Preface: A New Chapter

As we launch the ninth edition of *Pathologic Basis of Disease* we look to the future of pathology as a discipline and how this textbook can remain most useful to readers in the twenty-first century. It is obvious that an understanding of disease mechanisms is based more than ever on a strong foundation of basic science. We have always woven the relevant basic cell and molecular biology into the sections on pathophysiology in various chapters. *In this edition we go one step further and introduce a new chapter at the very beginning of the book titled "The Cell as a Unit of Health and Disease."* In this chapter we have attempted to encapsulate aspects of cell and molecular biology that we believe are helpful in preparing readers for the more detailed discussions of specific diseases. We would like to remind readers that the last time a new chapter was added to this book was in 1967 when Stanley Robbins, at that time the sole author, decided to add a chapter on genetic diseases, one of many farsighted decisions by Dr. Robbins. We hope that the new chapter will be in keeping with his legacy.

In the preface of the very first edition (1957), Stanley Robbins wrote:

"The pathologist is interested not only in the recognition of structural alterations, but also in their significance, i.e., the effects of these changes on cellular and tissue function and ultimately the effect of these changes on the patient. It is not a discipline isolated from the living patient, but rather a basic approach to a better understanding of disease and therefore a foundation of sound clinical medicine."

We hope we continue to illustrate the principles of pathology that Dr. Robbins enunciated with such elegance and clarity over half a century ago.

This edition, like all previous ones, has been extensively revised, and some areas have been completely rewritten. A few examples of significant changes are as follows:

- A feature new to this edition is the introduction of Key Concepts boxes, scattered in each chapter to summarize "take home" messages relating to major topics covered in each disease or disease group.
 - **Chapter 2** has been updated to include novel pathways of cell death beyond the long-established pathways of necrosis and apoptosis. Indeed, the distinction between these two is being blurred. Autophagy, which has begun to take center stage in diseases ranging from aging to cancer and neurodegeneration, has been revised, as have the possible molecular mechanisms of aging.
 - **Chapter 3** now combines the discussion of inflammation with repair, since these two processes run concurrently and share common mediators.
 - **Chapter 5** includes a completely rewritten section on molecular diagnosis that reflects rapid advances in DNA sequencing technology.
 - **Chapter 7** has been extensively revised to incorporate knowledge and concepts of tumor biology gleaned from deep sequencing of cancers.
 - The ongoing revolution in "genomic medicine" has provided the impetus for extensive updates of many disease entities associated with newly described germline or somatic genetic alterations. Throughout, we have taken pains to try to only emphasize the lesions that are most common and most informative in terms of disease pathogenesis.
 - **Chapter 18**, covering diseases of the liver, has been reorganized and extensively revised to include discussion of the molecular basis of hepatic fibrosis and its regression.
 - **Chapter 27**, covering diseases of nerves and muscles, also has a fresh look. The diseases are now organized anatomically, starting from neurons and going to muscles, with diseases of neuromuscular junction bridging the two.
 - In addition to the revision and reorganization of the text, many new photographs and schematics have been added and a large number of the older "gems" have been enhanced by digital technology.
- Despite the changes highlighted above, our goals remain the same as those articulated by Robbins and Cotran over the past many years.
- To integrate into the discussion of pathologic processes and disorders the newest established information available—morphologic as well as molecular.
 - To organize information into logical and uniform presentations, facilitating readability, comprehension, and learning.
 - To maintain the book at a reasonable size and yet provide adequate discussion of the significant lesions, processes, and disorders. Indeed, despite the addition of a new 30-page chapter and Key Concepts, we have kept the overall length of the book unchanged. One of our most challenging tasks is to decide what to eliminate to make room for new findings.
 - To place great emphasis on clarity of writing and proper use of language in the recognition that struggling to comprehend is time-consuming and wearisome and gets in the way of the learning process.
 - To make this first and foremost a student text—used by students throughout all years of medical school and into their residencies—but, at the same time, to provide sufficient detail and depth to meet the needs of more advanced readers.

We have repeatedly been told by readers that up-to-datedness is a special feature that makes this book very valuable. We have strived to remain current by providing new information from the recent literature, some from 2014, the current year. We have removed the references from the text and aggregated the most useful review articles in our lists of suggested readings.

We are now into the digital age, and so the text will be available online to those who own the print version. Such access gives the reader the ability to search across the entire text, bookmark passages, add personal notes, use PubMed to view references, and exploit many other exciting features. In addition, also available online are case studies developed by one of us (VK) in collaboration with Herb Hagler, PhD, and Nancy Schneider, MD, PhD, at the University of Texas Southwestern Medical School in Dallas. The cases are designed to enhance and reinforce learning

by challenging students to apply their knowledge to solve clinical cases. To assist in the classroom, we have also made the images available for instructors on the Evolve website. Instructors may register at <https://evolve.elsevier.com/> to gain access to the images for teaching purposes.

All three of us have reviewed, critiqued, and edited each chapter to ensure the uniformity of style and flow that have been the hallmarks of the book. Together, we hope that we have succeeded in equipping the readers with the scientific basis for the practice of medicine and in whetting their appetite for learning beyond what can be offered in any textbook.

Vinay Kumar
Abul K. Abbas
Jon C. Aster

Acknowledgments

First and foremost we wish to express our respects and deep gratitude to the late Dr. Nelson Fausto for having been the coeditor of the last two editions of this book. Many of his words are retained in this edition and will continue to benefit future readers. He shall be greatly missed.

All three of us offer thanks to our contributing authors for their commitment to this textbook. Many are veterans of previous editions; others are new to the ninth edition. All are acknowledged in the table of contents. Their names lend authority to this book, for which we are grateful. As in previous editions, the three of us have chosen not to add our own names to the chapters we have been responsible for writing, in part or whole.

Many colleagues have enhanced the text by reading various chapters and providing helpful critiques in their area of expertise. They include Drs. Seungmin Hwang, Kay McLeod, Megan Mc Nerney, Ivan Moskovitz, Jeremy Segal, Humaira Syed, Helen Te, and Shu-Yuan Xiao at the University of Chicago; Marcus Peter at Northwestern University, Chicago; Dr. Meenakshi Jolly at Rush University, Chicago; Drs. Kimberley Evason, Kuang-Yu Jen, Richard Jordan, Marta Margeta, and Zoltan Laszik at the University of California, San Francisco; Dr. Antony Rosen at Johns Hopkins University; Dr. Lundy Braun at Brown University; Dr. Peter Byers at the University of Washington; Drs. Frank Bunn, Glenn Dranoff, and John Luckey at Harvard Medical School; Dr. Richard H. Aster at the Milwaukee Blood Center and Medical College of Wisconsin; and Dr. Richard C. Aster at Colorado State University. Special thanks are due to Dr. Raminder Kumar for updating clinical information and extensive proofreading of many chapters in addition to her role as consulting clinical editor for several chapters. Many colleagues provided photographic gems from their collections. They are individually acknowledged in the text.

Our administrative staff needs special mention since they maintain order in the chaotic lives of the authors and have willingly chipped in when needed for multiple tasks relating to the text. At the University of Chicago, they include Ms. Nhu Trinh and Ms. Garcia Wilson; at the University of California at San Francisco, Ms. Ana Narvaez; and at the Brigham and Women's Hospital, Muriel Goutas. All of the graphic art in this book was created by Mr. James Perkins, Professor of Medical Illustration at Rochester Institute of Technology. His ability to convert complex ideas into simple and aesthetically pleasing sketches has considerably enhanced this book.

Many individuals associated with our publisher, Elsevier (under the imprint of WB Saunders), need our special thanks. Outstanding among them is Jennifer Nemeč, Project Manager, and our partner in the production of this book. Her understanding of the needs of the authors, promptness in responding to requests (both reasonable and unreasonable), and cheerful demeanor went a long way in reducing our stress and making our lives less complicated. Mr. William (Bill) Schmitt, Publishing Director of Medical Textbooks, has always been our cheerleader and is now a dear friend. Our thanks also go to Managing Editor Rebecca Gruliow and Design Manager Lou Forgione at Elsevier. Undoubtedly there are many others who may have been left out unwittingly—to them we say “thank you” and tender apologies for not acknowledging you individually.

Efforts of this magnitude take a toll on the families of the authors. We thank our spouses, Raminder Kumar, Ann Abbas, and Erin Malone for their patience, love, and support of this venture, and for their tolerance of our absences.

Pathology literally translates to the study of *suffering* (Greek *pathos* = suffering, *logos* = study); more prosaically, the term *pathology* is invoked to represent the study of *disease*. Germane to this opening chapter, Virchow coined the term *cellular pathology* to emphasize the basic tenet that all diseases originate at the cellular level. Thus, modern pathology is basically the study of *cellular* abnormalities. Therefore, diseases and the underlying mechanisms are best understood in the context of *normal* cellular structure and function.

It is unrealistic (and even undesirable) to condense the vast and fascinating field of cell biology into a single chapter. Moreover, students of biology are likely quite familiar with many of the broader concepts of cell structure and function. Consequently, rather than attempting a comprehensive review, our goal is to survey some basic principles and highlight some recent advances that are relevant to the pathologic basis of disease that is emphasized throughout the text. We hope this chapter will be useful to review key topics in normal cell biology as they apply to the areas of Pathology that are covered from [Chapter 2](#) onwards.

The Genome

The sequencing of the human genome represented a landmark achievement of biomedical science. Published in draft form in 2001 and more completely detailed in 2003, the information has already led to remarkable advances in science and medicine. Since then there has been an

exponential decrease in the cost of sequencing and an exponential increase in data accrual; this new information, now literally at our fingertips, promises to revolutionize our understanding of health and disease. However, the sheer volume of the data is formidable, and there is a dawning realization that we have only begun to scratch the surface of its complexity; uncovering the relevance to disease and then developing new therapies remain challenges that both excite and inspire scientists and the lay public alike.

Noncoding DNA

The human genome contains roughly 3.2 billion DNA base pairs. Within the genome there are about 20,000 protein-encoding genes, comprising only about 1.5% of the genome. These proteins variously function as enzymes, structural components, and signaling molecules and are used to assemble and maintain all of the cells in the body. Although 20,000 is an underestimation of the number of proteins encoded in the human genome (given that many genes produce multiple RNA transcripts encoding different protein isoforms), it is nevertheless startling to realize that worms composed of fewer than 1000 cells— with genomes of only about 0.1 billion DNA base pairs— are also assembled using about 20,000 genes to produce proteins. Even more surprising is that many of these proteins are recognizable homologs of molecules expressed in humans. What then separates humans from worms?

The answer is not completely known, but the weight of current evidence suggests that much of the difference

Figure 1-1 The organization of nuclear DNA. At the light microscopic level, the nuclear genetic material is organized into dispersed, transcriptionally active *euchromatin* or densely packed, transcriptionally inactive *heterochromatin*; chromatin can also be mechanically connected with the nuclear membrane, and nuclear membrane perturbation can thus influence transcription. Chromosomes (as shown) can only be visualized by light microscopy during cell division. During mitosis, they are organized into paired chromatids connected at *centromeres*; the centromeres act as the locus for the formation of a *kinetochore* protein complex that regulates chromosome segregation at metaphase. The *telomeres* are repetitive nucleotide sequences that cap the termini of chromatids and permit repeated chromosomal replication without loss of DNA at the chromosome ends. The chromatids are organized into short “P” (“*petite*”) and long “Q” (“*next letter in the alphabet*”) arms. The characteristic banding pattern of chromatids has been attributed to relative GC content (less GC content in bands relative to interbands), with genes tending to localize to interband regions. Individual chromatin fibers are comprised of a string of nucleosomes—DNA wound around octameric histone cores—with the nucleosomes connected via DNA linkers. Promoters are noncoding regions of DNA that initiate gene transcription; they are on the same strand and upstream of their associated gene. Enhancers are regulatory elements that can modulate gene expression over distances of 100 kB or more by looping back onto promoters and recruiting additional factors that are needed to drive the expression of pre-mRNA species. The intronic sequences are subsequently spliced out of the pre-mRNA to produce the definitive message that is translated into protein—without the 3′- and 5′-untranslated regions (UTR). In addition to the enhancer, promoter, and UTR sequences, noncoding elements are found throughout the genome; these include short repeats, regulatory factor binding regions, noncoding regulatory RNAs, and transposons.

lies in the 98.5% of the human genome that does not encode proteins. It has been known for some time that protein-coding genes in higher organisms are separated by long stretches of DNA whose function has been obscure for many years—sometime denoted as “dark matter” of the genome. That viewpoint has subsequently been modified, driven by the multinational ENCODE (Encyclopedia of DNA Elements) project that set out in 2007 to identify all regions of the genome that could be ascribed some function. The striking conclusion is that as much as **80% of the human genome either binds proteins, implying it is involved in regulating gene expression, or can be assigned some functional activity, mostly related to the regulation of gene expression, often in a cell-type specific fashion.** It follows that while proteins provide the building blocks and machinery required for assembling cells, tissues and organisms, it is the noncoding regions of the genome that provide the critical “architectural planning.” Practically stated, the difference between worms and humans apparently lies more in the genomic “blueprints” than in the construction materials.

The major classes of functional non-protein-coding sequences found in the human genome are the following (Fig. 1-1):

- *Promoter* and *enhancer* regions that provide binding sites for transcription factors
- Binding sites for factors that organize and maintain higher order *chromatin structures*
- *Noncoding regulatory RNAs*. More than 60% of the genome is transcribed into RNAs that are never translated into protein, but which nevertheless can regulate gene expression through a variety of mechanisms. The two best-studied varieties—micro-RNAs and long non-coding RNAs—are described later.
- *Mobile genetic elements* (e.g., *transposons*). Remarkably, more than one third of the human genome is composed of these elements, popularly denoted as “jumping genes.” These segments can move around the genome, exhibiting wide variation in number and positioning even amongst closely related species (i.e., humans and other primates). They are implicated in gene regulation and chromatin organization, but their function is still not well established.
- Special structural regions of DNA, in particular *telomeres* (chromosome ends) and *centromeres* (chromosome “tethers”)

One of the reasons these findings have generated so much interest is that many, and perhaps most, of the genetic variations (*polymorphisms*) associated with diseases are located in non-protein-coding regions of the genome. Thus, variation in gene regulation may prove to be more important in disease causation than structural changes in specific proteins.

Another surprising revelation from the recent genomic studies is that, on average, any two individuals share greater than 99.5% of their DNA sequences. It is perhaps more remarkable that we are 99% identical with chimpanzees! Thus, person-to-person variation, including differential susceptibility to diseases and in response to environmental agents and drugs, is encoded in less than 0.5% of our DNA. Though small when compared to the total nucleotide sequences, this 0.5% represents about 15 million base pairs. **The two most common forms of DNA variation in the human genome are single-nucleotide polymorphisms (SNPs) and copy number variations (CNVs).** SNPs are variants at single nucleotide positions and are almost always biallelic (i.e., only two choices exist at a given site within the population, such as A or T). Much effort has been devoted to mapping common SNPs in human populations. Over 6 million human SNPs have been identified, many of which show wide variation in frequency in different populations. SNPs occur across the genome—within exons, introns, intergenic regions, and coding regions. Overall, about 1% of SNPs occur in coding regions, which is about what would be expected by chance, since coding regions comprise about 1.5% of the genome. SNPs located in non-coding regions may fall in regulatory elements in the genome, thereby altering gene expression; in such instances the SNP may have a direct influence on disease susceptibility. In other instances, the SNP may be a “neutral” variant that has no effect on gene function or carrier phenotype. However, even “neutral” SNPs may be useful markers if they happen to be co-inherited with a disease-associated gene as a result of physical proximity. In other words, the SNP and the causative genetic factor are in *linkage disequilibrium*. There is hope that groups of SNPs may serve as markers of risk for multigenic complex diseases such as type II diabetes and hypertension. However, the effect of most SNPs on disease susceptibility is weak, and it remains to be seen if identification of such variants, alone or in combination, can be used to develop effective strategies for disease prevention.

CNVs are a more recently identified form of genetic variation consisting of different numbers of large contiguous stretches of DNA from 1000 base pairs to millions of base pairs. In some instances these loci are, like SNPs, biallelic and simply duplicated or deleted in a subset of the population. In other instances there are complex rearrangements of genomic material, with multiple alleles in the human population. Current estimates are that CNVs are responsible for between 5 and 24 million base pairs of sequence difference between any two individuals. Approximately 50% of CNVs involve gene-coding sequences; thus, CNVs may underlie a large portion of human phenotypic diversity. We currently know much less about CNVs than SNPs, therefore their influence on disease susceptibility is less established.

It should be pointed out that despite all these advances in the understanding of human genetic variation, it is clear that alterations in DNA sequence cannot by themselves explain the diversity of phenotypes in human populations. Nor can classic genetics explain how monozygotic twins can have differing phenotypes. The answer may lie in *epigenetics*, which is defined as heritable changes in gene expression that are not caused by alterations in DNA sequence. The molecular basis of epigenetic changes will be discussed next.

Histone Organization

Even though virtually all cells in the body contain the same genetic material, terminally differentiated cells have distinct structures and functions. Clearly, different cell types are distinguished by lineage-specific programs of gene expression. Such cell type-specific differences in DNA transcription and translation depend on *epigenetic factors* (literally, factors that are “above genetics”) that can be conceptualized as follows (Fig. 1-2):

- *Histones and histone modifying factors.* Nucleosomes consist of DNA segments 147 base pairs long that are wrapped around a central core structure of highly conserved low molecular weight proteins called *histones*. The resulting DNA-histone complex resembles a series of beads joined by short DNA linkers and is generically called *chromatin*. The naked DNA of a human cell is about 1.8 meters long, but wound around histones like spools, DNA can be packed into a nucleus as small as 7 to 8 micrometers in diameter—the width of a resting lymphocyte. In most cases, DNA is not *uniformly* and compactly wound. Thus, at the light microscopic level, nuclear chromatin exists in two basic forms: (1) cytochemically dense and transcriptionally inactive *heterochromatin* and (2) cytochemically dispersed and transcriptionally active *euchromatin* (Fig. 1-1). Moreover, which portion of the nuclear chromatin is “unwound” regulates gene expression and thereby dictates cellular identity and activity.

Histones are not static, but rather are highly dynamic structures regulated by a host of nuclear proteins and chemical modifications. Thus, *chromatin remodeling complexes* can reposition nucleosomes on DNA, exposing (or obscuring) gene regulatory elements such as promoters. “*Chromatin writer*” complexes, on the other hand, carry out more than 70 different histone modifications generically denoted as *marks*. Such covalent alterations include methylation, acetylation, or phosphorylation of specific amino acid residues on the histones.

Actively transcribed genes in euchromatin are associated with histone marks that make the DNA accessible to RNA polymerases. In contrast, inactive genes have histone marks that enable DNA compaction into heterochromatin. Histone marks are reversible through the activity of “*chromatin erasers*.” Still other proteins function as “*chromatin readers*,” binding histones that bear particular marks and thereby regulating gene expression.

- *Histone methylation.* Both lysines and arginines can be methylated by specific writer enzymes; in particular, methylation of lysine residues in histones may be associated with either transcriptional activation or repression, depending on the histone residue that is “marked”.
- *Histone acetylation.* Lysine residues are acetylated by histone acetyl transferases (HAT), whose modifications tend to open up the chromatin and increase transcription. In turn, these changes can be reversed by histone deacetylases (HDAC), leading to chromatin condensation.
- *Histone phosphorylation.* Serine residues can be modified by phosphorylation; depending on the specific residue,

Figure 1-2 Histone organization. **A**, Nucleosomes are comprised of octamers of histone proteins (two each of histone subunits H2A, H2B, H3, and H4) encircled by 1.8 loops of 147 base pairs of DNA; histone H1 sits on the 20-80 nucleotide linker DNA between nucleosomes and helps stabilize the overall chromatin architecture. The histone subunits are positively charged, thus allowing the compaction of the negatively charged DNA. **B**, The relative state of DNA unwinding (and thus access for transcription factors) is regulated by histone modification, for example, by acetylation, methylation, and/or phosphorylation (so-called “marks”); marks are dynamically written and erased. Certain marks such as histone acetylation “open up” the chromatin structure, whereas others, such as methylation of particular histone residues, tends to condense the DNA and leads to gene silencing. DNA itself can also be methylated, a modification that is associated with transcriptional inactivation.

the DNA may be opened up for transcription or condensed to become inactive.

- **DNA methylation.** High levels of DNA methylation in gene regulatory elements typically result in transcriptional silencing. Like histone modifications, DNA methylation is tightly regulated by methyltransferases, demethylating enzymes, and methylated-DNA-binding proteins.
- **Chromatin organizing factors.** Much less is known about these proteins, which are believed to bind to noncoding regions and control long-range looping of DNA, which is important in regulating the spatial relationships between gene enhancers and promoters that control gene expression.

Deciphering the mechanisms that allow epigenetic factors to control genomic organization and gene expression in a cell-type-specific fashion is an extraordinarily complex proposition. Despite the intricacies, there is already ample evidence that dysregulation of the “epigenome” has a central role in malignancy (Chapter 7), and there is growing evidence that many other diseases are

associated with inherited or acquired epigenetic alterations. Another reason for excitement is that—unlike genetic changes—many epigenetic alterations (e.g., histone acetylation and DNA methylation) are reversible and are amenable to therapeutic intervention; thus, HDAC inhibitors and DNA methylation inhibitors are already being tested in the treatment of various forms of cancer.

Micro-RNA and Long Noncoding RNA

Another mechanism of gene regulation depends on the functions of noncoding RNAs. As the name implies, these are encoded by genes that are transcribed but not translated. Although many distinct families of noncoding RNAs exist, we will only discuss two examples here: small RNA molecules called *microRNAs*, and *long noncoding RNAs* >200 nucleotides in length.

Micro-RNA (miRNA)

The miRNAs do not encode proteins; instead, they function primarily to modulate the translation of target mRNAs into their corresponding proteins. **Posttranscriptional**

silencing of gene expression by miRNA is a fundamental and well-conserved mechanism of gene regulation present in all eukaryotes (plants and animals). Even microorganisms have a more primitive version of the same general machinery that they can use to protect themselves against foreign DNA (e.g., from phages and viruses). Because of the profound influence of miRNAs on gene regulation, these relatively short RNAs (22 nucleotides on average) have assumed central importance in the illumination of both normal developmental pathways, as well as pathologic conditions like cancer. Indeed, the Nobel Prize in Physiology or Medicine in 2006 was awarded for the discovery of miRNAs.

By current estimates, the human genome encodes approximately 1000 miRNA genes, some 20-fold less than the number of protein-coding genes. However, individual miRNAs appear to regulate multiple protein-coding genes, allowing each miRNA to co-regulate entire programs of gene expression. Transcription of miRNA genes produces a primary miRNA, which is progressively processed through various steps including trimming by the enzyme *DICER*. This generates mature single-stranded miRNAs of 21 to 30 nucleotides that are associated with a multiprotein aggregate called RNA-induced silencing complex (RISC; Fig. 1-3). Subsequent base pairing between the miRNA strand and its target mRNA directs the RISC to either induce mRNA cleavage or repress its translation. All mRNAs contain a so-called *seed sequence* in their 3' untranslated region (UTR) that determines the specificity of miRNA binding and gene silencing. In this way, the target mRNA is *posttranscriptionally silenced*.

Small interfering RNAs (siRNAs) are short RNA sequences that can be introduced experimentally into cells. These serve as substrates for Dicer and interact with the RISC complex in a manner analogous to endogenous miRNAs. Synthetic siRNAs targeted against specific mRNA species have become useful laboratory tools to study gene function (so-called *knockdown* technology); they are also being developed as possible therapeutic agents to silence pathogenic genes, such as oncogenes involved in neoplastic transformation.

Long Noncoding RNA (lncRNA)

Recent studies have further identified an untapped universe of lncRNAs—by some calculations, the number of lncRNAs may exceed coding mRNAs by 10- to 20-fold. **lncRNAs modulate gene expression in many ways** (Fig. 1-4); for example, they can bind to regions of chromatin, restricting RNA polymerase access to coding genes within the region. The best known example of a repressive function involves XIST, which is transcribed from the X chromosome and plays an essential role in physiologic X chromosome inactivation. XIST itself escapes X inactivation, but forms a repressive “cloak” on the X chromosome from which it is transcribed, resulting in gene silencing. Conversely, it has recently been appreciated that many enhancers are sites of lncRNA synthesis, and these lncRNAs appear to often increase transcription from gene promoters through a variety of mechanisms (Fig. 1-4). Emerging studies are exploring the roles of lncRNAs in various human diseases, from atherosclerosis to cancer.

Figure 1-3 Generation of microRNAs (miRNA) and their mode of action in regulating gene function. miRNA genes are transcribed to produce a primary miRNA (*pri-miRNA*), which is processed within the nucleus to form *pre-miRNA* composed of a single RNA strand with secondary hairpin loop structures that form stretches of double-stranded RNA. After this *pre-miRNA* is exported out of the nucleus via specific transporter proteins, the cytoplasmic *Dicer* enzyme trims the *pre-miRNA* to generate mature double-stranded miRNAs of 21 to 30 nucleotides. The miRNA subsequently unwinds, and the resulting single strands are incorporated into the multiprotein *RNA-induced silencing complex (RISC)*. Base pairing between the single-stranded miRNA and its target mRNA directs RISC to either cleave the mRNA target or repress its translation. In either case, the target mRNA gene is silenced posttranscriptionally.

Figure 1-4 Roles of long noncoding RNAs. **A**, Long non-coding RNAs (lncRNAs) can facilitate transcription factor binding and thus promote gene activation. **B**, Conversely, lncRNAs can preemptively bind transcription factors and thus prevent gene transcription. **C**, Histone and DNA modification by acetylases or methylases (or deacetylases and demethylases) may be directed by the binding of lncRNAs. **D**, In other instances, lncRNAs may act as scaffolding to stabilize secondary or tertiary structures and/or multi-subunit complexes that influence general chromatin architecture or gene activity. (Adapted from Wang KC, Chang HY: Molecular mechanisms of long noncoding RNAs. *Mol Cell* 43:904, 2011.)

Cellular Housekeeping

The viability and normal activity of cells depend on a variety of fundamental housekeeping functions that all differentiated cells must perform. These functions include *protection from the environment, nutrient acquisition, communication, movement, renewal of senescent molecules, molecular catabolism, and energy generation.*

Many normal housekeeping functions are compartmentalized within membrane-bound intracellular organelles (Fig. 1-5). By isolating certain cellular functions within distinct compartments, functionally important, potentially injurious degradative enzymes or reactive metabolites can be concentrated or stored at high concentrations in specific organelles without risking damage to other cellular constituents. Moreover, compartmentalization allows the creation of unique intracellular environments (e.g., low pH or

high calcium) that may then selectively regulate the function of enzymes or metabolic pathways.

New proteins destined for the plasma membrane or points beyond are synthesized in the *rough endoplasmic reticulum (RER)* and physically assembled in the *Golgi apparatus*; proteins intended for the cytosol are synthesized on free ribosomes. *Smooth endoplasmic reticulum (SER)* may be abundant in certain cell types such as gonads and liver where it is used for steroid hormone and lipoprotein synthesis, as well as for the modification of hydrophobic compounds (for example, drugs) into water-soluble molecules for export.

Proteins and organelles must also be broken down if they become damaged, as must proteins and other molecules that are taken up into the cell by endocytosis. Catabolism of these constituents takes place at three different sites and serves different functions. *Lysosomes* are intracellular organelles that contain degradative enzymes that permit the digestion of a wide-range of macromolecules, including proteins, polysaccharides, lipids, and nucleic acids. *Proteasomes*, on the other hand are a specialized type of “grinder” that selectively chews up denatured proteins, releasing peptides. In some cases the peptides so generated can be presented in the context of class I major histocompatibility molecules (Chapter 6). In other cases signaling molecules trigger the proteasomal degradation of negative regulatory proteins, leading to activation of pathways that alter transcription. These are described in more detail later in the chapter. *Peroxisomes* play a specialized role in the breakdown of fatty acids, generating hydrogen peroxide in this process.

The contents and position of cellular organelles are also subject to regulation. *Endosomal vesicles* shuttle internalized material to the appropriate intracellular sites or direct newly synthesized materials to the cell surface or targeted organelle. Cell movement—both organelles and proteins *within* the cell, as well as movement of the cell in its environment—is accomplished through the *cytoskeleton*. These structural proteins also maintain basic cellular shape and intracellular organization, requisites for maintaining *cell polarity*. This is particularly critical in epithelium, in which the top of the cell (*apical*) and the bottom and side of the cell (*basolateral*) are often exposed to different environments and have distinct functions. Most of the ATP that powers cells is made through oxidative phosphorylation in the *mitochondria*. However, mitochondria also serve as an important source of metabolic intermediates that are needed for anabolic metabolism; they are sites of synthesis of certain macromolecules (e.g., heme), and contain important sensors of cell damage that can initiate and regulate the process of programmed cell death.

Cell growth and maintenance require a constant supply of both energy and the building blocks that are needed for synthesis of macromolecules. In growing and dividing cells, all of these organelles have to be replicated (*organellar biogenesis*) and correctly apportioned in daughter cells following mitosis. Moreover, because the macromolecules and organelles have finite lifespans (mitochondria, for example, last only about 10 days), mechanisms must also exist that allow for the recognition and degradation of “worn out” cellular components.

With this as a primer, we now move on to discuss cellular components and their function in greater detail.

Relative volumes of intracellular organelles (hepatocyte)

Compartment	% total volume	number/cell	role in the cell
Cytosol	54%	1	metabolism, transport, protein translation
Mitochondria	22%	1700	energy generation, apoptosis
Rough ER	9%	1*	synthesis of membrane and secreted proteins
Smooth ER, Golgi	6%	1*	protein modification, sorting, catabolism
Nucleus	6%	1	cell regulation, proliferation, DNA transcription
Endosomes	1%	200	intracellular transport and export, ingestion of extracellular substances
Lysosomes	1%	300	cellular catabolism
Peroxisomes	1%	400	very long-chain fatty acid metabolism

Figure 1-5 Basic subcellular constituents of cells. The table presents the number of the various organelles within a typical hepatocyte, as well as their volume within the cell. The figure shows geographic relationships but is not intended to be accurate to scale. (Adapted from Weibel ER, Stäubli W, Gnäggi HR, et al: Correlated morphometric and biochemical studies on the liver cell. I. Morphometric model, stereologic methods, and normal morphometric data for rat liver. *J Cell Biol* 42:68, 1969.)

Plasma Membrane: Protection and Nutrient Acquisition

Plasma membranes (and all other organellar membranes) are more than just static lipid sheaths. Rather, they are fluid bilayers of amphipathic phospholipids with hydrophilic head groups that face the aqueous environment and hydrophobic lipid tails that interact with each other to form a barrier to passive diffusion of large or charged molecules (Fig. 1-6). The bilayer is composed of a heterogeneous collection of different phospholipids, which are distributed asymmetrically—for example, certain membrane lipids preferentially associate with extracellular or cytosolic faces. Proper organization of phospholipids is important for cell health, as specific phospholipids interact with particular membrane proteins, influencing their distribution and function. In addition, asymmetric partitioning of phospholipids is important in several other cellular processes, as follows:

- *Phosphatidylinositol* on the inner membrane leaflet can be phosphorylated, serving as an electrostatic scaffold for intracellular proteins; alternatively, polyphosphoinositides can be hydrolyzed by phospholipase C to generate intracellular second signals like diacylglycerol and inositol trisphosphate.
- *Phosphatidylserine* is normally restricted to the inner face where it confers a negative charge involved in electrostatic protein interactions; however, when it flips to the extracellular face, which happens in cells undergoing apoptosis (programmed cell death), it becomes an “eat me” signal for phagocytes. In the special case of platelets, it serves as a cofactor in the clotting of blood.
- *Glycolipids* and *sphingomyelin* are preferentially expressed on the extracellular face; glycolipids (and particularly gangliosides, with complex sugar linkages and terminal sialic acids that confer negative charges) are important in cell-cell and cell-matrix interactions,

Figure 1-6 Plasma membrane organization and asymmetry. The plasma membrane is a bilayer of phospholipids, cholesterol, and associated proteins. The phospholipid distribution within the membrane is asymmetric due to the activity of *flippases*; *phosphatidylcholine* and *sphingomyelin* are overrepresented in the outer leaflet, and *phosphatidylserine* (negative charge) and *phosphatidylethanolamine* are predominantly found on the inner leaflet; glycolipids occur only on the outer face where they contribute to the extracellular glycocalyx. Although the membrane is laterally fluid and the various constituents can diffuse randomly, specific domains—*lipid rafts*—can also stably develop. Membrane-associated proteins may traverse the membrane (singly or multiply) via α -helical hydrophobic amino acid sequences; depending on the membrane lipid content and the hydrophobicity of protein domains, such proteins may have non-random distributions within the membrane. Proteins on the cytosolic face may associate with membranes through post-translational modifications, e.g., farnesylation, or addition of palmitic acid. Proteins on the extracytoplasmic face may associate with the membrane via glycosyl phosphatidyl inositol linkages. Besides protein-protein interactions within the membrane, membrane proteins can also associate with extracellular and/or intracytoplasmic proteins to generate large, relatively stable complexes (e.g., the *focal adhesion complex*). Transmembrane proteins can translate mechanical forces (e.g., from the cytoskeleton or extracellular matrix) as well as chemical signals across the membrane. It is worth remembering that a similar organization of lipids and associated proteins also occurs within the various organellar membranes.

including inflammatory cell recruitment and sperm-egg interactions.

Moreover, certain membrane components have a predilection for association through horizontal interactions in the bilayer, which leads to the creation of distinct lipid domains known as “*lipid rafts*.” Since inserted membrane proteins have different intrinsic solubilities in various lipid domains, they tend to accumulate in certain regions of the membrane and to become depleted from others. As might be imagined the nonrandom distribution of lipids and membrane proteins has important effects on cell-cell and cell-matrix interactions, as well as in intracellular signaling and the generation of specialized membrane regions involved in secretory or endocytic pathways.

The plasma membrane is liberally studded with a variety of proteins and glycoproteins involved in (1) ion and metabolite transport, (2) fluid-phase and receptor-mediated uptake of macromolecules, and (3) cell-ligand, cell-matrix, and cell-cell interactions. Proteins associate with the lipid bilayer by one of four general arrangements; how they integrate into the membrane informs function.

- Most proteins are integral or transmembrane proteins, having one or more relatively hydrophobic α -helical segments that traverse the lipid bilayer. Integral membrane proteins typically contain positively charged amino acids in their cytoplasmic domains, which anchor the proteins to the negatively charged head groups of membrane phospholipids.

- Proteins may be synthesized in the cytosol and post-translationally attached to prenyl groups (e.g., farnesyl, related to cholesterol) or fatty acids (e.g., palmitic or myristic acid), that insert into the cytosolic side of the plasma membrane.
- Insertion into the membrane may occur through glycosylphosphatidylinositol (GPI) anchors on the extracellular face of the membrane.
- Peripheral membrane proteins may noncovalently associate with true transmembrane proteins.

Many plasma membrane proteins function together as large complexes; these may either be aggregated under the control of chaperone molecules in the RER or by lateral diffusion in the plasma membrane followed by complex formation *in situ*. The latter mechanism is characteristic of many protein receptors (e.g., cytokine receptors) that dimerize or trimerize in the presence of ligand to form functional signaling units. Although lipid bilayers are fluid in the two-dimensional plane of the membrane, membrane components can also be confined to discrete domains. This may be achieved through localization to lipid rafts, already discussed, or through intercellular protein-protein interactions (e.g., at *tight junctions*) that establish discrete boundaries; indeed, this strategy is used to maintain *cell polarity* (e.g., top/apical vs bottom/basolateral) in epithelial layers. Alternatively, unique membrane domains can be generated by the interaction of proteins with cytoskeletal molecules or extracellular matrix.

The extracellular face of the plasma membrane is diffusely studded with carbohydrates, not only as complex oligosaccharides on glycoproteins and glycolipids, but also as polysaccharide chains attached to integral membrane proteoglycans. This *glycocalyx* functions as a chemical and mechanical barrier, and is also involved in *cell-cell* and *cell-matrix interactions*.

Passive Membrane Diffusion. Small, nonpolar molecules like O₂ and CO₂ readily dissolve in lipid bilayers and therefore rapidly diffuse across them; in addition, hydrophobic molecules (e.g., steroid-based molecules like estradiol or vitamin D) also cross lipid bilayers with relative impunity. Similarly, polar molecules smaller than 75 daltons in mass readily cross membranes (e.g., water, ethanol, and urea). However, in tissues where water is transported in large volumes (e.g., renal tubular epithelium), special integral membrane proteins called *aquaporins* augment passive water transport. In contrast, the lipid bilayer is an effective barrier to the passage of polar molecules of greater than 75 daltons in mass, even those that are only slightly larger, such as glucose. Lipid bilayers are also impermeant to ions, no matter how small, due to their charge and high degree of hydration. We will discuss next specialized mechanisms that regulate traffic across plasma membranes.

Carriers and Channels. For each of the larger polar molecules that must cross membranes to support normal cellular functions (e.g., for nutrient uptake and waste disposal), a unique plasma membrane protein is typically required. For low molecular weight species (ions and small molecules up to approximately 1000 daltons), *channel proteins* and *carrier proteins* may be used (although this discussion focuses on plasma membranes, it should be noted that similar pores and channels are needed for transport across organellar membranes). Each transported molecule (e.g., ion, sugar, nucleotide) requires a transporter, which are often highly specific for a select molecule in each class (e.g., glucose but not galactose):

- *Channel proteins* create hydrophilic pores, which, when open, permit rapid movement of solutes (usually restricted by size and charge, Fig. 1-7).
- *Carrier proteins* bind their specific solute and undergo a series of conformational changes to transfer the ligand across the membrane; their transport is relatively slow.

In most cases, a concentration and/or electrical gradient between the inside and outside of the cell drives solute movement via *passive transport* (virtually all plasma membranes have an electrical potential difference across them, with the inside negative relative to the outside). In some cases, *active transport* of certain solutes *against* a concentration gradient is accomplished by carrier molecules (not channels) using energy released by ATP hydrolysis or a coupled ion gradient. Transporter ATPases also include the infamous *multidrug resistance (MDR) protein*, which pumps polar compounds (e.g., chemotherapeutic drugs) out of cells and may render cancer cells resistant to treatment.

Because plasma membranes are freely permeable to water, it moves into and out of cells by osmosis, depending on relative solute concentrations. Thus, extracellular salt in

excess of that in the cytosol (*hypertonicity*) causes a net movement of water out of cells, while *hypotonicity* causes a net movement of water into cells. Since the cytosol is rich in charged metabolites and protein species that attract a large number of counterions that tend to increase the intracellular osmolarity, cells need to constantly pump out small inorganic ions (e.g., Na⁺ and Cl⁻), typically through the activity of the membrane sodium-potassium ATPase, lest they become overhydrated. Loss of the ability to generate energy (e.g., in a cell injured by toxins or ischemia) therefore results in osmotic swelling and eventual rupture of cells. Similar transport mechanisms also regulate intracellular and intraorganellar pH; most cytosolic enzymes prefer to work at pH 7.4 whereas lysosomal enzymes function best at pH 5 or less.

Receptor-mediated and fluid-phase uptake (Fig. 1-7). Uptake of fluids or macromolecules by the cell, called *endocytosis*, occurs by two fundamental mechanisms. Certain small molecules—including some vitamins—are taken up by invaginations of the plasma membrane called *caveolae*. For bigger molecules, uptake occurs after binding to specific cell-surface receptors; internalization occurs through a membrane invagination process driven by an intracellular coat of *clathrin* proteins. Clathrin is a hexamer of proteins that spontaneously assembles into a basket-like lattice to drive the invagination process. We shall come back to these later.

The process by which large molecules are exported from cells is called *exocytosis*; In this process, proteins synthesized and packaged within the RER and Golgi apparatus are concentrated in secretory vesicles, which then fuse with the plasma membrane and expel their contents.

Transcytosis is the movement of endocytosed vesicles between the apical and basolateral compartments of cells; this is a mechanism for transferring large amounts of intact proteins across epithelial barriers (e.g., ingested antibodies in maternal milk across intestinal epithelia) or for the rapid movement of large volumes of solute. In fact, increased transcytosis probably plays a role in the increased vascular wall permeability seen in healing wounds and in tumors.

We now return to the two forms of endocytosis mentioned earlier

- *Caveolae-mediated endocytosis.* Caveolae (“little caves”) are *noncoated* plasma membrane invaginations associated with GPI-linked molecules, cyclic adenosine monophosphate (cAMP) binding proteins, SRC-family kinases, and the folate receptor. Caveolin is the major structural protein of caveole. Internalization of caveolae with any bound molecules and associated extracellular fluid is sometimes called *potocytosis*—literally “cellular sipping.” Although caveolae likely participate in the transmembrane delivery of some molecules (e.g., folate), they are increasingly implicated in the regulation of transmembrane signaling and/or cellular adhesion via the internalization of receptors and integrins.
- *Pinocytosis and receptor-mediated endocytosis* (Fig. 1-7). *Pinocytosis* (“cellular drinking”) describes a fluid-phase process during which the plasma membrane invaginates and is pinched off to form a cytoplasmic vesicle. Endocytosed vesicles may recycle back to the plasma

Figure 1-7 Movement of small molecules and larger structures across membranes. The lipid bilayer is relatively impermeable to all but the smallest and/or most hydrophobic molecules. Thus, the import or export of charged species requires specific transmembrane transporter proteins; the internalization or externalization of large proteins, complex particles, or even cells requires encircling them with segments of the membrane.

Small charged solutes can move across the membrane using either channels or carriers; in general, each molecule requires a unique transporter. *Channels* are used when concentration gradients can drive the solute movement. *Carriers* are required when solute is moved *against* a concentration gradient.

