathophysiology and pathologic anatomy, it is convenient to consider cerebrovascular disease as two processes:

- *Hypoxia, ischemia, and infarction* resulting from impairment of blood supply and oxygenation of CNS tissue; in the brain, embolism is a more common etiology than thrombosis. This can either be a global process or focal, with the clinical manifestations determined by the region of brain affected.
- *Hemorrhage* resulting from rupture of CNS vessels. Common etiologies include hypertension and vascular anomalies (aneurysms and malformations).

Hypoxia, Ischemia, and Infarction

The brain requires a constant supply of glucose and oxygen, which is delivered by the cerebral blood vessels. Although the brain accounts for only 1% to 2% of body weight, it receives approximately 15% of the resting cardiac output and accounts for 20% of the body’s oxygen consumption. Cerebral blood flow remains relatively constant over a wide range of blood pressure and intracranial pressure because of autoregulation of vascular resistance. The brain is a highly aerobic tissue, in which oxygen rather than metabolic substrate is limiting. The brain may be deprived of oxygen by several mechanisms: *hypoxia* caused by a low partial pressure of oxygen (PO₂), impairment of the blood’s oxygen-carrying capacity, or inhibition of oxygen use in the tissue; or *ischemia*, either transient or permanent, caused by interruption of the normal circulatory flow. Cessation of blood flow can result from a reduction in perfusion

pressure (as in hypotension), small- or large-vessel obstruction, or both.

When blood flow to a portion of the brain is reduced, the survival of the tissue at risk depends on the presence of collateral circulation, the duration of ischemia, and the magnitude and rapidity of the reduction of flow. These factors determine, in turn, the precise anatomic site and size of the lesion and, consequently, the clinical deficit.

The general biochemical changes in cells resulting from ischemia are discussed in [Chapter 2](#). The brain is primarily dependent on oxidative metabolism for generation of ATP, with minimal capacity to use glycolysis or energy substrates other than circulation-delivered glucose. With ischemia, there is depletion of ATP and loss of the membrane potential that is essential for neuronal electrical activity. Accompanying this, there is elevation of cytoplasmic calcium levels, which in turn activates a cascade of enzymatic processes that contribute to cellular injury. In addition to processes shared with ischemia in other parts of the body, the metabolic depletion of energy associated with ischemia can result in inappropriate release of excitatory amino acid neurotransmitters such as glutamate, which can contribute to cell damage by allowing excessive influx of calcium ions through N-methyl-D-aspartate (NMDA)-type glutamate receptors. In the region of transition between necrotic tissue and the normal brain, there is an area of “at-risk” tissue, referred to as the *penumbra*. This region can be rescued from injury in many animal models with a variety of anti-apoptotic interventions, implying that cells in areas of ischemia may die by apoptosis as well.

Global Cerebral Ischemia

Global cerebral ischemia (diffuse ischemic/hypoxic encephalopathy) occurs when there is a generalized reduction of cerebral perfusion (as in cardiac arrest, shock, and severe hypotension). The clinical outcome of a severe hypotensive episode that produces *global cerebral ischemia* varies with the severity of the insult. In mild cases, there may be only a transient post-ischemic confusional state followed by complete recovery and no irreversible tissue damage. However, irreversible damage to CNS tissue may occur in some individuals who suffer mild or transient global ischemic insults. There is a hierarchy of sensitivity among CNS cells: neurons are the most sensitive, although glial cells (oligodendrocytes and astrocytes) are also vulnerable. The most sensitive neurons in the brain are in the pyramidal cell layer of the hippocampus (especially area CA1, also referred to as *Sommer sector*), cerebellar Purkinje cells and pyramidal neurons in cerebral cortex. With severe global cerebral ischemia, widespread neuronal death occurs, irrespective of regional vulnerability. Patients who survive this injury often remain in a persistent vegetative state. Other patients meet the current clinical criteria for “brain death,” including evidence of irreversible diffuse cortical injury (isoelectric, or “flat,” electroencephalogram) and brainstem damage, such as absent reflexes and respiratory drive, and absent cerebral perfusion. When individuals with this pervasive form of injury are maintained on mechanical ventilation, the brain gradually undergoes an autolytic process with gradual liquefaction producing the so-called “respirator brain.”

Border zone (“watershed”) infarcts occur in the regions of the brain or spinal cord that lie at the most distal reaches

of the arterial blood supply, the border zones between arterial territories. In the cerebral hemispheres, the border zone between the anterior and the middle cerebral artery distributions is at greatest risk. Damage to this region produces a sickle-shaped band of necrosis over the cerebral convexity a few centimeters lateral to the interhemispheric fissure. Border zone infarcts are usually seen after hypotensive episodes.

MORPHOLOGY

In the setting of global ischemia, the brain becomes edematous and swollen, producing widening of the gyri and narrowing of the sulci. The cut surface shows poor demarcation between gray and white matter. The microscopic features of irreversible ischemic injury (infarction) evolve over time. **Early changes**, occurring 12 to 24 hours after the insult, are seen in neurons (red neurons; [Figs. 28-13A and 28-13B](#)) and consist of microvacuolization, then eosinophilia of the neuronal cytoplasm, and later nuclear pyknosis and karyorrhexis. Similar acute changes occur somewhat later in astrocytes and oligodendroglia. After the acute injury, the reaction to tissue damage begins with infiltration by neutrophils ([Fig. 28-13C](#)). **Subacute changes**, occurring at 24 hours to 2 weeks, include tissue necrosis, influx of macrophages, vascular proliferation, and reactive gliosis ([Fig. 28-13D](#)). **Repair**, robust after approximately 2 weeks, is characterized by removal of necrotic tissue, loss of normal CNS architecture, and gliosis ([Fig. 28-13E](#)). In the cerebral neocortex the neuronal loss and gliosis are uneven, with preservation of some layers and destruction of others, producing a pattern of injury termed **pseudolaminar necrosis**.

Focal Cerebral Ischemia

Focal cerebral ischemia follows reduction or cessation of blood flow to a localized area of the brain due to arterial occlusion or hypoperfusion. When the ischemia is sustained, infarction follows in the territory of the compromised vessel. The size, location, and shape of the infarct and the extent of tissue damage that results are influenced by the duration of the ischemia and the adequacy of collateral flow. The major source of collateral flow is the circle of Willis (supplemented by the external carotid-ophthalmic pathway). Partial and inconstant reinforcement is available over the surface of the brain for the distal branches of the anterior, middle, and posterior cerebral arteries through cortical-leptomeningeal anastomoses. In contrast, there is little if any collateral flow for the deep penetrating vessels supplying structures such as the thalamus, basal ganglia, and deep white matter.

Occlusive vascular disease of severity sufficient to lead to cerebral infarction may be due to embolization from a distant source, in situ thrombosis, or various forms of vasculitides; the basic pathology of these conditions is discussed in [Chapters 4 and 11](#).

- **Embolism** to the brain occurs from a variety of sources. Cardiac mural thrombi are among the most common culprits; myocardial infarct, valvular disease, and atrial fibrillation are important predisposing factors. Next in importance are thromboemboli arising in arteries, most

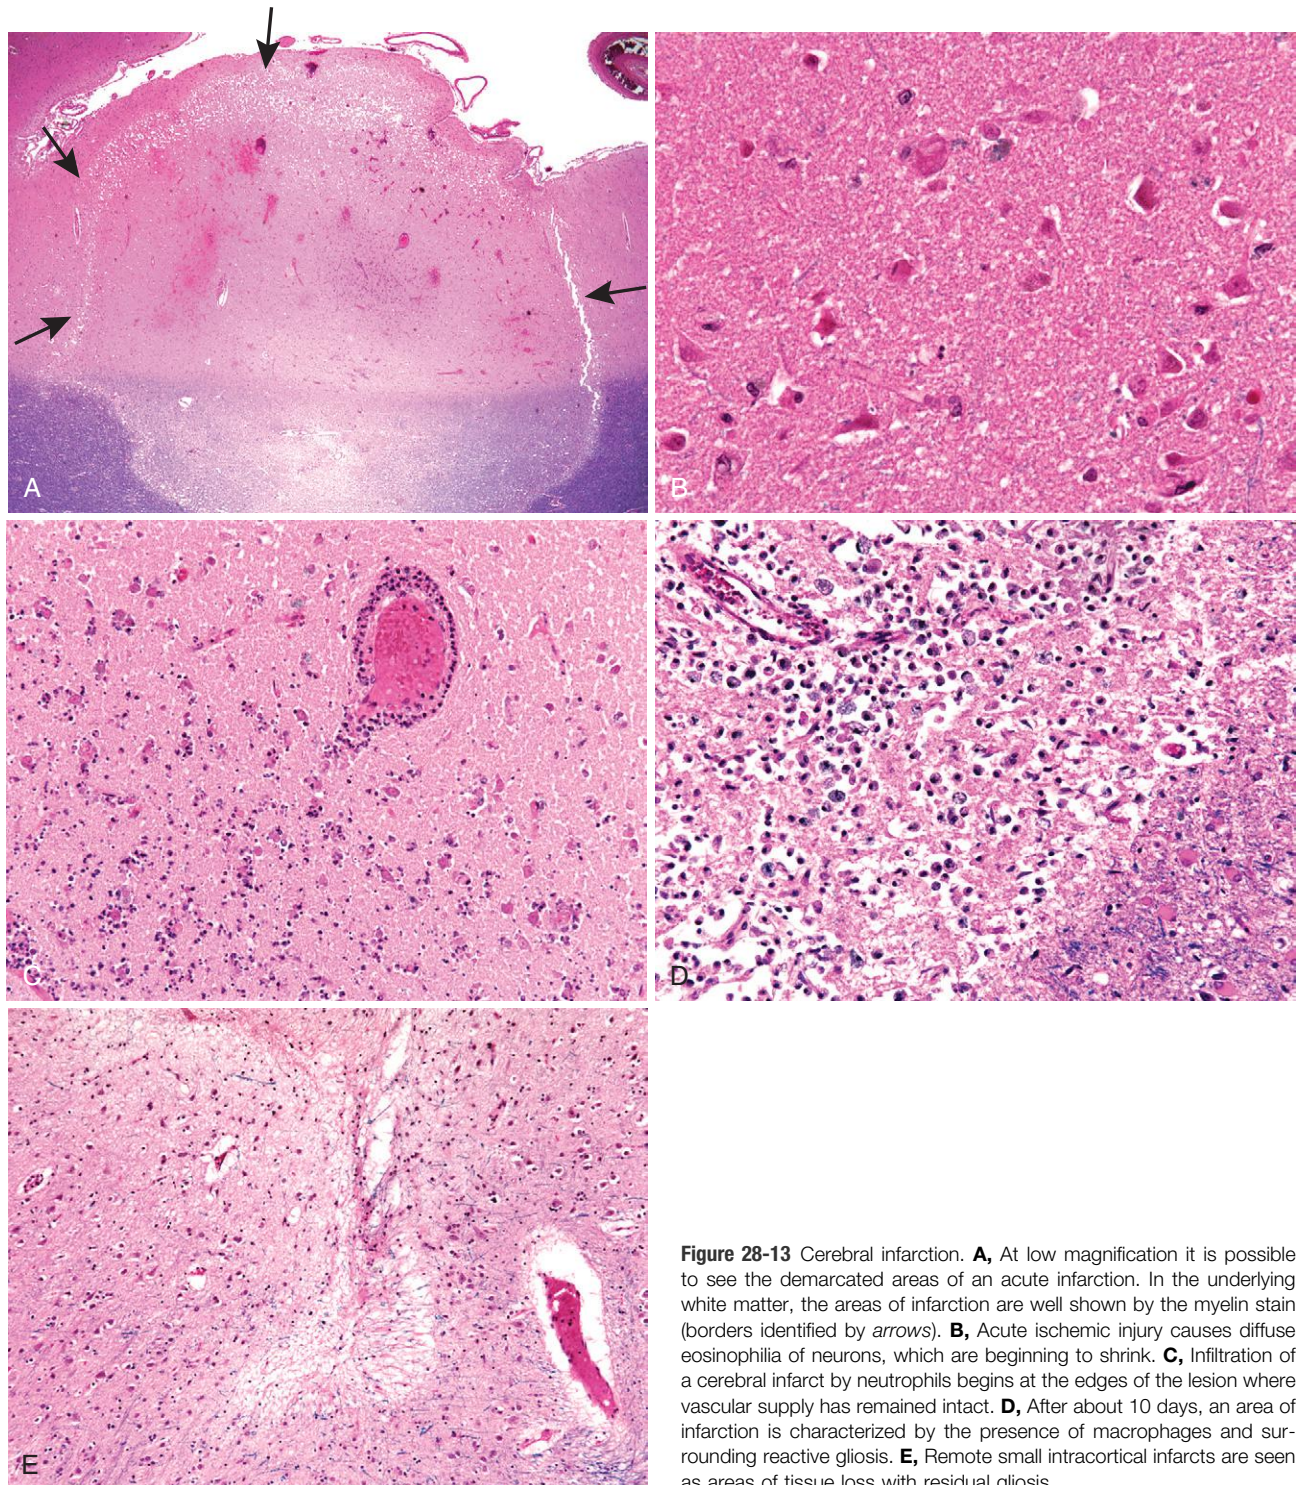

Figure 28-13 Cerebral infarction. **A**, At low magnification it is possible to see the demarcated areas of an acute infarction. In the underlying white matter, the areas of infarction are well shown by the myelin stain (borders identified by arrows). **B**, Acute ischemic injury causes diffuse eosinophilia of neurons, which are beginning to shrink. **C**, Infiltration of a cerebral infarct by neutrophils begins at the edges of the lesion where vascular supply has remained intact. **D**, After about 10 days, an area of infarction is characterized by the presence of macrophages and surrounding reactive gliosis. **E**, Remote small intracortical infarcts are seen as areas of tissue loss with residual gliosis.

often originating over atheromatous plaques within the carotid arteries. Other sources of emboli include paradoxical emboli, particularly in children with cardiac anomalies; emboli associated with cardiac surgery; and emboli of other material (tumor, fat, or air). The territory of distribution of the middle cerebral artery—the direct extension of the internal carotid artery—is most frequently affected by embolic infarction; the incidence is about equal in the two hemispheres. Emboli

tend to lodge where blood vessels branch or in areas of preexisting luminal stenosis. “Shower embolization,” as in fat embolism, may occur after fractures; affected individuals manifest generalized cerebral dysfunction with disturbances of higher cortical function and consciousness, often without localizing signs. Widespread hemorrhagic lesions involving the white matter are characteristic of embolization of bone marrow after trauma (Fig. 28-14).

Figure 28-14 Widespread white-matter hemorrhages are characteristic of bone marrow embolization.

- **Thrombotic occlusions are most commonly associated with atherosclerosis and plaque rupture.** The most common sites are the carotid bifurcation, the origin of the middle cerebral artery, and either end of the basilar artery. Thrombi cause progressive narrowing of the lumen, may be accompanied by anterograde extension, and may progress to fragmentation and distal embolization. Atherosclerotic cerebrovascular disease is frequently associated with systemic diseases such as hypertension and diabetes.
- Inflammatory processes that involve blood vessels may also lead to luminal narrowing, occlusion and hence cerebral infarcts. While *infectious vasculitis* of small and large vessels occurs with syphilis and tuberculosis, it is now more common in the setting of immunosuppression and opportunistic infection (e.g., aspergillosis or CMV encephalitis). *Polyarteritis nodosa* and other noninfectious vasculitides may involve cerebral vessels and cause single or multiple infarcts throughout the brain.

Primary angiitis of the CNS is an inflammatory disorder that involves multiple small- to medium-sized parenchymal and subarachnoid vessels and is characterized by chronic inflammation, multinucleated giant cells, and destruction of the vessel wall. As granulomas may be present, this disorder is also known as *granulomatous angiitis of the nervous system*. Affected individuals manifest a diffuse encephalopathic or multifocal clinical picture, often with cognitive dysfunction; patients improve with steroid and immunosuppressive treatment. Other conditions that may cause thrombosis and infarction (and intracranial hemorrhage) include hypercoagulable states, dissecting aneurysm of extracranial arteries in the neck supplying the brain, and drug abuse (amphetamines, heroin, cocaine).

Infarcts are subdivided into two broad groups based on the presence of hemorrhage. As infarcts begin with loss of blood supply, they are often initially nonhemorrhagic (Fig. 28-15A). Secondary hemorrhage can occur from ischemia-reperfusion injury, either through collaterals or following dissolution or fragmentation of the intravascular occlusive material. The hemorrhages are petechial in nature, and may be multiple or even confluent (Fig. 28-15B). The clinical management of patients with these two types of infarcts differs greatly as thrombolytic therapy is contraindicated in hemorrhagic infarcts.

MORPHOLOGY

The gross appearance of a **nonhemorrhagic infarct** varies with the time. There is little change in appearance during the first 6 hours of irreversible injury. By 48 hours, however, the tissue becomes pale, soft, and swollen, and the corticomedullary junction becomes indistinct. From 2 to 10 days, the brain becomes gelatinous and friable, and the previously ill-defined boundary between normal and infarcted tissue becomes more distinct as edema resolves in the viable adjacent tissue. From 10 days to 3 weeks, the tissue liquefies, eventually leaving a fluid-filled cavity that continues to expand until all of the dead tissue is removed (Fig. 28-16).

Figure 28-15 **A**, An ischemic infarction involves the territory of the middle cerebral artery, including the striatum of the left side of this brain. **B**, A bland infarct with punctate hemorrhages, consistent with ischemia-reperfusion injury, is present in the temporal lobe.

Figure 28-16 Old cystic infarct showing destruction of cortex with cavitation.

Microscopically, the tissue reaction evolves along the following sequence:

- *After the first 12 hours*, ischemic neuronal change (red neurons; see earlier) and both cytotoxic and vasogenic edema predominate. There is loss of the usual tinctorial characteristics of white- and gray matter structures. Endothelial and glial cells, mainly astrocytes, swell, and myelinated fibers begin to disintegrate.
- *Up to 48 hours*, neutrophilic emigration progressively increases and then falls off. Phagocytic cells, derived from circulating monocytes and activated microglia, are evident at *48 hours* and become the predominant cell type in the ensuing *2 to 3 weeks*. The macrophages become stuffed with the products of myelin breakdown or blood and may persist in the lesion for months to years.
- Reactive astrocytes can be seen as early as *1 week* after the insult. As the process of liquefaction and phagocytosis proceeds, astrocytes at the edges of the lesion progressively enlarge, divide, and develop a prominent network of cytoplasmic extensions.
- *After several months*, the astrocytic response recedes, leaving behind a dense meshwork of glial fibers admixed with new capillaries and some perivascular connective tissue. In the cerebral cortex, the cavity is separated from the meninges and subarachnoid space by a gliotic layer of tissue, derived from the molecular layer of the cortex. The pia and arachnoid are not affected and do not contribute to the healing process. Infarcts undergo these reactive and reparative stages from the edges inward; thus, different areas of a lesion may look different, particularly during the early stages, revealing the natural progression of the response.

The features and temporal evolution of **hemorrhagic infarctions** parallel ischemic infarctions, with the addition of blood extravasation and resorption. In individuals receiving anticoagulant treatment, hemorrhagic infarcts may be associated with extensive intracerebral hematomas. Venous infarcts are often hemorrhagic and may occur after thrombotic occlusion of the superior sagittal sinus or other sinuses or occlusion of the deep cerebral veins. Carcinoma, localized infections, and other conditions leading to a hypercoagulable state increase the risk for venous thrombosis.

Spinal cord infarction may be seen in the setting of hypoperfusion or as a consequence of traumatic interruption of the feeding tributaries derived from the aorta. Rarely, the cause is occlusion of the anterior spinal artery as a result of an embolus or vasculitis.

Clinical Features. Deficits produced by infarction are determined by the anatomic distribution of the damage, rather than the underlying cause. Neurologic symptoms referable to the area of injury often develop rapidly, over minutes, and may continue to evolve over hours. There can be improvement in severity of symptoms associated with reversal of injury in the ischemic penumbra as well as with resolution of associated local edema. In general, there is often a degree of slow improvement during a period of months. Because strokes are frequently associated with cardiovascular disease, many of the genetic and lifestyle risk factors are shared.

Hypertensive Cerebrovascular Disease

The most important effects of hypertension on the brain include lacunar infarcts, slit hemorrhages, and hypertensive encephalopathy, as well as massive hypertensive intracerebral hemorrhage. Aggressive management of hypertension is the primary approach to preventing this form of cerebrovascular disease.

Lacunar Infarcts

Hypertension affects the deep penetrating arteries and arterioles that supply the basal ganglia and hemispheric white matter as well as the brainstem. These cerebral vessels develop *arteriolar sclerosis* and may become occluded; the structural changes are similar to those described in the systemic vessels of individuals with hypertension ([Chapter 11](#)). An important clinical and pathologic consequence of CNS arterial lesions is the development of single or multiple, small, cavitory infarcts known as *lacunes* ([Fig. 28-17](#)). These are lakelike spaces, arbitrarily defined as less than 15 mm wide, which occur in the lenticular nucleus, thalamus, internal capsule, deep white matter, caudate nucleus, and pons, in descending order of frequency. On microscopic examination they show tissue loss surrounded by gliosis. Depending on their location in the CNS, lacunae can be clinically silent or cause severe neurologic impairment. Affected vessels may also be associated with widening of the perivascular spaces without tissue infarction (*état criblé*).

Slit Hemorrhages

Hypertension also gives rise to rupture of the small-caliber penetrating vessels and the development of small

Figure 28-17 Lacunar infarcts in the caudate and putamen (arrows).

hemorrhages. In time these hemorrhages resorb, leaving behind a slitlike cavity (*slit hemorrhage*) surrounded by brownish discoloration; on microscopic examination, slit hemorrhages show focal tissue destruction, pigment-laden macrophages, and gliosis.

Hypertensive Encephalopathy

Acute hypertensive encephalopathy is a clinicopathologic syndrome arising in the setting of malignant hypertension, and is characterized by diffuse cerebral dysfunction, including headaches, confusion, vomiting, and convulsions, sometimes leading to coma. Rapid therapeutic intervention to reduce the accompanying increased intracranial pressure is required, since the syndrome often does not remit spontaneously. At postmortem examination such individuals may show an edematous brain with or without transtentorial or tonsillar herniation. Petechiae and fibrinoid necrosis of arterioles in the gray and white matter may be seen microscopically.

Individuals who, over the course of many months and years, suffer multiple, bilateral, gray matter (cortex, thalamus, basal ganglia) and white matter (centrum semiovale) infarcts may develop a distinctive clinical syndrome characterized by dementia, gait abnormalities, and pseudobulbar signs, often with superimposed focal neurologic deficits. The syndrome, generally referred to as *vascular (multi-infarct) dementia*, is caused by multifocal vascular disease of several types, including (1) cerebral atherosclerosis, (2) vessel thrombosis or embolization from carotid vessels or from the heart, and (3) cerebral arteriolar sclerosis from chronic hypertension. When the pattern of injury preferentially involves large areas of the subcortical white matter with myelin and axon loss, the disorder is referred to as *Binswanger disease*; this distribution of vascular white-matter injury must be distinguished clinically and radiologically from other diseases that affect the hemispherical white matter. In addition, many individuals with neurodegenerative diseases resulting in cognitive impairment or dementia also have evidence of cerebrovascular disease. The presence of significant cerebrovascular disease increases risk of neurologic impairment for a given level of lesions associated with the degenerative diseases, suggesting that it is an independent contributing factor to disruption of normal brain function.

Intracranial Hemorrhage

Hemorrhages may occur at any site within the CNS—outside the brain or within it (intraparenchymal). Hemorrhages in the epidural or subdural space are typically associated with trauma and were discussed earlier. Hemorrhages within the brain parenchyma and in the subarachnoid space, in contrast, are more often a manifestation of underlying cerebrovascular disease.

Intraparenchymal Hemorrhage

Rupture of a small intraparenchymal vessel can result in a hemorrhage within the brain, often associated with sudden onset of neurologic symptoms (stroke). Spontaneous (non-traumatic) intraparenchymal hemorrhages occur most commonly in middle to late adult life, with a peak incidence at about age 60 years. Hemorrhages in the basal ganglia and thalamus are commonly designated “ganglionic hemorrhages,” whereas those that occur in the lobes of the cerebral hemispheres are called “lobar hemorrhages.” The two major causes of these patterns of hemorrhage are hypertension and cerebral amyloid angiopathy, respectively. In addition, other local and systemic factors may cause or contribute to nontraumatic hemorrhage, including systemic coagulation disorders, neoplasms, vasculitis, aneurysms, and vascular malformations.

Hypertension is the risk factor most commonly associated with deep brain parenchymal hemorrhages, accounting for more than 50% of clinically significant hemorrhages and for roughly 15% of deaths among individuals with chronic hypertension. Hemorrhages associated with hypertension are typically in deep white matter or deep gray structures, followed by the brainstem and cerebellum. Hypertension leads to a number of vessel wall abnormalities, including accelerated atherosclerosis in larger arteries, hyaline arteriosclerosis in smaller arteries, and (in severe cases) proliferative changes and frank necrosis of arterioles. Arteriolar walls affected by hyaline change are presumably weaker than are normal vessels and are therefore vulnerable to rupture. In some instances chronic hypertension is associated with the development of minute aneurysms, termed *Charcot-Bouchard microaneurysms*, which may be the site of rupture. Charcot-Bouchard aneurysms, not to be confused with saccular aneurysms of larger intracranial vessels in the subarachnoid space, occur in vessels that are less than 300 μm in diameter, most commonly within the basal ganglia.

MORPHOLOGY

Hypertensive intraparenchymal hemorrhage may originate in the putamen (50% to 60% of cases), thalamus, pons, cerebellar hemispheres (rarely), and other regions of the brain (Fig. 28-18A). Acute hemorrhages, independent of etiology, are characterized by extravasation of blood with compression of the adjacent parenchyma. Old hemorrhages show an area of cavitory destruction of brain with a rim of brownish discoloration. The early lesions consist of a central core of clotted blood surrounded by a rim of brain tissue showing anoxic neuronal and glial changes as well as edema. Eventually the edema resolves, hemosiderin- and lipid-laden macrophages appear, and proliferation of reactive astrocytes is seen at the periphery of the lesion. The cellular events then follow the same time course that is observed after cerebral infarction.

Figure 28-18 **A**, Massive hypertensive hemorrhage rupturing into a lateral ventricle. **B**, Amyloid deposition in a cortical arteriole in cerebral amyloid angiopathy; *inset*, immunohistochemical staining for A β shows the deposited material in the vessel wall. **C**, Electron micrograph shows granular osmophilic material in a case of CADASIL (cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy).

Cerebral amyloid angiopathy (CAA) is the risk factor most commonly associated with lobar hemorrhages. In CAA, amyloidogenic peptides, usually the same ones found in Alzheimer disease (A β_{40} ; see later), are deposited in the walls of medium- and small-caliber meningeal and cortical vessels. This deposition can weaken the vessel wall and lead to hemorrhage. Many individuals with CAA have evidence of numerous small hemorrhages within the brain (“microbleeds”), which can be visualized by various imaging methods. As with Alzheimer disease, in which there is a relationship between a polymorphism in the gene that encodes apolipoprotein E (ApoE) and risk of disease, there is an effect of the ApoE genotype on the risk of recurrence of hemorrhage from sporadic CAA. The presence of either an $\epsilon 2$ or $\epsilon 4$ allele increases the risk of repeat bleeding. While some mutations in the precursor protein for the A β peptide (amyloid precursor protein, APP) cause familial Alzheimer disease, others result in autosomal dominant forms of CAA.

MORPHOLOGY

The underlying vascular abnormality of CAA is typically restricted to the leptomeningeal and cerebral cortical arterioles and capillaries, although involvement of the molecular layer of the cerebellum can be observed as well. Involved vessels are rigid, and as a result fail to collapse during tissue processing and sectioning. Unlike with arteriolar sclerosis, there is no fibrosis; rather, dense and uniform deposits of amyloid are present (Fig. 28-18B).

Other forms of hereditary small-vessel diseases of the CNS have been identified recently. *Cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy* (CADASIL) is an autosomal dominant disorder caused by mutations in the *NOTCH3* gene that lead to misfolding of the extracellular domain of the NOTCH3 receptor. NOTCH3 is preferentially expressed in vascular smooth muscle, and mice engineered to express NOTCH3 receptors bearing CADASIL mutations recapitulate

features of the human disease, indicating that the disease is caused by vascular smooth muscle dysfunction.

The disease is characterized clinically by recurrent strokes (usually infarcts, less often hemorrhages) and dementia. Imaging studies show that the first detectable changes are in white matter, usually by around the age of 35 years, whereas infarcts typically occur 10-15 years later. Arteries in the CNS and in other tissues such as skin show concentric thickening of the media and adventitia, loss of smooth muscle cells, and the presence of basophilic, PAS-positive deposits. These appear as osmiophilic compact granular material by electron microscopy and are consistently detected in the walls of affected vessels (Fig. 28-18C). The characteristic deposits contain the misfolded NOTCH3 protein. How these deposits relate to the disease is not understood. The diagnosis is made through the identification of these deposits in the walls of vessels in biopsies of other tissues, such as skin or muscle, or by sequencing of *NOTCH3*.

Other forms of the heritable small vessel diseases include a disorder associated with mutations in the gene for COL4A1, a component of the vascular basement membrane.

Clinical Features. Intracerebral hemorrhage, independent of cause, can be clinically devastating if it affects large portions of the brain and extends into the ventricular system, but it can affect small regions and either be clinically silent or evolve like an infarct. Over weeks or months there is a gradual resolution of the hematoma, sometimes with considerable clinical improvement. Again, the location of the hemorrhage determines the clinical manifestations.

Subarachnoid Hemorrhage and Ruptured Saccular Aneurysms

The most frequent cause of clinically significant subarachnoid hemorrhage is rupture of a saccular (“berry”) aneurysm in a cerebral artery. Subarachnoid hemorrhage may also result from extension of a traumatic hematoma, rupture of a hypertensive intracerebral hemorrhage into

Figure 28-19 Common sites of saccular (berry) aneurysms in the circle of Willis.

the ventricular system, vascular malformation, hematologic disturbances, and tumors.

Saccular aneurysm is the most common type of intracranial aneurysm. Other aneurysm types include atherosclerotic (fusiform; mostly of the basilar artery), mycotic, traumatic, and dissecting. These latter three, like saccular aneurysms, are most often found in the anterior circulation, but differ in that they more often cause cerebral infarction rather than subarachnoid hemorrhage.

Saccular aneurysms are found in about 2% of the population according to recent data from community-based radiologic studies. About 90% of saccular aneurysms are found near major arterial branch points in the anterior circulation (Fig. 28-19); multiple aneurysms exist in 20% to 30% of cases in autopsy series.

Pathogenesis. While the etiology of saccular aneurysms remains obscure, the structural abnormality of the involved vessel (absence of smooth muscle and intimal elastic lamina) suggests that they represent a developmental disorder. Although the majority occur sporadically, genetic factors may be important in their pathogenesis, since there is an increased incidence of aneurysms in first-degree relatives of those affected. There is also an increased incidence in individuals with certain Mendelian disorders (e.g., autosomal dominant polycystic kidney disease, Ehlers-Danlos syndrome type IV, neurofibromatosis type 1 [NF1], and Marfan syndrome), fibromuscular dysplasia of extracranial arteries, and coarctation of the aorta. Other predisposing factors include cigarette smoking and hypertension (estimated to be present in about half of affected individuals). Although they are sometimes referred to as “congenital,” the aneurysms are not present at birth but develop over time because of an underlying defect in the media of the vessel.

MORPHOLOGY

An unruptured saccular aneurysm is a thin-walled outpouching, usually at an arterial branch point along the circle of Willis or a major vessel just beyond. Saccular aneurysms measure from a few millimeters to 2 or 3 cm in diameter and have a bright red, shiny surface and a thin, translucent wall (Fig. 28-20). Atheromatous plaques, calcification, or thrombi may be found in the wall or lumen of the aneurysm. Sometimes there is evidence of prior hemorrhage, in the form of brownish discoloration of the adjacent brain and meninges. The neck of the aneurysm may be wide or narrow. Rupture usually occurs at the apex of the sac and leads to extravasation of blood into the subarachnoid space, the substance of the brain, or both. The arterial wall adjacent to the neck of the aneurysm often shows some intimal thickening and attenuation of the media. Smooth muscle and intimal elastic lamina do not extend into the neck and are absent from the aneurysm sac itself, which is made up of thickened hyalinized intima and a covering of adventitia.

Figure 28-20 **A**, View of the base of the brain, dissected to show the circle of Willis with an aneurysm of the anterior cerebral artery (arrow). **B**, Dissected circle of Willis to show large aneurysm. **C**, Section through a saccular aneurysm showing the hyalinized fibrous vessel wall (hematoxylin and eosin).

Clinical Features. Rupture of an aneurysm leading to clinically significant subarachnoid hemorrhage is most frequent in the fifth decade and is slightly more frequent in females. Overall, in about 1.3% of individuals aneurysms will rupture over the course of 1 year, but the risk is higher for larger aneurysms. For example, aneurysms greater than 10 mm in diameter have a roughly 50% risk of bleeding per year. Rupture may occur at any time, but in about one third of cases it is associated with acute increases in intracranial pressure, such as with straining at stool or sexual orgasm. Blood under arterial pressure is forced into the subarachnoid space and affected individuals are stricken with a sudden, excruciating headache (“the worst headache I’ve ever had”) and rapidly lose consciousness. Between 25% and 50% of patients die with the first rupture, but patients who survive often improve and recover consciousness in minutes. Repeat bleeding is common in survivors and unpredictable in timing. With each episode of bleeding, the prognosis is worse.

The clinical consequences of blood in the subarachnoid space can be separated into acute events, occurring within hours to days after the hemorrhage, and late sequelae associated with the healing process. In the first few days after a subarachnoid hemorrhage, regardless of the etiology, there is an increased risk of additional ischemic injury from vasospasm affecting vessels bathed in the extravasated blood. This problem is of greatest significance in cases of basal subarachnoid hemorrhage, in which vasospasm can involve major vessels of the circle of Willis. Various mediators have been proposed to have a role in this process, including endothelins, nitric oxide, and arachidonic acid metabolites. In the healing phase of subarachnoid hemorrhage, meningeal fibrosis and scarring occur, sometimes leading to obstruction of CSF flow as well as interruption of the normal pathways of CSF resorption.

Vascular Malformations

Vascular malformations of the brain are classified into four principal groups: arteriovenous malformations, cavernous malformations, capillary telangiectasias, and venous angiomas. Of these, the first two are the types associated with risk of hemorrhage and development of neurologic symptoms.

MORPHOLOGY

Arteriovenous malformations (AVM) may involve vessels in the subarachnoid space, in the brain or both. This tangled network of wormlike vascular channels has prominent, pulsatile arteriovenous shunting with high blood flow. They are composed of greatly enlarged blood vessels separated by gliotic tissue, often showing evidence of prior hemorrhage. Some vessels can be recognized as arteries with duplication and fragmentation of the internal elastic lamina, while others show marked thickening or partial replacement of the media by hyalinized connective tissue.

Cavernous malformations consist of distended, loosely organized vascular channels arranged back to back with collagenized walls of variable thickness. There is usually no brain parenchyma between vessels in this type of malformation. They

occur most often in the cerebellum, pons, and subcortical regions, in decreasing order of frequency, and are “low-flow” channels that do not participate in arteriovenous shunting. Foci of old hemorrhage, infarction, and calcification frequently surround the abnormal vessels. **Capillary telangiectasias** are microscopic foci of dilated, thin-walled vascular channels separated by relatively normal brain parenchyma that occur most frequently in the pons. **Venous angiomas** (varices) consist of aggregates of ectatic venous channels. **Foix-Alajouanine disease** (angiodysgenetic necrotizing myelopathy) is a venous angiomatous malformation of the spinal cord and overlying meninges, most often in the lumbosacral region, associated with ischemic injury to the spinal cord and slowly progressive neurologic symptoms.

Clinical Features. Arteriovenous malformations are the most common type of clinically significant vascular malformation. Males are affected twice as frequently as females. The lesion often presents between the ages of 10 and 30 years as a seizure disorder, an intracerebral hemorrhage, or a subarachnoid hemorrhage. The most common site is the territory of the middle cerebral artery, particularly its posterior branches. Large arteriovenous malformations occurring in the newborn period can lead to congestive heart failure because of shunt effects, especially if the malformation involves the vein of Galen. Cavernous malformations are unique among this class of lesion in that familial forms are relatively common. Multiplicity of lesions is a hallmark of familial cases, which are inherited as a highly penetrant autosomal dominant trait.

KEY CONCEPTS

Cerebrovascular Diseases

- **Stroke** is the clinical term for acute-onset neurologic deficits resulting from hemorrhagic or obstructive vascular lesions.
- Cerebral infarction follows loss of blood supply and can be widespread or focal, or affect regions with the least robust vascular supply (boundary zones).
- Focal cerebral infarcts are most commonly embolic; with subsequent dissolution of an embolism and reperfusion, a nonhemorrhagic infarct can become hemorrhagic.
- Primary intraparenchymal hemorrhages typically are due to either hypertension (most commonly in white matter, deep gray matter, or posterior fossa contents) or cerebral amyloid angiopathy.
- Spontaneous subarachnoid hemorrhage usually is caused by a structural vascular abnormality, such as an aneurysm or arteriovenous malformation.

Infections

Infection may damage the nervous system directly through injury of neurons or glia by the infectious agent, or indirectly through microbial toxins, the destructive effects of the inflammatory response, or the result of immune-mediated mechanisms. There are four principal routes by

which microbes enter the nervous system. *Hematogenous spread* is the most common; infectious agents ordinarily gain access through the arterial circulation, but retrograde venous spread can occur via anastomoses with veins of the face. *Direct implantation* of microorganisms is most often traumatic or is sometimes associated with congenital malformations (e.g., meningocele) that provide ready access for microorganisms. *Local extension* can originate from infected adjacent structures, such as air sinuses, teeth, skull, or vertebrae. Viruses also may be transported along the *peripheral nervous system* as occurs with rabies and herpes zoster virus. General aspects of the pathology of infectious agents are discussed in [Chapter 8](#); distinctive forms of CNS infections are described herein ([Table 28-2](#)).

Acute Meningitis

Meningitis is an inflammatory process of the leptomeninges and CSF within the subarachnoid space, usually caused by an infection. *Meningoencephalitis* refers to inflammation of the meninges and brain parenchyma. Although infections are the most common causes of meningitis and meningoencephalitis, this reaction may also occur in response to a nonbacterial irritant introduced into the subarachnoid space (*chemical meningitis*). Based on the etiology and clinical evolution of the illness, infectious meningitis is broadly classified into *acute pyogenic* (usually bacterial), *aseptic* (usually acute or subacute viral), and *chronic* (usually tuberculous, spirochetal, or cryptococcal). Each type is accompanied by characteristic changes in the CSF.

Acute Pyogenic (Bacterial) Meningitis

Distinctive microorganisms cause acute pyogenic meningitis in various age groups: *Escherichia coli* and the group B streptococci in neonates; at the other extreme of life, *Streptococcus pneumoniae* and *Listeria monocytogenes* are most common; and *Neisseria meningitidis* in adolescents and in young adults, with clusters of cases raising public health concerns. The introduction of immunization against *Haemophilus influenzae* has markedly reduced the incidence of this infection in the developed world, particularly among infants, who used to be at high risk.

Affected individuals typically show systemic signs of infection superimposed on clinical evidence of meningeal irritation and neurologic impairment, including headache, photophobia, irritability, clouding of consciousness, and neck stiffness. A spinal tap yields cloudy or frankly purulent CSF, under increased pressure, with as many as 90,000 neutrophils per cubic millimeter, an increased protein concentration, and markedly reduced glucose content. Bacteria may be seen on a smear or may be cultured, sometimes a few hours before the neutrophils appear. Untreated pyogenic meningitis can be fatal, while effective treatment with antibiotics markedly reduces mortality. The Waterhouse-Friderichsen syndrome results from meningitis-associated septicemia with hemorrhagic infarction of the adrenal glands and cutaneous petechiae ([Chapter 24](#)). It occurs most often with meningococcal and pneumococcal meningitis. In the immunosuppressed individual, purulent meningitis may be caused by several other infectious agents, such as *Klebsiella* or anaerobic organisms, and may have an atypical clinical course and

Table 28-2 Common Central Nervous System Infections

Type of Infection	Clinical Syndrome	Common Causative Organisms
Bacterial Infections		
Meningitis	Acute pyogenic meningitis	<i>Escherichia coli</i> or group B streptococci (infants) <i>Neisseria meningitidis</i> (young adults) <i>Streptococcus pneumoniae</i> or <i>Listeria monocytogenes</i> (older adults)
	Chronic meningitis	<i>Mycobacterium tuberculosis</i>
Localized infections	Abscess	Streptococci and staphylococci
	Empyema	Polymicrobial (staphylococci, anaerobic gram-negative)
Viral Infections		
Meningitis	Acute aseptic meningitis	Enteroviruses Measles (subacute sclerosing panencephalitis) Influenza species Lymphocytic choriomeningitis virus
Encephalitis	Encephalitic syndromes	Herpes simplex (HSV-1, HSV-2) Cytomegalovirus Human immunodeficiency virus JC polyomavirus (progressive multifocal leukoencephalopathy)
	Arthropod-borne encephalitis	West Nile virus Eastern equine encephalitis virus Western equine encephalitis virus St. Louis encephalitis virus La Crosse encephalitis virus Venezuelan equine encephalitis virus Japanese encephalitis virus Tick-borne encephalitis virus
Brainstem and spinal cord syndromes	Rhombencephalitis	Rabies
	Spinal poliomyelitis	Polio West Nile virus
Rickettsia, Spirochetes, and Fungi		
Meningitic syndromes	Rocky Mountain spotted fever	<i>Rickettsia rickettsii</i>
	Neurosyphilis	<i>Treponema pallidum</i>
	Lyme disease (neuroborreliosis)	<i>Borrelia burgdorferi</i>
	Fungal meningitis	<i>Cryptococcus neoformans</i> <i>Candida albicans</i>
Protozoa and Metazoa		
Meningitic syndromes	Cerebral malaria	<i>Plasmodium falciparum</i>
	Amebic encephalitis	<i>Naegleria</i> species
Localized infections	Toxoplasmosis	<i>Toxoplasma gondii</i>
	Cysticercosis	<i>Taenia solium</i>

uncharacteristic CSF findings, rendering timely diagnosis more difficult.

Acute Aseptic (Viral) Meningitis

Aseptic meningitis is a clinical term that applies to a situation where there is an absence of organisms by

Figure 28-21 Pyogenic meningitis. A thick layer of suppurative exudate covers the brainstem and cerebellum and thickens the leptomeninges. (From Golden JA, Louis DN: Images in clinical medicine: acute bacterial meningitis. N Engl J Med 333:364, 1994.)

MORPHOLOGY

In acute meningitis, an exudate is evident within the leptomeninges over the surface of the brain (Fig. 28-21). The meningeal vessels are engorged and stand out prominently. The anatomic distribution of the exudate varies; in *H. influenzae* meningitis, for example, it is usually basal, whereas in pneumococcal meningitis it is often densest over the cerebral convexities near the sagittal sinus. From the areas of greatest accumulation, tracts of pus follow along blood vessels on the surface of the brain. When the meningitis is fulminant, the inflammation may extend to the ventricles, producing ventriculitis.

On microscopic examination, neutrophils fill the subarachnoid space in severely affected areas and are found predominantly around the leptomeningeal blood vessels in less severe cases. Particularly in untreated meningitis, Gram stain reveals variable numbers of bacteria. In fulminant meningitis, the inflammatory cells infiltrate the walls of the leptomeningeal veins and may extend focally into the substance of the brain (cerebritis). Phlebitis may lead to venous thrombosis and hemorrhagic infarction of the underlying brain.

Leptomeningeal fibrosis may follow pyogenic meningitis and cause hydrocephalus. Particularly in pneumococcal meningitis, large quantities of the capsular polysaccharide of the organism produce a gelatinous exudate that promotes arachnoid fibrosis, a condition referred to as **chronic adhesive arachnoiditis**.

bacterial culture in a patient with manifestations of meningitis, including meningeal irritation, fever, and alterations of consciousness of relatively acute onset. The disease is generally of viral etiology (in about 80% of cases enteroviruses), but may be bacterial, rickettsial, or autoimmune in origin. The clinical course is less fulminant than that of pyogenic meningitis, and the CSF findings also

differ; in aseptic meningitis there is a lymphocytic pleocytosis, the protein elevation is only moderate, and the glucose content is nearly always normal. The viral aseptic meningitides are usually self-limited and are treated symptomatically. Remarkably, even with molecular methods for detection of pathogens, the etiologic agent is identified in only a minority of cases. When pathogens are identified, enteroviruses are the most common etiology, accounting for 80% of the cases. The spectrum of pathogens varies seasonally and geographically. An aseptic meningitis-like picture may also develop subsequent to rupture of an epidermoid cyst into the subarachnoid space or the introduction of a chemical irritant (chemical meningitis). In these cases, the CSF is sterile and there is pleocytosis with neutrophils and an increased protein concentration, but the sugar content is usually normal.

Acute Focal Suppurative Infections

Brain Abscess

A brain abscess is a localized focus of necrosis of brain tissue with accompanying inflammation, usually caused by a bacterial infection. Brain abscesses may arise by direct implantation of organisms, local extension from adjacent foci (mastoiditis, paranasal sinusitis), or hematogenous spread (usually from a primary site in the heart, lungs, or bones of the extremities, or after tooth extraction). Predisposing conditions include acute bacterial endocarditis, which may give rise to multiple brain abscesses; congenital heart disease with right-to-left shunting and loss of pulmonary filtration of organisms; chronic pulmonary sepsis, as in bronchiectasis; and systemic disease with immunosuppression. Streptococci and staphylococci are the most common offending organisms identified in non-immunosuppressed patients.

MORPHOLOGY

Abscesses are discrete lesions with central liquefactive necrosis surrounded by brain swelling (Fig. 28-22). At the outer margin of the necrotic lesion there is exuberant granulation tissue with neovascularization around the necrosis. The newly formed vessels are abnormally permeable, accounting for marked vasogenic edema in the adjacent brain tissue. In well-established lesions, a collagenous capsule is produced by fibroblasts derived from the walls of blood vessels. Outside the fibrous capsule is a zone of reactive gliosis containing numerous gemistocytic astrocytes.

Cerebral abscesses are destructive lesions and patients often present with progressive focal neurologic deficits; signs and symptoms related to increased intracranial pressure may also develop. Typically, the CSF has a high white cell count and an increased protein concentration, but the glucose content is normal. The source of infection may be apparent or may be traced to a small distant focus that is not symptomatic. The increased intracranial pressure can lead to fatal herniation. Other complications include abscess rupture with ventriculitis or meningitis, and venous sinus thrombosis. With surgery and antibiotic

Figure 28-22 Cerebral abscesses (arrows).

treatment, the otherwise high mortality rate can be reduced to less than 10%.

Subdural Empyema

Bacterial, and rarely fungal, infections of the skull bones or air sinuses can spread to the subdural space, producing a subdural empyema. While the underlying arachnoid and subarachnoid spaces are usually unaffected, a large subdural empyema may produce a mass effect or a thrombophlebitis of the bridging veins that cross the subdural space, resulting in venous occlusion and infarction of the brain. In addition to symptoms referable to the source of the infection, most patients are febrile, have headache and neck stiffness. The CSF profile is similar to that seen in brain abscesses, because both are parameningeal infectious processes. If untreated, focal neurologic signs, lethargy, and coma may develop. With prompt diagnosis and treatment, including surgical drainage, resolution and full recovery is possible, the only residuum being a thickened dura.

Extradural Abscess

Extradural abscess, commonly associated with osteomyelitis, often arises from an adjacent focus of infection, such as sinusitis or following a surgical procedure. When the process occurs in the spinal epidural space, it may cause spinal cord compression and constitute a neurosurgical emergency.

Chronic Bacterial Meningoencephalitis

Chronic bacterial infection of the meninges and the brain may be caused by *Mycobacterium tuberculosis*, *Treponema pallidum*, and *Borrelia* species.

Tuberculosis

Tuberculosis of the CNS may be part of active disease elsewhere in the body or appear in isolation following seeding from silent lesions elsewhere, usually the lungs. It may involve the meninges or the brain.

Clinical Features. Patients with tuberculous meningitis usually have headache, malaise, mental confusion, and vomiting. The CSF typically shows a pleocytosis made up

MORPHOLOGY

The most common pattern of tuberculous involvement is a diffuse **meningoencephalitis**. The subarachnoid space contains a gelatinous or fibrinous exudate that characteristically involves the base of the brain, effacing the cisterns and encasing cranial nerves. There may be discrete, white areas of inflammation scattered over the leptomeninges. On microscopic examination, involved areas contain mixed inflammatory infiltrates containing lymphocytes, plasma cells, and macrophages. Florid cases show well-formed granulomas with caseous necrosis and giant cells. Arteries running through the subarachnoid space may show obliterative endarteritis and marked intimal thickening. Organisms can often be seen with acid-fast stains. The infectious process may spread to the choroid plexus and ependymal surface, traveling through the CSF. In long-standing cases, a dense, fibrous adhesive arachnoiditis may develop, most conspicuous around the base of the brain. Hydrocephalus may result.

CNS involvement may also take the form of one or more well-circumscribed intraparenchymal masses (**tuberculomas**), which may be associated with meningitis. A tuberculoma may be as large as several centimeters in diameter, causing significant mass effect. These lesions usually have a central area of caseous necrosis surrounded by granulomas; calcification may occur in inactive lesions.

of mononuclear cells or a mixture of neutrophils and mononuclear cells, an elevated protein concentration (often, strikingly so), and a moderately reduced or normal glucose. The most serious complications of chronic tuberculous meningitis are arachnoid fibrosis producing hydrocephalus, and obliterative endarteritis producing arterial occlusion and infarction of underlying brain. When the process involves the spinal cord subarachnoid space, nerve roots may also be affected. Tuberculomas produce symptoms typical of space-occupying brain lesions and must be distinguished from CNS tumors.

CNS tuberculosis in patients with acquired immunodeficiency syndrome (AIDS) is pathologically similar, but there may be less host reaction than in immunocompetent individuals. HIV-positive individuals are also at risk for infection by *Mycobacterium avium-intracellulare*, usually in the setting of disseminated infection. These lesions typically contain confluent sheets of macrophages filled with organisms, with few or no granulomas.

Neurosyphilis

Neurosyphilis is a manifestation of the tertiary stage of syphilis and occurs in only about 10% of individuals with untreated infection. The major patterns of CNS involvement are meningovascular neurosyphilis, paretic neurosyphilis, and tabes dorsalis. Affected individuals often show incomplete or mixed pictures, most commonly the combination of tabes dorsalis and paretic disease (taboparesis). Individuals infected with HIV are at increased risk for neurosyphilis, particularly to acute syphilitic meningitis or meningovascular disease, because of impaired cell-mediated immunity. The rate of progression and severity of the disease are also accelerated, for the same reason.

MORPHOLOGY

Neurosyphilis presents in several distinct forms.

- **Meningovascular neurosyphilis** is chronic meningitis involving the base of the brain and more variably the cerebral convexities and the spinal leptomeninges. In addition, there may be an associated obliterative endarteritis (Heubner arteritis) accompanied by a distinctive perivascular inflammatory reaction rich in plasma cells and lymphocytes. Cerebral gummas (plasma cell-rich mass lesions) may also occur in the meninges and extend into the parenchyma.
- **Paretic neurosyphilis** is caused by invasion of the brain by *T. pallidum* and is clinically manifested as insidious but progressive cognitive impairment associated with mood alterations (including delusions of grandeur) that terminate in severe dementia (**general paresis of the insane**). Parenchymal damage of the cerebral cortex is particularly common in the frontal lobe but also occurs in other areas of the isocortex. The lesions are characterized by loss of neurons, proliferation of microglia (rod cells), gliosis, and iron deposits. The latter are demonstrable with the Prussian blue stain perivascularly and in the neuropil, and are presumably the sequelae of small bleeds stemming from damage to the microcirculation. The spirochetes can, at times, be demonstrated in tissue sections.
- **Tabes dorsalis** is the result of damage to the sensory axons in the dorsal roots. This causes impaired joint position sense and ataxia (locomotor ataxia); loss of pain sensation, leading to skin and joint damage (Charcot joints); other sensory disturbances, particularly the characteristic “lightning pains”; and absence of deep tendon reflexes. On microscopic examination there is loss of both axons and myelin in the dorsal roots, with corresponding pallor and atrophy in the dorsal columns of the spinal cord. Organisms are not demonstrable in the cord lesions.

Neuroborreliosis (Lyme Disease)

Lyme disease is caused by the spirochete *Borrelia burgdorferi*, which is transmitted by various species of *Ixodes* tick (Chapter 8). Involvement of the nervous system is referred to as *neuroborreliosis*. Neurologic symptoms are highly variable and include aseptic meningitis, facial nerve palsies and other polyneuropathies, as well as encephalopathy. The rare cases that have come to autopsy have shown a focal proliferation of microglial cells in the brain as well as scattered extracellular organisms.

Viral Meningoencephalitis

Viral encephalitis is a parenchymal infection of the brain almost invariably associated with meningeal inflammation (meningoencephalitis) and sometimes with simultaneous involvement of the spinal cord (encephalomyelitis).

Some viruses have a propensity to infect the nervous system. Such neural tropism takes several forms: some infect specific cell types (e.g., oligodendrocytes), while others preferentially involve particular areas of the brain (e.g., medial temporal lobes or the limbic system). Latency is an important phase of several viral infections of the CNS (e.g., herpes zoster, progressive multifocal leukoencephalopathy). Systemic viral infections in the absence of direct

evidence of viral penetration into the CNS may be followed by an immune-mediated disease, such as perivenous demyelination (see “[Acute Disseminated Encephalomyelitis and Acute Necrotizing Hemorrhagic Encephalomyelitis](#)”). Intrauterine viral infection may cause congenital malformations, as occurs with rubella. A slowly progressive degenerative disease syndrome may follow many years after a viral illness; an example is postencephalitic parkinsonism after the 1918 viral influenza pandemic.

Arthropod-Borne Viral Encephalitis

Arboviruses are an important cause of epidemic encephalitis, especially in tropical regions of the world, and they are capable of causing serious morbidity and high mortality. In the Western hemisphere the most important types are Eastern and Western equine, West Nile, Venezuelan, St. Louis, and La Crosse; elsewhere in the world, pathogenic arboviruses include Japanese B (Far East), Murray Valley (Australia and New Guinea), and tick-borne (Russia and Eastern Europe).

All these viruses have animal hosts and insect vectors. Clinically, affected individuals develop generalized neurologic deficits, such as seizures, confusion, delirium, and stupor or coma, as well as focal signs, such as reflex asymmetry and ocular palsies. Involvement of the spinal cord in West Nile encephalitis can lead to a polio-like syndrome with paralysis. In general, the CSF is usually colorless, with slightly elevated pressure, an elevated protein level, and a normal glucose. Initially the CSF exhibits a neutrophilic pleocytosis, but this rapidly converts to a lymphocytosis.

MORPHOLOGY

The encephalitides caused by various arboviruses produce similar histopathologic changes that differ only in severity and extent. Characteristically, there is a meningoencephalitis marked by the perivascular accumulation of lymphocytes (and sometimes with neutrophils) (Fig. 28-23A). Multiple foci of necrosis of gray and white matter are found; in particular, there is evidence of single-cell neuronal necrosis with phagocytosis of the debris (**neuronophagia**). Microglial cells form small aggregates around foci of necrosis, called **microglial nodules** (Fig. 28-23B). In severe cases there may be a necrotizing vasculitis with associated focal hemorrhages. While some viruses declare their presence by formation of intracellular inclusion bodies, the causative virus is most often identified by a combination of ultrastructural, immunohistochemical, and molecular methods.

Herpes Simplex Virus Type 1

Herpes simplex virus type 1 (HSV-1) encephalitis occurs most commonly in children and young adults. Only about 10% of the affected individuals have a history of prior herpetic infection. The typical presenting symptoms are alterations in mood, memory, and behavior. Polymerase chain reaction (PCR)-based methods for virus detection in CSF samples have increased the ease of diagnosis and the recognition of a subset of patients with less severe disease. Antiviral agents now provide effective treatment in many cases, with a significant reduction in the mortality rate. In some individuals, HSV-1 encephalitis follows a subacute

Figure 28-23 Characteristic findings of viral encephalitis include perivascular cuffs of lymphocytes (**A**) and microglial nodules (**B**).

course with clinical manifestations (weakness, lethargy, ataxia, seizures) that evolve during a more protracted period (4 to 6 weeks). Recently, an increased incidence of HSV encephalitis has been observed in patients with rare inherited loss-of-function mutations in the TLR3 signaling pathway, supporting a role for Toll-like receptor signaling in the control of HSV infections.

MORPHOLOGY

This encephalitis starts in and most severely involves the inferior and medial regions of the temporal lobes and the orbital gyri of the frontal lobes (Fig. 28-24). The infection is necrotizing and often hemorrhagic in the most severely affected regions. Perivascular inflammatory infiltrates are usually present, and Cowdry type A intranuclear viral inclusion bodies may be found in both neurons and glia. In individuals with slowly evolving HSV-1 encephalitis, there is more diffuse involvement of the brain.

Herpes Simplex Virus Type 2

Herpes simplex virus type 2 (HSV-2) can infect the nervous system. In adults it causes meningitis, but as many as 50% of neonates born by vaginal delivery to women with active primary HSV genital infections acquire the infection during passage through the birth canal and develop severe encephalitis. In individuals with active HIV infection, HSV-2 may cause an acute hemorrhagic and necrotizing encephalitis.

Varicella-Zoster Virus (Herpes Zoster)

Primary infection with varicella causes one of the childhood exanthems (chickenpox), ordinarily without evidence of neurologic involvement. Following the cutaneous infection, the virus enters a latent phase within sensory neurons of the dorsal root or trigeminal ganglia. Reactivation of infection in adults (*shingles*) usually manifests as a painful, vesicular skin eruption confined to one or several dermatomes. Herpes zoster reactivation is typically self-limited,

Figure 28-24 **A**, Herpes encephalitis showing extensive destruction of inferior frontal and anterior temporal lobes (arrows) and the cingulate gyri (asterisks). **B**, Necrotizing inflammatory process characterizes acute herpes encephalitis. (**A**, Courtesy Dr. T. W. Smith, University of Massachusetts Medical School, Worcester, Mass.)

but there may be a postherpetic neuralgia syndrome (particularly after age 60 years) characterized by persistent pain, sometimes induced by stimuli that are otherwise not painful.

Overt CNS involvement by herpes zoster is much rarer, but can be severe. Herpes zoster can cause a granulomatous arteritis. In immunosuppressed individuals, herpes zoster may cause acute encephalitis characterized by numerous sharply circumscribed demyelinating lesions that subsequently undergo necrosis.

Cytomegalovirus

CMV infection of the nervous system occurs in fetuses and immunosuppressed individuals. The outcome of infection in utero is periventricular necrosis that produces severe brain destruction followed later by microcephaly and periventricular calcification. CMV is a common opportunistic viral pathogen in individuals with AIDS, with CNS involvement also occurring in this setting.

MORPHOLOGY

In the immunosuppressed individual, CMV most commonly causes subacute encephalitis, which may be associated with CMV inclusion-bearing cells (see Fig. 8-15). The infection tends to localize in the paraventricular subependymal regions of the brain, where it results in a severe hemorrhagic necrotizing ventriculoencephalitis and a choroid pleatitis. The virus can also attack the lower spinal cord and roots, producing a painful radiculoneuritis. Any cell in the CNS (neurons, glia, ependyma, or endothelium) may be infected. Prominent enlarged cells with intranuclear and intracytoplasmic inclusions can be readily identified by conventional light microscopy and CMV infection is confirmed by immunohistochemistry.

Poliomyelitis

While paralytic poliomyelitis has been eradicated by vaccination in many parts of the world, there are still a few countries where it remains a serious problem. In nonimmunized individuals poliovirus infection causes a subclinical or mild gastroenteritis, similar to that caused by other members of the picornavirus group of enteroviruses. In a small fraction of the vulnerable population, however, the virus secondarily invades the nervous system.

MORPHOLOGY

Acute cases show mononuclear cell perivascular cuffs and neuronophagia of the **anterior horn motor neurons of the spinal cord**. The inflammatory reaction is usually confined to the anterior horns but may extend into the posterior horns, and the damage is occasionally severe enough to produce cavitation. Poliovirus RNA has been detected in anterior horn cell motor neurons. The cranial motor nuclei are sometimes involved as well. Postmortem examination in long-term survivors of symptomatic poliomyelitis shows loss of neurons and gliosis in the affected anterior horns of the spinal cord, some residual inflammation, atrophy of the anterior (motor) spinal roots, and neurogenic atrophy of denervated muscle.

Clinical Features. CNS infection manifests initially with meningeal irritation and a CSF picture consistent with aseptic meningitis. The disease may progress no further or advance to involve the spinal cord. When the disease affects the motor neurons of the spinal cord, it produces a flaccid paralysis associated with muscle wasting and hyporeflexia in the corresponding region of the body—the permanent neurologic residue of poliomyelitis. Because of the destruction of motor neurons, paresis or paralysis follows; when the diaphragm and intercostal muscles are affected, severe respiratory compromise and even death may occur. A myocarditis sometimes complicates the acute infection. *Postpolio syndrome* can develop in patients 25 to 35 years after the resolution of the initial illness. It is characterized by progressive weakness associated with decreased muscle mass and pain, and has been attributed to superimposed neuronal loss of aging with inflammatory mechanisms, but without any convincing evidence of viral re-activation.

Rabies

Rabies is severe encephalitis transmitted to humans by the bite of a rabid animal, usually a dog or various wild mammals that are natural reservoirs. Exposure to certain species of bats, even without a known bite, can also lead to rabies.

MORPHOLOGY

External examination of the brain shows intense edema and vascular congestion. Microscopically, there is widespread neuronal degeneration and an inflammatory reaction that is most severe in the brainstem. The basal ganglia, spinal cord, and dorsal root ganglia may also be involved. **Negri bodies**, the pathognomonic microscopic finding, are cytoplasmic, round to oval, eosinophilic inclusions that can be found in pyramidal neurons of the hippocampus and Purkinje cells of the cerebellum, sites usually devoid of inflammation (Fig. 28-25). Rabies virus can be detected within Negri bodies by ultrastructural and immunohistochemical methods.

Figure 28-25 The diagnostic histologic finding in rabies is the eosinophilic Negri body, as seen here in a Purkinje cell (arrows).

Clinical Features. Since the virus enters the CNS by ascending along the peripheral nerves from the wound site, the incubation period (usually between 1 and 3 months) depends on the distance between the wound and the brain. The disease begins with nonspecific symptoms such as malaise, headache, and fever, but the conjunction of these symptoms with local paresthesias around the wound is diagnostic. As the infection advances, the affected individual exhibits extraordinary CNS excitability; the slightest touch is painful and produces violent motor responses or even convulsions. Contracture of the pharyngeal musculature on swallowing produces foaming at the mouth, which may create an aversion to swallowing even water (hydrophobia). There are signs of meningeal irritation and, as the disease progresses, flaccid paralysis. Alternating periods of mania and stupor progress to coma and eventually death from respiratory failure.

Human Immunodeficiency Virus

In the period before the availability of effective antiretroviral therapy, neuropathologic changes were demonstrated at postmortem examination in as many as 80% to 90% of cases of AIDS. These changes stem from direct effects of virus on the nervous system, opportunistic infections, and primary CNS lymphoma, a high fraction of which were EBV-positive B cell tumors. There has been a decrease in the frequency of these secondary effects of HIV infection thanks to the efficacy of multidrug antiretroviral therapy.

HIV aseptic meningitis occurs within 1 to 2 weeks of seroconversion in about 10% of patients; antibodies to HIV can be demonstrated and the virus can be isolated from the CSF. The neuropathologic studies of the early, acute phases of HIV invasion of the CNS have shown mild lymphocytic meningitis, perivascular inflammation, and some myelin loss. Among CNS cell types only microglia express both the CD4 coreceptor and the chemokine receptors (CCR5 or CXCR4) that are required in combination for efficient infection by HIV. During the chronic phase, HIV encephalitis is commonly found when symptomatic individuals come to autopsy.

An “immune reconstitution inflammatory syndrome” (IRIS) has been identified in patients with AIDS after effective treatment; the syndrome is recognized as a paradoxical deterioration after starting therapy, and consists of an exuberant “reconstituted” inflammatory response while on antiretroviral therapy (Chapter 6). In the CNS, IRIS has

Figure 28-26 HIV encephalitis. Note the microglial nodule and multinucleated giant cells.

caused paradoxical exacerbation of symptoms from opportunistic infections. Neuropathologic studies confirm intense inflammation with an influx of CD8+ lymphocytes.

Cognitive changes, some mild and others florid enough to be termed *HIV-associated dementia*, appear to have persisted in the era of effective anti-HIV treatment regimens. Rather than having a specific pathologic lesion as its correlate, this disorder is most closely related to inflammatory activation of microglial cells, not all of which are necessarily HIV-infected. A wide range of possible mechanisms for neuronal dysfunction and injury in this setting have been proposed, including the actions of inflammatory cytokines and a cascade of toxic effects of HIV-derived proteins; in all probability, both have contributory roles in the pathogenesis of brain injury (Chapter 6).

Progressive Multifocal Leukoencephalopathy

Progressive multifocal leukoencephalopathy (PML) is an encephalitis caused by the JC polyomavirus; because the virus preferentially infects oligodendrocytes, demyelination is its principal pathologic effect. The disease occurs almost exclusively in immunosuppressed individuals in various clinical settings, including chronic lymphoproliferative or myeloproliferative illnesses, immunosuppressive chemotherapy including monoclonal antibody therapy targeting integrins, granulomatous diseases, and AIDS.

Although most people have serologic evidence of exposure to JC virus by the age of 14 years, primary infection is asymptomatic. PML results from the reactivation of virus in the setting of immunosuppression. Clinically, affected individuals develop focal and relentlessly progressive

MORPHOLOGY

HIV encephalitis is a chronic inflammatory reaction associated with widely distributed **microglial nodules**, often containing macrophage-derived **multinucleated giant cells**; foci of tissue necrosis and reactive gliosis are sometimes seen together with these lesions (Fig. 28-26). Some of the microglial nodules are found near small blood vessels, which show abnormally prominent endothelial cells and perivascular foamy or pigment-laden macrophages. These changes are especially prominent in the subcortical white matter, diencephalon, and brainstem. In some cases there is also a disorder of white matter characterized by multifocal or diffuse areas of myelin pallor, axonal swelling and gliosis. HIV can be detected in CD4+ mononuclear and multinucleated macrophages and microglia.

MORPHOLOGY

The lesions consist of patches of irregular, ill-defined white matter injury that range in size from millimeters to near confluent involvement of large regions of the brain (Fig. 28-27). Microscopically, individual lesions show an area of demyelination, most often in a subcortical location, in the center of which are scattered lipid-laden macrophages and a reduced number of axons. Particularly at the edge of the lesion are greatly

Figure 28-27 Progressive multifocal leukoencephalopathy. Section stained for myelin showing irregular, poorly defined areas of demyelination, which become confluent in places. *Inset*, Enlarged oligodendrocyte nucleus represents the effect of viral infection.

enlarged oligodendrocyte nuclei containing glassy amphiphilic viral inclusions (Fig. 28-27, *inset*), which can be identified by immunohistochemistry. Within the lesions, there may be bizarre giant astrocytes with one to several irregular, hyperchromatic nuclei mixed with more typical reactive astrocytes. Infection of granule cell neurons in the cerebellum been demonstrated in rare instances.

neurologic symptoms and signs, and imaging studies show extensive, often multifocal, lesions in the hemispheric or cerebellar white matter.

Subacute Sclerosing Panencephalitis

Subacute sclerosing panencephalitis (SSPE) is a rare progressive clinical syndrome characterized by cognitive decline, spasticity of limbs, and seizures. It occurs in children or young adults, months or years after an initial, early-age acute infection with measles. The disease stems from persistent, but nonproductive, infection of the CNS by an altered measles virus; changes in several viral genes have been associated with the disease. It is characterized by widespread gliosis and myelin degeneration; viral inclusions, largely within the nuclei of oligodendrocytes and neurons; variable inflammation of white and gray matter; and neurofibrillary tangles. Ultrastructural study shows that the inclusions contain nucleocapsids characteristic of measles and immunohistochemistry for measles virus antigen is positive. The incidence of the disease has fallen sharply due to vaccination programs, but it persists in nonimmunized populations.

Fungal Meningoencephalitis

Fungal infections of the CNS are encountered primarily in immunocompromised individuals. The brain is usually involved following widespread hematogenous dissemination of fungi; the most frequent offenders are *Candida albicans*, *Mucor* species, *Aspergillus fumigatus*, and *Cryptococcus neoformans*. In endemic areas, pathogens such as *Histoplasma capsulatum*, *Coccidioides immitis*, and *Blastomyces*

dermatitidis may involve the CNS after a primary pulmonary or cutaneous infection; again, this often follows immunosuppression. Although most fungi reach the brain by hematogenous dissemination, direct extension may also occur, particularly in mucormycosis in the setting of diabetes mellitus.

The three main forms of injury in fungal infection in the CNS are chronic meningitis, vasculitis, and parenchymal invasion. Vasculitis is most frequently seen with *Mucormycosis* and *Aspergillosis*, both of which directly invade blood vessel walls, but it occasionally occurs with other infections such as candidiasis. The resultant vascular thrombosis produces infarction that is often strikingly hemorrhagic and that subsequently becomes septic from ingrowth of the causative fungus.

Parenchymal infection, usually in the form of granulomas or abscesses, can occur with most of the fungi and often coexists with meningitis. The most commonly encountered fungi that invade the brain are *Candida* and *Cryptococcus*. Candidiasis usually produces multiple microabscesses, with or without granuloma formation.

Cryptococcal meningitis, a common opportunistic infection in the setting of AIDS, may be fulminant and fatal in as little as 2 weeks or indolent, evolving over months or years. The CSF may contain few cells but usually has a high concentration of protein. The mucoid-encapsulated yeasts can be visualized in the CSF with special stains or detected indirectly using assays for cryptococcal antigens.

MORPHOLOGY

With cryptococcal infection, there is a chronic meningitis affecting the basal leptomeninges, which are opaque and thickened by reactive connective tissue that may obstruct the outflow of CSF from the foramina of Luschka and Magendie, giving rise to hydrocephalus. Sections of the brain disclose a gelatinous material within the subarachnoid space and small cysts within the parenchyma ("soap bubbles"), which are especially prominent in the basal ganglia in the distribution of the lenticulostriate arteries (Fig. 28-28A). Parenchymal lesions consist of aggregates of organisms within expanded perivascular (Virchow-Robin) spaces associated with minimal or absent inflammation or gliosis (Fig. 28-28B). The meningeal infiltrates consist of chronic inflammatory cells and fibroblasts admixed with cryptococci.

Other Infectious Diseases of the Nervous System

Protozoal diseases (including malaria, toxoplasmosis, amebiasis, and trypanosomiasis), rickettsial infections (e.g., typhus and Rocky Mountain spotted fever), and metazoal diseases (especially cysticercosis and echinococcosis) may also involve the CNS and are discussed in [Chapter 8](#).

- *Cerebral toxoplasmosis* is an opportunistic infection commonly found in the setting of HIV-associated immunosuppression. The clinical symptoms of infection of the brain by *Toxoplasma gondii* are subacute, evolving during a 1- or 2-week period, and may be both focal

Figure 28-28 Cryptococcal infection. **A**, Whole-brain section showing the numerous areas of tissue destruction (“soap bubbles”) associated with the spread of organisms in the perivascular spaces. **B**, At higher magnification it is possible to see the cryptococci in the lesions.

and diffuse. Computed tomography and magnetic resonance imaging studies may show multiple ring-enhancing lesions; however, this radiographic appearance is not specific, as CNS lymphoma, tuberculosis, and fungal infections produce similar findings. In non-immunosuppressed hosts, the impact of toxoplasmosis on the brain is most often seen when primary maternal infection occurs early in pregnancy. Such infections often spread to the brain of the developing fetus and cause severe damage in the form of multifocal necrotizing lesions that may calcify.

MORPHOLOGY

Toxoplasmosis of the CNS produces brain abscesses, which are found most often in the cerebral cortex (near the gray-white junction) and deep gray nuclei, less often in the cerebellum and brainstem, and rarely in the spinal cord (Fig. 28-29). Acute lesions exhibit central necrosis, petechial hemorrhages surrounded by acute and chronic inflammation, macrophage infiltration, and vascular proliferation. Both free tachyzoites and encysted bradyzoites (Fig. 28-29B) may be found at the periphery of the necrotic foci. The organisms are often seen on routine hematoxylin and eosin (H & E) or Giemsa stains, but are more easily recognized by immunohistochemical methods. The blood vessels near these lesions may show marked intimal proliferation or even frank vasculitis with fibrinoid necrosis and thrombosis. After treatment, the lesions consist of large, well-demarcated areas of coagulative necrosis surrounded by lipid-laden macrophages. Cysts and free tachyzoites can also be found adjacent to these lesions but may be considerably reduced in number or absent if effective therapy has been received. Chronic lesions consist of small cystic spaces containing scattered lipid- and hemosiderin-laden macrophages that are surrounded by gliotic brain. Organisms are difficult to detect in these older lesions.

- *Cerebral amebiasis*. A rapidly fatal necrotizing encephalitis results from infection with *Naegleria* species, and a chronic granulomatous meningoencephalitis has been associated with infection with *Acanthamoeba*. The amoebae may be difficult to distinguish morphologically from activated macrophages (Fig. 28-30). Methenamine silver or PAS stains are helpful in visualizing the organisms, although definitive identification ultimately depends on immunofluorescence studies, culture, and molecular methods.
- *Cerebral malaria*. A rapidly progressive encephalitis, cerebral malaria is the complication of infection by *Plasmodium falciparum* with the highest mortality. Most likely the result of vascular dysfunction, cerebral involvement by malaria is accompanied by reduced cerebral blood flow and results in ataxia, seizures, and coma in the acute phase, with long-term cognitive deficits in up to 20% of children after cerebral malaria (Chapter 8).

KEY CONCEPTS

Infections

- Pathogens from viruses through parasites can infect the brain. Different pathogens use distinct routes to reach the brain and cause different patterns of disease.
- Routes of access of organisms to the brain include: hematogenous spread (e.g., abscess formation in the setting of endocarditis), direct extension (following trauma or with extension from the sinuses with *Mucor*) and retrograde transport along nerves (as with rabies).
- Bacterial infections may cause meningitis, cerebral abscesses, or a chronic meningoencephalitis. The distribution of pathogens is influenced by various host factors, such as age and level of immune function.
- Viral infections can cause meningitis or meningoencephalitis. Some viruses have characteristic patterns of

Figure 28-29 **A**, *Toxoplasma* abscesses in the putamen and thalamus. **B**, Free tachyzoites demonstrated by immunostaining; *inset*: *Toxoplasma* pseudocyst with bradyzoites highlighted by immunostaining.

infection (HSV-1 in the temporal lobes, polio in anterior horn).

- HIV can directly cause meningoencephalitis, or indirectly affect the brain by increasing the risk of opportunistic infections (toxoplasmosis, CMV) or EBV-positive CNS lymphoma.

Prion Diseases

Prions are abnormal forms of a cellular protein that cause rapidly progressive neurodegenerative disorders that may be sporadic, familial or transmitted. This group of diseases includes Creutzfeldt-Jakob disease, Gerstmann-Sträussler-Scheinker syndrome, fatal familial insomnia, and kuru in humans; scrapie in sheep and goats; mink-transmissible encephalopathy; chronic wasting disease of deer and elk; and bovine spongiform encephalopathy. These disorders share an etiologic basis

Figure 28-30 Necrotizing amebic meningoencephalitis involving the cerebellum (organism highlighted by arrow).

as they are all associated with abnormal forms of a specific protein termed *prion protein* (PrP). They are all characterized morphologically by “spongiform change” caused by intracellular vacuoles in neurons and glia, and clinically by a rapidly progressive dementia.

Pathogenesis and Molecular Genetics. Prion diseases are conceptually important because they exemplify degenerative disorders that are caused by “spreading” of misfolded proteins, a remarkable phenomenon that allows a pathogenic protein to acquire many of the characteristics of an infectious organism. Normal PrP is a 30-kD cytoplasmic protein present in neurons. Disease occurs when PrP undergoes a conformational change from its normal α -helix-containing isoform (PrP^c) to an abnormal β -pleated sheet isoform, usually termed PrP^{sc} (for scrapie) (Fig. 28-31). Associated with the conformational change, PrP acquires resistance to digestion with proteases, such as proteinase K. Accumulation of PrP^{sc} in neural tissue seems to be the cause of the pathologic changes in these diseases, but how this material induces the development of cytoplasmic vacuoles and eventual neuronal death is still unknown. Western blotting of tissue extracts after partial digestion with proteinase K allows detection of PrP^{sc}, which is diagnostic.

The conformational change resulting in PrP^{sc} may occur spontaneously at an extremely low rate (resulting in sporadic cases) or at a higher rate if various mutations are present in PrP^c, such as occurs in familial forms of Creutzfeldt-Jakob disease (CJD) and in Gerstmann-Sträussler-Scheinker syndrome (GSS) and fatal familial insomnia (FFI). PrP^{sc}, independent of the means by which it originates, then facilitates, in a cooperative fashion, the conversion of other PrP^c molecules to PrP^{sc} molecules. It is this propagation of PrP^{sc} that accounts for the transmissible nature of prion diseases. This capacity for a protein in an abnormal conformation to induce similar structural change in other molecules as a self-propagating process has recently been demonstrated for many of the aggregating proteins associated with traditional neurodegenerative diseases. The suggestion that, at least within an individual, there may be

Figure 28-31 Pathogenesis of prion disease. α -helical PrP^C may spontaneously shift to the β -sheet PrP^{Sc} conformation, an event that occurs at a much higher rate in familial disease associated with germ line PrP mutations. PrP^{Sc} may also be acquired from exogenous sources, such as contaminated food, medical instrumentation, or medicines. Once present, PrP^{Sc} converts additional molecules of PrP^C into PrP^{Sc} through physical interaction, eventually leading to the formation of pathogenic PrP^{Sc} aggregates.

cell-to-cell spread of disease-associated protein aggregates provides a link between prion diseases and other disorders such as Alzheimer disease and Parkinson disease.

The gene encoding PrP, termed *PRNP*, shows a high degree of conservation across species. A variety of mutations in *PRNP* have been found to underlie familial forms of prion diseases. In addition, a polymorphism at codon 129 that encodes either methionine (Met) or valine (Val) influences development of the disease: individuals who are homozygous for either Met or Val are overrepresented among cases of CJD compared with the general population, implying that heterozygosity at codon 129 is protective against development of the disease. The same protective effect of heterozygosity at codon 129 is observed for iatrogenic CJD (mostly cases that followed exposure to naturally derived pituitary hormone replacement).

Creutzfeldt-Jakob Disease (CJD)

Although the most common prion disease, CJD is a rare disorder that manifests clinically as a rapidly progressive dementia. The sporadic form of CJD has an annual incidence of approximately 1 per 1,000,000 people and accounts for about 90% of cases; familial forms are caused by mutations in *PRNP*. The disease has a peak incidence in the seventh decade. There are also well-established cases of iatrogenic transmission, notably by corneal

transplantation, deep implantation of electrodes in the brain, and administration of contaminated preparations of naturally derived human growth hormone. The onset is marked by subtle changes in memory and behavior followed by a rapidly progressive dementia, often associated with pronounced involuntary jerking muscle contractions on sudden stimulation (startle myoclonus). Signs of cerebellar dysfunction, usually manifested as ataxia, are present in a minority of affected individuals. The disease is uniformly fatal. The average survival is only 7 months after the onset of symptoms. A few patients have lived for several years, and these long-surviving cases show extensive atrophy of involved gray matter.

Variant Creutzfeldt-Jakob Disease

Starting in 1995, a series of cases of a CJD-like illness came to medical attention in the United Kingdom. This illness was different from typical CJD in several important respects: the disease affected young adults, behavioral disorders figured prominently in the early stages of the disease, and the neurologic syndrome progressed more slowly than in individuals with other forms of CJD. The neuropathologic findings and molecular features of these new cases were similar to those of CJD, suggesting a close relationship between the two illnesses, with multiple lines of evidence indicating that the new variant form of CJD was linked to exposure to bovine spongiform encephalopathy. Pathologically, variant CJD (vCJD) is characterized by the presence of extensive cortical plaques surrounded by a “halo” of spongiform change. No alterations in the *PRNP* gene are present and the disease appears to be limited to date to codon 129 Met/Met homozygotes. Onset of vCJD is linked to consumption of the bovine spongiform encephalopathy agent in contaminated foods or blood transfusion, raising significant public health issues.

MORPHOLOGY

The progression of the dementia in CJD is usually so rapid that there is little if any grossly evident brain atrophy. The pathognomonic finding is a **spongiform** transformation of the cerebral cortex and, often, deep gray matter structures (caudate, putamen); this multifocal process results in the uneven formation of small, apparently empty, microscopic vacuoles of varying sizes within the neuropil and sometimes in the perikaryon of neurons (Fig. 28-32A). In advanced cases there is severe neuronal loss, reactive gliosis, and sometimes expansion of the vacuolated areas into cystlike spaces (“status spongiosus”). Inflammation is notably absent. Electron microscopy shows the vacuoles to be membrane-bound and located within the cytoplasm of neuronal processes. **Kuru plaques** are extracellular deposits of aggregated abnormal protein; they are Congo red- and PAS-positive and usually occur in the cerebellum (Fig. 28-32B), but are abundant in the cerebral cortex in cases of vCJD (Fig. 28-32C). In all forms of prion disease, immunohistochemical staining demonstrates the presence of proteinase K-resistant PrP^{Sc} in tissue.

Fatal Familial Insomnia (FFI)

Fatal familial insomnia (FFI), named in part for the sleep disturbances that characterize its initial stages, is also

Figure 28-32 Prion disease. **A**, Spongiform change in the cerebral cortex. *Inset*, High magnification of neuron with vacuoles. **B**, Cerebellar cortex showing *kuru* plaques (periodic acid-Schiff stain) representing aggregated PrP^{Sc}. **C**, Cortical plaques surrounded by spongiform change in vCJD.

caused by a specific mutation in the *PRNP* gene. The mutation, which leads to an aspartate substitution for asparagine at residue 178 of PrP^c, results in FFI when it occurs in a *PRNP* allele encoding methionine at codon 129, but causes CJD when present in tandem with a valine at this

MORPHOLOGY

Unlike other prion diseases, FFI does not show spongiform pathology. Instead, the most striking alteration is neuronal loss and reactive gliosis in the anterior ventral and dorsomedial nuclei of the thalamus; neuronal loss is also prominent in the inferior olivary nuclei. Proteinase K-resistant PrP^{Sc} can be detected by immunostaining or western blotting.

KEY CONCEPTS

Prion Diseases

- Prion diseases may be sporadic, familial or transmissible (infectious). The disease is driven by the conversion of a normal cellular protein (PrP^c) into an abnormal conformation (PrP^{Sc}), with the acquisition of distinct characteristics including relative resistance to protease digestion, self-propagation, and the ability to spread.
- Familial forms of these diseases are linked to mutations in the gene encoding PrP^c (*PRNP*). A polymorphic locus in *PRNP* (codon 129 may be either Met or Val) determines disease phenotype, with homozygosity at this site increasing risk of sporadic disease.
- Disease phenotypes include Creutzfeldt-Jakob disease (rapidly progressive dementia), Gerstmann-Sträussler-Scheinker syndrome (progressive cerebellar ataxia) and fatal familial insomnia.

position. How these amino acids influence disease phenotype is not understood. In the course of the illness, which typically lasts fewer than 3 years, affected individuals develop other neurologic signs, such as ataxia, autonomic disturbances, stupor, and finally coma. A noninherited form of the disorder (fatal sporadic insomnia) has also been described.

Demyelinating Diseases

Demyelinating diseases of the CNS are acquired conditions characterized by preferential damage to myelin with relative preservation of axons. The clinical deficits are due to the effect of myelin loss on the transmission of electrical impulses along axons. The natural history of demyelinating diseases is determined, in part, by the limited capacity of the CNS to regenerate normal myelin and by the degree of secondary damage to axons that occurs as the disease runs its course.

Several pathologic processes can cause loss of myelin. These include immune-mediated destruction of myelin, as in multiple sclerosis, and infections. In progressive multifocal leukoencephalopathy, JC virus infection of oligodendrocytes results in loss of myelin (described earlier). In addition, inherited disorders may affect synthesis or turnover of myelin components; these are termed *leukodystrophies* and are discussed with metabolic disorders.

Multiple Sclerosis

Multiple sclerosis (MS) is an autoimmune demyelinating disorder characterized by distinct episodes of neurologic deficits, separated in time, attributable to white matter lesions that are separated in space. It is the most common of the demyelinating disorders, having a prevalence of

approximately 1 per 1000 persons in most of the United States and Europe. The disease may become clinically apparent at any age, although onset in childhood or after age 50 years is relatively rare. Women are affected twice as often as are men. In most individuals with MS, the clinical course takes the form of relapsing and remitting episodes of variable duration (weeks to months to years) marked by neurologic defects, followed by gradual, partial recovery of neurologic function. The frequency of relapses tends to decrease during the course of time, but there is a steady neurologic deterioration in most affected individuals.

Pathogenesis. The lesions of MS are caused by an **autoimmune response directed against components of the myelin sheath**. As in other autoimmune disorders, the pathogenesis of this disease involves both genetic and environmental factors (Chapter 6). The incidence of MS is 15-fold higher when the disease is present in a first-degree relative and roughly 150-fold higher with an affected monozygotic twin. Despite a series of well-powered studies, only a portion of the genetic basis of the disease has been explained. There is a strong effect from the DR2 extended haplotype of the major histocompatibility complex; each copy of the DRB1*1501 allele an individual inherits brings with it a roughly 3-fold increase in the risk of MS. Genome-wide association studies first identified additional associations with the IL-2 and IL-7 receptor genes, and subsequently with a number of other genes encoding proteins involved in the immune response, including cytokines and their receptors, co-stimulatory molecules, and cytoplasmic signaling molecules. Many of these loci have been found to be associated with other autoimmune diseases. These genetic studies have not explained variations in clinical course for individuals with MS.

Immune mechanisms that underlie the destruction of myelin are the focus of much investigation. The available evidence indicates that the disease is initiated by T_H1 and T_H17 T cells that react against myelin antigens and secrete cytokines. T_H1 cells secrete IFN- γ , which activates macrophages, and T_H17 cells promote the recruitment of leukocytes (Chapter 6). The demyelination is caused by these activated leukocytes and their injurious products. The infiltrate in plaques and surrounding regions of the brain consists of T cells (mainly CD4+, some CD8+) and macrophages. How the autoimmune reaction is initiated is not understood; a role of viral infection (e.g., EBV) in activating self-reactive T cells has been proposed but remains controversial.

Experimental autoimmune encephalomyelitis is an animal model of MS in which demyelination and inflammation occur after immunization of animals with myelin proteins. Many of our concepts of MS pathogenesis have been derived from studies in this model. The experimental disorder can be passively transferred to unimmunized animals with T_H1 and T_H17 cells that recognize myelin antigens.

Based on the growing understanding of the pathogenesis of MS, therapies are being developed that modulate or inhibit T-cell responses and block the recruitment of T cells into the brain. A potential contribution of humoral immunity has also been suspected for a long time, based on the early observation of oligoclonal bands of immunoglobulin in CSF. The demonstration that treatment with agents that deplete B-cells decreases the incidence of demyelinating lesions in patients with MS lends support to this idea.

Figure 28-33 Multiple sclerosis. Section of fresh brain showing brown plaque around occipital horn of the lateral ventricle.

Figure 28-34 Multiple sclerosis (MS). Unstained regions of demyelination (MS plaques) around the fourth ventricle (Luxol fast blue periodic acid-Schiff stain for myelin).