Receptor-mediated and fluid-phase uptake of material involves membrane bound vacuoles. *Caveolae* endocytose extracellular fluid, membrane proteins, and some receptor bound molecules (e.g., folate) in a process driven by caveolin proteins concentrated within lipid rafts (*potocytosis*). *Pinocytosis* of extracellular fluid and most surface receptor-ligand pairs involves *clathrin-coated pits and vesicles*. After internalization, the clathrin dissociates and can be re-used, while the resulting vesicle progressively matures and acidifies. In the early and/or late endosome, ligand can be released from its receptor (e.g., iron released from transferrin bound to the transferrin receptor) with receptor recycling to the cell surface for another round. Alternatively, receptor and ligand within endosomes can be targeted to fuse with lysosomes (e.g., epidermal growth factor bound to its receptor); after complete degradation, the late endosome-lysosome fusion vesicle can regenerate lysosomes. *Phagocytosis* involves the non-clathrin-mediated membrane invagination of large particles—typically by specialized phagocytes (e.g., macrophages or neutrophils). The resulting phagosomes eventually fuse with lysosomes to facilitate the degradation of the internalized material. *Transcytosis* involves the transcellular endocytotic transport of solute and/or bound ligand from one face of a cell to another. *Exocytosis* is the process by which membrane-bound vesicles fuse with the plasma membrane and discharge their contents to the extracellular space.

membrane (*exocytosis*) for another round of ingestion. Endocytosis and exocytosis must be tightly coupled since a cell will typically pinocytose 10% to 20% of its own cell volume each hour, or about 1% to 2% of its plasma membrane each minute. Pinocytosis and receptor-mediated endocytosis begin at a specialized region of the plasma membrane called the *clathrin-coated pit*, which rapidly invaginates and pinches off to form a *clathrin-coated vesicle*; trapped within the vesicle is a gulp of the extracellular milieu and in some cases receptor bound macromolecules described below. The vesicles then rapidly uncoat and fuse with an acidic intracellular structure called the *early endosome* where they discharge their contents for digestion and further passage to the lysosome.

Receptor-mediated endocytosis is the major uptake mechanism for certain macromolecules, as exemplified by transferrin and low-density lipoprotein (LDL). These macromolecules bind to receptors that are localized in clathrin

coated pits. After binding to their specific receptors, LDL and transferrin are endocytosed in vesicles that fuse with lysosomes. In the acidic environment of the lysosome, LDL and transferrin release their cargo (cholesterol and iron, respectively), which is subsequently taken up into the cytoplasm. Remarkably, the LDL receptor and the transferrin receptor are resistant to the harsh environment of the lysosome, allowing them to be recycled back to the plasma membrane. Defects in receptor-mediated transport of LDL are responsible for familial hypercholesterolemia, as described in [Chapter 5](#).

Cytoskeleton and Cell-Cell Interactions

The ability of cells to adopt a particular shape, maintain polarity, organize the relationship of intracellular organelles, and move about depends on the intracellular scaffolding of proteins called the *cytoskeleton* (Fig. 1-8). In eukaryotic cells, there are three major classes of cytoskeletal proteins:

Figure 1-8 Cytoskeletal elements and cell-cell interactions. Interepithelial adhesion involves several different surface protein interactions, including through *tight junctions* and *desmosomes*; adhesion to the extracellular matrix involves cellular integrins (and associated proteins) within *hemidesmosomes*. See text for details.

- *Actin microfilaments* are 5- to 9-nm diameter fibrils formed from the globular protein actin (G-actin), the most abundant cytosolic protein in cells. The G-actin monomers noncovalently polymerize into long filaments (F-actin) that intertwine to form double-stranded helices with a defined polarity; new globular subunits are added (or lost) at the “positive” end of the strand. In muscle cells, the filamentous protein *myosin* binds to actin, and moves along it, driven by ATP hydrolysis (the basis of muscle contraction). In non-muscle cells, F-actin assembles via an assortment of actin-binding proteins into well-organized bundles and networks that control cell shape and movement.
 - *Intermediate filaments* are 10-nm diameter fibrils that comprise a large and heterogeneous family. Individual types have characteristic tissue-specific patterns of expression that can be useful for assigning a cell of origin for poorly differentiated tumors.
 - *Lamin A, B, and C*: nuclear lamina of all cells
 - *Vimentin*: mesenchymal cells (fibroblasts, endothelium)
 - *Desmin*: muscle cells, forming the scaffold on which actin and myosin contract
 - *Neurofilaments*: axons of neurons, imparting strength and rigidity
 - *Glial fibrillary acidic protein*: glial cells around neurons
 - *Cytokeratins*: at least 30 distinct varieties, subdivided into acidic (type I) and neutral/basic (type II); different types present in different cells, hence can be used as cell markers

These ropelike *intermediate filament* fibers are found predominantly in a polymerized form within cells and do not usually actively reorganize like actin
 - and microtubules. They impart tensile strength and allow cells to bear mechanical stress. The nuclear membrane lamins are important not only for maintaining nuclear morphology but also for regulating normal nuclear transcription. The importance of lamins is seen in rare but fascinating disorders caused by lamin mutations, which range from certain forms of muscular dystrophy to progeria, a disease of premature aging. Intermediate filaments also form the major structural proteins of skin and hair.
 - *Microtubules* are 25-nm-thick fibrils composed of noncovalently polymerized dimers of α - and β -tubulin arrayed in constantly elongating or shrinking hollow tubes with a defined polarity; the ends are designated “+” or “-”. The “-” end is typically embedded in a *microtubule organizing center (MTOC or centrosome)* near the nucleus where it is associated with paired *centrioles*; the “+” end elongates or recedes in response to various stimuli by the addition or subtraction of tubulin dimers. Within cells, microtubules can serve as connecting cables for “molecular motor” proteins that use ATP to move vesicles, organelles, or other molecules around cells along microtubules. There are two varieties of these motor proteins: *kinesins*, for anterograde (- to +) transport, and *dyneins*, for retrograde (+ to -) transport; they also participate in sister chromatid separation during mitosis. Notably, microtubules (and their associated motors) have been adapted to form motile cilia (e.g., in bronchial epithelium) or flagella (in sperm).
- Cell-Cell Interactions.** Cells interact and communicate with one another by forming junctions that provide mechanical links and enable surface receptors to recognize ligands on other cells. Cell junctions are organized into three basic types (Fig. 1-8):
- *Ocluding junctions (tight junctions)* seal adjacent cells together to create a continuous barrier that restricts the paracellular (between cells) movement of ions and other molecules. Viewed en face, occluding junctions form a tight meshlike network of macromolecular contacts between neighboring cells. The complexes that mediate the cell-cell interactions are composed of multiple transmembrane proteins, including *occludin*, *claudin*, *zonulin*, and *catenin*. Besides forming a high-resistance barrier to solute movement, this zone also represents the boundary that allows the segregation of apical and basolateral domains of cells, helping to maintain cellular polarity. Nevertheless, these junctions (as well as the desmosomes described later) are dynamic structures that can dissociate and reform as required to facilitate epithelial proliferation or inflammatory cell migration.
 - *Anchoring junctions (desmosomes)* mechanically attach cells—and their intracellular cytoskeletons—to other cells or to the extracellular matrix (ECM). When the adhesion focus is between cells, and is small and rivet-like, it is designated a *spot desmosome* or *macula adherens*. When such a focus attaches the cell to the ECM, it is called a *hemidesmosome*. Similar adhesion domains can also occur as broad bands between cells, where they are denoted as *belt desmosomes*.

Cell-cell desmosomal junctions are formed by homotypic association of transmembrane glycoproteins called *cadherins*. In spot desmosomes, the cadherins are called *desmogleins* and *desmocollins*; they are linked to intracellular intermediate filaments and allow extracellular forces to be mechanically communicated (and dissipated) over multiple cells. In belt desmosomes, the transmembrane adhesion molecules are called *E-cadherins* and are associated with intracellular actin microfilaments, by which they can influence cell shape and/or motility. In hemidesmosomes, the transmembrane connector proteins are called *integrins*; like cadherins, these attach to intracellular intermediate filaments, and thus functionally link the cytoskeleton to the extracellular matrix. *Focal adhesion complexes* are large (>100 proteins) macromolecular complexes that can be localized at hemidesmosomes, and include proteins that can generate intracellular signals when cells are subjected to increased shear stress, such as endothelium in the bloodstream, or cardiac myocytes in a failing heart.

- *Communicating junctions (gap junctions)* mediate the passage of chemical or electrical signals from one cell to another. The junction consists of a dense planar array of 1.5- to 2-nm pores (called *connexons*) formed by hexamers of transmembrane proteins called *connexins*. These pores permit the passage of ions, nucleotides, sugars, amino acids, vitamins, and other small molecules; the permeability of the junction is rapidly reduced by lowered intracellular pH or increased intracellular calcium. Gap junctions play a critical role in cell-cell communication; in cardiac myocytes, for example, cell-to-cell calcium fluxes through gap junctions allow the myocardium to behave like a functional syncytium capable of coordinated waves of contraction—the beating of the heart.

Biosynthetic Machinery: Endoplasmic Reticulum and Golgi

The structural proteins and enzymes of the cell are constantly renewed by ongoing synthesis tightly balanced with intracellular degradation. The endoplasmic reticulum (ER) is the site for synthesis of all the transmembrane proteins and lipids for plasma membrane and cellular organelles, including ER itself. It is also the initial site for the synthesis of all molecules destined for export out of the cell. The ER is organized into a meshlike interconnected maze of branching tubes and flattened lamellae forming a continuous sheet around a single lumen that is topologically equivalent to the extracellular environment. The ER is composed of contiguous but distinct domains, distinguished by the *presence* (rough ER or RER) or *absence* (smooth ER or SER) of ribosomes (Fig. 1-5).

Membrane-bound ribosomes on the cytosolic face of RER translate mRNA into proteins that are extruded into the ER lumen or become integrated into the ER membrane. This process is directed by specific *signal sequences* on the N-termini of nascent proteins. For proteins lacking a signal sequence, translation occurs on free ribosomes in the cytosol. Typically, such transcripts are read simultaneously

by multiple ribosomes (*polyribosomes*) and the vast majority of such proteins remain in the cytoplasm. Proteins inserted into the ER fold and can form polypeptide complexes (*oligomerize*); in addition, disulfide bonds are formed, and *N-linked oligosaccharides* (sugar moieties attached to asparagine residues) are added. *Chaperone molecules* retain proteins in the ER until these modifications are complete and the proper conformation is achieved. If a protein fails to appropriately fold or oligomerize, it is retained and degraded within the ER. The most common pathogenic mutation involving the CFTR protein, a membrane transporter that is defective in cystic fibrosis (Chapter 5), illustrates this quality control mechanism. This mutation causes the absence of a single amino acid (phe₅₀₈), which leads to misfolding, ER retention, and degradation of the CFTR protein. Moreover, excess accumulation of misfolded proteins—exceeding the capacity of the ER to edit and degrade them—leads to the *ER stress response* (also called the *unfolded protein response* or UPR) that triggers cell death through *apoptosis* (Chapter 2).

From the RER, proteins and lipids destined for other organelles or for extracellular export are shuttled into the *Golgi apparatus*. This organelle consists of stacked cisternae that progressively modify proteins in an orderly fashion from *cis* (near the ER) to *trans* (near the plasma membrane); macromolecules are shuttled between the various cisternae within membrane-bound vesicles. As molecules move from *cis* to *trans*, the *N-linked oligosaccharides* originally added to proteins in the ER are pruned and further modified in a step-wise fashion; *O-linked oligosaccharides* (sugar moieties linked to serine or threonine) are also appended. Some of this glycosylation is important in directing molecules to lysosomes (via the *mannose-6-phosphate receptor*, Chapter 5); other glycosylation adducts may be important for cell-cell or cell-matrix interactions, or for clearing senescent cells (e.g., platelets and red cells). In addition to the stepwise glycosylation of lipids and proteins, the *cis Golgi network* can recycle proteins back to the ER; the *trans Golgi network* sorts proteins and lipids and dispatches them to other organelles (including the plasma membrane), or to secretory vesicles destined for extracellular release. The Golgi complex is especially prominent in cells specialized for secretion, including goblet cells of the intestine, bronchial epithelium (secreting large amounts of polysaccharide-rich mucus), and plasma cells (secreting large quantities of antibodies).

The SER in most cells is relatively sparse and primarily exists as the transition zone from RER to transport vesicles moving to the Golgi. However, in cells that synthesize steroid hormones (e.g., in the gonads or adrenals), or that catabolize lipid-soluble molecules (e.g., in the liver), the SER may be particularly conspicuous. Indeed, repeated exposure to compounds that are metabolized by the SER (e.g., phenobarbital catabolism by the cytochrome P-450 system), can lead to a reactive SER hyperplasia. The SER is also responsible for sequestering intracellular calcium; subsequent release from the SER into the cytosol can mediate a number of responses to extracellular signals (including apoptotic cell death). In addition, in muscle cells, specialized SER called *sarcoplasmic reticulum* is responsible for the cyclical release and sequestration of calcium ions that regulates muscle contraction and relaxation, respectively.

Waste Disposal: Lysosomes and Proteasomes

As already mentioned in brief, **cellular waste disposal depends on the activities of lysosomes and proteasomes** (Fig. 1-9).

- **Lysosomes** are membrane-bound organelles containing roughly 40 different acid hydrolases (i.e., enzymes

that function best in acidic pH ≤ 5); these hydrolases include proteases, nucleases, lipases, glycosidases, phosphatases, and sulfatases. Lysosomal enzymes are initially synthesized in the ER lumen and then tagged with a mannose-6-phosphate (M6P) residue within the Golgi apparatus. Such M6P-modified proteins are subsequently delivered to lysosomes through trans-Golgi vesicles that express M6P receptors. The other

A. LYSOSOMAL DEGRADATION

B. PROTEASOMAL DEGRADATION

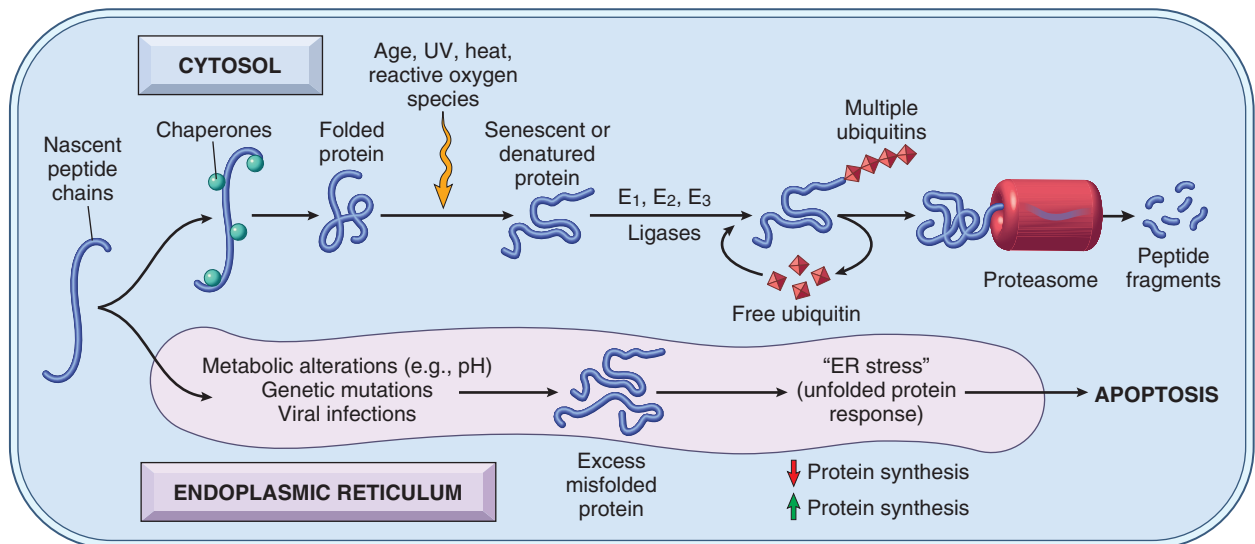

Figure 1-9 Intracellular catabolism. **A**, Lysosomal degradation. In *heterophagy* (right side), lysosomes fuse with endosomes or phagosomes to facilitate the degradation of their internalized contents (see Fig. 1-7). The end-products may be released into the cytosol for nutrition or discharged into the extracellular space (*exocytosis*). In *autophagy* (left side), senescent organelles or denatured proteins are targeted for lysosome-driven degradation by encircling them with a double membrane derived from the endoplasmic reticulum and marked by LC3 proteins (microtubule-associated protein 1A/1B-light chain 3). Cell stressors such as nutrient depletion or certain intracellular infections can also activate the autophagocytic pathway. **B**, Proteasome degradation. Cytosolic proteins destined for turnover (e.g., transcription factors or regulatory proteins), senescent proteins, or proteins that have become denatured due to extrinsic mechanical or chemical stresses can be tagged by multiple ubiquitin molecules (through the activity of E₁, E₂, and E₃ ubiquitin ligases). This marks the proteins for degradation by proteasomes, cytosolic multi-subunit complexes that degrade proteins to small peptide fragments. High levels of misfolded proteins within the endoplasmic reticulum (ER) trigger a protective *unfolded protein response*—engendering a broad reduction in protein synthesis, but specific increases in chaperone proteins that can facilitate protein refolding. If this is inadequate to cope with the levels of misfolded proteins, apoptosis is induced.

macromolecules destined for catabolism in the lysosomes arrive by one of three other pathways (Fig. 1-9):

- Material internalized by *fluid-phase pinocytosis* or *receptor-mediated endocytosis* passes from plasma membrane to early endosome to late endosome, and ultimately into the lysosome. The early endosome is the first acidic compartment encountered, while proteolytic enzymes only begin significant digestion in the late endosome; late endosomes mature into lysosomes. During the maturation process, the organelle becomes progressively more acidic.
- Senescent organelles and large, denatured protein complexes are shuttled into lysosomes by a process called *autophagy*. Through poorly understood mechanisms, obsolete organelles are corralled by a double membrane derived from the endoplasmic reticulum; the membrane progressively expands to encircle a collection of structures and forms an *autophagosome* which then fuses with lysosomes and the contents are catabolized. In addition to facilitating the turnover of aged and defunct structures, autophagy is also used to preserve cell viability during nutrient depletion. Autophagy is discussed in more detail in [Chapter 2](#).
- *Phagocytosis* of microorganisms or large fragments of matrix or debris occurs primarily in professional phagocytes (macrophages or neutrophils). The material is engulfed to form a *phagosome* that subsequently fuses with a lysosome.
- **Proteasomes** play an important role in degrading cytosolic proteins (Fig. 1-9); these include denatured or misfolded proteins (akin to what occurs within the ER), as well as any other macromolecule whose lifespan needs to be regulated (e.g., transcription factors). Many proteins destined for destruction are identified by covalently binding to a small 76-amino acid protein called *ubiquitin*. Poly-ubiquitinated molecules are then unfolded and funneled into the polymeric proteasome complex, a cylinder containing multiple different protease activities, each with its active site pointed at the hollow core. Proteasomes digest proteins into small (6 to 12 amino acids) fragments that can subsequently be degraded to their constituent amino acids and recycled.

Cellular Metabolism and Mitochondrial Function

Mitochondria evolved from ancestral prokaryotes that were engulfed by primitive eukaryotes about 1.5 billion years ago. Their origin explains why mitochondria contain their own DNA (circularized, about 1% of the total cellular DNA), encoding roughly 1% of the total cellular proteins and approximately 20% of the proteins involved in *oxidative phosphorylation*. Although their genomes are small, mitochondria can nevertheless carry out all the steps of DNA replication, transcription, and translation. Interestingly, the mitochondrial machinery is similar to present-day bacteria; for example, mitochondria initiate protein synthesis with N-formylmethionine and are sensitive to antibacterial antibiotics. Moreover, since the ovum

contributes the vast majority of cytoplasmic organelles to the fertilized zygote, mitochondrial DNA is virtually entirely *maternally inherited*. Nevertheless, because the protein constituents of mitochondria derive from both nuclear and mitochondrial genetic transcription, mitochondrial disorders may be X-linked, autosomal, or maternally inherited.

Mitochondria provide the enzymatic machinery for oxidative phosphorylation (and thus the relatively efficient generation of energy from glucose and fatty acid substrates). They also have an important role in anabolic metabolism and play a fundamental role in regulating programmed cell death, so-called *apoptosis* (Fig. 1-10).

Energy Generation. Each mitochondrion has two separate and specialized membranes. The inner membrane contains the enzymes of the respiratory chain folded into *cristae*. This encloses a core *matrix space* that harbors the bulk of certain metabolic enzymes, such as the enzymes of the citric acid cycle. Outside the inner membrane is the *intermembrane space*, site of ATP synthesis, which is, in turn, enclosed by the *outer membrane*; the latter is studded with *porin* proteins that form aqueous channels permeable to small (<5000 daltons) molecules. Larger molecules (and even some smaller polar species) require specific transporters.

The major source of the energy to run all the basic cellular functions derives from oxidative metabolism. Mitochondria oxidize substrates to CO₂, transferring the high-energy electrons from the original molecule (e.g., sugar) to molecular oxygen, and generating the low-energy electrons of water. The oxidation of various metabolites drives *hydrogen ion (proton) pumps* that transfer H⁺ from the core matrix into the intermembrane space. As the H⁺ ions flow back down their electrochemical gradient, the energy released is used in the synthesis of *adenosine triphosphate (ATP)*.

It should be noted that the electron transport chain need not necessarily be coupled to ATP generation. Through the function of *thermogenin*, an inner membrane protein, the energy can be used to generate heat. Hence tissues with high levels of thermogenin, such as brown fat, can generate heat by non-shivering thermogenesis. As a natural (albeit usually low-level) byproduct of substrate oxidation and electron transport, mitochondria are also an important source of reactive oxygen species (e.g., oxygen free radicals, hydrogen peroxide); importantly, hypoxia, toxic injury, or even mitochondrial aging can lead to significantly increased levels of intracellular oxidative stress. Mitochondria are constantly turning over, with estimated half-lives ranging from 1 to 10 days, depending on the tissue, nutritional status, metabolic demands, and intercurrent injury.

Intermediate metabolism. As described in [Chapter 7](#), pure oxidative phosphorylation produces abundant ATP, but also “burns” glucose to CO₂ and H₂O, leaving no carbon moieties suitable for use as building blocks for lipids or proteins. For this reason, rapidly growing cells (both benign and malignant) upregulate glucose and glutamine uptake and decrease their production of ATP per glucose molecule, a phenomenon called the Warburg effect. Both glucose and glutamine provide carbon moieties that prime

Figure 1-10 Roles of the mitochondria. Besides the efficient generation of ATP from carbohydrate and fatty acid substrates, mitochondria have an important role in intermediary metabolism, serving as the source of molecules used to synthesize lipids and proteins, and are also centrally involved in cell life-and-death decisions.

the mitochondrial TCA cycle, but instead of being used to make ATP, intermediates are “spun-off” to make lipids, nucleic acids, and proteins. Thus, depending on the growth state of the cell, mitochondrial metabolism can be modulated to support either cellular maintenance or cellular growth. Ultimately, these metabolic decisions are governed by growth factors, nutrient and oxygen supplies, and cellular signaling pathways and sensors that respond to these exogenous factors.

Cell Death. In addition to providing ATP and metabolites that enable the bulk of cellular activity, mitochondria also regulate the balance of cell survival and death. There are two major pathways of cell death (Chapter 2):

- **Necrosis:** External cellular injury (toxin, ischemia, trauma) can damage mitochondria, inducing the formation of mitochondrial permeability transition pores in the outer membrane. These channels allow the dissipation of the proton potential so that mitochondrial ATP generation fails and the cell dies.
- **Apoptosis:** Programmed cell death is a central feature of normal tissue development and turnover and can be triggered by extrinsic signals (including cytotoxic T cells and inflammatory cytokines), or intrinsic pathways (including DNA damage and intracellular stress). Mitochondria play a central role in the intrinsic pathway of apoptosis. If mitochondria are damaged (a sign of irreversible cell injury or stress) or the cell cannot synthesize adequate amounts of survival proteins (because of deficient growth signals), mitochondria become leaky. Cytochrome c, which is normally sequestered inside the mitochondria, leaks into the cytosol, where it

forms a complex with other proteins that ultimately activate caspases, the enzymes that induce apoptosis. This process is described in more detail in Chapter 2. Failure of apoptosis can contribute to malignancy (Chapter 7) and too much apoptosis can lead to premature cell death, as occurs in some neurodegenerative disorders (Chapter 28).

Although mitochondria were discovered well over 100 years ago, the secrets of their functions continue to be unraveled.

Cellular Activation

Cell communication is critical in multicellular organisms. At the most basic level, extracellular signals determine whether a cell lives or dies, or whether it remains quiescent or is stimulated to perform its specific function. Intercellular signaling is clearly important in the developing embryo, and in maintaining tissue organization; it is also important in the intact organism, assuring that tissues respond in an adaptive and effective fashion to various threats, such as local tissue trauma or a systemic infection. Loss of cellular communication and the “social controls” that maintain normal relationships of cells can variously lead to unregulated growth (cancer) or an ineffective response to an extrinsic stress (as in shock).

Cell Signaling

An individual cell is chronically exposed to a remarkable variety of signals, which it must sort through and integrate

into some sort of rational output. Some signals may induce a given cell type to differentiate, others may stimulate proliferation, and yet others may direct the cell to perform a specialized function. Multiple signals received in combination may trigger yet another totally unique response. Many cells require certain inputs just to continue living; in the absence of appropriate exogenous signals, they die by apoptosis.

The signals that most cells respond to can be classified into several groups:

- *Damage to neighboring cells and pathogens.* Many cells have an innate capacity to sense and respond to damaged cells (*danger signals*), as well as foreign invaders such as microbes. The receptors that detect these dangers are discussed in [Chapters 3](#) and [6](#).
- *Contact with neighboring cells,* mediated through adhesion molecules and/or gap junctions. As mentioned previously, *gap junction signaling* is accomplished between adjacent cells via hydrophilic connexons that permit the movement of small ions (e.g., calcium), various metabolites, and potential second messenger molecules like cAMP, but not larger macromolecules.
- *Contact with ECM,* mediated through integrins, which are discussed in the context of leukocyte attachment to other cells during inflammation in [Chapter 3](#).
- *Secreted molecules.* The most important secreted molecules include *growth factors*, discussed later; *cytokines*, a term reserved for mediators of inflammation and immune responses (also discussed in [Chapters 3](#) and [6](#)); and *hormones*, which are secreted by endocrine organs and act on different cell types ([Chapter 24](#)).

Extracellular cell-cell signaling pathways are classified into different types, based on the distance over which the signal functions:

- *Paracrine signaling.* Cells in just the immediate vicinity are affected. To accomplish this, there can be only minimal diffusion, with the signal being rapidly degraded, taken up by other cells, or trapped in the ECM.
- *Autocrine signaling* occurs when molecules secreted by a cell affect that same cell. This can be a means to entrain groups of cells undergoing synchronous differentiation during development, or can be used to amplify a response or for its feedback inhibition.
- *Synaptic signaling.* Activated neurons secrete *neurotransmitters* at specialized cell junctions (*synapses*) onto target cells.
- *Endocrine signaling.* A mediator is released into the bloodstream and acts on target cells at a distance.

Regardless of the nature of an extracellular stimulus (paracrine, synaptic, or endocrine), the signal it conveys is transmitted to the cell via a specific receptor protein. Signaling molecules (*ligands*) bind their respective receptors and initiate a cascade of intracellular events culminating in the desired cellular response. Ligands usually have high affinities for receptors and at physiologic concentrations bind receptors with exquisite specificity. Receptors may be present on the cell surface or located within the cell ([Fig. 1-11](#)):

- *Intracellular receptors* are transcription factors that are activated by lipid-soluble ligands that can easily cross

the plasma membrane. Examples of cell-permeable, hydrophobic ligands for this class of receptor include vitamin D and steroid hormones, which activate nuclear hormone receptors. Uncommonly, the signaling ligand diffuses into adjacent cells; this is the case with nitric oxide, which directly activates the enzyme guanylyl cyclase to generate cyclic GMP, an intracellular second signal.

- *Cell-surface receptors* are generally transmembrane proteins with extracellular domains that bind soluble secreted ligands. Depending on the receptor, ligand binding can then (1) open ion channels (typically at the synapse between electrically excitable cells), (2) activate an associated GTP-binding regulatory protein (*Gprotein*), (3) activate an endogenous or associated enzyme, often a tyrosine kinase; or (4) trigger a proteolytic event or a change in protein binding or stability that activates a latent transcription factor. Activities (2) and (3) are associated with growth factor signaling pathways that drive cell proliferation, while activity (4) is a common feature of multiple pathways (e.g., Notch, Wnt, and Hedgehog) that regulate normal development. Understandably, signals transduced by cell surface receptors are often deranged in developmental disorders and in cancers.

Signal Transduction Pathways

Binding of a ligand to a cell surface receptor mediates signaling by inducing clustering of the receptor (*receptor cross-linking*) or other types of physical perturbations ([Fig. 1-11](#)). The common theme is that all of these perturbations cause a change in the physical state of the intracellular domain of the receptor, which then triggers additional biochemical events that lead to signal transduction.

Cellular receptors are grouped into several types based on the signaling mechanisms they use and the intracellular biochemical pathways they activate ([Fig. 1-11](#)). Receptor signaling typically leads to the formation or modification of biochemical intermediates and/or activation of enzymes, and ultimately to the generation of active transcription factors that enter the nucleus and alter gene expression:

- *Receptors associated with kinase activity.* Downstream phosphorylation is a common pathway (but not the only one) by which these signals are transduced. Thus, alterations in receptor geometry can elicit intrinsic receptor *protein kinase* activity or promote the enzymatic activity of recruited intracellular kinases—resulting in the addition of charged phosphate residues to target molecules. *Tyrosine kinases* phosphorylate specific tyrosine residues, whereas *serine/threonine kinases* add phosphates to distinct serine or threonine residues, and *lipid kinases* phosphorylate lipid substrates. For every phosphorylation event, there is also a *phosphatase*, an enzyme that can remove the phosphate residue and thus modulate signaling; usually, phosphatases play an inhibitory role in signal transduction.
 - *Receptor tyrosine kinases (RTKs)* are integral membrane proteins (e.g., receptors for insulin, epidermal growth factor, and platelet derived growth factor); ligand-induced cross-linking activates intrinsic

Figure 1-11 Receptor-mediated signaling. **A**, Categories of signaling receptors, including receptors that utilize a nonreceptor tyrosine kinase; a receptor tyrosine kinase; a nuclear receptor that binds its ligand and can then influence transcription; a seven-transmembrane receptor linked to heterotrimeric G proteins; Notch, which recognizes a ligand on a distinct cell and is cleaved yielding an intracellular fragment that can enter the nucleus and influence transcription of specific target genes; and the Wnt/Frizzled pathway where activation releases intracellular β -catenin from a protein complex that normally drives its constitutive degradation. The released β -catenin can then migrate to the nucleus and act as a transcription factor. Lrp5/Lrp6, low-density-lipoprotein (LDL) receptor related proteins 5 and 6, are highly homologous and act as co-receptors in Wnt/Frizzled signaling. **B**, Signaling from a tyrosine kinase-based receptor. Binding of the growth factor (ligand) causes receptor dimerization and autophosphorylation of tyrosine residues. Attachment of adapter (or bridging) proteins couples the receptor to inactive, GDP-bound RAS, allowing the GDP to be displaced in favor of GTP and yielding activated RAS. Activated RAS interacts with and activates RAF (also known as *MAP kinase kinase kinase*). This kinase then phosphorylates MAPK (mitogen-activated protein kinase) and activated MAP kinase phosphorylates other cytoplasmic proteins and nuclear transcription factors, generating cellular responses. The phosphorylated tyrosine kinase receptor can also bind other components, such as phosphatidylyl 3-kinase (PI3 kinase), which activates other signaling systems. The cascade is turned off when the activated RAS eventually hydrolyzes GTP to GDP converting RAS to its inactive form. Mutations in RAS that lead to delayed GTP hydrolysis can thus lead to augmented proliferative signaling. GDP, Guanosine diphosphate; GTP, guanosine triphosphate; mTOR, mammalian target of rapamycin.

tyrosine kinase domains located in their cytoplasmic tails.

- Several kinds of receptors have no intrinsic catalytic activity (e.g., immune receptors, some cytokine receptors, and integrins). For these, a separate intracellular protein—known as a *nonreceptor tyrosine kinase*—phosphorylates specific motifs on the receptor or other proteins. The cellular homolog of the transforming protein of the Rous sarcoma virus, called SRC, is the prototype for an important family

of such nonreceptor tyrosine kinases (*Src-family kinases*). SRC contains unique functional regions, such as *Src-homology 2* (SH2) and *Src-homology 3* (SH3) domains. SH2 domains typically bind to receptors phosphorylated by another kinase, allowing the aggregation of multiple enzymes. SH3 domains mediate other protein-protein interactions, often involving proline-rich domains.

- *G-protein coupled receptors* are polypeptides that characteristically traverse the plasma membrane seven times

(hence their designation as seven-transmembrane or serpentine receptors); more than 1500 such receptors have been identified. After ligand binding, the receptor associates with an intracellular guanosine triphosphate (GTP)-binding protein (G protein) that contains guanosine diphosphate (GDP). G-protein interaction with a receptor-ligand complex results in activation through the exchange of GDP for GTP. Downstream receptor-mediated signaling events result in the generation of cyclic AMP (cAMP), and inositol-1,4,5,-triphosphate (IP₃), the latter releasing calcium from the endoplasmic reticulum.

- **Nuclear receptors.** Lipid-soluble ligands can diffuse into cells where they interact with intracellular proteins to form a receptor-ligand complex that directly binds to nuclear DNA; the results can be either activation or repression of gene transcription.
- **Other classes of receptors.** Other receptors—originally recognized as important for embryonic development and cell fate determination—have since been shown to participate in the functions of mature cells, particularly within the immune system.
 - Receptor proteins of the *Notch* family fall in this category; ligand binding to Notch receptors leads to proteolytic cleavage of the receptor and subsequent nuclear translocation of the cytoplasmic piece (intracellular Notch) to form a transcription complex.
 - *Wnt* protein ligands can also influence cell development through a pathway involving transmembrane *Frizzled* family receptors, which regulate the intracellular levels of β -catenin. Normally, β -catenin is constantly targeted for ubiquitin-directed proteasome degradation. However, *Wnt* binding to *Frizzled* (and other co-receptors) recruits yet another intracellular protein (*Dishevelled*) that leads to disruption of the degradation-targeting complex. The stabilized pool of β -catenin molecules then translocates to the nucleus, where β -catenin forms a transcriptional complex.

Modular Signaling Proteins, Hubs, and Nodes. The traditional *linear* view of signaling—that receptor activation triggers an orderly sequence of biochemical intermediates that ultimately leads to changes in gene expression and the desired biological response—is almost certainly oversimplified. Instead, it is increasingly clear that any initial signal results in multiple diverging effects, each of which contributes in varying degrees to the final outcome. For example, specific phosphorylation of any given protein can allow it to associate with a host of other molecules, resulting in multiple effects such as:

- Enzyme activation (or inactivation)
- Nuclear (or cytoplasmic) localization of transcription factors (see later)
- Transcription factor activation (or inactivation)
- Actin polymerization (or depolymerization)
- Protein degradation (or stabilization)
- Activation of feedback inhibitory (or stimulatory) loops

Adaptor proteins play a key role in organizing intracellular signaling pathways. These proteins function as

molecular connectors that physically link different enzymes and promote the assembly of complexes; adaptors can be integral membrane proteins or cytosolic proteins. A typical adaptor may contain a few specific domains (e.g., SH2 or SH3) that mediate protein-protein interactions. By influencing which proteins are recruited to signaling complexes, adaptors can determine downstream signaling events.

By analogy with computer networks, the protein-protein complexes can be considered *nodes* and the biochemical events feeding into or emanating from these nodes can be thought of as *hubs*. Signal transduction can therefore be visualized as a kind of networking phenomenon; understanding this higher order complexity is the province of *systems biology*, involving a “marriage” of biology and computation.

Transcription Factors. Most signal transduction pathways ultimately influence cellular function by modulating gene transcription through the activation and nuclear localization of transcription factors. Conformational changes of transcription factors (e.g., following phosphorylation) can allow their translocation into the nucleus or can expose specific DNA or protein binding motifs. Transcription factors may drive the expression of a relatively limited set of genes or may have much more widespread effects on gene expression. Among the transcription factors that regulate the expression of genes that are needed for growth are MYC and JUN, while a transcription factor that triggers the expression of genes that lead to growth arrest is p53. Transcription factors have a modular design, often containing domains that bind DNA and that interact with other proteins, such as components of the RNA polymerase complex, that are needed to drive transcription.

- The DNA-binding domain permits specific binding to short DNA sequences. While most interest historically has been focused on binding of transcription factors to gene promoters, it is now appreciated that most transcription factors bind widely throughout genomes, with the majority of binding occurring in long-range regulatory elements such as enhancers. Enhancers are usually located in the “neighborhood” close to genes, but are sometimes far away; it is even suspected that some may be located on other chromosomes! These insights highlight the importance of chromatin organization in regulating gene expression, both normal and pathologic.
- For a transcription factor to induce transcription, it must also possess protein:protein interaction domains that directly or indirectly recruit histone modifying enzymes, chromatin remodeling complexes, and (most importantly) RNA polymerase—the large multiprotein enzymatic complex that is responsible for RNA synthesis.

Growth Factors and Receptors

A major role of growth factors is to stimulate the activity of genes that are required for cell growth and cell division. Growth factor activity is mediated through binding to specific receptors, ultimately influencing the expression of genes that can:

- Promote entry of cells into the cell cycle
- Relieve blocks on cell cycle progression (thus promoting replication)
- Prevent apoptosis
- Enhance biosynthesis of cellular components (nucleic acids, proteins, lipids, carbohydrates) required for a mother cell to give rise to two daughter cells

Although growth factors are characteristically thought of as proteins that stimulate cell proliferation and/or survival, it is important to remember that they can also drive a host of nongrowth activities, including migration, differentiation, and synthetic capacity.

Growth factors are involved in the proliferation of cells at steady state as well as after injury, when irreversibly damaged cells must be replaced. Uncontrolled proliferation can result when the growth factor activity is dysregulated, or when growth factor signaling pathways are altered to become constitutively active. Thus, many growth factor pathway genes are *proto-oncogenes*; gain-of-function mutations in these genes can convert them into oncogenes capable of driving unfettered cell proliferation and tumor formation. [Table 1-1](#) (and the following discussion) summarizes selected growth factors that are involved in two important proliferative processes, tissue repair and tumor development. Although the growth factors described here all involve receptors with intrinsic kinase activity, other growth factors may signal through each of the various pathways shown in [Figure 1-11](#).

Epidermal Growth Factor and Transforming Growth Factor- α . Both of these factors belong to the EGF family and bind to the same receptors, which explains why they share many biologic activities. EGF and TGF- α are produced by macrophages and a variety of epithelial cells, and are mitogenic for hepatocytes, fibroblasts, and a host of epithelial cells. The “EGF receptor family” includes four membrane receptors with intrinsic tyrosine kinase activity; the best-characterized is EGFR1, also known as ERB-B1, or

simply EGFR. EGFR1 mutations and/or amplification frequently occur in a number of cancers including those of the lung, head and neck, breast, and brain. The *ERBB2 receptor* (also known as *HER2*) is overexpressed in a subset of breast cancers. Many of these receptors have been successfully targeted by antibodies and small molecule antagonists.

Hepatocyte Growth Factor. Hepatocyte growth factor (HGF; also known as scatter factor) has mitogenic effects on hepatocytes and most epithelial cells, including biliary, pulmonary, renal, mammary, and epidermal. HGF acts as a *morphogen* in embryonic development (i.e., it influences the pattern of tissue differentiation), promotes cell migration (hence its designation as *scatter factor*), and enhances hepatocyte survival. HGF is produced by fibroblasts and most mesenchymal cells, as well as endothelium and non-hepatocyte liver cells. It is synthesized as an inactive precursor (pro-HGF) that is proteolytically activated by serine proteases released at sites of injury. MET is the receptor for HGF, it has intrinsic tyrosine kinase activity and is frequently overexpressed or mutated in tumors, particularly renal and thyroid papillary carcinomas. Consequently, MET inhibitors may be of value for cancer therapy.

Platelet-Derived Growth Factor. Platelet-derived growth factor (PDGF) is a family of several closely related proteins, each consisting of two chains (designated by pairs of letters). Three isoforms of PDGF (AA, AB, and BB) are constitutively active; PDGF-CC and PDGF-DD must be activated by proteolytic cleavage. PDGF is stored in platelet granules and is released on platelet activation. Although originally isolated from platelets (hence the name), it is also produced by many other cells, including activated macrophages, endothelium, smooth muscle cells, and a variety of tumors. All PDGF isoforms exert their effects by binding to two cell surface receptors (PDGFR α and β), both having intrinsic tyrosine kinase activity. PDGF induces fibroblast, endothelial, and smooth muscle cell proliferation and matrix synthesis, and is chemotactic for these cells (and

Table 1-1 Growth Factors Involved in Regeneration and Repair

Growth Factor	Sources	Functions
Epidermal growth factor (EGF)	Activated macrophages, salivary glands, keratinocytes, and many other cells	Mitogenic for keratinocytes and fibroblasts; stimulates keratinocyte migration; stimulates formation of granulation tissue
Transforming growth factor- α (TGF- α)	Activated macrophages, keratinocytes, many other cell types	Stimulates proliferation of hepatocytes and many other epithelial cells
Hepatocyte growth factor (HGF) (scatter factor)	Fibroblasts, stromal cells in the liver, endothelial cells	Enhances proliferation of hepatocytes and other epithelial cells; increases cell motility
Vascular endothelial growth factor (VEGF)	Mesenchymal cells	Stimulates proliferation of endothelial cells; increases vascular permeability
Platelet-derived growth factor (PDGF)	Platelets, macrophages, endothelial cells, smooth muscle cells, keratinocytes	Chemotactic for neutrophils, macrophages, fibroblasts, and smooth muscle cells; activates and stimulates proliferation of fibroblasts, endothelial, and other cells; stimulates ECM protein synthesis
Fibroblast growth factors (FGFs), including acidic (FGF-1) and basic (FGF-2)	Macrophages, mast cells, endothelial cells, many other cell types	Chemotactic and mitogenic for fibroblasts; stimulates angiogenesis and ECM protein synthesis
Transforming growth factor- β (TGF- β)	Platelets, T lymphocytes, macrophages, endothelial cells, keratinocytes, smooth muscle cells, fibroblasts	Chemotactic for leukocytes and fibroblasts; stimulates ECM protein synthesis; suppresses acute inflammation
Keratinocyte growth factor (KGF) (i.e., FGF-7)	Fibroblasts	Stimulates keratinocyte migration, proliferation, and differentiation

ECM, Extracellular membrane.

inflammatory cells), thus promoting recruitment of the cells into areas of inflammation and tissue injury.

Vascular Endothelial Growth Factor. Vascular endothelial growth factors (VEGFs)—VEGF-A, -B, -C, and -D, and PlGF (placental growth factor)—are a family of homodimeric proteins. VEGF-A is generally referred to simply as VEGF; it is the major *angiogenic* factor (inducing blood vessel development) after injury and in tumors. In comparison, VEGF-B and PlGF are involved in embryonic vessel development, and VEGF-C and -D stimulate both angiogenesis and lymphatic development (*lymphangiogenesis*). VEGFs are also involved in the maintenance of normal adult endothelium (i.e., not involved in angiogenesis), with the highest expression in epithelial cells adjacent to fenestrated epithelium (e.g., podocytes in the kidney, pigment epithelium in the retina, and choroid plexus in the brain). VEGF induces angiogenesis by promoting endothelial cell migration, proliferation (capillary sprouting), and formation of the vascular lumen. VEGFs also induce vascular dilation and increased vascular permeability. As might be anticipated, hypoxia is the most important inducer of VEGF production, through pathways that involve intracellular hypoxia-inducible factor (HIF-1). Other VEGF inducers—produced at sites of inflammation or wound healing—include PDGF and TGF- α .