MORPHOLOGY

MS is a white matter disease that is best appreciated in sections of the brain and spinal cord. In the fresh state, the lesions are firmer than the surrounding white matter (**sclerosis**) and appear as well circumscribed, somewhat depressed, glassy, gray-tan, irregularly shaped **plaques** (Fig. 28-33). The area of demyelination often has sharply defined borders, a feature best appreciated with stains for myelin (Fig. 28-34). The size of lesions varies considerably, from small foci that are only recognizable

Figure 28-35 Multiple sclerosis. **A**, Myelin-stained section shows the sharp edge of a demyelinated plaque and perivascular lymphocytic cuffs. **B**, The same lesion stained for axons shows relative preservation.

microscopically to confluent plaques that involve large portions of the deep white matter. Plaques commonly occur adjacent to the lateral ventricles, and are also frequent in the optic nerves and chiasm, brainstem, ascending and descending fiber tracts, cerebellum, and spinal cord. Plaques can also extend into gray matter, since myelinated fibers are present there as well.

Microscopically, in an **active plaque** there is ongoing myelin breakdown associated with abundant macrophages containing lipid-rich, PAS-positive debris. Lymphocytes and monocytes are also present, mostly as perivascular cuffs, especially at the outer edge of the lesion (Fig. 28-35A). Active lesions are often centered on small veins. Within a plaque there is relative preservation of axons (Fig. 28-35B) and depletion of oligodendrocytes. In time, astrocytes undergo reactive changes. As lesions become quiescent, the inflammatory cells slowly disappear. Within **inactive plaques**, little to no myelin is found, and there is a reduction in the number of oligodendrocyte nuclei; instead, astrocytic proliferation and gliosis are prominent. Axons in old gliotic plaques show severe demyelination and are also greatly diminished in number.

In some MS plaques (**shadow plaques**), the border between normal and affected white matter is not sharply circumscribed. In this type of lesion some abnormally thinned-out myelin sheaths can be demonstrated, especially at the outer edges. This phenomenon is most commonly interpreted as evidence of partial and incomplete remyelination by surviving oligodendrocytes. Abnormally myelinated fibers have also been observed at the edges of typical plaques. Although these histologic findings suggest a limited potential for remyelination in the CNS, the remaining axons within most MS plaques remain unmyelinated; studies aimed at promoting remyelination are an important focus of research.

Clinical Features. Although MS lesions can occur anywhere in the CNS and consequently may induce a wide range of clinical manifestations, certain patterns of neurologic symptoms and signs are more common. Unilateral visual impairment due to involvement of the optic nerve (*optic neuritis*, *retrobulbar neuritis*) is a frequent initial manifestation of MS. However, only a minority of individuals

(10% to 50%, depending on the population studied) with an episode of optic neuritis go on to develop MS (which requires multiple episodes to support the diagnosis). Involvement of the brainstem produces cranial nerve signs, ataxia, nystagmus, and internuclear ophthalmoplegia from interruption of the fibers of the medial longitudinal fasciculus. Spinal cord lesions give rise to motor and sensory impairment of trunk and limbs, spasticity, and difficulties with the voluntary control of bladder function.

Examination of the CSF in individuals with MS shows a mildly elevated protein level and in one third of cases a moderate pleocytosis. IgG levels in the CSF are increased and oligoclonal IgG bands are usually observed on immunoelectrophoresis; these are indicative of the presence of a small number of activated B cell clones, postulated to be self-reactive, in the CNS. Radiologic studies using magnetic resonance imaging have taken on a prominent role in assessing disease progression; these studies, when correlated with autopsy studies as well as clinical findings, indicate that some plaques may be clinically silent even in otherwise symptomatic patients.

Neuromyelitis Optica

Neuromyelitis optica (NMO) is a syndrome with synchronous (or near synchronous) bilateral optic neuritis and spinal cord demyelination. Once considered a variant of MS, it is now clear that it has distinct epidemiology and pathophysiology. NMO has an even greater skewing toward affecting women than MS, is more commonly associated with poor recovery from the first attack, and is characterized by the presence of antibodies against aquaporin-4. This protein is the major water channel of astrocytes, and areas of demyelination in NMO show loss of aquaporin-4. These antibodies injure astrocytes through complement-dependent mechanisms; they are not, however, capable of transferring disease in animal models. In NMO, white cells are common in the CSF, often including neutrophils. Within the damaged areas of white matter, there is typically necrosis, an inflammatory infiltrate including neutrophils, and vascular deposition of immunoglobulin and

complement. Therapies include approaches to reduce the antibody burden, either through plasmapheresis or depletion of B cells with anti-CD20 antibody.

Acute Disseminated Encephalomyelitis and Acute Necrotizing Hemorrhagic Encephalomyelitis

Acute disseminated encephalomyelitis is a diffuse, monophasic demyelinating disease that follows either a viral infection or, rarely, a viral immunization. Symptoms typically develop a week or two after the antecedent infection and include headache, lethargy, and coma rather than focal findings, as seen in MS. The clinical course is rapid, and as many as 20% of those affected die; the remaining patients recover completely.

Acute necrotizing hemorrhagic encephalomyelitis (also known as *acute hemorrhagic leukoencephalitis of Weston Hurst*) is a fulminant syndrome of CNS demyelination, typically affecting young adults and children. The illness is almost invariably preceded by a recent episode of upper respiratory infection, most often of unknown cause. The disease is fatal in many patients, with significant deficits present in most survivors.

MORPHOLOGY

In acute disseminated encephalomyelitis, cut sections of brain show only grayish discoloration around white-matter vessels. On microscopic examination, myelin loss with relative preservation of axons can be found throughout the white matter. In the early stages, neutrophils are found within the lesions; later, mononuclear infiltrates predominate. The breakdown of myelin is associated with the accumulation of lipid-laden macrophages. In contrast to MS, all lesions appear similar, consistent with the clinically monophasic nature of the disorder.

Acute necrotizing hemorrhagic encephalomyelitis shows histologic similarities with acute disseminated encephalomyelitis, including a perivenular distribution of demyelination throughout the CNS (sometimes producing confluent lesions). However, the damage is more severe and includes destruction of small blood vessels, disseminated necrosis of white and gray matter with acute hemorrhage, fibrin deposition, and abundant neutrophils. Scattered lymphocytes are seen in foci of demyelination.

The lesions of acute disseminated encephalomyelitis are similar to those induced by immunization of animals with myelin components or with early rabies vaccines that had been prepared from brains of infected animals. This has led to the suggestion that acute disseminated encephalomyelitis is an acute autoimmune reaction to myelin and that acute necrotizing hemorrhagic encephalomyelitis is a hyperacute variant, but inciting antigens have yet to be identified.

Central Pontine Myelinolysis

Central pontine myelinolysis is an acute disorder characterized by loss of myelin in the basis pontis and portions of the pontine tegmentum, typically in a roughly symmetric

pattern. It most commonly arises 2 to 6 days after rapid correction of hyponatremia, although it can also be associated with other severe electrolyte disturbances or osmolar imbalances and may also be known as *osmotic demyelination disorder*. It appears that rapid increases in osmolality damage oligodendrocytes through uncertain mechanisms. Inflammation is absent from the lesions, and neurons and axons are well preserved. Because of the synchronous onset of damage, all lesions appear to be at the same stage of myelin loss and reaction. Although originally described in the pons, extra-pontine lesions with similar appearance and apparent etiology may also occur.

While it can involve most parts of the brain, periventricular and subpial regions are spared, and it is extremely rare for the process to extend below the pontomedullary junction. The clinical presentation of pontine lesions is that of a rapidly evolving quadriplegia, which may be fatal or lead to severe long-term deficits, including the “locked-in” syndrome, in which patients are fully conscious yet unresponsive. It is imperative that hyponatremia be corrected slowly and carefully in order to prevent this tragic complication.

KEY CONCEPTS

Demyelinating Diseases

- Because of the critical role of myelin in nerve conduction, diseases of myelin can lead to widespread and severe neurologic deficits.
- Demyelinating diseases show evidence of breakdown and destruction of previously normal myelin, often by inflammatory processes. Secondary injury to axons typically emerges over time as well.
- Multiple sclerosis, an autoimmune demyelinating disease, is the most common disorder of myelin, affecting young adults. It often pursues a relapsing-remitting course, with eventual progressive accumulation of neurologic deficits.
- Other, less common forms of immune-mediated demyelination often follow infections and are more acute illnesses.

Neurodegenerative Diseases

Neurodegenerative diseases are disorders characterized by the progressive loss of neurons, typically affecting groups of neurons with functional relationships even if they are not immediately adjacent. Thus, different diseases tend to involve particular neural systems and therefore have relatively stereotypic presenting signs and symptoms. Recent genetic and molecular studies have shaped the current classification of neurodegenerative diseases, in part from the recognition that there are many shared features.

The pathologic process that is common across most of the neurodegenerative diseases is the accumulation of protein aggregates, which can be used as a morphologic hallmark of the disease (hence the occasional use of the term “proteinopathy”). Protein aggregates may arise because of mutations that alter the protein’s conformation or disrupt the pathways involved in processing or

clearance of the proteins. In other situations, there may be a subtle imbalance between protein synthesis and clearance (from genetic, environmental or stochastic factors) that allows gradual accumulation of proteins.

Regardless of how they arise, the protein aggregates typically are resistant to degradation, show aberrant localization within neurons, and elicit a stress response from the cell; in addition, they are often directly toxic to neurons. As the abnormal proteins aggregate, there is often both an associated “toxic” gain-of-function and a loss-of-function, as more and more protein is shunted into the aggregates rather than performing normal physiologic functions. Recently, it has also become clear that these aggregates are capable of behaving like prions; that is, aggregates derived from one cell are taken up by another, thereby giving rise to more aggregates. The data supporting this concept are largely derived from experimental animal studies, but some case studies of patients who died with Alzheimer disease suggest that the disease spreads from one site in the brain to another. However, in contrast to prion diseases, there is no evidence that these diseases are transmissible.

The protein aggregates are recognized histologically as inclusions, which often are the diagnostic hallmark of the disease. The basis for aggregation varies from one disease to another. It may be directly related to an intrinsic feature of a mutated protein (e.g., expanded polyglutamine repeats in Huntington disease), an intrinsic feature of a peptide derived from a larger precursor protein (e.g., A β in Alzheimer disease), or an unexplained alteration of a normal cellular protein (e.g., α -synuclein in sporadic Parkinson disease).

Neurodegenerative diseases differ both with respect to the anatomic localization of involved areas and in their specific cellular abnormalities (e.g., tangles, plaques, Lewy bodies). Accordingly, they can be considered for discussion using two approaches:

- *Symptomatic/anatomic*: based on the anatomic regions of the CNS that are primarily affected, which is typically reflected in the clinical symptoms (e.g., neocortical involvement resulting in cognitive impairment and dementia)
- *Pathologic*: based on the types of inclusions or abnormal structures observed (e.g., diseases with inclusions containing tau or containing synuclein)

Nevertheless, within the spectrum of degenerative diseases there is a remarkable overlap, both in terms of characteristic neurologic deficits, functional/anatomic distribution of lesions, and cellular pathology (Tables 28-3 and 28-4). For the sake of simplicity we will follow the time honored classification based on the original description of these diseases.

Alzheimer Disease

Alzheimer disease (AD) is the most common cause of dementia in older adults, with an increasing incidence as a function of age. The disease usually becomes clinically apparent as insidious impairment of higher cognitive functions. As the disease progresses, deficits in memory, visuospatial orientation, judgment, personality and language emerge. Typically over a course of 5 to 10 years, the affected individual becomes profoundly disabled, mute, and

Table 28-3 Features of the Major Neurodegenerative Diseases

Disease	Clinical pattern	Inclusions	Genetic causes
Alzheimer disease (AD)	Dementia	A β (plaques) Tau (tangles)	APP, PS1, PS2
Frontotemporal lobar degeneration (FTLD)	Behavioral changes, language disturbance	Tau TDP-43 FUS	Tau TDP-43, progranulin, C9orf72 FUS
Parkinson disease (PD)	Hypokinetic movement disorder	α -synuclein Tau	α -synuclein LRRK2
Progressive supranuclear palsy (PSP)	Parkinsonism with abnormal eye movements	Tau	Tau
Corticobasal degeneration (CBD)	Parkinsonism with asymmetric movement disorder	Tau	
Multiple system atrophy (MSA)	Parkinsonism, cerebellar ataxia, autonomic failure	α -synuclein	
Huntington disease (HD)	Hyperkinetic movement disorder	Huntington (polyglutamine)	Htt
Spinocerebellar ataxias (SCA1, 2, 3, 6, 7, 17 and DRPLA)	Cerebellar ataxia	Various proteins (polyglutamine containing)	Multiple loci
Amyotrophic lateral sclerosis (ALS)	Weakness with upper and lower motor neurons signs	SOD1 TDP-43 FUS	SOD1 TDP-43, C9orf72 FUS
Spinal bulbar muscular atrophy (SBMA)	Lower motor neuron weakness, diminished androgen	Androgen receptor (polyglutamine containing)	Androgen receptor

Table 28-4 Relationship Between Proteins and Neurodegenerative Diseases

Protein	Diseases with Inclusions
A β	Alzheimer disease
Tau	Alzheimer disease Frontotemporal lobar degeneration Parkinson disease (with <i>LRRK2</i> mutations) Progressive supranuclear palsy Corticobasal degeneration
TPD-43	Frontotemporal lobar degeneration Amyotrophic lateral sclerosis
FUS	Frontotemporal lobar degeneration Amyotrophic lateral sclerosis
α -synuclein	Parkinson disease Multiple system atrophy
Polyglutamine aggregates (distinct proteins per disease)	Huntington disease Some forms of spinocerebellar ataxia Spinal bulbar muscular atrophy

immobile. Patients rarely become symptomatic before 50 years of age; the incidence of the disease increases with age, and the prevalence roughly doubles every 5 years, starting from a level of 1% for the 60- to 64-year-old population and reaching 40% or more for the 85- to 89-year-old cohort. This progressive increase in the incidence with increasing age has given rise to major medical, social, and economic concerns in countries with aging populations. About 5% to 10% of cases are familial forms of AD; these have provided important insight into the pathogenesis of the more common sporadic form of the disease. While pathologic examination of brain tissue remains necessary for the definitive diagnosis of AD, the combination of clinical assessment and modern radiologic methods allows accurate diagnosis in 80% to 90% of cases as confirmed at autopsy.

Molecular Genetics and Pathogenesis. The fundamental abnormality in AD is the accumulation of two proteins (A β and tau) in specific brain regions, likely as a result of excessive production and defective removal (Fig. 28-36). The two pathologic hallmarks of AD, particularly evident in the end stages of the illness, are *plaques* and *tangles*. Plaques are deposits of aggregated A β peptides in the neuropil, while tangles are aggregates of the microtubule binding protein tau, which develop intracellularly and then persist extracellularly after neuronal death. Both plaques and tangles appear to contribute to the neural dysfunction, and the interplay between the processes that lead to the accumulation of these abnormal aggregates is a critically important aspect of AD pathogenesis that has yet to be unraveled.

Several lines of evidence strongly support a model in which **A β generation is the critical initiating event for the development of AD**. First, there are diseases in which tau deposits appear, such as frontotemporal lobar degenerations, progressive supranuclear palsy, and corticobasal degeneration (discussed later), but A β deposits do not ensue. This suggests that having abnormal deposits of tau in the brain is not a sufficient stimulus to elicit deposition of A β . Additionally, multiple lines of genetic evidence

point to the likely importance of altered A β metabolism; mutations in the protein from which A β is derived (APP) cause familial AD, as does increased copy number (either from small duplications or from trisomy 21) of the *APP* gene. Furthermore, point mutations in proteins that are part of the protease complexes that generate A β from APP also give rise to AD. In contrast, mutations in the gene for tau do not give rise to AD but rather cause frontotemporal lobar degenerations (discussed later).

The pathogenesis of AD involves not only A β and tau but several other genetic and host factors.

- **Role of A β .** Amyloid precursor protein (APP) is a cell surface protein with a single transmembrane domain that may function as a receptor, possibly for prion protein (PrP^{Sc}) among other ligands. The A β portion of the protein extends from the extracellular region into the transmembrane domain (Fig. 28-36). Processing of APP begins with cleavage in the extracellular domain, followed by an intramembranous cleavage. There are two potential pathways, determined by the type of initial proteolytic event. If the first cut occurs at the α -secretase site within the A β sequence, then A β is not generated (the non-amyloidogenic pathway). This mostly occurs at the cell surface, since the various proteases with α -secretase activity are involved in the shedding of surface proteins. Surface APP can also be endocytosed and may undergo cleavage by β -secretase, which cuts at the N-terminal region of the A β sequence (the amyloidogenic pathway). Following cleavage of APP at either of these sites, the γ -secretase complex performs an intramembranous cleavage. When paired with a first cut by α -secretase, it produces a soluble fragment, but when paired with β -secretase cleavage, it generates A β . The variation in peptide length (A β_{40} vs A β_{42}) arises from alterations in the exact location of the γ -secretase cleavage. The γ -secretase complex—containing presenilin, nicastrin, pen-2, and aph-1—is also responsible for processing of Notch receptors as well as many other membrane proteins. Once generated, A β is highly prone to aggregation—first into small oligomers (which may be the toxic form responsible for neuronal dysfunction), and eventually into large aggregates and fibrils.

As mentioned earlier, part of the support for the central role of A β generation as a critical step for at least initiation of AD pathogenesis comes from familial AD. The gene encoding APP, on chromosome 21, lies in the Down syndrome region; AD pathology is an eventual feature of the cognitive impairment of these individuals. Histologic findings appear in the second and third decades followed by neurologic decline about 20 years later. A similar gene dosage effect is produced by localized chromosome 21 duplications that span the *APP* locus in some patients with familial AD. Point mutations in APP are another cause of familial AD. Some mutations lie near the β -secretase and γ -secretase cleavage sites, and others sit in the A β sequence and increase its propensity to aggregate. The two loci identified as causes of the majority of early-onset familial AD encode the two presenilins (PS1 on chromosome 14 and PS2 on chromosome 1). These mutations lead to a gain of function, such that the γ -secretase complex generates increased amounts of A β , particularly A β_{42} .

Figure 28-36 Protein aggregation in Alzheimer disease. Amyloid precursor protein cleavage by α -secretase and γ -secretase produces a harmless soluble peptide, whereas amyloid precursor protein cleavage by β -amyloid-converting enzyme (BACE) and γ -secretase releases $A\beta$ peptides, which form pathogenic aggregates and contribute to the characteristic plaques and tangles of Alzheimer disease.

- **Role of tau.** Because neurofibrillary tangles contain the tau protein, there has been much interest in the role of this protein in AD. Tau is a microtubule-associated protein present in axons in association with the microtubular network. With the development of tangles in AD, it shifts to a somatic-dendritic distribution, becomes hyperphosphorylated, and loses the ability to bind to microtubules. The formation of tangles is an important component of AD, and the increased tangle burden in the brain over the course of the illness eventually appears to become independent of the $A\beta$. The mechanism of tangle injury to neurons remains poorly understood but two possible pathways have been suggested. First, the aggregates of tau protein elicit a stress response and second, the microtubule stabilizing function of tau protein is lost.
- **Other genetic risk factors.** The genetic locus on chromosome 19 that encodes apolipoprotein E (ApoE) has a strong influence on the risk of developing AD. Three alleles exist ($\epsilon 2$, $\epsilon 3$, and $\epsilon 4$) based on two amino acid

polymorphisms. The dosage of the $\epsilon 4$ allele increases the risk of AD and lowers the age of onset of the disease, such that individuals with the $\epsilon 4$ allele are overrepresented in populations of patients with AD. This ApoE isoform promotes $A\beta$ generation and deposition, although the mechanisms have not been established. Overall, this locus has been estimated to convey about a quarter of the risk for development of late-onset AD. Genome-wide association studies have identified several other loci that contribute to the risk of AD. The connection between these genetic loci and the pathogenesis of AD remains to be explored.

- **Role of inflammation.** Both small aggregates and larger deposits of $A\beta$ elicit an inflammatory response from microglia and astrocytes. This response probably assists in the clearance of the aggregated peptide, but may also stimulate the secretion of mediators that cause damage. Additional consequences of the activation of these inflammatory cascades may include alterations in tau phosphorylation, along with oxidative injury to the neurons.

- **Basis for cognitive impairment.** While there remains disagreement regarding the best correlate of dementia in individuals with AD, it is clear that the presence of a large burden of plaques and tangles is highly associated with severe cognitive dysfunction. The number of neurofibrillary tangles correlates better with the degree of dementia than does the number of neuritic plaques. Biochemical markers that have been correlated with the degree of dementia include loss of choline acetyltransferase, synaptophysin immunoreactivity, and amyloid burden.
- **Biomarkers.** Among the more important recent developments in the understanding of AD is the discovery of possible biomarkers. These draw on the understanding of the biologic processes discussed above. It is now possible to demonstrate A β deposition in the brain through imaging methods that rely on ¹⁸F-labeled amyloid-binding compounds. The experience to date suggests that this approach can identify asymptomatic patients who are at high risk for developing AD. Additional evidence of neuronal degeneration associated with AD-related pathologic processes includes the presence of increased phosphorylated tau and reduced A β in the CSF. Together, these biomarkers have allowed for the identification of preclinical stages of AD, well in advance of the development of dementia or other clinical signs and symptoms. This in turn has enabled the focus of pharmacologic trials to shift towards individuals in the earliest stages of the illness, in whom it is hoped interventions will slow or prevent disease progression and limit disability.

Figure 28-37 Alzheimer disease with cortical atrophy most evident on the right, where meninges have been removed. (Courtesy the late Dr. E. P. Richardson, Jr., Massachusetts General Hospital, Boston, Mass.)

MORPHOLOGY

Grossly, the brain shows a variable degree of **cortical atrophy** marked by widening of the cerebral sulci that is most pronounced in the frontal, temporal, and parietal lobes (Fig. 28-37). With significant atrophy, there is compensatory ventricular enlargement (hydrocephalus ex vacuo) secondary to reduced brain volume. Structures of the medial temporal lobe, including hippocampus, entorhinal cortex and amygdala, are involved early in the course and are usually severely atrophied in the later stages. The major microscopic abnormalities of AD are **neuritic (senile) plaques** and **neurofibrillary tangles**. There is progressive, eventually severe, neuronal loss and reactive gliosis in the same regions that bear the burden of plaques and tangles.

Neuritic plaques are focal, spherical collections of dilated, tortuous, neuritic processes (dystrophic neurites) often around a central amyloid core, which may be surrounded by a clear halo (Fig. 28-38A). Neuritic plaques range in size from 20 to 200 μ m in diameter; microglial cells and reactive astrocytes are present at their periphery. Plaques are found in the hippocampus, amygdala, and neocortex, although there is usually relative sparing of primary motor and sensory cortices (this also applies to neurofibrillary tangles). The amyloid core, which can be stained by Congo red, contains several abnormal proteins. The dominant component of the amyloid plaque core is A β , a peptide derived by proteolytic cleavage of amyloid precursor protein (APP) (Fig. 28-38 and see Fig. 28-36). The two dominant species of A β , called A β ₄₀ and A β ₄₂, have the same N-terminus and differ in length by two amino acids at the C-terminus. Other

proteins are present in plaques in lesser abundance, including components of the complement cascade, proinflammatory cytokines, α_1 -antichymotrypsin, and apolipoproteins. In some cases, there is deposition of A β peptides with staining characteristics of amyloid in the absence of the surrounding neuritic processes. These lesions, termed **diffuse plaques**, are found mainly in superficial portions of cerebral cortex, the basal ganglia, and cerebellar cortex. Diffuse plaques are believed to be an early stage of plaque development, based on studies of individuals with trisomy 21. While neuritic plaques contain both A β ₄₀ and A β ₄₂, diffuse plaques are predominantly made up of A β ₄₂.

Neurofibrillary tangles are tau-containing bundles of filaments in the cytoplasm of the neurons that displace or encircle the nucleus. In pyramidal neurons, they often have an elongated “flame” shape; in rounder cells, the basket weave of fibers around the nucleus takes on a rounded contour (“globose” tangles). Neurofibrillary tangles are visible as basophilic fibrillary structures with H & E staining (Fig. 28-38C) but are demonstrated much more clearly by silver (Bielschowsky) staining (Fig. 28-38D) and with immunohistochemistry directed against tau (Fig. 28-38E). They are commonly found in cortical neurons, especially in the entorhinal cortex, as well as in other sites such as pyramidal cells of the hippocampus, the amygdala, the basal forebrain, and the raphe nuclei. Neurofibrillary tangles are insoluble and apparently resistant to clearance in vivo, thus remaining visible in tissue sections as “ghost” or “tombstone” tangles long after the death of the parent neuron. Ultrastructurally, neurofibrillary tangles are composed predominantly of paired helical filaments along with some straight filaments that appear to have a similar composition. Aggregated tau is also present in dystrophic neurites that form the outer portions of neuritic plaques and in axons coursing through the affected gray matter as neuropil threads. Tangles are not specific to AD, being found in other diseases as well.

In addition to the diagnostic features of plaques and tangles, several other pathologic findings are seen in the setting of AD.

Figure 28-38 Alzheimer disease. **A**, Plaques with dystrophic neurites surrounding amyloid cores are visible (arrows). **B**, Plaque core and surrounding neuropil are immunoreactive for A β . **C**, Neurofibrillary tangle is present within one neuron, and several extracellular tangles are also present (arrows). **D**, Silver stain showing a neurofibrillary tangle within the neuronal cytoplasm. **E**, Tangle (upper left) and neurites around a plaque (lower right) contain tau, demonstrated by immunohistochemistry.

Cerebral amyloid angiopathy is an almost invariable accompaniment of AD; however, it can also be found in brains of individuals without AD (Fig. 28-18B). Vascular amyloid is predominantly A β ₄₀, as is also the case when cerebral amyloid angiopathy occurs without AD.

While abundant burdens of plaques and tangles characterize the end-stage of AD, in which affected individuals are fully demented, it is clear that these histologic changes first appear well in advance of clinical symptoms. In order to provide a correlation between neuropathologic findings and clinical symptomatology, the most recent recommendations for describing these lesions consider all deposition of A β in brain parenchyma to be a form of Alzheimer disease neuropathologic change. The scheme then generates a histopathologic score based on the distribution of A β deposits, plaques and tangles, which is used to predict the likelihood of an individual being cognitively impaired, drawing on population studies.

Clinical Features. The progression of AD is slow but relentless, with a symptomatic course often running more than 10 years. Initial symptoms are forgetfulness and other memory disturbances; with progression of the disease other symptoms emerge, including language deficits, loss of mathematical skills, and loss of learned motor skills. In the final stages of AD, affected individuals may become incontinent, mute, and unable to walk. Intercurrent disease, often pneumonia, is usually the terminal event. Current clinical trials are focused on treating subjects in early, preclinical stages of the illness, using strategies that include clearing A β from the brain through immunologic approaches, disruption of the generation of A β with pharmacologic agents that target either γ -secretase or BACE (β -secretase 1), as well as approaches aimed at preventing alterations in tau.

Frontotemporal Lobar Degenerations (FTLDs)

FTLDs are a heterogeneous set of disorders associated with focal degeneration of frontal and/or temporal lobes. They are distinguished from AD by the fact that alterations in personality, behavior and language (aphasias) precede memory loss. Global dementia does occur with progressive disease. A subset of patients also develop extrapyramidal motor loss. Several clinical variants have been described based on whether the behavioral change or aphasias dominate but they have overlapping features. FTLDs are one of the more common causes of early onset dementia and occur at the same frequency as Alzheimer disease in those under the age of 65 years. Commonly referred to in the clinical setting as *frontotemporal dementia* (FTD), the preferred pathologic terminology highlights the lobar degeneration rather than the clinical symptom of dementia.

As with many neurodegenerative diseases, FTLD is associated with cellular inclusions of specific proteins. The two most common patterns are those with tau-containing inclusions (FTLD-tau) and those with TDP43-containing inclusions (FTLD-TDP). Within each of these groups, there are heritable forms as well as sporadic cases. There is no fixed relationship between the clinical subtypes of FTLD and the type of neuronal inclusions.

FTLD-Tau

These are forms of FTLD in which the affected cortical regions demonstrate progressive neuronal loss and reactive gliosis, along with the presence of tau-containing inclusions in the cytoplasm of neurons. While Alzheimer disease is characterized by the combination of A β and tau deposition, FTLD-tau shows only tau aggregation and accumulation. In some cases FTLD-tau inclusions resemble the tangles seen in Alzheimer disease while in other forms of the disease there are smooth contoured inclusions (Pick bodies). The distinctive inclusions, as well as the severe atrophy with stereotypic lobar restriction, are the hallmarks of *Pick disease* within the category of FTLD-tau.

Molecular Genetics and Pathogenesis. FTLD-tau may be associated with mutations affecting tau, or may arise sporadically in the absence of tau mutations. As mentioned earlier, tau is a phosphoprotein that interacts with microtubules through specific binding domains, with superimposed regulation through a range of potential phosphorylation sites. There is an inverse relationship between the degree of phosphorylation and the ability of tau to bind to microtubules. Tau, particularly when phosphorylated, also has a propensity to aggregate. Tau also exists as a complex series of isoforms that are encoded by different mRNA splice variants. The balance between these isoforms appears to be critical for normal tau function in neurons, and disturbances in isoform ratio may also provoke tau aggregation.

Two different types of tau mutations are described. Some missense point mutations effect tau phosphorylation, tipping the balance from active microtubule binding towards aggregating forms. Other mutations include point mutations that affect splicing; many of these are intronic and alter the loop-stem structures recognized by the spliceosome. The resulting change in isoform ratio is thought to lead to neuronal dysfunction and, as discussed above, may also enhance tau aggregation.

It remains unclear how abnormal tau injures neurons, although there appears to be both a loss-of-function component, as aggregation depletes the neurons of tau, and a toxic gain-of-function component from the presence of aberrantly hyperphosphorylated aggregated protein in the neuron.

MORPHOLOGY

There is atrophy of frontal and temporal lobes to variable extent and severity. The pattern of atrophy can often be predicted in part by the clinical symptomatology. The atrophic regions of cortex are marked by neuronal loss, gliosis, and the presence of tau-containing neurofibrillary tangles (Fig. 28-39A). These tangles may contain a variety of tau isoforms. Nigral degeneration may also occur. Inclusions can also be found in glial cells in some forms of the disease.

In Pick disease, the brain invariably shows a pronounced, frequently asymmetric, atrophy of the frontal and temporal lobes with conspicuous sparing of the posterior two thirds of the superior temporal gyrus and only rare involvement of either the parietal or occipital lobe. The atrophy can be severe, reducing the gyri to a wafer-thin (“knife-edge”) appearance.

Figure 28-39 Frontotemporal lobar degenerations (FTLDs). **A**, FTLD-tau. A tangle is present along with numerous tau-containing neurites. **B**, Pick disease. Pick bodies are round, homogeneous neuronal cytoplasmic inclusions that stain intensely with silver stains. **C**, FTLD-TDP. Cytoplasmic inclusions containing TDP-43 are seen in association with loss of normal nuclear immunoreactivity. **D**, FTLD-TDP. With progranulin mutations, the TDP-43-containing inclusions are commonly intranuclear.

Microscopically, neuronal loss is most severe in the outer three layers of the cortex. Some of the surviving neurons show a characteristic swelling (**Pick cells**), while others contain **Pick bodies**, which are cytoplasmic, round to oval, filamentous inclusions that are only weakly basophilic but stain strongly with silver methods and contain 3R tau (Fig. 28-39B).

FTLD-TDP

Some individuals with clinically diagnosed FTLD and macroscopic changes of relatively localized cortical atrophy (the 'lobar degeneration' of the term) have inclusions that contain TDP-43, an RNA-binding protein, and do not contain tau. Individuals with this type of neurodegeneration may present with either behavioral problems or language complaints, just as with FTLD-tau.

Molecular Genetics and Pathogenesis. There are three well-established genetic forms of FLTD-TDP, as well as sporadic forms. Three different mutations have been found in the inherited forms of FTLD-TDP.

- The most common genetic form of familial FTLD-TDP is the result of an expansion of a hexanucleotide repeat in the 5' UTR of C9orf72 (a gene encoding a protein of unknown function). The spectrum of disease associated with C9orf72 expansion also includes amyotrophic lateral sclerosis (ALS). How the repeat expansion results in formation of aggregates of TDP-43 is a mystery at present.
- Mutations in the gene encoding the TDP-43 protein are less common in FTLD-TDP and also occur in some familial cases of ALS. TDP-43 is an RNA-binding protein with roles in RNA processing as well as in the formation of stress granules. Both loss of function and gain of

function with toxic effects may contribute to the phenotype observed in these patients.

- A third genetic form of FTLT-DTP is the result of mutations in the gene encoding progranulin. In contrast to TDP-43 and C9orf72 mutations, these have not been linked to ALS. Progranulin mutations cause loss of function and the disease mechanism is believed to stem from deficient progranulin activity. Progranulin is a secreted protein expressed in glia and neurons that is cleaved into multiple small peptides. These peptides have been implicated in regulation of inflammation in the brain, but the link between this activity and the accumulation of TDP-43 containing inclusions in FTLT is currently obscure.

MORPHOLOGY

The gross appearance is similar to the other forms of FTLT, with atrophy of frontal and temporal lobes of variable extent and severity. This is accompanied by varying degrees of neuronal loss and gliosis. Normally, TDP-43 is found diffusely in the nucleus; with disease, there is loss of this staining and formation of inclusions (Fig. 28-39C). These may be found in the cell body (neuronal cytoplasmic inclusions or NCI), in the nucleus (neuronal intranuclear inclusions or NII), or in neurites. In the inclusions, TDP-43 is phosphorylated and ubiquitinated. Inclusions are most abundant in the frontal and temporal cortex, in the striatum and in the dentate gyrus of the hippocampus. There is an extremely strong correlation between the presence of needle-like NII's and progranulin mutations (Fig. 28-39D).

There are forms of FTLT in which there are neither tau- nor TDP-containing inclusions. While these are infrequent, the underlying genetic causes show overlap with the pathways identified as contributors to pathogenesis of FTLT-TPD. Mutations in the *FUS* (fused in sarcoma) gene may cause either FTLT or ALS, and *FUS* is another RNA-binding protein that may be involved in formation of stress granules.

Parkinson Disease (PD)

PD is a neurodegenerative disease marked by a prominent hypokinetic movement disorder that is caused by loss of dopaminergic neurons from the substantia nigra. The clinical syndrome of *parkinsonism* combines diminished facial expression (often termed *masked facies*), stooped posture, slowing of voluntary movement, festinating gait (progressively shortened, accelerated steps), rigidity, and a "pill-rolling" tremor. **This type of motor disturbance is seen in a number of conditions that have in common damage to the nigrostriatal dopaminergic system.** Several neurodegenerative diseases include symptoms of parkinsonism. In addition, similar symptoms may be pharmacologically induced by dopaminergic antagonists or by toxins that selectively damage the dopaminergic system. The principal degenerative disease that involves the nigrostriatal system is PD. Also discussed later are other rare diseases that have parkinsonism as part of the clinical presentation.

The presumptive diagnosis of PD can be based on the presence of the central triad of parkinsonism—tremor,

rigidity, and bradykinesia—in the absence of a toxic or other known underlying etiology. This impression is confirmed by symptomatic response to L-DOPA replacement therapy. Although the diagnosis of PD is based in large part on the presence of the motor symptoms, which reflect the decreased dopaminergic innervation of the striatum, there is clear evidence that the disease is not restricted to dopaminergic neurons or to the basal ganglia; in fact, there is evidence from pathologic investigations that the degeneration of the substantia nigra (which results in the motor symptoms) represents a mid-stage in a progressive disease that begins lower in the brainstem and can eventually progress to involve the cerebral cortex, leading to cognitive impairment (see [Dementia with Lewy Bodies](#), later).

The dopaminergic neurons of the substantia nigra project to the striatum, and their degeneration in PD is associated with a reduction in the striatal dopamine content. The severity of the motor syndrome is proportional to the dopamine deficiency, which can, at least in part, be corrected by replacement therapy with L-DOPA (the immediate precursor of dopamine). Treatment does not, however, reverse the morphologic changes or arrest the progress of the disease; moreover, with progression, drug therapy tends to become less effective and symptoms become more difficult to manage. Deep brain stimulation has emerged over the past decade as a therapy for the motor symptoms of PD. In addition, the well-characterized neural and biochemical deficits in PD have also provided a rationale for early therapeutic trials of neural transplantation and gene therapy.

An acute parkinsonian syndrome and destruction of neurons in the substantia nigra follows exposure to MPTP (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine), discovered as a contaminant in illicitly synthesized batches of the opioid meperidine. This toxin has been used to generate animal models of PD that are being exploited to test new therapies. Epidemiologic evidence has also suggested that pesticide exposure is a risk factor for PD, while caffeine and nicotine may be protective.

Molecular Genetics and Pathogenesis. PD is associated with protein accumulation and aggregation, mitochondrial abnormalities, and neuronal loss in the substantia nigra and elsewhere in the brain. While most PD is sporadic, a series of genetic causes have been identified that shed light on its pathogenesis.

- The first gene to be identified as a cause of autosomal dominant PD encodes α -synuclein, an abundant lipid-binding protein normally associated with synapses. This protein was then demonstrated to be a major component of the Lewy body, which is the diagnostic hallmark of PD. Mutations in α -synuclein are rare; they take the form of point mutations and amplifications of the region of chromosome 4q21 that contains the gene. The occurrence of disease caused by changes in gene copy number implies a gene dosage effect, and suggests that polymorphisms in the α -synuclein promoter that alter its expression may influence the risk of PD. Like A β in Alzheimer disease, α -synuclein has been demonstrated to form aggregates; of these, small oligomers appear to be the most toxic to neurons. There is also evidence that

aggregates can be released from one neuron and taken up by another, suggesting a capacity for a prion-like pattern of spread within the brain. Consistent with this idea, α -synuclein containing aggregates (in the form of Lewy bodies and Lewy neurites) first appear in the medulla and then in contiguous areas of the brain, ascending through the brainstem and extending into limbic structures and finally the neocortex.

- *Mitochondrial dysfunction* has been implicated as a contributing factor for PD based on autosomal recessive forms of PD that are caused by mutations in genes that encode the proteins DJ-1, PINK1, and parkin. DJ-1 has multiple cellular roles, including acting as a transcriptional regulator, but in settings of oxidative stress it can relocate to the mitochondria and have cytoprotective effects. PINK1 is a kinase that is degraded in the mitochondria under normal circumstances; with mitochondrial dysfunction, it recruits parkin, which is an E3 ubiquitin ligase. Under normal circumstances, the combination of PINK1 and parkin results in clearance of dysfunctional mitochondria through mitophagy. Intriguingly, levels of mitochondrial complex I, a component of the oxidative phosphorylation cascade, are reduced in the brains of patients with sporadic PD.
- Mutations in the gene encoding *LRRK2* (leucine-rich repeat kinase 2) are a more common cause of autosomal dominant PD and are found in some sporadic cases of the disease. LRRK2 is a cytoplasmic kinase. Several of the pathogenic mutations increase the kinase activity of LRRK2, suggesting that gains in LRRK2 function—either hyperphosphorylation of normal targets or emergence of novel targets—might contribute to the development of PD.

MORPHOLOGY

A characteristic finding in PD is **pallor of the substantia nigra** (compare Fig. 28-40A and B) and locus ceruleus, which is due to loss of the pigmented, catecholaminergic neurons in these regions. Lewy bodies (Fig. 28-40C) may be found in some of the remaining neurons. These are single or multiple cytoplasmic, eosinophilic, round to elongated inclusions that often have a dense core surrounded by a pale halo. Ultrastructurally, Lewy bodies are composed of fine filaments, densely packed in the core but loose at the rim; these filaments are composed of α -synuclein. Lewy bodies may also be found in the cholinergic cells of the basal nucleus of Meynert, which is depleted of neurons (particularly in patients with abnormal cognitive function), as well as in other brainstem nuclei including the locus ceruleus and the dorsal motor nucleus of the vagus. Areas of neuronal loss also typically show gliosis. Lewy neurites are dystrophic processes that contain aggregated α -synuclein.

Dementia with Lewy Bodies

About 10% to 15% of individuals with PD develop dementia, particularly with advancing age. Characteristic features of this disorder include a fluctuating course, hallucinations, and prominent frontal signs. While some affected individuals have pathologic evidence of Alzheimer disease (or, less frequently, other degenerative diseases associated with cognitive changes) in combination with PD, in others the

Figure 28-40 Parkinson disease. **A**, Normal substantia nigra. **B**, Depigmented substantia nigra in idiopathic Parkinson disease. **C**, Lewy body in a substantia nigra neuron, staining bright pink (arrow).

most prominent histologic correlate is the presence of widespread Lewy bodies in neurons in the cortex and brainstem. As already mentioned, dementia with Lewy bodies may represent an advanced stage of PD in which protein aggregates appear to have “spread”, possibly through propagation of misfolded proteins, to neurons in the cerebral cortex.

Cortical Lewy bodies are less distinct than those observed in the brainstem but are also composed

predominantly of α -synuclein. Immunohistochemical staining for α -synuclein also reveals the presence of abnormal neurites, that contain aggregated protein—called *Lewy neurites*, even though Lewy never saw them! In this setting, the pathologic findings typically include depigmentation of the substantia nigra and locus ceruleus, paired with relative preservation of the cortex, hippocampus, and amygdala. The burden of cortical Lewy bodies is usually extremely low, and the mechanism by which this disease wreaks havoc on cognitive functioning is not clear. There is evidence that the burden of oligomeric α -synuclein in the cortex is more important than the Lewy bodies, even though neuropathologists use the latter as the diagnostic hallmark of the disease.

Atypical Parkinsonism Syndromes

As discussed earlier, the clinical syndrome of parkinsonism, with bradykinesia and rigidity, reflects dysfunction of the extrapyramidal circuitry, particularly the dopaminergic nigrostriatal projection. In addition to the forms of Parkinson disease already discussed, there are a variety of disorders which include parkinsonism as a component of the symptoms. These diseases, in general, are minimally responsive to treatment with L-DOPA; they are also distinguished from Parkinson disease through the presence of additional signs and symptoms. For these reasons, they are considered to be “atypical parkinsonism syndromes,” with the alternative terminology of “Parkinson-plus syndromes” applied by others. In addition to progressive supranuclear palsy and corticobasal degeneration, which are both tauopathies, another synucleinopathy (multisystem atrophy, discussed separately later) is also in this group of disorders.

Progressive Supranuclear Palsy (PSP)

PSP is a tauopathy in that affected individuals commonly develop progressive truncal rigidity, disequilibrium with frequent falls and difficulty with voluntary eye movements. Other symptoms that are frequently observed include nuchal dystonia, pseudobulbar palsy and a mild progressive dementia. The onset is usually between the fifth and seventh decades, with males affected approximately twice as frequently as females. The disease is often fatal within 5 to 7 years of onset.

Although the pathologic hallmark of PSP is the presence of tau-containing inclusions in neurons and glia, causative mutations in the tau gene have been identified in only a few cases. However, risk for sporadic PSP is linked to single nucleotide polymorphisms that map near the tau gene locus. Other risk alleles have been identified through genome-wide association studies, but the mechanisms by which they influence development of PSP are still unclear.

MORPHOLOGY

There is widespread neuronal loss in the globus pallidus, subthalamic nucleus, substantia nigra, colliculi, periaqueductal gray matter, and dentate nucleus of the cerebellum. Globose fibrillary tangles are found in these affected regions, in neurons as well as in glia. Ultrastructural analysis reveals 15-nm straight filaments that are composed of 4R tau.

Corticobasal Degeneration (CBD)

CBD is a progressive tauopathy that is most often characterized by extrapyramidal rigidity, asymmetric motor disturbances (jerking movements of limbs), and impaired higher cortical function (typically in the form of apraxias). As with PSP, cognitive decline may occur, typically later in the illness. The same tau variant linked to PSP is also highly associated with CBD. Overall, CBD and PSP share many clinical and pathologic features; in general, with PSP there is a greater burden of tau-containing lesions in brainstem and deep gray matter, while in CBD the balance is shifted more toward cerebral cortical involvement.