VEGFs bind to a family of receptor tyrosine kinases (VEGFR-1, -2, and -3); VEGFR-2 is highly expressed in endothelium and is the most important for angiogenesis. Antibodies against VEGF are approved for the treatment of several tumors such as renal and colon cancers since they require angiogenesis for their spread and growth. Anti-VEGF antibodies are also being used for a number of ophthalmic diseases including “wet” age-related macular degeneration (AMD is a disorder of inappropriate angiogenesis and vascular permeability that causes adult-onset blindness); the angiogenesis associated with retinopathy of prematurity; and the leaky vessels that lead to diabetic macular edema. Finally, increased levels of soluble versions of VEGFR-1 (s-FLT-1) in pregnant women may cause preeclampsia (hypertension and proteinuria) by “sopping up” the free VEGF required for maintaining normal endothelium.

Fibroblast Growth Factor. Fibroblast growth factor (FGF) is a family of growth factors with of more than 20 members. Acidic FGF (aFGF, or FGF-1) and basic FGF (bFGF, or FGF-2) are the best characterized; FGF-7 is also referred to as keratinocyte growth factor (KGF). Released FGFs associate with heparan sulfate in the extracellular matrix, which serves as a reservoir for inactive factors that can be subsequently released by proteolysis (e.g., at sites of wound healing). FGFs transduce signals through four tyrosine kinase receptors (FGFR 1-4). FGFs contribute to wound healing responses, hematopoiesis, and development; bFGF has all the activities necessary for angiogenesis as well.

Transforming Growth Factor- β . TGF- β , which is distinct from TGF- α , has three isoforms (TGF- β 1, TGF- β 2, TGF- β 3), each belonging to a family of about 30 members that includes bone morphogenetic proteins (BMPs), activins, inhibins, and müllerian inhibiting substance. TGF- β 1 has

the most widespread distribution, and is more commonly referred to as TGF- β . It is a homodimeric protein produced by multiple cell types, including platelets, endothelium, and mononuclear inflammatory cells; TGF- β is secreted as a precursor that requires proteolysis to yield the biologically active protein. There are two TGF- β receptors (types I and II), both with serine/threonine kinase activity that induce the phosphorylation of a variety of downstream cytoplasmic transcription factors called *Smads*. Phosphorylated Smads form heterodimers with Smad4, allowing nuclear translocation and association with other DNA-binding proteins to activate or inhibit gene transcription. TGF- β has multiple and often opposing effects depending on the tissue and concurrent signals. Agents with such multiplicity of effects are called *pleiotropic*. Because of the bewildering diversity of TGF- β effects (see later), this growth factor is said to be “pleiotropic with a vengeance.” Primarily, however, TGF- β drives scar formation, and applies brakes on the inflammation that accompanies wound healing.

- TGF- β stimulates the production of collagen, fibronectin, and proteoglycans, and it inhibits collagen degradation by both decreasing matrix metalloproteinase (MMP) activity and increasing the activity of tissue inhibitors of proteinases (TIMPs; discussed later). TGF- β is involved not only in scar formation after injury, but also drives fibrosis in lung, liver, and kidneys in the setting of chronic inflammation.
- TGF- β is an antiinflammatory cytokine that serves to limit and terminate inflammatory responses. It does this by inhibiting lymphocyte proliferation and the activity of other leukocytes. Animal models lacking TGF- β have widespread and persistent inflammation.

Interaction with the Extracellular Matrix

Extracellular matrix (ECM) is a network of interstitial proteins that constitutes a significant proportion of any tissue. **Cell interactions with ECM are critical for development and healing, as well as for maintaining normal tissue architecture** (Fig. 1-12). Much more than a simple “space filler” around cells, ECM serves several key functions:

- *Mechanical support* for cell anchorage and cell migration, and maintenance of cell polarity
- *Control of cell proliferation*, by binding and displaying growth factors and by signaling through cellular receptors of the integrin family. As discussed earlier, the ECM provides a depot for a variety of latent growth factors that can be activated within foci of injury or inflammation.
- *Scaffolding for tissue renewal*. Because maintenance of normal tissue structure requires a basement membrane or stromal scaffold, the integrity of the basement membrane or the stroma of parenchymal cells is critical for the organized regeneration of tissues. Thus, ECM disruption results in defective tissue regeneration and repair, as occurs in the development of liver cirrhosis following injury to the liver cells and the collapse of the hepatic stroma.
- *Establishment of tissue microenvironments*. Basement membrane acts as a boundary between epithelium and

Figure 1-12 Interactions of extracellular matrix (ECM) and growth factors mediated cell signaling. Cell surface integrins interact with the cytoskeleton at focal adhesion complexes (protein aggregates that include vinculin, α -actinin, and talin; see Fig. 1-16C). This can initiate the production of intracellular messengers or can directly transduce signals to the nucleus. Cell surface receptors for growth factors can activate signal transduction pathways that overlap with those mediated through integrins. Signals from ECM components and growth factors can be integrated by the cells to produce a given response, including changes in proliferation, locomotion, and/or differentiation.

underlying connective tissue; it does not just provide support to the epithelium but is also functional. For example, in the kidney, it forms part of the filtration apparatus.

The ECM is constantly being remodeled; its synthesis and degradation accompany morphogenesis, tissue regeneration and repair, chronic fibrosis, and tumor invasion and metastasis. The appreciation of the structure and functions of the ECM has led to many recent attempts to create “artificial organs” by growing epithelia on various ECM substrates. This is a potential approach for replacing damaged tissues and organs.

ECM occurs in two basic forms: interstitial matrix and basement membrane (Fig. 1-13).

- *Interstitial matrix* is present in the spaces between cells in connective tissue, and between parenchymal epithelium and the underlying supportive vascular and smooth muscle structures. Interstitial matrix is synthesized by mesenchymal cells (e.g., fibroblasts),

forming a three-dimensional, relatively amorphous gel. Its major constituents are fibrillar and nonfibrillar collagens, as well as fibronectin, elastin, proteoglycans, hyaluronate, and other constituents (see later).

- *Basement membrane.* The seemingly random array of interstitial matrix in connective tissues becomes highly organized around epithelial cells, endothelial cells, and smooth muscle cells, forming the specialized basement membrane. The basement membrane is synthesized by contributions from the overlying epithelium and underlying mesenchymal cells, forming a flat lamellar “chicken wire” mesh (although labeled as a *membrane*, it is quite porous). The major constituents are amorphous nonfibrillar type IV collagen and laminin.

Components of the Extracellular Matrix. The components of ECM fall into three groups of proteins (Fig. 1-14):

- *Fibrous structural proteins* such as collagens and elastins that confer tensile strength and recoil

Figure 1-13 Main components of the extracellular matrix (ECM), including collagens, proteoglycans, and adhesive glycoproteins. Both epithelial and mesenchymal cells (e.g., fibroblasts) interact with ECM via integrins. Basement membranes and interstitial ECM have different architecture and general composition, although certain components are present in both. For the sake of clarity, many ECM components (e.g., elastin, fibrillin, hyaluronan, and syndecan) are not included.

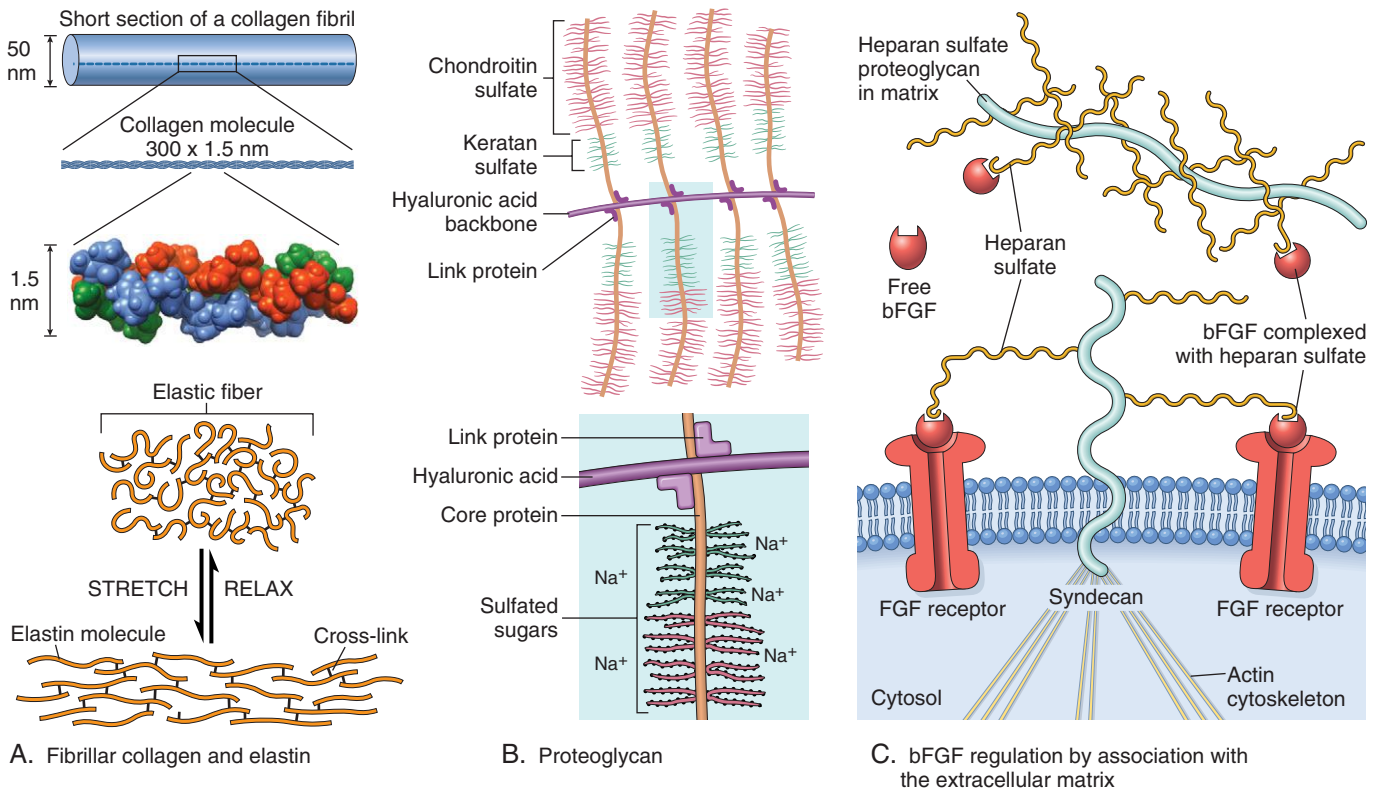

Figure 1-14 Extracellular matrix (ECM) components. **A**, Fibrillar collagen, and elastic tissue structures. Due to rodlike fibril stacking and extensive lateral cross-linking (through the activity of lysyl oxidase), collagen fibers have marked tensile strength but do not have much elasticity. Elastin is also massively cross-linked through lysyl oxidase activity but differs in having large hydrophobic segments that form a dense globular configuration at rest. As stretch is exerted, the hydrophobic domains are pulled open, but the cross-links keep the tissue intact; release of the stretch tension allows the hydrophobic domains of the proteins to refold. **B**, Proteoglycan structure. The highly negatively charged sulfated sugars on the proteoglycan “bristles” recruit sodium and water to generate a viscous, but compressible matrix. **C**, Regulation of basic fibroblast growth factor (bFGF, FGF-2) activity by ECM and cellular proteoglycans. Heparan sulfate binds bFGF secreted in the ECM. Syndecan is a cell surface proteoglycan with a transmembrane core protein and extracellular glycosaminoglycan side chains that can bind bFGF, with a cytoplasmic tail that interacts with the intracellular actin cytoskeleton. Syndecan side chains bind bFGF released from damaged ECM, thus facilitating a concentrated interaction with cell surface receptors.

Figure 1-15 Collagen biosynthetic pathway. The α -chains that make up a fibrillar collagen molecule are synthesized as precursor pro- α -chains, with large globular polypeptide regions flanking the central triple-helical domain. After proline and lysine hydroxylation and lysine glycosylation within the endoplasmic reticulum, three procollagen chains align to form a triple helix. For all the fibrillar collagens, the C-propeptide is completely removed by endoprotease activity after secretion, and the resulting triple-helical rod-like domains polymerize in a staggered fashion into fibrillar arrays. After secretion, the collagen achieves lateral stability through collagen cross-linking involving lysyl oxidase and the previously hydroxylated residues. Defects in primary sequence, procollagen endoprotease processing, hydroxylation, or cross-linking can all lead to weak connective tissues. The specific tissues affected (e.g., blood vessels, skin, bone, ligaments) by such disorders is based on the type of collagen that predominates in that tissue.

- *Water-hydrated gels* such as proteoglycans and hyaluronan that permit compressive resistance and lubrication
- *Adhesive glycoproteins* that connect ECM elements to one another and to cells

Collagens. Collagens are typically composed of three separate polypeptide chains braided into a ropelike triple helix (Fig. 1-15). About 30 collagen types have been identified, some of which are unique to specific cells and tissues.

- Some collagen types (e.g., types I, II, III, and V collagens) form linear fibrils stabilized by interchain hydrogen bonding; such *fibrillar collagens* form a major proportion of the connective tissue in structures such as bone, tendon, cartilage, blood vessels, and skin, as well as in healing wounds and particularly scars. The tensile strength of the fibrillar collagens derives from lateral cross-linking of the triple helices, formed by covalent bonds facilitated by the activity of lysyl oxidase. Since this process is dependent on vitamin C, children with ascorbate deficiency have skeletal deformities, and people of any age with vitamin C deficiency bleed easily because of weak vascular wall basement membrane, and heal poorly. Genetic defects in collagens cause diseases such as *osteogenesis imperfecta* and certain forms of *Ehlers-Danlos syndrome* (Chapter 5).
- *Non-fibrillar collagens* may contribute to the structures of planar basement membranes (type IV collagen); help

regulate collagen fibril diameters or collagen-collagen interactions via so-called *fibril-associated collagen with interrupted triple helices* (FACITs, such as type IX collagen in cartilage); or provide anchoring fibrils to basement membrane beneath stratified squamous epithelium (type VII collagen).

Elastin. The ability of tissues to recoil and recover their shape after physical deformation is conferred by elastin (Fig. 1-14). This is especially important in cardiac valves and for large blood vessels (that must accommodate recurrent pulsatile flow), as well as in the uterus, skin, and ligaments. Morphologically, elastic fibers consist of a central core of elastin with an associated meshlike network composed of fibrillin. The latter relationship partially explains why fibrillin synthetic defects lead to skeletal abnormalities and weakened aortic walls, as in individuals with Marfan syndrome (Chapter 5).

Proteoglycans and hyaluronan (Fig. 1-14). Proteoglycans form highly hydrated compressible gels that confer resistance to compressive forces; in joint cartilage, proteoglycans also provide a layer of lubrication between adjacent bony surfaces. Proteoglycans consist of long polysaccharides, called *glycosaminoglycans* (examples are keratan sulfate and chondroitin sulfate) attached to a core protein; these are then linked to a long hyaluronic acid polymer

Figure 1-16 Cell and extracellular matrix (ECM) interactions: adhesive glycoproteins and integrin signaling. **A**, *Fibronectin* consists of a disulfide-linked dimer, with several distinct domains that allow binding to ECM and to integrins, the latter through arginine-glycine-aspartic acid (RGD) motifs. **B**, The cross-shaped *laminin* molecule is one of the major components of basement membranes; its multi-domain structure allows interactions between type IV collagen, other ECM components, and cell-surface receptors. **C**, Integrins and integrin-mediated signaling events at focal adhesion complexes. Each α - β heterodimeric integrin receptor is a transmembrane dimer that links ECM and intracellular cytoskeleton. It is also associated with a complex of linking molecules (e.g., vinculin, and talin) that can recruit and activate kinases that ultimately trigger downstream signaling cascades.

called *hyaluronan*, in a manner reminiscent of the bristles on a test tube brush. The highly negatively charged nature of the densely packed sulfated sugars pulls in cations (mostly sodium) that, in turn, osmotically attract water; the result is a viscous, gelatin-like matrix. Besides providing compressibility to tissues, proteoglycans also serve as reservoirs for growth factors secreted into the ECM (e.g., FGF and HGF). Some proteoglycans are integral cell membrane proteins that have roles in cell proliferation, migration, and adhesion, for example, by binding growth factors and chemokines and providing high local concentrations of these mediators (Fig. 1-14).

Adhesive glycoproteins and adhesion receptors are structurally diverse molecules variously involved in cell-to-cell adhesion, linking cells to the ECM, and the interactions between ECM components (Fig. 1-16). Prototypical adhesive glycoproteins include *fibronectin* (a major component of the interstitial ECM) and *laminin* (a major constituent of basement membrane). *Integrins* are representative of the adhesion receptors, also known as cell adhesion molecules (CAMs); the CAMs also include immunoglobulins, cadherins, and selectins.

- *Fibronectin* is a large (450 kD) disulfide-linked heterodimer that exists in tissue and plasma forms; it is synthesized by a variety of cells, including fibroblasts, monocytes, and endothelium. Fibronectin has specific domains that can bind to distinct ECM components

(e.g., collagen, fibrin, heparin, and proteoglycans), as well as integrins (Fig. 1-16). In healing wounds, tissue and plasma fibronectin provide the scaffolding for subsequent ECM deposition, angiogenesis, and reepithelialization.

- *Laminin* is the most abundant glycoprotein in basement membrane. It is an 820-kD cross-shaped heterotrimer that connects cells to underlying ECM components such as type IV collagen and heparan sulfate (Fig. 1-16). Besides mediating attachment to basement membrane, laminin can also modulate cell proliferation, differentiation, and motility.
- *Integrins* are a large family of transmembrane heterodimeric glycoproteins (composed of α - and β -subunits) that allow cells to attach to ECM constituents such as laminin and fibronectin, thus functionally and structurally linking the intracellular cytoskeleton with the outside world. Integrins on the surface of leukocytes are also essential in mediating firm adhesion and transmigration across endothelium at sites of inflammation (Chapter 3), and they play a critical role in platelet aggregation (Chapter 4). Integrins attach to ECM components via a tripeptide arginine-glycine-aspartic acid motif (abbreviated RGD). Besides providing focal attachment to underlying substrates, binding through the integrin receptors can also trigger signaling cascades that can influence cell locomotion, proliferation, shape, and differentiation (Fig. 1-16).

Maintaining Cell Populations

Proliferation and the Cell Cycle

Cell proliferation is fundamental to development, maintenance of steady-state tissue homeostasis, and replacement of dead or damaged cells. The key elements of cellular proliferation are accurate DNA replication accompanied by the coordinated synthesis of all other cellular constituents, followed by equal apportionment of DNA and other cellular constituents (e.g., organelles) to daughter cells through mitosis and cytokinesis.

The sequence of events that results in cell division is called the *cell cycle*; it consists of G_1 (presynthetic *growth*), S (DNA *synthesis*), G_2 (premitotic *growth*), and M (*mitotic*) phases (Fig. 1-17). Quiescent cells that are not actively cycling are said to be in the G_0 state. Cells can enter G_1 either from the G_0 quiescent cell pool, or after completing a round of mitosis, as for continuously replicating cells. Each stage requires completion of the previous step, as well as activation of necessary factors (see later); nonfidelity of DNA replication, or cofactor deficiency result in arrest at the various transition points.

The cell cycle is regulated by activators and inhibitors. Cell cycle progression is driven by proteins called *cyclins*—named for the cyclic nature of their production and degradation—and cyclin-associated enzymes called *cyclin-dependent kinases* (CDKs) (Fig. 1-18). CDKs acquire the ability to phosphorylate protein substrates (i.e., kinase activity) by forming complexes with the relevant cyclins. Transiently increased synthesis of a particular cyclin leads to increased kinase activity of the appropriate CDK binding partner; as the CDK completes its round of phosphorylation, the associated cyclin is degraded and the CDK activity

abates. Thus, as cyclin levels rise and fall, the activity of associated CDKs likewise wax and wane.

More than 15 cyclins have been identified; cyclins D, E, A, and B appear sequentially during the cell cycle and bind to one or more CDKs. The cell cycle can thus be conceived as a relay race in which each leg is regulated by a distinct set of cyclins: as one collection of cyclins leaves the track, the next set takes over.

Embedded in the cell cycle are surveillance mechanisms primed to sense DNA or chromosomal damage. These quality control *checkpoints* ensure that cells with genetic imperfections do not complete replication. Thus, the G_1 -S checkpoint monitors the integrity of DNA before irreversibly committing cellular resources to DNA replication. Later in the cell cycle, the G_2 -M restriction point ensures that there has been accurate genetic replication before the cell actually divides. When cells do detect DNA irregularities, checkpoint activation delays cell cycle progression and triggers DNA repair mechanisms. If the genetic derangement is too severe to be repaired, the cells will undergo apoptosis; alternatively, they may enter a nonreplicative state called *senescence*—primarily through p53-dependent mechanisms (see later).

Enforcing the cell cycle checkpoints is the job of *CDK inhibitors* (CDKIs); they accomplish this by modulating CDK-cyclin complex activity. There are several different CDKIs:

- One family—composed of three proteins called *p21* (CDKN1A), *p27* (CDKN1B), and *p57* (CDKN1C)—broadly inhibits multiple CDKs.
- The other family of CDKI proteins has selective effects on cyclin CDK4 and cyclin CDK6; these proteins are called *p15* (CDKN2B), *p16* (CDKN2A), *p18* (CDKN2C), and *p19* (CDKN2D).

Figure 1-17 Cell cycle landmarks. The figure shows the cell cycle phases (G_0 , G_1 , G_2 , S, and M), the location of the G_1 restriction point, and the G_1/S and G_2/M cell cycle checkpoints. Cells from labile tissues such as the epidermis and the GI tract may cycle continuously; stable cells such as hepatocytes are quiescent but can enter the cell cycle; permanent cells such as neurons and cardiac myocytes have lost the capacity to proliferate. (Modified from Pollard TD, Earnshaw WC: Cell Biology. Philadelphia, Saunders, 2002.)

Figure 1-18 Role of cyclins, cyclin-dependent kinases (CDKs), and CDK inhibitors in regulating the cell cycle. The shaded arrows represent the phases of the cell cycle during which specific cyclin-CDK complexes are active. As illustrated, cyclin D-CDK4, cyclin D-CDK6, and cyclin E-CDK2 regulate the G₁-to-S transition by phosphorylating the Rb protein (pRb). Cyclin A-CDK2 and cyclin A-CDK1 are active in the S phase. Cyclin B-CDK1 is essential for the G₂-to-M transition. Two families of CDK inhibitors can block activity of CDKs and progression through the cell cycle. The so-called INK4 inhibitors, composed of p16, p15, p18, and p19, act on cyclin D-CDK4 and cyclin D-CDK6. The other family of three inhibitors, p21, p27, and p57, can inhibit all CDKs.

Defective CDKI checkpoint proteins allow cells with damaged DNA to divide, resulting in mutated daughter cells with the potential of developing into malignant tumors.

An equally important aspect of cell growth and division is the biosynthesis of other cellular components needed to make two daughter cells, such as membranes and organelles. At the same time that growth factor receptor signaling stimulates cell cycle progression, it also activates events that promote changes in cellular metabolism that support growth. Chief among these is the Warburg effect, mentioned earlier, which is marked by increased cellular uptake of glucose and glutamine, increased glycolysis, and (counter-intuitively) decreased oxidative phosphorylation. These changes become fixed in cancer cells and are discussed in greater detail in [Chapter 7](#).

Stem Cells

During development, stem cells give rise to all the various differentiated tissues; in the adult organism, stem cells

replace damaged cells and maintain tissue populations as individual cells within them undergo replicative senescence due to attrition of telomeres (described in [chapter 2](#)). There is a homeostatic equilibrium between the replication, self-renewal, and differentiation of stem cells and the death of the mature, fully differentiated cells ([Fig. 1-19](#)). The dynamic relationship between stem cells and terminally differentiated parenchyma is particularly evident in the continuously dividing epithelium of the skin. Thus, stem cells at the basal layer of the epithelium progressively differentiate as they migrate to the upper layers of the epithelium before dying and being shed.

Stem cells are characterized by two important properties:

- *Self-renewal*, which permits stem cells to maintain their numbers.
- *Asymmetric division*, in which one daughter cell enters a differentiation pathway and gives rise to mature cells, while the other remains undifferentiated and retains its self-renewal capacity.

Figure 1-19 Mechanisms regulating cell populations. Cell numbers can be altered by increased or decreased rates of stem cell input, cell death due to apoptosis, or changes in the rates of proliferation or differentiation. (Modified from McCarthy NJ, et al: Apoptosis in the development of the immune system: growth factors, clonal selection and bcl-2. *Cancer Metastasis Rev* 11:157, 1992.)

Although there is a tendency in the scientific literature to partition stem cells into several different subsets, fundamentally there are only two varieties:

- **Embryonic stem cells (ES cells)** are the most undifferentiated. They are present in the inner cell mass of the blastocyst, have virtually limitless cell renewal capacity, and can give rise to every cell in the body; they are thus

said to be *totipotent* (Fig. 1-20). While ES cells can be maintained for extended periods without differentiating, they can be induced under appropriate culture conditions to form specialized cells of all three germ cell layers, including neurons, cardiac muscle, liver cells, and pancreatic islet cells.

- **Tissue stem cells** (also called *adult stem cells*) are found in intimate association with the differentiated cells of a given tissue. They are normally protected within specialized tissue microenvironments called *stem cell niches*. Such niches have been demonstrated in many organs—including the brain, where neural stem cells inhabit the subventricular zone and dentate gyrus. Skin stem cells are found in the bulge region of the hair follicle, and in the cornea they are found at the limbus. Soluble factors and other cells within the niches keep the stem cells quiescent until there is a need for expansion and differentiation of the precursor pool (Fig. 1-21). Adult stem cells have a limited repertoire of differentiated cells that they can generate. Thus, although adult stem cells can maintain tissues with high (e.g., skin, and gastrointestinal tract) or low (e.g., heart and brain) cell turnover, the adult stem cells in any given tissue can usually only produce cells that are normal constituents of that tissue.

The most extensively studied of the tissue stem cells are the hematopoietic stem cells that continuously replenish all the cellular elements of the blood as they are consumed. Hematopoietic stem cells may be isolated directly from bone marrow, as well as from the peripheral blood after administration of certain colony stimulating factors (CSF) that induce their release from bone marrow niches. Although rare, hematopoietic stem cells can be purified to virtual homogeneity based on cell surface markers and ability to give rise to blood cell of lineages. Clinically, these stem cells can be used to repopulate marrows depleted

Figure 1-20 Embryonic stem cells. The zygote, formed by the union of sperm and egg, divides to form blastocysts, and the inner cell mass of the blastocyst generates the embryo. The pluripotent cells of the inner cell mass, known as embryonic stem (ES) cells, can be induced to differentiate into cells of multiple lineages. In the embryo, pluripotent stem cells can asymmetrically divide to yield a residual stable pool of ES cells in addition to generating populations that have progressively more restricted developmental capacity, eventually generating stem cells that are committed to just specific lineages. ES cells can be cultured *in vitro* and be induced to give rise to cells of all three lineages.

Figure 1-21 Stem cell niches in various tissues. **A**, Skin stem cells are located in the bulge area of the hair follicle, in sebaceous glands, and in the lower layer of the epidermis. **B**, Small intestine stem cells are located near the base of the crypt, above Paneth cells. **C**, Liver stem cells (*oval cells*) are located in the canals of Hering (*thick arrow*), structures that connect bile ductules (*thin arrow*) to parenchymal hepatocytes. Bile duct cells and canals of Hering are stained here with an immunohistochemical stain for cytokeratin 7. (**C**, Courtesy Tania Roskams, MD, University of Leuven, Belgium).

after chemotherapy (e.g., for leukemia), or to provide normal precursors to correct various blood cell defects (e.g., sickle cell disease, [Chapter 14](#)).

Besides hematopoietic stem cells, the bone marrow (and notably, other tissues such as fat) also contains a population of *mesenchymal stem cells*. These are multipotent cells that can differentiate into a variety of stromal cells including chondrocytes (cartilage), osteocytes (bone), adipocytes (fat), and myocytes (muscle). Because these cells can be expanded to large numbers, and can also generate a locally immunosuppressive microenvironment (thus potentially evading rejection), they may represent a ready means of manufacturing the stromal cellular scaffolding for tissue regeneration.

Regenerative Medicine

The ability to identify, isolate, expand, and transplant stem cells has given birth to the new field of regenerative medicine. Theoretically, the differentiated progeny of ES or adult stem cells can be used to repopulate damaged tissues, or to construct entire organs for replacement. In particular, there is considerable excitement about the therapeutic opportunities for restoring damaged tissues that have low intrinsic regenerative capacity, such as myocardium after a myocardial infarct or neurons after a stroke. Unfortunately, despite an improving ability to purify and expand stem cell populations, much of the initial enthusiasm has been tempered by difficulties encountered in introducing and *functionally integrating* the replacement cells into sites of damage.

Another potential problem is the immunogenicity of most stem cells; although mesenchymal stem cells may be weakly immunogenic, most other adult stem cells, as well as ES cells (from fertilized blastocysts), express histocompatibility (HLA) molecules of the sperm and egg donors that provoke immunologic rejection by the host ([Chapter 6](#)). Hence, considerable effort has been expended to generate cells that are totipotent like ES cells but are derived from the patient into whom they will be implanted. To accomplish this, a handful of genes have been identified whose products can—remarkably—reprogram somatic

cells to achieve the “stem-ness” of ES cells. When such genes are introduced into fully differentiated cells (e.g., fibroblasts), *induced pluripotent stem cells (iPS cells)* are generated ([Fig. 1-22](#)). Since these cells are derived from the patient, their differentiated progeny (e.g., insulin-secreting β -cells in a patient with diabetes) can be engrafted without eliciting a rejection reaction. Another exciting recent development is genomic editing, a process using a nuclease

Figure 1-22 The production of induced pluripotent stem cells (iPS cells). Genes that confer stem cell properties are introduced into a patient's differentiated cells, giving rise to stem cells that can be induced to differentiate into various lineages. (Modified from Hochedlinger K, Jaenisch R: Nuclear transplantation, embryonic stem cells, and the potential for cell therapy. *N Engl J Med* 349:275-286, 2003.)

called Cas9 that was originally identified in prokaryotes that can be used together with guide RNAs called CRISPRs to selectively alter or correct DNA sequences, such as disease-causing mutations. While iPS cells and Cas9 technology hold considerable promise, whether they are the Holy Grail of tissue regeneration remains to be seen.

Concluding Remarks. This survey of selected topics in cell biology will serve as a basis for our later discussions of pathology, and we will refer back to it throughout the book. Students should, however, remember that this summary is intentionally brief, and more information about some of the fascinating topics reviewed here can be readily found in textbooks devoted to cell and molecular biology.

Introduction to Pathology

Pathology is devoted to the study of the structural, biochemical, and functional changes in cells, tissues, and organs that underlie disease. By the use of molecular, microbiologic, immunologic, and morphologic techniques, pathology attempts to explain the whys and wherefores of the signs and symptoms manifested by patients while providing a rational basis for clinical care and therapy. It thus serves as the bridge between the basic sciences and clinical medicine, and is the scientific foundation for all of

medicine. In [chapter 1](#) we examined the cellular and molecular mechanisms that “define” healthy cells. In this chapter we will build upon that knowledge to discuss the fundamental mechanisms that underlie various forms of cell injury and death.

Traditionally the study of pathology is divided into general pathology and systemic pathology. General pathology is concerned with the common reactions of cells and tissues to injurious stimuli. Such reactions are often not tissue specific: thus acute inflammation in response to bacterial infections produces a very similar reaction in most tissues. On the other hand, systemic pathology examines

the alterations and underlying mechanisms in organ specific diseases such as ischemic heart disease. In this book we first cover the principles of general pathology and then proceed to specific disease processes as they affect particular organs or systems.

The four aspects of a disease process that form the core of pathology are its cause (*etiology*), the biochemical and molecular mechanisms of its development (*pathogenesis*), the structural alterations induced in the cells and organs of the body (*morphologic changes*), and the functional consequences of these changes (*clinical manifestations*).

Etiology or Cause. Although there are myriads of factors that cause disease, they can all be grouped into two classes: genetic (e.g., inherited mutations and disease-associated gene variants, or polymorphisms) and acquired (e.g., infectious, nutritional, chemical, physical). The idea that one etiologic agent is the cause of one disease—developed from the study of infections and inherited disorders caused by single genes—is not applicable to the majority of diseases. In fact, most of our common afflictions, such as atherosclerosis and cancer, are multifactorial and arise from the effects of various external triggers on a genetically susceptible individual. The relative contribution of inherited susceptibility and external influences varies in different diseases.

Pathogenesis. *Pathogenesis refers to the sequence of cellular, biochemical, and molecular events that follow the exposure of cells or tissues to an injurious agent.* The study of pathogenesis remains one of the main domains of pathology. Even when the initial cause is known (e.g., infection or mutation), it is many steps removed from the expression of the disease. For example, to understand cystic fibrosis it is essential to know not only the defective gene and gene product, but also the biochemical and morphologic events leading to the formation of cysts and fibrosis in the lungs, pancreas, and other organs. Indeed, as we shall see throughout the book, the mutated genes underlying a great number of diseases have been identified, but the functions of the encoded proteins and how mutations induce disease—the pathogenesis—are still not fully understood. With more research into clinical genomics it may become feasible to link specific molecular abnormalities to disease manifestations and to possibly use this knowledge to design new therapeutic approaches. For these reasons, the study of pathogenesis has never been more exciting scientifically or more relevant to medicine.

Morphologic Changes. *Morphologic changes refer to the structural alterations in cells or tissues that are either characteristic of a disease or diagnostic of an etiologic process.* Traditionally, the practice of diagnostic pathology has used morphology to determine the nature of disease and to follow its progression. Although morphology remains a diagnostic cornerstone, its limitations have been evident for many years. For example, morphologically identical lesions may arise by distinct molecular mechanisms. Nowhere is this more striking than in the study of tumors; breast cancers that are indistinguishable morphologically may have widely different courses, therapeutic responses, and prognosis. Molecular analysis by techniques such as next generation sequencing (Chapter 5) has

begun to reveal genetic differences that predict the behavior of the tumors as well as their responsiveness to different therapies. Increasingly, targeted therapies based on molecular alterations are being used for the treatment of cancers. Hence the field of diagnostic pathology has expanded to include molecular biologic and proteomic approaches for analyzing disease states.

Functional Derangements and Clinical Manifestations. The end results of genetic, biochemical, and structural changes in cells and tissues are functional abnormalities, which lead to the clinical manifestations (symptoms and signs) of disease, as well as its progress (clinical course and outcome). Hence, clinicopathologic correlations are very important in the study of disease.

Virtually all forms of disease start with molecular or structural alterations in cells. This concept of the cellular basis of disease was first put forth in the nineteenth century by Rudolf Virchow, known as the father of modern pathology. We therefore begin our consideration of pathology with the study of the causes, mechanisms, and morphologic and biochemical correlates of *cell injury*. Injury to cells and to extracellular matrix ultimately leads to *tissue and organ injury*, which determines the morphologic and clinical patterns of disease.

Overview: Cellular Responses to Stress and Noxious Stimuli

The normal cell is confined to a fairly narrow range of function and structure by its state of metabolism, differentiation, and specialization; by constraints of neighboring cells; and by the availability of metabolic substrates. It is nevertheless able to handle physiologic demands, maintaining a steady state called *homeostasis*. *Adaptations* are reversible functional and structural responses to changes

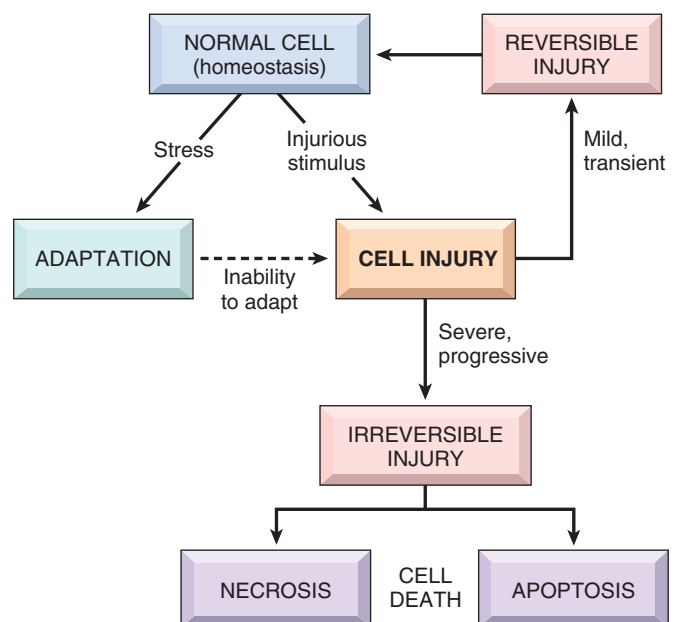

Figure 2-1 Stages of the cellular response to stress and injurious stimuli.

Table 2-1 Cellular Responses to Injury

Nature of Injurious Stimulus	Cellular Response
Altered physiologic stimuli; some nonlethal injurious stimuli	Cellular adaptations
Increased demand, increased stimulation (e.g., by growth factors, hormones)	Hyperplasia, hypertrophy
Decreased nutrients, decreased stimulation	Atrophy
Chronic irritation (physical or chemical)	Metaplasia
Reduced oxygen supply; chemical injury; microbial infection	Cell injury
Acute and transient	Acute reversible injury Cellular swelling fatty change
Progressive and severe (including DNA damage)	Irreversible injury → cell death Necrosis Apoptosis
Metabolic alterations, genetic or acquired; chronic injury	Intracellular accumulations; calcification
Cumulative sublethal injury over long life span	Cellular aging

in physiologic states (e.g., pregnancy) and some pathologic stimuli, during which new but altered steady states are achieved, allowing the cell to survive and continue to function (Fig. 2-1 and Table 2-1). The adaptive response may consist of an increase in the size of cells (hypertrophy) and functional activity, an increase in their number

(hyperplasia), a decrease in the size and metabolic activity of cells (atrophy), or a change in the phenotype of cells (metaplasia). When the stress is eliminated the cell can recover to its original state without having suffered any harmful consequences.

If the limits of adaptive responses are exceeded or if cells are exposed to injurious agents or stress, deprived of essential nutrients, or become compromised by mutations that affect essential cellular constituents, a sequence of events follows that is termed **cell injury** (Fig. 2-1). Cell injury is *reversible* up to a certain point, but if the stimulus persists or is severe enough from the beginning, the cell suffers *irreversible injury* and ultimately undergoes *cell death*. *Adaptation*, *reversible injury*, and *cell death* may be stages of progressive impairment following different types of insults. For instance, in response to increased hemodynamic loads, the heart muscle becomes enlarged, a form of adaptation, and can then become injured. If the blood supply to the myocardium is compromised or inadequate, the muscle first suffers reversible injury, manifested by certain cytoplasmic changes (described later). Eventually, the cells suffer irreversible injury and die (Fig. 2-2).

Cell death, the end result of progressive cell injury, is one of the most crucial events in the evolution of disease in any tissue or organ. It results from diverse causes, including ischemia (reduced blood flow), infection, and toxins. Cell death is also a normal and essential process in embryogenesis, the development of organs, and the maintenance of

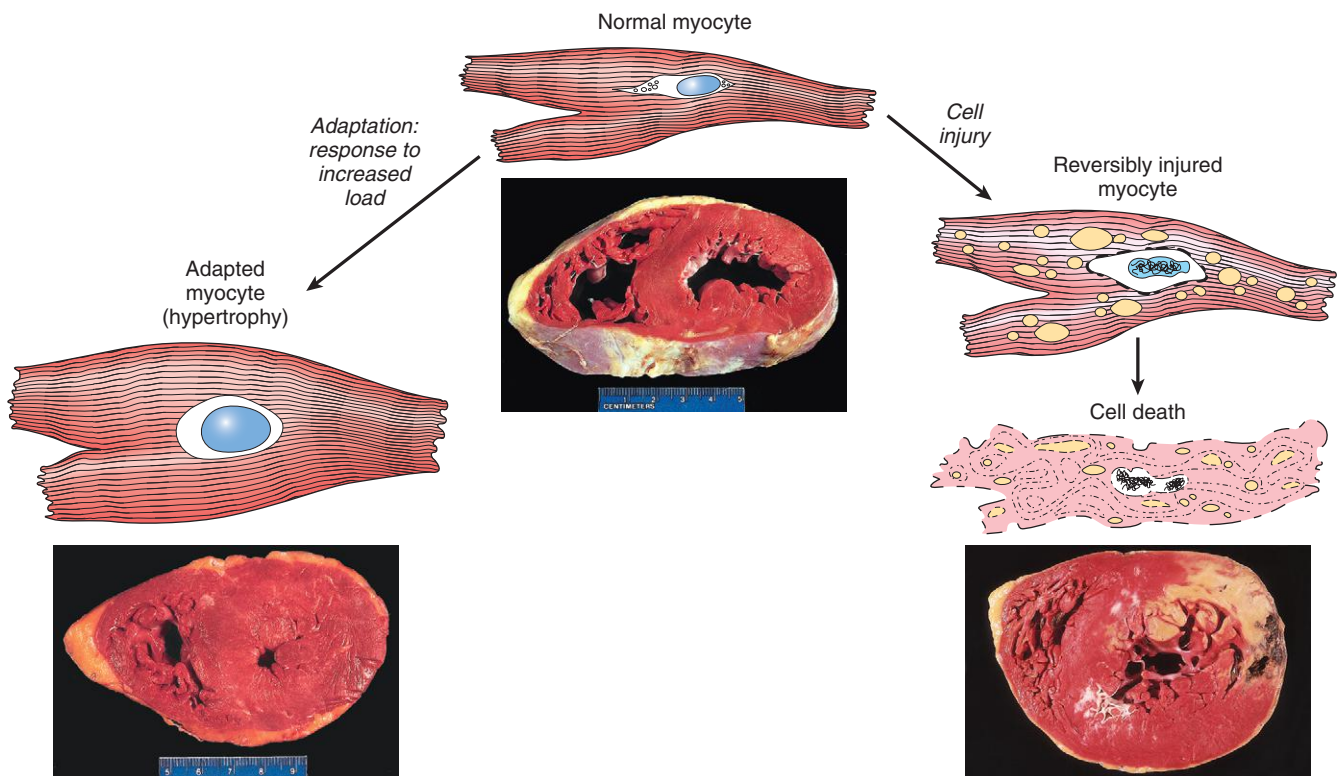

Figure 2-2 The relationship between normal, adapted, reversibly injured, and dead myocardial cells. All three transverse sections of the heart have been stained with triphenyltetrazolium chloride, an enzyme substrate that colors viable myocardium magenta. The cellular adaptation shown here is myocardial hypertrophy (lower left), caused by increased blood pressure requiring greater mechanical effort by myocardial cells. This adaptation leads to thickening of the left ventricular wall (compare with the normal heart). In reversibly injured myocardium (illustrated schematically, right), there are functional alterations, usually without any gross or microscopic changes but sometimes with cytoplasmic changes such as cellular swelling and fat accumulation. In the specimen showing necrosis, a form of cell death (lower right), the light area in the posterolateral left ventricle represents an acute myocardial infarction caused by reduced blood flow (ischemia).

homeostasis. There are two principal pathways of cell death, *necrosis* and *apoptosis*. Nutrient deprivation triggers an adaptive cellular response called *autophagy* that may also culminate in cell death. A detailed discussion of these pathways of cell death follows later in the chapter.

Stresses of different types may induce changes in cells and tissues other than typical adaptations, cell injury, and death (Table 2-1). Metabolic derangements in cells and sublethal, chronic injury may be associated with *intracellular accumulations* of a number of substances, including proteins, lipids, and carbohydrates. Calcium is often deposited at sites of cell death, resulting in *pathologic calcification*. Finally, the normal process of *aging* is accompanied by characteristic morphologic and functional changes in cells.

This chapter discusses first how cells adapt to stresses, and then the causes, mechanisms, and consequences of the various forms of acute cell damage, including reversible cell injury, and cell death. We conclude with three other processes that affect cells and tissues: intracellular accumulations, pathologic calcification, and cell aging.

Adaptations of Cellular Growth and Differentiation

Adaptations are reversible changes in the size, number, phenotype, metabolic activity, or functions of cells in response to changes in their environment. Such adaptations may take several distinct forms.

Hypertrophy

Hypertrophy refers to an increase in the size of cells, that results in an increase in the size of the affected organ. The hypertrophied organ has no new cells, just larger cells. The increased size of the cells is due to the synthesis and assembly of additional intracellular structural components.

Cells capable of division may respond to stress by undergoing both hyperplasia (described later) and hypertrophy, whereas in non dividing (e.g., myocardial fibers) increased tissue mass is due to hypertrophy. In many organs hypertrophy and hyperplasia may coexist and contribute to increased size.

Hypertrophy can be *physiologic* or *pathologic*; the former is caused by increased functional demand or by stimulation by hormones and growth factors. The striated muscle cells in the heart and skeletal muscles have only a limited capacity for division, and respond to increased metabolic demands mainly by undergoing hypertrophy. *The most common stimulus for hypertrophy of muscle is increased workload.* For example, the bulging muscles of bodybuilders engaged in “pumping iron” result from enlargement of individual muscle fibers in response to increased demand. In the heart, the stimulus for hypertrophy is usually chronic hemodynamic overload, resulting from either hypertension or faulty valves (Fig. 2-2). In both tissue types the muscle cells synthesize more proteins and the number of myofilaments increases. This increases the amount of force each myocyte can generate, and thus increases the strength and work capacity of the muscle as a whole.

The massive physiologic growth of the uterus during pregnancy is a good example of hormone-induced enlargement of an organ that results mainly from hypertrophy of muscle fibers (Fig. 2-3). Uterine hypertrophy is stimulated by estrogenic hormones acting on smooth muscle through estrogen receptors, eventually resulting in increased synthesis of smooth muscle proteins and an increase in cell size.

Mechanisms of Hypertrophy

Hypertrophy is the result of increased production of cellular proteins. Much of our understanding of hypertrophy is based on studies of the heart. There is great interest in defining the molecular basis of hypertrophy since beyond a certain point, hypertrophy of the heart becomes maladaptive and can lead to heart failure, arrhythmias and

Figure 2-3 Physiologic hypertrophy of the uterus during pregnancy. **A**, Gross appearance of a normal uterus (*right*) and a gravid uterus (removed for postpartum bleeding) (*left*). **B**, Small spindle-shaped uterine smooth muscle cells from a normal uterus, compared with **C**, large plump cells from the gravid uterus, at the same magnification.

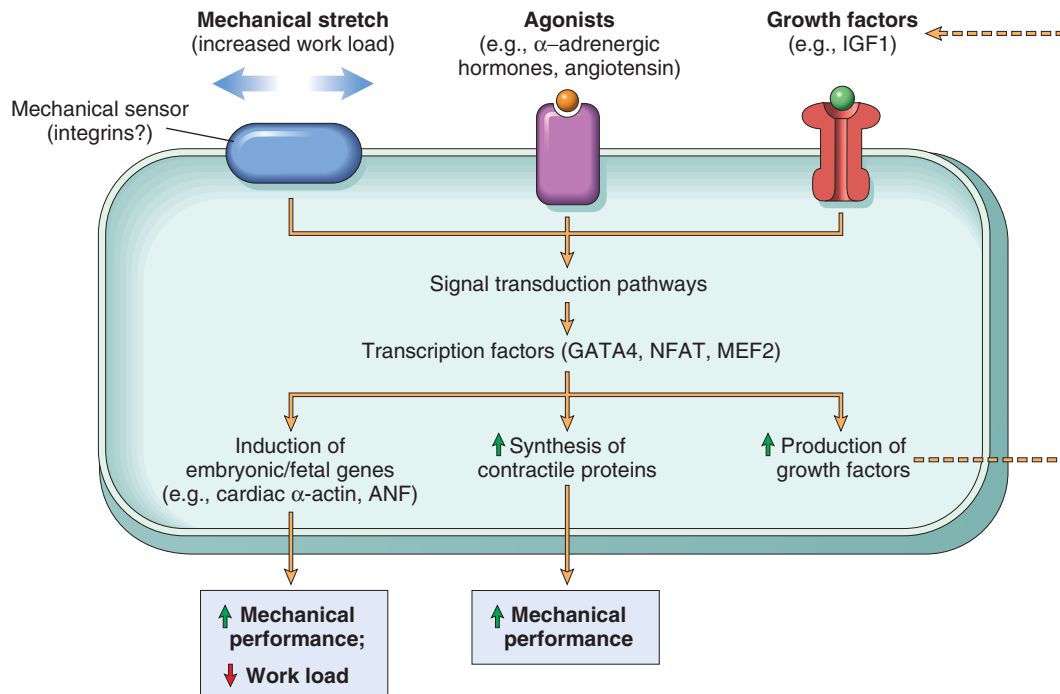

Figure 2-4 Biochemical mechanisms of myocardial hypertrophy. The major known signaling pathways and their functional effects are shown. Mechanical sensors appear to be the major triggers for physiologic hypertrophy, and agonists and growth factors may be more important in pathologic states. ANF, Atrial natriuretic factor; GATA4, transcription factor that binds to DNA sequence GATA; IGF1, insulin-like growth factor; NFAT, nuclear factor activated T cells; MEF2, myocardial enhancing factor 2.

sudden death (Chapter 11). There are three basic steps in the molecular pathogenesis of cardiac hypertrophy:

- The integrated actions of mechanical sensors (that are triggered by increased workload), growth factors (including TGF- β , insulin-like growth factor 1 [IGF1], fibroblast growth factor), and vasoactive agents (e.g., α -adrenergic agonists, endothelin-1, and angiotensin II). Indeed, mechanical sensors themselves induce production of growth factors and agonists (Fig. 2-4).
- These signals originating in the cell membrane activate a complex web of signal transduction pathways. Two such biochemical pathways involved in muscle hypertrophy are the phosphoinositide 3-kinase (PI3K)/AKT pathway (postulated to be most important in physiologic, e.g., exercise-induced, hypertrophy) and signaling downstream of G-protein-coupled receptors (induced by many growth factors and vasoactive agents, and thought to be more important in pathologic hypertrophy).
- These signaling pathways activate a set of transcription factors such as GATA4, nuclear factor of activated T cells (NFAT), and myocyte enhancer factor 2 (MEF2). These transcription factors work coordinately to increase the synthesis of muscle proteins that are responsible for hypertrophy.

Hypertrophy is also associated with a switch of contractile proteins from adult to fetal or neonatal forms. For example, during muscle hypertrophy, the α isoform of myosin heavy chain is replaced by the β isoform, which has a slower, more energetically economical contraction. In addition, some genes that are expressed only during early

development are reexpressed in hypertrophic cells, and the products of these genes participate in the cellular response to stress. For example, the gene for atrial natriuretic factor is expressed in both the atrium and the ventricle in the embryonic heart, but it is down-regulated after birth. Cardiac hypertrophy is associated with increased atrial natriuretic factor gene expression. Atrial natriuretic factor is a peptide hormone that causes salt secretion by the kidney, decreases blood volume and pressure, and therefore serves to reduce hemodynamic load.

Whatever the exact cause and mechanism of cardiac hypertrophy, it eventually reaches a limit beyond which enlargement of muscle mass is no longer able to cope with the increased burden. At this stage several regressive changes occur in the myocardial fibers, of which the most important are lysis and loss of myofibrillar contractile elements. In extreme cases myocyte death can occur. The net result of these changes is cardiac failure, a sequence of events that illustrates how an adaptation to stress can progress to functionally significant cell injury if the stress is not relieved.

To prevent such consequences, several drugs that inhibit key signaling pathways involving NFAT, GATA4, and MEF2 genes are in phase 1 or 2 clinical trials.

Hyperplasia

Hyperplasia is defined as an increase in the number of cells in an organ or tissue in response to a stimulus. Although hyperplasia and hypertrophy are distinct processes, they frequently occur together, and may be triggered by the same external stimulus. Hyperplasia can only

take place if the tissue contains cells capable of dividing; thus increasing the number of cells. It can be physiologic or pathologic.

Physiologic Hyperplasia

Physiologic hyperplasia due to the action of hormones or growth factors occurs in several circumstances: when there is a need to increase functional capacity of hormone sensitive organs; when there is need for compensatory increase after damage or resection. Hormonal hyperplasia is well illustrated by the proliferation of the glandular epithelium of the female breast at puberty and during pregnancy, usually accompanied by enlargement (hypertrophy) of the glandular epithelial cells. The classic illustration of compensatory hyperplasia comes from the study of liver regeneration. In individuals who donate one lobe of the liver for transplantation, the remaining cells proliferate so that the organ soon grows back to its original size. Experimental models of partial hepatectomy have been very useful for defining the mechanisms that stimulate regeneration of the liver (Chapter 3). Marrow is remarkable in its capacity to undergo rapid hyperplasia in response to a deficiency of terminally differentiated blood cells. For example, in the setting of an acute bleed or premature breakdown of red cells (hemolysis), feedback loops involving the growth factor erythropoietin are activated that stimulate the growth of red cell progenitors, allowing red cell production to increase as much as 8-fold. The regulation of hematopoiesis is discussed further in Chapter 13.

Pathologic Hyperplasia

Most forms of pathologic hyperplasia are caused by excessive or inappropriate actions of hormones or growth factors acting on target cells. Endometrial hyperplasia is an example of abnormal hormone-induced hyperplasia. Normally, after a menstrual period there is a rapid burst of proliferative activity in the endometrium that is stimulated by pituitary hormones and ovarian estrogen. It is brought to a halt by the rising levels of progesterone, usually about 10 to 14 days before the end of the menstrual period. In some instances, however, the balance between estrogen and progesterone is disturbed, resulting in absolute or relative increases in the amount of estrogen, with consequent hyperplasia of the endometrial glands. This form of pathologic hyperplasia is a common cause of abnormal menstrual bleeding. Benign prostatic hyperplasia is another common example of pathologic hyperplasia induced in responses to hormonal stimulation by androgens. Although these forms of pathologic hyperplasias are abnormal, the process remains controlled and the hyperplasia regresses if the hormonal stimulation is eliminated. As is discussed in Chapter 7, in cancer the growth control mechanisms become deregulated or ineffective because of genetic aberrations, that drive unrestrained proliferation. Thus, while hyperplasia is distinct from cancer, pathologic hyperplasia constitutes a fertile soil in which cancerous proliferations may eventually arise. For instance, patients with hyperplasia of the endometrium are at increased risk for developing endometrial cancer (Chapter 22).

Hyperplasia is a characteristic response to certain viral infections, such as papillomaviruses, which cause skin warts and several mucosal lesions composed of masses of hyperplastic epithelium. Here, the viruses make factors

that interfere with host proteins that regulate cell proliferation. Like other forms of hyperplasia, some of these virally induced proliferations are also precursors to cancer (Chapter 7).

Mechanisms of Hyperplasia

Hyperplasia is the result of growth factor-driven proliferation of mature cells and, in some cases, by increased output of new cells from tissue stem cells. For instance, after partial hepatectomy growth factors are produced in the liver that engage receptors on the surviving cells and activate signaling pathways that stimulate cell proliferation. But if the proliferative capacity of the liver cells is compromised, as in some forms of hepatitis causing cell injury, hepatocytes can instead regenerate from intrahepatic stem cells. The roles of growth factors and stem cells in cellular replication and tissue hyperplasia are discussed in more detail in Chapter 3.

Atrophy

Atrophy is defined as a reduction in the size of an organ or tissue due to a decrease in cell size and number. Atrophy can be physiologic or pathologic. *Physiologic atrophy* is common during normal development. Some embryonic structures, such as the notochord and thyroglossal duct, undergo atrophy during fetal development. The decrease in the size of the uterus that occurs shortly after parturition is another form of physiologic atrophy.

Pathologic atrophy has several causes and it can be local or generalized. The common causes of atrophy are the following:

- *Decreased workload (atrophy of disuse).* When a fractured bone is immobilized in a plaster cast or when a patient is restricted to complete bed rest, skeletal muscle atrophy rapidly ensues. The initial decrease in cell size is reversible once activity is resumed. With more prolonged disuse, skeletal muscle fibers decrease in number (due to apoptosis) as well as in size; muscle atrophy can be accompanied by increased bone resorption, leading to osteoporosis of disuse.
- *Loss of innervation (denervation atrophy).* The normal metabolism and function of skeletal muscle are dependent on its nerve supply. Damage to the nerves leads to atrophy of the muscle fibers supplied by those nerves (Chapter 27).
- *Diminished blood supply.* A gradual decrease in blood supply (ischemia) to a tissue as a result of slowly developing arterial occlusive disease results in atrophy of the tissue. In late adult life, the brain may undergo progressive atrophy, mainly because of reduced blood supply as a result of atherosclerosis (Fig. 2-5). This is called *senile atrophy*, which also affects the heart.
- *Inadequate nutrition.* Profound protein-calorie malnutrition (marasmus) is associated with the utilization of skeletal muscle proteins as a source of energy after other reserves such as adipose stores have been depleted. This results in marked muscle wasting (*cachexia*; Chapter 9). Cachexia is also seen in patients with chronic inflammatory diseases and cancer. In the former, chronic overproduction of the inflammatory cytokine tumor necrosis factor (TNF) is thought to be responsible for appetite

Figure 2-5 Atrophy. **A**, Normal brain of a young adult. **B**, Atrophy of the brain in an 82-year-old man with atherosclerotic cerebrovascular disease, resulting in reduced blood supply. Note that loss of brain substance narrows the gyri and widens the sulci. The meninges have been stripped from the right half of each specimen to reveal the surface of the brain.

suppression and lipid depletion, culminating in muscle atrophy.

- *Loss of endocrine stimulation.* Many hormone-responsive tissues, such as the breast and reproductive organs, are dependent on endocrine stimulation for normal metabolism and function. The loss of estrogen stimulation after menopause results in physiologic atrophy of the endometrium, vaginal epithelium, and breast.
- *Pressure.* Tissue compression for any length of time can cause atrophy. An enlarging benign tumor can cause atrophy in the surrounding uninvolved tissues. Atrophy in this setting is probably the result of ischemic changes caused by compromise of the blood supply by the pressure exerted by the expanding mass.

The fundamental cellular changes associated with atrophy are identical in all of these settings. The initial response is a decrease in cell size and organelles, which may reduce the metabolic needs of the cell sufficiently to permit its survival. In atrophic muscle, the cells contain fewer mitochondria and myofilaments and a reduced amount of rough endoplasmic reticulum (RER). By bringing into balance the cell's metabolic demands and the lower levels of blood supply, nutrition, or trophic stimulation, a new equilibrium is achieved. *Early in the process atrophic cells and tissues have diminished function, but cell death is minimal.* However, atrophy caused by gradually reduced blood supply may progress to the point at which cells are irreversibly injured and die, often by apoptosis. Cell death by apoptosis also contributes to the atrophy of endocrine organs after hormone withdrawal.

Mechanisms of Atrophy

Atrophy results from decreased protein synthesis and increased protein degradation in cells. Protein synthesis decreases because of reduced metabolic activity.

The degradation of cellular proteins occurs mainly by the ubiquitin-proteasome pathway. Nutrient deficiency and

disuse may activate ubiquitin ligases, which attach the small peptide ubiquitin to cellular proteins and target these proteins for degradation in *proteasomes*. This pathway is also thought to be responsible for the accelerated proteolysis seen in a variety of catabolic conditions, including cancer cachexia. In many situations, atrophy is also accompanied by increased *autophagy*, marked by the appearance of increased numbers of *autophagic vacuoles*. Autophagy ("self-eating") is the process in which the starved cell eats its own components in an attempt to reduce nutrient demand to match the supply. Some of the cell debris within the autophagic vacuoles may resist digestion and persist in the cytoplasm as membrane-bound *residual bodies*. An example of residual bodies is *lipofuscin granules*, discussed later in the chapter. When present in sufficient amounts, they impart a brown discoloration to the tissue (*brown atrophy*). Autophagy is associated with various types of cell injury, and we will discuss it in more detail later.

Metaplasia

Metaplasia is a reversible change in which one differentiated cell type (epithelial or mesenchymal) is replaced by another cell type. It often represents an adaptive response in which one cell type that is sensitive to a particular stress is replaced by another cell type that is better able to withstand the adverse environment.

The most common epithelial metaplasia is *columnar to squamous* (Fig. 2-6), as occurs in the respiratory tract in response to chronic irritation. In the habitual cigarette smoker, the normal ciliated columnar epithelial cells of the trachea and bronchi are often replaced by stratified squamous epithelial cells. Stones in the excretory ducts of the salivary glands, pancreas, or bile ducts, which are normally lined by secretory columnar epithelium, may also lead to squamous metaplasia by stratified squamous epithelium. A deficiency of vitamin A (retinoic acid) induces squamous metaplasia in the respiratory epithelium (Chapter 9). In all

Figure 2-6 Metaplasia of columnar to squamous epithelium. **A**, Schematic diagram. **B**, Metaplasia of columnar epithelium (*left*) to squamous epithelium (*right*) in a bronchus.

these instances the more rugged stratified squamous epithelium is able to survive under circumstances in which the more fragile specialized columnar epithelium might have succumbed. However, the change to metaplastic squamous cells comes with a price. In the respiratory tract, for example, although the epithelial lining becomes tough, important mechanisms of protection against infection—mucus secretion and the ciliary action of the columnar epithelium—are lost. Thus, epithelial metaplasia is a double-edged sword and, in most circumstances, represents an undesirable change. Moreover, *the influences that predispose to metaplasia, if persistent, can initiate malignant transformation in metaplastic epithelium.* Thus, a common form of cancer in the respiratory tract is composed of squamous cells, which can arise in areas where the normal columnar epithelium has been replaced by squamous epithelium.

Metaplasia from squamous to columnar type may also occur, as in *Barrett esophagus*, in which the esophageal squamous epithelium is replaced by intestinal-like columnar cells under the influence of refluxed gastric acid. Cancers may arise in these areas; these are typically glandular (adenocarcinomas) ([Chapter 17](#)).

Connective tissue metaplasia is the formation of cartilage, bone, or adipose tissue (mesenchymal tissues) in tissues that normally do not contain these elements. For example, bone formation in muscle, designated *myositis ossificans*, occasionally occurs after intramuscular hemorrhage. This type of metaplasia is less clearly seen as an adaptive response, and may be a result of cell or tissue injury.

Mechanisms of Metaplasia

Metaplasia does not result from a change in the phenotype of an already differentiated cell type; instead it is

the result of a reprogramming of stem cells that are known to exist in normal tissues, or of undifferentiated mesenchymal cells present in connective tissue. In a metaplastic change, these precursor cells differentiate along a new pathway. The differentiation of stem cells to a particular lineage is brought about by signals generated by cytokines, growth factors, and extracellular matrix components in the cells' environment. These external stimuli promote the expression of genes that drive cells toward a specific differentiation pathway. A direct link between transcription factor dysregulation and metaplasia is seen with vitamin A (retinoic acid) deficiency or excess, both of which may cause metaplasia. Retinoic acid regulates gene transcription directly through nuclear retinoid receptors ([Chapter 9](#)), which can influence the differentiation of progenitors derived from tissue stem cells. How other external stresses cause metaplasia is unknown, but it is clear that they too somehow alter the activity of transcription factors that regulate differentiation.

KEY CONCEPTS

Cellular Adaptations to Stress

- **Hypertrophy:** increased cell and organ size, often in response to increased workload; induced by growth factors produced in response to mechanical stress or other stimuli; occurs in tissues incapable of cell division
- **Hyperplasia:** increased cell numbers in response to hormones and other growth factors; occurs in tissues whose cells are able to divide or contain abundant tissue stem cells
- **Atrophy:** decreased cell and organ size, as a result of decreased nutrient supply or disuse; associated with decreased synthesis of cellular building blocks and increased breakdown of cellular organelles
- **Metaplasia:** change in phenotype of differentiated cells, often in response to chronic irritation, that makes cells better able to withstand the stress; usually induced by altered differentiation pathway of tissue stem cells; may result in reduced functions or increased propensity for malignant transformation

Overview of Cell Injury and Cell Death

As stated at the beginning of the chapter, cell injury results when cells are stressed so severely that they are no longer able to adapt or when cells are exposed to inherently damaging agents or suffer from intrinsic abnormalities. Injury may progress through a reversible stage and culminate in cell death ([Fig. 2-1](#)).

- **Reversible cell injury.** In early stages or mild forms of injury, the functional and morphologic changes are reversible if the damaging stimulus is removed. The hallmarks of reversible injury are reduced oxidative phosphorylation with resultant depletion of energy stores in the form of adenosine triphosphate (ATP), and cellular swelling caused by changes in ion concentrations and water influx. In addition, various intracellular organelles, such as mitochondria and the cytoskeleton, may show alterations.

- **Cell death.** With continuing damage the injury becomes irreversible, at which time the cell cannot recover and it dies. *Historically, two principal types of cell death, necrosis and apoptosis, which differ in their morphology, mechanisms, and roles in physiology and disease, have been recognized.*
 - Necrosis has been considered an “accidental” and unregulated form of cell death resulting from damage to cell membranes and loss of ion homeostasis. When damage to membranes is severe, lysosomal enzymes enter the cytoplasm and digest the cell giving rise to a set of morphologic changes described as necrosis. Cellular contents also leak through the damaged plasma membrane into the extracellular space, where they elicit a host reaction (inflammation). Necrosis is the pathway of cell death in many commonly encountered injuries, such as those resulting from ischemia, exposure to toxins, various infections, and trauma.
 - In contrast to necrosis, when the cell’s DNA or proteins are damaged beyond repair, the cell kills itself by *apoptosis*, a form of cell death that is characterized by nuclear dissolution, fragmentation of the cell without complete loss of membrane integrity, and rapid removal of the cellular debris. Because cellular contents do not leak out, unlike in necrosis, there is no inflammatory reaction. Mechanistically, apoptosis is known to be a highly regulated process driven by a series of genetic pathways. It is hence also sometimes called “programmed cell death.”
 - *Whereas necrosis is always a pathologic process, apoptosis serves many normal functions and is not necessarily associated with cell injury.* Despite the distinctive morphologic manifestations of necrosis and apoptosis, it is now clear that the mechanistic distinction between necrosis and apoptosis is not as clear cut as previously imagined. In some cases necrosis is also regulated by a series of signaling pathways, albeit largely distinct from those that are involved in apoptosis. In other words, in some cases necrosis, like apoptosis, is also a form of programmed cell death. In recognition of this similarity, this form of necrosis has been called *necroptosis* as will be discussed later. Despite some potential overlap of mechanisms, it is still useful to discuss necrosis and apoptosis, the two principal pathways of cell death, separately because of the differing circumstances in which they develop.

The morphologic features, mechanisms, and significance of these death pathways are discussed in more detail later in the chapter. We will discuss first the causes of cell injury.

Causes of Cell Injury

The causes of cell injury range from the physical violence of an automobile accident to subtle cellular abnormalities, such as a mutation causing lack of a vital enzyme that impairs normal metabolic function. Most injurious stimuli can be grouped into the following broad categories.

Oxygen Deprivation. *Hypoxia* is a deficiency of oxygen, which causes cell injury by reducing aerobic oxidative

respiration. Hypoxia is an extremely important and common cause of cell injury and cell death. *Causes of hypoxia* include reduced blood flow (*ischemia*), inadequate oxygenation of the blood due to cardiorespiratory failure, and decreased oxygen-carrying capacity of the blood, as in anemia or carbon monoxide poisoning (producing a stable carbon monoxyhemoglobin that blocks oxygen carriage) or after severe blood loss. Depending on the severity of the hypoxic state, cells may adapt, undergo injury, or die. For example, if an artery is narrowed, the tissue supplied by that vessel may initially shrink in size (atrophy), whereas more severe or sudden hypoxia induces injury and cell death.

Physical Agents. Physical agents capable of causing cell injury include mechanical trauma, extremes of temperature (burns and deep cold), sudden changes in atmospheric pressure, radiation, and electric shock ([Chapter 9](#)).

Chemical Agents and Drugs. The list of chemicals that may produce cell injury defies compilation. Simple chemicals such as glucose or salt in hypertonic concentrations may cause cell injury directly or by deranging electrolyte balance in cells. Even oxygen at high concentrations is toxic. Trace amounts of *poisons*, such as arsenic, cyanide, or mercuric salts, may damage sufficient numbers of cells within minutes or hours to cause death. Other potentially injurious substances are our daily companions: environmental and air pollutants, insecticides, and herbicides; industrial and occupational hazards, such as carbon monoxide and asbestos; recreational drugs such as alcohol; and the ever-increasing variety of therapeutic drugs. Many of these are discussed further in [Chapter 9](#).

Infectious Agents. These agents range from the submicroscopic viruses to tapeworms several feet in length. In between are the rickettsiae, bacteria, fungi, and higher forms of parasites. The ways by which these biologic agents cause injury are diverse ([Chapter 8](#)).

Immunologic Reactions. The immune system serves an essential function in defense against infectious pathogens, but immune reactions may also cause cell injury. Injurious reactions to endogenous self antigens are responsible for several autoimmune diseases ([Chapter 6](#)). Immune reactions to many external agents, such as viruses and environmental substances, are also important causes of cell and tissue injury ([Chapters 3 and 6](#)).

Genetic Derangements. As described in [Chapter 5](#), genetic abnormalities as obvious as an extra chromosome, as in Down syndrome, or as subtle as a single base pair substitution leading to an amino acid substitution, as in sickle cell anemia, may produce highly characteristic clinical phenotypes ranging from congenital malformations to anemias. Genetic defects may cause cell injury because of deficiency of functional proteins, such as enzyme defects in inborn errors of metabolism, or accumulation of damaged DNA or misfolded proteins, both of which trigger cell death when they are beyond repair. DNA sequence variants that are common in human populations (polymorphisms) can also influence the susceptibility of cells to injury by chemicals and other environmental insults.

Nutritional Imbalances. Nutritional imbalances continue to be major causes of cell injury. Protein-calorie deficiencies cause an appalling number of deaths, chiefly among underprivileged populations. Deficiencies of specific vitamins are found throughout the world (Chapter 9). Nutritional problems can be self-imposed, as in anorexia nervosa (self-induced starvation). Ironically, nutritional excesses have also become important causes of cell injury. Excess of cholesterol predisposes to atherosclerosis; obesity is associated with increased incidence of several important diseases, such as diabetes and cancer. Atherosclerosis is virtually endemic in the United States, and obesity is rampant. In addition to the problems of undernutrition and overnutrition, the composition of the diet makes a significant contribution to a number of diseases.

Morphologic Alterations in Cell Injury

It is useful to describe the basic alterations that occur in damaged cells before discussing the biochemical mechanisms that bring about these changes. All stresses and noxious influences exert their effects first at the molecular or biochemical level. There is a time lag between the stress and the morphologic changes of cell injury or death; the duration of this delay may vary with the sensitivity of the methods used to detect these changes (Fig. 2-7). With histochemical or ultrastructural techniques, changes may be seen in minutes to hours after injury; however, it may take considerably longer (hours to days) before changes can be seen by light microscopy or on gross examination. As would be expected, the morphologic manifestations of necrosis take more time to develop than those of reversible

Figure 2-7 Sequential development of biochemical and morphologic changes in cell injury. Cells may become rapidly nonfunctional after the onset of injury, although they may still be viable, with potentially reversible damage; a longer duration of injury may lead to irreversible injury and cell death. Note that irreversible biochemical alterations may cause cell death, and typically this precedes ultrastructural, light microscopic, and grossly visible morphologic changes.

Table 2-2 Features of Necrosis and Apoptosis

Feature	Necrosis	Apoptosis
Cell size	Enlarged (swelling)	Reduced (shrinkage)
Nucleus	Pyknosis → karyorrhexis → karyolysis	Fragmentation into nucleosome-size fragments
Plasma membrane	Disrupted	Intact; altered structure, especially orientation of lipids
Cellular contents	Enzymatic digestion; may leak out of cell	Intact; may be released in apoptotic bodies
Adjacent inflammation	Frequent	No
Physiologic or pathologic role	Invariably pathologic (culmination of irreversible cell injury)	Often physiologic, means of eliminating unwanted cells; may be pathologic after some forms of cell injury, especially DNA damage

damage. For example, in ischemia of the myocardium, cell swelling is a reversible morphologic change that may occur in a matter of minutes, and may progress to irreversibility within an hour or two. Unmistakable light microscopic changes of cell death, however, may not be seen until 4 to 12 hours after onset of ischemia.

The sequential morphologic changes in cell injury progressing to cell death are illustrated in Figure 2-8. Reversible injury is characterized by generalized swelling of the cell and its organelles, blebbing of the plasma membrane, detachment of ribosomes from the ER, and clumping of nuclear chromatin. These morphologic changes are associated with decreased generation of ATP, loss of cell membrane integrity, defects in protein synthesis, cytoskeletal damage, and DNA damage. Within limits, the cell can repair these derangements and, if the injurious stimulus abates, will return to normalcy. Persistent or excessive injury, however, causes cells to pass the rather nebulous “point of no return” into irreversible injury and cell death. Different injurious stimuli may induce death by necrosis or apoptosis (Fig. 2-8 and Table 2-2). Severe mitochondrial damage with depletion of ATP and rupture of lysosomal and plasma membranes are typically associated with necrosis. Necrosis occurs in many commonly encountered injuries, such as those following ischemia, exposure to toxins, various infections, and trauma. Apoptosis has many unique features (see later).

Reversible Injury

Two features of reversible cell injury can be recognized under the light microscope: cellular swelling and fatty change. Cellular swelling appears whenever cells are incapable of maintaining ionic and fluid homeostasis and is the result of failure of energy-dependent ion pumps in the plasma membrane. Fatty change occurs in hypoxic injury and various forms of toxic or metabolic injury. It is manifested by the appearance of lipid vacuoles in the cytoplasm. It is seen mainly in cells involved in and dependent on fat metabolism, such as hepatocytes and myocardial cells. The mechanisms of fatty change are discussed later in the chapter.

Figure 2-8 Schematic illustration of the morphologic changes in cell injury culminating in necrosis or apoptosis.

MORPHOLOGY

Cellular swelling is the first manifestation of almost all forms of injury to cells (Fig. 2-9B). It is a difficult morphologic change to appreciate with the light microscope; it may be more apparent at the level of the whole organ. When it affects many cells, it causes some pallor, increased turgor, and increase in weight of the organ. On microscopic examination, small clear vacuoles may be seen within the cytoplasm; these represent distended and pinched-off segments of the ER. This pattern of nonlethal injury is sometimes called **hydropic change** or **vacuolar degeneration**. Swelling of cells is reversible. Cells may also show increased eosinophilic staining, which becomes much more pronounced with progression to necrosis (described later).

The ultrastructural changes of reversible cell injury (Fig. 2-10B) include:

- 1. Plasma membrane alterations**, such as blebbing, blunting, and loss of microvilli
- 2. Mitochondrial changes**, including swelling and the appearance of small amorphous densities
- 3. Dilation of the ER**, with detachment of polysomes; intracytoplasmic myelin figures may be present (see later)

- 4. Nuclear alterations**, with disaggregation of granular and fibrillar elements

Necrosis

The morphologic appearance of necrosis as well as necroptosis is the result of denaturation of intracellular proteins and enzymatic digestion of the lethally injured cell. Necrotic cells are unable to maintain membrane integrity and their contents often leak out, a process that may elicit inflammation in the surrounding tissue. The enzymes that digest the necrotic cell are derived from the lysosomes of the dying cells themselves and from the lysosomes of leukocytes that are called in as part of the inflammatory reaction. Digestion of cellular contents and the host response may take hours to develop, and so there would be no detectable changes in cells if, for example, a myocardial infarct caused sudden death. The earliest histologic evidence of myocardial necrosis does not become apparent until 4 to 12 hours later. However, because of the loss of plasma membrane integrity, cardiac-specific enzymes and proteins are rapidly released from necrotic muscle and can be detected in the blood as early as 2 hours after myocardial cell necrosis (Chapter 12).

Figure 2-9 Morphologic changes in reversible cell injury and necrosis. **A**, Normal kidney tubules with viable epithelial cells. **B**, Early (reversible) ischemic injury showing surface blebs, increased eosinophilia of cytoplasm, and swelling of occasional cells. **C**, Necrosis (irreversible injury) of epithelial cells, with loss of nuclei, fragmentation of cells, and leakage of contents. The ultrastructural features of these stages of cell injury are shown in Fig. 2-10. (Courtesy Drs. Neal Pinckard and M. A. Venkatachalam, University of Texas Health Sciences Center, San Antonio, Texas.)

MORPHOLOGY

Necrotic cells show **increased eosinophilia** in hematoxylin and eosin (H & E) stains, attributable in part to the loss of cytoplasmic RNA (which binds the blue dye, hematoxylin) and in part to denatured cytoplasmic proteins (which bind the red dye, eosin). The necrotic cell may have a more glassy homogeneous appearance than do normal cells, mainly as a result of the loss of glycogen particles (Fig. 2-9C). When enzymes have digested the cytoplasmic organelles, the cytoplasm becomes vacuolated and appears moth-eaten. Dead cells may be replaced by large, whorled phospholipid masses called **myelin figures** that are derived from damaged cell membranes. These phospholipid precipitates are then either phagocytosed by other cells or further degraded into fatty acids; calcification of such fatty acid residues results in the generation of calcium soaps. Thus, the dead cells may ultimately become calcified. By electron

microscopy, necrotic cells are characterized by discontinuities in plasma and organelle membranes, marked dilation of mitochondria with the appearance of large amorphous densities, intracytoplasmic myelin figures, amorphous debris, and aggregates of fluffy material probably representing denatured protein (Fig. 2-10C).

Nuclear changes appear in one of three patterns, all due to nonspecific breakdown of DNA (Fig. 2-9C). The basophilia of the chromatin may fade (**karyolysis**), a change that presumably reflects loss of DNA because of enzymatic degradation by endonucleases. A second pattern (which is also seen in apoptotic cell death) is **pyknosis**, characterized by nuclear shrinkage and increased basophilia. Here the chromatin condenses into a solid, shrunken basophilic mass. In the third pattern, known as **karyorrhexis**, the pyknotic nucleus undergoes fragmentation. With the passage of time (a day or two), the nucleus in the necrotic cell totally disappears.

Figure 2-10 Ultrastructural features of reversible and irreversible cell injury (necrosis) in a rabbit kidney. **A**, Electron micrograph of a normal epithelial cell of the proximal kidney tubule. Note abundant microvilli (mv) lining the luminal surface (L). **B**, Epithelial cell of the proximal tubule showing early cell injury resulting from reperfusion following ischemia. The microvilli are lost and have been incorporated in apical cytoplasm; blebs have formed and are extruded in the lumen. Mitochondria would have been swollen during ischemia; with reperfusion, they rapidly undergo condensation and become electron-dense. **C**, Proximal tubular cell showing late injury, expected to be irreversible. Note the markedly swollen mitochondria containing electron-dense deposits, expected to contain precipitated calcium and proteins. Higher magnification micrographs of the cell would show disrupted plasma membrane and swelling and fragmentation of organelles. Venkatachalam, University of Texas Health Sciences Center, San Antonio, Texas.)

Figure 2-11 Coagulative necrosis. **A**, A wedge-shaped kidney infarct (yellow). **B**, Microscopic view of the edge of the infarct, with normal kidney (N) and necrotic cells in the infarct (I) showing preserved cellular outlines with loss of nuclei and an inflammatory infiltrate (seen as nuclei of inflammatory cells in between necrotic tubules).

Patterns of Tissue Necrosis

The discussion of necrosis has focused so far on changes in individual cells. When large numbers of cells die the tissue or organ is said to be necrotic; thus, a myocardial infarct is necrosis of a portion of the heart caused by death of many myocardial cells. Necrosis of tissues has several morphologically distinct patterns, which are important to recognize because they may provide clues about the underlying cause. Although the terms that describe these patterns are somewhat outdated, they are used often and their implications are understood by pathologists and clinicians.

MORPHOLOGY

Coagulative necrosis is a form of necrosis in which the architecture of dead tissues is preserved for a span of at least some days (Fig. 2-11). The affected tissues exhibit a firm texture. Presumably, the injury denatures not only structural proteins but also enzymes and so blocks the proteolysis of the dead cells; as a result, eosinophilic, anucleate cells may persist for days or weeks. Ultimately the necrotic cells are removed by phagocytosis of the cellular debris by infiltrating leukocytes and by digestion of the dead cells by the action of lysosomal enzymes of the leukocytes. Ischemia caused by obstruction in a vessel may lead to coagulative necrosis of the supplied tissue in all organs except the brain. A localized area of coagulative necrosis is called an **infarct**.

Liquefactive necrosis, in contrast to coagulative necrosis, is characterized by digestion of the dead cells, resulting in transformation of the tissue into a liquid viscous mass. It is seen in focal bacterial or, occasionally, fungal infections, because microbes stimulate the accumulation of leukocytes and the liberation of enzymes from these cells. The necrotic material is frequently creamy yellow because of the presence of dead leukocytes and is called **pus**. For unknown reasons, hypoxic death of cells within the central nervous system often manifests as liquefactive necrosis (Fig. 2-12).

Gangrenous necrosis is not a specific pattern of cell death, but the term is commonly used in clinical practice. It is usually

applied to a limb, generally the lower leg, that has lost its blood supply and has undergone necrosis (typically coagulative necrosis) involving multiple tissue planes. When bacterial infection is superimposed there is more liquefactive necrosis because of the actions of degradative enzymes in the bacteria and the attracted leukocytes (giving rise to so-called **wet gangrene**).

Caseous necrosis is encountered most often in foci of tuberculous infection (Chapter 8). The term “caseous” (cheese-like) is derived from the friable white appearance of the area of necrosis (Fig. 2-13). On microscopic examination, the necrotic area appears as a structureless collection of fragmented or lysed cells and amorphous granular debris enclosed within a distinctive inflammatory border; this appearance is characteristic of a focus of inflammation known as a **granuloma** (Chapter 3).

Fat necrosis is a term that is entrenched in medical parlance but does not in reality denote a specific pattern of necrosis. Rather, it refers to focal areas of fat destruction, typically

Figure 2-12 Liquefactive necrosis. An infarct in the brain, showing dissolution of the tissue.

Figure 2-13 Caseous necrosis. Tuberculosis of the lung, with a large area of caseous necrosis containing yellow-white and cheesy debris.

resulting from release of activated pancreatic lipases into the substance of the pancreas and the peritoneal cavity. This occurs in the calamitous abdominal emergency known as acute pancreatitis (Chapter 19). In this disorder pancreatic enzymes leak out of acinar cells and liquefy the membranes of fat cells in the peritoneum. The released lipases split the triglyceride esters contained within fat cells. The fatty acids, so derived, combine with calcium to produce grossly visible chalky-white areas (fat saponification), which enable the surgeon and the pathologist to identify the lesions (Fig. 2-14). On histologic examination the necrosis takes the form of foci of shadowy outlines of necrotic fat cells, with basophilic calcium deposits, surrounded by an inflammatory reaction.

Fibrinoid necrosis is a special form of necrosis usually seen in immune reactions involving blood vessels. This pattern of necrosis typically occurs when complexes of antigens and antibodies are deposited in the walls of arteries. Deposits of these “immune complexes,” together with fibrin that has leaked out of vessels, result in a bright pink and amorphous appearance in H&E stains, called “fibrinoid” (fibrin-like) by pathologists (Fig. 2-15). The immunologically mediated vasculitis syndromes in which this type of necrosis is seen are described in Chapter 11.

Figure 2-14 Fat necrosis. The areas of white chalky deposits represent foci of fat necrosis with calcium soap formation (saponification) at sites of lipid breakdown in the mesentery.

Figure 2-15 Fibrinoid necrosis in an artery. The wall of the artery shows a circumferential bright pink area of necrosis with inflammation (neutrophils with dark nuclei).

Ultimately, in the living patient most necrotic cells and their contents disappear due to enzymatic digestion and phagocytosis of the debris by leukocytes. If necrotic cells and cellular debris are not promptly destroyed and reabsorbed, they provide a nidus for the deposition of calcium salts and other minerals and thus tend to become calcified. This phenomenon, called *dystrophic calcification*, is considered later in the chapter.