MORPHOLOGY

The brain shows cortical atrophy, mainly of the motor, premotor, and anterior parietal lobes. In affected regions of cortex there is severe loss of neurons, gliosis, and “**ballooned**” neurons (neuronal achromasia). Tau immunoreactivity has been found in astrocytes (“tufted astrocytes”), oligodendrocytes (“coiled bodies”), basal ganglionic neurons, and, variably, cortical neurons. Clusters of tau-positive processes around astrocytes (“astrocytic plaques”) and the presence of tau-positive threads in gray and white matter may be the most specific pathologic findings of CBD. The substantia nigra and locus ceruleus show loss of pigmented neurons, neuronal achromasia, and tangles.

Multiple System Atrophy (MSA)

MSA is a sporadic disorder that affects several functional systems in the brain and is characterized by cytoplasmic inclusions of α -synuclein in oligodendrocytes. Unlike the other degenerative diseases, the primary pathologic hallmark of MSA is observed in glial cells and is commonly associated with degeneration of white matter tracts. In addition, there is accompanying neuronal degeneration but typically without the presence of inclusions. The “multiple” in the term *multiple system atrophy* refers to three distinct neuroanatomic circuits that are commonly involved: the striatonigral circuit (leading to parkinsonism), olivopontocerebellar circuit (leading to ataxia), and the autonomic nervous system including the central elements (leading to autonomic dysfunction, with orthostatic hypotension as a prominent component). In a given individual, one of these components may predominate at the onset of the illness, but typically the other systems are affected as MSA progresses.

Pathogenesis. As in Parkinson disease, α -synuclein is the major component of the inclusions. MSA is a sporadic disease and no mutations in the gene encoding α -synuclein have identified as being causative; nonetheless, there does appear to be a set of polymorphisms near this gene that confer increased risk. The relationship between glial cytoplasmic inclusions and disease is supported by the observation that the burden of inclusions increases as the disease progresses, although inclusions eventually disappear as cells die in the final stages. It appears that glial cytoplasmic inclusions can occur in the absence of neuronal loss, suggesting that they are the primary pathologic event; for

example, glial cytoplasmic inclusions are consistently observed in the white matter projecting to and from the motor cortex. The origin of the α -synuclein in oligodendrocytes remains perplexing, since this is a neuronal protein associated with synaptic vesicles. Several studies have shown that there is no up-regulation of α -synuclein expression in white matter or in oligodendrocytes in MSA. It has been suggested that oligodendrocytes may acquire α -synuclein aggregates secondarily from injured or dying neurons. When α -synuclein is present in oligodendrocytes, they become more sensitive to oxidative stress and show impaired interaction with the extracellular matrix.

MORPHOLOGY

The pathologic findings in MSA match the clinical presentation in any particular case. In cerebellar forms there is atrophy of the cerebellum, including the cerebellar peduncles, pons (especially the basis pontis, Fig. 28-41A), and medulla (especially the inferior olive), while in parkinsonian forms the atrophy involves both the substantia nigra and striatum (especially putamen). Autonomic symptoms are related to cell loss from the catecholaminergic nuclei of the medulla and the intermediolateral cell column of the spinal cord. Atrophic brain regions show evidence of neuronal loss as well as variable numbers of neuronal cytoplasmic and nuclear inclusions.

The diagnostic glial cytoplasmic inclusions were originally demonstrated in oligodendrocytes with silver impregnation methods and contain α -synuclein as well as ubiquitin (Fig. 28-41B). The inclusions are ultrastructurally distinct from those found in other neurodegenerative diseases and are composed primarily of 20- to 40-nm tubules. Similar inclusions may also be found in the cytoplasm of neurons, sometimes in neuronal and glial nuclei, and in axons.

Huntington Disease

Huntington disease (HD) is an autosomal dominant disease characterized by progressive movement disorders and dementia, caused by degeneration of striatal neurons. Jerky, hyperkinetic, sometimes dystonic movements involving all parts of the body (chorea) are characteristic;

affected individuals may later develop bradykinesia and rigidity. The disease is relentlessly progressive and uniformly fatal, with an average course of about 15 years.

Molecular Genetics and Pathogenesis. HD is the prototype of the polyglutamine trinucleotide repeat expansion diseases (Chapter 5). The gene for HD, *HTT*, located on chromosome 4p16.3, encodes a 348-kD protein known as *huntingtin*. In the first exon of the gene there is a stretch of CAG repeats that encodes a polyglutamine region near the N terminus of the protein. Normal *HTT* genes contain six to 35 copies of the repeat; when the number of repeats is increased beyond this level it is associated with disease. There is an inverse relationship between repeat number and age of onset, such that longer repeats tend to be associated with earlier onset. However, determination of repeat length is not by itself an accurate predictor of age of onset. Repeat expansions occur during spermatogenesis, so that paternal transmission is associated with early onset in the next generation, a phenomenon termed *anticipation*. In contrast to many of the other degenerative diseases, there is no sporadic form of HD. Newly occurring mutations are uncommon; most apparently sporadic cases are explained by non-paternity, the death of a parent before the disease is expressed, or an unaffected father with a mild repeat expansion that is expanded to a pathogenic size during spermatogenesis.

The biologic function of normal huntingtin remains unknown, but it appears that the expansion of the polyglutamine region bestows a toxic gain-of-function on huntingtin. For this reason, various approaches to silencing expression of the mutant allele are being investigated as potential therapies. It is interesting to note that while huntingtin is expressed in all the tissues of the body, the deleterious effects of mutant huntingtin occur only in selected parts of the central nervous system.

While protein aggregation and development of intranuclear inclusions containing huntingtin are pathologic hallmarks of HD, it remains uncertain whether these processes are directly involved in cellular injury or if they are incidental to critical disease processes. There is emerging evidence that aggregated huntingtin can be taken up by neurons, again suggesting a prion-like spread from one

Figure 28-41 Multiple system atrophy (MSA). **A**, Severe atrophy of the basis pontis is evidence in a case of MSA-C. **B**, Inclusions in oligodendrocytes contain α -synuclein.

neuron to another. Transcriptional dysregulation has been implicated in HD, based on the observation that mutant forms of huntingtin bind various transcriptional regulators. Some of the transcription factors that are sequestered by mutant huntingtin include those involved in mitochondrial biogenesis and protection against oxidative injury, and their reduced activity may result in increased susceptibility of affected cells to oxidative stress. Other implicated pathways that may contribute to the pathogenesis of HD include altered expression of the growth factor brain-derived neurotrophic factor (BDNF), and deleterious effects of protein aggregates, which may disrupt both proteasomal and autophagic degradation pathways.

MORPHOLOGY

The brain is small and shows striking **atrophy of the caudate nucleus** and, less markedly at early stages, the putamen (Fig. 28-42). The globus pallidus may atrophy secondarily, and the lateral and third ventricles are dilated. Atrophy is frequently also seen in the frontal lobe, less often in the parietal lobe, and occasionally throughout the entire cortex. On microscopic examination, there is profound loss of striatal neurons; the most marked changes are found in the caudate nucleus, especially in the tail and in portions nearer the ventricle. Pathologic changes develop in a medial-to-lateral direction in the caudate and from dorsal to ventral in the putamen. The nucleus accumbens is the best-preserved portion of the striatum. Both the large and small neurons are affected, but loss of the small neurons generally occurs first. The medium-sized, spiny neurons that use γ -aminobutyric acid as their neurotransmitter, along with enkephalin, dynorphin, and substance P, are especially affected. Two populations of neurons are relatively spared: the diaphorase-positive neurons that express nitric oxide synthase and the large cholinesterase-positive neurons. Both appear to serve as local interneurons. There is also fibrillary gliosis that is more extensive than in the usual reaction to neuronal loss. There is a direct relationship between the degree of degeneration in the striatum and the severity of clinical symptoms. Protein aggregates containing huntingtin can be found in neurons in the striatum and cerebral cortex (Fig. 28-42, inset).

Figure 28-42 Huntington disease. Normal hemisphere on the left compared with the hemisphere with Huntington disease on the right showing atrophy of the striatum and ventricular dilation. Inset, Intranuclear inclusions in neurons are highlighted by immunohistochemistry against ubiquitin. (Courtesy Dr. J-P Vonsattel, Columbia University, New York.)

Clinical Features. The loss of medium spiny striatal neurons leads to dysregulation of the basal ganglia circuitry that modulates motor output. These neurons normally function to dampen motor activity; thus, their degeneration in HD results in increased motor output, often manifested as choreoathetosis. The cognitive changes associated with the disease are probably related to the neuronal loss from cerebral cortex.

The age at onset is most commonly in the fourth and fifth decades and is related to the length of the CAG repeat in the *HTT* gene. Motor symptoms often precede the cognitive impairment. The movement disorder of HD is choreiform, with increased and involuntary jerky movements of all parts of the body; writhing movements of the extremities are typical. Early symptoms of higher cortical dysfunction include forgetfulness and thought and affective disorders, but there is progression to a severe dementia. Although individuals with HD have an increased risk of suicide, intercurrent infection is the most common natural cause of death. Given the ability to screen for disease-causing mutations, one might assume that genetic screening of individuals at risk would be routine. However, this is an example of a situation where the ability to detect the likelihood of disease has surpassed any possible treatment. Thus, in the absence of effective therapy and given the devastating nature of the disease, it is not entirely clear that screening is ethical.

Spinocerebellar Degenerations

These degenerative diseases involve the cerebellum along with other components of the nervous system, commonly the spinal cord (both tracts that project to the cerebellum as well as the dorsal columns, which do not) and peripheral nerve. Because of the anatomic location of the lesions, clinical symptoms commonly include cerebellar and sensory ataxia, spasticity, and sensorimotor peripheral neuropathy. Despite the overlap in regions of involvement, this is a highly heterogeneous group of illnesses at the clinical, genetic and pathologic level, with differences in patterns of inheritance, age at onset, and signs and symptoms. What is common across them is the presence of neuronal loss, often without other distinctive changes apart from gliosis, in the affected areas. Genetic analysis continues to change our classification of these illnesses, but frustratingly this has yet to lead to clearer insight into their pathogenesis or to effective treatments.

The term *spinocerebellar ataxia* (SCA) is usually applied to a series of autosomal dominantly inherited disorders. We will also briefly discuss two of the more common autosomal recessive disorders that are characterized by spinocerebellar degeneration, Friedreich ataxia and ataxia-telangiectasia. Finally, there is a small set of hereditary disorders characterized by episodes of ataxia or other symptoms of cerebellar dysfunction, which are mostly associated with mutations in genes for ion channel subunits.

Spinocerebellar Ataxias

This group of genetic disorders presents with signs and symptoms referable to the cerebellum (progressive ataxia), brainstem, spinal cord, and peripheral nerves, as well as other brain regions in different subtypes.

Pathologically, they are characterized by neuronal loss from the affected areas and secondary degeneration of white-matter tracts.

Molecular Genetics. The list of SCAs has expanded to more than 30 distinct entities, with genetic loci determined for more than half of them. Three distinct types of mutations have been recognized:

- *Polyglutamine diseases* linked to expansion of a CAG repeat, similar to HD. Each of the seven forms of SCA associated with this mechanism has a distinct protein in which the expanded polyglutamine tract occurs, with intranuclear inclusions occurring in neurons, suggesting the involvement of pathogenic mechanisms previously discussed for Huntington disease. The group of polyglutamine diseases includes SCA1, SCA2, SCA3 (also known as *Machado-Joseph disease*), SCA6, SCA7 (relatively unique in that it includes visual impairment), SCA17, and dentatorubropallidoluysian atrophy (DRPLA).
- *Expansion of non-coding region repeats*, similar to myotonic dystrophy. There are currently five forms of SCA in which this mechanism appears to underlie the disease, each linked to a different genetic locus. This group includes SCA8, SCA10, SCA12, SCA31, and SCA36. The connection between the expansion of these repeats and disease manifestations remains obscure.
- *Point mutations.* Another 10 of the SCAs are associated with mutations in a variety of genes whose expression is not restricted to neurons and which code for proteins of mostly unknown functions.

There remains a significant need for investigation to bridge this gap between genetic insight and disease pathogenesis.

Friedreich Ataxia

Friedreich ataxia is an autosomal recessive disease with progressive ataxia, spasticity, weakness, sensory neuropathy, and a cardiomyopathy. It generally begins in the first decade of life with gait ataxia, followed by hand clumsiness and dysarthria. Deep tendon reflexes are depressed or absent, but an extensor plantar reflex is typically present. Joint position and vibratory sense are impaired, and there is sometimes loss of pain, temperature sensation, and light touch. Most affected individuals develop pes cavus and kyphoscoliosis. Most patients become wheelchair-bound within about 5 years of onset, and life expectancy is typically limited to 40 or 50 years of age. The accompanying cardiomyopathy is associated with a high incidence of arrhythmias and congestive heart failure, which contribute to the deaths of most affected individuals. Concomitant diabetes is found in up to 25% of patients.

Friedreich ataxia is caused by expansion of a GAA trinucleotide repeat in the first intron of a gene on chromosome 9q13 that encodes *frataxin*, a protein found in the mitochondrial inner membrane where it is involved in assembly of iron-sulfur cluster enzymes of complex I and II. Affected individuals have extremely low levels of the protein, and the severity of the disease course may correlate better with the level of frataxin than with the degree of GAA-repeat expansion. With reduced mitochondrial frataxin, there is decreased mitochondrial oxidative

phosphorylation (similar to the defect in mitochondrial encephalomyopathies) as well as increased free iron; the presence of free iron within the mitochondria may contribute to oxidative stress. Nearly all cases of Friedreich ataxia are associated with GAA repeat expansion in both alleles, but the same disease phenotype is observed when one allele has a repeat expansion and the other harbors a point mutation.

MORPHOLOGY

The spinal cord shows loss of axons and gliosis in the posterior columns, the distal portions of corticospinal tracts, and the spinocerebellar tracts. There is degeneration of neurons in the spinal cord (Clarke column), the brainstem (cranial nerve nuclei VIII, X, and XII), the cerebellum (dentate nucleus and the Purkinje cells of the superior vermis), and the Betz cells of the motor cortex. Large dorsal root ganglion neurons are also decreased in number; their large myelinated axons, traveling both in the dorsal roots and in dorsal columns, undergo secondary degeneration. The heart is enlarged and may have pericardial adhesions. Multifocal destruction of myocardial fibers with inflammation and fibrosis is detectable in about half the affected individuals who come to autopsy.

Ataxia-Telangiectasia

Ataxia-telangiectasia ([Chapter 7](#)) is an autosomal recessive disorder characterized by an ataxic-dyskinetic syndrome beginning in early childhood, with the subsequent development of telangiectasias in the conjunctiva and skin, along with immunodeficiency. The ataxia-telangiectasia mutated (*ATM*) gene on chromosome 11q22-q23 encodes a kinase with a critical role in orchestrating the cellular response to double-stranded DNA breaks. In addition to this critical cellular role, the ATM protein also contributes to various other pathways including facilitation of apoptosis, maintenance of telomeres, mitochondrial homeostasis, response to oxidative stress, and maintenance of the ubiquitin-proteasomal degradation system. It remains unclear which of these pathways contribute to the degenerative phenotype observed in the setting of loss of ATM protein in neurons. Intriguingly, there are comparable patterns of neurodegeneration associated with other diseases linked to disruption in single-stranded DNA break repair processes.

MORPHOLOGY

The abnormalities are predominantly in the cerebellum, with loss of Purkinje and granule cells; there is also degeneration of the dorsal columns, spinocerebellar tracts, and anterior horn cells, and a peripheral neuropathy. Telangiectatic lesions are found in the CNS as well as in the conjunctiva and skin of the face, neck, and arms. Cells in many organs (e.g., Schwann cells in dorsal root ganglia and peripheral nerves, endothelial cells, pituicytes) show a bizarre enlargement of the nucleus to two to five times normal size and are referred to as *amphicytes*. The lymph nodes, thymus, and gonads are hypoplastic.

Clinical Features. The disease is relentlessly progressive, with death early in the second decade. The initial symptoms are commonly recurrent sinopulmonary infections

and unsteadiness in walking. Later on, speech is noted to become dysarthric, and eye movement abnormalities develop. Many affected individuals develop lymphoid neoplasms, which are most often T-cell leukemias.

Amiotrophic Lateral Sclerosis (ALS)

ALS is a progressive disorder in which there is loss of upper motor neurons in the cerebral cortex and lower motor neurons in the spinal cord and brainstem. Loss of these neurons results in denervation of muscles, producing weakness that becomes profound as the disease progresses. The disease has an overall incidence of about 2 cases per 100,000 population, affects men slightly more frequently than women, and commonly emerges in the fifth decade or later. Sporadic ALS is more common than familial ALS (FALS), which may account for up to 20% of cases.

Molecular Genetics and Pathogenesis. Both sporadic and familial ALS are associated with degeneration of upper and lower motor neurons, often in association with evidence of toxic protein accumulation. Close to two dozen genetic loci have been identified as causing familial ALS, with nearly all being autosomal dominant disorders. One of the earliest discovered hereditary forms of ALS has mutations in the gene encoding copper-zinc superoxide dismutase (*SOD1*) on chromosome 21; this variant accounts for about 20% of familial cases. A wide variety of missense mutations have been identified throughout the gene. The A4V mutation is the most common in the United States; it is associated with a rapid course and rarely involvement of upper motor neurons.

Initially, identification of *SOD1* mutations suggested that neuronal injury in ALS might reflect an impaired capacity to detoxify free radicals, but it is now believed that mutations lead to an adverse gain-of-function phenotype associated with mutant *SOD1* protein. It appears that mutated *SOD1* protein misfolds and forms aggregates (that can include wild type protein) and result in cellular injury through a variety of mechanisms including disruption of proteasome function and autophagy, direct effects on axonal transport and mitochondrial function or sequestration of other proteins within the aggregates. Accumulation of protein aggregates can eventually trigger the unfolded protein response, with subsequent initiation of apoptosis. Development of aggregated *SOD1* has also been observed in ALS without mutations in this gene, suggesting that this path to cellular injury may contribute to sporadic ALS as well. For this reason, methods for clearing misfolded *SOD1* are being developed as therapeutic approaches. The overall importance of protein degradation pathways is reinforced by discovery of a range of uncommon mutations in genes implicated in protein degradation that are also associated with familial ALS.

The most common mutation that gives rise to ALS and FTLN simultaneously is an expansion of a hexanucleotide repeat in the 5'-untranslated region of a transcript of unknown function, *C9orf72*. This mutation is estimated to be the basis of up to 40% of familial ALS and a smaller fraction of what appear to be sporadic cases of ALS. Non-AUG-initiated translation (in all three reading frames) can occur from these expanded repeats, and neuronal deposits of the derived proteins have been found in the setting of

the mutation. Whether these novel protein aggregates contribute to cellular injury remains obscure.

Other genetic loci that cause ALS and FTLN encode proteins with RNA-binding capacity, such as TDP-43 and FUS. The underlying link between altered RNA-binding proteins and manifestations of motor neuron disease remain unclear. Possibly, nuclear depletion of TDP-43 results in inappropriate processing of some RNAs, while the aggregation of the protein in the cytoplasm activates the unfolded protein response common to many of the proteinopathies.

MORPHOLOGY

The anterior roots of the spinal cord are thin (Fig. 28-43A), due to loss of lower motor neuron fibers, and the precentral motor gyrus in the cortex may be atrophic in especially severe cases. There is a reduction in the number of anterior-horn neurons throughout the length of the spinal cord, associated with reactive gliosis. Similar findings are seen in the hypoglossal, ambiguous, and motor trigeminal cranial nerve nuclei. Remaining neurons often contain PAS-positive cytoplasmic inclusions called Bunina bodies, which appear to be remnants of autophagic vacuoles. Skeletal muscles innervated by the degenerated lower motor neurons show neurogenic atrophy. Loss of the upper motor neurons leads to degeneration of the corticospinal tracts, resulting in volume loss and absence of myelinated fibers, which may be particularly evident at the lower segmental levels (Fig. 28-43B).

Clinical Features. Early symptoms of ALS include asymmetric weakness of the hands, manifested as dropping of objects and difficulty in performing fine motor tasks, and cramping and spasticity of the arms and legs. As the disease progresses, muscle strength and bulk diminish, and involuntary contractions of individual motor units, termed fasciculations, occur. The disease eventually involves the respiratory muscles, leading to recurrent bouts of pulmonary infection. While most affected individuals have a combination of both upper and lower motor neuron involvement as determined by clinical features and pathologic examination, there are other patterns observed. The term *progressive muscular atrophy* applies to those relatively uncommon cases in which lower motor neuron involvement predominates, while *primary lateral sclerosis* refers to those cases with mostly upper motor neuron involvement. In some affected individuals, degeneration of the lower brainstem cranial motor nuclei occurs early and progresses rapidly, a pattern referred to as *progressive bulbar palsy* or *bulbar ALS*. In these individuals, abnormalities of deglutition and phonation dominate, and the clinical course is inexorable during a 1- or 2-year period; when bulbar involvement is less severe, about half of affected individuals are alive 2 years after diagnosis. The motor neurons innervating extra-ocular muscles are among the last to be involved in ALS; with long survival, usually associated with ventilator support, even this form of motor output fails. Familial cases develop symptoms earlier than most sporadic cases, but the clinical course is comparable.

While ALS is considered a disease of the motor system, it is clear that a significant fraction of affected individuals

Figure 28-43 Amyotrophic lateral sclerosis. **A**, Segment of spinal cord viewed from anterior (upper) and posterior (lower) surfaces showing attenuation of anterior (motor) roots compared with posterior (sensory) roots. **B**, Spinal cord showing loss of myelinated fibers (lack of stain) in corticospinal tracts as well as degeneration of anterior roots.

also have evidence of more widespread cerebral cortical disease. The clinical presentation of cerebral disease is usually as a frontotemporal lobar dementia (FTLD), with pathologic findings most often matching those of FTLD associated with TDP-43 inclusions. The mechanistic link between these two processes is further strengthened by the presence of TDP-43 containing inclusions in many cases of ALS as well as partial sharing of genetic alterations in ALS and FTLD.

Other Motor Neuron Diseases

Spinal and Bulbar Muscular Atrophy (Kennedy Disease)

This X-linked polyglutamine repeat-expansion disease is characterized by distal limb amyotrophy and bulbar signs, such as atrophy and fasciculations of the tongue and dysphagia, associated with degeneration of lower motor neurons in the spinal cord and brainstem. The expanded repeat occurs in the first exon of the androgen receptor, and results in androgen insensitivity, gynecomastia, testicular atrophy, and oligospermia. The basis for the selective motor neuron involvement is unclear, but as in other polyglutamine expansion diseases such as Huntington disease and forms of spinocerebellar atrophy, there are intranuclear inclusions that contain the involved protein.

Cellular injury depends on the binding of androgen to the abnormal receptor and the subsequent interaction with DNA. Therapies aimed at reducing androgen levels have been effective in animal models and may be able to ameliorate the disease in humans as well.

Spinal Muscular Atrophy

Spinal muscular atrophy (SMA) includes a group of genetically linked disorders of childhood with marked loss of lower motor neurons resulting in progressive weakness. The most severe form is that with the earliest onset (SMA type I, Werdnig-Hoffmann disease) with onset during the first year of life and death typically within 2 years. Other forms, with later onset, have more gradual courses; in SMA type III (Kugelberg-Welander disease) motor disability usually emerges during later childhood and adolescence. The severity of disease is related to the level of a protein (termed SMN) that is involved in the assembly of the spliceosome; there are decreased nuclear puncta containing SMN in cells from affected individuals. Most SMN protein comes from mRNA transcripts derived from the *SMN1* gene on chromosome 5q. There is an adjacent *SMN2* gene that differs by a few base pairs, including changes which decrease the efficiency of inclusion of one exon in the mRNA. SMN protein lacking this region is much less stable than the full-length protein. All of the forms of SMA are associated with disruption of *SMN1* (usually through deletion), with the differences in clinical phenotype determined by copy number variation for the *SMN2* gene. Methods of altering the splicing of *SMN2*-derived transcripts are being explored as novel therapeutic approaches for these diseases.

KEY CONCEPTS

Neurodegenerative Diseases

- Neurodegenerative diseases are characterized by progressive neuronal loss involving specific neuronal circuits and brain regions. Most of these diseases are associated with accumulation of abnormal protein aggregates, typically in the form of cellular inclusions. The clinical phenotype reflects the patterns of brain involvement more than the type of inclusions.
- These diseases can be grouped by clinical presentation into: dementias, hypokinetic movement disorders (including forms of parkinsonism), hyperkinetic movement disorders, cerebellar ataxias, and motor neuron diseases.
- Among dementias, AD (with plaques of A β and tangles of tau) is the most common; other predominantly dementing diseases include the various forms of FTLDs (both forms with tau-containing lesions and with other types of inclusions) and dementia with Lewy bodies (with α -synuclein containing lesions).
- Among the hypokinetic movement disorders, Parkinson disease is the most common, again with α -synuclein containing inclusions; other diseases which include parkinsonism as part of the symptoms, include PSP and CBD (both forms of tauopathy).
- Amyotrophic lateral sclerosis (ALS) is the most common form of motor neuron disease, with diverse genetic causes as well as sporadic forms.

Genetic Metabolic Diseases

Disruption of metabolic processes in neurons and glia, particularly those involved in synthetic or degradation pathways that are specific to the nervous system, results in diseases that typically present early in life and progress. Some of these disorders manifest in the immediate post-natal period, while others emerge later in development. Overall, forms of these diseases with earlier onset tend to have more rapid and aggressive clinical courses.

Current classification systems are based on the cells or compartment affected (neuronal or white matter), subcellular organelle affected (e.g., lysosome, peroxisome, or mitochondrion), or metabolic pathway affected (e.g., sphingolipidoses or glycogenoses). The classification that follows is based largely on the cellular compartments that are primarily affected, since this correlates well with clinical symptoms and radiologic imaging.

- *Neuronal storage diseases* are predominantly autosomal recessive disorders caused by the deficiency of a specific enzyme involved in the catabolism of sphingolipids (including the gangliosides), mucopolysaccharides, or mucolipids. They are often characterized by the accumulation of the missing enzyme's substrate within the lysosomes of neurons, leading to neuronal death. Cortical neuronal involvement leads to loss of cognitive function and may also cause seizures.
- *Leukodystrophies* are mostly autosomal recessive disorders caused by mutations in genes encoding enzymes involved in myelin synthesis or catabolism. Some of these disorders involve lysosomal enzymes, while others affect peroxisomal enzymes. There is typically diffuse involvement of white matter leading to deterioration in motor skills, spasticity, hypotonia, or ataxia.
- *Mitochondrial encephalomyopathies* are a group of disorders of oxidative phosphorylation, often affecting multiple tissues including skeletal muscle (Chapter 27). When they involve brain, gray matter is more severely affected than white matter, as would be expected because of the greater metabolic requirements of neurons. These disorders may be caused by mutations in the mitochondrial or the nuclear genomes.

Neuronal Storage Diseases

These disorders are characterized by the accumulation of storage material within neurons, typically followed by death of the neurons. The neurologic manifestations that result from this neuronal dysfunction or death are most often seizures as well as generalized loss of neurologic function. While many of these disorders are associated with deficits of specific enzymes that result in accumulation of substrate, others appear to be caused by defects in protein or lipid trafficking within neurons. This is a large class of disorders, with genetic heterogeneity even for clinically homogeneous entities. Current molecular methods allow whole exome and genome sequencing, which are leading to changes in the classification of these disorders. Several examples of these diseases, such as Tay-Sachs and Niemann-Pick diseases and mucopolysaccharidoses, are described in Chapter 5. Ceroid lipofuscinoses are rare

disorders in which lipid pigments accumulate in neurons, and the resulting neuronal dysfunction leads to a combination of blindness, cognitive and motor deterioration and seizures.

Leukodystrophies

These disorders are caused by mutations of genes whose products are involved in the generation, turnover, or maintenance of myelin. Normal brain function depends as much on the connections between neurons as it does on the integrity of the neurons themselves and therefore the progressive and cumulative damage to myelinated fibers that appears in the leukodystrophies has devastating consequences. Several clinical features separate leukodystrophies from demyelinating diseases: the leukodystrophies typically present with an insidious and progressive loss of cerebral function, often at younger ages, and are associated with diffuse and symmetric changes on imaging studies. While many of the leukodystrophies are caused by single enzyme defects resulting in altered metabolism of myelin-associated lipids, a variety of other genetic alterations can lead to white matter diseases. The following examples are representative of this spectrum of disorders.

- **Krabbe disease** is an autosomal recessive leukodystrophy resulting from a deficiency of *galactocerebroside β -galactosidase* (galactosylceramidase), the enzyme required for the catabolism of galactocerebroside to ceramide and galactose. As a consequence of the impaired catabolism of galactocerebroside in the brain, an alternative catabolic pathway shunts galactocerebroside to galactosylsphingosine; elevated levels of this compound are cytotoxic. The clinical course is rapidly progressive, with onset of symptoms (dominated by motor signs such as stiffness and weakness) often between the ages of 3 and 6 months. Survival beyond 2 years of age is uncommon. The brain shows loss of myelin and oligodendrocytes in the CNS and a similar process in peripheral nerves (Fig. 28-44). Neurons and axons are relatively spared. A unique and diagnostic feature of Krabbe disease is the aggregation of engorged macrophages (*globoid cells*) in the brain parenchyma and around blood vessels (Fig. 28-44, inset). Hematopoietic stem cell transplantation, which allows repopulation of the CNS with enzymatically competent microglia, has been shown to be of benefit, particularly when performed before the neurologic deficits appear (this is also true of metachromatic leukodystrophy).
- **Metachromatic leukodystrophy** is an autosomal recessive disease that results from a deficiency of the *lysosomal enzyme arylsulfatase A*. This enzyme, present in a variety of tissues, cleaves the sulfate from sulfate-containing lipids (sulfatides) as the first step in their degradation. Enzyme deficiency therefore leads to an accumulation of the sulfatides, especially cerebroside sulfate. These sulfatides have a range of biological actions that can contribute to white matter injury, including inhibiting differentiation of oligodendrocytes and eliciting a proinflammatory response from microglia and astrocytes. The most striking histologic finding is demyelination with resulting gliosis. Macrophages with vacuolated cytoplasm are scattered throughout the

Figure 28-44 Krabbe disease. Much of the white matter is gray/yellow because of the loss of myelin. Inset, “Globoid” cells are the hallmark of the disease.

white matter. The membrane-bound vacuoles contain complex crystalloid structures composed of sulfatides; when bound to certain dyes such as toluidine blue, sulfatides shift the absorbance spectrum of the dye, a property called *metachromasia*. Similar metachromatic material can be detected in peripheral nerves and in the urine, the latter being a sensitive method of establishing the diagnosis.

- **Adrenoleukodystrophy** is an X-linked recessive disease associated with mutations in a member of the ATP-binding cassette transporter family of proteins (ABCD1), which is involved in the transport of molecules into the peroxisome. In the typical form of the disease, young males present with behavioral changes and adrenal insufficiency. The disease is characterized by the inability to catabolize very-long-chain fatty acids (VLCFAs) within peroxisomes, resulting in elevated levels of VLCFAs in serum. The symptoms result from a progressive loss of myelin in the CNS and peripheral nerves, as well as adrenal insufficiency. In the white matter, there is loss of myelin accompanied by gliosis and extensive lymphocytic infiltration. Atrophy of the adrenal cortex is present, and VLCFA accumulation can be seen in remaining cells. An allelic disorder presents in adults (both male and female) as a slowly progressive predominantly peripheral nerve disorder known as *adrenomyeloneuropathy*; the symptoms in female carriers are usually more mild. Some of the disorders of peroxisomal biogenesis also manifest as leukodystrophies, particularly Zellweger spectrum disorder.

A wide range of other forms of leukodystrophy occurs, some with defects in lipid metabolism. Several other

mechanisms of selective injury to white matter have been identified, including mutations in genes that encode proteins required for myelin formation (*Pelizaeus-Merzbacher disease*) or intermediate filament proteins such as GFAP (*Alexander disease*), and genes for various subunits of translation initiation factor eIF2B (*vanishing white matter leukoencephalopathy*).

Mitochondrial Encephalomyopathies

Disorders of energy generation can cause a range of neurologic disease, often in association with abnormalities in other tissues. While many of the inherited disorders of mitochondrial oxidative phosphorylation present as muscle diseases ([Chapter 27](#)), the critical dependence of neurons on oxidative phosphorylation for generation of ATP is reflected in the frequent involvement of the CNS in these disorders.

The mitochondrial genome, which is entirely inherited from the mother, encodes only 13 proteins, 22 tRNAs, and two rRNAs. The remainder of the proteins involved in mitochondrial function are encoded by the nuclear genome, including those involved in oxidative phosphorylation, mitochondrial metabolism and structure, as well as mitochondrial biogenesis, fission and fusion and replication of mitochondrial DNA. Thus, some mitochondrial disorders show maternal transmission because the affected genes lie in the mitochondrial genome, but many others do not. There is a complex genotype-phenotype relationship in these disorders: the same mutation may manifest as different phenotypes, and the same phenotype may result from one of several mutations.

An additional critical aspect to understanding mitochondrial diseases is *heteroplasmy*, which describes the condition in which cells have a mixture of normal and abnormal mitochondria (typically in the setting of a mitochondrial genome mutation). The expression of the disease may differ from cell to cell depending on the ratio of cells carrying the normal and mutant mitochondria. In general, mitochondrial disorders in the CNS selectively target neurons and gray matter; the disruption of energy generation is often reflected in elevated tissue lactate levels, which can be demonstrated by spectroscopic imaging methods. At the histologic level, there can be loss of staining for enzymatic activity of cytochrome C oxidase.

- **Mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes (MELAS)** is characterized by recurrent episodes of acute neurologic dysfunction, cognitive changes, and evidence of muscle involvement with weakness and lactic acidosis. The stroke-like episodes are often associated with reversible deficits that do not correspond to specific vascular territories. Pathologically, areas of infarction are observed, sometimes with vascular proliferation and focal calcification. Studies have shown that both neurons and vascular smooth muscle cells have altered expression of cytochrome c oxidase, suggesting that the underlying pathogenesis is driven both by the metabolic changes in neurons as well as the ability of the cerebral vasculature to respond. The most common mutation observed in MELAS is in the gene encoding mitochondrial tRNA-leucine (MTTL1).

- **Myoclonic epilepsy and ragged red fibers (MERRF)** is a maternally transmitted disease in which affected individuals have myoclonus, a seizure disorder, and evidence of a myopathy. The myopathy is often characterized by ragged red fibers on muscle biopsy (Chapter 27). Ataxia, associated with neuronal loss from the cerebellar system (including the inferior olive in the medulla, cerebellar cortex, and deep nuclei), is also a common component. Most cases of MERRF are associated with mutations in tRNAs other than the specific tRNA mutation associated with MELAS.
- **Leigh syndrome** is a disease of infancy characterized by lactic acidemia, arrest of psychomotor development, feeding problems, seizures, extraocular palsies, and weakness with hypotonia. Death usually occurs within 1 to 2 years. On histologic examination there are multifocal regions of destruction of brain tissue associated with a spongiform appearance and proliferation of blood vessels. Brainstem nuclei, thalamus, and hypothalamus are typically involved, usually in a symmetric manner. A wide spectrum of mutations has been identified as causing Leigh syndrome, including both nuclear and mitochondrial DNA mutations involving components of oxidative phosphorylation complexes and proteins involved in the assembly of the electron transport chain.

KEY CONCEPTS

Genetic Metabolic Diseases

- Mutations that disrupt metabolic or synthetic pathways can affect the nervous system. These pathways can involve general cellular processes or those that are relatively specific to the nervous system.
- Diseases with earlier onset are typically more severe in the degree of damage and pace of illness.
- Neuronal storage diseases are commonly autosomal recessive disorders. The characteristic finding is usually accumulation of material within neurons, along with evidence of neuronal death. Seizures are common components of the clinical presentation, along with loss of cognitive function.
- Leukodystrophies are also typically autosomal recessive, with disruption of the synthesis or turnover of myelin components. Motor dysfunction, including spasticity, hypertonia or hypotonia and ataxia are common aspects of the clinical presentation.
- Mitochondrial encephalomyopathies are a pleiotropic set of disorders that involves neurons as well as tissues outside of the nervous system. These can be associated with mutations in the nuclear as well as the mitochondrial genome.

Toxic and Acquired Metabolic Diseases

Toxic and acquired metabolic diseases are relatively common causes of neurologic illnesses. These diseases are discussed in Chapter 9; only aspects that are relevant to CNS pathology are presented here.

Vitamin Deficiencies

Thiamine (Vitamin B₁) Deficiency

Wernicke encephalopathy is caused by thiamine deficiency and is characterized by the acute appearance of a combination of psychotic symptoms and ophthalmoplegia. The acute symptoms are reversible when treated with thiamine. However, if unrecognized and untreated, they may be followed by a prolonged and largely irreversible condition, called *Korsakoff syndrome*, that is characterized clinically by disturbances of short term memory and confabulation. The syndrome is particularly common in the setting of chronic alcoholism, but it may also be encountered in individuals with thiamine deficiency resulting from gastric disorders, including carcinoma, chronic gastritis, or persistent vomiting.

MORPHOLOGY

Wernicke encephalopathy is characterized by foci of hemorrhage and necrosis in the mammillary bodies and the walls of the third and fourth ventricles. Early lesions show dilated capillaries with prominent endothelial cells. Subsequently, the capillaries become leaky, producing hemorrhagic areas. With time, there is infiltration of macrophages and development of a cystic space with hemosiderin-laden macrophages. These chronic lesions predominate in individuals with Korsakoff syndrome. Lesions in the dorsomedial nucleus of the thalamus seem to be the best correlate of the memory disturbance and confabulation.

Vitamin B₁₂ Deficiency

Subacute combined degeneration of the spinal cord is caused by deficiency of vitamin B₁₂ resulting in degeneration of both ascending and descending spinal tracts. The lesions are caused by a defect in myelin formation; the mechanism of this defect is not known. Symptoms may present over a few weeks, initially with bilaterally symmetrical numbness, tingling, and slight ataxia in the lower extremities, but may progress to include spastic weakness of the lower extremities. Complete paraplegia may occur, usually only later in the course. With prompt vitamin replacement therapy, clinical improvement occurs; however, once complete paraplegia has developed, recovery is poor. On microscopic examination, there is swelling of myelin layers, producing vacuoles, in the affected tracts; with time, axons degenerate as well. In the early stages of the disease the mid-thoracic level of the spinal cord is affected, from where the process may extend proximally and distally.

Neurologic Sequelae of Metabolic Disturbances

Hypoglycemia

Since the brain requires glucose and oxygen for its energy production, the cellular effects of diminished glucose resemble those of oxygen deprivation, described earlier. Some regions of the brain are more sensitive to hypoglycemia than are others. Glucose deprivation initially leads to selective injury to large pyramidal neurons of the cerebral cortex, which, if severe, may result in pseudolaminar

necrosis of the cortex, predominantly involving deep layers. The hippocampus is also vulnerable to glucose depletion and may show a marked loss of pyramidal neurons in Sommer sector (area CA1) of the hippocampus. Purkinje cells of the cerebellum are also sensitive to hypoglycemia, although to a lesser extent than to hypoxia. If the level and duration of hypoglycemia are of sufficient severity, there may be widespread injury to many areas of the brain.

Hyperglycemia

Hyperglycemia, most commonly associated with inadequately controlled diabetes mellitus and associated with either ketoacidosis or hyperosmolar coma, does not elicit significant morphologic changes in the brain. The affected individual becomes dehydrated and develops confusion, stupor, and eventually coma. The fluid depletion must be corrected gradually; otherwise, severe cerebral edema may follow.

Hepatic Encephalopathy

The encephalopathy found in the setting of impaired liver function is accompanied by a glial response within the CNS. Critical mediators appear to include elevated ammonia levels as well as proinflammatory cytokines. Astrocytes with enlarged nuclei and minimal reactive cytoplasm, known as Alzheimer type II cells, appear in the cerebral cortex and basal ganglia and other subcortical gray matter regions.

Toxic Disorders

Cellular and tissue injury from toxic agents is discussed in [Chapter 9](#). Aspects of several important toxic disorders that are of unique neurologic importance are discussed here.

Carbon Monoxide

Many of the pathologic findings that follow acute carbon monoxide exposure are the result of impaired oxygen-carrying capacity of hemoglobin. There can also be local effects from the interaction of CO with the heme of cytochrome C oxidase, inhibiting electron transport in the mitochondria. Selective injury of the neurons of layers III and V of the cerebral cortex, Sommer sector of the hippocampus, and Purkinje cells is characteristic. Bilateral necrosis of the globus pallidus may also occur; it is more common in carbon monoxide-induced hypoxia than in hypoxia from other causes. Demyelination of white matter tracts may be a later event.

Methanol

Methanol toxicity preferentially affects the retina, where degeneration of retinal ganglion cells may cause blindness. Selective bilateral necrosis of the putamen and focal white-matter necrosis also occur when the exposure is severe. Formate and other metabolites of methanol appear to contribute to toxicity through disruption of oxidative phosphorylation and through nonenzymatic protein modification. Methanol toxicity occurs by ingestion of illicit liquor (moonshine) contaminated with methanol or when it is used as a substitute for ethanol.

Ethanol

Experience tells us that the effects of acute ethanol intoxication are reversible, but chronic alcohol abuse is associated

Figure 28-45 Alcoholic cerebellar degeneration. The anterior portion of the vermis (upper portion of figure) is atrophic with widened spaces between the folia.

with a variety of neurologic sequelae, including Wernicke-Korsakoff syndrome from thiamine deficiency (see earlier). The toxic effects of chronic alcohol intake may be either direct or secondary to nutritional deficits. Cerebellar dysfunction occurs in about 1% of chronic alcoholics, associated with a clinical syndrome of truncal ataxia, unsteady gait, and nystagmus. The histologic changes are atrophy and loss of granule cells predominantly in the anterior vermis ([Fig. 28-45](#)). In advanced cases there is loss of Purkinje cells and proliferation of the adjacent astrocytes (*Bergmann gliosis*) between the depleted granular cell layer and the molecular layer of the cerebellum. The fetal alcohol syndrome is discussed in [Chapter 10](#).

Radiation

Exposure of the brain to radiation can occur accidentally or as part of therapeutic regimens for brain tumors. As discussed in [Chapter 9](#), exposure to very high doses of radiation (>10 Gy) can cause intractable nausea, confusion, convulsions, and rapid onset of coma, followed by death. Delayed effects of radiation can also present with rapidly evolving symptoms, including headaches, nausea, vomiting, and papilledema that may appear months to years after irradiation.

The pathologic findings consist of large areas of coagulative necrosis, primarily in white matter, with all tissue elements within the area undergoing necrosis. This is accompanied by marked edema in the surrounding tissue, along with vascular fibrinoid necrosis and eventual sclerosis. The combination of radiation and methotrexate, administered either concurrently or sequentially, can act synergistically to cause tissue injury. While similar in appearance to that caused by radiation alone, these lesions are often adjacent to the lateral ventricles but may be distributed throughout the white matter or in the brainstem. Axons and cell bodies in the vicinity of the lesions undergo dystrophic mineralization, and there is adjacent gliosis. Radiation can also induce tumors, which usually develop years after radiation therapy and include sarcomas, gliomas, and meningiomas.

KEY CONCEPTS

Toxic and Acquired Metabolic Diseases

- Certain vitamin deficiency states result in neurologic disease as well as systemic disorders, with thiamine and vitamin B₁₂ being the two most common.
- The metabolic demand of the CNS makes it highly susceptible to injury from hypoglycemia and loss of oxygen-carrying capacity of hemoglobin with carbon monoxide toxicity.
- Chronic alcohol exposure may result in injury to the cerebellum, particularly to the anterior vermis.
- Metabolic disarray may disrupt brain function, often without detectable morphologic changes.

Tumors

The annual incidence of tumors of the CNS ranges from 10 to 17 per 100,000 persons for intracranial tumors and 1 to 2 per 100,000 persons for intraspinal tumors; the majority of these are primary tumors, and only one fourth to one half are metastatic. Tumors of the CNS account for nearly 20% of all cancers of childhood. Seventy percent of childhood CNS tumors arise in the posterior fossa; a comparable number of tumors in adults arise within the cerebral hemispheres above the tentorium.