KEY CONCEPTS

Morphologic Alterations in Injured Cells and Tissues

- **Reversible cell injury:** Cellular swelling, fatty change, plasma membrane blebbing and loss of microvilli, mitochondrial swelling, dilation of the ER, eosinophilia (due to decreased cytoplasmic RNA)
- **Necrosis:** Increased eosinophilia; nuclear shrinkage, fragmentation, and dissolution; breakdown of plasma membrane and organellar membranes; abundant myelin figures; leakage and enzymatic digestion of cellular contents
- **Patterns of tissue necrosis:** Under different conditions, necrosis in tissues may assume specific patterns: coagulative, liquefactive, gangrenous, caseous, fat, and fibrinoid

Mechanisms of Cell Injury

The discussion of the cellular pathology of cell injury and necrosis sets the stage for a consideration of the mechanisms and biochemical pathways of cell injury. The molecular pathways that lead to cell injury are complex and are best understood in the context of normal cell biology (Chapter 1). There are, however, several principles that are relevant to most forms of cell injury:

- **The cellular response to injurious stimuli depends on the nature of the injury, its duration, and its severity.** Small doses of a chemical toxin or brief periods of ischemia may induce reversible injury, whereas large doses of the same toxin or more prolonged ischemia might

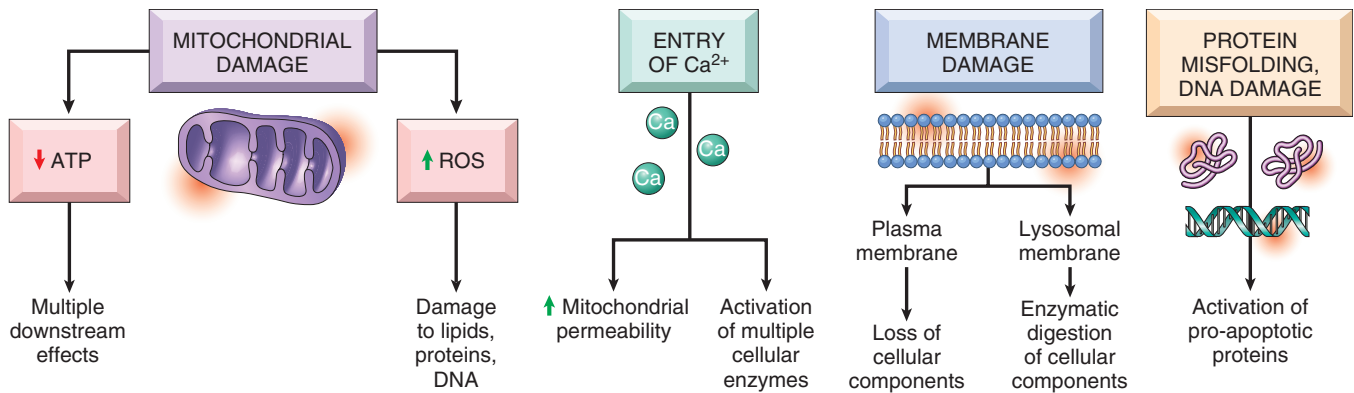

Figure 2-16 The principal biochemical mechanisms and sites of damage in cell injury. ATP, Adenosine triphosphate; ROS, reactive oxygen species.

result either in instantaneous cell death or in slow, irreversible injury leading in time to cell death.

- **The consequences of cell injury depend on the type, state, and adaptability of the injured cell.** The cell's nutritional and hormonal status and its metabolic needs are important in its response to injury. How vulnerable is a cell, for example, to loss of blood supply and hypoxia? When the striated muscle cell in the leg is deprived of its blood supply, it can be placed at rest and preserved; not so the striated muscle of the heart. Exposure of two individuals to identical concentrations of a toxin, such as carbon tetrachloride, may produce no effect in one and cell death in the other. This may be due to polymorphisms in genes encoding hepatic enzymes that metabolize carbon tetrachloride (CCl_4) to toxic by-products (Chapter 9). With the complete mapping of the human genome, there is great interest in identifying genetic polymorphisms that affect the responses of different individuals to various injurious agents.
- **Cell injury results from different biochemical mechanisms acting on several essential cellular components (Fig. 2-16).** These mechanisms are described individually in subsequent paragraphs. The cellular components that are most frequently damaged by injurious stimuli include mitochondria, cell membranes, the machinery of protein synthesis and packaging, and DNA. Any injurious stimulus may simultaneously trigger multiple interconnected mechanisms that damage cells. This is one reason why it is difficult to ascribe cell injury in a particular situation to a single or even dominant biochemical derangement.

The following section describes the biochemical mechanisms that may be activated by different injurious stimuli and that contribute to cell injury and necrosis. Apoptosis is described next, and finally necroptosis, which shares features with necrosis and apoptosis, is discussed.

Depletion of ATP

Reduction in ATP levels is fundamental cause of necrotic cell death. ATP depletion and decreased ATP synthesis are frequently associated with both hypoxic and chemical (toxic) injury (Fig. 2-17). ATP is produced in two ways. The major pathway in mammalian cells is oxidative

phosphorylation of adenosine diphosphate, in a reaction that results in reduction of oxygen by the electron transfer system of mitochondria. The second is the glycolytic pathway, which can generate ATP in the absence of oxygen using glucose derived either from body fluids or from the hydrolysis of glycogen. *The major causes of ATP depletion are reduced supply of oxygen and nutrients, mitochondrial damage, and the actions of some toxins (e.g., cyanide).*

High-energy phosphate in the form of ATP is required for virtually all synthetic and degradative processes within the cell. These include membrane transport, protein synthesis, lipogenesis, and the deacylation-reacylation reactions necessary for phospholipid turnover. *Depletion of*

Figure 2-17 Functional and morphologic consequences of decreased intracellular adenosine triphosphate (ATP) during cell injury. The morphologic changes shown here are indicative of reversible cell injury. Further depletion of ATP results in cell death, typically by necrosis. ER, Endoplasmic reticulum.

ATP to 5% to 10% of normal levels has widespread effects on many critical cellular systems:

- The activity of the *plasma membrane energy-dependent sodium pump* (ouabain-sensitive Na^+ , K^+ -ATPase) is reduced (Chapter 1). Failure of this active transport system causes sodium to enter and accumulate inside cells and potassium to diffuse out. The net gain of solute is accompanied by isosmotic gain of water, causing *cell swelling*, and dilation of the ER.
- *Cellular energy metabolism is altered*. If the supply of oxygen to cells is reduced, as in ischemia, oxidative phosphorylation ceases, resulting in a decrease in cellular ATP and associated increase in adenosine monophosphate. These changes stimulate phosphofructokinase and phosphorylase activities, leading to an increased rate of *anaerobic glycolysis*, which is designed to maintain the cell's energy sources by generating ATP through metabolism of glucose derived from glycogen. As a consequence *glycogen stores are rapidly depleted*. Anaerobic glycolysis results in the accumulation of *lactic acid* and inorganic phosphates from the hydrolysis of phosphate esters. This reduces the intracellular pH, resulting in decreased activity of many cellular enzymes.
- Failure of the Ca^{2+} pump leads to influx of Ca^{2+} , with damaging effects on numerous cellular components, described later.
- With prolonged or worsening depletion of ATP, structural disruption of the protein synthetic apparatus occurs, manifested as detachment of ribosomes from the rough ER and dissociation of polysomes, with a consequent *reduction in protein synthesis*.
- In cells deprived of oxygen or glucose, proteins may become misfolded, and accumulation of misfolded proteins in the endoplasmic reticulum (ER) triggers a cellular reaction called the *unfolded protein response* that may culminate in cell injury and even death (Chapter 1). This process is described further later in this chapter.
- Ultimately, there is irreversible damage to mitochondrial and lysosomal membranes, and the cell undergoes *nekrosis*.

Mitochondrial Damage

Mitochondria are critical players in cell injury and cell death by all pathways. This should be expected because they supply life-sustaining energy by producing ATP. Mitochondria can be damaged by increases of cytosolic Ca^{2+} , reactive oxygen species (discussed later), and oxygen deprivation, and so they are sensitive to virtually all types of injurious stimuli, including hypoxia and toxins. In addition, mutations in mitochondrial genes are the cause of some inherited diseases (Chapter 5).

There are three major *consequences of mitochondrial damage*.

- Mitochondrial damage often results in the formation of a high-conductance channel in the mitochondrial membrane, called the *mitochondrial permeability transition pore* (Fig. 2-18). The opening of this conductance channel leads to the loss of mitochondrial membrane potential, resulting in failure of oxidative phosphorylation and progressive depletion of ATP, culminating in

Figure 2-18 Role of mitochondria in cell injury and death. Mitochondria are affected by a variety of injurious stimuli and their abnormalities lead to nekrosis or apoptosis. ATP, Adenosine triphosphate; ROS, reactive oxygen species.

nekrosis of the cell. One of the structural components of the mitochondrial permeability transition pore is the protein cyclophilin D, which is one of several cyclophilins that are targeted by the immunosuppressive drug cyclosporine (used to prevent graft rejection). In some experimental models of ischemia, cyclosporine reduces injury by preventing opening of the mitochondrial permeability transition pore—an interesting example of molecularly targeted therapy for cell injury. The role of cyclosporine in reducing ischemic myocardial injury in humans is under investigation.

- Abnormal oxidative phosphorylation also leads to the formation of *reactive oxygen species*, which have many deleterious effects, described later.
- The mitochondria sequester between their outer and inner membranes several proteins that are capable of activating apoptotic pathways; these include cytochrome c and proteins that indirectly activate apoptosis-inducing enzymes called *caspases*. Increased permeability of the outer mitochondrial membrane may result in leakage of these proteins into the cytosol and death by apoptosis (discussed later).

Influx of Calcium and Loss of Calcium Homeostasis

Calcium ions are important mediators of cell injury. In keeping with this, depleting calcium protects cells from injury induced by a variety of harmful stimuli. Cytosolic free calcium is normally maintained at very low concentrations ($\sim 0.1 \mu\text{mol}$) compared with extracellular levels of 1.3 mmol , and most intracellular calcium is sequestered in mitochondria and the ER. Ischemia and certain toxins cause an increase in cytosolic calcium concentration, initially because of release of Ca^{2+} from intracellular stores,

Figure 2-19 The role of increased cytosolic calcium in cell injury. ER, Endoplasmic reticulum.

and later due to increased influx across the plasma membrane (Fig. 2-19). Increased intracellular Ca^{2+} causes cell injury by several mechanisms.

- The accumulation of Ca^{2+} in mitochondria results in opening of the mitochondrial permeability transition pore and, as described earlier, failure of ATP generation.
- Increased cytosolic Ca^{2+} activates a number of enzymes with potentially deleterious effects on cells. These enzymes include *phospholipases* (which cause membrane damage), *proteases* (which break down both membrane and cytoskeletal proteins), *endonucleases* (which are responsible for DNA and chromatin fragmentation), and *ATPases* (thereby hastening ATP depletion).
- Increased intracellular Ca^{2+} levels also result in the induction of apoptosis, by direct activation of caspases and by increasing mitochondrial permeability.

Accumulation of Oxygen-Derived Free Radicals (Oxidative Stress)

Cell injury induced by free radicals, particularly reactive oxygen species, is an important mechanism of cell damage in many pathologic conditions, such as chemical and radiation injury, ischemia-reperfusion injury (induced by restoration of blood flow in ischemic tissue), cellular aging, and microbial killing by phagocytes. *Free radicals* are

chemical species that have a single unpaired electron in an outer orbit. Unpaired electrons are highly reactive and “attack” and modify adjacent molecules, such as inorganic or organic chemicals—proteins, lipids, carbohydrates, nucleic acids—many of which are key components of cell membranes and nuclei. Some of these reactions are autocatalytic, whereby molecules that react with free radicals are themselves converted into free radicals, thus propagating the chain of damage.

Reactive oxygen species (ROS) are a type of oxygen-derived free radical whose role in cell injury is well established. ROS are produced normally in cells during mitochondrial respiration and energy generation, but they are degraded and removed by cellular defense systems. Thus, cells are able to maintain a steady state in which free radicals may be present transiently at low concentrations but do not cause damage. Increased production or decreased scavenging of ROS may lead to an excess of these free radicals, a condition called *oxidative stress*. Oxidative stress has been implicated in a wide variety of pathologic processes, including cell injury, cancer, aging, and some degenerative diseases such as Alzheimer disease. ROS are also produced in large amounts by activated leukocytes, particularly neutrophils and macrophages, during inflammatory reactions aimed at destroying microbes and cleaning up dead cells and other unwanted substances (Chapter 3).

The following section discusses the generation and removal of ROS, and how they contribute to cell injury. The properties of some of the most important free radicals are summarized in Table 2-3.

Generation of Free Radicals. Free radicals may be generated within cells in several ways (Fig. 2-20):

- *The reduction-oxidation reactions that occur during normal metabolic processes.* As a part of normal respiration, molecular O_2 is reduced by the transfer of four electrons to H_2 to generate two water molecules. This conversion is catalyzed by oxidative enzymes in the ER, cytosol, mitochondria, peroxisomes, and lysosomes. During this process small amounts of partially reduced intermediates are produced in which different numbers of electrons have been transferred from O_2 ; these include superoxide anion (O_2^- , one electron), hydrogen peroxide (H_2O_2 , two electrons), and hydroxyl ions ($^{\cdot}\text{OH}$, three electrons).
- *Absorption of radiant energy* (e.g., ultraviolet light, x-rays). For example, ionizing radiation can hydrolyze water into $^{\cdot}\text{OH}$ and hydrogen (H) free radicals.
- Rapid bursts of ROS are produced in activated leukocytes during *inflammation*. This occurs in a precisely controlled reaction carried out by a plasma membrane multiprotein complex that uses NADPH oxidase for the redox reaction (Chapter 3). In addition, some intracellular oxidases (e.g., xanthine oxidase) generate O_2^- .
- *Enzymatic metabolism of exogenous chemicals or drugs* can generate free radicals that are not ROS but have similar effects (e.g., CCl_4 can generate $^{\cdot}\text{CCl}_3$, described later in the chapter).
- *Transition metals* such as iron and copper donate or accept free electrons during intracellular reactions and catalyze free radical formation, as in the Fenton reaction

Table 2-3 Properties of the Principal Free Radicals Involved in Cell Injury

Properties	O_2^-	H_2O_2	$\cdot OH$	$ONOO^-$
Mechanisms of production	Incomplete reduction of O_2 during oxidative phosphorylation; by phagocyte oxidase in leukocytes	Generated by SOD from O_2^- and by oxidases in peroxisomes	Generated from H_2O by hydrolysis, e.g., by radiation; from H_2O_2 by Fenton reaction; from O_2^-	Produced by interaction of O_2^- and NO generated by NO synthase in many cell types (endothelial cells, leukocytes, neurons, others)
Mechanisms of inactivation	Conversion to H_2O_2 and O_2 by SOD	Conversion to H_2O and O_2 by catalase (peroxisomes), glutathione peroxidase (cytosol, mitochondria)	Conversion to H_2O by glutathione peroxidase	Conversion to HNO_2 by peroxiredoxins (cytosol, mitochondria)
Pathologic effects	Stimulates production of degradative enzymes in leukocytes and other cells; may directly damage lipids, proteins, DNA; acts close to site of production	Can be converted to $\cdot OH$ and OCl^- , which destroy microbes and cells; can act distant from site of production	Most reactive oxygen-derived free radical; principal ROS responsible for damaging lipids, proteins, and DNA	Damages lipids, proteins, DNA

HNO_2 , nitrite; H_2O_2 , hydrogen peroxide; NO, nitric oxide; O_2^- , superoxide anion; OCl^- , hypochlorite; $\cdot OH$, hydroxyl radical; $ONOO^-$, peroxynitrite; ROS, reactive oxygen species; SOD, superoxide dismutase.

($H_2O_2 + Fe^{2+} \rightarrow Fe^{3+} + \cdot OH + OH^-$). Because most of the intracellular free iron is in the ferric (Fe^{3+}) state, it must be reduced to the ferrous (Fe^{2+}) form to participate in the Fenton reaction. This reduction can be enhanced by O_2^- , and thus sources of iron and O_2^- may cooperate in oxidative cell damage.

- *Nitric oxide (NO)*, an important chemical mediator generated by endothelial cells, macrophages, neurons, and other cell types (Chapter 3), can act as a free radical and can also be converted to highly reactive peroxynitrite anion ($ONOO^-$) as well as NO_2 and NO_3^- .

Removal of Free Radicals. Free radicals are inherently unstable and generally decay spontaneously. O_2^- , for example, is unstable and decays (dismutates) spontaneously to O_2 and H_2O_2 in the presence of water. In addition, cells have developed multiple nonenzymatic and enzymatic mechanisms to remove free radicals and thereby minimize injury (Fig. 2-20). These include the following:

- *Antioxidants* either block free radical formation or inactivate (e.g., scavenge) free radicals. Examples are the lipid-soluble vitamins E and A as well as ascorbic acid and glutathione in the cytosol.
- As we have seen, free *iron* and *copper* can catalyze the formation of ROS. Under normal circumstances, the

reactivity of these metals is minimized by their binding to storage and transport proteins (e.g., transferrin, ferritin, lactoferrin, and ceruloplasmin), which prevents these metals from participating in reactions that generate ROS.

- A series of *enzymes* acts as free radical-scavenging systems and breaks down H_2O_2 and O_2^- . These enzymes are located near the sites of generation of the oxidants and include the following:
 1. *Catalase*, present in peroxisomes, decomposes H_2O_2 ($2H_2O_2 \rightarrow O_2 + 2H_2O$).
 2. *Superoxide dismutases (SODs)* are found in many cell types and convert O_2^- to H_2O_2 ($2O_2^- + 2H^+ \rightarrow H_2O_2 + O_2$). This group of enzymes includes both manganese-SOD, which is localized in mitochondria, and copper-zinc-SOD, which is found in the cytosol.
 3. *Glutathione peroxidase* also protects against injury by catalyzing free radical breakdown ($H_2O_2 + 2GSH \rightarrow GSSG$ [glutathione homodimer] + $2H_2O$, or $2\cdot OH + 2GSH \rightarrow GSSG + 2H_2O$). The intracellular ratio of oxidized glutathione (GSSG) to reduced glutathione (GSH) is a reflection of the oxidative state of the cell and is an important indicator of the cell's ability to detoxify ROS.

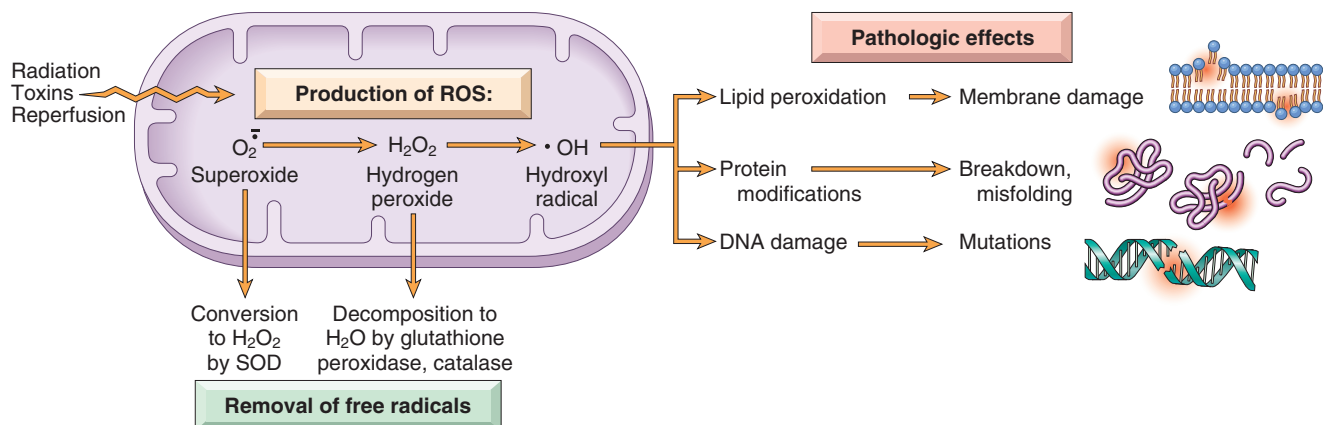

Figure 2-20 The generation, removal, and role of reactive oxygen species (ROS) in cell injury. The production of ROS is increased by many injurious stimuli. These free radicals are removed by spontaneous decay and by specialized enzymatic systems. Excessive production or inadequate removal leads to accumulation of free radicals in cells, which may damage lipids (by peroxidation), proteins, and deoxyribonucleic acid (DNA), resulting in cell injury.

Pathologic Effects of Free Radicals. The effects of ROS and other free radicals are wide-ranging, but three reactions are particularly relevant to cell injury (Fig. 2-20):

- **Lipid peroxidation in membranes.** In the presence of O_2 , free radicals may cause peroxidation of lipids within plasma and organellar membranes. Oxidative damage is initiated when the double bonds in unsaturated fatty acids of membrane lipids are attacked by O_2 -derived free radicals, particularly by $\cdot OH$. The lipid-free radical interactions yield peroxides, which are themselves unstable and reactive, and an autocatalytic chain reaction ensues (called *propagation*) that can result in extensive membrane damage.
- **Oxidative modification of proteins.** Free radicals promote oxidation of amino acid side chains, formation of covalent protein-protein cross-links (e.g., disulfide bonds), and oxidation of the protein backbone. Oxidative modification of proteins may damage the active sites of enzymes, disrupt the conformation of structural proteins, and enhance proteasomal degradation of unfolded or misfolded proteins, raising havoc throughout the cell.
- **Lesions in DNA.** Free radicals are capable of causing single- and double-strand breaks in DNA, cross-linking of DNA strands, and formation of adducts. Oxidative DNA damage has been implicated in cell aging (discussed later in this chapter) and in malignant transformation of cells (Chapter 7).

The traditional thinking about free radicals was that they cause cell injury and death by necrosis, and, in fact, the production of ROS is a frequent prelude to necrosis. However, it is now clear that free radicals can trigger apoptosis as well. Recent studies have also revealed a role of ROS in signaling by a variety of cellular receptors and biochemical intermediates. In fact, according to one hypothesis, the major actions of O_2^- stem from its ability to stimulate the production of degradative enzymes rather than direct damage of macromolecules. It is also possible that these potentially deadly molecules, when produced under physiologic conditions in the “right” dose, serve important physiologic functions.

Defects in Membrane Permeability

Early loss of selective membrane permeability, leading ultimately to overt membrane damage, is a consistent feature of most forms of cell injury (except apoptosis). Membrane damage may affect the functions and integrity of all cellular membranes. The following paragraphs discuss the mechanisms and pathologic consequences of membrane damage.

Mechanisms of Membrane Damage. In ischemic cells, membrane defects may be the result of ATP depletion and calcium-mediated activation of phospholipases. The plasma membrane can also be damaged directly by various bacterial toxins, viral proteins, lytic complement components, and a variety of physical and chemical agents. Several biochemical mechanisms may contribute to membrane damage (Fig. 2-21):

- **Reactive oxygen species.** Oxygen free radicals cause injury to cell membranes by lipid peroxidation, discussed earlier.

Figure 2-21 Mechanisms of membrane damage in cell injury. Decreased O_2 and increased cytosolic Ca^{2+} are typically seen in ischemia but may accompany other forms of cell injury. Reactive oxygen species, which are often produced on reperfusion of ischemic tissues, also cause membrane damage (not shown).

- **Decreased phospholipid synthesis.** The production of phospholipids in cells may be reduced as a consequence of defective mitochondrial function or hypoxia, both of which decrease the production of ATP and thus affect energy-dependent biosynthetic pathways. The decreased phospholipid synthesis may affect all cellular membranes, including the mitochondria themselves.
- **Increased phospholipid breakdown.** Severe cell injury is associated with increased degradation of membrane phospholipids, probably due to activation of calcium-dependent phospholipases by increased levels of cytosolic and mitochondrial Ca^{2+} . Phospholipid breakdown leads to the accumulation of *lipid breakdown products*, including unesterified free fatty acids, acyl carnitine, and lysophospholipids, which have a detergent effect on membranes. They may also either insert into the lipid bilayer of the membrane or exchange with membrane phospholipids, potentially causing changes in permeability and electrophysiologic alterations.
- **Cytoskeletal abnormalities.** Cytoskeletal filaments serve as anchors connecting the plasma membrane to the cell interior. Activation of proteases by increased cytosolic calcium may cause damage to elements of the cytoskeleton. In the presence of cell swelling, this damage results, particularly in myocardial cells, in detachment of the cell membrane from the cytoskeleton, rendering it susceptible to stretching and rupture.

Consequences of Membrane Damage. The most important sites of membrane damage during cell injury are the mitochondrial membrane, the plasma membrane, and membranes of lysosomes.

- **Mitochondrial membrane damage.** As discussed earlier, damage to mitochondrial membranes results in opening of the mitochondrial permeability transition pore, leading to decreased ATP generation and release of proteins that trigger apoptotic death.
- **Plasma membrane damage.** Plasma membrane damage results in loss of osmotic balance and influx of fluids and ions, as well as loss of cellular contents. The cells may

also leak metabolites that are vital for the reconstitution of ATP, thus further depleting energy stores.

- *Injury to lysosomal membranes* results in leakage of their enzymes into the cytoplasm and activation of the acid hydrolases in the acidic intracellular pH of the injured cell. Lysosomes contain RNases, DNases, proteases, phosphatases, and glucosidases. Activation of these enzymes leads to enzymatic digestion of proteins, RNA, DNA, and glycogen, and the cells die by necrosis.

Damage to DNA and Proteins

Cells have mechanisms that repair damage to DNA, but if DNA damage is too severe to be corrected (e.g., after exposure to DNA damaging drugs, radiation, or oxidative stress), the cell initiates a suicide program that results in death by apoptosis. A similar reaction is triggered by improperly folded proteins, which may be the result of inherited mutations or acquired triggers such as free radicals. Because these mechanisms of cell injury typically cause apoptosis, they are discussed later in the chapter.

Reversible vs Irreversible Injury. Before concluding the discussion of the mechanisms of cell injury, it is useful to consider the possible events that determine when reversible injury becomes irreversible and progresses to cell death. The clinical relevance of this question is obvious—if we can answer it, we may be able to devise strategies for preventing cell injury from having permanent deleterious consequences. However, the molecular mechanisms connecting most forms of cell injury to ultimate cell death have proved elusive, for several reasons. The “point of no return,” at which the damage becomes irreversible, is still largely undefined, and there are no reliable morphologic or biochemical correlates of irreversibility. *Two phenomena consistently characterize irreversibility—the inability to reverse mitochondrial dysfunction* (lack of oxidative phosphorylation and ATP generation) even after resolution of the original injury, and *profound disturbances in membrane function*. As mentioned earlier, injury to lysosomal membranes results in the enzymatic dissolution of the injured cell that is characteristic of necrosis.

Leakage of intracellular proteins through the damaged cell membrane and ultimately into the circulation provides a means of detecting tissue-specific cellular injury and necrosis using blood serum samples. Cardiac muscle, for example, contains a specific isoform of the enzyme creatine kinase and of the contractile protein troponin; liver (and specifically bile duct epithelium) contains an isoform of the enzyme alkaline phosphatase; and hepatocytes contain transaminases. Irreversible injury and cell death in these tissues are reflected in increased levels of such proteins in the blood, and measurement of these biomarkers is used clinically to assess damage to these tissues.

KEY CONCEPTS

Mechanisms of Cell Injury

- ATP depletion: failure of energy-dependent functions → reversible injury → necrosis
- Mitochondrial damage: ATP depletion → failure of energy-dependent cellular functions → ultimately, necrosis; under

some conditions, leakage of mitochondrial proteins that cause apoptosis

- Influx of calcium: activation of enzymes that damage cellular components and may also trigger apoptosis
- Accumulation of reactive oxygen species: covalent modification of cellular proteins, lipids, nucleic acids
- Increased permeability of cellular membranes: may affect plasma membrane, lysosomal membranes, mitochondrial membranes; typically culminates in necrosis
- Accumulation of damaged DNA and misfolded proteins: triggers apoptosis

Clinicopathologic Correlations: Selected Examples of Cell Injury and Necrosis

Having briefly reviewed the causes, morphology, and mechanisms of cell injury and necrotic cell death, we now describe some common and clinically significant forms of cell injury that typically culminate in necrosis. These examples illustrate many of the mechanisms and sequence of events in cell injury described earlier.

Ischemic and Hypoxic Injury

Ischemia is the most common type of cell injury in clinical medicine and it results from hypoxia induced by reduced blood flow, most commonly due to a mechanical arterial obstruction. It can also be caused by reduced venous drainage. In contrast to hypoxia, during which energy production by anaerobic glycolysis can continue, ischemia compromises the delivery of substrates for glycolysis. Thus, in ischemic tissues, not only is aerobic metabolism compromised but anaerobic energy generation also stops after glycolytic substrates are exhausted, or glycolysis is inhibited by the accumulation of metabolites that would otherwise be washed out by flowing blood. For this reason, *ischemia tends to cause more rapid and severe cell and tissue injury than does hypoxia in the absence of ischemia.*

Mechanisms of Ischemic Cell Injury

The sequence of events following hypoxia or ischemia reflects many of the biochemical alterations in cell injury described earlier and summarized here. As the oxygen tension within the cell falls, there is loss of oxidative phosphorylation and decreased generation of ATP. The depletion of ATP results in failure of the sodium pump, leading to efflux of potassium, influx of sodium and water, and cell swelling. There is also influx of Ca^{2+} , with its many deleterious effects. There is progressive loss of glycogen and decreased protein synthesis. The functional consequences may be severe at this stage. For instance, heart muscle ceases to contract within 60 seconds of coronary artery occlusion. Note, however, that loss of contractility does not mean cell death. If hypoxia continues, worsening ATP depletion causes further deterioration. The cytoskeleton disperses, resulting in the loss of ultrastructural features such as microvilli and the formation of “blebs” at the cell surface (Figs. 2-9 and 2-10). “Myelin figures,” derived from degenerating cellular membranes, may be seen within the cytoplasm (in autophagic vacuoles) or extracellularly. They

are thought to result from unmasking of phosphatide groups, promoting the uptake and intercalation of water between the lamellar stacks of membranes. At this time the mitochondria are usually swollen, as a result of loss of volume control in these organelles; the ER remains dilated; and the entire cell is markedly swollen, with increased concentrations of water, sodium, and chloride and a decreased concentration of potassium. *If oxygen is restored, all of these disturbances are reversible.*

If ischemia persists, irreversible injury and necrosis ensue. Irreversible injury is associated morphologically with severe swelling of mitochondria, extensive damage to plasma membranes (giving rise to myelin figures) and swelling of lysosomes (Fig. 2-10C). Large, flocculent, amorphous densities develop in the mitochondrial matrix. In the myocardium, these are indications of irreversible injury and can be seen as early as 30 to 40 minutes after ischemia. Massive influx of calcium into the cell then occurs, particularly if the ischemic zone is reperfused. Death is mainly by necrosis, but apoptosis also contributes; the apoptotic pathway is probably activated by release of pro-apoptotic molecules from leaky mitochondria. The cell's components are progressively degraded, and there is widespread leakage of cellular enzymes into the extracellular space and, conversely, entry of extracellular macromolecules from the interstitial space into the dying cells. Finally, the dead cells may become replaced by large masses composed of phospholipids in the form of myelin figures. These are then either phagocytosed by leukocytes or degraded further into fatty acids. Calcification of such fatty acid residues may occur, with the formation of calcium soaps.

As mentioned before, leakage of intracellular enzymes and other proteins across the abnormally permeable plasma membrane and into the blood provides important clinical indicators of cell death. For example, elevated serum levels of cardiac muscle creatine kinase MB and troponin are early signs of myocardial infarction, and may be seen before the infarct is detectable morphologically (Chapter 12).

Mammalian cells have developed protective responses to deal with hypoxic stress. The best-defined of these is induction of a transcription factor called *hypoxia-inducible factor-1*, which promotes new blood vessel formation, stimulates cell survival pathways, and enhances anaerobic glycolysis. It remains to be seen if understanding of such oxygen-sensing mechanisms will lead to new strategies for preventing or treating ischemic and hypoxic cell injury.

Despite many investigations in experimental models there are still no reliable therapeutic approaches for reducing the injurious consequences of ischemia in clinical situations. The strategy that is perhaps the most useful in ischemic (and traumatic) brain and spinal cord injury is the transient induction of hypothermia (reducing the core body temperature to 92°F). This treatment reduces the metabolic demands of the stressed cells, decreases cell swelling, suppresses the formation of free radicals, and inhibits the host inflammatory response. All of these may contribute to decreased cell and tissue injury.

Ischemia-Reperfusion Injury

Restoration of blood flow to ischemic tissues can promote recovery of cells if they are reversibly injured, but can

also paradoxically exacerbate the injury and cause cell death. As a consequence, reperfused tissues may sustain loss of cells in addition to the cells that are irreversibly damaged at the end of ischemia. This process, called *ischemia-reperfusion injury*, is clinically important because it contributes to tissue damage during myocardial and cerebral infarction and following therapies to restore blood flow (Chapters 12 and 28).

How does reperfusion injury occur? The likely answer is that new damaging processes are set in motion during reperfusion, causing the death of cells that might have recovered otherwise. Several mechanisms have been proposed:

- **Oxidative stress.** New damage may be initiated during reoxygenation by increased generation of *reactive oxygen and nitrogen species*. These free radicals may be produced in reperfused tissue as a result of incomplete reduction of oxygen by damaged mitochondria, or because of the action of oxidases in leukocytes, endothelial cells, or parenchymal cells. Cellular antioxidant defense mechanisms may be compromised by ischemia, favoring the accumulation of free radicals.
- **Intracellular calcium overload.** As mentioned earlier, intracellular and mitochondrial calcium overload begins during acute ischemia; it is exacerbated during reperfusion due to influx of calcium resulting from cell membrane damage and ROS mediated injury to sarcoplasmic reticulum. Calcium overload favors opening of the mitochondrial permeability transition pore with resultant depletion of ATP. This in turn causes further cell injury.
- **Inflammation.** Ischemic injury is associated with inflammation as a result of “danger signals” released from dead cells, cytokines secreted by resident immune cells such as macrophages, and increased expression of adhesion molecules by hypoxic parenchymal and endothelial cells, all of which act to recruit circulating neutrophils to reperfused tissue. The inflammation causes additional tissue injury (Chapter 3). The importance of neutrophil influx in reperfusion injury has been demonstrated experimentally by the salutary effects of treatment with antibodies that block cytokines or adhesion molecules and thereby reduce neutrophil extravasation.
- Activation of the *complement system* may contribute to ischemia-reperfusion injury. Some IgM antibodies have a propensity to deposit in ischemic tissues, for unknown reasons, and when blood flow is resumed, complement proteins bind to the deposited antibodies, are activated, and cause more cell injury and inflammation.

Chemical (Toxic) Injury

Chemical injury remains a frequent problem in clinical medicine and is a major limitation to drug therapy. Because many drugs are metabolized in the liver, this organ is a frequent target of drug toxicity. In fact, toxic liver injury is perhaps the most frequent reason for terminating the therapeutic use or development of a drug. The mechanisms by which chemicals, certain drugs, and toxins produce injury are described in greater detail in Chapter 9 in the discussion of environmental diseases. Here the major pathways of chemically induced injury with selected examples are described.

Chemicals induce cell injury by one of two general mechanisms:

- **Direct toxicity.** Some chemicals can injure cells directly by combining with critical molecular components. For example, in mercuric chloride poisoning, mercury binds to the sulfhydryl groups of cell membrane proteins, causing increased membrane permeability and inhibition of ion transport. In such instances, the greatest damage is usually to the cells that use, absorb, excrete, or concentrate the chemicals—in the case of mercuric chloride, the cells of the gastrointestinal tract and kidney (Chapter 9). **Cyanide** poisons mitochondrial cytochrome oxidase and thus inhibits oxidative phosphorylation. Many antineoplastic chemotherapeutic agents and antibiotics also induce cell damage by direct cytotoxic effects.
- **Conversion to toxic metabolites.** Most toxic chemicals are not biologically active in their native form but must be converted to reactive toxic metabolites, which then act on target molecules. This modification is usually accomplished by the cytochrome P-450 mixed-function oxidases in the smooth ER of the liver and other organs. The toxic metabolites cause membrane damage and cell injury mainly by formation of *free radicals* and subsequent lipid peroxidation; direct covalent binding to membrane proteins and lipids may also contribute. For instance, CCl_4 , which was once widely used in the dry cleaning industry, is converted by cytochrome P-450 to the highly reactive free radical $\cdot\text{CCl}_3$, which causes lipid peroxidation and damages many cellular structures. Acetaminophen, an analgesic drug, is also converted to a toxic product during detoxification in the liver, leading to cell injury. These and other examples of chemical injury are described in Chapter 9.

KEY CONCEPTS

Ischemic and Toxic Injury

- **Mild Ischemia:** Reduced oxidative phosphorylation → reduced ATP generation → failure of Na pump → influx of sodium and water → organelle and cellular swelling (reversible)
- **Severe/prolonged ischemia:** severe swelling of mitochondria, calcium influx into mitochondria and into the cell with rupture of lysosomes and plasma membrane. Death by necrosis and apoptosis due the release of cytochrome c from mitochondria
- **Reperfusion injury** follows blood flow into ischemic area is caused by oxidative stress due to release of free radicals from leukocytes and endothelial cells. Blood brings calcium that overloads reversibly injured cells with consequent mitochondrial injury. Influx of leukocytes generates free radicals and cytokines. Local activation of complement by IgM antibodies deposited in ischemic tissues.
- **Chemicals may cause injury directly or by conversion into toxic metabolites.** The organs chiefly affected are those involved in absorption or excretion of chemicals or others such as liver where the chemicals are converted to toxic metabolites. Direct injury to critical organelles such as mitochondria or indirect injury from free radicals generated from the chemicals/toxins is involved.

Apoptosis

Apoptosis is a pathway of cell death that is induced by a tightly regulated suicide program in which cells destined to die activate intrinsic enzymes that degrade the cells' own nuclear DNA and nuclear and cytoplasmic proteins. Apoptotic cells break up into fragments, called *apoptotic bodies*, which contain portions of the cytoplasm and nucleus. The plasma membrane of the apoptotic cell and bodies remains intact, but its structure is altered in such a way that these become “tasty” targets for phagocytes. The dead cell and its fragments are rapidly devoured, before the contents have leaked out, and therefore cell death by this pathway does not elicit an inflammatory reaction in the host. The process was recognized in 1972 by the distinctive morphologic appearance of membrane-bound fragments derived from cells, and named after the Greek designation for “falling off.” It was quickly appreciated that apoptosis was a unique mechanism of cell death, distinct from necrosis, which is characterized by loss of membrane integrity, enzymatic digestion of cells, leakage of cellular contents, and frequently a host reaction (Fig. 2-8 and Table 2-2). Because it is genetically regulated, apoptosis is sometimes referred to as *programmed cell death*. As already alluded to, certain forms of necrosis, called *necroptosis*, are also genetically programmed, but by a distinct set of genes.

Causes of Apoptosis

Apoptosis occurs normally both during development and throughout adulthood, and serves to remove unwanted, aged, or potentially harmful cells. It is also a pathologic event when diseased cells become damaged beyond repair and are eliminated.

Apoptosis in Physiologic Situations

Death by apoptosis is a normal phenomenon that serves to eliminate cells that are no longer needed, and to maintain a steady number of various cell populations in tissues. It is important in the following physiologic situations:

- *The destruction of cells during embryogenesis*, including implantation, organogenesis, developmental involution, and metamorphosis. The term *programmed cell death* was originally coined to denote death of specific cell types that was precisely regulated and occurred at defined times during the development of multicellular organisms. Apoptosis is a generic term for this pattern of cell death, regardless of the context, but it is often used interchangeably with programmed cell death. However, it is best to avoid this term to denote apoptosis, since in some cases necrosis may also be a form of programmed cell death
- *Involution of hormone-dependent tissues upon hormone withdrawal*, such as endometrial cell breakdown during the menstrual cycle, ovarian follicular atresia in menopause, the regression of the lactating breast after weaning, and prostatic atrophy after castration.
- *Cell loss in proliferating cell populations*, such as immature lymphocytes in the bone marrow and thymus and B

lymphocytes in germinal centers that fail to express useful antigen receptors (Chapter 6), and epithelial cells in intestinal crypts, so as to maintain a constant number (*homeostasis*).

- *Elimination of potentially harmful self-reactive lymphocytes*, either before or after they have completed their maturation, so as to prevent reactions against one's own tissues (Chapter 6).
- Death of host cells that have served their useful purpose, such as neutrophils in an *acute inflammatory response*, and lymphocytes at the end of an *immune response*. In these situations cells undergo apoptosis because they are deprived of necessary survival signals, such as growth factors.

Apoptosis in Pathologic Conditions

Apoptosis eliminates cells that are injured beyond repair without eliciting a host reaction, thus limiting collateral tissue damage. Death by apoptosis is responsible for loss of cells in a variety of pathologic states:

- *DNA damage*. Radiation, cytotoxic anticancer drugs, and hypoxia can damage DNA, either directly or via production of free radicals. If repair mechanisms cannot cope with the injury, the cell triggers intrinsic mechanisms that induce apoptosis. In these situations elimination of the cell may be a better alternative than risking mutations in the damaged DNA, which may result in malignant transformation.
- *Accumulation of misfolded proteins*. Improperly folded proteins may arise because of mutations in the genes encoding these proteins or because of extrinsic factors, such as damage caused by free radicals. Excessive accumulation of these proteins in the ER leads to a condition called *ER stress*, which culminates in apoptotic cell death. Apoptosis caused by the accumulation of misfolded proteins has been invoked as the basis of several degenerative diseases of the central nervous system and other organs.
- *Cell death in certain infections*, particularly viral infections, in which loss of infected cells is largely due to apoptosis that may be induced by the virus (as in adenovirus and HIV infections) or by the host immune response (as in viral hepatitis). An important host response to viruses consists of cytotoxic T lymphocytes specific for viral proteins, which induce apoptosis of infected cells in an attempt to eliminate reservoirs of infection. During this process there can be significant tissue damage. The same T-cell-mediated mechanism is responsible for cell death in *tumors* and cellular rejection of *transplants*.
- *Pathologic atrophy in parenchymal organs after duct obstruction*, such as occurs in the pancreas, parotid gland, and kidney.

Morphologic and Biochemical Changes in Apoptosis

Before discussing the mechanisms of apoptosis, the morphologic and biochemical characteristics of this process are described.

MORPHOLOGY

The following morphologic features, some best seen with the electron microscope, characterize cells undergoing apoptosis (Fig. 2-22, and see Fig. 2-8).

Cell shrinkage. The cell is smaller in size, the cytoplasm is dense (Fig. 2-22A), and the organelles, although relatively normal, are more tightly packed. (Recall that in other forms of cell injury, an early feature is cell swelling, not shrinkage.)

Chromatin condensation. This is the most characteristic feature of apoptosis. The chromatin aggregates peripherally, under the nuclear membrane, into dense masses of various shapes and sizes (Fig. 2-22B). The nucleus itself may break up, producing two or more fragments.