While pathologists have developed classification schemes that distinguish between benign and malignant lesions on histologic grounds, the clinical course of a patient with a brain tumor is strongly influenced by patterns of growth and location. Thus, some glial tumors with low grade histologic features (low mitotic rate, cellular uniformity, and slow growth) infiltrate large regions of the brain and lead to serious clinical deficits and poor prognosis. Because of this capacity to diffusely infiltrate the white and gray matter, a tumor may not be amenable to complete surgical resection without compromising neurologic function. Also, any CNS neoplasm, regardless of histologic grade or classification, may have lethal consequences if situated in a critical brain region; for example, a benign meningioma may cause cardiorespiratory arrest if situated in the posterior fossa in a position to compress vital centers in the medulla. Even the most highly malignant gliomas rarely metastasize outside the CNS. Tumors are able to spread through the CSF if they encroach upon the subarachnoid space, and thus may be associated with implantation along the brain and spinal cord at a distance from the original tumor site.

Classification of tumors is one of the arts of pathology, drawing on traditional recognition of histologic and biologic features, combined with newer molecular analyses. Treatment protocols and experimental trials of glial tumors are usually based on the World Health Organization (WHO) classification, which segregates tumors into one of four grades according to their biologic behavior, ranging from grade I to grade IV. Under the current classification scheme, lesions of different grade are always given distinct names. When tumors recur, they often show progression to a higher histologic grade and designation; this actually represents clonal evolution of the same tumor, rather than a new disease. There is great interest in identifying

tumor-initiating (or stem-like) cells that maintain tumor growth and, therefore, may be key targets of new therapies.

The major classes of primary brain tumors to be considered here include gliomas, neuronal tumors, poorly differentiated tumors, and a group of other less common tumors. In addition, we will discuss tumors of the meninges as well as familial tumor syndromes.

Gliomas

Gliomas, the most common group of primary brain tumors, include *astrocytomas*, *oligodendrogliomas*, and *ependymomas*. These tumor types have characteristic histologic features that form the basis for the classification. It is no longer thought that these tumors derive from their specific, mature cell types (astrocytes, oligodendrocytes, and ependymal), but rather that they arise from a progenitor cell that preferentially differentiates down one of the cellular lineages. Many of the tumors typically occur in certain anatomic regions within the brain, with characteristic age distribution and clinical course.

Astrocytoma

The two major categories of astrocytic tumors are the diffusely infiltrating astrocytomas and the more localized astrocytomas, of which the most common are the pilocytic astrocytomas. Astrocytomas may range from WHO grade I to grade IV, may occur from the first decade of life onward and may be found anywhere along the neuroaxis from the cerebral hemispheres to the spinal cord.

Infiltrating Astrocytomas

Infiltrating astrocytomas account for about 80% of adult primary brain tumors in adults. Usually found in the cerebral hemispheres, they may also occur in the cerebellum, brainstem, or spinal cord, most often in the fourth through sixth decades. The most common presenting signs and symptoms are seizures, headaches, and focal neurologic deficits related to the anatomic site of involvement. Infiltrating astrocytomas show a spectrum of histologic differentiation that correlates well with clinical course and outcome; within this spectrum, tumors range from *diffuse astrocytoma* (grade II/IV) to *anaplastic astrocytoma* (grade III/IV) to *glioblastoma* (grade IV/IV). There are no WHO grade I infiltrating astrocytomas.

Molecular Genetics. It was recognized well before modern advances in genetic analyses that glioblastoma tends to occur in one of two clinical settings—most commonly as a new onset disease, typically in older individuals (*primary glioblastoma*), and less frequently in younger patients due to progression of a lower-grade astrocytoma (*secondary glioblastoma*). Data from the Cancer Genome Atlas Network based on sequencing the genome of malignant gliomas have identified **patterns of molecular alteration in glioblastoma that place these tumors into four molecular subtypes: classic, proneural, neural, and mesenchymal.**

- The *classic subtype*, comprising the majority of primary glioblastoma, is characterized by mutations of the *PTEN* tumor suppressor gene, deletions of chromosome 10, and amplification of the *EGFR* oncogene. Focal deletions

involving chromosome 9p21, resulting in hemizygous deletion of the *CDKN2A* tumor suppressor gene, are also common; you will recall that this unusual locus encodes two tumor suppressors, p16/INK4a and p14ARF, which function by augmenting the activity of RB and p53, respectively.

- The *proneural type*, which is the most common type associated with secondary glioblastoma, is characterized by mutations of *TP53*, and point mutations in the isocitrate dehydrogenase genes, *IDH1* and *IDH2*. The proneural glioblastoma also often shows an overexpression of the receptor for platelet-derived growth factor receptor α (PDGFRA). Low grade gliomas (grades II and III astrocytomas) also tend to have mutations in *TP53* and in the *IDH* genes, a molecular signature that is carried forward as the neoplasm evolves to the higher grade, secondary glioblastoma.
- The *neural type* is characterized by higher levels of expression of neuronal markers, including NEFL, GABRA1, SYT1, and SLC12A5.
- The *mesenchymal type* is characterized by deletions of the *NF1* gene on chromosome 17, and lower expression of the NF1 protein. Genes involved in the TNF pathway and the NF- κ B pathway are highly expressed in the mesenchymal glioblastoma.

The common theme of these diverse genotypic changes is that most affect two cancer hallmarks, sustained proliferative signaling and evasion of growth suppressors.

For example, overexpression of PDGFRA in proneural glioblastomas, and mutation and amplification of *EGFR* genes in classic glioblastomas, both lead to increased receptor tyrosine kinase signaling. You will recall from [Chapter 7](#) that tyrosine kinases stimulate RAS and PI3K/AKT signaling, which act together to drive cells from the G1 to S phase of the cell cycle and to deregulate cellular metabolism so as to promote growth. Other common events directly or indirectly inhibit RB and p53 function. Based on whole genome sequencing, it is estimated that mutations that activate RAS and PI-3 kinase and inactivate p53 and RB are present in 80% to 90% of primary glioblastomas.

Additionally, among the higher grade astrocytomas (WHO grades III and IV), the presence of the mutant form of *IDH1* (predominantly the R132H mutation) is associated with a significantly better outcome than in tumors with wild type *IDH1*. You will recall that *IDH1* mutations create a neomorphic enzyme activity that generates 2-hydroxyglutarate, which appears to contribute to oncogenesis by inhibiting enzymes that regulate DNA methylation, an example of oncogenesis by epigenetic dysregulation ([Chapter 7](#)).

MORPHOLOGY

Diffuse astrocytomas are poorly defined, gray, infiltrative tumors that expand and distort the invaded brain ([Fig. 28-46](#)). These tumors range in size from a few centimeters to enormous lesions that replace an entire hemisphere. The cut surface of the tumor may be either firm or soft and gelatinous; cystic degeneration may be seen. The tumor may appear well demarcated from the surrounding brain tissue, but infiltration beyond the outer margins is always present.

Figure 28-46 Diffuse astrocytoma. **A**, The right frontal tumor has expanded gyri, which led to flattening (arrows). **B**, There is bilateral expansion of the septum pellucidum by gray, glassy tumor.

Microscopically, diffuse astrocytomas have a cellular density that is greater than normal white matter. Between the tumor cell nuclei there is an extensive feltwork of fine, GFAP-positive astrocytic processes that create a fibrillary background appearance. There are variable degrees of nuclear pleomorphism. The transition between neoplastic and normal tissue is indistinct, and tumor cells infiltrate normal tissue some distance away from the main lesion.

Anaplastic astrocytomas are more densely cellular and have greater nuclear pleomorphism; mitotic figures are often observed. The term **gemistocytic astrocytoma** is used for

Figure 28-47 **A**, Contrast T1-weighted coronal magnetic resonance image shows a large mass in the right parietal lobe with “ring” enhancement. **B**, Glioblastoma appearing as a necrotic, hemorrhagic, infiltrating mass.

tumors in which the predominant neoplastic astrocyte shows a brightly eosinophilic cell body from which emanate abundant, stout processes.

In **glioblastoma** (previously called *glioblastoma multiforme*, and sometimes still abbreviated GBM), variation in the appearance of the tumor from region to region is characteristic (Fig. 28-47). Some areas are firm and white, others are soft and yellow due to necrosis, and yet others show cystic degeneration and hemorrhage. The histologic appearance of glioblastoma is similar to anaplastic astrocytoma with the additional features of **necrosis** and **vascular/endothelial cell proliferation**. Necrosis in glioblastoma often occurs in a serpentine pattern in areas of hypercellularity. Tumor cells collect along the edges of the necrotic regions, producing a histologic pattern referred to as **pseudo-palisading** (Fig. 28-48). The vascular cell proliferation produces tufts of cells that pile up and bulge into the

lumen; the minimal criterion for this feature is a double layer of endothelial cells. With marked vascular cell proliferation the tuft forms a ball-like structure, the glomeruloid body. VEGF, produced by malignant astrocytes in response to hypoxia, contributes to this distinctive vascular change. Since histologic features can be extremely variable from one region to another, small biopsy specimens may not be representative of the entire tumor.

Gliomatosis cerebri is a diffuse glioma with extensive infiltration of multiple regions of the brain, in some cases the entire brain. Because of the widespread infiltration, this process follows an aggressive course and is considered to be a grade III/IV lesion.

Figure 28-48 Glioblastoma. Foci of necrosis with pseudo-palisading of malignant nuclei and endothelial cell proliferation.

Clinical Features. The presenting symptoms of infiltrating astrocytomas depend, in part, on the location and growth rate of the tumor. Well-differentiated diffuse astrocytomas may remain stable or progress only slowly over a number of years; the mean survival is more than 5 years. Eventually, however, clinical deterioration invariably occurs and is usually due to the emergence of a more rapidly growing tumor of higher histologic grade. Radiologic studies show mass effect as well as changes in the brain adjacent to the tumor, such as edema. High-grade astrocytomas have abnormal vessels that are “leaky,” with an abnormally permeable blood-brain barrier, and therefore, demonstrate contrast enhancement on imaging studies. The prognosis for individuals with glioblastoma is very poor, although the use of newer chemotherapeutic agents has provided some benefit. Epigenetic silencing of the promoter for the gene encoding the DNA repair enzyme MGMT predicts responsiveness to DNA alkylating drugs—as would be expected since MGMT is critical for the repair of the chemotherapeutically induced DNA modification. With current treatment, consisting of resection followed by radiation therapy and chemotherapy, the mean length of survival after diagnosis has increased to 15 months; 25%

of such patients are alive after 2 years. Survival is substantially shorter in older patients and in patients with lower performance status or with large unresectable lesions. Most of the molecular characteristics of gliomas do not have specific prognostic significance, apart from the beneficial effects of the presence of *IDH1* mutations. Nevertheless, identification of molecular aberrations may provide targets for therapies.

Pilocytic Astrocytoma

Pilocytic astrocytomas (grade I/IV) are distinguished from the other types by their gross and microscopic appearance and relatively benign behavior. They typically occur in children and young adults, and are usually located in the cerebellum but may also appear in the floor and walls of the third ventricle, the optic nerves, and occasionally the cerebral hemispheres. The histologic separation of these tumors from other astrocytomas is supported by the rarity of *TP53* mutations or molecular signatures of infiltrating astrocytomas. Those pilocytic astrocytomas that occur in patients with neurofibromatosis type 1 show functional loss of neurofibromin; this genetic alteration is not observed in sporadic forms. Two types of alterations in the BRAF signaling pathway have been found in pilocytic astrocytoma: translocations which serve to separate the kinase domain from the inhibitory domain, and an activating point mutation (V600E) that is also found in an increasing number of other tumor types (Chapter 7). These findings suggest that targeted therapy with BRAF inhibitors might play a role in the treatment of pilocytic astrocytomas, particularly for lesions in regions not suitable for resection.

MORPHOLOGY

Pilocytic astrocytoma is often cystic (Fig. 28-49); if solid, it may be well circumscribed or, less frequently, infiltrative. The tumor is composed of bipolar cells with long, thin “hairlike” processes that are GFAP-positive and form dense fibrillary meshworks; Rosenthal fibers and eosinophilic granular bodies, are characteristic findings. Tumors are often biphasic, with both loose “microcystic” and fibrillary areas. An increase in the number of blood vessels, often with thickened walls or vascular cell proliferation, is seen but does not imply an unfavorable prognosis. Necrosis and brisk mitotic activity is uncommon. Unlike diffuse fibrillary astrocytomas of any grade, pilocytic astrocytomas show limited infiltration of the surrounding brain.

These tumors grow very slowly, and, in the cerebellum particularly, may be treated by resection. Symptomatic recurrence of incompletely resected lesions is often associated with cyst enlargement rather than growth of the solid component. Tumors that extend into the hypothalamic region from the optic tract can have a more ominous clinical course because of their location.

Pleomorphic Xanthoastrocytoma

This tumor occurs most often in the temporal lobe in children and young adults, usually with a history of seizures. The tumor consists of neoplastic, occasionally bizarre, astrocytes, which are sometimes filled with lipids; these cells can express neuronal and glial markers. The degree

Figure 28-49 Pilocytic astrocytoma in the cerebellum with a nodule of tumor in a cyst.

of nuclear atypia can be extreme and may suggest a high-grade astrocytoma, but the presence of abundant reticulin deposits, relative circumscription, and chronic inflammatory cell infiltrates, along with the absence of necrosis and mitotic activity, distinguish this tumor from more malignant types. The pleomorphic xanthoastrocytoma is usually a low-grade tumor (WHO grade II/IV) with a 5-year survival rate estimated at 80%. Necrosis and mitotic activity are indicative of higher grade tumors and predict a more aggressive course.

Brainstem Glioma

A clinical subgroup of astrocytomas, brainstem gliomas, occur most often in the first 2 decades of life and make up 10% to 20% of all brain tumors in this age group. Several distinct anatomic patterns have been defined in the pediatric age group, each differing in clinical course: intrinsic pontine gliomas (the most common), with an aggressive course and short survival; cervicomedullary junction tumors, often exophytic, with a less aggressive course; and dorsally exophytic gliomas, with an even more benign course which may arise in the tectum of the midbrain, pons, or medulla. Among the rarer brainstem gliomas affecting adults, most are intrinsic pontine gliomas. These can be separated into low-grade diffuse fibrillary astrocytomas and glioblastoma, with the expected differences in clinical course and survival.

The concept that these are a distinct type of glioma is supported by sequencing the genomes of childhood pontine gliomas. Surprisingly, this has revealed that most tumors of this type have a lysine to methionine mutation at position 27 (K27M) in histone H3.1 or H3.3. Of note, H3K27 is a position that is subject to acetylation and methylation events that regulate chromatin structure and gene expression, yet another example of oncogenic mutations that directly impact the epigenome.

Oligodendroglioma

These are infiltrating gliomas comprised of cells that resemble oligodendrocytes. These tumors constitute 5% to 15% of gliomas and are most common in the fourth and fifth decades. Patients may have had several years of neurologic complaints, often including seizures. The lesions are found mostly in the cerebral hemispheres, with a predilection for white matter.

Molecular Genetics. Molecular abnormalities as well as histologic appearance distinguish oligodendrogliomas from astrocytic tumors. The most common genetic alterations in oligodendrogliomas are mutations of the isocitrate dehydrogenase genes (*IDH1* and *IDH2*), which occur in up to 90% of oligodendrogliomas and portend a better prognosis, as they do for astrocytic tumors. Deletions of portions of chromosomes 1p and 19q, typically occurring together as a co-deletion, are seen in up to 80% of cases. Additional genetic alterations occur with progression to anaplastic oligodendroglioma. The more common of these include loss of 9p, loss of 10q, and mutations in *CDKN2A*. In contrast to high-grade astrocytic tumors, *EGFR* gene amplification is not seen, but a significant proportion do show increased *EGFR* protein levels.

In addition to having implications for the biology of the tumors, the molecular alterations in anaplastic oligodendrogliomas have relevance to the choice of treatment modalities. Tumors with co-deletion of 1p/19q have consistent, long-lasting responses to chemotherapy and radiation, whereas those without loss of 1p or 19q appear to be resistant to chemotherapy regimens.

MORPHOLOGY

Oligodendrogliomas are well circumscribed, gelatinous, gray masses, often with cysts, focal hemorrhage, and calcification. The tumors are composed of sheets of regular cells with spherical nuclei containing finely granular chromatin (similar to normal oligodendrocytes) surrounded by a clear halo of vacuolated cytoplasm (Fig. 28-50). The tumor typically contains a delicate network of anastomosing capillaries. Calcification, present in as many as 90% of these tumors, ranges from microscopic foci to massive depositions. Tumor cells infiltrating the cerebral cortex often collect around neurons (perineuronal satellitosis). Mitotic activity is minimal or absent, and proliferation indices are low. Oligodendrogliomas are considered to be WHO grade II/IV lesions.

Anaplastic oligodendrogliomas (WHO grade III/IV) are characterized by a higher cell density, nuclear anaplasia, detectable mitotic activity, and necrosis. These changes can often be found in nodules within an otherwise typical grade II oligodendroglioma. Some of these high-grade oligodendroglial tumors also show patterns that are indistinguishable from glioblastoma. Because several studies have shown that such appearance correlates with worse behavior, these tumors are grouped with glioblastoma.

Clinical Features. In general, individuals with oligodendrogliomas have a better prognosis than do those with astrocytomas. Current treatment with surgery, chemotherapy, and radiation therapy has yielded an average survival of 5 to 10 years. Individuals with anaplastic oligodendroglioma have an overall worse prognosis. Progression from low to higher grade lesions occurs, typically over about 6 years.

Ependymoma and Related Paraventricular Mass Lesions

Ependymomas are tumors that most often arise next to the ependyma-lined ventricular system, including the oft-obliterated central canal of the spinal cord. In the first two decades of life they typically occur near the fourth

Figure 28-50 Oligodendroglioma. Tumor nuclei are round, with cleared cytoplasm forming "halos" and vasculature composed of thin-walled capillaries.

ventricle and constitute 5% to 10% of the primary brain tumors in this age group. In adults the spinal cord is the most common location; tumors in this site are particularly frequent in the setting of neurofibromatosis type 2 (NF2).

Molecular Genetics. Given the association of spinal ependymomas with NF2, it is not surprising that the *NF2* gene on chromosome 22 is commonly mutated in ependymomas in the spinal cord but not at other sites. Ependymomas do not share the genetic alterations that are found in infiltrating gliomas, such as mutations in *TP53*. There appear to be at least two separate subtypes, one expressing a mesenchymal phenotype, typically in younger patients with a higher propensity to develop metastases, and a second with aberrations of large regions of chromosomes or whole chromosomes that tends to have a better overall prognosis.

MORPHOLOGY

In the fourth ventricle, ependymomas are typically solid or papillary masses arising from the floor of the ventricle (Fig. 28-51A). Although ependymomas are moderately well demarcated from adjacent brain, the proximity of vital pontine and medullary nuclei usually makes complete extirpation impossible. In the intraspinal tumors, the sharp demarcation sometimes makes total removal feasible. Ependymomas are composed of cells with regular, round to oval nuclei and abundant granular chromatin. Between the nuclei there is a variably dense fibrillary background. Tumor cells may form gland-like round or elongated structures (rosettes, canals) that resemble the embryologic ependymal canal, with long, delicate processes extending into a lumen (Fig. 28-51B); more frequently present are **perivascular pseudorosettes** (Fig. 28-51B), in which tumor cells are arranged around vessels with an intervening zone consisting of thin ependymal processes directed toward the wall of the vessel. GFAP expression is found in most ependymomas. While most ependymomas are well differentiated and behave as WHO grade II/IV lesions, anaplastic ependymomas (WHO grade III/IV) reveal increased cell density, high mitotic rates, areas of necrosis, and less evident ependymal differentiation.

Figure 28-51 Ependymoma. **A**, Tumor growing into the fourth ventricle, distorting, compressing, and infiltrating surrounding structures. **B**, Microscopic appearance of ependymoma.

Myxopapillary ependymomas are distinct but related lesions that occur in the filum terminale of the spinal cord and contain papillary elements in a myxoid background, admixed with ependymoma-like cells. Cuboidal cells, sometimes with clear cytoplasm, are arranged around papillary cores containing connective tissue and blood vessels. The myxoid areas contain neutral and acidic mucopolysaccharides. Prognosis depends on completeness of surgical resection; if the tumor has extended into the subarachnoid space and surrounded the roots of the cauda equina, recurrence is likely.

Clinical Features. Posterior fossa ependymomas often manifest with hydrocephalus secondary to progressive obstruction of the fourth ventricle. Because of the relationship of ependymomas to the ventricular system, CSF dissemination is a common occurrence and portends a poor prognosis. Posterior fossa lesions have the worst overall outcome, particularly in younger children, in whom the 5-year survival is roughly 50%. The clinical outcome for completely resected supratentorial and spinal ependymomas is better.

Several other tumors occur either immediately below the ependymal lining of the ventricle or in association with the choroid plexus, which sits in continuity with the ependyma. With the exception of the rare choroid plexus carcinoma, these are benign; however, because of location they may cause clinical problems.

- *Subependymomas* are solid, sometimes calcified, slow-growing nodules attached to the ventricular lining and protruding into the ventricle. They are usually asymptomatic and are incidental findings at autopsy or imaging; if they are sufficiently large or strategically located, they may cause hydrocephalus. They are most often found in the lateral and fourth ventricles and have a characteristic microscopic appearance, with clusters of ependymal-appearing nuclei scattered in a dense, fine, glial fibrillar background.
- *Choroid plexus papillomas* may occur anywhere along the choroid plexus and are most common in children, in

whom they are usually found in the lateral ventricles. In adults, they more often involve the fourth ventricle. These papillary growths almost exactly recapitulate the structure of the normal choroid plexus. The papillae have connective tissue stalks covered with a cuboidal or columnar epithelium. Clinically, choroid plexus papillomas usually present with hydrocephalus due to obstruction of the ventricular system by tumor or overproduction of CSF. The far rarer *choroid plexus carcinomas* resemble adenocarcinoma. These tumors are usually found in children; in adults, they must be differentiated from metastatic carcinoma, which is much more common than primary carcinomas of the choroid.

- *Colloid cyst of the third ventricle* is a non-neoplastic enlarging cyst that most often occurs in young adults. The cyst is attached to the roof of the third ventricle, where it can obstruct one or both of the foramina of Monro and, as a result, causes noncommunicating hydrocephalus which may be rapidly fatal. Headache, sometimes positional, is an important clinical symptom. The cyst has a thin, fibrous capsule and a lining of low to flat cuboidal epithelium; it contains gelatinous, proteinaceous material.

Neuronal Tumors

Far less common than glial tumors are those that exhibit neuronal differentiation. In general, neuronal tumors are more often seen in younger adults and often present with seizures.

- *Gangliogliomas* are tumors comprised of a mixture of mature neuronal and glial cells. They are typically superficial lesions that present with seizures. These are the most common of the neuronal tumors of the CNS. Most of these tumors are slow growing, but the glial component occasionally becomes anaplastic, and the disease then progresses rapidly. When gangliogliomas present because of a seizure disorder, surgical resection of the tumor is usually effective in controlling the seizures. Approximately 20% of these tumors have an

activating mutation in the *BRAF* gene (V600E), and are associated with a shorter recurrence-free survival.

Gangliogliomas are most commonly found in the temporal lobe and often have a cystic component. The neoplastic ganglion cells are irregularly clustered and have apparently random orientation of neurites. Binucleate forms are found. The glial component of these lesions usually resembles a low-grade astrocytoma, lacking mitotic activity and necrosis.

- *Dysembryoplastic neuroepithelial tumor* is a rare, low-grade (WHO Grade I) tumor of childhood that often presents as a seizure disorder. It has a good prognosis following surgical resection, with both low recurrence rates and favorable seizure control. These lesions are typically located in the superficial temporal lobe, although other cortical sites are seen. There is often attenuation of the overlying skull, suggesting that the lesion has been present for some time.

These lesions typically form multiple discrete intracortical nodules of small, round cells, arranged in columns around central cores of processes, and are associated with a myxoid background. There are well-differentiated “floating neurons” that sit in the pools of mucopolysaccharide-rich fluid of the myxoid background. The larger neurons and the small, round cells of the specific element express neuronal markers. Surrounding the nodules, there may be focal cortical dysplasia; lesions that show both the specific element and a glial component are termed complex.

- *Central neurocytoma* typically is a low-grade (WHO Grade II) neuronal neoplasm found within the ventricular system (most commonly the lateral or third ventricles), characterized by evenly spaced, round, uniform nuclei and often islands of neuropil. Although in pattern and shape the cells resemble oligodendroglioma, ultrastructural and immunohistochemical studies reveal the neuronal lineage of the tumor cells.

Poorly Differentiated Neoplasms

Some tumors, though of neuroectodermal origin, express few if any markers of mature neural cells and are described as poorly differentiated or embryonal, meaning that they retain cellular features of primitive, undifferentiated cells. The most common is the *medulloblastoma*, which accounts for 20% of brain tumors in children.

Medulloblastoma

This malignant embryonal tumor occurs predominantly in children and exclusively in the cerebellum (by definition). Neuronal and glial markers may be expressed, but the tumor is often largely undifferentiated and corresponds to WHO grade IV.

Molecular Genetics. Molecular subtypes of medulloblastoma have been identified through genomic studies, revealing alterations of signaling pathways involved in normal cerebellar development, such as the sonic hedgehog-patched (SHH) pathway involved in control of normal proliferation of cerebellar granule cells, and the WNT/ β -catenin signaling pathway. On the basis of molecular alterations, medulloblastoma can be divided into four groups:

- The *WNT type*, characterized by mutations in the WNT signaling pathway, tends to occur in older children, has a classic medulloblastoma histology, and shows monosomy of chromosome 6 and nuclear expression of β -catenin. The prognosis is best in this subtype with 90% 5-year survival.
- The *SHH type*, characterized by mutations involving the sonic hedgehog signaling pathway, tends to occur in infants or young adults, tends to have a nodular desmoplastic histology and may have *MYCN* amplification. The prognosis is intermediate between the WNT subtype and groups 3 and 4.
- *Group 3 medulloblastoma*, often with *MYC* amplification and isochromosome 17 (i17q), tends to occur in infants and children, with a classic or large cell histology and the worst prognosis.
- *Group 4* is characterized by an i17q cytogenetic alteration, classic or large cell histology, without *MYC* amplification, but sometimes with *MYCN* amplification. The prognosis in group 4 is intermediate. In general, isochromosome 17q signals a poor prognosis, and is restricted to groups 3 and 4.

MORPHOLOGY

In children, medulloblastomas are located in the midline of the cerebellum, but lateral locations are more often found in adults. Rapid growth may occlude the flow of CSF, leading to hydrocephalus. The tumor is often well circumscribed, gray, and friable, and may be seen extending to the surface of the cerebellar folia and involving the leptomeninges (Fig. 28-52A). On microscopic examination, medulloblastoma is very densely cellular, with sheets of anaplastic cells (Fig. 28-52B). Individual tumor cells are small, with scant cytoplasm and hyperchromatic nuclei that are frequently elongated or crescent shaped. Mitoses are abundant, and markers of cellular proliferation, such as Ki-67, are detected in a high percentage of the cells. The tumor may express neuronal (neurosecretory) granules, form Homer-Wright rosettes, as occur in neuroblastoma (Chapter 10), and express glial markers (e.g., GFAP). The **nodular desmoplastic variant** is characterized by areas of stromal response, marked by collagen and reticulin deposition and nodules of cells forming “pale islands” that have more neuropil and show greater expression of neuronal markers. The **large cell variant** is characterized by large irregular vesicular nuclei, prominent nucleoli, and frequent mitoses and apoptotic cells.

At the edges of the main tumor mass, medulloblastoma cells have a propensity to form linear chains of cells infiltrating through cerebellar cortex and penetrating the pia, spreading into the subarachnoid space. Dissemination through the CSF is a common complication, giving rise to nodular masses at some distance from the primary tumor (e.g. as far as the cauda equina); these are sometimes termed “drop metastases.”

Clinical Features. The tumor is highly malignant, and the prognosis for untreated patients is dismal; however, it is exquisitely radiosensitive. With total excision and irradiation, the 5-year survival rate may be as high as 75%. How the different molecular subtypes of medulloblastoma respond to therapies is under active investigation; early clinical trials suggest some medulloblastomas may respond to inhibitors of the hedgehog signaling pathway.

Figure 28-52 Medulloblastoma. **A**, Sagittal section of brain showing medulloblastoma destroying the superior midline cerebellum. **B**, Microscopic appearance of medulloblastoma.

Tumors of similar poorly differentiated histology and resembling medulloblastomas may occur in the cerebral hemispheres. These lesions are known as CNS supratentorial primitive neuroectodermal tumors (CNS PNET). This term unfortunately can lead to confusion with the peripheral lesion (peripheral neuroectodermal tumor), which shares a genetic alteration with Ewing sarcoma. In the CNS, PNET is distinct from medulloblastoma and from the peripheral tumor.

Atypical Teratoid/Rhabdoid Tumor

This highly malignant tumor of young children is a WHO grade IV tumor occurring in the posterior fossa and supratentorial compartments in nearly equal proportions. It is characterized by divergent differentiation with epithelial, mesenchymal, neuronal, and glial components, and often includes rhabdoid cells, resembling those of a rhabdomyosarcoma.

Molecular Genetics. Consistent genetic alterations in chromosome 22 (>90% of cases) are a hallmark of rhabdoid tumor. The relevant gene is *hSNF5/INI1*, which encodes a protein that is part of a large chromatin-remodeling complex; deletions of the locus and loss of nuclear staining for INI1 protein are seen in the majority of tumors.

MORPHOLOGY

Atypical teratoid/rhabdoid tumors tend to be large, with a soft consistency, and spread along the surface of the brain. The rhabdoid cells have eosinophilic cytoplasm, sharp cell borders and eccentrically located nuclei. When these cells are smaller, the cytoplasm can take on an elongated appearance that mimics a rhabdomyosarcoma cell. The cytoplasm of the rhabdoid cell contains intermediate filaments and is immunoreactive for epithelial membrane antigen and vimentin. Some other markers that may be positive include smooth muscle actin and keratins. Other muscle markers such as desmin and myoglobin are not present. Rhabdoid cells are rarely a major component of the tumor; instead, islands of tumor with this pattern of differentiation are mixed with a small-cell component, as well as other histologic patterns (including mesenchymal, epithelial, and neuroglial differentiation). Mitotic activity is extremely prominent.

Clinical Features. These are highly aggressive tumors of the very young. Nearly all tumors occur before the age of 5 and most patients live less than a year after diagnosis.

Other Parenchymal Tumors

Primary CNS Lymphoma

Primary CNS lymphoma accounts for 2% of extranodal lymphomas and 1% of intracranial tumors. It is the most common CNS neoplasm in immunosuppressed individuals, including those with AIDS and immunosuppression after transplantation. In non-immunosuppressed populations, the age spectrum is relatively wide, but the frequency increases after 60 years of age.

The term *primary* emphasizes the distinction between these lesions and secondary involvement of the CNS by lymphoma arising elsewhere in the body (Chapter 13). Primary brain lymphoma is often multifocal within the brain parenchyma, yet involvement outside of the CNS in lymph nodes or bone marrow is a rare and late complication. Conversely, lymphoma arising outside the CNS rarely involves the brain parenchyma; involvement of the nervous system, when it occurs in systemic lymphoma, usually occurs in the setting of significant disease burden outside of the CNS. In this situation, secondary involvement of the CNS is usually manifested by the presence of malignant cells within the CSF and around intradural nerve roots, and occasionally by the infiltration of superficial areas of the cerebrum or spinal cord by malignant cells.

The vast majority of primary brain lymphomas are of B-cell origin. Overall, primary lymphomas of the CNS are aggressive and have worse outcomes than tumors of comparable histology occurring at non-CNS sites. In the setting of immunosuppression, the cells in nearly all primary brain lymphomas are latently infected by Epstein-Barr virus, and in the setting of organ transplantation, may be associated with a systemic post-transplantation lymphoproliferative disorder. When not associated with immunosuppression, these lymphomas show a phenotype typical of postgerminal center B-cell differentiation.

MORPHOLOGY

Lesions are frequently multiple and often involve deep gray matter as well as white matter and cortex. Periventricular spread is common. The tumors are relatively well defined in comparison with glial neoplasms but are not as discrete as metastases and often show extensive areas of central necrosis. Diffuse large-cell B-cell lymphomas are the most common histologic group. Within the tumor malignant cells infiltrate the parenchyma of the brain and accumulate around blood vessels. Reticulin stains demonstrate that the infiltrating cells are separated from one another by silver-staining material; this pattern, referred to as “hooping,” is characteristic of primary brain lymphoma. The tumors express B cell markers such as CD20 and usually have a high growth fraction. When tumors arise in the setting of immunosuppression, various markers of Epstein-Barr virus are usually present in the tumor cells; the virus is usually detected by doing in situ hybridization for EBERS, small nuclear RNAs that are encoded by the viral genome.

Intravascular lymphoma, an unusual large cell lymphoma that grows within small vessels, often involves the brain along with other regions of the body. Instead of presenting as a mass lesion, the occlusion of vessels by malignant cells can result in widespread microscopic infarcts. Affected individuals often present with nonlocalizing neurologic symptoms, with the differential diagnosis usually including processes such as vasculitis or even dementia.

Germ Cell Tumors

Primary brain germ cell tumors occur along the midline, most commonly in the pineal and the suprasellar regions. They account for 0.2% to 1% of brain tumors in people of European descent but up to 10% in Japan. They are tumors of the young, with 90% occurring during the first two decades. Germ cell tumors, particularly teratomas, are among the more common congenital tumors. Germ cell tumors in the pineal region show a strong male predominance; this gender difference is not seen for suprasellar lesions.

The source of germ cells in the CNS is not clear; they may be “rests” that remain in the CNS or perhaps migrate there from other sites late in development. Germ cell tumors share many features with their counterparts in the gonads and mediastinum. In contrast to lymphomas, however, metastasis of a gonadal germ cell tumor to the CNS is common; thus, the presence of a non-CNS primary tumor must be excluded before a diagnosis of primary germ cell tumor of the CNS is made. The histologic classification of brain germ cell tumors is similar to that used in the testis (Chapter 21), but the tumor that is histologically similar to the seminoma in the testis is referred to as *germinoma* in the CNS. The responses to radiation therapy and chemotherapy parallel those of germ cell tumors arising at other sites. As in the periphery, CSF levels of tumor markers including α -fetoprotein and β -human chorionic gonadotropin may be useful for assisting diagnosis and tracking response to therapy.

Pineal Parenchymal Tumors

These lesions arise from specialized cells of the pineal gland (pineocytes) that have features of neuronal

differentiation. The tumors range from well-differentiated lesions (*pineocytomas*), with areas of neuropil, cells with small, round nuclei, and no evidence of mitoses or necrosis, to high-grade tumors (*pineoblastomas*), with little evidence of neuronal differentiation, densely packed small cells with necrosis, and frequent mitotic figures. An intermediate form between these two extremes is also recognized. High-grade pineal tumors tend to affect children, while lower-grade lesions are found more often in adults. The highly aggressive pineoblastoma commonly spreads throughout the CSF space. It occurs with increased frequency in individuals with germ line mutations in *RB*. Gliomas are also found in the pineal region, arising from the glial stroma of the gland. Often low grade, these gliomas may extend into the posterior third ventricle.

Meningiomas

Meningiomas are predominantly benign tumors of adults, usually attached to the dura, that arise from the meningotheial cells of the arachnoid. Meningiomas may be found along any of the external surfaces of the brain as well as within the ventricular system, where they arise from the stromal arachnoid cells of the choroid plexus. Prior radiation therapy to the head and neck, typically decades earlier, is a risk factor for development of meningiomas. Other tumors such as metastases, solitary fibrous tumors, and a range of poorly differentiated sarcomas may also grow as dural-based masses.

Molecular Genetics. The most common cytogenetic abnormality is loss of chromosome 22, especially the long arm (22q). The deletions include the region of 22q12 that harbors the *NF2* gene, which encodes the protein merlin; as expected, meningiomas are a common lesion in the setting of *NF2* (see later). Of sporadic meningiomas, 50% to 60% harbor mutations in the *NF2* gene; most of these mutations are predicted to result in absence of functional merlin protein. In meningiomas without *NF2* mutations, the most common mutations occur in TNF-receptor associated factor 7 (*TRAF7*), and identify a separate molecular subset of meningiomas with a tendency toward lower histologic grade and greater chromosomal stability. By contrast, higher grade meningiomas are more often associated with *NF2* mutations, loss of chromosome 22, and evidence of chromosomal instability (e.g., the presence of additional chromosomal aberrations).

MORPHOLOGY

Meningiomas are usually rounded masses with well-defined dural bases that compress underlying brain but are easily separated from it (Fig. 28-53A). Extension into the overlying bone may be present. The surface of the mass is usually encapsulated by thin, fibrous tissue and may have a bosselated or polypoid appearance. They may also grow **en plaque**, in which the tumor spreads in a sheetlike fashion along the surface of the dura. This form is commonly associated with hyperostotic reactive changes in the adjacent bone. The lesions range from firm and fibrous to finely gritty, or they may contain numerous calcified psammoma bodies. Grossly evident necrosis and extensive hemorrhage are absent.

Figure 28-53 **A**, Parasagittal multilobular meningioma attached to the dura with compression of underlying brain. **B**, Meningioma with a whorled pattern of cell growth and psammoma bodies.

Most meningiomas have a relatively low risk of recurrence or aggressive growth, and so are considered WHO grade I/IV. Various histologic patterns are observed, with no prognostic significance. These include **syncytial** (“meningothelial”), appropriately named for the whorled clusters of cells that sit in tight groups without visible cell membranes; **fibroblastic**, with elongated cells and abundant collagen deposition between them; **transitional**, which share features of the syncytial and fibroblastic types; **psammomatous**, with psammoma bodies, apparently formed from calcification of the syncytial nests of meningothelial cells (Fig. 28-53B); **secretory**, with PAS-positive intracytoplasmic droplets and intracellular lumens by electron microscopy; and **microcystic**, with a loose, spongy appearance. Only the secretory subtype appears to be associated with a specific genotype; in initial reports all have had mutations of the *TRAF7* and *KLF4* genes. Xanthomatous degeneration, metaplasia (often osseous), and moderate nuclear pleomorphism are common in meningiomas. Among these lesions, proliferation index has been shown to be a predictor of biologic behavior.

Atypical meningiomas (WHO grade II/IV) are lesions with a higher rate of recurrence and more aggressive local growth, and may require radiation therapy in addition to surgery. They are distinguished from lower grade meningiomas by having four or more mitoses per 10 high power fields or at least three atypical features (increased cellularity, small cells with a high nuclear-to-cytoplasmic ratio, prominent nucleoli, patternless growth, or necrosis). Certain histologic patterns (**clear cell** and **chordoid**) are also considered to be grade II/IV because of their more aggressive behavior.

Anaplastic (malignant) meningioma (WHO grade III/IV) is a highly aggressive tumor with the appearance of a high-grade sarcoma, but retaining some histologic evidence of meningothelial origin. Mitotic rates are often high (>20 mitoses per 10 high power fields). **Papillary** meningioma (with pleomorphic cells arranged around fibrovascular cores) and **rhabdoid** meningioma (with sheets of tumor cells with hyaline eosinophilic cytoplasm containing intermediate filaments) both have such a high propensity to recur that they are also considered to be WHO grade III/IV tumors.

While most meningiomas are easily separable from the brain, some tumors invade the brain, either as broad, pushing edges

or as single cells. The presence of brain invasion is associated with increased risk of recurrence but does not alter the histologic grade of the lesion. Meningiomas are commonly immunoreactive for epithelial membrane antigen, in contrast to other tumors arising in this region. Keratin is restricted to lesions with the secretory pattern, and these tumors are also positive for carcinoembryonic antigen.

Clinical Features. Meningiomas are usually slow-growing tumors. Patients present either with vague nonlocalizing symptoms or with focal findings referable to compression of underlying brain. Common sites of involvement include the parasagittal aspect of the brain convexity, dura over the lateral convexity, wing of the sphenoid, olfactory groove, sella turcica, and foramen magnum. They are uncommon in children and generally show a moderate (3:2) female predominance, although the ratio is 10:1 for spinal meningiomas, which are also commonly psammomatous. Lesions are usually solitary, but when present at multiple sites, especially in association with acoustic neuromas or glial tumors, the possibility of neurofibromatosis type 2 should be considered. Genetic studies indicate that multiple lesions are much more likely to represent dissemination from a single tumor than clonally distinct tumors. Meningiomas often express progesterone receptors and may grow more rapidly during pregnancy.

Metastatic Tumors

Metastatic lesions, mostly carcinomas, account for approximately a quarter to half of intra-cranial tumors in hospitalized patients. The five most common primary sites are lung, breast, skin (melanoma), kidney, and gastrointestinal tract, accounting for about 80% of all metastases. Some rare tumors (e.g., choriocarcinoma) have a high likelihood of metastasizing to the brain, whereas other more common tumors (e.g., prostatic adenocarcinoma) almost never do so. The meninges are also a frequent site of involvement by metastatic disease. Metastatic tumors present clinically as mass lesions and may occasionally be the first manifestation of the cancer. In general, localized treatment of solitary brain metastases improves the quality of the patient's

remaining life. Metastases to the epidural or subdural space can cause spinal cord compression, which requires emergency treatment.

MORPHOLOGY

Intraparenchymal metastases form sharply demarcated masses, often at the junction of gray and white matter, usually surrounded by a zone of edema. The boundary between tumor and brain parenchyma is usually well-defined microscopically; melanoma does not always follow this rule and individual cells may invade the brain. Nodules of tumor, often with central areas of necrosis, are surrounded by reactive gliosis. Meningeal carcinomatosis, with tumor nodules studding the surface of the brain, spinal cord, and intradural nerve roots, is most commonly associated with carcinoma of the lung and the breast.

Paraneoplastic Syndromes

In addition to the direct and localized effects produced by metastases, patients with diverse tumors develop *paraneoplastic syndromes* that involve the peripheral and/or central nervous systems, sometimes even preceding the clinical recognition of the malignant neoplasm. A variety of clinical paraneoplastic syndromes have been described. An underlying mechanism of these syndromes appears to be the development of an immune response against tumor antigens that cross-react with antigens in the central or peripheral nervous systems. Certain malignancies are typically associated with a particular clinical syndrome. The circulating antibodies and target antigens are in the process of being defined in some of the clinical syndromes. Illustrative examples of these are described below:

- *Subacute cerebellar degeneration* is associated with destruction of Purkinje cells, gliosis, and a mild chronic inflammatory cell infiltrate. One group of these patients has a circulating PCA-1 antibody (anti-Yo) that recognizes cerebellar Purkinje cells; this antibody occurs predominantly in women with ovarian, uterine, or breast carcinoma.
- *Limbic encephalitis* is characterized by subacute dementia and marked by perivascular inflammatory cuffs, microglial nodules, some neuronal loss, and gliosis, most evident in the anterior and medial portions of the temporal lobe; the microscopic picture resembles that of an infectious process. A comparable process involving the brainstem can be seen in isolation or together with limbic system involvement. Some of these patients have a circulating ANNA-1 antibody (anti-Hu) that recognizes neuronal nuclei in the central and peripheral nervous systems; ANNA-1 is most commonly associated with small cell carcinoma of the lung. Another group of these patients has a circulating antibody that recognizes the NMDA receptor and cross-reacts with hippocampal neurons. Originally identified in women with ovarian teratomas, the same clinical syndrome is now also recognized in a small proportion of patients with sporadic encephalitis. A third group of patients has a circulating VGKC-complex antibody that recognizes the voltage-gated potassium channel; the presence of this antibody may be associated with peripheral

neuropathy as well. It is important to note that in many cases of limbic encephalitis, the syndrome appears before any malignancy is suspected and as such triggers the search for a tumor elsewhere in the body.

- *Eye movement disorders*, most commonly opsoclonus, may be found, often in association with other evidence of cerebellar and brainstem dysfunction. In children this is most commonly associated with neuroblastoma and is often accompanied by myoclonus.

The peripheral nervous system can also be affected:

- *Subacute sensory neuropathy* may be found in association with limbic encephalitis or in isolation. It is marked by loss of sensory neurons from dorsal root ganglia, in association with lymphocytic inflammation.
- *Lambert-Eaton myasthenic syndrome* is caused by antibodies against the voltage-gated calcium channel in the presynaptic elements of the neuromuscular junction. This can be seen in the absence of malignancy as well.