Formation of cytoplasmic blebs and apoptotic bodies.

The apoptotic cell first shows extensive surface blebbing, then undergoes fragmentation into membrane-bound apoptotic bodies composed of cytoplasm and tightly packed organelles, with or without nuclear fragments (Fig. 2-22C).

Phagocytosis of apoptotic cells or cell bodies, usually by macrophages. The apoptotic bodies are rapidly ingested by phagocytes and degraded by the phagocyte's lysosomal enzymes.

Plasma membranes are thought to remain intact during apoptosis, until the last stages, when they become permeable to normally retained solutes.

On histologic examination, in tissues stained with hematoxylin and eosin, the apoptotic cell appears as a round or oval mass of intensely eosinophilic cytoplasm with fragments of dense nuclear chromatin (Fig. 2-22A). Because the cell shrinkage and formation of apoptotic bodies are rapid and the pieces are quickly phagocytosed, considerable apoptosis may occur in tissues before it becomes apparent in histologic sections. In addition, apoptosis—in contrast to necrosis—does not elicit inflammation, making it more difficult to detect histologically.

Mechanisms of Apoptosis

Apoptosis results from the activation of enzymes called caspases (so named because they are cysteine proteases that cleave proteins after aspartic residues). Like many proteases, caspases exist as inactive proenzymes, or zymogens, and must undergo enzymatic cleavage to become active. The presence of cleaved, active caspases is a marker for cells undergoing apoptosis (Fig. 2-22C). The process of apoptosis may be divided into an *initiation phase*, during which some caspases become catalytically active, and an *execution phase*, during which other caspases trigger the degradation of critical cellular components. The activation of caspases depends on a finely tuned balance between production of pro-apoptotic and anti-apoptotic proteins.

Two distinct pathways converge on caspase activation: the mitochondrial pathway and the death receptor pathway (Fig 2-23). Although these pathways can intersect, they are generally induced under different conditions, involve different molecules, and serve distinct roles in physiology and disease.

The Intrinsic (Mitochondrial) Pathway of Apoptosis

The mitochondrial pathway is the major mechanism of apoptosis in all mammalian cells. It results from increased permeability of the mitochondrial outer membrane with consequent release of death-inducing (pro-apoptotic)

Figure 2-22 Morphologic features of apoptosis. **A**, Apoptosis of an epidermal cell in an immune reaction. The cell is reduced in size and contains brightly eosinophilic cytoplasm and a condensed nucleus. **B**, This electron micrograph of cultured cells undergoing apoptosis shows some nuclei with peripheral crescents of compacted chromatin, and others that are uniformly dense or fragmented. **C**, These images of cultured cells undergoing apoptosis show blebbing and formation of apoptotic bodies (*left panel*, phase contrast micrograph), a stain for DNA showing nuclear fragmentation (*middle panel*), and activation of caspase-3 (*right panel*, immunofluorescence stain with an antibody specific for the active form of caspase-3, revealed as red color). (**B**, From Kerr JFR, Harmon BV: Definition and incidence of apoptosis: a historical perspective. In Tomei LD, Cope FO (eds): Apoptosis: The Molecular Basis of Cell Death. Cold Spring Harbor, NY, Cold Spring Harbor Laboratory Press, 1991, pp 5-29; **C**, Courtesy Dr. Zheng Dong, Medical College of Georgia, Augusta, Ga.)

Figure 2-23 Mechanisms of apoptosis. The two pathways of apoptosis differ in their induction and regulation, and both culminate in the activation of caspases. In the mitochondrial pathway, proteins of the BCL2 family, which regulate mitochondrial permeability, become imbalanced and leakage of various substances from mitochondria leads to caspase activation. In death receptor pathway, signals from plasma membrane receptors lead to the assembly of adaptor proteins into a "death-including signaling complex," which activates caspases, and the end result is the same.

Figure 2-24 The intrinsic (mitochondrial) pathway of apoptosis. **A**, Cell viability is maintained by the induction of anti-apoptotic proteins such as BCL2 by survival signals. These proteins maintain the integrity of mitochondrial membranes and prevent leakage of mitochondrial proteins. **B**, Loss of survival signals, DNA damage, and other insults activate sensors that antagonize the anti-apoptotic proteins and activate the pro-apoptotic proteins BAX and BAK, which form channels in the mitochondrial membrane. The subsequent leakage of cytochrome c (and other proteins, not shown) leads to caspase activation and apoptosis.

molecules from the mitochondrial intermembrane space into the cytoplasm (Fig. 2-24). Mitochondria are remarkable organelles in that they contain proteins such as cytochrome c that are essential for life, but some of the same proteins, in particular cytochrome c, when released into the cytoplasm (an indication that the cell is not healthy), initiate the suicide program of apoptosis. The release of mitochondrial pro-apoptotic proteins is tightly controlled by the BCL2 family of proteins. This family is named after BCL2, which is frequently overexpressed due to chromosomal translocations and resulting rearrangements in certain B cell lymphomas (Chapter 13). There are more than 20 members of the BCL family, which can be divided into three groups based on their pro-apoptotic or anti-apoptotic function and the BCL2 homology (BH) domains they possess.

- **Anti-apoptotic.** BCL2, BCL-XL, and MCL1 are the principal members of this group; they possess four BH domains (called BH1-4). These proteins reside in the

outer mitochondrial membranes as well as the cytosol and ER membranes. By keeping the mitochondrial outer membrane impermeable they prevent leakage of cytochrome c and other death-inducing proteins into the cytosol (Fig. 2-24A).

- **Pro-apoptotic.** BAX and BAK are the two prototypic members of this group. Like their anti-apoptotic cousins they also have four BH domains. Upon activation, BAX and BAK oligomerize within the outer mitochondrial protein and promote mitochondrial outer membrane permeability. The precise mechanism by which Bax-Bak permeabilize membranes is not settled. According to one model illustrated in Fig 2-24B, they form a channel in the outer mitochondrial membrane, allowing leakage of cytochrome c from the intermembranous space.
- **Sensors.** Members of this group, including BAD, BIM, BID, Puma, and Noxa, contain only one BH domain, the third of the four BH domains, and hence are sometimes called BH3-only proteins. BH3-only proteins act as sensors of cellular stress and damage, and regulate the balance between the other two groups, thus acting as arbiters of apoptosis.

Growth factors and other survival signals stimulate the production of anti-apoptotic proteins such as BCL2, thus preventing the leakage of death-inducing proteins from the outer mitochondrial membrane. When cells are deprived of survival signals or their DNA is damaged, or misfolded proteins induce ER stress, the BH3-only proteins “sense” such damage and are activated. These sensors in turn activate the two critical (pro-apoptotic) effectors, BAX and BAK, which form oligomers that insert into the mitochondrial membrane and allow proteins from the inner mitochondrial membrane to leak out into the cytoplasm. BH3-only proteins may also bind to and block the function of BCL2 and BCL-XL. At the same time, the synthesis of BCL2 and BCL-XL may decline because of the relative deficiency of survival signals. The net result of BAX-BAK activation coupled with loss of the protective functions of the anti-apoptotic BCL2 family members is the release into the cytoplasm of several mitochondrial proteins that can activate the caspase cascade (Fig. 2-24). As already mentioned, one of these proteins is cytochrome c, well known for its role in mitochondrial respiration.

Once released into the cytosol, cytochrome c binds to a protein called APAF-1 (apoptosis-activating factor-1), which forms a wheel-like hexamer that has been called the *apoptosome*. This complex is able to bind caspase-9, the critical initiator caspase of the mitochondrial pathway, and the enzyme cleaves adjacent caspase-9 molecules, thus setting up an autoamplification process. Cleavage activates caspase-9, which triggers a cascade of caspase activation by cleaving and thereby activating other pro-caspases, and the active enzymes mediate the execution phase of apoptosis (discussed later). Other mitochondrial proteins, with arcane names like Smac/Diablo, enter the cytoplasm, where they bind to and neutralize cytoplasmic proteins that function as physiologic inhibitors of apoptosis (called IAPs). The normal function of the IAPs is to block the activation of caspases, including executioners like caspase-3, and keep cells alive. Thus, the neutralization of these IAPs permits the initiation of a caspase cascade.

The Extrinsic (Death Receptor-Initiated) Pathway of Apoptosis

This pathway is initiated by engagement of plasma membrane death receptors on a variety of cells. Death receptors are members of the TNF receptor family that contain a cytoplasmic domain involved in protein-protein interactions that is called the *death domain* because it is essential for delivering apoptotic signals. (Some TNF receptor family members do not contain cytoplasmic death domains; their function is to activate inflammatory cascades [Chapter 3], and their role in triggering apoptosis is much less established.) The best known death receptors are the type 1 TNF receptor (TNFR1) and a related protein called Fas (CD95), but several others have been described. The mechanism of apoptosis induced by these death receptors is well illustrated by Fas, a death receptor expressed on many cell types (Fig. 2-25). The ligand for Fas is called Fas ligand (FasL). FasL is expressed on T cells that recognize self antigens (and functions to eliminate self-reactive lymphocytes), and on some cytotoxic T lymphocytes (which kill virus-infected and tumor cells). When FasL binds to Fas, three or more molecules of Fas are brought together, and their cytoplasmic death domains form a binding site for an adaptor protein that also contains a death domain and is called FADD (*Fas-associated death domain*). FADD that is attached to the death receptors in turn binds an inactive form of caspase-8 (and, in humans, caspase-10), again via a death domain. Multiple pro-caspase-8 molecules are thus brought into proximity, and they cleave one another to

Figure 2-25 The extrinsic (death receptor initiated) pathway of apoptosis, illustrated by the events following Fas engagement. FADD, Fas-associated death domain; FasL, Fas ligand.

generate active caspase-8. The subsequent events are the same as in the mitochondrial pathway, and culminate in the activation of multiple executioner caspases. This pathway of apoptosis can be inhibited by a protein called FLIP, which binds to pro-caspase-8 but cannot cleave and activate the caspase because it lacks a protease domain. Some viruses and normal cells produce FLIP and use this inhibitor to protect themselves from Fas-mediated apoptosis.

The extrinsic and intrinsic pathways of apoptosis involve fundamentally different molecules for their initiation, but there may be interconnections between them. For instance, in hepatocytes and pancreatic β cells, caspase-8 produced by Fas signaling cleaves and activates the BH3-only protein BID, which then feeds into the mitochondrial pathway. The combined activation of both pathways delivers a fatal blow to the cells.

The Execution Phase of Apoptosis

The two initiating pathways converge to a cascade of caspase activation, which mediates the final phase of apoptosis. The mitochondrial pathway leads to activation of the initiator caspase-9, and the death receptor pathway to the initiator caspases-8 and -10. After an initiator caspase is cleaved to generate its active form, the enzymatic death program is set in motion by rapid and sequential activation of the executioner caspases. Executioner caspases, such as caspase-3 and -6, act on many cellular components. For instance, these caspases, once activated, cleave an inhibitor of a cytoplasmic DNase and thus make the DNase enzymatically active; this enzyme induces cleavage of DNA. Caspases also degrade structural components of the nuclear matrix and thus promote fragmentation of nuclei. Some of the steps in apoptosis are not fully defined. For instance, we do not know how the structure of the plasma membrane is changed in apoptotic cells, or how membrane blebs and apoptotic bodies are formed.

Removal of Dead Cells

The formation of apoptotic bodies breaks cells up into "bite-sized" fragments that are edible for phagocytes. Apoptotic cells and their fragments also undergo several changes in their membranes that actively promote their phagocytosis so they are most often cleared before they undergo secondary necrosis and release their cellular contents (which can result in injurious inflammation). In healthy cells, phosphatidylserine is present on the inner leaflet of the plasma membrane, but in apoptotic cells this phospholipid "flips" out and is expressed on the outer layer of the membrane, where it is recognized by several macrophage receptors. Cells that are dying by apoptosis secrete soluble factors that recruit phagocytes. Some apoptotic bodies are coated by thrombospondin, an adhesive glycoprotein that is recognized by phagocytes, and macrophages themselves may produce proteins that bind to apoptotic cells (but not to live cells) and thus target the dead cells for engulfment. Apoptotic bodies may also become coated with natural antibodies and proteins of the complement system, notably C1q, which are recognized by phagocytes. Thus, numerous receptors on phagocytes and ligands induced on apoptotic cells serve as "eat me" signals and are involved in the binding and engulfment of these cells. This process of phagocytosis of apoptotic cells is so

efficient that dead cells disappear, often within minutes, without leaving a trace, and inflammation is absent even in the face of extensive apoptosis.

Clinicopathologic Correlations: Apoptosis in Health and Disease

Examples of Apoptosis

Cell death in many situations is known to be caused by apoptosis, and the selected examples listed illustrate the role of this death pathway in normal physiology and in disease.

Growth Factor Deprivation. Hormone-sensitive cells deprived of the relevant hormone, lymphocytes that are not stimulated by antigens and cytokines, and neurons deprived of nerve growth factor die by apoptosis. In all these situations, apoptosis is triggered by the intrinsic (mitochondrial) pathway and is attributable to decreased synthesis of BCL2 and BCL-XL and activation of BIM and other pro-apoptotic members of the BCL2 family.

DNA Damage. Exposure of cells to radiation or chemotherapeutic agents induces apoptosis by a mechanism that is initiated by DNA damage (genotoxic stress) and that involves the tumor-suppressor gene *TP53*. p53 protein accumulates in cells when DNA is damaged, and it arrests the cell cycle (at the G₁ phase) to allow time for repair (Chapter 7). However, if the damage is too great to be repaired successfully, p53 triggers apoptosis. When *TP53* is mutated or absent (as it is in many cancers), cells with damaged DNA fail to undergo p53-mediated apoptosis

and instead survive. In such cells, the DNA damage may result in mutations of various types that lead to neoplastic transformation (Chapter 7). Thus, p53 serves as a critical “life or death” switch following genotoxic stress. The mechanism by which p53 triggers the distal death effector machinery – the caspases – is complex but seems to involve its function as a DNA-binding transcription factor. Among the proteins whose production is stimulated by p53 are several pro-apoptotic members of the BCL2 family, notably BAX, BAK and some BH3-only proteins, mentioned earlier.

Protein Misfolding. Chaperones in the ER control the proper folding of newly synthesized proteins, and misfolded polypeptides are ubiquitinated and targeted for proteolysis in proteasomes (Chapter 1). If, however, unfolded or misfolded proteins accumulate in the ER because of inherited mutations or stresses, they trigger a number of cellular responses, collectively called the *unfolded protein response*. The unfolded protein response activates signaling pathways that increase the production of chaperones, enhance proteasomal degradation of abnormal proteins, and slow protein translation, thus reducing the load of misfolded proteins in the cell (Fig. 2-26). However, if this cytoprotective response is unable to cope with the accumulation of misfolded proteins, the cell activates caspases and induces apoptosis. This process is called *ER stress*. Intracellular accumulation of abnormally folded proteins, caused by genetic mutations, aging, or unknown environmental factors, is now recognized as a feature of a number of neurodegenerative diseases, including Alzheimer, Huntington, and Parkinson diseases (Chapter 28), and possibly type 2 diabetes. Deprivation of glucose and oxygen, and stress such as heat, also result in protein

Figure 2-26 The unfolded protein response and endoplasmic reticulum (ER) stress. **A**, In healthy cells, newly synthesized proteins are folded with the help of chaperones and are then incorporated into the cell or secreted. **B**, Various external stresses or mutations induce a state called ER stress, in which the cell is unable to cope with the load of misfolded proteins. Accumulation of these proteins in the ER triggers the unfolded protein response, which tries to restore protein homeostasis; if this response is inadequate, the cell dies by apoptosis.

Table 2-4 Selected Examples of Diseases Caused by Misfolding of Proteins

Disease	Affected Protein	Pathogenesis
Cystic fibrosis	Cystic fibrosis transmembrane conductance regulator (CFTR)	Loss of CFTR leads to defects in chloride transport
Familial hypercholesterolemia	LDL receptor	Loss of LDL receptor leading to hypercholesterolemia
Tay-Sachs disease	Hexosaminidase β subunit	Lack of the lysosomal enzyme leads to storage of GM ₂ gangliosides in neurons
Alpha-1-antitrypsin deficiency	α_1 -antitrypsin	Storage of nonfunctional protein in hepatocytes causes apoptosis; absence of enzymatic activity in lungs causes destruction of elastic tissue giving rise to emphysema
Creutzfeldt-Jacob disease	Prions	Abnormal folding of PrP ^{sc} causes neuronal cell death
Alzheimer disease	A β peptide	Abnormal folding of A β peptides causes aggregation within neurons and apoptosis

misfolding, culminating in cell injury and death. A list of diseases associated with protein misfolding is provided in Table 2-4).

Apoptosis Induced by the TNF Receptor Family. FasL on T cells binds to Fas on the same or neighboring lymphocytes. This interaction plays a role in the elimination of lymphocytes that recognize self antigens, and mutations affecting Fas or FasL result in autoimmune diseases in humans and mice (Chapter 6).

Cytotoxic T Lymphocyte-Mediated Apoptosis. Cytotoxic T lymphocytes (CTLs) recognize foreign antigens presented on the surface of infected host cells (Chapter 6). Upon activation, CTLs secrete *perforin*, a transmembrane pore-forming molecule, which promotes entry of the CTL granule serine proteases called *granzymes*. Granzymes cleave proteins at aspartate residues and thus activate a variety of cellular caspases. In this way the CTL kills target cells by directly inducing the effector phase of apoptosis.

Disorders Associated with Dysregulated Apoptosis

Dysregulated apoptosis (“too little or too much”) has been postulated to explain aspects of a wide range of diseases.

- *Disorders associated with defective apoptosis and increased cell survival.* An inappropriately low rate of apoptosis may permit the survival of abnormal cells, which may have a variety of consequences. For instance, as discussed earlier, cells that carry mutations in *TP53* are susceptible to the accumulation of mutations because of defective DNA repair, which in turn can give rise to cancer. The importance of apoptosis in preventing cancer development is emphasized by the fact that mutation of *TP53* is the most common genetic abnormality found in human cancers (Chapter 7). In other situations, defective apoptosis results in failure to eliminate potentially harmful cells, such as lymphocytes that can react against self antigens, and failure to eliminate dead cells, a potential source of self antigens. Thus, defective apoptosis may be the basis of *autoimmune disorders* (Chapter 6).
- *Disorders associated with increased apoptosis and excessive cell death.* These diseases are characterized by a loss of cells and include (1) *neurodegenerative diseases*, manifested by loss of specific sets of neurons, in which apoptosis is caused by mutations and misfolded proteins

(Chapter 28); (2) *ischemic injury*, as in myocardial infarction (Chapter 12) and stroke (Chapter 28); and (3) *death of virus-infected cells* in many viral infections (Chapter 8).

KEY CONCEPTS

Apoptosis

- Regulated mechanism of cell death that serves to eliminate unwanted and irreparably damaged cells, with the least possible host reaction
- Characterized by enzymatic degradation of proteins and DNA, initiated by caspases; and by recognition and removal of dead cells by phagocytes
- Initiated by two major pathways:
 - Mitochondrial (intrinsic) pathway is triggered by loss of survival signals, DNA damage, and accumulation of misfolded proteins (ER stress); associated with leakage of pro-apoptotic proteins from mitochondrial membrane into the cytoplasm, where they activate caspases; inhibited by anti-apoptotic members of the BCL2 family, which are induced by survival signals including growth factors
 - Death receptor (extrinsic) pathway is responsible for elimination of self-reactive lymphocytes and damage by cytotoxic T lymphocytes; is initiated by engagement of death receptors (members of the TNF receptor family) by ligands on adjacent cells.

Necroptosis

As the name indicates, this form of cell death is a hybrid that shares aspects of both necrosis and apoptosis. The following features characterize necroptosis:

- Morphologically, and to some extent biochemically, it resembles necrosis, both characterized by loss of ATP, swelling of the cell and organelles, generation of ROS, release of lysosomal enzymes and ultimately rupture of the plasma membrane as discussed earlier.
- Mechanistically, it is triggered by genetically programmed signal transduction events that culminate in cell death. In this respect it resembles programmed cell death, which is considered the hallmark of apoptosis.

Because of the duality of these features, necroptosis is sometimes called *programmed necrosis* to distinguish it from the more usual forms of necrosis driven passively by toxic or anoxic injury to the cell. *In sharp contrast to apoptosis, the genetic program that drives necroptosis does not result in caspase activation* and hence it is also sometimes referred to as “caspase-independent” programmed cell death.

The process of necroptosis starts in a manner similar to that of the extrinsic form of apoptosis, that is, by ligation of a receptor by its ligand. While ligation of TNFR1 is the most widely studied model of necroptosis, many other signals, including ligation of Fas, and yet to be identified sensors of viral DNA and RNA, as well as genotoxic agents, can also trigger necroptosis. Since TNF can cause both apoptosis and necroptosis, the mechanisms underlying these effects of TNF are especially illustrative (Fig. 2-27).

While the entire set of signaling molecules and their interactions is not known, necroptosis involves two unique kinases called receptor associated kinase 1 and 3 (RIP1 and RIP3). As indicated in Fig. 2-27, ligation of TNFR1 recruits RIP1 and RIP3 into a multiprotein complex that also contains caspase-8. While events downstream of RIP1 and RIP3 kinase activation are still murky, it is clear that unlike in apoptosis, caspases are not activated and as in necrosis the terminal events include permeabilization of lysosomal membranes, generation of ROS, damage to the mitochondria, and reduction of ATP levels. *This explains the morphologic similarity of necroptosis with necrosis initiated by other injuries.*

Necroptosis is being recognized as an important death pathway both in physiologic and pathologic conditions. For example, necroptosis occurs during the formation of the mammalian bone growth plate; it is associated with cell death in steatohepatitis, acute pancreatitis, reperfusion injury, and neurodegenerative diseases such as Parkinson disease. Necroptosis also acts as a backup mechanism in host defense against certain viruses that encode caspase inhibitors (e.g., cytomegalovirus).

Before closing this discussion, we should briefly mention another form of programmed cell death called *pyroptosis*, so called because it is accompanied by the release of fever inducing cytokine IL-1 and because it bears some biochemical similarities with apoptosis.

As is well known, microbial products that enter the cytoplasm of infected cells are recognized by cytoplasmic innate immune receptors and can activate the multiprotein complex called the *inflammasome* (Chapter 6). The function of the inflammasome is to activate caspase-1, (also known as interleukin-1 β converting enzyme) which cleaves a precursor form of IL-1 and releases its biologically active form. IL-1 is a mediator of many aspects of inflammation, including leukocyte recruitment and fever (Chapter 3). Caspase-1 and, more importantly, the closely related caspase-11 also induce death of the cells. Unlike classical apoptosis, this pathway of cell death is characterized by swelling of cells, loss of plasma membrane integrity, and release of inflammatory mediators. Pyroptosis results in the death of some microbes that gain access to the cytosol and promotes the release of inflammasome-generated IL-1.

Figure 2-27 Molecular mechanism of TNF-mediated necroptosis. Cross-linking of TNFR1 by TNF causes recruitment of RIP1 and RIP3 along with caspase 8. Activation of the caspase leads to apoptosis as described in the text. Inhibition of caspase 8, as may occur in some viral infections, allows RIP1 and RIP3 to initiate signals that affect mitochondrial generation of ATP and ROS. This is followed by events typical of necrosis. (Adapted from Galluzzi L, et al: Programmed necrosis from molecules to health and disease. *Int Rev Cell Molec Biol* 289:1, 2011.)

KEY CONCEPTS

Necroptosis and Pyroptosis

- Necroptosis resembles necrosis morphologically and apoptosis mechanistically as a form of programmed cell death.
- Necroptosis is triggered by ligation of TNFR1, and viral proteins of RNA and DNA viruses.
- Necroptosis is caspase-independent but dependent on signaling by the RIP1 and RIP3 complex.
- RIP1-RIP3 signaling reduces mitochondrial ATP generation, causes production of ROS, and permeabilizes lysosomal membranes, thereby causing cellular swelling and membrane damage as occurs in necrosis.
- Release of cellular contents evokes an inflammatory reaction as in necrosis.
- Pyroptosis occurs in cells infected by microbes. It involves activation of caspase-1 which cleaves the precursor form of IL-1 to generate biologically active IL-1. Caspase-1 along with closely related caspase-11 also cause death of the infected cell.

Autophagy

Autophagy is a process in which a cell eats its own contents (Greek: **auto**, *self*; **phagy**, *eating*). It involves the delivery of cytoplasmic materials to the lysosome for degradation. Depending on how the material is delivered, autophagy can be categorized into three types:

- *Chaperone-mediated autophagy* (direct translocation across the lysosomal membrane by chaperone proteins)
- *Microautophagy* (inward invagination of lysosomal membrane for delivery)
- *Macroautophagy* (hereafter referred to as *autophagy*), the major form of autophagy involving the sequestration and transportation of portions of cytosol in a double-membrane bound autophagic vacuole (autophagosome)

Autophagy is seen in single-celled organisms as well as mammalian cells. It is an evolutionarily conserved survival

mechanism whereby, in states of nutrient deprivation, the starved cell lives by cannibalizing itself and recycling the digested contents. Autophagy is implicated in many physiologic states (e.g., aging and exercise) and pathologic processes. It proceeds through several steps (Fig. 2-28):

- Formation of an isolation membrane, also called phagophore, and its nucleation; the isolation membrane is believed to be derived from the ER
- Elongation of the vesicle
- Maturation of the autophagosome, its fusion with lysosomes, and eventual degradation of the contents

In recent years, more than a dozen “autophagy-related genes” called *Atgs* have been identified whose products are required for the creation of the autophagosome. While the details of the process are still not fully understood, its outlines have been defined. In a simple model, environmental cues like starvation or depletion of growth factors activate an initiation complex of four proteins that stimulates the assembly of a nucleation complex. This in turn promotes the nucleation of the autophagosomal membrane. The autophagosomal membrane elongates further, surrounds and captures its cytosolic cargo, and closes to form the autophagosome. The elongation and closure of the autophagosomal membrane requires the coordinated action of several ubiquitin-like conjugation systems, including the microtubule-associated protein light chain 3 (LC3). The synthesis of LC3 is augmented during autophagy and it is therefore a useful marker for identifying cells in which autophagy is occurring. The newly formed autophagosome fuses with endosomes and then finally with lysosomes to form an autophagolysosome. In the terminal step, the inner membrane and enclosed cytosolic cargoes are degraded by lysosomal enzymes. There is some evidence that autophagy is not a random process that engulfs cytosolic contents indiscriminately. Instead, it appears that the loading of cargo into the autophagosome is “selective” and that one of the functions of the LC3 system is to “target” protein aggregates and effete organelles.

Autophagy functions as a survival mechanism under various stress conditions, maintaining the integrity of cells by recycling essential metabolites and clearing cellular debris. It is therefore prominent in atrophic cells, which are

Figure 2-28 Autophagy. Cellular stresses, such as nutrient deprivation, activate an autophagy pathway that proceeds through several phases (initiation, nucleation, and elongation of isolation membrane) and eventually creates double-membrane-bound vacuoles (autophagosome) in which cytoplasmic materials including organelles are sequestered and then degraded following fusion of the vesicles with lysosomes. In the final stage, the digested materials are released for recycling of metabolites. See text for details. (Modified from Choi, AMK, Ryter S, Levine B: Autophagy in human health and disease. *N Engl J Med* 368:651, 2013.)

exposed to severe nutrient deprivation. Autophagy is also involved in the turnover of organelles like ER, mitochondria, and lysosomes and the clearance of intracellular aggregates that accumulate during aging, stress and various other disease states. Autophagy can trigger cell death if it is inadequate to cope with the stress imposed on the cell. This pathway of cell death is distinct from necrosis and apoptosis, but the mechanism is unknown. Furthermore, it is not clear whether cell death is caused by autophagy or by the stress that triggered autophagy. Nevertheless, autophagic vacuolization often precedes or accompanies cell death.

There is increasing evidence that autophagy plays a role in human diseases. Some examples are listed:

- **Cancer:** This is an area of active investigation and as discussed in [Chapter 7](#), autophagy can both promote cancer growth and act as a defense against cancers.
- **Neurodegenerative disorders:** Many neurodegenerative disorders are associated with dysregulation of autophagy. In Alzheimer disease, formation of autophagosomes is accelerated and in mouse models genetic defects in autophagy accelerate neurodegeneration. In Huntington disease, mutant huntingtin impairs autophagy.
- **Infectious diseases:** Many pathogens are degraded by autophagy; these include mycobacteria, *Shigella* spp., and HSV-1. This is one way by which microbial proteins are digested and delivered to antigen presentation pathways. Macrophage-specific deletion of Atg5 increases susceptibility to tuberculosis.
- **Inflammatory bowel diseases:** Genome-wide association studies have linked both Crohn disease and ulcerative colitis to SNPs in autophagy related genes.

KEY CONCEPTS

Autophagy

- Autophagy involves sequestration of cellular organelles into cytoplasmic autophagic vacuoles (autophagosomes) that fuse with lysosomes and digest the enclosed material.
- Autophagy is an adaptive response that is enhanced during nutrient deprivation, allowing the cell to cannibalize itself to survive.
- Autophagosome formation is regulated by more than a dozen proteins that act in a coordinated and sequential manner.
- Dysregulation of autophagy occurs in many disease states including cancers, inflammatory bowel diseases, and neurodegenerative disorders. Autophagy plays a role in host defense against certain microbes.

Intracellular Accumulations

One of the manifestations of metabolic derangements in cells is the intracellular accumulation of abnormal amounts of various substances that may be harmless or associated with varying degrees of injury. The substance may be

Figure 2-29 Mechanisms of intracellular accumulations discussed in the text.

located in the cytoplasm, within organelles (typically lysosomes), or in the nucleus, and it may be synthesized by the affected cells or may be produced elsewhere.

There are four main pathways of abnormal intracellular accumulations ([Fig. 2-29](#)):

- Inadequate removal of a normal substance secondary to defects in mechanisms of packaging and transport, as in fatty change (steatosis) in the liver (Chapter 18)
- Accumulation of an abnormal endogenous substance as a result of genetic or acquired defects in its folding, packaging, transport, or secretion, as with certain mutated forms of α_1 -antitrypsin (Chapter 15)
- Failure to degrade a metabolite due to inherited enzyme deficiencies. The resulting disorders are called *storage diseases* (Chapter 5).
- Deposition and accumulation of an abnormal exogenous substance when the cell has neither the enzymatic machinery to degrade the substance nor the ability to transport it to other sites. Accumulation of carbon or silica particles is an example of this type of alteration (Chapter 15).

In many cases, if the overload can be controlled or stopped, the accumulation is reversible. In inherited storage diseases, accumulation is progressive, and the overload may cause cellular injury, leading in some instances to death of the tissue and the patient.

Lipids

All major classes of lipids can accumulate in cells: triglycerides, cholesterol/cholesterol esters, and phospholipids. Phospholipids are components of the myelin figures found in necrotic cells. In addition, abnormal complexes of lipids and carbohydrates accumulate in the lysosomal storage diseases (Chapter 5). Triglyceride and cholesterol accumulations are discussed here.

Steatosis (Fatty Change)

The terms **steatosis and fatty change describe abnormal accumulations of triglycerides within parenchymal cells.** Fatty change is often seen in the liver because it is the major organ involved in fat metabolism (Fig. 2-30), but it also occurs in heart, muscle, and kidney. The causes of steatosis

Figure 2-30 Fatty liver. High-power detail of fatty change of the liver. In most cells the well-preserved nucleus is squeezed into the displaced rim of cytoplasm about the fat vacuole. (Courtesy Dr. James Crawford, Department of Pathology, University of Florida School of Medicine, Gainesville, Fla.)

Figure 2-31 Cholesterosis. Cholesterol-laden macrophages (foam cells, arrow) in a focus of gallbladder cholesterosis. (Courtesy Dr. Matthew Yeh, Department of Pathology, University of Washington, Seattle, Wash.)

include toxins, protein malnutrition, diabetes mellitus, obesity, and anoxia. In developed nations, the most common causes of significant fatty change in the liver (fatty liver) are alcohol abuse and nonalcoholic fatty liver disease, which is often associated with diabetes and obesity. Fatty liver is discussed in more detail in Chapter 18.

Cholesterol and Cholesterol Esters

The cellular metabolism of cholesterol (Chapter 5) is tightly regulated such that most cells use cholesterol for the synthesis of cell membranes without intracellular accumulation of cholesterol or cholesterol esters. Accumulations manifested histologically by intracellular vacuoles are seen in several pathologic processes.

- **Atherosclerosis.** In atherosclerotic plaques, smooth muscle cells and macrophages within the intimal layer of the aorta and large arteries are filled with lipid vacuoles, most of which are made up of cholesterol and cholesterol esters. Such cells have a foamy appearance (foam cells), and aggregates of them in the intima produce the yellow cholesterol-laden atheromas characteristic of this serious disorder. Some of these fat-laden cells may rupture, releasing lipids into the extracellular space. The mechanisms of cholesterol accumulation in atherosclerosis are discussed in detail in Chapter 11. The extracellular cholesterol esters may crystallize in the shape of long needles, producing quite distinctive clefts in tissue sections.
- **Xanthomas.** Intracellular accumulation of cholesterol within macrophages is also characteristic of acquired and hereditary hyperlipidemic states. Clusters of foamy cells are found in the subepithelial connective tissue of the skin and in tendons, producing tumorous masses known as xanthomas.
- **Cholesterosis.** This refers to the focal accumulations of cholesterol-laden macrophages in the lamina propria of the gallbladder (Fig. 2-31). The mechanism of accumulation is unknown.
- **Niemann-Pick disease, type C.** This lysosomal storage disease is caused by mutations affecting an enzyme involved in cholesterol trafficking, resulting in cholesterol accumulation in multiple organs (Chapter 5).

Proteins

Intracellular accumulations of proteins usually appear as rounded, eosinophilic droplets, vacuoles, or aggregates in the cytoplasm. By electron microscopy they can be amorphous, fibrillar, or crystalline in appearance. In some disorders, such as certain forms of amyloidosis, abnormal proteins deposit primarily in extracellular spaces (Chapter 6).

Excesses of proteins within the cells sufficient to cause morphologically visible accumulation have diverse causes.

- **Reabsorption droplets in proximal renal tubules** are seen in renal diseases associated with protein loss in the urine (proteinuria). In the kidney small amounts of protein filtered through the glomerulus are normally reabsorbed by pinocytosis in the proximal tubule. In disorders with heavy protein leakage across the glomerular filter there is increased reabsorption of the protein into vesicles, and the protein appears as pink hyaline droplets within the cytoplasm of the tubular cell (Fig. 2-32). The process is reversible; if the proteinuria diminishes, the protein droplets are metabolized and disappear.
- The proteins that accumulate may be normal secreted proteins that are produced in excessive amounts, as occurs in certain plasma cells engaged in active synthesis of immunoglobulins. The ER becomes hugely distended, producing large, homogeneous eosinophilic inclusions called *Russell bodies*.
- **Defective intracellular transport and secretion of critical proteins.** In α_1 -antitrypsin deficiency, mutations in the protein significantly slow folding, resulting in the buildup of partially folded intermediates, which aggregate in the ER of the liver and are not secreted. The resultant deficiency of the circulating enzyme causes emphysema (Chapter 15). In many of these diseases the pathology results not only from loss of protein function but also ER stress caused by the misfolded proteins, culminating in apoptotic death of cells (discussed earlier).
- **Accumulation of cytoskeletal proteins.** There are several types of cytoskeletal proteins, including microtubules

Figure 2-32 Protein reabsorption droplets in the renal tubular epithelium. (Courtesy Dr. Helmut Rennke, Department of Pathology, Brigham and Women's Hospital, Boston, Mass.)

(20 to 25 nm in diameter), thin actin filaments (6 to 8 nm), thick myosin filaments (15 nm), and intermediate filaments (10 nm). Intermediate filaments, which provide a flexible intracellular scaffold that organizes the cytoplasm and resists forces applied to the cell, are divided into five classes: keratin filaments (characteristic of epithelial cells), neurofilaments (neurons), desmin filaments (muscle cells), vimentin filaments (connective tissue cells), and glial filaments (astrocytes). Accumulations of keratin filaments and neurofilaments are associated with certain types of cell injury. Alcoholic hyaline is an eosinophilic cytoplasmic inclusion in liver cells that is characteristic of alcoholic liver disease, and is composed predominantly of *keratin* intermediate filaments (Chapter 18). The *neurofibrillary tangle* found in the brain in Alzheimer disease contains neurofilaments and other proteins (Chapter 28).

- **Aggregation of abnormal proteins.** Abnormal or misfolded proteins may deposit in tissues and interfere with normal functions. The deposits can be intracellular, extracellular, or both, and the aggregates may either directly or indirectly cause the pathologic changes. Certain forms of *amyloidosis* (Chapter 6) fall in this category of diseases. These disorders are sometimes called *proteinopathies* or *protein-aggregation diseases*.

Hyaline Change

The term hyaline usually refers to an alteration within cells or in the extracellular space that gives a homogeneous, glassy, pink appearance in routine histologic sections stained with hematoxylin and eosin. It is widely used as a descriptive histologic term rather than a specific marker for cell injury. This morphologic change is produced by a variety of alterations and does not represent a specific pattern of accumulation. Intracellular accumulations of protein, described earlier (reabsorption droplets, Russell bodies, alcoholic hyaline), are examples of intracellular hyaline deposits.

Extracellular hyaline has been more difficult to analyze. Collagenous fibrous tissue in old scars may appear hyalinized, but the biochemical basis of this change is not clear. In long-standing hypertension and diabetes mellitus, the walls of arterioles, especially in the kidney, become hyalinized, resulting from extravasated plasma protein and deposition of basement membrane material.

Glycogen

Glycogen is a readily available energy source stored in the cytoplasm of healthy cells. Excessive intracellular deposits of glycogen are seen in patients with an abnormality in either glucose or glycogen metabolism. Whatever the clinical setting, the glycogen masses appear as clear vacuoles within the cytoplasm. Glycogen dissolves in aqueous fixatives; thus, it is most readily identified when tissues are fixed in absolute alcohol. Staining with Best carmine or the PAS reaction imparts a rose-to-violet color to the glycogen, and diastase digestion of a parallel section before staining serves as a further control by hydrolyzing the glycogen.

Diabetes mellitus is the prime example of a disorder of glucose metabolism. In this disease glycogen is found

Figure 2-33 Lipofuscin granules in a cardiac myocyte shown by (A) light microscopy (deposits indicated by arrows), and (B) electron microscopy (note the perinuclear, intralysosomal location).

in renal tubular epithelial cells, as well as within liver cells, β cells of the islets of Langerhans, and heart muscle cells.

Glycogen accumulates within the cells in a group of related genetic disorders that are collectively referred to as the *glycogen storage diseases*, or *glycogenoses* (Chapter 5). In these diseases enzymatic defects in the synthesis or breakdown of glycogen result in massive accumulation, causing cell injury and cell death.

Pigments

Pigments are colored substances, some of which are normal constituents of cells (e.g., melanin), whereas others are abnormal and accumulate in cells only under special circumstances. Pigments can be exogenous, coming from outside the body, or endogenous, synthesized within the body itself.

Exogenous Pigments

The most common exogenous pigment is carbon (coal dust), a ubiquitous air pollutant in urban areas. When inhaled it is picked up by macrophages within the alveoli and is then transported through lymphatic channels to the regional lymph nodes in the tracheobronchial region. Accumulations of this pigment blacken the tissues of the lungs (*anthracosis*) and the involved lymph nodes. In coal miners the aggregates of carbon dust may induce a fibroblastic reaction or even emphysema and thus cause a serious lung disease known as *coal worker's pneumoconiosis* (Chapter 15). *Tattooing* is a form of localized, exogenous pigmentation of the skin. The pigments inoculated are phagocytosed by dermal macrophages, in which they reside for the remainder of the life of the embellished (sometimes with embarrassing consequences for the bearer of the tattoo when proposing to Mary while the tattoo says Valerie!). The pigments do not usually evoke any inflammatory response.

Endogenous Pigments

Lipofuscin is an insoluble pigment, also known as lipochrome or wear-and-tear pigment. Lipofuscin is composed of polymers of lipids and phospholipids in complex with protein, suggesting that it is derived through lipid peroxidation of polyunsaturated lipids of subcellular membranes.

Lipofuscin is not injurious to the cell or its functions. Its importance lies in its being a telltale sign of free radical injury and lipid peroxidation. The term is derived from the Latin (*fuscus*, brown), referring to brown lipid. In tissue sections it appears as a yellow-brown, finely granular cytoplasmic, often perinuclear, pigment (Fig. 2-33). It is seen in cells undergoing slow, regressive changes and is particularly prominent in the liver and heart of aging patients or patients with severe malnutrition and cancer cachexia.

Melanin, derived from the Greek (*melas*, black), is an endogenous, brown-black, pigment formed when the enzyme tyrosinase catalyzes the oxidation of tyrosine to dihydroxyphenylalanine in melanocytes. It is discussed further in Chapter 25. For practical purposes melanin is the only endogenous brown-black pigment. The only other that could be considered in this category is homogentisic acid, a black pigment that occurs in patients with *alkaptonuria*, a rare metabolic disease. Here the pigment is deposited in the skin, connective tissue, and cartilage, and the pigmentation is known as *ochronosis*.

Hemosiderin, a hemoglobin-derived, golden yellow-to-brown, granular or crystalline pigment is one of the major storage forms of iron. Iron metabolism and hemosiderin are considered in detail in Chapters 14 and 18. Iron is normally carried by specific transport protein called transferrin. In cells, it is stored in association with a protein, apoferritin, to form ferritin micelles. Ferritin is a constituent of most cell types. *When there is a local or systemic excess of iron, ferritin forms hemosiderin granules*, which are easily seen with the light microscope. Hemosiderin pigment represents aggregates of ferritin micelles. Under normal conditions small amounts of hemosiderin can be seen in the mononuclear phagocytes of the bone marrow, spleen, and liver, which are actively engaged in red cell breakdown.

Local or systemic excesses of iron cause hemosiderin to accumulate within cells. *Local excesses* result from hemorrhages in tissues. The best example of localized hemosiderosis is the common bruise. Extravasated red cells at the site of injury are phagocytosed over several days by macrophages, which break down the hemoglobin and recover the iron. After removal of iron, the heme moiety is converted first to biliverdin ("green bile") and then to bilirubin ("red bile"). In parallel, the iron released from heme is incorporated into ferritin and eventually hemosiderin.

These conversions account for the often dramatic play of colors seen in a healing bruise, which typically changes from red-blue to green-blue to golden-yellow before it is resolved.