For some paraneoplastic syndromes, there is evidence that immunotherapy (removal of circulating antibodies and immunosuppression) and tumor removal result in clinical improvement. In general, those clinical syndromes with plasma membrane-reactive antibodies (e.g., VGKC and NMDAR) respond to immunotherapy better than those associated with intracellular antigens (e.g., ANNA-1 and PCA-1).

Familial Tumor Syndromes

A number of inherited diseases are associated with the occurrence of tumors (Chapter 7). In several of these, tumors of the nervous system are a prominent aspect of the disease and these are discussed below. Other syndromes include tumors of the CNS as part of their spectrum, but the bulk of disease burden lies elsewhere.

- *Cowden syndrome*: Dysplastic ganglioglioma of the cerebellum (Lhermitte-Duclos disease), caused by mutations in *PTEN* resulting in PI3K/AKT signaling pathway activity (Chapter 7)
- *Li-Fraumeni syndrome*: Medulloblastomas, caused by mutations in *TP53* (Chapter 7)
- *Turcot syndrome*: Medulloblastoma or glioblastoma, caused by mutations in *APC* or mismatch repair genes (as for familial colon cancer; Chapter 17)
- *Gorlin syndrome*: Medulloblastoma, caused by mutations in the *PTCH* gene resulting in up-regulation of sonic hedgehog signaling pathways (Chapter 25).

Tuberous Sclerosis Complex

Tuberous sclerosis is an autosomal dominant syndrome occurring at a frequency of approximately 1 in 6000 births. It is characterized by the development of hamartomas and benign neoplasms involving the brain and other tissues; the most frequent clinical manifestations are seizures, autism, and mental retardation. Hamartomas within the CNS take the form of cortical tubers and subependymal nodules; subependymal giant-cell astrocytomas are low grade neoplasms that appear to develop from the hamartomatous nodules in the same location. Cortical tubers are often epileptogenic, and surgical resection can be beneficial when

medical management of the seizures fails. Elsewhere in the body, renal angiomyolipomas, retinal glial hamartomas, pulmonary lymphangiomyomatosis and cardiac rhabdomyomas develop over childhood and adolescence. Cysts may be found at various sites, including the liver, kidneys, and pancreas. Cutaneous lesions include angiofibromas, localized leathery thickenings (shagreen patches), hypopigmented areas (ash-leaf patches), and subungual fibromas.

One tuberous sclerosis locus (*TSC1*) is found on chromosome 9q34, and encodes a protein known as hamartin; the more commonly mutated tuberous sclerosis locus (*TSC2*) is at 16p13.3 and encodes tuberin. These two proteins associate to form a complex that inhibits the kinase mTOR, which is a key regulator of protein synthesis and other aspects of anabolic metabolism. Of note, mTOR controls cell size, and the tumors associated with tuberous sclerosis are remarkable for having voluminous amounts of cytoplasm, particularly giant-cell astrocytomas in the CNS, and cardiac rhabdomyomas. Cortical and subependymal tubers are associated with an intact copy of the wild-type allele, while in subependymal giant-cell astrocytomas there is biallelic loss. Treatment is symptomatic, including anticonvulsant therapy for control of seizures. Treatment of patients with mTOR inhibitors has resulted in some clinical improvement.

MORPHOLOGY

Cortical hamartomas of tuberous sclerosis are firm areas of the cortex that, in contrast to the softer adjacent cortex, have been likened to potatoes, hence the appellation “tubers.” These hamartomas are composed of haphazardly arranged neurons that lack the normal laminar organization of neocortex. In addition, some large cells have appearances intermediate between glia and neurons (large vesicular nuclei with nucleoli, resembling neurons, and abundant eosinophilic cytoplasm resembling gemistocytic astrocytes) and often express intermediate filaments of both neuronal (neurofilament) and glial (GFAP) types. Consistent with the preservation of the wild-type allele, these cells usually stain for both tuberin and hamartin. Similar hamartomatous features are present in the subependymal nodules, where the large astrocyte-like cells cluster beneath the ventricular surface. These multiple droplike masses that bulge into the ventricular system gave rise to the term *candle-guttering*. In subependymal areas a tumor unique to tuberous sclerosis, subependymal giant-cell astrocytoma, occurs, which is marked by having very large amounts of eosinophilic cytoplasm.

Von Hippel-Lindau Disease

Individuals with this autosomal dominant disease develop hemangioblastomas of the CNS and cysts involving the pancreas, liver, and kidneys, and have a propensity to develop renal cell carcinoma and pheochromocytoma. Hemangioblastomas are most common in the cerebellum and retina, but may also occur in other locations in the CNS. The disease frequency is 1 in 30,000 to 40,000.

The gene associated with von Hippel-Lindau disease (*VHL*), a tumor suppressor gene, is located on chromosome 3p25.3 and encodes a protein (VHL) that, among its other functions, is a component of a ubiquitin ligase complex that down-regulates hypoxia-induced factor 1 (HIF-1), a transcription factor involved in regulating expression of

vascular endothelial growth factor, erythropoietin, and other growth factors. It is the dysregulation of erythropoietin that is responsible for the polycythemia observed in association with hemangioblastomas in about 10% of cases. HIF also regulates the expression of genes that control cellular metabolism and cell growth, activities that likely contribute to tumor formation. Why particular cell types are uniquely susceptible to transformation by HIF hyperactivity, however, remains uncertain.

MORPHOLOGY

Hemangioblastomas are highly vascular neoplasms that occur as a mural nodule associated with a large fluid-filled cyst. The lesion consists of variable proportions of capillary-size or somewhat larger thin-walled vessels and intervening stromal cells of uncertain histogenesis characterized by vacuolated, lightly PAS-positive, lipid-rich cytoplasm. The stromal cells are of uncertain origin but can be demonstrated to express inhibin by immunohistochemistry. These are the cells that show the presence of a second “hit” in the previously normal *VHL* allele, and on this basis they are considered to be the neoplastic element in hemangioblastoma.

Therapy is directed at the symptomatic neoplasms, including resection of the cerebellar hemangioblastomas and laser therapy for retinal hemangioblastomas.

Neurofibromatosis

Two autosomal dominant disorders, NF1 and NF2, are familial tumor syndromes characterized by tumors of the PNS and CNS. NF1 is the more common, with a frequency of 1 in 3,000, and is characterized by neurofibromas of peripheral nerve, gliomas of the optic nerve, pigmented nodules of the iris (*Lisch nodules*), and cutaneous hyperpigmented macules (*café au lait spots*). NF2 is most commonly characterized by bilateral schwannomas of the vestibulocochlear nerves (cranial nerve VIII) and multiple meningiomas. Gliomas may also occur in these patients; typically these are ependymomas of the spinal cord. This disorder is much less common than NF1, having a frequency of 1 in 40,000 to 50,000. Both types of neurofibromatosis are discussed in more detail in [Chapter 27](#).

KEY CONCEPTS

Tumors

- Tumors of the CNS may arise from the cells of the coverings (meningiomas), the brain (gliomas, neuronal tumors, choroid plexus tumors), or other CNS cell populations (primary CNS lymphoma, germ cell tumors), or they may originate elsewhere in the body (metastases).
- Even low-grade or benign tumors can have poor clinical outcomes, depending on where they occur in the brain.
- Distinct types of tumors affect specific brain regions (e.g., cerebellum for medulloblastoma, an intraventricular location for central neurocytoma) and specific age populations (medulloblastoma and pilocytic astrocytomas in pediatric age groups, and glioblastoma and lymphoma in older patients).

- Glial tumors are broadly classified into astrocytomas, oligodendrogliomas, and ependymomas. Increasing tumor malignancy is associated with more cytologic anaplasia, increased cell density, necrosis, and mitotic activity. There are distinct associations between combinations of genetic alterations in tumors and morphologic appearance; some of these also carry prognostic significance.
- Metastatic spread of brain tumors to other regions of the body is rare, but the brain is not comparably protected against spread of distant tumors. Carcinomas are the dominant type of systemic tumors that metastasize to the nervous system.

SUGGESTED READINGS

General

In general, many areas of neuropathology and neurologic diseases are well covered in the following standard texts:

Although this chapter comes at the end of the book, it is not the least important. Vision is a major quality-of-life issue. Before the public awareness of acquired immunodeficiency syndrome (AIDS) and Alzheimer disease, the most feared disease among Americans was cancer, and the second most feared disease was blindness. So great is the fear of blindness that even today, people often tell their physicians, "Doctor, I'd rather be dead than be blind!"

In general, diseases that produce loss of vision do not attract as much attention as do many of the life-threatening conditions described in this book. For example, age-related macular degeneration (AMD) is the most common cause of irreversible visual loss in the United States. Most individuals with AMD do not even suffer from a total loss of vision – an immersion into darkness. The histopathology is unimpressive: small scars develop in the macula. But consider the effect of these tiny scars in a retired schoolteacher with AMD. The central portion of her or his vision is lost. The faces of spouse or grandchildren are not visible. He or she cannot read a book or newspaper. Once a model of independence, this teacher can no longer drive a car and

must be chauffeured everywhere. In short, this person is robbed of the common joys that most of us take for granted.

To study the eye, one needs to comprehend all that has come before. For example, the pathology of the eyelids builds on knowledge of dermatopathology (Chapter 25), and the pathology of the retina and optic nerve extends what was learned in Chapter 28 about the brain and central nervous system. However, the study of ocular pathology does not merely repeat what has been presented thus far. The eye provides the only site in which a physician can directly visualize a variety of microcirculatory disturbances ranging from arteriosclerosis to angiogenesis in the clinic. Although there are conditions that are unique to the eye (e.g., cataract and glaucoma), many ocular conditions share similarities with disease processes elsewhere in the body that are modified by the unique structure and function of the eye (Fig. 29-1).

The eye has much to teach us about important mechanisms of disease that extend far beyond the visual system. For example, the tumor suppressor gene, *RB*, was described in retinoblastoma, a quite uncommon ocular tumor of

Figure 29-1 Anatomy of the eye.

infants and very young children, but the discovery of *RB* opened an important pathway to the understanding of the regulation of cellular replication.

In recent years, the elucidation of the molecular pathogenesis of disease been translated rapidly to therapeutic applications in the eye. Many blinding conditions such as corneal neovascularization, diabetic retinopathy, and certain forms of age-related neovascularization, result from pathologic angiogenesis. Successful treatment of these conditions with vascular endothelial growth factor (VEGF) antagonists has saved vision in patients who might have been blinded just a few years ago.

This chapter is organized on the basis of ocular anatomy. The discussion of each region of the eye begins with anatomic and functional considerations, and their impact on the understanding of ocular diseases.

Orbit

Functional Anatomy and Proptosis

The orbit is a compartment that is closed medially, laterally, and posteriorly. Diseases that increase orbital contents therefore displace the eye forward, a condition known as *proptosis*. Aside from the obvious cosmetic concerns, the proptotic eye might not be covered completely by the eyelids, and the tear film might not be distributed evenly across the cornea. Chronic corneal exposure to air is injurious, leading to pain and predisposing to corneal ulceration and infection. Proptosis may be axial

(directly forward) or positional. For example, any enlargement of the lacrimal gland from inflammation (e.g., *sarcoidosis*) or neoplasm (e.g., *lymphoma*, *pleomorphic adenoma*, or *adenoid cystic carcinoma*) produces a proptosis that displaces the eye inferiorly and medially, because the lacrimal gland is positioned superotemporally within the orbit.

Masses contained within the cone formed by the horizontal rectus muscles generate axial proptosis: the eye bulges straight forward. The two most common primary tumors of the optic nerve (a tract of the central nervous system), *glioma* and *meningioma*, produce axial proptosis because the optic nerve is positioned within the muscle cone. The orbital contents are subject to the same disease processes that affect other tissues. Representative inflammatory conditions and neoplasms of the orbit are discussed briefly next.

Thyroid Ophthalmopathy (Graves Disease)

In the chapter on endocrine disorders (Chapter 24) it was noted that axial proptosis is an important clinical manifestation of Graves disease. Proptosis is caused by the accumulation of extracellular matrix proteins and variable degrees of fibrosis in the rectus muscles (Fig. 29-2). The development of thyroid ophthalmopathy may be independent of the status of thyroid function.

Other Orbital Inflammatory Conditions

The floor of the orbit is the roof of the maxillary sinus, and the medial wall of the orbit—the lamina papyracea—separates the orbit from the ethmoidal sinuses. As a result, uncontrolled sinus infection may spread to the orbit either

Figure 29-2 The extraocular muscles are greatly distended in this postmortem dissection of tissues from a patient with thyroid (Graves) ophthalmopathy. Note that the tendons of the muscles are spared. (Courtesy Dr. Ralph C. Eagle, Jr., Wills Eye Hospital, Philadelphia, Pa.)

as an acute bacterial infection or as a component of a fungal infection. This occurs most commonly in immunosuppressed individuals, in patients with diabetic ketoacidosis, or, rarely, in persons without any predisposition. Systemic conditions such as *Wegener granulomatosis* (Chapter 11) may present first in the orbit and may be confined there for prolonged periods of time, or alternatively, it may involve the orbit secondarily by extension from the sinuses.

Idiopathic orbital inflammation, also known as orbital inflammatory pseudotumor (Fig. 29-3), is another inflammatory condition affecting the orbit. This condition may be unilateral or bilateral, and may affect all orbital tissue elements or may be confined to the lacrimal gland (*sclerosing dacryoadenitis*), the extraocular muscles (*orbital myositis*), or the Tenon's capsule, the fascial layer that wraps around the eye (*posterior scleritis*). IgG4-related disease (Chapter 6) should be excluded before declaring an orbital inflammation to be idiopathic.

Figure 29-3 In idiopathic orbital inflammation (orbital inflammatory pseudotumor) the orbital fat is replaced by fibrosis. Note the chronic inflammation, accompanied in this case by eosinophils.

MORPHOLOGY

Idiopathic orbital inflammation is characterized histologically by chronic inflammation and variable degrees of fibrosis. The inflammatory infiltrate typically includes lymphocytes and plasma cells and occasionally eosinophils. Germinal centers, when present, raise the suspicion of a reactive lymphoid hyperplasia. Vasculitis may be present, suggesting an underlying systemic condition. The presence of necrosis and degenerating collagen along with vasculitis should raise the suspicion of *Wegener granulomatosis*. Idiopathic orbital inflammation is typically confined to the orbit but may develop concomitantly with sclerosing inflammation in the retroperitoneum, the mediastinum, and the thyroid, especially as a manifestation of IgG4-related disease.

Neoplasms

The most frequently encountered primary neoplasms of the orbit are vascular in origin: the capillary hemangioma of infancy and early childhood, and the lymphangioma (both of which are unencapsulated), and the encapsulated cavernous hemangioma found typically in adults. These are described in other chapters. Only a handful of orbital masses are encapsulated (e.g., pleomorphic adenoma of the lacrimal gland, dermoid cyst, neurilemmoma), and the recognition of encapsulation on imaging studies allows the surgeon to anticipate pathologic findings.

Non-Hodgkin lymphoma, like idiopathic orbital inflammation, can affect the entire orbit or can be confined to compartments of the orbit such as the lacrimal gland. Orbital lymphomas are classified according to the WHO classification system (Chapter 13).

Primary orbital malignancies may arise from any of the orbital tissues and are classified according to the scheme used for the parent tissue. For example, the lacrimal gland may be considered a minor salivary gland, and tumors of the lacrimal gland are classified as salivary gland tumors.

Metastases to the orbit may present with distinctive signs and symptoms that point to the origin of the tumor. For example, metastatic prostatic carcinoma may present clinically like idiopathic orbital inflammation; metastatic neuroblastoma and Wilms tumor—richly vascular neoplasms—may produce characteristic periocular ecchymoses. Neoplasms may also invade from the sinuses into the orbit.

KEY CONCEPTS

- Proptosis results from lesions or pathologic changes in tissue that occupy space in the orbit. The orbit is a compartment that is only open anteriorly and is closed in all other dimensions by bone.
- Inflammation in the orbit may develop by extension of local disease in adjacent tissues (e.g., sinusitis) or as a component of systemic disease (e.g., *Wegener granulomatosis*)
- The most common primary tumors of the orbit are vascular (e.g., capillary and cavernous hemangiomas).

Eyelid

Functional Anatomy

The eyelid is composed of skin externally and mucosa (the conjunctiva) on the surface apposed to the eye (Fig. 29-4). In addition to covering and protecting the eye, elements within the eyelid generate critical components of the tear film. If the drainage system of the sebaceous glands is obstructed by chronic inflammation at the eyelid margin (blepharitis) or, less commonly, by neoplasm, then lipid may extravasate into surrounding tissue and provoke a granulomatous response producing a lipogranuloma, or *chalazion*.

Neoplasms

The most common malignancy of the eyelid is basal cell carcinoma. Surprisingly, primary melanomas of the eyelid skin are extremely rare. Regardless of histogenesis, eyelid neoplasms may distort tissue and prevent the eyelids from closing completely. Because chronic exposure to air damages the cornea, prompt treatment of locally invasive basal cell carcinomas is imperative to preserve vision. Basal cell carcinoma has a distinct predilection for the lower eyelid and the medial canthus.

Sebaceous carcinoma may form a local mass that mimics *chalazion* or may diffusely thicken the eyelid. This neoplasm may also resemble inflammatory processes such as blepharitis or *ocular cicatricial pemphigoid* because of a predilection for intraepithelial spread as occurs in Paget disease of the nipple (Chapter 23) or vulva (Chapter 22). Sebaceous carcinoma tends to spread first to the parotid and submandibular nodes. The overall mortality rate can be as high as 22%. Sebaceous carcinoma of the eyelid is less likely to be associated with the Muir-Torre syndrome than sebaceous neoplasms developing elsewhere.

Figure 29-4 Anatomy of the conjunctiva and eyelids.

Figure 29-5 Pagetoid spread of sebaceous carcinoma. Neoplastic cells with foamy cytoplasm are present within the epidermis (arrow). Invasive sebaceous carcinoma was identified elsewhere in this biopsy sample.

MORPHOLOGY

In moderately differentiated or well-differentiated sebaceous carcinoma, vacuolization of the cytoplasm is present and helps in the diagnosis. This cancer may, however, resemble a variety of other malignancies histologically, including basal cell carcinoma, hence establishing the correct diagnosis can be difficult. Pagetoid spread (Fig. 29-5) may mimic Bowenoid actinic keratosis in the eyelid and carcinoma in situ in the conjunctiva. Sebaceous carcinoma may spread through the conjunctival epithelium and the epidermis to the lacrimal drainage system and the nasopharynx. It may also extend into the lacrimal gland ductules and thereby into the main lacrimal gland.

In individuals with AIDS, *Kaposi sarcoma* may develop in either the eyelid or the conjunctiva. In the eyelid the lesion may appear clinically to have a purple hue because the vascular lesion is embedded in the dermis, but in the thin mucous membrane of the conjunctiva, Kaposi sarcoma appears bright red and may be confused clinically with a subconjunctival hemorrhage.

KEY CONCEPTS

- Basal cell carcinoma is the most common primary malignancy of the eyelid and may be very invasive locally.
- Sebaceous carcinoma of the eyelid, by contrast, may metastasize and is therefore a serious and potentially life-threatening condition.

Conjunctiva

Functional Anatomy

The conjunctiva is divided into zones (Fig. 29-4), each with distinctive histologic features and responses to disease.

The conjunctiva lining the interior of the eyelid, the *palpebral conjunctiva*, is tightly tethered to the tarsus and may respond to inflammation by being thrown into minute papillary folds as may occur in allergic conjunctivitis and bacterial conjunctivitis. The conjunctiva in the *fornix* is a pseudostratified columnar epithelium rich in goblet cells. The fornix also contains accessory lacrimal tissue, and the ductules of the main lacrimal gland pierce through the conjunctiva in the fornix superiorly and laterally. The lymphoid population of the conjunctiva is most noticeable in the fornix, and in *viral conjunctivitis*, lymphoid follicles may enlarge sufficiently to be visualized clinically by slit-lamp examination. Granulomas associated with systemic sarcoidosis may be detected in the conjunctival fornix, and the yield of granulomas from a nondirected conjunctival biopsy in individuals suspected of having sarcoid may be as high as 50%. Primary lymphoma of the conjunctiva (typically indolent marginal zone B-cell lymphoma) is most likely to develop in the fornix. The *bulbar conjunctiva*—the conjunctiva that covers the surface of the eye—is a nonkeratinizing stratified squamous epithelium. The limbus, the intersection between the sclera and cornea, also marks the transition between conjunctival and corneal epithelium (Fig. 29-1).

The conjunctiva, like the eyelid, is richly invested with lymphatic channels. Malignant neoplasms arising in the eyelid and conjunctiva tend to spread to regional lymph nodes (parotid and submandibular node groups).

Conjunctival Scarring

Many cases of bacterial or viral conjunctivitis cause redness and itching, but most heal without sequelae. However, infection with *Chlamydia trachomatis* (trachoma) may produce significant conjunctival scarring. Conjunctival scarring is also seen after exposure of the ocular surface to caustic alkalis or as a sequela to ocular cicatricial *pemphigoid* (Chapter 25). A reduction in the number of goblet cells due to conjunctival scarring leads to a decrease in surface mucin, which is essential for the adherence of the aqueous component of tears to the corneal epithelium. Thus, even if the aqueous component of the tear film is adequate, the affected individual will suffer from a dry eye. More commonly, however, dry eye results from a deficiency in the aqueous component of the tear film generated by the accessory lacrimal glands embedded within the eyelid and fornix.

The conjunctiva may be scarred iatrogenically through reaction to drugs or as a consequence of surgery. In other parts of the body, cancer surgery requires excision of the lesion with a margin of normal tissue to ensure complete removal. However, extensive surgical excision of even diseased conjunctiva can remove a large number of goblet cells or compromise lacrimal gland ductules that traverse the conjunctiva. Thus, removal of a conjunctival neoplasm or a precursor lesion may leave the affected individual with a painful dry eye that can compromise vision. Therefore, surgeons often remove only the invasive components of conjunctival neoplasms, and treat the intraepithelial components with tissue-sparing modalities such as cryotherapy or topical chemotherapy delivered as eyedrops.

Pinguecula and Pterygium

Both *pinguecula* and *pterygium* appear as submucosal elevations on the conjunctiva. They result from actinic damage and are therefore located in the sun-exposed regions of the conjunctiva (i.e., in the fissure between both the upper and lower eyelids—the interpalpebral fissure). Pterygium typically originates in the conjunctiva astride the limbus. It is formed by a submucosal growth of *fibrovascular connective tissue that migrates onto the cornea*, dissecting into the plane occupied normally by the Bowman layer. Pterygium does not cross the pupillary axis and, aside from the possible induction of mild astigmatism, does not pose a threat to vision. Although most pterygia are entirely benign, it is worthwhile submitting the excised tissue for pathologic examination because, on occasion, precursors of actinic-induced neoplasms—squamous cell carcinoma and melanoma—are detected in these lesions.

Pinguecula, which, like pterygium, appears astride the limbus, is a small, yellowish submucosal elevation. Although the pinguecula does not invade the cornea as pterygium does, the presence of a focal conjunctival elevation near the limbus can result in an uneven distribution of the tear film over the adjacent cornea. As a consequence of focal dehydration, a saucer-like depression in the corneal tissue—a *delle*—may develop.

Neoplasms

Both squamous neoplasms and melanocytic neoplasms and their precursors tend to develop at the limbus. Conjunctival *squamous cell carcinoma* may be preceded by intraepithelial neoplastic changes analogous to those seen in the evolution of cervical squamous cell carcinoma. In the conjunctiva the spectrum of changes from mild dysplasia through carcinoma in situ is designated as *conjunctival intraepithelial neoplasia*. Squamous papillomas and conjunctival intraepithelial neoplasia may be associated with the presence of human papillomavirus types 16 and 18. Although conjunctival squamous cell carcinoma tends to follow an indolent course, *mucoepidermoid carcinoma* of the conjunctiva (reflecting the ability of conjunctival stem cells to differentiate into squamous epithelium and goblet cells) follows a much more aggressive course.

Conjunctival nevi are encountered commonly but seldom invade the cornea or appear in the fornix or over the palpebral conjunctiva. Pigmented lesions in these zones of the conjunctiva most likely represent melanomas or melanoma precursors. Compound nevi of the conjunctiva characteristically contain subepithelial cysts lined by surface epithelium (Fig. 29-6A, B). In late childhood or adolescence, conjunctival nevi may acquire an inflammatory component rich in lymphocytes, plasma cells, and eosinophils. The resultant *inflamed juvenile nevus* is completely benign.

Conjunctival melanomas are unilateral neoplasms, typically affecting fair-complexioned individuals in middle age (Fig. 29-6C, D). Most cases of conjunctival melanoma develop through a phase of intraepithelial growth termed *primary acquired melanosis with atypia*, which is roughly analogous to *melanoma in situ* but does not correspond neatly to the radial growth phase of cutaneous melanoma (Chapter 25). Between 50% and 90% of individuals with incompletely treated primary acquired melanosis with

Figure 29-6 A, B, Cystic compound nevus of the conjunctiva. C, D, Conjunctival malignant melanoma. In C, note the deflection of the beam of the slit lamp over the surface of the lesion, indicative of invasion. (A, B, From Folberg R, et al: Benign conjunctival melanocytic lesions: clinicopathologic features. *Ophthalmology* 96:436, 1989.)

atypia develop conjunctival melanoma; the best treatment of conjunctival melanoma is its prevention through extirpation of its precursor lesion. The lesions tend to spread first to the parotid or submandibular lymph nodes. Approximately 25% of conjunctival melanomas prove to be fatal.

KEY CONCEPTS

- Conjunctival scarring, a consequence of a variety of conditions, may result in painful loss of vision by interfering with the delivery and maintenance of the tear film.
- Many conjunctival neoplasms originate at the limbus, the seat of stem cells of the ocular surface.
- Conjunctival malignancies—especially conjunctival melanomas—tend to spread through the rich lymphatics of the conjunctiva to regional lymph nodes.

Sclera

The sclera consists mainly of collagen and contains few blood vessels and fibroblasts; hence, wounds and surgical incisions tend to heal poorly. Immune complex deposits within the sclera, such as in *rheumatoid arthritis*, may produce a necrotizing *scleritis*.

The sclera may appear “blue” in a variety of conditions. Some of these are:

- It may become thin following episodes of scleritis, and the normally brown color of the uvea may appear blue clinically because of the optical Tyndall effect.
- Sclera may be thinned in eyes with exceptionally high intraocular pressure and because this zone of scleral ectasia is lined by uveal tissue, the resulting lesion, known as a *staphyloma*, also appears blue.
- The sclera may appear blue in osteogenesis imperfecta.
- The sclera may appear blue because of a heavily pigmented congenital nevus of the underlying uvea, a condition known as *congenital melanosis oculi*. When accompanied by periocular cutaneous pigmentation, this condition is known as *nevus of Ota*.

Cornea

Functional Anatomy

The cornea and its overlying tear film—not the lens—make up the major refractive surface of the eye (Fig. 29-7). Parenthetically, *myopia* typically develops because the eye is too long for its refractive power, and *hyperopia* results from an eye that is too short. The popularity of procedures such as laser-assisted in situ keratomileusis (LASIK) to sculpt the cornea and change its refractive properties

Figure 29-7 Normal corneal microarchitecture. The corneal tissue is stained by periodic acid–Schiff (PAS) to highlight basement membranes. The inset at the upper left is a high magnification of the anterior layers of the cornea: the epithelium (*e*), Bowman layer (*b*), and the stroma (*s*). A very thin PAS-positive basement membrane separates the epithelium from the Bowman layer. Note that the Bowman layer is acellular. The inset at the lower right is a high magnification of the PAS-positive Descemet membrane and the corneal endothelium. The “holes” in the stroma are artifactual spaces between parallel collagenous stromal lamellae.

attests to the importance of corneal shape in contributing to the refractive power of the eye.

Anteriorly, the cornea is covered by *epithelium* that rests on a basement membrane. The *Bowman layer*, situated just beneath the epithelial basement membrane, is acellular and forms an efficient barrier against the penetration of malignant cells from the epithelium into the underlying stroma.

The *corneal stroma* lacks blood vessels and lymphatics, a feature that contributes not only to the transparency of the cornea, but also to high rate of success of corneal transplantation. Indeed, nonimmunologic graft failure (associated with loss of endothelial cells and subsequent corneal edema) is seen more commonly than is immunologic graft rejection. The risk of corneal graft rejection increases with stromal vascularization and inflammation. A precise alignment of collagen in the corneal stroma also contributes to transparency.

Corneal vascularization may accompany chronic corneal edema, inflammation, and scarring. The application of topical VEGF antagonists affords a promising approach to preventing corneal vascularization. Scarring and edema both disrupt the spatial alignment of stromal collagen and contribute to corneal opacification. Scars may result from trauma or inflammation. Normally, the corneal stroma is in a state of relative deturgescence (dehydration), maintained in large part by active pumping of fluid from the stroma back into the anterior chamber by the corneal endothelium.

The corneal *endothelium* is derived from neural crest and is not related to vascular endothelium. It rests on its basement membrane, Descemet membrane. A decrease in endothelial cells or a malfunction of endothelium results in stromal edema, which may be complicated by bullous separation of the epithelium (*bullous keratopathy*). *Descemet membrane* increases in thickness with age. It is the site of copper deposition in the Kayser-Fleischer ring of Wilson disease (Chapter 18).

Figure 29-8 Chronic herpes simplex keratitis. The cornea is thin and scarred (note the increased number of fibroblast nuclei). Granulomatous reaction in the Descemet membrane, illustrated in this photomicrograph (arrows), is a histologic hallmark of chronic herpes simplex keratitis.

Keratitis and Ulcers

Various pathogens—bacterial, fungal, viral (especially herpes simplex and herpes zoster), and protozoal (*Acanthamoeba*)—can cause corneal ulceration. In all forms of keratitis, dissolution of the corneal stroma may be accelerated by activation of collagenases within corneal epithelium and stromal fibroblasts (also known as keratocytes). Exudate and cells leaking from iris and ciliary body vessels into the anterior chamber may be visible by slit-lamp examination and may accumulate in sufficient quantity to become visible even by a penlight examination (*hypopyon*). Although the corneal ulcer may be infectious, the hypopyon seldom contains organisms and is an example par excellence of the vascular response to acute inflammation. The specific forms of keratitis may have certain distinctive features. For example, chronic herpes simplex keratitis may be associated with a granulomatous reaction involving the Descemet membrane (Fig. 29-8).

Corneal Degenerations and Dystrophies

Ophthalmologists have traditionally divided many corneal disorders into degenerations and dystrophies. Corneal degenerations may be either unilateral or bilateral and are typically nonfamilial. By contrast, corneal dystrophies are typically bilateral and are hereditary. Corneal dystrophies may affect selective corneal layers (e.g., *Reis-Bückler dystrophy* affects Bowman layer, and *posterior polymorphous dystrophy* affects the endothelium), or the changes may be distributed throughout multiple layers.

Band Keratopathies

Two types of band keratopathy serve as examples of corneal degenerations. *Calcific band keratopathy* is characterized by deposition of calcium in the Bowman layer. This condition may complicate chronic uveitis, especially in individuals with chronic juvenile rheumatoid arthritis. *Actinic band keratopathy* develops in individuals who are exposed chronically to high levels of ultraviolet light. In this condition, extensive solar elastosis develops in the superficial layers of corneal collagen in the sun-exposed interpalpebral fissure, hence the horizontally distributed band of pathology. Similar to pinguecula, the sun-damaged collagen of the cornea may take on a yellow hue to the point that this condition is sometimes erroneously called “oil-droplet keratopathy.”

Figure 29-9 Keratoconus. The tissue section is stained by periodic acid-Schiff to highlight the epithelial basement membrane (ebm), which is intact, the Bowman layer (bl), situated between the epithelial basement membrane, and the stroma (s). Following the Bowman layer from the *right side* of the photomicrograph toward the *center*, there is a discontinuity, diagnostic of keratoconus. The epithelial separation just to the *left* of the Bowman layer discontinuity resulted from an episode of corneal hydrops, caused by a break in the Descemet membrane (not shown).

Keratoconus

With an incidence of 1 in 2000, *keratoconus* is a fairly common disorder characterized by progressive thinning and ectasia of the cornea without evidence of inflammation or vascularization. Such thinning results in a cornea that has a conical rather than spherical shape. This abnormal shape generates irregular astigmatism that is difficult to correct with spectacles. Rigid contact lenses generate a smooth, spherical surface to the cornea and may provide refractive relief for individuals with keratoconus. Patients whose vision cannot be corrected with spectacles or contact lenses are excellent candidates for corneal transplantation, which has a high degree of success in this condition. Unlike many types of degeneration, keratoconus is typically bilateral. Keratoconus is associated with Down syndrome, Marfan syndrome, and atopic disorders. Its development may stem from a genetic predisposition superimposed by an environmental insult, such as eye rubbing in response to atopic conditions.

MORPHOLOGY

Thinning of the cornea with breaks in the Bowman layer are the histologic hallmarks of keratoconus (Fig. 29-9). In some patients the Descemet membrane may rupture precipitously, allowing the aqueous humor in the anterior chamber to gain access to the corneal stroma. The sudden effusion of aqueous humor through a gap in the Descemet membrane—corneal **hydrops**—may also cause vision to worsen suddenly. An episode of hydrops may be followed by corneal scarring that can also contribute to visual loss. Acute corneal hydrops can complicate Descemet membrane ruptures that develop secondary to extraordinary elevations of intraocular pressure in *infantile glaucoma* (*Haab striae*) or following the now uncommon obstetric forceps injury to the eye.

Figure 29-10 Fuchs dystrophy. This tissue section is stained by periodic acid-Schiff to highlight the Descemet membrane, which is thick. Numerous droplike excrescences—guttata—protrude downward from the Descemet membrane. Endothelial cell nuclei are not seen. Epithelial bullae, not shown in this micrograph, were present, reflecting corneal edema.

Fuchs Endothelial Dystrophy

This condition, one of several dystrophies results from loss of endothelial cells and the resulting edema and thickening of the stroma. It is one of the principal indications for corneal transplantation in the United States. The two major clinical manifestations of Fuchs endothelial dystrophy—*stromal edema and bullous keratopathy*—are both related to a primary loss of endothelial cells. Early in the course of the disease endothelial cells produce droplike deposits of abnormal basement membrane material (*guttata*) that resemble the fetal component of the Descemet membrane ultrastructurally. Guttata can be visualized clinically by slit-lamp examination. With disease progression, there is a decrease in the total number of endothelial cells, and the residual cells are incapable of maintaining stromal deturgescence. Consequently the stroma becomes edematous and thickens; it acquires a ground-glass appearance clinically, and vision is blurred (Fig. 29-10). Because of chronic edema, the stroma may eventually become vascularized. On occasion the number of endothelial cells may decrease following cataract surgery even in individuals who do not have early forms of Fuchs dystrophy. This condition, known as *pseudophakic bullous keratopathy*, is also a common indication for corneal transplantation.

With increasing stromal edema, the epithelium undergoes hydropic change, and the detachment of the epithelium from the Bowman layer produces epithelial bullae that may eventually rupture. Fibrous connective tissue may be deposited between the epithelium and Bowman layer (*degenerative pannus*) either by ingrowth from the limbus or perhaps through fibrous metaplasia of the corneal epithelium.

Stromal Dystrophies

In these conditions stromal deposits generate discrete opacities in the cornea that may eventually compromise vision. Deposits in the vicinity of the epithelium, its basement membrane, and Bowman layer may result in painful

epithelial erosions. Scarring in the vicinity of Bowman layer may generate an irregular corneal surface, further compromising vision.

The identification of specific mutations responsible for various stromal dystrophies is generating a new molecular classification of these disorders that has been correlated with the conventional phenotypic classifications. One such dystrophy, inherited as an autosomal dominant, is caused by mutations in the *TGFB1* gene which encodes an extracellular matrix protein called keratoepithelin. Some mutations cause improper folding of this protein which in turn causes depositions in the cornea.

KEY CONCEPTS

- The cornea—not the lens—is the major refractive surface of the eye. **Keratoconus** is an example of a condition that distorts the contour of the cornea and alters this refractive surface, producing an irregular form of astigmatism.
- The normal cornea is avascular, a feature that contributes to transparency and the low incidence of graft rejection after corneal transplantation.
- Inflammations of the cornea may be accompanied by a non-infectious exudative process in the anterior chamber that may organize to distort anterior segment anatomy and contribute to secondary glaucoma and to cataract.
- **Corneal dystrophies** are generally inherited and **degenerations** are typically not inherited. Fuchs dystrophy and pseudophakic bullous keratopathy both produce visual loss through the final common pathway of corneal edema and both of these conditions are leading indications for corneal transplantation in the United States.

Anterior Segment

Functional Anatomy

The anterior chamber is bounded anteriorly by the cornea, laterally by the trabecular meshwork, and posteriorly by the iris (Fig. 29-11). Aqueous humor, formed by the pars plicata of the ciliary body, enters the posterior chamber, bathes the lens, and circulates through the pupil to gain access to the anterior chamber. The posterior chamber lies behind the iris and in front of the lens.

The lens is a closed epithelial system; the basement membrane of the lens epithelium (known as the lens capsule) totally envelops the lens. Thus, the lens epithelium does not exfoliate like the epidermis or a mucosal epithelium. Instead, the lens epithelium and its derivative fibers accumulate within the confines of the lens capsule, thus “infolding.” With aging, therefore, the size of the lens increases. Neoplasms of the lens have not been described.

Cataract

The term *cataract* describes lenticular opacities that may be congenital or acquired. Systemic diseases (e.g., galac-

tosemia, diabetes mellitus, Wilson disease, and atopic dermatitis), drugs (especially corticosteroids), radiation, trauma, and many intraocular disorders are associated with cataract. Age-related cataract typically results from opacification of the lens nucleus (*nuclear sclerosis*). The accumulation of urochrome pigment may render the lens nucleus brown, thus distorting the individual’s perception of blue color (the predominance of yellow hues in Rembrandt’s paintings later in life might have been a consequence of nuclear sclerotic cataracts). Other physical changes in the lens may generate opacities. For example, the lens cortex may liquefy. Migration of the lens epithelium posterior to the lens equator may result in *posterior subcapsular cataract* secondary to enlargement of abnormally positioned lens epithelium. The technique that is most commonly used to remove opacified lenses extracts the lens contents, leaving the lens capsule intact (extracapsular cataract extraction). A prosthetic intraocular lens is typically inserted into the eye. Residual lens epithelial cells may migrate over the lens capsule, contributing to opacification of the capsule and reduction in vision after surgery.

Occasionally, the lens cortex may liquefy nearly entirely, a condition known as hypermature or *morgagnian cataract*. High-molecular-weight proteins from liquefied lens cortex may leak through the lens capsule (*phacolysis*). This phacolytic protein—either free or contained within macrophages—may clog the trabecular meshwork and contribute to elevation in intraocular pressure and optic nerve damage; phacolytic glaucoma is an example of secondary open-angle glaucoma.

The Anterior Segment and Glaucoma

The term *glaucoma* refers to a collection of diseases characterized by distinctive changes in the visual field and in the cup of the optic nerve. Most of the glaucomas are associated with elevated intraocular pressure, although some individuals with normal intraocular pressure may develop characteristic optic nerve and visual field changes (*normal or low-tension glaucoma*). The relationship between intraocular pressure and optic nerve damage is discussed later under “Optic Nerve.”

To understand the pathophysiology of glaucoma it is useful to consider the formation and drainage of aqueous humor. As Figure 29-11 illustrates, aqueous humor is produced in the ciliary body and passes from the posterior chamber through the pupil into the anterior chamber. Although there are multiple pathways for the egress of fluid from the anterior chamber, most of the aqueous humor drains through the trabecular meshwork, situated in the angle formed by the intersection between the corneal periphery and the anterior surface of the iris. With this background, glaucoma can be classified into two major categories.

- In *open-angle glaucoma* the aqueous humor has complete physical access to the trabecular meshwork, and the elevation in intraocular pressure results from an increased resistance to aqueous outflow in the open angle.
- In *angle-closure glaucoma* the peripheral zone of the iris adheres to the trabecular meshwork and physically impedes the egress of aqueous humor from the eye.

Figure 29-11 *Upper left*, The normal eye. Note that the surface of the iris is highly textured with crypts and folds. *Upper right*, The normal flow of aqueous humor. Aqueous humor, produced in the posterior chamber, flows through the pupil into the anterior chamber. The major pathway for the egress of aqueous humor is through the trabecular meshwork, into the Schlemm canal. Minor outflow pathways (uveoscleral and iris, not depicted) contribute to a limited extent to aqueous outflow. *Lower left*, Primary angle-closure glaucoma. In anatomically predisposed eyes, transient apposition of the iris at the pupillary margin to the lens blocks the passage of aqueous humor from the posterior chamber to the anterior chamber, bowing the iris forward (iris bombé) and occluding the trabecular meshwork. Pressure builds in the posterior chamber. *Lower right*, A neovascular membrane has grown over the surface of the iris, smoothing the iris folds and crypts. Myofibroblasts within the neovascular membrane cause the membrane to contract and to become apposed to the trabecular meshwork (peripheral anterior synechiae). Outflow of aqueous humor is blocked, and the intraocular pressure becomes elevated.

Both open-angle and angle-closure glaucoma can be subclassified into primary and secondary types. In *primary open-angle glaucoma*, the most common form of glaucoma, the angle is open, and few changes are apparent structurally. Mutations in the myocilin (*MYOC*) gene have been associated with a subset of individuals with juvenile and adult primary open-angle glaucoma. Mutations in optineurin (*OPTN*) may also be responsible for a subset of adult patients with open angle glaucoma. The role of these genes in the pathogenesis of glaucoma is not clear.

There are multiple causes of *secondary open-angle glaucoma*. Pseudoexfoliation glaucoma, perhaps the most common form of secondary open angle glaucoma, is associated with the deposition of fibrillar material of varying composition throughout the anterior segment. Pseudoexfoliation glaucoma has been associated with

single nucleotide polymorphisms in the lysyl oxidase like 1 (*LOX1*) gene. In addition to deposition in the anterior chamber, fibrillar material is deposited around blood vessels in connective tissue and in many visceral organs such as liver, kidney and gall bladder.

Particulate material such as high-molecular-weight lens proteins produced by phacolysis, senescent red cells after trauma (*ghost cell glaucoma*), iris epithelial pigment granules (*pigmentary glaucoma*), and necrotic tumors (*melanolytic glaucoma*) can clog the trabecular meshwork in the presence of an open angle. Elevations in the pressure on the surface of the eye (episcleral venous pressure) in the presence of an open angle also contribute to secondary open-angle glaucoma. This type of glaucoma is associated with surface ocular vascular malformations seen in *Sturge-Weber syndrome* or as a consequence of arterIALIZATION of the

Figure 29-12 Sequelae of anterior segment inflammation. This eye was removed for complications of chronic corneal inflammation (not visible at this magnification). The exudate (e) present in the anterior chamber would have been visualized with a slit lamp as an optical “flare.” The iris is adherent focally to the cornea, obstructing the trabecular meshwork (anterior synechia, *arrow*), and to the lens (posterior synechia, *arrowheads*). An anterior subcapsular cataract (asc) has formed. The radial folds in the lens are artifacts.

episcleral veins following a spontaneous or traumatic carotid-cavernous fistula.

Primary angle-closure glaucoma typically develops in eyes with shallow anterior chambers, often found in individuals with hyperopia. Transient apposition of the pupillary margin of the iris to the anterior surface of the lens may result in obstruction to the flow of aqueous humor through the pupillary aperture (*pupillary block*). Continued production of aqueous humor by the ciliary body thus elevates pressure in the posterior chamber and may bow the iris periphery forward (*iris bombé*), apposing it to the trabecular meshwork. These anatomic changes provoke a marked elevation in intraocular pressure (Fig. 29-11). Since the crystalline lens is avascular and the lens epithelium receives its nutrition from the aqueous humor, unremitting elevation in intraocular pressure in primary angle-closure glaucoma can damage the lens epithelium. This leads to minute anterior subcapsular opacities that are visible by slit-lamp examination (*glaukomflecken*). Although the affected individual might have a normal complement of healthy corneal endothelial cells, sustained elevated intraocular pressure can produce corneal edema and bullous keratopathy.