When there is *systemic overload of iron* hemosiderin may be deposited in many organs and tissues, a condition called *hemosiderosis*. The main causes of hemosiderosis are (1) increased absorption of dietary iron due to an inborn error of metabolism called hemochromatosis, (2) hemolytic anemias, in which premature lysis of red cells leads to release of abnormal quantities of iron, and (3) repeated blood transfusions, because transfused red cells constitute an exogenous load of iron. These conditions are discussed in [Chapters 14](#) and [18](#).

Pathologic Calcification

Pathologic calcification is the abnormal tissue deposition of calcium salts, together with smaller amounts of iron, magnesium, and other mineral salts. There are two forms of pathologic calcification. When the deposition occurs locally in dying tissues it is known as *dystrophic calcification*; it occurs despite normal serum levels of calcium and in the absence of derangements in calcium metabolism. In contrast, the deposition of calcium salts in otherwise normal tissues is known as *metastatic calcification*, and it almost always results from hypercalcemia secondary to some disturbance in calcium metabolism.

Dystrophic Calcification

Dystrophic calcification is encountered in areas of necrosis, whether they are of coagulative, caseous, or liquefactive type, and in foci of enzymatic necrosis of fat. Calcification is almost always present in the atheromas of advanced atherosclerosis. It also commonly develops in aging or damaged heart valves, further hampering their function ([Fig. 2-34](#)). Whatever the site of deposition, the calcium salts appear macroscopically as fine, white granules or clumps, often felt as gritty deposits. Sometimes a tuberculous lymph node is virtually converted to stone.

Figure 2-34 Dystrophic calcification of the aortic valve. View looking down onto the unopened aortic valve in a heart with calcific aortic stenosis. It is markedly narrowed (stenosis). The semilunar cusps are thickened and fibrotic, and behind each cusp are irregular masses of piled-up dystrophic calcification.

MORPHOLOGY

Histologically, with the usual hematoxylin and eosin stain, calcium salts have a basophilic, amorphous granular, sometimes clumped appearance. They can be intracellular, extracellular, or in both locations. In the course of time, **heterotopic** bone may be formed in the focus of calcification. On occasion single necrotic cells may constitute seed crystals that become encrusted by the mineral deposits. The progressive acquisition of outer layers may create lamellated configurations, called **psammoma bodies** because of their resemblance to grains of sand. Some types of papillary cancers (e.g., thyroid) are apt to develop psammoma bodies. In asbestosis, calcium and iron salts gather about long slender spicules of asbestos in the lung, creating exotic, beaded dumbbell forms ([Chapter 15](#)).

Although dystrophic calcification may simply be a telltale sign of previous cell injury, it is often a cause of organ dysfunction. Such is the case in calcific valvular disease and atherosclerosis, as will become clear in further discussion of these diseases. Serum calcium is normal in dystrophic calcification.

Metastatic Calcification

Metastatic calcification may occur in normal tissues whenever there is hypercalcemia. Hypercalcemia also accentuates dystrophic calcification. There are four principal causes of hypercalcemia: (1) increased secretion of parathyroid hormone (PTH) with subsequent bone resorption, as in *hyperparathyroidism* due to parathyroid tumors, and ectopic secretion of PTH-related protein by malignant tumors ([Chapter 7](#)); (2) *resorption of bone tissue*, secondary to primary tumors of bone marrow (e.g., multiple myeloma, leukemia) or diffuse skeletal metastasis (e.g., breast cancer), accelerated bone turnover (e.g., Paget disease), or immobilization; (3) *vitamin D-related disorders*, including vitamin D intoxication, sarcoidosis (in which macrophages activate a vitamin D precursor), and idiopathic hypercalcemia of infancy (Williams syndrome), characterized by abnormal sensitivity to vitamin D; and (4) *renal failure*, which causes retention of phosphate, leading to secondary hyperparathyroidism. Less common causes include aluminum intoxication, which occurs in patients on chronic renal dialysis, and milk-alkali syndrome, which is due to excessive ingestion of calcium and absorbable antacids such as milk or calcium carbonate.

Metastatic calcification may occur widely throughout the body but principally affects the interstitial tissues of the gastric mucosa, kidneys, lungs, systemic arteries, and pulmonary veins. Although quite different in location, all of these tissues excrete acid and therefore have an internal alkaline compartment that predisposes them to metastatic calcification. In all these sites, the calcium salts morphologically resemble those described in dystrophic calcification. Thus, they may occur as noncrystalline amorphous deposits or, at other times, as hydroxyapatite crystals.

Usually the mineral salts cause no clinical dysfunction, but on occasion massive involvement of the lungs produces remarkable x-ray images and respiratory compromise. Massive deposits in the kidney (nephrocalcinosis) may in time cause renal damage ([Chapter 20](#)).

KEY CONCEPTS

Abnormal Intracellular Depositions and Calcifications

Abnormal deposits of materials in cells and tissues are the result of excessive intake or defective transport or catabolism.

- **Deposition of lipids**

- **Fatty change:** Accumulation of free triglycerides in cells, resulting from excessive intake or defective transport (often because of defects in synthesis of transport proteins); manifestation of reversible cell injury
- **Cholesterol deposition:** Result of defective catabolism and excessive intake; in macrophages and smooth muscle cells of vessel walls in atherosclerosis

- **Deposition of proteins:** Reabsorbed proteins in kidney tubules; immunoglobulins in plasma cells

- **Deposition of glycogen:** In macrophages of patients with defects in lysosomal enzymes that break down glycogen (glycogen storage diseases)

- **Deposition of pigments:** Typically indigestible pigments, such as carbon, lipofuscin (breakdown product of lipid peroxidation), or iron (usually due to overload, as in hemosiderosis)

- **Pathologic calcifications**

- **Dystrophic calcification:** Deposition of calcium at sites of cell injury and necrosis
- **Metastatic calcification:** Deposition of calcium in normal tissues, caused by hypercalcemia (usually a consequence of parathyroid hormone excess)

Cellular Aging

Mankind has pursued immortality from time immemorial. Toth and Hermes, two Egyptian and Greek deities, are said to have discovered the elixir of youth and become immortal. Sadly, despite intense search, that elixir is nowhere to be found. Shakespeare probably characterized aging best in his elegant description of the seven ages of man. It begins at the moment of conception, involves the differentiation and maturation of the organism and its cells, at

some variable point in time leads to the progressive loss of functional capacity characteristic of senescence, and ends in death.

Individuals age because their cells age. Although public attention on the aging process has traditionally focused on its cosmetic manifestations, aging has important health consequences, because age is one of the strongest independent risk factors for many chronic diseases, such as cancer, Alzheimer disease, and ischemic heart disease. Perhaps one of the most striking discoveries about cellular aging is that it is not simply a consequence of cells “running out of steam,” but in fact is regulated by genes that are evolutionarily conserved from yeast to worms to mammals.

Cellular aging is the result of a progressive decline in cellular function and viability caused by genetic abnormalities and the accumulation of cellular and molecular damage due to the effects of exposure to exogenous influences (Fig. 2-35). Studies in model systems have clearly established that aging is influenced by a limited number of genes, and genetic anomalies underlie syndromes resembling premature aging in humans as well. Such findings suggest that aging is associated with definable mechanistic alterations. Several mechanisms, some cell intrinsic and others environmentally induced, are believed to play a role in aging.

DNA Damage. A variety of exogenous (physical, chemical, and biologic) agents and endogenous factors such as ROS threaten the integrity of nuclear and mitochondrial DNA. Although most DNA damage is repaired by DNA repair enzymes, some persists and accumulates as cells age. Several lines of evidence point to the importance of DNA repair in the aging process. Next generation DNA sequencing studies have shown that the average hematopoietic stem cell suffers 14 new mutations per year, and it is likely that this accumulating damage explains why, like most cancers, the most common hematologic malignancies are diseases of the aged. Patients with *Werner syndrome* show premature aging, and the defective gene product is a DNA helicase, a protein involved in DNA replication and repair and other functions requiring DNA unwinding. A defect in this enzyme causes rapid accumulation of chromosomal damage that may mimic the injury that normally accumulates during cellular aging. Genetic instability in somatic

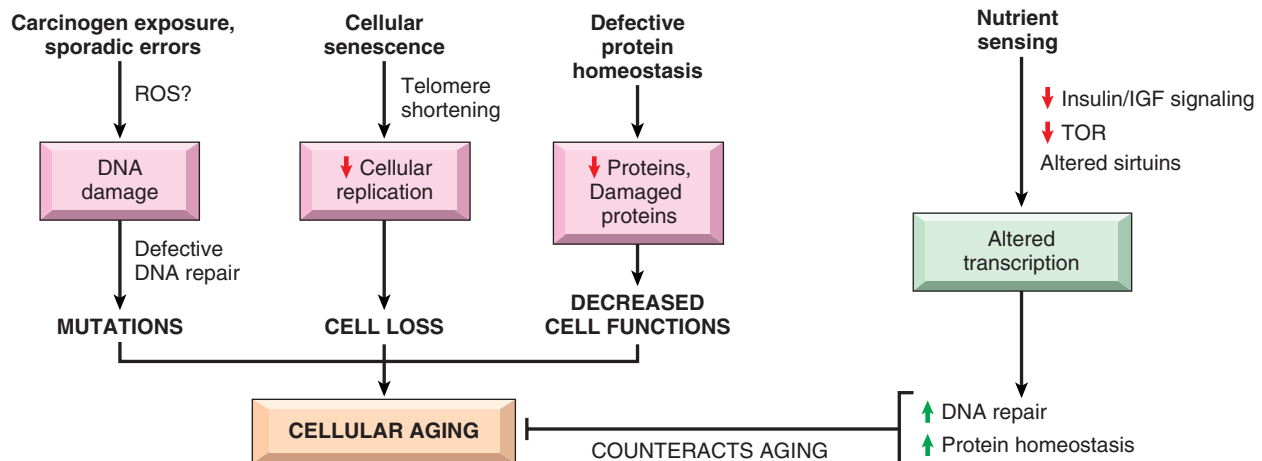

Figure 2-35 Mechanisms that cause and counteract cellular aging. DNA damage, replicative senescence, and decreased and misfolded proteins are among the best described mechanisms of cellular aging. Nutrient sensing exemplified by calorie restriction, counteracts aging by activating various signaling pathways and transcription factors. IG, Insulin-like growth factor; TOR, target of rapamycin.

cells is also characteristic of other disorders in which patients display some of the manifestations of aging at an increased rate, such as *Bloom syndrome* and *ataxia-telangiectasia*, in which the mutated genes encode a proteins involved in repairing double-strand breaks in DNA (Chapter 7).

Cellular Senescence. All normal cells have a limited capacity for replication, and after a fixed number of divisions cells become arrested in a terminally nondividing state, known as replicative senescence. Aging is associated with progressive replicative senescence of cells. Cells from children have the capacity to undergo more rounds of replication than do cells from older people. Two mechanisms are believed to underlie cellular senescence:

- **Telomere attrition.** One mechanism of replicative senescence involves progressive shortening of telomeres, which ultimately results in cell cycle arrest. Telomeres are short repeated sequences of DNA present at the ends of linear chromosomes that are important for ensuring the complete replication of chromosome ends and for protecting the ends from fusion and degradation. When somatic cells replicate, a small section of the telomere is not duplicated and telomeres become progressively shortened. As the telomeres become shorter, the ends of chromosomes cannot be protected and are seen as broken DNA, which signals cell cycle arrest. Telomere length is maintained by nucleotide addition mediated by an enzyme called *telomerase*. Telomerase is a specialized RNA-protein complex that uses its own RNA as a template for adding nucleotides to the ends of chromosomes. Telomerase activity is expressed in germ cells and is present at low levels in stem cells, but it is absent in most somatic tissues (Fig. 2-36) Therefore, as most somatic cells age, their telomeres become shorter and they exit the cell cycle, resulting in an inability to generate new cells to replace damaged ones. Conversely, in immortalized cancer cells, telomerase is usually reactivated and telomere length is stabilized, allowing the cells to proliferate indefinitely. This is discussed more fully in Chapter 7. The causal links between telomere length and cellular senescence have been established in mouse models. Genetically engineered mice with shortened telomeres exhibit reduced life spans that can be restored to normal by telomere activation. As discussed in other chapters, telomere shortening has also been associated with premature development of diseases, such as pulmonary fibrosis (Chapter 15) and aplastic anemia (Chapter 14).
- **Activation of tumor suppressor genes.** In addition to telomere attrition, activation of certain tumor suppressor genes, particularly those encoded by the *CDKN2A* locus, also seems to be involved in controlling replicative senescence. The *CDKN2A* locus encodes two tumor suppressor proteins, expression of one of which, known as p16 or INK4a, is correlated with chronologic age in virtually all human and mouse tissues examined. By controlling G1 to S phase progression during the cell cycle (Chapter 1), p16 protects the cells from uncontrolled mitogenic signals and pushes cells along the senescence pathway. This is discussed further in Chapter 7.

Defective Protein Homeostasis. Protein homeostasis involves two mechanisms: those that maintain proteins in

Figure 2-36 The role of telomeres and telomerase in replicative senescence of cells. Telomere length is plotted against the number of cell divisions. In most somatic cells there is no telomerase activity and telomeres progressively shorten with increasing cell divisions until growth arrest or until senescence occurs. Germ cells and stem cells both contain telomerase, but only germ cells have sufficient levels of the enzyme to stabilize telomere length completely. In cancer cells, telomerase is often reactivated. (Data from Holt SE, et al: Refining the telomere-telomerase hypothesis of aging and cancer. *Nat Biotechnol* 14:836, 1996, MacMillan Publishers Ltd.)

there correctly folded conformations (mediated by chaperones) and others that degrade misfolded proteins by the autophagy-lysosome system and ubiquitin-proteasome system. There is evidence that both normal folding and degradation of misfolded proteins are impaired with aging. Mutant mice deficient in chaperones of the heat shock protein family age rapidly, and conversely, those that over-express such chaperones are long-lived. Similar data exist for the role of autophagy and proteasomal degradation of proteins. Of interest, administration of rapamycin, which inhibits the mTOR pathway, increases the life span of middle aged mice. Rapamycin has multiple effects including promotion of autophagy. Abnormal protein homeostasis can have many effects on cell survival, replication, and functions. In addition, it may lead to accumulation of misfolded proteins, which can trigger pathways of apoptosis.

Deregulated Nutrient Sensing. Paradoxical though it may seem, eating less increases longevity. Caloric restriction increases life span in all eukaryotic species in which it has been tested, with encouraging results even in nonhuman primates and a few usually disciplined people who are the envy of others! Because of these observations, there has been much interest in deciphering the role of nutrient sensing in aging. The following paragraphs review two major neurohormonal circuits that regulate metabolism.

- **Insulin and insulin-like growth factor 1 (IGF-1) signaling pathway.** IGF-1 is produced in many cell types in response to growth hormone secretion by the pituitary. IGF-1, as indicated by its name, mimics intracellular signaling by insulin and thereby informs the cells of the availability of glucose, promoting an anabolic state as well as cell growth and replication. IGF-1 signaling has multiple downstream targets; relevant to this discussion are two kinases: AKT and its downstream target, mTOR (mammalian target of rapamycin), which, as the name implies, is inhibited by rapamycin.
- **Sirtuins.** Sirtuins are a family of NAD-dependent protein deacetylases. There are at least seven types of sirtuins

that are distributed in different cellular compartments and have nonredundant functions designed to adapt bodily functions to various environmental stresses, including food deprivation and DNA damage. Sirtuins are thought to promote the expression of several genes whose products increase longevity. These include proteins that inhibit metabolic activity, reduce apoptosis, stimulate protein folding, and inhibit the harmful effects of oxygen free radicals. Sirtuins also increase insulin sensitivity and glucose metabolism, and may be targets for the treatment of diabetes.

It is thought that caloric restriction increases longevity both by reducing the signaling intensity of the IGF-1 pathway and by increasing sirtuins. Attenuation of IGF-1 signaling leads to lower rates of cell growth and metabolism and possibly reduced cellular damage. This effect can be mimicked by rapamycin. An increase in sirtuins, particularly sirtuin-6, serves dual functions: the sirtuins (1) contribute to metabolic adaptations of caloric restriction and (2) promote genomic integrity by activating DNA repair enzymes through deacylation. Although the antiaging effects of sirtuins have been widely publicized, much remains to be known before sirtuin-activating pills will be available to increase longevity. Nevertheless, optimistic wine-lovers have been delighted to hear that a constituent of red wine may activate sirtuins and thus increase life span!

The various forms of cellular derangements and adaptations described in this chapter cover a wide spectrum, ranging from adaptations in cell size, growth, and function; to the reversible and irreversible forms of acute cell injury; to the regulated type of cell death represented by apoptosis; to the pathologic alterations in cell organelles; to the less ominous forms of intracellular accumulations, including pigmentations. Reference is made to all these alterations throughout this book, because all organ injury and ultimately all clinical disease arise from derangements in cell structure and function.

KEY CONCEPTS

Cellular Aging

- Cellular aging results from a combination of accumulating cellular damage (e.g., by free radicals), reduced capacity to divide (replicative senescence), reduced ability to repair damaged DNA, and defective protein homeostasis
 - **Accumulation of DNA damage:** Defective DNA repair mechanisms; conversely, caloric restriction activates DNA repair and is known to prolong aging in model organisms
 - **Replicative senescence:** Reduced capacity of cells to divide secondary to progressive shortening of chromosomal ends (telomeres)
 - **Defective protein homeostasis:** Resulting from impaired chaperone and proteasome functions.
 - **Nutrient sensing system:** Caloric restriction increases longevity. Mediators may be reduced IGF-1 signaling and increases in sirtuins.

Overview of Inflammation: Definitions and General Features

Inflammation is a response of vascularized tissues to infections and damaged tissues that brings cells and molecules of host defense from the circulation to the sites where they are needed, in order to eliminate the offending agents. Although in common medical and lay parlance, inflammation suggests a harmful reaction, it is actually a protective response that is essential for survival. It serves to rid the host of both the initial cause of cell injury (e.g., microbes, toxins) and the consequences of such injury

(e.g., necrotic cells and tissues). The mediators of defense include phagocytic leukocytes, antibodies, and complement proteins. Most of these normally circulate in the blood, from which they can be rapidly recruited to any site in the body; some of the cells also reside in tissues. The process of inflammation delivers these cells and proteins to damaged or necrotic tissues and foreign invaders, such as microbes, and activates the recruited cells and molecules, which then function to get rid of the harmful or unwanted substances. Without inflammation, infections would go unchecked, wounds would never heal, and injured tissues might remain permanent festering sores. In addition to inflammatory cells, components of innate

immunity include other cells, such as natural killer cells, dendritic cells, and epithelial cells, as well as soluble factors such as the proteins of the complement system. Together, these components of innate immunity serve as the first responders to infection. They also function to eliminate damaged cells and foreign bodies.

The typical inflammatory reaction develops through a series of sequential steps:

- The offending agent, which is located in extravascular tissues, is recognized by host cells and molecules.
- Leukocytes and plasma proteins are recruited from the circulation to the site where the offending agent is located.
- The leukocytes and proteins are activated and work together to destroy and eliminate the offending substance.
- The reaction is controlled and terminated.
- The damaged tissue is repaired.

Before discussing the mechanisms, functions, and pathology of the inflammatory response, it is useful to review some of its fundamental properties.

- **Components of the inflammatory response.** The major participants in the inflammatory reaction in tissues are blood vessels and leukocytes (Fig. 3-1). As will be discussed in more detail later, blood vessels dilate to slow down blood flow, and by increasing their permeability, they enable selected circulating proteins to enter the site of infection or tissue damage. Characteristics of the endothelium lining blood vessels also change, such that circulating leukocytes first come to a halt and then migrate into the tissues. Leukocytes, once recruited, are activated and acquire the ability to ingest and destroy microbes and dead cells, as well as foreign bodies and other unwanted materials in the tissues.
- **Harmful consequences of inflammation.** Protective inflammatory reactions to infections are often accompanied by local tissue damage and its associated signs and symptoms (e.g., pain and functional impairment). Typically, however, these harmful consequences are self-limited and resolve as the inflammation abates, leaving little or no permanent damage. In contrast, there are many diseases in which the inflammatory reaction is misdirected (e.g., against self tissues in autoimmune diseases), occurs against normally harmless environmental substances (e.g., in allergies), or is inadequately controlled. In these cases, the normally protective inflammatory reaction becomes the cause of the disease, and the damage it causes is the dominant feature. In clinical medicine, great attention is given to the injurious consequences of inflammation (Table 3-1). Inflammatory reactions underlie common chronic diseases, such as rheumatoid arthritis, atherosclerosis, and lung fibrosis, as well as life-threatening hypersensitivity reactions to insect bites, drugs, and toxins. For this reason our pharmacies abound with antiinflammatory drugs, which ideally would control the harmful sequelae of inflammation yet not interfere with its beneficial effects. In fact, inflammation may contribute to a variety of diseases that are thought to be primarily metabolic, degenerative, or genetic disorders, such as type 2

Figure 3-1 Sequence of events in an inflammatory reaction. Macrophages and other cells in tissues recognize microbes and damaged cells and liberate mediators, which trigger the vascular and cellular reactions of inflammation.

diabetes, Alzheimer disease, and cancer. In recognition of the wide-ranging harmful consequences of inflammation, the lay press has rather melodramatically referred to it as “the silent killer.”

- **Local and systemic inflammation.** Much of this discussion of inflammation focuses on the tissue reaction that is a local response to an infection or to localized damage. Although even such local reactions can have some systemic manifestations (e.g., fever in the setting of bacterial or viral pharyngitis), the reaction is largely confined to the site of infection or damage. In rare situations, such as some disseminated bacterial infections, the inflammatory reaction is systemic and causes widespread pathologic abnormalities. This reaction has been called *sepsis*, which is one form of the *systemic inflammatory response syndrome*. This serious disorder is discussed in Chapter 4.
- **Mediators of inflammation.** The vascular and cellular reactions of inflammation are triggered by soluble factors that are produced by various cells or derived from plasma proteins and are generated or activated

Table 3-1 Diseases Caused by Inflammatory Reactions

Disorders	Cells and Molecules Involved in Injury
Acute	
Acute respiratory distress syndrome	Neutrophils
Asthma	Eosinophils; IgE antibodies
Glomerulonephritis	Antibodies and complement; neutrophils, monocytes
Septic shock	Cytokines
Chronic	
Arthritis	Lymphocytes, macrophages; antibodies?
Asthma	Eosinophils; IgE antibodies
Atherosclerosis	Macrophages; lymphocytes
Pulmonary fibrosis	Macrophages; fibroblasts

Listed are selected examples of diseases in which the inflammatory response plays a significant role in tissue injury. Some, such as asthma, can present with acute inflammation or a chronic illness with repeated bouts of acute exacerbation. These diseases and their pathogenesis are discussed in relevant chapters.

in response to the inflammatory stimulus. Microbes, necrotic cells (whatever the cause of cell death), and even hypoxia can trigger the elaboration of inflammatory mediators and thus elicit inflammation. Such mediators initiate and amplify the inflammatory response and determine its pattern, severity, and clinical and pathologic manifestations.

- **Acute and chronic inflammation** (Table 3-2). The initial, rapid response to infections and tissue damage is called *acute inflammation*. It typically develops within minutes or hours and is of short duration, lasting for several hours or a few days; its main characteristics are the exudation of fluid and plasma proteins (edema) and the emigration of leukocytes, predominantly neutrophils (also called polymorphonuclear leukocytes). When acute inflammation achieves its desired goal of eliminating the offenders, the reaction subsides, but if the response fails to clear the stimulus, the reaction can progress to a protracted phase that is called *chronic inflammation*. Chronic inflammation is of longer duration and is associated with more tissue destruction, the presence of lymphocytes and macrophages, the proliferation of blood vessels, and the deposition of connective tissue. Chronic inflammation is discussed later in this chapter. Acute inflammation is one of the reactions of the type of host defense known as *innate immunity*, and chronic inflammation is more prominent in the reactions of *adaptive immunity* (Chapter 6).
- **Termination of inflammation and initiation of tissue repair.** Inflammation is terminated when the offending

Table 3-2 Features of Acute and Chronic Inflammation

Feature	Acute	Chronic
Onset	Fast: minutes or hours	Slow: days
Cellular infiltrate	Mainly neutrophils	Monocytes/macrophages and lymphocytes
Tissue injury, fibrosis	Usually mild and self-limited	Often severe and progressive
Local and systemic signs	Prominent	Less

agent is eliminated. The reaction resolves because mediators are broken down and dissipated, and leukocytes have short life spans in tissues. In addition, antiinflammatory mechanisms are activated, serving to control the response and prevent it from causing excessive damage to the host. Once inflammation has achieved its goal of eliminating the offending agents, it also sets into motion the process of *tissue repair*. Repair consists of a series of events that heal damaged tissue. In this process, the injured tissue is replaced through *regeneration* of surviving cells and filling of residual defects with connective tissue (*scarring*).

This chapter describes the causes (etiology) of and stimuli for inflammation, and then the sequence of events, mediators, and morphologic patterns of acute inflammation. This is followed by a discussion of chronic inflammation, and then the process of tissue repair. The study of inflammation has a rich history, and we first touch on past work that paved the way for our current understanding of this fascinating process.

Historical Highlights

Although clinical features of inflammation were described in an Egyptian papyrus dated around 3000 BC, Celsus, a Roman writer of the first century AD, first listed the four cardinal signs of inflammation: *rubor* (redness), *tumor* (swelling), *calor* (heat), and *dolor* (pain). These signs are hallmarks of acute inflammation. A fifth clinical sign, loss of function (*functio laesa*), was added by Rudolf Virchow in the 19th century. In 1793, the Scottish surgeon John Hunter noted what is now considered an obvious fact: inflammation is not a disease but a stereotypic response that has a salutary effect on its host. In the 1880s, Russian biologist Elie Metchnikoff discovered the process of *phagocytosis* by observing the ingestion of rose thorns by amebocytes of starfish larvae and of bacteria by mammalian leukocytes. He concluded that the purpose of inflammation was to bring phagocytic cells to the injured area to engulf invading bacteria. This concept was satirized by George Bernard Shaw in his play “The Doctor’s Dilemma,” in which one physician’s cure-all is to “stimulate the phagocytes!” Sir Thomas Lewis, studying the inflammatory response in skin, established the concept that *chemical substances, such as histamine (produced locally in response to injury), mediate the vascular changes of inflammation*. This fundamental concept underlies the important discoveries of chemical mediators of inflammation and the use of antiinflammatory drugs in clinical medicine.

Causes of Inflammation

Inflammatory reactions may be triggered by a variety of stimuli:

- **Infections** (bacterial, viral, fungal, parasitic) and microbial toxins are among the most common and medically important causes of inflammation. Different infectious pathogens elicit varied inflammatory responses, from mild acute inflammation that causes little or no lasting damage and successfully eradicates the infection, to severe systemic reactions that can be fatal, to prolonged

chronic reactions that cause extensive tissue injury. The outcomes are determined largely by the type of pathogen and, to some extent, by characteristics of the host that remain poorly defined.

- **Tissue necrosis** elicits inflammation regardless of the cause of cell death, which may include *ischemia* (reduced blood flow, the cause of myocardial infarction), *trauma*, and *physical and chemical injury* (e.g., thermal injury, as in burns or frostbite; irradiation; exposure to some environmental chemicals). Several molecules released from necrotic cells are known to trigger inflammation; some of these are described below.
- **Foreign bodies** (splinters, dirt, sutures) may elicit inflammation by themselves or because they cause traumatic tissue injury or carry microbes. Even some endogenous substances can be considered potentially harmful if large amounts are deposited in tissues; such substances include urate crystals (in the disease gout), cholesterol crystals (in atherosclerosis), and lipids (in obesity-associated metabolic syndrome).
- **Immune reactions** (also called *hypersensitivity*) are reactions in which the normally protective immune system damages the individual's own tissues. The injurious immune responses may be directed against self antigens, causing *autoimmune diseases*, or may be inappropriate reactions against environmental substances, as in *allergies*, or against microbes. Inflammation is a major cause of tissue injury in these diseases (Chapter 6). Because the stimuli for the inflammatory responses (e.g., self and environmental antigens) cannot be eliminated, autoimmune and allergic reactions tend to be persistent and difficult to cure, are often associated with chronic inflammation, and are important causes of morbidity and mortality. The inflammation is induced by cytokines produced by T lymphocytes and other cells of the immune system (Chapter 6).

Recognition of Microbes and Damaged Cells

Recognition of offending agents is the first step in all inflammatory reactions. The cells and receptors that perform this function of recognizing invaders evolved as adaptation of multicellular organisms to the presence of microbes in the environment, and the responses they trigger are critical for the survival of the organisms. Several cellular receptors and circulating proteins are capable of recognizing microbes and products of cell damage and triggering inflammation.

- **Cellular receptors for microbes.** Cells express receptors in the plasma membrane (for extracellular microbes), the endosomes (for ingested microbes), and the cytosol (for intracellular microbes) that enable the cells to sense the presence of foreign invaders in any cellular compartment. The best defined of these receptors belong to the family of *Toll-like receptors (TLRs)*; these and other cellular receptors of innate immunity are described in Chapter 6. The receptors are expressed on many cell types, including epithelial cells (through which microbes enter from the external environment), dendritic cells, macrophages, and other leukocytes (which may encounter microbes in various tissues). Engagement

of these receptors triggers production of molecules involved in inflammation, including adhesion molecules on endothelial cells, cytokines, and other mediators.

- **Sensors of cell damage.** All cells have cytosolic receptors that recognize a diverse set of molecules that are liberated or altered as a consequence of cell damage. These molecules include uric acid (a product of DNA breakdown), ATP (released from damaged mitochondria), reduced intracellular K⁺ concentrations (reflecting loss of ions because of plasma membrane injury), even DNA when it is released into the cytoplasm and not sequestered in nuclei, as it should be normally, and many others. These receptors activate a multiprotein cytosolic complex called the *inflammasome* (Chapter 6), which induces the production of the cytokine interleukin-1 (IL-1). IL-1 recruits leukocytes and thus induces inflammation (see later). Gain-of-function mutations in the sensor are the cause of rare diseases known as *autoinflammatory syndromes* that are characterized by spontaneous inflammation; IL-1 antagonists are effective treatments for these disorders. The inflammasome has also been implicated in inflammatory reactions to urate crystals (the cause of *gout*), lipids (in metabolic syndrome), cholesterol crystals (in atherosclerosis), and even amyloid deposits in the brain (in Alzheimer disease). These disorders are discussed later in this and other chapters.
- **Other cellular receptors involved in inflammation.** In addition to directly recognizing microbes, many leukocytes express receptors for the Fc tails of antibodies and for complement proteins. These receptors recognize microbes coated with antibodies and complement (the coating process is called *opsonization*) and promote ingestion and destruction of the microbes as well as inflammation.
- **Circulating proteins.** The *complement system* reacts against microbes and produces mediators of inflammation (discussed later). A circulating protein called *mannose-binding lectin* recognizes microbial sugars and promotes ingestion of the microbes and the activation of the complement system. Other proteins called *collectins* also bind to and combat microbes.

KEY CONCEPTS

General Features and Causes of Inflammation

- Inflammation is a beneficial host response to foreign invaders and necrotic tissue, but it may also cause tissue damage.
- The main components of inflammation are a vascular reaction and a cellular response; both are activated by mediators that are derived from plasma proteins and various cells.
- The steps of the inflammatory response can be remembered as the five Rs: (1) recognition of the injurious agent, (2) recruitment of leukocytes, (3) removal of the agent, (4) regulation (control) of the response, and (5) resolution (repair).
- The causes of inflammation include infections, tissue necrosis, foreign bodies, trauma, and immune responses.

- Epithelial cells, tissue macrophages and dendritic cells, leukocytes, and other cell types express receptors that sense the presence of microbes and damage. Circulating proteins recognize microbes that have entered the blood.
- The outcome of acute inflammation is either elimination of the noxious stimulus followed by decline of the reaction and repair of the damaged tissue, or persistent injury resulting in chronic inflammation.

Acute Inflammation

Acute inflammation has three major components: (1) dilation of small vessels leading to an increase in blood flow, (2) increased permeability of the microvasculature enabling plasma proteins and leukocytes to leave the circulation, and (3) emigration of the leukocytes from the microcirculation, their accumulation in the focus of injury, and their activation to eliminate the offending agent (Fig. 3-1). When an individual encounters an injurious agent, such as an infectious microbe or dead cells, phagocytes that reside in all tissues try to eliminate these agents. At the same time, phagocytes and other sentinel cells in the tissues recognize the presence of the foreign or abnormal substance and react by liberating cytokines, lipid messengers, and other mediators of inflammation. Some of these mediators act on small blood vessels in the vicinity and promote the efflux of plasma and the recruitment of circulating leukocytes to the site where the offending agent is located.

Reactions of Blood Vessels in Acute Inflammation

The vascular reactions of acute inflammation consist of changes in the flow of blood and the permeability of vessels, both designed to maximize the movement of plasma proteins and leukocytes out of the circulation and into the site of infection or injury. The escape of fluid, proteins, and blood cells from the vascular system into the interstitial tissue or body cavities is known as *exudation* (Fig. 3-2). An *exudate* is an extravascular fluid that has a high protein concentration and contains cellular debris. Its presence implies that there is an increase in the permeability of small blood vessels triggered by some sort of tissue injury and an ongoing inflammatory reaction. In contrast, a *transudate* is a fluid with low protein content (most of which is albumin), little or no cellular material, and low specific gravity. It is essentially an ultrafiltrate of blood plasma that is produced as a result of osmotic or hydrostatic imbalance across the vessel wall without an increase in vascular permeability (Chapter 4). *Edema* denotes an excess of fluid in the interstitial tissue or serous cavities; it can be either an exudate or a transudate. *Pus*, a *purulent exudate*, is an inflammatory exudate rich in leukocytes (mostly neutrophils), the debris of dead cells and, in many cases, microbes.

Changes in Vascular Flow and Caliber

Changes in vascular flow and caliber begin early after injury and consist of the following.

- Vasodilation is induced by the action of several mediators, notably histamine, on vascular smooth muscle.

Figure 3-2 Formation of exudates and transudates. **A**, Normal hydrostatic pressure (blue arrow) is about 32 mm Hg at the arterial end of a capillary bed and 12 mm Hg at the venous end; the mean colloid osmotic pressure of tissues is approximately 25 mm Hg (green arrow), which is equal to the mean capillary pressure. Therefore, the net flow of fluid across the vascular bed is almost nil. **B**, An exudate is formed in inflammation, because vascular permeability increases as a result of increased interendothelial spaces. **C**, A transudate is formed when fluid leaks out because of increased hydrostatic pressure or decreased osmotic pressure.

It is one of the earliest manifestations of acute inflammation. Vasodilation first involves the arterioles and then leads to opening of new capillary beds in the area. The result is *increased blood flow*, which is the cause of heat and redness (*erythema*) at the site of inflammation.

- Vasodilation is quickly followed by **increased permeability of the microvasculature**, with the outpouring of protein-rich fluid into the extravascular tissues; this process is described in detail below.
- The loss of fluid and increased vessel diameter lead to slower blood flow, concentration of red cells in small vessels, and increased viscosity of the blood. These changes result in **engorgement of small vessels with slowly moving red cells, a condition termed stasis**, which is seen as *vascular congestion* and localized redness of the involved tissue.
- As stasis develops, **blood leukocytes, principally neutrophils, accumulate along the vascular endothelium**. At the same time endothelial cells are activated by mediators produced at sites of infection and tissue damage, and express increased levels of adhesion molecules. Leukocytes then adhere to the endothelium, and soon afterward they migrate through the vascular wall into the interstitial tissue, in a sequence that is described later.

Increased Vascular Permeability (Vascular Leakage)

Several mechanisms are responsible for the increased permeability of postcapillary venules, a hallmark of acute inflammation (Fig. 3-3):

- **Contraction of endothelial cells resulting in increased interendothelial spaces is the most common mechanism of vascular leakage.** It is elicited by histamine, bradykinin, leukotrienes, and other chemical mediators. It is called the *immediate transient response* because it occurs rapidly after exposure to the mediator and is usually short-lived (15 to 30 minutes). In some forms of mild injury (e.g., after burns, irradiation or ultraviolet radiation, and exposure to certain bacterial toxins), vascular leakage begins after a delay of 2 to 12 hours and lasts for several hours or even days; this *delayed prolonged leakage* may be caused by contraction of endothelial cells or mild endothelial damage. Late-appearing sunburn is a good example of this type of leakage.
- **Endothelial injury, resulting in endothelial cell necrosis and detachment.** Direct damage to the endothelium is encountered in severe injuries, for example, in burns, or is induced by the actions of microbes and microbial toxins that target endothelial cells. Neutrophils that adhere to the endothelium during inflammation may also injure the endothelial cells and thus amplify the reaction. In most instances leakage starts immediately after injury and is sustained for several hours until the damaged vessels are thrombosed or repaired.
- Increased transport of fluids and proteins, called *transcytosis*, through the endothelial cell. This process may involve intracellular channels that may be stimulated by certain factors, such as vascular endothelial growth factor (VEGF), that promote vascular leakage. However, the contribution of this process to the vascular permeability of acute inflammation is uncertain.

Figure 3-3 Principal mechanisms of increased vascular permeability in inflammation and their features and underlying causes.

Although these mechanisms of increased vascular permeability are described separately, all probably contribute in varying degrees in responses to most stimuli. For example, at different stages of a thermal burn, leakage results from chemically mediated endothelial contraction and direct and leukocyte-dependent endothelial injury. The vascular leakage induced by these mechanisms can cause life-threatening loss of fluid in severely burned patients.

Responses of Lymphatic Vessels and Lymph Nodes

In addition to blood vessels, lymphatic vessels also participate in acute inflammation. The system of lymphatics and lymph nodes filters and polices the extravascular fluids. Lymphatics normally drain the small amount of extravascular fluid that has seeped out of capillaries. In inflammation, lymph flow is increased and helps drain edema fluid that accumulates because of increased vascular permeability. In addition to fluid, leukocytes and cell debris, as well as microbes, may find their way into lymph. Lymphatic vessels, like blood vessels, proliferate during inflammatory reactions to handle the increased load. The lymphatics may become secondarily inflamed (*lymphangitis*), as may the draining lymph nodes (*lymphadenitis*). Inflamed lymph nodes are often enlarged because of hyperplasia of the lymphoid follicles and increased numbers of lymphocytes and macrophages. This constellation of pathologic changes is termed *reactive, or inflammatory, lymphadenitis* (Chapter 13). For clinicians the presence of red streaks near a skin wound is a telltale sign of an infection in the wound. This

streaking follows the course of the lymphatic channels and is diagnostic of lymphangitis; it may be accompanied by painful enlargement of the draining lymph nodes, indicating lymphadenitis.

KEY CONCEPTS

Vascular Reactions in Acute Inflammation

- Vasodilation is induced by chemical mediators such as histamine (described later), and is the cause of erythema and stasis of blood flow.
- Increased vascular permeability is induced by histamine, kinins, and other mediators that produce gaps between endothelial cells, by direct or leukocyte-induced endothelial injury, and by increased passage of fluids through the endothelium.
- Increased vascular permeability allows plasma proteins and leukocytes, the mediators of host defense, to enter sites of infection or tissue damage. Fluid leak from blood vessels results in edema.
- Lymphatic vessels and lymph nodes are also involved in inflammation, and often show redness and swelling.

Leukocyte Recruitment to Sites of Inflammation

The changes in blood flow and vascular permeability are quickly followed by an influx of leukocytes into the tissue. These leukocytes perform the key function of eliminating the offending agents. The most important leukocytes in typical inflammatory reactions are the ones capable of phagocytosis, namely neutrophils and macrophages.

These leukocytes ingest and destroy bacteria and other microbes, as well as necrotic tissue and foreign substances. Leukocytes also produce growth factors that aid in repair. A price that is paid for the defensive potency of leukocytes is that, when strongly activated, they may induce tissue damage and prolong inflammation, because the leukocyte products that destroy microbes and help “clean up” necrotic tissues can also injure normal bystander host tissues.

The journey of leukocytes from the vessel lumen to the tissue is a multistep process that is mediated and controlled by adhesion molecules and cytokines called chemokines. This process can be divided into sequential phases (Fig. 3-4):

1. In the lumen: *margination, rolling, and adhesion to endothelium.* Vascular endothelium in its normal, unactivated state does not bind circulating cells or impede their passage. In inflammation, the endothelium is activated and can bind leukocytes as a prelude to their exit from the blood vessels.
2. Migration across the endothelium and vessel wall
3. Migration in the tissues toward a chemotactic stimulus

Leukocyte Adhesion to Endothelium

In normally flowing blood in venules, red cells are confined to a central axial column, displacing the leukocytes toward the wall of the vessel. Because blood flow slows early in inflammation (stasis), hemodynamic conditions change (wall shear stress decreases), and more white cells assume a peripheral position along the endothelial surface. This process of leukocyte redistribution is called *margination*. Subsequently, leukocytes adhere transiently to the

Figure 3-4 The multistep process of leukocyte migration through blood vessels, shown here for neutrophils. The leukocytes first roll, then become activated and adhere to endothelium, then transmigrate across the endothelium, pierce the basement membrane, and migrate toward chemoattractants emanating from the source of injury. Different molecules play predominant roles in different steps of this process: selectins in rolling; chemokines (usually displayed bound to proteoglycans) in activating the neutrophils to increase avidity of integrins; integrins in firm adhesion; and CD31 (PECAM-1) in transmigration. ICAM-1, Intercellular adhesion molecule 1; PECAM-1 (CD31), platelet endothelial cell adhesion molecule-1; TNF, tumor necrosis factor.

endothelium, detach and bind again, thus *rolling* on the vessel wall. The cells finally come to rest at some point where they *adhere* firmly (resembling pebbles over which a stream runs without disturbing them).

The attachment of leukocytes to endothelial cells is mediated by complementary adhesion molecules on the two cell types whose expression is enhanced by cytokines. Cytokines are secreted by sentinel cells in tissues in response to microbes and other injurious agents, thus ensuring that leukocytes are recruited to the tissues where these stimuli are present.

The two major families of molecules involved in leukocyte adhesion and migration are the selectins and integrins, and their ligands. They are expressed on leukocytes and endothelial cells.