There are many causes of *secondary angle-closure glaucoma*. Contraction of various types of pathologic membranes that form over the surface of the iris can draw the iris over the trabecular meshwork, occluding aqueous outflow. For example, chronic retinal ischemia is associated with the up-regulation of VEGF and other proangiogenic factors. The appearance of VEGF in the aqueous humor is thought to induce the development of thin, clinically transparent fibrovascular membranes over the surface of the iris. Contraction of myofibroblastic elements in these membranes leads to occlusion of the trabecular meshwork by the iris: *neovascular glaucoma* (Fig. 29-11). Necrotic tumors, especially retinoblastomas, can also induce iris neovascularization and glaucoma. Secondary angle-closure glaucoma may be caused by other mechanisms as well; for example, tumors in the ciliary body can mechanically compress the iris onto the trabecular meshwork, closing off the major pathway of aqueous outflow.

Endophthalmitis and Panophthalmitis

In intraocular inflammation, vessels in the ciliary body and iris become leaky, allowing cells and exudate to accumulate in the anterior chamber. These changes can be visualized with a slit lamp; at times the inflammatory cells may adhere to the corneal endothelium, forming clinically visible *keratic precipitates*. The size and shape of these precipitates can provide clues to the underlying cause of the inflammation. For example, aggregates of macrophages on the endothelium in sarcoid produce characteristic “mutton-fat” keratic precipitates.

Just as pleural exudate in acute bronchopneumonia can lead to adhesions between the visceral and parietal pleura, the presence of exudate in the anterior chamber can facilitate the formation of adhesions between the iris and the trabecular meshwork or cornea (*anterior synechia*) or between the iris and anterior surface of the lens (*posterior synechia*). Anterior synechia can lead to elevation in intraocular pressure, which may lead to optic nerve damage. Prolonged contact between the iris and the anterior surface of the lens can deprive lens epithelium of contact with aqueous humor and can induce fibrous metaplasia of the lens epithelium: *anterior subcapsular cataract* (Fig. 29-12). The pharmacologic induction of pupillary dilation and cycloplegia in individuals with intraocular inflammation is intended in part to prevent the formation of synechia and their sequelae.

Although inflammation confined to the anterior segment is technically intraocular inflammation, the term *endophthalmitis* is reserved for inflammation within the vitreous humor. The retina lines the vitreous cavity, and suppurative inflammation in the vitreous humor is poorly tolerated by the retina; a few hours may be sufficient to cause irreversible retinal injury. Endophthalmitis is classified as *exogenous* (originating in the environment and gaining access to the interior of the eye through a wound) or *endogenous* (delivered to the eye hematogenously). The term *panophthalmitis* is applied to inflammation within the eye that involves the retina, choroid, and sclera and extends into the orbit (Fig. 29-13).

Figure 29-13 Exogenous panophthalmitis. This eye was removed after a foreign body injury. Note the suppurative inflammation behind the lens that is drawn up to the right of the lens to the cornea, the site of the wound. The central portion of the vitreous humor was extracted surgically (by vitrectomy). Note the adhesions to the surface of the eye at the 8 o'clock position, indicating that the intraocular inflammation has spread through the sclera into the orbit: panophthalmitis. (From Folberg R: *The Eye*. In Spencer WH (ed): *Ophthalmic Pathology—An Atlas and Textbook*, 4th ed. Philadelphia, WB Saunders, 1985.)

KEY CONCEPTS

- The term **cataract** describes opacities of the lens that may be congenital or acquired.
- The term **glaucoma** describes a group of conditions characterized by distinctive changes in the visual field and the size and shape of the optic nerve cup and usually by an elevation in intraocular pressure.
- Glaucoma may develop in the context of either an open or closed angle. Open angle and angle closure glaucomas are further subclassified into primary and secondary types.
- Mutations in the myocilin (*MYOC*) and optineurin (*OPTN*) genes have been associated with subsets of individuals with juvenile and adult primary open-angle glaucoma
- **Endophthalmitis** is a term used to describe inflammation of the interior of the eye involving the vitreous humor and panophthalmitis is the term used to describe inflammation of the interior of the eye that also extends into the uvea and sclera.
- Endophthalmitis may originate from infection within the body (endogenous endophthalmitis complicating generalized sepsis) or as a complication of corneal infection or a wound, accidental injury, or a surgical procedure (exogenous endophthalmitis).
- In panophthalmitis, inflammation extends from the interior of the eye into the ocular coats: the retina, choroid, and the sclera.

Uvea

Together with the iris, the choroid and ciliary body constitute the uvea. The choroid is among the most richly vascularized sites in the body.

Uveitis

The term *uveitis* can be applied to any type of inflammation in one or more of the tissues that compose the uvea. Thus, the iritis that develops after blunt trauma to the eye or that accompanies a corneal ulcer is technically a form of uveitis. However, in clinical practice the term *uveitis* is restricted to a diverse group of chronic diseases that may be either components of a systemic process or localized to the eye. Uveal inflammation may be manifest principally in the anterior segment (e.g., in *juvenile rheumatoid arthritis*) or may affect both the anterior and posterior segments. The complications of chronic anterior segment inflammation were discussed earlier; the remainder of this discussion therefore focuses on the effects of uveal inflammation on the posterior segment of the eye. As will be described briefly, uveitis is frequently accompanied by retinal pathology. Uveitis may be caused by infectious agents (e.g., *Pneumocystis carinii*), may be idiopathic (e.g., sarcoidosis), or may be autoimmune in origin (sympathetic ophthalmia). Examples are described later.

Granulomatous uveitis is a common complication of sarcoidosis (**Chapter 15**). In the anterior segment it gives rise to an exudate that evolves into “mutton-fat” keratic precipitates described earlier. In the posterior segment, sarcoid may involve the choroid and retina. Thus, granulomas may be seen in the choroid. Retinal pathology is characterized by perivascular inflammation; this is responsible for the well-known ophthalmoscopic sign of “candle wax drippings.” Conjunctival biopsy can be used to detect granulomatous inflammation and confirm the diagnosis of ocular sarcoid.

Numerous infectious processes can affect the choroid or the retina. Inflammation in one compartment is typically associated with inflammation in the other. Retinal *toxoplasmosis* is usually accompanied by uveitis and even scleritis. Individuals with AIDS may develop cytomegalovirus retinitis and uveal infection such as *Pneumocystis* or mycobacterial choroiditis.

Sympathetic ophthalmia is an example of noninfectious uveitis limited to the eye. This condition is characterized by bilateral granulomatous inflammation typically affecting all components of the uvea: a panuveitis. Sympathetic ophthalmia, which blinded young Louis Braille, may complicate a penetrating injury of the eye. In the injured eye, retinal antigens sequestered from the immune system may gain access to lymphatics in the conjunctiva and thus set up a delayed hypersensitivity reaction that affects not only the injured eye but also the contralateral, noninjured eye. The condition may develop from 2 weeks to many years after injury. Enucleation of a blind eye (which can be the sympathizing eye rather than the directly injured eye) may yield diagnostic findings. It is characterized by diffuse granulomatous inflammation of the uvea (choroid, ciliary body, and iris). Plasma cells are typically absent, but eosinophils may be identified in the infiltrate (**Fig. 29-14**).

Figure 29-14 Sympathetic ophthalmia. The granulomatous inflammation depicted here was identified diffusely throughout the uvea. The uveal granulomas may contain melanin pigment and may be accompanied by eosinophils.

Sympathetic ophthalmia is treated by the administration of systemic immunosuppressive agents.

Neoplasms

The most common intraocular malignancy of adults is metastasis to the uvea, typically to the choroid. The occurrence of metastases to the eye is associated with an extremely short survival, and treatment of ocular metastases, usually by radiotherapy, is palliative.

Uveal Nevi and Melanomas

Uveal melanoma is the most common primary intraocular malignancy of adults. In the United States, these tumors account for approximately 5% of melanomas and have an age-adjusted incidence of 5.1 per million per year. Uveal nevi, especially choroidal nevi, are rather common, affecting an estimated 10% of the Caucasian population.

Epidemiology and Pathogenesis. Unlike cutaneous melanoma, the occurrence of uveal melanoma has remained stable over many years and there is no clear link between exposure to ultraviolet light and risk. In line with this observation, sequencing of tumor genomes has revealed that the molecular pathogenesis of uveal melanoma is distinct from that of cutaneous melanoma. The most important oncogenes in uveal melanoma are *GNAQ* and *GNA11*, both of which encode G-protein coupled receptors. Roughly 85% of uveal melanomas harbor a gain-of-function mutation in one of these genes that activate pathways that promote proliferation, such as the MAPK pathway (Chapter 7). Notably, uveal nevi are also associated with *GNAQ* and *GNA11* mutations yet rarely transform to melanoma, indicating that other genetic events also contribute to the development of uveal melanoma. One such event is loss of chromosome 3, which appears to be selected for because it leads to deletion of *BAP1*, a tumor suppressor gene on chromosome 3 that encodes a deubiquitinating enzyme. *BAP1* is a component of protein complexes that place repressive marks on chromatin that lead to gene silencing;

thus, uveal melanoma has joined the increasing list of cancers in which epigenetic alterations appear to have a central role in tumor pathogenesis (Chapter 7).

MORPHOLOGY

Histologically, uveal melanomas may contain two types of cells, spindle and epithelioid, in various proportions (Fig. 29-15).

Spindle cells are fusiform in shape, whereas **epithelioid cells** are spherical and have greater cytologic atypicality. Like cutaneous melanomas, large numbers of tumor-infiltrating lymphocytes may be seen in some cases. An unusual feature that is commonly seen is the presence of looping slit-like spaces lined by laminin that surround packets of tumor cells. These spaces (which are not blood vessels) connect to blood vessels and serve as extravascular conduits for the transport of plasma and possibly blood. In vitro studies and examination of human tissues suggest that these unusual growth patterns are promoted by tumor cells through a process termed **vasculogenic mimicry**.

Uveal melanomas, with very rare exception, spread exclusively by a hematogenous route (the only exception being the rare case of melanoma that spreads through the sclera and invades the conjunctiva, thereby gaining access to conjunctival lymphatics). Most uveal melanomas spread first to the liver, an excellent example of a tumor-specific tropism for a particular metastatic site.

Clinical Features. Most uveal melanomas are incidental findings or present with visual symptoms, which may be related to retinal detachment or glaucoma. The prognosis of choroidal and ciliary body melanomas is related to (1) size (in contrast to cutaneous melanoma, the lateral extent of the tumor rather than tumor depth is the size dimension related to adverse outcome); (2) cell type (tumors containing epithelioid cells have a worse prognosis than do those containing exclusively spindle cells); (3) and proliferative index. Cytogenetic profiles, especially monosomy 3, and gene expression profiling may be helpful in stratifying patients into categories with differing risks of developing metastatic disease.

There seems to be no difference in survival between tumors treated by removal of the eye (enucleation) and those receiving eye-sparing radiotherapy, which is the treatment of choice. Melanomas situated exclusively in the iris tend to follow a relatively indolent course, whereas melanomas of the ciliary body and choroid are more aggressive.

Because these tumors are hidden from sight and are likely to have been present for some time before diagnosis, the prognosis is worse than for cutaneous melanoma. Although the 5-year survival rate is approximately 80%, the cumulative melanoma mortality rate is 40% at 10 years, increasing 1% per year thereafter. Metastases may appear “out of the blue” many years after treatment, making uveal melanoma a prime candidate for the investigation of the phenomenon of tumor dormancy. Targeted therapies such as MAPK inhibitors have shown some encouraging responses in clinical trials, but currently there is no proven effective treatment for metastatic uveal melanoma.

Figure 29-15 Uveal melanoma. **A**, Fundus photograph from an individual with a relatively flat pigmented lesion of the choroid near the optic disc. **B**, Fundus photograph of the same individual several years later; the tumor has grown and has ruptured through the Bruch membrane. **C**, Gross photograph of a choroidal melanoma that has ruptured the Bruch membrane. The overlying retina is detached. **D**, Epithelioid melanoma cells associated with an adverse outcome. (A to C, From Folberg R: Pathology of the Eye—an Interactive CD-ROM Program. Philadelphia, Mosby, 1996.)

KEY CONCEPTS

- **Uveitis** is restricted to a diverse group of chronic diseases that may be either components of a systemic process or localized to the eye.
- **Sarcoid** is an example of a systemic condition that may produce granulomatous uveitis and sympathetic ophthalmia may produce bilateral granulomatous inflammation as a possible consequence of penetrating injury to one eye.
- The most common intraocular tumor of adults is metastasis to the eye.
- The most common primary intraocular tumor of adults is **uveal melanoma**.
- Uveal melanoma disseminates hematogenously and the first evidence of metastasis is typically detected in the liver.
- Uveal melanoma shows marked differences in epidemiologic risk factors and driver mutations as compared to cutaneous melanoma.

Retina and Vitreous

Functional Anatomy

The neurosensory retina, like the optic nerve, is an embryologic derivative of the diencephalon. The retina therefore responds to injury by means of gliosis. As in the brain, there are no lymphatics. The architecture of the retina accounts for the ophthalmoscopic appearance of a variety of ocular disorders. Hemorrhages in the nerve fiber layer of the retina are oriented horizontally and appear as streaks or “flames”; the external retinal layers are oriented perpendicular to the retinal surface, and hemorrhages in these outer layers appear as dots (the tips of cylinders). Exudates tend to accumulate in the outer plexiform layer of the retina, especially in the macula (Fig. 29-16).

The retinal pigment epithelium (RPE), like the retina, is derived embryologically from the primary optic vesicle, an outpouching of the brain. Separation of the neurosensory retina from the RPE defines a *retinal detachment*. The RPE

Figure 29-16 Clinicopathologic correlations of retinal hemorrhages and exudates. The location of the hemorrhage within the retina determines its appearance by ophthalmoscopy. The retinal nerve fiber layer is oriented parallel to the internal limiting membrane, and hemorrhages of this layer appear to be flame-shaped ophthalmoscopically. The deeper retinal layers are oriented perpendicular to the internal limiting membrane and hemorrhages in this location appear as cross-sections of a cylinder or “dot” hemorrhages. Exudates that originate from leaky retinal vessels accumulate in the outer plexiform layer.

has an important role in the maintenance of the outer segments of the photoreceptors. Disturbances in the RPE-photoreceptor interface are implicated in hereditary retinal degenerations such as *retinitis pigmentosa*.

The adult vitreous humor is avascular. Incomplete regression of fetal vasculature running through the vitreous humor can produce significant pathology as a retrolental mass (*persistent hyperplastic primary vitreous*). The vitreous humor can be opacified by hemorrhage from trauma or retinal neovascularization. With age the vitreous humor may liquefy and collapse, creating the visual sensation of “floaters.” Also, with aging, the posterior face of the vitreous humor—the posterior hyaloid—may separate from the neurosensory retina (*posterior vitreous detachment*). The relationship between the posterior hyaloid and the neurosensory retina has a key role in the pathogenesis of retinal neovascularization and in some forms of retinal detachment.

Retinal Detachment

Retinal detachment (separation of the neurosensory retina from the RPE) is broadly classified by etiology based on the presence or absence of a break in the retina. *Rhegmatogenous retinal detachment* is associated with a full-thickness retinal defect. Retinal tears may develop after the vitreous collapses structurally, and the posterior hyaloid exerts traction on points of abnormally strong adhesion to the retinal internal limiting membrane. Liquefied vitreous

humor then seeps through the tear and gains access to the potential space between the neurosensory retina and the RPE (Fig. 29-17). Re-attachment of the retina to the RPE generally requires relief of vitreous traction through indenting of the sclera by surgical procedures. This can be accomplished by the application of strips of silicon to the surface of the eye (scleral buckling) and possibly by removal of vitreous material (vitrectomy). Rhegmatogenous retinal detachment may be complicated by *proliferative vitreoretinopathy*, the formation of epiretinal or subretinal membranes by retinal glial cells (Müller cells) or RPE cells.

Non-rhegmatogenous retinal detachment (retinal detachment without retinal break) may complicate retinal vascular disorders associated with significant exudation and any condition that damages the RPE and permits fluid to leak from the choroidal circulation under the retina. Retinal detachments associated with choroidal tumors and malignant hypertension are examples of nonrhegmatogenous retinal detachment.

Retinal Vascular Disease

Hypertension

Normally, the thin walls of retinal arterioles permit a direct visualization of the circulating blood by ophthalmoscopy. In retinal arteriosclerosis the thickened arteriolar wall changes the ophthalmic perception of circulating blood: vessels may appear narrowed, and the

NON-RHEGMATOGENOUS
RETINAL DETACHMENT

VITREOUS DETACHMENT

RHEGMATOGENOUS
RETINAL DETACHMENT

Figure 29-17 Retinal detachment is defined as the separation of the neurosensory retina from the RPE. Retinal detachments are classified broadly into non-rhegmatogenous (without a retinal break) and rhegmatogenous (with a retinal break) types. *Top*, In non-rhegmatogenous retinal detachment the subretinal space is filled with protein-rich exudate. Note that the outer segments of the photoreceptors are missing (see Fig. 29-16 for orientation of layers). This indicates a chronic retinal detachment, a finding that can be seen in both non-rhegmatogenous and rhegmatogenous detachments. *Middle*, Posterior vitreous detachment involves the separation of the posterior hyaloid from the internal limiting membrane of the retina and is a normal occurrence in the aging eye. *Bottom*, If during a posterior vitreous detachment the posterior hyaloid does not separate cleanly from the internal limiting membrane of the retina, the vitreous humor will exert traction on the retina, which will be torn at this point. Liquefied vitreous humor seeps through the retinal defect, and the retina is separated from the RPE. The photoreceptor outer segments are intact, illustrating an acute detachment.

color of the blood column may change from bright red to copper and to silver depending on the degree of vascular wall thickness (Fig. 29-18A). Retinal arterioles and veins share a common adventitial sheath. Therefore, in pronounced retinal arteriosclerosis the arteriole may compress the vein at points where both vessels cross (Fig. 29-18B). Venous stasis distal to arteriolar-venous crossing may precipitate occlusions of the retinal vein branches.

In malignant hypertension vessels in the retina and choroid may be damaged. Damage to choroidal vessels may produce focal choroidal infarcts, seen clinically as *Elschnig spots*. Damage to the choriocapillaris, the internal layer of the choroidal vasculature, may, in turn, damage the overlying RPE and permit the exudate to accumulate in the potential space between the neurosensory retina and the RPE, thereby producing a retinal detachment. Exudate from damaged retinal arterioles typically accumulates in the outer plexiform layer of the retina (Fig. 29-18A). The ophthalmoscopic finding of a macular star—a spokelike arrangement of exudate in the macula in malignant hypertension—results from exudate accumulating in the outer plexiform layer of the macula that is oriented obliquely instead of perpendicular to the retinal surface.

Occlusion of retinal arterioles may produce infarcts of the nerve fiber layer of the retina (axons of the retinal ganglion cell layer populate the nerve fiber layer). Axoplasmic transport in the nerve fiber layer is interrupted at the point of axonal damage, and accumulation of mitochondria at the swollen ends of damaged axons creates the histologic illusion of cells (*cytoid bodies*). Collections of cytoid bodies populate the nerve fiber layer infarct, seen ophthalmoscopically as “cotton-wool spots” (Fig. 29-19). Although nerve fiber layer infarcts are described here in the context of hypertension, they may be detected in a variety of retinal occlusive vasculopathies. For example, retinal nerve fiber layer infarcts may develop in individuals with AIDS due to a retinal vasculopathy that is similar to the brain vasculopathy that may develop in this condition.

Diabetes Mellitus

The eye is profoundly affected by diabetes mellitus. The effects of hyperglycemia on the lens and iris have already been mentioned. Thickening of the basement membrane of the epithelium of the pars plicata of the ciliary body is a reliable histologic marker of diabetes mellitus in the eye (Fig. 29-20) and is reminiscent of similar

Figure 29-18 The retina in hypertension. **A**, The wall of the retinal arteriole (*arrow*) is thick. Note the exudate (*e*) in the retinal outer plexiform layer. **B**, The fundus in hypertension. The diameter of the arterioles is reduced, and the color of the blood column appears to be less saturated (copper wire–like). If the wall of the vessel were thicker still, the degree of red color would diminish such that the vessels might appear clinically to have a “silver wire” appearance. In this fundus photograph, note that the vein is compressed where the sclerotic arteriole crosses over it. (**B**, Courtesy Dr. Thomas A. Weingeist, Department of Ophthalmology and Visual Science, University of Iowa, Iowa City, Ia.)

Figure 29-19 Nerve fiber layer infarct. A “cotton-wool spot” is illustrated in the *inset*, adjacent to a flame-shaped (nerve fiber layer) hemorrhage. The histology of a cotton-wool spot—an infarct of the nerve fiber layer of the retina—is illustrated in the photomicrograph. A focal swelling of the nerve fiber layer is occupied by numerous red to pink cytod bodies (*arrowheads*). Hemorrhage (*arrows*) surrounding the nerve fiber layer infarct as illustrated here is a variable and inconsistent finding. (Fundus photograph, Courtesy Dr. Thomas A. Weingeist, Department of Ophthalmology and Visual Science, University of Iowa, Iowa City, Ia.)

Figure 29-20 The ciliary body in chronic diabetes mellitus, periodic acid–Schiff stain. Note the massive thickening of the basement membrane of the ciliary body epithelia, reminiscent of changes in the mesangium of the renal glomerulus.

changes in the glomerular mesangium. This discussion focuses on the retinal microangiopathy associated with diabetes mellitus, a prototype for the consideration of other retinal microangiopathies.

MORPHOLOGY

The retinal vasculopathy of diabetes mellitus can be classified into **nonproliferative** and **proliferative diabetic retinopathy**.

Nonproliferative diabetic retinopathy includes a spectrum of changes resulting from structural and functional abnormalities of retinal vessels (i.e., confined beneath the internal limiting membrane of the retina). As with diabetic microangiopathy in general, the **basement membrane of retinal blood vessels is thickened**. In addition, the number of pericytes relative to endothelial cells diminishes. **Microaneurysms** are an important manifestation of diabetic microangiopathy. They are typically smaller than the resolution of direct ophthalmoscopes, and findings customarily described as microaneurysms by ophthalmoscopy may in fact be retinal microhemorrhages. Structural changes in the retinal microcirculation have been associated with a physiologic breakdown in the blood-retinal barrier. Recall that VEGF was initially called vascular permeability factor. Thus, the retinal microcirculation in diabetics may be exceptionally leaky, giving rise to **macular edema**, a common cause of visual loss in these patients. The vascular changes may also produce **exudates** that accumulate in the outer plexiform layer. Although the retinal microcirculation is often hyperpermeable, it is also subject to the effects of micro-occlusion. Both vascular incompetence and vascular micro-occlusions can be visualized clinically after intravenous injection of fluorescein. Nonperfusion of the retina due to the microcirculatory change described earlier is associated with up-regulation of VEGF and intra-retinal angiogenesis (located beneath the internal limiting membrane of the retina).

Proliferative diabetic retinopathy is defined by the appearance of new vessels sprouting on the surface of either the optic nerve head (termed “neovascularization of the disc”) or the surface of the retina (“designated by the nebulous term neovascularization elsewhere”) (Fig. 24-42C). The term “retinal neovascularization” is only applied when the newly formed vessels breach the internal limiting membrane of the retina. The quantity and location of retinal neovascularization guide the ophthalmologist in the treatment of proliferative diabetic retinopathy. The web of newly formed vessels is referred to as a neovascular membrane. It is composed of angiogenic vessels with or without a substantial supportive fibrous or glial stroma (Fig. 29-21B).

If the vitreous humor has not detached and the posterior hyaloid is intact, neovascular membranes extend along the potential plane between the retinal internal limiting membrane and the posterior hyaloid. If vitreous humor later separates from the internal limiting membrane of the retina (**posterior vitreous detachment**) there may be massive hemorrhage from the disrupted neovascular membrane. In addition, scarring associated with the organization of the retinal neovascular membrane may wrinkle the retina, disrupting the orientation of retinal photoreceptors and producing visual distortion, and may exert traction on the retina, separating it from the RPE (retinal detachment).

Traction retinal detachment may begin as a non-rhegmatogenous detachment, but severe traction may tear the retina, producing a traction rhegmatogenous detachment.

Retinal neovascularization may be accompanied by the development of a neovascular membrane on the iris surface, presumably secondary to increased levels of VEGF in the aqueous humor. Contraction of the iris neovascular membrane may lead to adhesions between the iris and trabecular meshwork (anterior synechiae), thus occluding a major pathway for aqueous outflow and thereby contributing to elevation of the intraocular pressure (**neovascular glaucoma**).

Ablating nonperfused retina by laser photocoagulation or cryopexy triggers regression of both retinal and iris neovascularization, emphasizing the central role that retinal hypoxia has in these disorders. More recently, the injection of VEGF inhibitors into the vitreous has been used to treat diabetic macular edema and retinal neovascularization, a successful example of how knowledge of the molecular pathogenesis of a condition may evolve into a successful therapeutic strategy.

Retinopathy of Prematurity (Retrolental Fibroplasia)

At term, the temporal (lateral) aspect of the retinal periphery is incompletely vascularized whereas the medial aspect is vascularized. In premature or low-birth-weight infants treated with oxygen, immature retinal vessels in the temporal retinal periphery constrict, rendering the retinal tissue distal to this zone ischemic. Retinal ischemia may result in up-regulation of proangiogenic factors such as VEGF and lead to retinal angiogenesis. Contraction of the resulting peripheral retinal neovascular membrane may “drag” the temporal aspect of the retina toward the peripheral zone, displacing the macula (situated temporal to the optic nerve) laterally. Neovascular membrane contraction may create sufficient force to cause retinal detachment. The use of VEGF inhibition in this condition is under investigation.

Sickle Retinopathy, Retinal Vasculitis, Radiation Retinopathy

Retinopathy affecting individuals with sickle hemoglobinopathies (Chapter 14) has been divided into two types that roughly parallel those used for diabetic retinopathy: nonproliferative (intraretinal angiopathic changes) and proliferative (retinal neovascularization). The final common pathway in both types is vascular occlusion. Low oxygen tension within the blood vessels in the retinal periphery results in red cell sickling and microvascular occlusions. In the nonproliferative form (which occurs in individuals with hemoglobin SS and SC genotypes), *vascular occlusions* are thought to contribute to preretinal, intraretinal, and subretinal hemorrhages. The resolution of these hemorrhages may give rise to several ophthalmoscopically visible changes, known as *salmon patches*, *iridescent spots*, and *black sunburst lesions*. Organization of pre-retinal hemorrhage may result in retinal traction and *retinal detachment*. Vascular occlusions may also contribute to angiogenesis secondary to up-regulation of both VEGF and basic fibroblast growth factor. This can give rise to

Figure 29-21 The retina in diabetes mellitus (see Fig. 29-16 for a schematic of retinal structure). **A**, A tangle of abnormal vessels lies just beneath the internal limiting membrane of the retina on the right half of the photomicrograph (*between arrows*). This is an example of intraretinal angiogenesis known as intraretinal microangiopathy (IRMA). Note the retinal hemorrhage in the outer plexiform layer in the *left half*. The ganglion cell layer and the nerve fiber layer—the axons of the ganglion cells—are absent. The rarefied space beneath internal limiting membrane to the *left* of the focus of IRMA consists largely of elements of retinal glial (Müller) cells. Absence of the ganglion cell and nerve fiber layers is a hallmark of glaucoma. The chronic diabetes mellitus in this individual was complicated by iris neovascularization and secondary angle-closure glaucoma (neovascular glaucoma). **B**, In this section stained by periodic acid–Schiff, the internal limiting membrane is indicated by the *thick arrows* and the posterior hyaloid of the vitreous by the *thin arrow*. In the potential space between these two landmarks, the vessels to the left of the *thin arrow* are invested with a fibrous–glial stroma and would appear ophthalmoscopically as a white neovascular membrane. The thin-walled vessel to the right of the *thin arrow* is not invested with connective tissue. A posterior vitreous detachment in an eye such as this might exert traction on these new vessels and precipitate a massive vitreous hemorrhage. **C**, Ophthalmoscopic view of retinal neovascularization (known clinically as neovascularization “elsewhere” in contrast with neovascularization of the optic disc) creating a neovascular membrane.

ple, the lumen of the central retinal artery can be narrowed significantly by atherosclerosis, thus predisposing to thrombosis. Emboli to the central retinal artery can originate from thrombi in the heart or from ulcerated atheromatous plaques in the carotid arteries. Fragments of atherosclerotic plaques can lodge within the retinal circulation (*Hollenhorst plaques*). Total occlusion of a branch of retinal artery can produce a segmental infarct of the retina. With sudden cessation of blood supply, the retina (an embryologic derivative of brain tissue) swells acutely and becomes optically opaque. By ophthalmoscopy the fundus in the affected area appears white instead of red or orange, because the retinal opacity blocks the view of the richly vascular choroid.

Total occlusion of the central retinal artery can produce a *diffuse infarct* of the retina. Following an acute occlusion, the retina appears relatively opaque by ophthalmoscopy. The fovea and foveola are physiologically thin; therefore, the normal orange-red of the choroid is not only visible but also highlighted by the surrounding opaque retina—the origin of the *cherry-red spot* of the central retinal artery occlusion. Cherry-red spots can also be seen in rare storage diseases such as *Tay-Sachs* and *Niemann-Pick* diseases because of the structural organization of the retina. The storage material accumulates in retinal ganglion cells: the ganglion cell layer of the macula surrounding the fovea is thick, but there are no ganglion cells in the center of the macula, the fovea. Thus, the fovea is relatively transparent to the underlying choroidal vasculature but is rimmed by relatively opaque retina, the result of storage material accumulating in the perifoveal macular ganglion cells (Fig. 29-22).

Retinal vein occlusion may occur with or without ischemia. In ischemic retinal vein occlusion, VEGF and other proangiogenic factors are up-regulated in the retina, leading to neovascularization of the retina and surface of the optic nerve head as well as neovascularization of the iris and subsequent angle-closure glaucoma. It follows that

areas of florid neovascularization in the periphery of the retina, described clinically as “sea-fans.”

Neovascularization also occurs in a variety of other clinical settings such as peripheral retinal vasculitis, and in irradiation used to treat intraocular tumors. The feature common to these conditions is damage to retinal vessels, producing zones of retinal ischemia that trigger retinal angiogenesis and its complications, hemorrhage and traction which in turn may cause detachment.

Retinal Artery and Vein Occlusions

The central retinal artery or its branches can be occluded by disorders that affect the vessels in general. For exam-

Figure 29-22 The cherry-red spot in Tay-Sachs disease. **A**, Fundus photograph of the cherry-red spot in Tay-Sachs disease. **B**, Photomicrograph of the macula in an individual with Tay-Sachs disease, stained with periodic acid-Schiff to highlight the accumulation of ganglioside material in the retinal ganglion cells. The presence of ganglion cells filled with gangliosides outside the fovea blocks the transmission of the normal orange-red color of the choroid, but absence of ganglion cells within the fovea (to the right of the vertical bar) permits the normal orange-red color to be visualized, accounting for the so-called cherry-red spot. (**A**, Courtesy Dr. Thomas A. Weingeist, Department of Ophthalmology and Visual Science, University of Iowa, Iowa City, Ia.; **B**, from the teaching collection of the Armed Forces Institute of Pathology.)

the injection of VEGF antagonists into the vitreous may have an important role in the treatment of this disorder. Nonischemic retinal vein occlusion may be complicated by hemorrhages, exudates, and macular edema but is seldom complicated by retinal or iris neovascularization.

Age-Related Macular Degeneration (AMD)

AMD results from damage to the macula which is required for central vision. It occurs in two forms, dry and wet that are distinguished by the presence of neovascularization in the wet form and its absence in the dry form. From the name of this disorder, it is clear that advancing age is a risk factor. The cumulative incidence of age-related macular degeneration (AMD) in individuals 75 years of age and older is 8%, and with increasing longevity AMD is becoming a major health problem.

Atrophic or “dry” AMD is characterized ophthalmoscopically by diffuse or discrete deposits in the Bruch membrane (drusen) and geographic atrophy of the RPE. Loss of vision is severe in these individuals and there is currently no effective treatment for “dry” or atrophic AMD; a regenerative approach to replacing diseased RPE cells with stem cells is under investigation.

Neovascular or “wet” AMD is characterized by *choroidal neovascularization*, defined by the presence of angiogenic vessels that presumably originate from the choriocapillaris and penetrate through the Bruch membrane beneath the RPE (Fig. 29-23). This neovascular membrane may also penetrate the RPE and become situated directly beneath the neurosensory retina. The vessels in this membrane may leak, and the exuded blood may be organized by RPE cells into macular scars. Occasionally, these vessels are the source of hemorrhage, leading to the localized suffusion of blood that may be mistaken clinically for an intraocular neoplasm, or give rise to diffuse vitreous hemorrhage. Currently the mainstay of treatment for neovascular AMD is the injection of VEGF antagonists into the vitreous of the affected eye.

Choroidal neovascular membranes can develop in diverse conditions that are unrelated to age, such as

pathologic myopia (Fuchs spot), following disruption of the Bruch membrane (due to trauma or other causes), or an immunologic response to systemic histoplasmosis (presumed ocular histoplasmosis syndrome).

To understand the pathogenesis of AMD it is important to appreciate the existence of a structural and functional unit composed of the retinal pigment epithelium (RPE), Bruch membrane (which contains the basement membrane of the RPE), and the innermost layer of the choroidal vasculature, the choriocapillaris. Disturbance in any component of this “unit” affects the health of the overlying photoreceptors, producing visual loss.

Nearly 71% of cases are estimated to have a genetic component. Attention is now focused on the roles of several genes, especially *CFH* (complement factor H) and other complement regulatory genes in the pathogenesis of this condition. The complement regulatory gene variants that are associated with AMD all appear to decrease

Figure 29-23 “Wet” age-related macular degeneration. A neovascular membrane is positioned between the RPE and Bruch membrane (BM). Note the blue discoloration of Bruch membrane to the right of the label, indicating focal calcification.

their function, implying that AMD may stem from an excess of complement activity. Environmental exposures such as a cigarette smoking or intense light exposure also increase the incidence of AMD in the genetically predisposed. For example, individuals with the risk-associated genotype who have smoked at least 10 pack-years (i.e., at least 20 cigarettes per day for 10 years) have a 144-fold increased risk for developing the neovascular form of AMD than individuals with this genotype who have smoked fewer than 10 pack-years. Much of the current work in the field is focused on determining the mechanism of complement-induced retinal damage in AMD, and how environmental exposures such as smoking impact AMD development.

Other Retinal Degenerations

Retinitis Pigmentosa

Retinitis pigmentosa is an inherited condition resulting from mutations that affect rods and cones, or RPE. It can cause varying degrees of visual impairment including, in some cases, total blindness. The term “retinitis pigmentosa” is an unfortunate relic of the time when these disorders were incorrectly presumed to be inflammatory. The conditions that are grouped under the rubric of retinitis pigmentosa are fairly common and have an incidence of 1 in 3600. They may be inherited as X-linked recessive, autosomal recessive, or autosomal dominant (the age of onset correlates with the inheritance pattern, with autosomal dominant retinitis pigmentosa appearing later in life). Retinitis pigmentosa may be part of a syndrome such as the *Bardet-Biedl syndrome*, *Usher syndrome*, or *Refsum disease*, or may develop in isolation (nonsyndromic retinitis pigmentosa).

Retinitis pigmentosa is linked to mutations in over 60 genes that regulate the functions of either the photoreceptor cells or the RPE. These include genes that regulate the visual cascade and visual cycle, structural genes (transpansins), transcription factors, retinal catabolic pathways, and mitochondrial metabolism. *Typically, both rods and cones are lost to apoptosis*, though in varying proportions. Loss of rods may lead to early *night blindness* and constricted visual fields. As cones are lost, *central visual acuity* may be affected. Clinically, retinal atrophy is accompanied by constriction of retinal vessels and optic nerve head atrophy (“waxy pallor” of the optic disc) and the accumulation of retinal pigment around blood vessels, thus accounting for the “pigmentosa” in the disease name. The electroretinogram reveals abnormalities characteristic of this disease.

Retinitis

A variety of pathogens can contribute to the development of infectious retinitis. For example, *Candida* may disseminate to the retina hematogenously, especially in the setting of intravenous drug abuse or in systemic candidemia from other causes. Hematogenous dissemination of pathogens to the retina typically results in multiple retinal abscesses. As was mentioned previously, cytomegalovirus retinitis is an important cause of visual morbidity in immunocompromised individuals, especially those with AIDS.

Retinal Neoplasms

Retinoblastoma

Retinoblastoma is the most common primary intraocular malignancy of children. The molecular genetics of retinoblastoma are discussed in detail (Chapter 7). Although the name *retinoblastoma* might suggest origin from a primitive retinal cell that is capable of differentiation into both glial and neuronal cells, it is now clear that the cell of origin of retinoblastoma is a neuronal progenitor. Recall that in approximately 40% of cases, retinoblastoma occurs in individuals who inherit a germline mutation of one *RB* allele. Retinoblastoma arises when the retinal progenitor suffers a second, somatic mutation and the *RB* gene function is lost. In the sporadic cases, both *RB* alleles are lost by somatic mutations. Retinoblastomas arising in the context of germline mutations are often bilateral. In addition, they may be associated with pinealoblastoma (“trilateral” retinoblastoma), which is associated with a dismal outcome.

MORPHOLOGY

The pathology of retinoblastoma, both hereditary and sporadic types, is identical. Tumors may contain both undifferentiated and differentiated elements. The former appear as collections of small, round cells with hyperchromatic nuclei. In well-differentiated tumors there are **Flexner-Wintersteiner rosettes** and fleurettes reflecting photoreceptor differentiation. It should be noted, however, that the degree of tumor differentiation does not appear to be associated with the prognosis. As seen in Figure 29-24, viable tumor cells are found encircling tumor blood vessels with zones of necrosis typically found in relatively avascular areas, illustrating the dependence of retinoblastoma on its blood supply. Focal zones of dystrophic calcification are characteristic of retinoblastoma.

In an effort to preserve vision and eradicate the tumor, many ophthalmic oncologists now attempt to reduce tumor burden by administration of chemotherapy, including selective delivery of the drug to the eye through the ophthalmic artery; after chemoreduction, tumors may be obliterated by laser treatment or cryopexy. Retinoblastoma tends to spread to the brain and bone marrow and seldom disseminates to the lungs. Prognosis is adversely affected by extraocular extension and invasion along the optic nerve, and by choroidal invasion. A variant of retinoblastoma—retinocytoma or retinoma—has been reported and appears to be a premalignant lesion. The appearance of retinoblastoma in one eye and retinocytoma in the other eye is characteristic of heritable retinoblastoma.

Retinal Lymphoma

Primary retinal lymphoma is an aggressive tumor that characteristically involves the two retinal layers derived from brain, the neurosensory retina and the RPE. Primary intraocular lymphoma tends to occur in older individuals and may mimic uveitis clinically. Most are diffuse large B cell lymphomas (Chapter 13). Spread to the brain commonly occurs via the optic nerve. The diagnosis depends on a demonstration of lymphoma cells in vitreous aspirates.

Figure 29-24 Retinoblastoma. **A**, Gross photograph of retinoblastoma. **B**, Tumor cells appear viable when in proximity to blood vessels, but necrosis is seen as the distance from the vessel increases. Dystrophic calcification (*dark arrow*) is present in the zones of tumor necrosis. Flexner-Wintersteiner rosettes—arrangements of a single layer of tumor cells around an apparent “lumen”—are seen throughout the tumor, and one such rosette is indicated by the *white arrow*.

KEY CONCEPTS

- **Retinal detachment**, a separation of the neurosensory retina from the retinal pigment epithelium, may be the consequence of a break in the retina (rhegmatogenous retinal detachment) or may develop without a retinal break because of pathology within or beneath the retina (non-rhegmatogenous retinal detachment).
- The clinical appearance of the retina by ophthalmoscopy can be linked to specific pathologic changes: the change in caliber and color of retinal blood vessels may reflect varying degrees of arteriolosclerosis and the location of hemorrhages and exudates in the retina is related to their locations within the retinal layers.
- Several major causes of blindness result from pathologic intraocular angiogenesis including proliferative diabetic retinopathy and exudative (wet) age-related macular degeneration, among many other conditions. VEGF antagonists may prevent visual loss in many of these conditions.
- Retinoblastoma is the most common primary intraocular tumor of children.
- Primary retinal lymphoma is a aggressive tumor that often involves the brain as well.

Optic Nerve

As a sensory tract of the central nervous system, the optic nerve is surrounded by meninges, and cerebrospinal fluid circulates around the nerve. The pathology of the optic nerve is similar to the pathology of the brain. For example, the most common primary neoplasms of the optic nerve are glioma (typically *pilocytic astrocytomas*) and meningioma.

Anterior Ischemic Optic Neuropathy

There are striking similarities between stroke and a condition known in ophthalmic terminology as *anterior ischemic optic neuropathy* (AION). As used clinically, the

term AION includes a spectrum of injuries to the optic nerve varying from ischemia to infarction. Thus, transient partial interruptions in blood flow to the optic nerve can produce episodes of transient loss of vision, whereas total interruption in blood flow can give rise to an optic nerve infarct which may be segmental or total. Zones of relative ischemia may surround segmental infarcts of the optic nerve. Optic nerve function in these poorly perfused but not infarcted zones may recover. The optic nerve does not regenerate, and visual loss from infarction is permanent.

Interruption in the blood supply to the optic nerve can result from inflammation of the vessels that supply the optic nerve or from embolic or thrombotic events. Bilateral total infarcts of the optic nerve resulting in total blindness have been reported in temporal arteritis, adding urgency to the treatment of this condition with high doses of corticosteroids.

Papilledema

Edema of the head of the optic nerve may develop as a consequence of compression of the nerve (as in a primary neoplasm of the optic nerve when swelling of the nerve head produces unilateral disc edema) or from elevations of cerebrospinal fluid pressure surrounding the nerve (resulting typically in bilateral disc edema). The concentric increase in pressure encircling the nerve contributes to venous stasis and also interferes with axoplasmic transport, leading to nerve head swelling. Swelling of the optic nerve head in elevated intracranial pressure is typically bilateral and is commonly termed *papilledema*. Typically, acute papilledema from increased intracranial pressure is not associated with visual loss. Ophthalmoscopically, the optic nerve head is swollen and hyperemic; by contrast, the optic nerve head in the relatively acute phases of anterior ischemic optic neuropathy appears swollen and pale because of decreased nerve perfusion (Fig. 29-25). In papilledema secondary to increased intracranial pressure, the optic nerve may remain congested for a prolonged period of time.

Figure 29-25 The optic nerve in anterior ischemic optic neuropathy (AION) and papilledema. **A**, In the acute phases of AION the optic nerve may be swollen, but it is relatively pale because of decreased perfusion. **B**, In papilledema secondary to increased intracranial pressure, the optic nerve is typically swollen and hyperemic. **C**, Normally, the termination of Bruch membrane (*arrowhead*) is aligned with the beginning of the neurosensory retina, as indicated by the presence of stratified nuclei (*arrow*), but in papilledema the optic nerve is swollen, and the retina is displaced laterally. This is the histologic explanation for the blurred margins of the optic nerve head seen clinically in this condition. (**A** and **B**, Courtesy Dr. Sohan S. Hayreh, Department of Ophthalmology and Visual Science, University of Iowa, Iowa City, Ia.; **C**, from the teaching collection of the Armed Forces Institute of Pathology.)

Glaucomatous Optic Nerve Damage

As discussed, the majority of individuals with glaucoma have elevated intraocular pressure. However, there is a small group that develops the visual field and optic nerve changes typical of glaucoma with normal intraocular pressure: so-called *normal-tension glaucoma*. Conversely, some individuals with elevated intraocular pressure who are followed over long periods of time never develop visual field changes or optic nerve cupping. Therefore, it is clear that there is a spectrum of neuronal susceptibility to the effects of elevated intraocular pressure. Considerable research is now directed toward understanding mechanisms by which the optic nerve axons may be protected from injury.

MORPHOLOGY

Characteristically, there is a diffuse loss of ganglion cells and thinning of the retinal nerve fiber layer (Fig. 29-26), which can be measured by optical coherence tomography. In advanced cases, the optic nerve is both cupped and atrophic, a combination unique to glaucoma. Elevated intraocular pressure in infants and children can lead to diffuse enlargement of the eye

(**buphthalmos**) or enlargement of the cornea (**megalocornea**). After the eye reaches its adult size, prolonged elevation of intraocular pressure can lead to focal thinning of the sclera, and uveal tissue may line ectatic sclera (**staphyloma**).

Other Optic Neuropathies

Optic neuropathy may be inherited or may be secondary to nutritional deficiencies or toxins such as methanol. Individuals may suffer severe visual compromise. If the nerve fibers that originate from the macula are affected then central visual acuity is lost.

Leber hereditary optic neuropathy results from inheritance of mitochondrial gene mutations (Chapter 5). Since neuronal health is dependent on axoplasmic transport of mitochondria, mitochondrial dysfunctions give rise to neurologic disorders including optic neuropathy. Lebers optic neuropathy, shows maternal inheritance pattern typical of mitochondrial gene mutations. However, due to unclear reasons, male are affected far more commonly (9:1) than females. The usual age of onset is between 10 and 30 years. It begins with clouding of vision that may progress to total loss of vision.

Optic Neuritis

Many unrelated conditions have historically been grouped under the heading of optic neuritis. Unfortunately, the term itself suggests optic nerve inflammation, which might not accurately describe the pathophysiologic changes. In common clinical usage the term *optic neuritis* is used to describe a loss of vision secondary to demyelination of the optic nerve. One of the most important causes of optic neuritis is multiple sclerosis (Chapter 28). Indeed, optic neuritis may be the first manifestation of this disease. The 10-year risk of developing multiple sclerosis after the first attack of optic neuritis increases if the affected person has concomitant evidence of brain lesions as detected by magnetic resonance imaging. Individuals with a single episode of optic nerve demyelination may recover vision and remain disease free.

KEY CONCEPTS

- The term “**anterior ischemic optic neuropathy**” refers to a spectrum of ischemic injuries to the optic nerve varying from transient ischemia to infarction.
- Bilateral swelling of the optic nerve head known as **papilledema** may develop as a consequence of elevated cerebrospinal fluid pressure and stasis of axoplasmic transport within the optic nerve. Unilateral optic nerve head swelling may result from compression of the optic nerve such as in primary tumors of the nerve.
- In **chronic glaucoma**, the optic nerve may atrophy and the cup on the surface of the nerve may enlarge and deepen.
- **Optic neuropathy** may be inherited (as in Leber hereditary optic neuropathy) or may result from nutritional deficiencies or toxins such as methanol.

Figure 29-26 The retina and optic nerve in glaucoma. **A**, *Left panel*, normal retina; *right panel*, the retina in long-standing glaucoma (same magnification). The full thickness of the glaucomatous retina is captured (*right*), a reflection of the thinning of the retina in glaucoma. In the glaucomatous retina, the areas corresponding to the nerve fiber layer (NFL) and ganglion cell layer (GC) are atrophic; the inner plexiform layer (IPL) is labeled for reference. Note also that the outer nuclear layer of the glaucomatous retina is aligned with the inner nuclear layer of the normal retina due to the thinning of the retina in glaucoma. See [Figure 29-16](#) for orientation. **B**, Glaucomatous optic nerve cupping results in part from loss of retinal ganglion cells, the axons of which populate the optic nerve. **C**, The arrows point to the dura of the optic nerve. Notice the wide subdural space, a result of atrophy of the optic nerve. There is a striking degree of cupping on the surface of the nerve as a consequence of long-standing glaucoma.

The End-Stage Eye: Phthisis Bulbi

Trauma, intraocular inflammation, chronic retinal detachment, and many other conditions can give rise to an eye that is both small (atrophic) and internally disorganized: **phthisis bulbi**. Congenitally small eyes—hypoplastic or *microphthalmic* eyes—are generally not disorganized internally. Phthisical eyes typically show the following changes: the presence of exudate or blood between the ciliary body and sclera and the choroid and sclera (*ciliochoroidal effusion*); the presence of a membrane extending across the eye from one aspect of the ciliary body to the other (*cyclitic membrane*); chronic retinal detachment; optic nerve atrophy; the presence of intraocular bone, which is thought by many to originate from *osseous metaplasia* of the RPE; and a thickened sclera, especially posteriorly. Ciliochoroidal effusion is typically associated with the physiologic state of low intraocular pressure (*hypotony*). The normal pull of the extraocular muscles on a hypotonous eye may render the appearance of the eye as square rather than round.

detection of molecules of prognostic or therapeutic significance in, 334
development of, 281f
diet and, 277, 448-449
enabling inflammation and, 315-316
epidemiology of, 275-280, 280b
acquired predisposing conditions in, 278-279
age in, 278
environmental factors in, 276-278
genetic predisposition in, 279-280
geographic variation in, 277f
global impact of, 275-276
Cancer (*Continued*)
incidence in, 275, 276f
grading and staging of, 332
growth factor signaling pathways in, 285f
hereditary predisposition to, 335
host defense, evasion of, 310-314
antitumor effector mechanisms in, 312
immune surveillance and escape as, 310, 312-314, 314b
tumor antigens in, 310-312, 311f
laboratory diagnosis of, 332-338, 338b
molecular basis of, 280-321
angiogenesis in, 283, 305-306, 306b, 316
cellular and molecular hallmarks of, 280-283, 283f
chromosomal changes in, 316-319
chromosomal translocations in, 316-317
dysregulation of cancer-associated genes in, 316-320
epigenetic changes in, 319-320
evasion of apoptosis in, 283
gene amplification in, 318
genetic lesions in, 319b
genomic instability in, 283, 314-315, 315b
immunodeficiency states and, 279
invasion and metastasis in, 283, 310b, 316
local and hormonal effects of, 330
microRNAs (miRNAs) in, 320
as multistep, 320-321
mutations in, 281
noncoding RNAs and, 320
oncogenes in, 283-290, 284t
regulatory genes in, 280
tumor suppressor genes in, 290-300, 291t
Warburg effects in, 300-301
molecular profiles of, 335-336
nomenclature for, 266-267
obesity and, 277-278, 447f, 448
occupational, 278t
paraneoplastic syndromes due to, 330-332, 331t
precursor lesions and, 279
promoting inflammation and, 283
reproductive history and, 278
risks from exposures to radiation, 431-432
tumor markers for, 337-338
Cancer immunoediting, 310
Cancer stem cells, 281
Cancer-testis antigens, 311
Candida albicans, 386
Candida esophagitis, 386b-387b, 387f
Candida vaginitis, 386b-387b
Candidiasis, 386-387, 386b-387b, 387f
in AIDS, 253
cutaneous, 386b-387b
invasive, 386b-387b
Canker sores, 728, 728f
Capillaries, structure and function of, 485
Capillary hemangiomas, 516
Capillary telangiectasias, 1271b
Carbon dioxide (CO₂), in greenhouse effect, 405
Carbon monoxide
as air pollutant, 409, 409b
CNS toxicity of, 1305
Carbon tetrachloride, occupational health risks, 413
Carbonic anhydrase 2 (CA2) gene, 1186
Carbuncle, 364b

- Carcinogenesis
 diet and, 448-449
 DNA damage and, 430-431
 molecular basis of multistep, 320-321
 nonlethal genetic damage in, 280
- Carcinogens
 direct-acting, 322
 environmental, 278
 indirect-acting, 323-324
 ultimate, 323
- Carcinoid heart disease, 562, 562b, 562f
- Carcinoid tumor, gastric, 773-775, 774b, 774t, 775f
- Carcinoma en cuirasse, 1068
- Carcinoma in situ, 271, 271f
 of bladder, 964, 965f, 966, 967f
 of breast
 ductal, 1057-1058, 1058f, 1059f
 lobular, 1059-1060, 1059f
 of penis, 971, 971f
- Carcinomas, 266

- Central nervous system (CNS), 1251-1318
cellular pathology in, 1252-1254, 1254b
cerebral edema as, 1254-1255, 1255b-1256b
cerebrovascular disease as, 1263-1271, 1271b
hypertensive, 1267-1268
hypoxia, ischemia, and infarction as, 1263-1267, 1265f, 1266f, 1267f, 1268f
intracranial hemorrhage as, 1268-1271, 1269f
demyelinating, 1283-1286, 1286b
acute disseminated encephalomyelitis as, 1286
acute necrotizing hemorrhagic encephalomyelitis as, 1286
central pontine myelinolysis as, 1286
multiple sclerosis as, 1283-1285, 1284f, 1285f
neuromyelitis optica as, 1285-1286
hydrocephalus as, 1254-1255, 1254f, 1255b-1256b
infections in, 1271-1280, 1272t, 1280b-1281b
abscess
brain, 1273-1274
extradural, 1274
acute focal suppurative, 1273-1274
acute meningitis as, 1272-1273
meningoencephalitis as
chronic bacterial, 1274-1275
fungal, 1279
viral, 1275-1279
protozoal, 1279-1280
subdural empyema as, 1274
malformations and developmental diseases as, 1256-1258, 1258b
of forebrain, 1256-1258
neural tube defects as, 1256
of posterior fossa, 1258, 1258f
syringomyelia and hydromyelia as, 1258
metabolic diseases as
acquired, 1304-1305, 1306b
Alexander disease as, 1303
due to hyperglycemia, 1305
due to hypoglycemia, 1304-1305
due to vitamin deficiencies, 1304
genetic, 1302-1304, 1304b
- Central nervous system (CNS) (*Continued*)
hepatic encephalopathy as, 1305
Krabbe disease as, 1302, 1303f
Leigh syndrome as, 1304
leukodystrophies as, 1283, 1302-1303
mitochondrial encephalomyopathies as, 1302-1304
myoclonic epilepsy and ragged red fibers as, 1304
neuronal storage diseases as, 1302
Pelizaeus-Merzbacher disease as, 1303
Tay-Sachs disease, 1302
neurodegenerative, 1286-1301, 1287t-1288t, 1301b
Alzheimer disease as, 1287-1292, 1289f, 1290f, 1291f
amyotrophic lateral sclerosis as, 1300-1301, 1301f
ataxia-telangiectasia as, 1299-1300
atypical parkinsonism syndromes as, 1296
corticobasal degeneration as, 1296
dementia with Lewy bodies as, 1295-1296
Friedreich ataxia as, 1299
frontotemporal dementia as, 1292
Huntington disease as, 1297-1298, 1298f
of motor neurons, 1301
multiple system atrophy as, 1296-1297
Parkinson disease as, 1294-1296, 1295f
Pick disease as, 1292, 1293f
progressive supranuclear palsy as, 1296
spinal and bulbar muscular atrophy (Kennedy disease) as, 1301
spinal muscular atrophy as, 1301
spinocerebellar, 1298-1300
vascular (multi-infarct) dementia as, 1268
perinatal brain injury as, 1258-1259, 1263b
raised intracranial pressure and herniation as, 1254-1255, 1255b-1256b, 1255f
toxic, 1304-1305, 1306b
trauma, 1259-1263
concussion as, 1259
diffuse axonal injury as, 1261
parenchymal injuries as, 1259-1261
sequelae of, 1262-1263
skull fractures as, 1259
spinal cord, 1263
vascular injury, 1261-1262, 1261t
tumors, 1306-1317, 1317b-1318b
astrocytoma as, 1306-1309, 1307f, 1309f
atypical teratoid/rhabdoid tumor as, 1313
ependymoma as, 1310-1311, 1311f
familial tumor syndromes of, 1316-1317
germ cell tumors as, 1314
gliomas as, 1306-1311
medulloblastoma as, 1312-1313, 1313f
meningiomas as, 1314-1315, 1315f
metastatic, 1315-1316
neurofibromatosis as, 1317
neuronal, 1311-1312
other parenchymal, 1313-1314
paraneoplastic syndromes due to, 1316
pineal parenchymal tumors as, 1314
poorly differentiated, 1312-1313
primary CNS lymphoma as, 1313-1314
- Central nervous system involvement
in AIDS, 255
pathogenesis of, 250

 Chromatin condensation, in apoptosis, 53b, 54f
 Chromatin organizing factors, 4
 Chromium, as carcinogen, 278t
 Chromophobe renal carcinoma, 954, 954b-955b
 Chromosomal disorder(s), 158-167
 chromosome 22q11.2 deletion syndrome as, 163-164
 fetal growth restriction due to, 457
 hermaphroditism and
 pseudohermaphroditism as, 167
 involving autosomes, 161-164, 164b
 Klinefelter syndrome, 165-166
 normal karyotype and, 158-159
 prevalence of, 454
 trisomy 21 (Down syndrome) as, 161-163
 Turner syndrome, 166-167, 167f
 Chromosomal rearrangements, 160f
 Chromosome 22q11.2 deletion syndrome, 163-164
 Chromosomes, structural abnormalities of, 159-161
 Chromothripsis, in cancer, 318-319
 Chronic antibody-mediated rejection, 233
 Chronic bronchitis, 674t, 677t, 678-679, 679b
 Chronic cholecystitis, 878-879, 879f
 morphology of, 878b-879b
 Chronic diffuse interstitial (restrictive) diseases, 684-697, 685t, 687b
 Chronic disease, anemia of, 652-653, 655b
 Chronic granulomatous disease, 238
 Chronic GVHD, 236
 Chronic hepatitis, 836, 838f
 Chronic illness, and malnutrition, 433
 Chronic inflammation, 71, 93-98, 98b-99b
 features of, 71t
 Chronic inflammatory demyelinating poly(radiculo)neuropathy, 1231, 1231f
 Chronic kidney disease, 898, 899t
 Chronic liver failure, 827-828
 Chronic lymphocytic leukemia (CLL), 591t, 593-594, 593f, 594f, 598b
 morphology of, 593b
 Chronic myelogenous leukemia (CML), 616-618, 617f
 morphology of, 617b
 pathogenesis of, 617f
 Chronic myeloproliferative disorders, 586
 Chronic neuronal injury, 1252b-1253b
 Chronic nonspecific lymphadenitis, 585
 Chronic obstructive pulmonary disease (COPD), 675, 675f
 Chronic pancreatic injury, 888
 Chronic pelvic pain syndrome, 962-963
 Chronic rejection, 233b-234b
 Chronic renal failure, anemia due to, 655
 Chronic tophaceous arthritis, 1216, 1216b
 Chronic traumatic encephalopathy (CTE), 1263
 Chronic viral hepatitis, 837b-838b, 838f
 cirrhosis from, 827f
 Churg-Strauss syndrome, 511
 Chvostek sign, in hypoparathyroidism, 1104-1105
 Chylocele, 980
 Chylothorax, 722
 Cigarette smoke, as teratogen, 454-455
 Cigarette smoking
 and atherosclerosis, 493
 and bladder cancer, 964
 and cancer, 276-277
 and pancreatic carcinoma, 893, 895b
 Ciliary body, 1320f
 Ciliochoroidal effusion, 1342
 Circulating proteins, 72
 Cirrhosis, 827-828, 828f
 by chronic liver diseases, 849
 from chronic viral hepatitis, 827f
 hepatitis C-related, 827f
 morphology of, 827b-828b
 Citrullinated peptides (CCPs), 1210
 Civatte bodies, 1167b
 Class switching, 587
 Classic KS, 518, 518b-519b
 Classical pathway, 88
 Clathrin, 9
 Clathrin-coated pit, 9-10
 CLC1, mutations of, 1246
 Clear cell carcinoma
 in kidney, 953, 954b-955b, 954f
 of ovaries, 1028
 Clear cell chondrosarcoma, 1202b
 Cleft lip, 453f
 Cleft palate, 453f
 Cleidocranial dysplasia, 1184, 1184t
 Climate change, health effects of, 405-406, 405f
 Clonal evolution model, of metastasis, 309
 Clonal selection, 190
 Close-up, of cortical surface in benign nephrosclerosis, 939f
 Clostridial cellulitis, 383b
 Clostridial infections, 382-383, 383b
 Clostridium perfringens, 382-383, 383f
 Clotting, in inflammation, 89
 Clotting factor, abnormalities in, 661-663, 661f
 CNS. *See* Central nervous system (CNS).
 Coagulation
 disseminated intravascular, 127, 663-665
 in septic shock, 133
 in inflammation, 89
 Coagulation cascade, in hemostasis, 118-120, 118f, 119f
 Coagulation system, in glomerular injury, 907-908
 Coagulative necrosis, 43b-44b, 43f
 Coagulopathy, consumptive, 127
 Coal dust
 intracellular accumulation of, 64
 lung diseases due to, 688t
 pneumoconioses due to, 414
 Coal workers' pneumoconiosis, 64, 689-690, 689b, 689f
 Coarctation of the aorta, 537, 537f
 Coated pits, 9-10
 Cocaine, abuse of, 423-424, 423f
 Coccidioides immitis, 710-711
 Co-deletion, in oligodendroglioma, 1310
 Codominance, 140
 Cofactor, 119
 Cognitive impairment, in Alzheimer disease, 1290
 Co-infection, in HDV, 835
 COL7A1 gene, in epidermolysis bullosa, 1171
 Cold agglutinin type immunohemolytic anemia, 643t, 644
 Cold hemolysin type immunohemolytic anemia, 643t, 644
 Cold sores, 357b-358b
 Collagen biosynthetic pathway, 23f

- Collagen vascular diseases, 217
Collagens, extracellular matrix and, 23
Collar-button lesion, 719b-720b
Collecting duct carcinoma, 954, 954b-955b
Collectins, 72
Colloid carcinoma
 of breast, 1065, 1065f
 of prostate, 990
Colloid cyst, of third ventricle, 1311
Colon. *See also* Intestine
 angiodyplasia of, 780-781
 ischemic bowel disease of, 779-780, 779b
Colon cancer, 448
Colon carcinoma, 273f
Colonic polyp, 267f
Colony-forming units (CFUs), 580-581, 580f
Colony-stimulating factors (CSFs), 101, 196
Colorectal cancer, molecular model for
 evolution of, 321f
Colostrum, 1043-1044
Combination antiretroviral therapy, 255-256
Comedo ductal carcinoma in situ, 1057, 1058f
Communicating hydrocephalus, 1254-1255
Communicating junctions, 12
Complement, in glomerular injury, 907
Complement cascade, in septic shock, 131-132
Complement pathway, alternative, in membranoproliferative glomerulonephritis, 906-907
Complement system, 88-89
 activation and function of, 88f
 deficiencies affecting, 238
 in innate immunity, 187
Complex karyotype, 1219
Complex multigenic disorders, 158
Complex sclerosing lesion, of breast, 1049, 1050f
Compression atelectasis, 671
Compression neuropathy, 1234
Concussion, 1259
Conduction system, of heart, 524-525
Condyloma acuminatum, 1175b
 of penis, 970-971, 970b, 970f
 of vulva, 997, 997f
Condylomata lata, in syphilis, 379
Confluent necrosis, in hepatocytes, 823
Congenital abnormalities, of gastrointestinal tract, 750-752, 752b
 atresia, fistulae, and duplications as, 750f
 diaphragmatic hernia, omphalocele, and gastroschisis as, 750
 ectopia as, 750-751
 Hirschsprung disease as, 751-752, 752b, 752f
 Meckel diverticulum as, 751, 751f
 pyloric stenosis as, 751
Congenital adrenal hyperplasia, 1128, 1128b
Congenital aganglionic megacolon, 751-752, 752b, 752f
Congenital anomalies, 452-456
 of bladder, 961-962, 962f
 causes of, 454-456, 454t
 of kidney, 944-945
 agenesis as, 944
 ectopic kidneys as, 945
 horseshoe kidneys as, 945
 hypoplasia as, 944-945
 pathogenesis of, 455-456, 455f
 of penis, 970
 of testes, 972-973, 973f
 of ureters, 960
Congenital contractural arachnodactyly, 144
Congenital fiber type disproportion, 1241t
Congenital heart disease (CHD), 531-538, 538b
 cardiac development and, 531-532, 532f
 clinical features of, 533
 cyanotic, 535
 etiology and pathogenesis of, 532-533
 incidence of, 531, 531t
 with left-to-right shunts, 533-535, 534f
 atrial septal defects as, 534-535, 534f
 patent ductus arteriosus as, 534f, 535
 patent foramen ovale as, 534-535
 ventricular septal defects as, 534f, 535f, 535
 obstructive, 537-538
 aortic stenosis and atresia as, 537-538
 coarctation of the aorta as, 537, 537f
 pulmonary stenosis or atresia as, 537
 with right-to-left shunts, 533, 535-537, 536f
 persistent truncus arteriosus as, 535
 tetralogy of Fallot as, 535-536, 536f
 total anomalous pulmonary venous connection as, 535
 transposition of the great arteries as, 536-537, 536f
 tricuspid atresia as, 535
Congenital hepatic fibrosis, 861-862, 862f
Congenital hypothyroidism, 1085
Congenital infections, with
 cytomegalovirus, 359-360
Congenital melanosis oculi, 1324
Congenital myasthenic syndromes, 1236
Congenital nevus, 1144t
Congenital syphilis, 380, 380b-381b
Congestion, 115-116
 edema due to, 115-116
 morphology of, 116b
Congestive heart failure (CHF), 526
 edema due to, 114
 therapy for, 530
Congestive hepatomegaly, in right-sided heart failure, 530
Congestive splenomegaly, 624
 morphology of, 624b
 in right-sided heart failure, 530
Conidia, 385
Conjugated hyperbilirubinemia, 854t
Conjunctiva, 1320f, 1322-1324, 1324b

 in retinal vascular disease, 1335f, 1337f
 type 1, 209t
 pathogenesis of, 1109-1111
 stages in development of, 1110f
 vs. type 2, 1108t
 type 2
 development of, 1111f
 pathogenesis of, 1111-1112
 Diabetic ketoacidosis, 1113-1114
 Diabetic macrovascular disease, 1115, 1117b-1119b
 Diabetic microangiopathy, 1117b-1119b
 Diabetic microvascular disease, 1115
 Diabetic nephropathy, 926, 1117b-1119b, 1120
 Diabetic neuropathy, 1117b-1119b, 1119
 Diabetic ocular complications, 1117b-1119b
 Diabetic retinopathy, 1117b-1119b
 Dialysis-associated cystic disease, 949
 Diapedesis, of leukocyte through endothelium, 76-77
 Diaphragmatic hernia, 750
 Diarrhea, 781-784. *See also* Malabsorption
 exudative, 781
 malabsorptive, 781
 osmotic, 781
 secretory, 781
 Diastolic dysfunction, 527
 Diastolic failure, 529-530
 Dichlorodiphenyltrichloroethane (DDT), 413-414
 Diet
 and atherosclerosis, 449
 and breast cancer, 1053
 and cancer, 277, 448-449
 Dietary insufficiency, 432-433
 Diethylstilbestrol (DES), developmental anomalies of vagina, 1000
 Differentiation, in neoplasia, 268-271, 274t
 Differentiation antigens, cell type-specific, 312
 Differentiation therapy, 317
 Diffuse alveolar damage (DAD). *See* Acute respiratory distress syndrome (ARDS).
 Diffuse axonal injury, 1261, 1261b
 Diffuse cortical necrosis, 944, 944b, 944f
 Diffuse cutaneous leishmaniasis, 393b-394b
 Diffuse hyperplasia, in adrenal glands, 1124b, 1124f
 Diffuse large B-cell lymphoma (DLBCL), 591t, 595-597, 596f, 597f, 598b
 morphology of, 596b
 Diffuse lupus nephritis, 222b-225b
 Diffuse mesangial sclerosis, 1117b-1119b
 Diffuse microvesicular steatosis, 825b-826b
 Diffuse neurofibromas, 1247, 1247b-1248b
 Diffuse plaques, in Alzheimer disease, 1290b-1292b
 Diffuse sclerosing variant, 1096b-1097b
 DiGeorge syndrome, 163, 164f, 241, 626
 in hypoparathyroidism, 1104
 Dihydrotestosterone (DHT), in benign prostatic hyperplasia, 982, 983f
 1,25-Dihydroxyvitamin D [$1\alpha, 25(\text{OH})_2\text{D}_3$], 438, 439f
 Dilated cardiomyopathy, 565-568, 565t, 566f, 567f, 568f, 567b
 Dimorphic fungi, 390
 Dioxin (TCDD; 2,3,7,8-tetrachlorodibenzo-*p*-dioxin), 413-414
 Dipeptidyl peptidase (DPPs), 1108
 Diphtheria, 365, 365b, 365f
 peripheral neuropathy in, 1232
 Direct Coombs antiglobulin test, 643
 Discoid rash, in systemic lupus erythematosus, 218t
 Disruptions, 452, 453f
 Dissecting osteitis, 1191b-1192b, 1192f
 Disseminated intravascular coagulation (DIC), 127, 663-665
 due to cancer, 332
 morphology of, 664b
 pathophysiology of, 664f
 in septic shock, 133
 Disseminated peritoneal leiomyomatosis, 1020b
 Dissolution, of thrombi, 125-126
 Distal symmetric diabetic polyneuropathy, 1233
 Disuse, atrophy of, 36
 Divalent metal transporter 1 (DMT1), 650, 651f
 Diverticulum(a)
 Meckel, 751, 751f
 of ureters, 960
 DNA-anti-DNA complexes, 221-222
 DNA damage
 apoptosis due to, 53
 cell injury due to, 50
 in cellular aging, 66-67, 66f
 due to ionizing radiation, 430-431
 DNA methylation, 4
 in cancer, 319
 DNA microarrays, 334-335
 DNA mismatch repair, 314
 DNA polymorphisms, 179f
 Döhle bodies, 583, 584f
 Dolor, 71, 93
 Dormancy, of metastasis, 308-309
 Double minutes, in cancer, 318
 Double stranded breaks (DSBs), 430-431
 Down-regulation
 of ANF gene expression, 35
 of BMPR2, 699
 of growth, 457
 of GSTP1 expression, 985
 Downstream phosphorylation, 16-17
 Dressler syndrome, 548f, 549
 Driver mutations, in cancer, 281
 Drug(s)
 cell injury due to, 39
 congenital anomalies due to, 454-455
 genetically determined adverse reactions to, 144
 Drug abuse, 423-425, 423t
 of 3,4 methylenedioxymethamphetamine (MDMA), 425
 of amphetamines, 424-425
 of cocaine, 423-424, 423f
 of marijuana, 425
 of methamphetamine, 424-425
 of opiates, 424
 Drug hypersensitivity vasculitis, 507
 Drug injury, 425b-426b
 Drug reactions, bleeding disorder due to, 657
 Drug toxicity, agranulocytosis and, 582
 Drug-induced interstitial nephritis, 935-936, 935f
 Drug-induced liver injury, 840-841, 841b
 patterns of injury in, 841t
 Drug-induced lupus erythematosus, 226
 Drug-induced thrombocytopenia, 659
 Dubin-Johnson syndrome, 854t
 Duchenne muscular dystrophy, 1242-1243, 1243f
 morphology of, 1242b-1243b
 Duct ectasia, 1046-1047, 1047b, 1047f
 Duct of Santorini, 883, 884f
 Duct of Wirsung, 883, 884f
 Ductal carcinoma in situ (DCIS), 1057-1058, 1057b, 1058f, 1059f
 Ductal hyperplasia, atypical, 1050, 1051f
 Ductular cholestasis, 854-855, 856f
 Ductus arteriosus, patent, 534f, 535
 coarctation of the aorta with, 537, 537f
 Duncan disease, 362
 Duodenal ulcers, 92f
 Dupuytren contracture, 1221
 Duret hemorrhages, 1255, 1255f
 Dysembryoplastic neuroepithelial tumor, 1312
 Dysfunctional uterine bleeding (DUB), 1008-1010, 1009f, 1009t
 Dysgerminoma
 ovarian, 1030-1031, 1031b, 1031f
 testicular, 976
 Dyskeratosis, 1143t
 Dyslipoproteinemias, in atherosclerosis, 495
 Dysostoses, of bone, 1183
 Dysphagia, in systemic sclerosis, 229-230
 Dysplasia, 270-271, 453-454
 of bone, 1183
 Dysplastic nevi, 1144t, 1145-1146, 1146b-1147b, 1146f, 1147f
 Dysplastic nevus syndrome, 1145-1146
 Dysplastic nodules, in liver, 871-873
 Dyspnea, 677
 in left-sided heart failure, 529
 paroxysmal nocturnal, 529
 Dystrophic calcification, 65, 65f, 1082b
 Dystrophin, 1242, 1242f
 Dystrophinopathies, 1242
 E
 E6 proteins, oncogenic activities of, 326
 E7 proteins, oncogenic activities of, 326, 326f
 Early endosome, 9-10
 Ears, disorders of, 740-741, 741b

- Eating disorders, 435
 EBNA-2 gene, 327
 E-cadherin, 12, 297
 in invasive lobular carcinoma, 1065
 in metastasis, 306-307

 erythematous, 1168
 foliaceus, 1168, 1169f
 vegetans, 1168
 vulgaris, 206t, 1168, 1169f
 Penis, 970-972
 Bowen disease of, 971, 971f
 bowenoid papulosis of, 971
 carcinoma of
 invasive, 971-972
 in situ, 971, 971f
 congenital anomalies of, 970
 inflammation of, 970
 lesions of, 972b
 tumors of, 970-972, 970f
 Penumbra, 1264
 Peptic ulcer, 91
 in Zollinger-Ellison syndrome (gastrinomas), 1121
 Peptic ulcer disease (PUD), 766-768, 766b-767b, 767f
 Peptide display system, of adaptive immunity, 194-196
 Peptide YY (PYY), in energy balance, 444, 445f, 446f, 446
 Perfusion, poor, tissue repair and, 106
 Periapical cyst, 734
 Periapical granuloma, 734
 Pericardial disease, 573-575
 Pericardial effusion, 573
 Pericardial spaces, in right-sided heart failure, 530
 Pericarditis, 549, 573-575, 574b, 574f, 574t
 in systemic lupus erythematosus, 222b-225b
 Pericytes, 485
 Periductal mastitis, 1046
 Perifascicular atrophy, 1238b-1239b, 1239f
 Perinatal brain injury, 1258-1259
 Perinatal infections, 360, 459-461
 Perineural invasion, in prostate cancer, 986, 987f
 Perineurium, 1227-1228
 Periodic acid-Schiff stain, 346f, 902, 1079b
 Periodontitis, 728
 Periorchitis, syphilitic, 380b-381b
 Peripheral B-cell neoplasms, 593-604
 morphology of, 593b
 Peripheral giant cell granuloma, of oral cavity, 729
 Peripheral lymphoid organs, 193-194
 Peripheral nerves, diseases of, 1227-1235, 1228f
 Peripheral nerve injury, general types of, 1228-1230
 Peripheral nerve sheath tumors, 1246-1249, 1249b
 malignant, 1248
 morphology of, 1248b-1249b
 Peripheral neuropathies, 1235b
 accompanying inherited metabolic disorders, 1235
 anatomic patterns of, 1230
 specific, 1230-1235
 Peripheral ossifying fibroma, of oral cavity, 729
 Peripheral resistance, in blood pressure regulation, 488
 Peripheral T-cell lymphoma, unspecified, 591t, 604, 605f
 Peripheral tolerance, 213-214
 Peritoneal cavity, 817
 infection of, 817
 inflammatory disease of, 817, 817b
 sclerosing retroperitonitis of, 817
 tumors of, 817
 Peritoneal mesothelioma, 724
 Peritoneal spaces, in right-sided heart failure, 530
 Perivascular amyloidosis, 657
 Periventricular leukomalacia, 1259
 Permanent tissues, 101
 Pernicious anemia, 206t, 645-648, 645t
 clinical features of, 648
 incidence of, 647
 morphology of, 648b
 pathogenesis of, 647-648
 Peroxisome proliferator-activated receptors (PPARs), 407, 437
 Peroxisomes, 6
 Peroxynitrite (ONOO⁻)
 cell injury due to, 48t
 in phagocytosis, 80
 Persistent diarrhea, 253
 Persistent lymphedema, 399b, 399f
 Persistent truncus arteriosus, 535
 Pertussis, 368-369, 369b, 369f
 Petechiae, 122f
 Peyronie disease, 1222
 Phacolysis, 1327
 Phagocytes, killing by, resistance to, 346
 Phagocyte oxidase, 79
 Phagocytic receptors, in inflammation, 78
 Phagocytosis, 9-10, 14
 in antibody-mediated hypersensitivity, 205
 complement system in, 88f, 89
 discovery of, 71
 frustrated, 82
 in inflammation, 78-82, 80f
 Phagolysosome, 79
 Phagosome, 78
 Pharyngitis, 736
 Phenotypic sex, 167
 Phenylketonuria (PKU), 464-465, 464f
 Pheochromocytoma(s), 1134-1136, 1134b-1135b, 1135f
 clinical course of, 1135-1136
 Philadelphia chromosome, 317
 Phimosis, 970
 Phlebothrombosis, 125-126, 514-515
 Phosphatase and tensin homologue (PTEN) gene, 286-287, 298
 in endometrial carcinoma, 1014
 in endometrial hyperplasia, 1013
 Phosphate nephropathy, acute, 937
 Phosphatidylinositol, 7

- Phosphatidylinositol glycan complementation group A gene (PIGA), 642
- Phosphatidylserine, 7
- Phosphatonins, 440
- Phospholipid breakdown, increased, cell injury due to, 49
- Phospholipid synthesis, decreased, cell injury due to, 49

- Vascular flow and caliber, in inflammation, 73-74
- Vascular injury, of central nervous system, 1261-1262, 1261t
- Vascular intervention, pathology of, 520-521, 521f
- Vascular leakage, in inflammation, 74, 74f
- Vascular malformations, of brain, 1271
- Vascular (multi-infarct) dementia, 1268
- Vascular pattern, of acute T cell-mediated rejection, 233b-234b
- Vascular permeability, in inflammation, 74, 74f
- Vascular reactions, in acute inflammation, 73, 75
- Vascular replacement, 521, 521f
- Vascular tumors, 515-520, 520b
benign, 516-518
bacillary angiomatosis as, 517-518
classification of, 515t
glomus tumor (glomangioma), 517
hemangioma as, 516
lymphangiomas as, 516-517
intermediate-grade (borderline) tumors as, 518-519
hemangioendothelioma, 519
Kaposi sarcoma, 518
malignant tumors, 519-520
angiosarcoma as, 519
hemangiopericytoma as, 520
- Vascular wall cells, response to injury of, 487b
- Vasculature, regional specializations of, 484f
- Vasculitis, 505-513, 506f, 513b
ANCA-associated small vessel, 511f
Behçet disease, 511
caused by ANCA, 206t
Churg-Strauss syndrome, 511
immune complex-associated, 506-507
Kawasaki disease as, 510
microscopic polyangiitis, 510-511
neuropathy associated with, 1231
noninfectious, 506-513
polyarteritis nodosa, 509-510
primary forms of, 506t
- Vasculogenic mimicry, 1331b
- Vaso-occlusive crises, in sickle cell disease, 637-638
- Vasoactive amines
in immediate hypersensitivity, 203
in inflammation, 83
- Vasoconstriction, 501
due to shock, 133
in hemostasis, 116, 117f
influences, 490
- Vasodilation
due to shock, 133
in inflammation, 73-74
- Vasogenic edema, 1254
- Vasopressin, 1074-1075
- Vasospasm, coronary artery occlusion due to, 540
- Vector-borne infectious diseases, climate change and, 406
- Vegetative endocarditis, 560f
- Veins
and lymphatics, 514-515
superior and inferior vena cava syndromes of, 515
thrombophlebitis and phlebothrombosis, 514-515
varicose, 514
- Velocardiofacial syndrome, 163
- Venous angiomas, of brain, 1271b
- Venous thrombosis, 125-126
- Ventricular aneurysm, due to myocardial infarction, 549
- Ventricular remodeling, 527, 549
- Ventricular septal defect (VSD), 534f, 535f, 535, 535b
in tetralogy of Fallot, 535-536, 536f
in transposition of the great arteries, 536-537, 536f
- Verruca vulgaris, 1175b, 1176f
- Verrucous carcinoma
of penis, 972
of vulva, 991
- Vertical transmission, 344
during birth, 344
placental-fetal, 344
postnatal, 344
- Very-long-chain fatty acids (VLCFAs), in adrenoleukodystrophy, 1303
- Very-low-density lipoproteins (VLDLs), 147
- Vesicle, 1143t
- Vesicoureteral reflux, 931, 931f, 961-962
- Vesicouterine fistulae, congenital, 961-962
- Vessel wall abnormalities, bleeding disorders caused by, 656-657
- Vinyl chloride
as carcinogen, 278t
occupational health risks, 414
- VPoma, 1122
- Viral arthritis, 1214
- Viral hemorrhagic fever (VHF), 357
- Viral hepatitis, 830-839, 838b-839b
acute asymptomatic infection with recovery in, 836
acute symptomatic infection with recovery in, 836
clinicopathologic syndromes of, 835-839
HIV and chronic, 837-839
morphology of, 837b-838b
- Viral infections, 354-362
acute, 354-357
chronic
latent (herpesvirus), 357-360, 357b-358b
productive, 360
Epstein-Barr virus, 360-362
herpes simplex viruses, 357
measles, 355, 355b, 355f
mumps, 355-356, 356b
poliovirus, 356
transforming, 360-362
West Nile virus, 356-357
- Viral injury, mechanisms of, 348-349, 349f
- Viral meningitis, 1272-1273
- Viral meningoencephalitis, 1275-1279
- Virchow, Rudolf, 71, 1141
- Virchow triad, 122, 122f
- Virus(es)
sexually transmitted infections, 351t
tropism, 348
- Visceral epithelial cells, 900, 901f, 903b
- Visceral leishmaniasis, 393b-394b
- Vision, maintenance of normal, vitamin A in, 436-437
- Visual impairment, due to diabetes mellitus, 1120
- Vitamin A, 436-438
deficiency of, 437-438, 437f
forms of, 436-437
functions of, 436-437
metabolism of, 436f
sources of, 436
toxicity of, 438
- Vitamin B₁ deficiency, 419, 1233
CNS effects of, 1304
- Vitamin B₆ (pyridoxine), deficiency of, 1233
- Vitamin B₁₂
functions of, 647, 647f
metabolism of, 645-647, 646f
- Vitamin B₁₂ deficiency, 1233, 1304
- Vitamin B₁₂ deficiency anemia, 645-647, 645t, 646f, 647f
- Vitamin C, 442-443
deficiency states of, 442f, 443
function of, 443
- Vitamin D, 438-442
on calcium and phosphorus homeostasis, effects of, 439-440
deficiency states of, 440-441, 441b, 441f
functions of, 438
metabolism of, 438, 439f
nonskeletal effects of, 441-442
toxicity of, 442
- Vitamin D₃, 438
- Vitamin deficiencies, 435-443, 442t
primary malnutrition, 432
secondary malnutrition, 432
of vitamin A, 437-438
of vitamin C, 442-443
of vitamin D, 439f, 440-441, 443
- Vitamin E, deficiency of, 1233
- Vocal cords, 670
- Volume-overload hypertrophy, 527
- von Hippel-Lindau disease, 1317
- von Hippel-Lindau (VHL) gene, 299
- von Hippel-Lindau (VHL) syndrome, 1134t
in renal cell carcinoma, 953
- von Meyenburg complexes, 861, 861f
- von Recklinghausen disease of bone, 1102b-1103b, 1191b-1192b
- von Willebrand disease, 662, 665
- von Willebrand factor (vWF), 116, 118f, 660, 661f
- Vulva, 995-999, 999b
benign exophytic lesions of, 996-997
condyloma acuminatum, 997, 997f
extramammary Paget disease, 999, 999b, 1000f
glandular neoplastic lesions, 999
lichen sclerosus, 996, 996f
nonneoplastic epithelial disorders of, 996
papillary hidradenoma, 999, 999f
squamous cell hyperplasia, 996, 996f
squamous neoplastic lesions, 997-999
vulvar carcinoma, 997-999
vulvar intraepithelial neoplasia, 997-999, 998b, 998f
- Vulvar carcinoma, 997-999
- Vulvar intraepithelial neoplasia (VIN), 997-999, 998b, 998f
- vWF metalloprotease, in thrombotic microangiopathies, 660
- W**
- Waardenburg syndrome, 1184t
- WAGR syndrome, 445
- Waldenström macroglobulinemia, 598
- Wallerian degeneration, 1228

- Warburg effect, 282-283, 300-301
 Warm antibody type immunohemolytic anemia, 643, 643t
 Warthin-Finkeldey cells, 355b
 Warthin tumor, 745, 745b, 745f, 746f
 Water retention, edema due to, 114
 Water-soluble vitamins, 435-436, 442t
 Waterhouse-Friderichsen syndrome, 1129-1130, 1129f, 1130f, 1131b
 in septic shock, 133
 Wear-and-tear pigment, 64
 Weber-Christian disease, 1175
 Weber-Osler-Rendu syndrome, 657
 Wegener granulomatosis, 701-702
 Weibel-Palade bodies, in inflammation, 76
 Well-defined noninvasive precursor lesions, 892
 Well-differentiated liposarcoma, 1220b, 1221f
 Wen, 1152
 Wermer syndrome, 1136
 Werner syndrome, 66-67
 Wernicke encephalopathy, 1304, 1304b
 West Nile virus, 356-357
 Wheal, 1143t
 White cells
 disorders of, 582-622
 neoplasia, etiologic/pathogenetic factors in, 586-587, 587f
 neoplastic proliferations of, 586-622
 reactive proliferations of, 583-586
 Whole exome sequencing (WES), 182
 Whole genome sequencing (WGS), 182
 Wickham striae, 1167b
 Williams-Beuren syndrome, 538
 Wilms tumor, 479-481
 clinical features of, 481
 morphology of, 480b-481b, 481f
 pathogenesis and genetics of, 479-481
 Wilson disease, 849-850, 850b, 852b
 Wiskott-Aldrich syndrome, 242
 Wiskott-Aldrich syndrome protein (WASP), 242
 Wnt protein ligands, 18
 WNT signaling pathway, 1082
 APC in, 296-297, 297f
 Wood smoke, in indoor air pollution, 409
 Work-up, diagnostic, 711
 Workload
 decreased, 36
 increased, 34
 World Health Organization (WHO), criteria for the metabolic syndrome, 845t
 Wound healing, cutaneous
 and pathologic aspects of repair, 110b
 regeneration and repair in, 100-101
 Wound strength, 108-109
 Woven bone, 1180, 1180f, 1193
 WT1 tumor suppressor gene, 298

X
 X chromosome, 142
 Xanthogranulomatous pyelonephritis, 934b
 Xanthomas, 62
 Xenobiotics, 406, 408f
 Xenografts, 231-233
 Xeroderma pigmentosum, 314, 324-325, 1156t
 Xerophthalmia, 438
 Xerostomia, in Sjögren syndrome, 226
 X-inactivation, 164
 XIST, 164
 X-linked agammaglobulinemia, 240-241
 X-linked disorders, 142, 142t
 X-linked lymphoproliferative syndrome, 242, 312-313
 X-linked muscular dystrophy, with dystrophin mutation, 1242-1243
 X-linked severe combined immunodeficiency, 239

Y
 Y chromosome, 142
 Yeast, 386-388
Yersinia pestis, 370
 Yolk sac tumor
 ovarian, 1031
 testicular, 977-978, 977b

Z
 Zellballen, in pheochromocytoma, 1134b-1135b
 Zenker diverticulum, 753
 Zigzag, 1167
 Zinc, deficiency of, 1233
 Zollinger-Ellison syndrome, 769, 1121-1122, 1122b
 Zonule, 1320f
 Zoonotic infections, 345
 Zuska disease, 1046
 Zygomycosis, 389-390, 389b-390b

Smarter search. Faster answers.

Smarter, Faster Search for Better Patient Care

Unlike a conventional search engine, ClinicalKey is specifically designed to serve doctors by providing three core components:

1 Comprehensive Content

The most current, evidence-based answers available for every medical and surgical specialty.

2 Trusted Answers

Content supplied by Elsevier, the world's leading provider of health and science information.

3 Unrivalled Speed to Answer

Faster, more relevant clinical answers, so you can spend less time searching and more time caring for patients.

Start searching with ClinicalKey today!

Visit ClinicalKey.com for more information and subscription options.