- The initial rolling interactions are mediated by a family of proteins called *selectins* (Table 3-3). There are three types of selectins: one expressed on leukocytes (L-selectin), one on endothelium (E-selectin), and one in platelets and on endothelium (P-selectin). The ligands for selectins are sialylated oligosaccharides bound to mucin-like glycoprotein backbones. The expression of selectins and their ligands is regulated by cytokines produced in response to infection and injury. Tissue macrophages, mast cells, and endothelial cells that encounter microbes and dead tissues respond by secreting several cytokines, including tumor necrosis factor (TNF), IL-1, and chemokines (*chemoattractant cytokines*). (Cytokines are described in more detail later and in Chapter 6.) TNF and IL-1 act on the endothelial cells of postcapillary venules adjacent to the infection and induce the coordinate expression of numerous adhesion molecules. Within 1 to 2 hours the endothelial cells begin to express E-selectin and the ligands for L-selectin. Other mediators such as histamine and thrombin, described later, stimulate the redistribution of P-selectin from its normal intracellular stores in endothelial cell granules (called *Weibel-Palade bodies*) to the cell surface. Leukocytes express L-selectin at the tips of their microvilli and also express ligands for E- and P-selectins, all of which bind

to the complementary molecules on the endothelial cells. These are low-affinity interactions with a fast off-rate, and they are easily disrupted by the flowing blood. As a result, the bound leukocytes bind, detach, and bind again, and thus begin to roll along the endothelial surface.

- These weak rolling interactions slow down the leukocytes and give them the opportunity to bind more firmly to the endothelium. Firm adhesion is mediated by a family of heterodimeric leukocyte surface proteins called *integrins* (Table 3-3). TNF and IL-1 induce endothelial expression of ligands for integrins, mainly vascular cell adhesion molecule 1 (VCAM-1, the ligand for the β 1 integrin VLA-4) and intercellular adhesion molecule-1 (ICAM-1, the ligand for the β 2 integrins LFA-1 and Mac-1). Leukocytes normally express integrins in a low-affinity state. Chemokines that were produced at the site of injury bind to endothelial cell proteoglycans, and are displayed at high concentrations on the endothelial surface. These chemokines bind to and activate the rolling leukocytes. One of the consequences of activation is the conversion of VLA-4 and LFA-1 integrins on the leukocytes to a high-affinity state. The combination of cytokine-induced expression of integrin ligands on the endothelium and increased integrin affinity on the leukocytes results in firm integrin-mediated binding of the leukocytes to the endothelium at the site of inflammation. The leukocytes stop rolling, their cytoskeleton is reorganized, and they spread out on the endothelial surface.

Leukocyte Migration Through Endothelium

The next step in the process of leukocyte recruitment is migration of the leukocytes through the endothelium, called *transmigration* or *diapedesis*. Transmigration of leukocytes occurs mainly in postcapillary venules. Chemokines act on the adherent leukocytes and stimulate the cells to migrate through interendothelial spaces toward the chemical concentration gradient, that is, toward the site of injury or infection where the chemokines are being

Table 3-3 Endothelial and Leukocyte Adhesion Molecules

Family	Molecule	Distribution	Ligand
Selectin	L-selectin (CD62L)	Neutrophils, monocytes T cells (naïve and central memory) B cells (naïve)	Sialyl-Lewis X/PNAd on GlyCAM-1, CD34, MAdCAM-1, others; expressed on endothelium (HEV)
	E-selectin (CD62E)	Endothelium activated by cytokines (TNF, IL-1)	Sialyl-Lewis X (e.g., CLA) on glycoproteins; expressed on neutrophils, monocytes, T cells (effector, memory)
	P-selectin (CD62P)	Endothelium activated by cytokines (TNF, IL-1), histamine, or thrombin	Sialyl-Lewis X on PSGL-1 and other glycoproteins; expressed on neutrophils, monocytes, T cells (effector, memory)
Integrin	LFA-1 (CD11aCD18)	Neutrophils, monocytes, T cells (naïve, effector, memory)	ICAM-1 (CD54), ICAM-2 (CD102); expressed on endothelium (upregulated on activated endothelium)
	MAC-1 (CD11bCD18)	Monocytes, DCs	ICAM-1 (CD54), ICAM-2 (CD102); expressed on endothelium (upregulated on activated endothelium)
	VLA-4 (CD49aCD29)	Monocytes T cells (naïve, effector, memory)	VCAM-1 (CD106); expressed on endothelium (upregulated on activated endothelium)
	α 4 β 7 (CD49DCD29)	Monocytes T cells (gut homing naïve effector, memory)	VCAM-1 (CD106), MAdCAM-1; expressed on endothelium in gut and gut-associated lymphoid tissues
Ig	CD31	Endothelial cells, leukocytes	CD31 (homotypic interaction)

CLA, Cutaneous lymphocyte antigen-1; GlyCAM-1, glycan-bearing cell adhesion molecule-1; HEV, high endothelial venule; Ig, immunoglobulin; IL-1, interleukin-1; ICAM, intercellular adhesion molecule; MAdCAM-1, mucosal adhesion cell adhesion molecule-1; PSGL-1, P-selectin glycoprotein ligand-1; TNF, tumor necrosis factor; VCAM, vascular cell adhesion molecule.

produced. Several adhesion molecules present in the intercellular junctions between endothelial cells are involved in the migration of leukocytes. These molecules include a member of the immunoglobulin superfamily called *CD31* or *PECAM-1* (platelet endothelial cell adhesion molecule). After traversing the endothelium, leukocytes pierce the basement membrane, probably by secreting collagenases, and enter the extravascular tissue. The cells then migrate toward the chemotactic gradient created by chemokines and other chemoattractants and accumulate in the extravascular site.

The most telling proof of the importance of leukocyte adhesion molecules is the existence of genetic deficiencies in these molecules that result in recurrent bacterial infections as a consequence of impaired leukocyte adhesion and defective inflammation. These leukocyte adhesion deficiencies are described in [Chapter 6](#).

Chemotaxis of Leukocytes

After exiting the circulation, leukocytes move in the tissues toward the site of injury by a process called *chemotaxis*, which is defined as locomotion along a chemical gradient. Both exogenous and endogenous substances can act as chemoattractants. The most common exogenous agents are *bacterial products*, including peptides that possess an *N*-formylmethionine terminal amino acid and some lipids. Endogenous chemoattractants include several chemical mediators (described later): (1) *cytokines*, particularly those of the chemokine family (e.g., IL-8); (2) *components of the complement system*, particularly *C5a*; and (3) *arachidonic acid (AA) metabolites*, mainly *leukotriene B₄* (*LTB₄*). All these chemotactic agents bind to specific seven-transmembrane G protein-coupled receptors on the surface of leukocytes. Signals initiated from these receptors result in activation of second messengers that increase cytosolic calcium and activate small guanosine triphosphatases of the Rac/Rho/cdc42 family as well as numerous kinases. These signals induce polymerization of actin, resulting in increased amounts of polymerized actin at the leading edge of the cell and localization of myosin filaments at the back. The leukocyte moves by extending filopodia that pull the back of the cell in the direction of extension, much as an automobile with front-wheel drive is pulled by the wheels in front ([Fig. 3-5](#)). The net result is that leukocytes migrate toward the inflammatory stimulus in the direction of the locally produced chemoattractants.

The nature of the leukocyte infiltrate varies with the age of the inflammatory response and the type of stimulus. In most forms of acute inflammation neutrophils predominate in the inflammatory infiltrate during the first 6 to 24 hours and are replaced by monocytes in 24 to 48 hours ([Fig. 3-6](#)). There are several reasons for the early preponderance of neutrophils: they are more numerous in the blood than other leukocytes, they respond more rapidly to chemokines, and they may attach more firmly to the adhesion molecules that are rapidly induced on endothelial cells, such as P- and E-selectins. After entering tissues, neutrophils are short-lived; they undergo apoptosis and disappear within 24 to 48 hours. Monocytes not only survive longer but may also proliferate in the tissues, and thus they become the dominant population in prolonged inflammatory reactions. There are, however, exceptions to this stereotypic pattern of cellular infiltration.

Figure 3-5 Scanning electron micrograph of a moving leukocyte in culture showing a filopodium (upper left) and a trailing tail. (Courtesy Dr. Morris J. Karnovsky, Harvard Medical School, Boston, Mass.)

In certain infections—for example, those produced by *Pseudomonas* bacteria—the cellular infiltrate is dominated by continuously recruited neutrophils for several days; in viral infections, lymphocytes may be the first cells to arrive; some hypersensitivity reactions are dominated by activated lymphocytes, macrophages, and plasma cells (reflecting the immune response); and in allergic reactions, eosinophils may be the main cell type.

The molecular understanding of leukocyte recruitment and migration has provided a large number of potential therapeutic targets for controlling harmful inflammation. Agents that block TNF, one of the major cytokines in leukocyte recruitment, are among the most successful therapeutics ever developed for chronic inflammatory diseases, and antagonists of leukocyte integrins are approved for inflammatory diseases or are being tested in clinical trials. Predictably, these antagonists not only have the desired effect of controlling the inflammation but can also compromise the ability of treated patients to defend themselves against microbes, which, of course, is the physiologic function of the inflammatory response.

KEY CONCEPTS

Leukocyte Recruitment to Sites of Inflammation

- Leukocytes are recruited from the blood into the extravascular tissue where infectious pathogens or damaged tissues may be located, migrate to the site of infection or tissue injury, and are activated to perform their functions.
- Leukocyte recruitment is a multistep process consisting of loose attachment to and rolling on endothelium (mediated

Figure 3-6 Nature of leukocyte infiltrates in inflammatory reactions. The photomicrographs show an inflammatory reaction in the myocardium after ischemic necrosis (infarction). **A**, Early (neutrophilic) infiltrates and congested blood vessels. **B**, Later (mononuclear) cellular infiltrates. **C**, The approximate kinetics of edema and cellular infiltration. For simplicity, edema is shown as an acute transient response, although secondary waves of delayed edema and neutrophil infiltration can also occur.

by selectins); firm attachment to endothelium (mediated by integrins); and migration through interendothelial spaces.

- Various cytokines promote expression of selectins and integrin ligands on endothelium (TNF, IL-1), increase the avidity of integrins for their ligands (chemokines), and promote directional migration of leukocytes (also chemokines); many of these cytokines are produced by tissue macrophages and other cells responding to the pathogens or damaged tissues.
- Neutrophils predominate in the early inflammatory infiltrate and are later replaced by monocytes and macrophages.

Once leukocytes (particularly neutrophils and monocytes) have been recruited to a site of infection or cell death, they must be activated to perform their functions. The responses of these leukocytes consist of (1) recognition of the offending agents by TLRs and other receptors, described earlier, which deliver signals that (2) activate the leukocytes to phagocytose and destroy the offending agents.

Phagocytosis and Clearance of the Offending Agent

Recognition of microbes or dead cells induces several responses in leukocytes that are collectively called leukocyte activation (Fig. 3-7). Activation results from signaling pathways that are triggered in leukocytes, resulting in increases in cytosolic Ca^{2+} and activation of enzymes such as protein kinase C and phospholipase A_2 . The functional responses that are most important for destruction of microbes and other offenders are phagocytosis and intracellular killing. Several other responses aid in the defensive functions of inflammation and may contribute to its injurious consequences.

Phagocytosis

Phagocytosis involves three sequential steps (Fig. 3-8): (1) *recognition* and *attachment* of the particle to be ingested by the leukocyte; (2) *engulfment*, with subsequent formation of a phagocytic vacuole; and (3) *killing* or *degradation* of the ingested material.

Phagocytic Receptors. Mannose receptors, scavenger receptors, and receptors for various opsonins bind and ingest microbes. The macrophage *mannose receptor* is a lectin that binds terminal mannose and fucose residues of glycoproteins and glycolipids. These sugars are typically part of molecules found on microbial cell walls, whereas mammalian glycoproteins and glycolipids contain terminal sialic acid or *N*-acetylgalactosamine. Therefore, the mannose receptor recognizes microbes and not host cells. *Scavenger receptors* were originally defined as molecules that bind and mediate endocytosis of oxidized or acetylated low-density lipoprotein (LDL) particles that can no longer interact with the conventional LDL receptor. Macrophage scavenger receptors bind a variety of microbes in addition to modified LDL particles. Macrophage integrins, notably Mac-1 (CD11b/CD18), may also bind microbes for phagocytosis. The efficiency of phagocytosis is greatly enhanced when microbes are opsonized by specific proteins (opsonins) for which the phagocytes express high-affinity receptors. The major opsonins are IgG antibodies, the C3b breakdown product of complement, and certain plasma lectins, notably mannose-binding lectin, all of which are recognized by specific receptors on leukocytes.

Engulfment. After a particle is bound to phagocyte receptors, extensions of the cytoplasm (pseudopods) flow around it, and the plasma membrane pinches off to form a vesicle (phagosome) that encloses the particle. The phagosome then fuses with a lysosomal granule, resulting in discharge of the granule's contents into the phagolysosome (Fig. 3-8). During this process the phagocyte may also release granule contents into the extracellular space.

Figure 3-7 Leukocyte activation. Different classes of cell surface receptors of leukocytes recognize different stimuli. The receptors initiate responses that mediate the functions of the leukocytes. Only some receptors are depicted (see text for details). LPS first binds to a circulating LPS-binding protein (not shown). IFN- γ , Interferon- γ ; LPS, lipopolysaccharide.

The process of phagocytosis is complex and involves the integration of many receptor-initiated signals that lead to membrane remodeling and cytoskeletal changes. Phagocytosis is dependent on polymerization of actin filaments; it is, therefore, not surprising that the signals that trigger phagocytosis are many of the same that are involved in chemotaxis.

Intracellular Destruction of Microbes and Debris

Killing of microbes is accomplished by reactive oxygen species (ROS, also called reactive oxygen intermediates) and reactive nitrogen species, mainly derived from nitric oxide (NO), and these as well as lysosomal enzymes destroy phagocytosed debris (Fig. 3-8). This is the final step in the elimination of infectious agents and necrotic cells. The killing and degradation of microbes and dead cell debris within neutrophils and macrophages occur most efficiently after activation of the phagocytes. All these killing mechanisms are normally sequestered in lysosomes, to which phagocytosed materials are brought. Thus, potentially harmful substances are segregated from the cell's cytoplasm and nucleus to avoid damage to the phagocyte while it is performing its normal function.

Reactive Oxygen Species. ROS are produced by the rapid assembly and activation of a multicomponent oxidase, NADPH oxidase (also called phagocyte oxidase), which oxidizes NADPH (reduced nicotinamide-adenine dinucleotide phosphate) and, in the process, reduces oxygen to superoxide anion (O_2^-). In neutrophils, this oxidative

reaction is triggered by activating signals and accompanies phagocytosis, and is called the *respiratory burst*. Phagocyte oxidase is an enzyme complex consisting of at least seven proteins. In resting neutrophils, different components of the enzyme are located in the plasma membrane and the cytoplasm. In response to activating stimuli, the cytosolic protein components translocate to the phagosomal membrane, where they assemble and form the functional enzyme complex. Thus, the ROS are produced within the lysosome and phagolysosome, where they can act on ingested particles without damaging the host cell. O_2^- is then converted into hydrogen peroxide (H_2O_2), mostly by spontaneous dismutation. H_2O_2 is not able to efficiently kill microbes by itself. However, the azurophilic granules of neutrophils contain the enzyme *myeloperoxidase* (MPO), which, in the presence of a halide such as Cl^- , converts H_2O_2 to hypochlorite (OCl_2^- , the active ingredient in household bleach). The latter is a potent antimicrobial agent that destroys microbes by *halogenation* (in which the halide is bound covalently to cellular constituents) or by *oxidation* of proteins and lipids (lipid peroxidation). The H_2O_2 -MPO-halide system is the most efficient bactericidal system of neutrophils. Nevertheless, inherited deficiency of MPO by itself leads to minimal increase in susceptibility to infection, emphasizing the redundancy of microbicidal mechanisms in leukocytes. H_2O_2 is also converted to hydroxyl radical ($\cdot OH$), another powerful destructive agent. As discussed in Chapter 2, these oxygen-derived free radicals bind to and modify cellular lipids, proteins, and nucleic acids, and thus destroy cells such as microbes.

Figure 3-8 Phagocytosis and intracellular destruction of microbes. Phagocytosis of a particle (e.g., a bacterium) involves binding to receptors on the leukocyte membrane, engulfment, and fusion of the phagocytic vacuoles with lysosomes. This is followed by destruction of ingested particles within the phagolysosomes by lysosomal enzymes and by reactive oxygen and nitrogen species. The microbicidal products generated from superoxide (O_2^-) are hypochlorite ($HOCl$) and hydroxyl radical ($\cdot OH$), and from nitric oxide (NO) it is peroxynitrite ($OONO\cdot$). During phagocytosis, granule contents may be released into extracellular tissues (not shown). MPO, Myeloperoxidase; iNOS, inducible NO synthase; ROS, reactive oxygen species.

Oxygen-derived radicals may be released extracellularly from leukocytes after exposure to microbes, chemokines, and antigen-antibody complexes, or following a phagocytic challenge. These ROS are implicated in tissue damage accompanying inflammation.

Serum, tissue fluids, and host cells possess *antioxidant mechanisms* that protect against these potentially harmful oxygen-derived radicals. These antioxidants are discussed in [Chapter 2](#); they include (1) the enzyme *superoxide dismutase*, which is found in or can be activated in a variety of cell types; (2) the enzyme *catalase*, which detoxifies H_2O_2 ; (3) *glutathione peroxidase*, another powerful H_2O_2 detoxifier; (4) the copper-containing serum protein *ceruloplasmin*; and (5) the iron-free fraction of serum *transferrin*. Thus, the influence of oxygen-derived free radicals in any given inflammatory reaction depends on the balance between production and inactivation of these metabolites by cells and tissues.

Nitric Oxide. NO , a soluble gas produced from arginine by the action of nitric oxide synthase (NOS), also participates in microbial killing. There are three different types of NOS: endothelial (eNOS), neuronal (nNOS), and inducible (iNOS). eNOS and nNOS are constitutively expressed at low levels and the NO they generate functions to maintain vascular tone and as a neurotransmitter, respectively. iNOS, the type that is involved in microbial killing, is induced when macrophages and neutrophils are activated by cytokines (e.g., $IFN-\gamma$) or microbial products. In macrophages, NO reacts with superoxide (O_2^-) to generate the highly reactive free radical peroxynitrite ($ONOO\cdot$). These nitrogen-derived free radicals, similar to ROS, attack and damage the lipids, proteins, and nucleic acids of microbes

and host cells ([Chapter 2](#)). Reactive oxygen and nitrogen species have overlapping actions, as shown by the observation that knockout mice lacking either phagocyte oxidase or iNOS are only mildly susceptible to infections but mice lacking both succumb rapidly to disseminated infections by normally harmless commensal bacteria.

In addition to its role as a microbicidal substance, NO relaxes vascular smooth muscle and promotes vasodilation. It is not clear if this action of NO plays an important role in the vascular reactions of acute inflammation.

Lysosomal Enzymes and Other Lysosomal Proteins. Neutrophils and monocytes contain lysosomal granules that contribute to microbial killing and, when released, may contribute to tissue damage. Neutrophils have two main types of granules. The smaller *specific* (or secondary) granules contain lysozyme, collagenase, gelatinase, lactoferrin, plasminogen activator, histaminase, and alkaline phosphatase. The larger *azurophil* (or primary) granules contain myeloperoxidase, bactericidal factors (lysozyme, defensins), acid hydrolases, and a variety of neutral proteases (elastase, cathepsin G, nonspecific collagenases, proteinase 3). Both types of granules can fuse with phagocytic vacuoles containing engulfed material, or the granule contents can be released into the extracellular space.

Different granule enzymes serve different functions. *Acid proteases* degrade bacteria and debris within the phagolysosomes, which are acidified by membrane-bound proton pumps. *Neutral proteases* are capable of degrading various extracellular components, such as collagen, basement membrane, fibrin, elastin, and cartilage, resulting in the tissue destruction that accompanies inflammatory processes. Neutral proteases can also cleave C3 and C5

Figure 3-9 Neutrophil extracellular traps (NETs). **A**, Healthy neutrophils with nuclei stained red and cytoplasm green. **B**, Release of nuclear material from neutrophils (note that two have lost their nuclei), forming extracellular traps. **C**, An electron micrograph of bacteria (staphylococci) trapped in NETs. (From Brinkmann V, Zychlinsky A. Beneficial suicide: why neutrophils die to make NETs. *Nat Rev Microbiol* 2007;5:577, with permission.)

complement proteins directly, yielding anaphylatoxins, and release a kinin-like peptide from kininogen. Neutrophil elastase has been shown to degrade virulence factors of bacteria and thus combat bacterial infections. Macrophages also contain acid hydrolases, collagenase, elastase, phospholipase, and plasminogen activator.

Because of the destructive effects of lysosomal enzymes, the initial leukocytic infiltration, if unchecked, can potentiate further inflammation by damaging tissues. These harmful proteases, however, are normally controlled by a system of *antiproteases* in the serum and tissue fluids. Foremost among these is α_1 -antitrypsin, which is the major inhibitor of neutrophil elastase. A deficiency of these inhibitors may lead to sustained action of leukocyte proteases, as is the case in patients with α_1 -antitrypsin deficiency (Chapter 15). α_2 -Macroglobulin is another antiprotease found in serum and various secretions.

Other microbicidal granule contents include *defensins*, cationic arginine-rich granule peptides that are toxic to microbes; *cathelicidins*, antimicrobial proteins found in neutrophils and other cells; *lysozyme*, which hydrolyzes the muramic acid-*N*-acetylglucosamine bond, found in the glycopeptide coat of all bacteria; *lactoferrin*, an iron-binding protein present in specific granules; and *major basic protein*, a cationic protein of eosinophils, which has limited bactericidal activity but is cytotoxic to many parasites.

Neutrophil Extracellular Traps

Neutrophil extracellular traps (NETs) are extracellular fibrillar networks that provide a high concentration of antimicrobial substances at sites of infection and prevent the spread of the microbes by trapping them in the fibrils. They are produced by neutrophils in response to

infectious pathogens (mainly bacteria and fungi) and inflammatory mediators (e.g., chemokines, cytokines [mainly interferons], complement proteins, and ROS). The extracellular traps consist of a viscous meshwork of nuclear chromatin that binds and concentrates granule proteins such as antimicrobial peptides and enzymes (Fig. 3-9). In the process of NET formation, the nuclei of the neutrophils are lost, leading to death of the cells. NETs have also been detected in the blood during sepsis, and it is believed that their formation in the circulation is dependent on platelet activation. The nuclear chromatin in the NETs, which includes histones and associated DNA, has been postulated to be a source of nuclear antigens in systemic autoimmune diseases, particularly lupus, in which individuals react against their own DNA and nucleoproteins (Chapter 6).

Leukocyte-Mediated Tissue Injury

Leukocytes are important causes of injury to normal cells and tissues under several circumstances:

- As part of a normal defense reaction against infectious microbes, when adjacent tissues suffer collateral damage. In some infections that are difficult to eradicate, such as tuberculosis and certain viral diseases, the prolonged host response contributes more to the pathology than does the microbe itself.
- When the inflammatory response is inappropriately directed against host tissues, as in certain autoimmune diseases.
- When the host reacts excessively against usually harmless environmental substances, as in allergic diseases, including asthma.

In all these situations, **the mechanisms by which leukocytes damage normal tissues are the same as the mechanisms involved in antimicrobial defense**, because once the leukocytes are activated, their effector mechanisms do not distinguish between offender and host. During activation and phagocytosis, neutrophils and macrophages produce microbicidal substances (ROS, NO, and lysosomal enzymes) within the phagolysosome; these substances are also released into the extracellular space. These released substances are capable of damaging normal cells and vascular endothelium, and may thus amplify the effects of the initial injurious agent. If unchecked or inappropriately directed against host tissues, the leukocyte infiltrate itself becomes the offender, and indeed leukocyte-dependent tissue injury underlies many acute and chronic human diseases (Table 3-1). This fact becomes evident in the discussion of specific disorders throughout the book.

The contents of lysosomal granules are secreted by leukocytes into the extracellular milieu by several mechanisms. Controlled secretion of granule contents is a normal response of activated leukocytes. If phagocytes encounter materials that cannot be easily ingested, such as immune complexes deposited on immovable flat surfaces (e.g., glomerular basement membrane), the inability of the leukocytes to surround and ingest these substances (*frustrated phagocytosis*) triggers strong activation, and the release of large amounts of lysosomal enzymes into the extracellular environment. Some phagocytosed substances, such as urate crystals, may damage the membrane of the phagolysosome and also lead to the release of lysosomal granule contents.

Other Functional Responses of Activated Leukocytes

In addition to eliminating microbes and dead cells, activated leukocytes play several other roles in host defense. Importantly, these cells, especially macrophages, produce cytokines that can either amplify or limit inflammatory reactions, growth factors that stimulate the proliferation of endothelial cells and fibroblasts and the synthesis of collagen, and enzymes that remodel connective tissues. Because of these activities, macrophages are also critical cells of chronic inflammation and tissue repair, after the inflammation has subsided. These functions of macrophages are discussed later in the chapter.

In this discussion of acute inflammation, we emphasize the importance of neutrophils and macrophages. However, it has recently become clear that some T lymphocytes, which are cells of adaptive immunity, also contribute to acute inflammation. The most important of these cells are those that produce the cytokine IL-17 (so-called T_H17 cells), which are discussed in more detail in Chapter 6. IL-17 induces the secretion of chemokines that recruit other leukocytes. In the absence of effective T_H17 responses, individuals are susceptible to fungal and bacterial infections, and the skin abscesses that develop are “cold abscesses,” lacking the classic features of acute inflammation, such as warmth and redness.

Termination of the Acute Inflammatory Response

Such a powerful system of host defense, with its inherent capacity to cause tissue injury, needs tight controls to minimize damage. In part, inflammation declines after the

offending agents are removed simply because the mediators of inflammation are produced in rapid bursts, only as long as the stimulus persists, have short half-lives, and are degraded after their release. Neutrophils also have short half-lives in tissues and die by apoptosis within a few hours after leaving the blood. In addition, as inflammation develops, the process itself triggers a variety of stop signals that actively terminate the reaction. These active termination mechanisms include a switch in the type of arachidonic acid metabolite produced, from proinflammatory leukotrienes to antiinflammatory lipoxins (described later), and the liberation of antiinflammatory cytokines, including transforming growth factor- β (TGF- β) and IL-10, from macrophages and other cells. Other control mechanisms that have been demonstrated experimentally include neural impulses (cholinergic discharge) that inhibit the production of TNF in macrophages.

KEY CONCEPTS

Leukocyte Activation and Removal of Offending Agents

- Leukocytes can eliminate microbes and dead cells by phagocytosis, followed by their destruction in phagolysosomes.
- Destruction is caused by free radicals (ROS, NO) generated in activated leukocytes and lysosomal enzymes.
- Neutrophils can extrude their nuclear contents to form extracellular nets that trap and destroy microbes.
- Enzymes and ROS may be released into the extracellular environment.
- The mechanisms that function to eliminate microbes and dead cells (the physiologic role of inflammation) are also capable of damaging normal tissues (the pathologic consequences of inflammation).
- Antiinflammatory mediators terminate the acute inflammatory reaction when it is no longer needed.

Mediators of Inflammation

The mediators of inflammation are the substances that initiate and regulate inflammatory reactions. Many mediators have been identified and targeted therapeutically to limit inflammation. In this discussion, we review their shared properties and the general principles of their production and actions.

- **The most important mediators of acute inflammation are vasoactive amines, lipid products (prostaglandins and leukotrienes), cytokines (including chemokines), and products of complement activation (Table 3-4).** These mediators induce various components of the inflammatory response typically by distinct mechanisms, which is why inhibiting each has been therapeutically beneficial. However, there is also some overlap (redundancy) in the actions of the mediators.
- **Mediators are either secreted by cells or generated from plasma proteins.** *Cell-derived mediators* are normally sequestered in intracellular granules and can be rapidly secreted by granule exocytosis (e.g., histamine in mast cell granules) or are synthesized de novo (e.g., prostaglandins and leukotrienes, cytokines) in response

Table 3-4 Principal Mediators of Inflammation

Mediator	Source	Action
Histamine	Mast cells, basophils, platelets	Vasodilation, increased vascular permeability, endothelial activation
Prostaglandins	Mast cells, leukocytes	Vasodilation, pain, fever
Leukotrienes	Mast cells, leukocytes	Increased vascular permeability, chemotaxis, leukocyte adhesion, and activation
Cytokines (TNF, IL-1, IL-6)	Macrophages, endothelial cells, mast cells	Local: endothelial activation (expression of adhesion molecules). Systemic: fever, metabolic abnormalities, hypotension (shock)
Chemokines	Leukocytes, activated macrophages	Chemotaxis, leukocyte activation
Platelet-activating factor	Leukocytes, mast cells	Vasodilation, increased vascular permeability, leukocyte adhesion, chemotaxis, degranulation, oxidative burst
Complement	Plasma (produced in liver)	Leukocyte chemotaxis and activation, direct target killing (membrane attack complex), vasodilation (mast cell stimulation)
Kinins	Plasma (produced in liver)	Increased vascular permeability, smooth muscle contraction, vasodilation, pain

to a stimulus. **The major cell types that produce mediators of acute inflammation are the sentinels that detect invaders and damage in tissues, that is, macrophages, dendritic cells, and mast cells,** but platelets, neutrophils, endothelial cells, and most epithelia can also be induced to elaborate some of the mediators. *Plasma-derived mediators* (e.g., complement proteins) are produced mainly in the liver and are present in the circulation as inactive precursors that must be activated, usually by a series of proteolytic cleavages, to acquire their biologic properties.

- **Active mediators are produced only in response to various stimuli.** These stimuli include microbial products and substances released from necrotic cells. Some of the stimuli trigger well-defined receptors and signaling pathways, described earlier, but we still do not know how other stimuli induce the secretion of mediators (e.g., from mast cells in response to cell injury or mechanical irritation). The usual requirement for microbes or dead tissues as the initiating stimulus ensures that inflammation is normally triggered only when and where it is needed.
- **Most of the mediators are short-lived.** They quickly decay, or are inactivated by enzymes, or they are otherwise scavenged or inhibited. There is thus a system of checks and balances that regulates mediator actions. These built-in control mechanisms are discussed with each class of mediator.
- **One mediator can stimulate the release of other mediators.** For instance, products of complement activation stimulate the release of histamine, and the cytokine TNF acts on endothelial cells to stimulate the production of another cytokine, IL-1, and many chemokines. The secondary mediators may have the same actions as the initial mediators but may also have different and even opposing activities. Such cascades provide mechanisms for amplifying—or, in certain instances, counteracting—the initial action of a mediator.

We next discuss the more important mediators of acute inflammation, focusing on their mechanisms of action and roles in acute inflammation.

Vasoactive Amines: Histamine and Serotonin

The two major vasoactive amines, so named because they have important actions on blood vessels, are histamine

and serotonin. They are stored as preformed molecules in cells and are therefore among the first mediators to be released during inflammation. The richest sources of histamine are the mast cells that are normally present in the connective tissue adjacent to blood vessels. It is also found in blood basophils and platelets. Histamine is stored in mast cell granules and is released by mast cell degranulation in response to a variety of stimuli, including (1) physical injury, such as trauma, cold, or heat, by unknown mechanisms; (2) binding of antibodies to mast cells, which underlies immediate hypersensitivity (allergic) reactions (Chapter 6); and (3) products of complement called *anaphylatoxins* (C3a and C5a), described later. Antibodies and complement products bind to specific receptors on mast cells and trigger signaling pathways that induce rapid degranulation. In addition, leukocytes are thought to secrete some histamine-releasing proteins but these have not been characterized. Neuropeptides (e.g., substance P) and cytokines (IL-1, IL-8) may also trigger release of histamine.

Histamine causes dilation of arterioles and increases the permeability of venules. Histamine is considered to be the principal mediator of the immediate transient phase of increased vascular permeability, producing interendothelial gaps in venules, as discussed earlier. Its vasoactive effects are mediated mainly via binding to receptors, called H_1 receptors, on microvascular endothelial cells. The anti-histamine drugs that are commonly used to treat some inflammatory reactions, such as allergies, are H_1 receptor antagonists that bind to and block the receptor. Histamine also causes contraction of some smooth muscles.

Serotonin (5-hydroxytryptamine) is a preformed vasoactive mediator present in platelets and certain neuroendocrine cells, such as in the gastrointestinal tract, and in mast cells in rodents but not humans. Its primary function is as a neurotransmitter in the gastrointestinal tract. It is also a vasoconstrictor, but the importance of this action in inflammation is unclear.

Arachidonic Acid Metabolites

The lipid mediators prostaglandins and leukotrienes are produced from arachidonic acid (AA) present in membrane phospholipids, and stimulate vascular and cellular reactions in acute inflammation. AA is a 20-carbon polyunsaturated fatty acid (5,8,11,14-eicosatetraenoic acid) that is derived from dietary sources or by conversion from the

Figure 3-10 Production of arachidonic acid metabolites and their roles in inflammation. Note the enzymatic activities whose inhibition through pharmacologic intervention blocks major pathways (denoted with a red X). COX-1, COX-2, Cyclooxygenase 1 and 2; HETE, hydroxyeicosatetraenoic acid; HPETE, hydroperoxyeicosatetraenoic acid.

essential fatty acid linoleic acid. It does not occur free in the cell but is normally esterified in membrane phospholipids. Mechanical, chemical, and physical stimuli or other mediators (e.g., C5a) release AA from membrane phospholipids through the action of cellular phospholipases, mainly phospholipase A₂. The biochemical signals involved in the activation of phospholipase A₂ include an increase in cytoplasmic Ca²⁺ and activation of various kinases in response to external stimuli. AA-derived mediators, also called *eicosanoids* (because they are derived from 20-carbon fatty acids; Greek *eicosa* = 20), are synthesized by two major classes of enzymes: cyclooxygenases (which generate prostaglandins) and lipoxygenases (which produce leukotrienes and lipoxins) (Fig. 3-10). Eicosanoids bind to G protein-coupled receptors on many cell types and can mediate virtually every step of inflammation (Table 3-5).

Prostaglandins

Prostaglandins (PGs) are produced by mast cells, macrophages, endothelial cells, and many other cell types, and are involved in the vascular and systemic reactions of inflammation. They are generated by the actions of two

Table 3-5 Principal Actions of Arachidonic Acid Metabolites in Inflammation

Action	Eicosanoid
Vasodilation	Prostaglandins PGI ₂ (prostacyclin), PGE ₁ , PGE ₂ , PGD ₂
Vasoconstriction	Thromboxane A ₂ , leukotrienes C ₄ , D ₄ , E ₄
Increased vascular permeability	Leukotrienes C ₄ , D ₄ , E ₄
Chemotaxis, leukocyte adhesion	Leukotrienes B ₄ , HETE

HETE, Hydroxyeicosatetraenoic acid.

cyclooxygenases, called COX-1 and COX-2. COX-1 is produced in response to inflammatory stimuli and is also constitutively expressed in most tissues, where it may serve a homeostatic function (e.g., fluid and electrolyte balance in the kidneys, cytoprotection in the gastrointestinal tract). In contrast, COX-2 is induced by inflammatory stimuli and thus generates the prostaglandins that are involved in inflammatory reactions, but it is low or absent in most normal tissues.

Prostaglandins are divided into series based on structural features as coded by a letter (PGD, PGE, PGF, PGG, and PGH) and a subscript numeral (e.g., 1, 2), which indicates the number of double bonds in the compound. The most important ones in inflammation are PGE₂, PGD₂, PGF_{2α}, PGI₂ (prostacyclin), and TxA₂ (thromboxane A₂), each of which is derived by the action of a specific enzyme on an intermediate in the pathway. Some of these enzymes have restricted tissue distribution. For example, platelets contain the enzyme thromboxane synthase, and hence TxA₂ is the major product in these cells. TxA₂, a potent platelet-aggregating agent and vasoconstrictor, is itself unstable and rapidly converted to its inactive form TxB₂. Vascular endothelium lacks thromboxane synthase but possesses prostacyclin synthase, which is responsible for the formation of prostacyclin (PGI₂) and its stable end product PGF_{1α}. Prostacyclin is a vasodilator and a potent inhibitor of platelet aggregation, and also markedly potentiates the permeability-increasing and chemotactic effects of other mediators. A thromboxane-prostacyclin imbalance has been implicated as an early event in thrombus formation in coronary and cerebral blood vessels. PGD₂ is the major prostaglandin made by mast cells; along with PGE₂ (which is more widely distributed), it causes vasodilation and increases the permeability of postcapillary venules, thus potentiating edema formation. PGF_{2α} stimulates the contraction of uterine and bronchial smooth muscle and small arterioles, and PGD₂ is a chemoattractant for neutrophils.

In addition to their local effects, the prostaglandins are involved in the pathogenesis of *pain* and *fever* in inflammation. PGE₂ is hyperalgesic and makes the skin hypersensitive to painful stimuli, such as intradermal injection of suboptimal concentrations of histamine and bradykinin. It is involved in cytokine-induced fever during infections (described later).

Leukotrienes

Leukotrienes are produced by leukocytes and mast cells by the action of lipoxygenase and are involved in vascular and smooth muscle reactions and leukocyte recruitment. There are three different lipoxygenases, 5-lipoxygenase being the predominant one in neutrophils. This enzyme converts AA to 5-hydroxyeicosatetraenoic acid, which is chemotactic for neutrophils, and is the precursor of the leukotrienes. LTB₄ is a potent chemotactic agent and activator of neutrophils, causing aggregation and adhesion of the cells to venular endothelium, generation of ROS, and release of lysosomal enzymes. The cysteinyl-containing leukotrienes LTC₄, LTD₄, and LTE₄ cause intense vasoconstriction, bronchospasm (important in asthma), and increased permeability of venules. Leukotrienes are more potent than is histamine in increasing vascular permeability and causing bronchospasm.

Lipoxins

Lipoxins are also generated from AA by the lipoxygenase pathway, but unlike prostaglandins and leukotrienes, the lipoxins suppress inflammation by inhibiting the recruitment of leukocytes. They inhibit neutrophil chemotaxis and adhesion to endothelium. They are also unusual in that two cell populations are required for the transcellular biosynthesis of these mediators. Leukocytes, particularly neutrophils, produce intermediates in lipoxin synthesis, and these are converted to lipoxins by platelets interacting with the leukocytes.

Pharmacologic Inhibitors of Prostaglandins and Leukotrienes

The importance of eicosanoids in inflammation has driven attempts to develop drugs that inhibit their production or actions and thus suppress inflammation. These anti-inflammatory drugs include the following.

- **Cyclooxygenase inhibitors** include aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs), such as ibuprofen. They inhibit both COX-1 and COX-2 and thus inhibit prostaglandin synthesis (hence their efficacy in treating pain and fever); aspirin does this by irreversibly acetylating and inactivating cyclooxygenases. Selective COX-2 inhibitors are a newer class of these drugs; they are 200-300 fold more potent in blocking COX-2 than COX-1. There has been great interest in COX-2 as a therapeutic target because of the possibility that COX-1 is responsible for the production of prostaglandins that are involved in both inflammation and homeostatic functions (e.g., fluid and electrolyte balance in the kidneys, cytoprotection in the gastrointestinal tract), whereas COX-2 generates prostaglandins that are involved only in inflammatory reactions. If this idea is correct, the selective COX-2 inhibitors should be anti-inflammatory without having the toxicities of the non-selective inhibitors, such as gastric ulceration. However, these distinctions are not absolute, as COX-2 also seems to play a role in normal homeostasis. Furthermore, selective COX-2 inhibitors may increase the risk of cardiovascular and cerebrovascular events, possibly because they impair endothelial cell production of prostacyclin (PGI₂), a vasodilator and inhibitor of platelet aggregation, but leave intact the COX-1-mediated production by platelets of thromboxane A₂ (TxA₂), an important mediator of platelet aggregation and vasoconstriction. Thus, selective COX-2 inhibition may tilt the balance towards thromboxane and promote vascular thrombosis, especially in individuals with other factors that increase the risk of thrombosis. Nevertheless, these drugs are still used in individuals who do not have risk factors for cardiovascular disease when their benefits outweigh their risks.
- **Lipoxygenase inhibitors.** 5-lipoxygenase is not affected by NSAIDs, and many new inhibitors of this enzyme pathway have been developed. Pharmacologic agents that inhibit leukotriene production (e.g., Zileuton) are useful in the treatment of asthma.
- **Corticosteroids** are broad-spectrum antiinflammatory agents that reduce the transcription of genes encoding COX-2, phospholipase A₂, proinflammatory cytokines (e.g., IL-1 and TNF), and iNOS.

- **Leukotriene receptor antagonists** block leukotriene receptors and prevent the actions of the leukotrienes. These drugs (e.g., Montelukast) are useful in the treatment of asthma.
- Another approach to manipulating inflammatory responses has been to modify the intake and content of dietary lipids by increasing the consumption of fish oil. The proposed explanation for the effectiveness of this approach is that the polyunsaturated fatty acids in fish oil are poor substrates for conversion to active metabolites by the cyclooxygenase and lipoxygenase pathways but are better substrates for the production of antiinflammatory lipid products.

Cytokines and Chemokines

Cytokines are proteins produced by many cell types (principally activated lymphocytes, macrophages, and dendritic cells, but also endothelial, epithelial, and connective tissue cells) that mediate and regulate immune and inflammatory reactions. By convention, growth factors that act on epithelial and mesenchymal cells are not grouped under cytokines. The general properties and functions of cytokines are discussed in [Chapter 6](#). Here the cytokines involved in acute inflammation are reviewed ([Table 3-6](#)).

Tumor Necrosis Factor (TNF) and Interleukin-1 (IL-1)

TNF and IL-1 serve critical roles in leukocyte recruitment by promoting adhesion of leukocytes to endothelium and their migration through vessels. These cytokines are produced mainly by activated macrophages and dendritic cells; TNF is also produced by T lymphocytes and mast cells, and IL-1 is produced by some epithelial cells as well. The secretion of TNF and IL-1 can be stimulated by microbial products, immune complexes, foreign bodies, physical injury, and a variety of other inflammatory stimuli. The production of TNF is induced by signals through TLRs and other microbial sensors, and the synthesis of IL-1 is stimulated by the same signals but the generation of the biologically active form of this cytokine is dependent on the inflammasome, described earlier.

The actions of TNF and IL-1 contribute to the local and systemic reactions of inflammation ([Fig. 3-11](#)). The most important roles of these cytokines in inflammation are the following.

- **Endothelial activation.** Both TNF and IL-1 act on endothelium to induce a spectrum of changes referred to as *endothelial activation*. These changes include increased expression of endothelial adhesion molecules, mostly E- and P-selectins and ligands for leukocyte integrins; increased production of various mediators, including other cytokines and chemokines, growth factors, and eicosanoids; and increased procoagulant activity of the endothelium.
- **Activation of leukocytes and other cells.** TNF augments responses of neutrophils to other stimuli such as bacterial endotoxin and stimulates the microbicidal activity of macrophages, in part by inducing production of NO. IL-1 activates fibroblasts to synthesize collagen and stimulates proliferation of synovial and other mesenchymal cells. IL-1 also stimulates T_H17 responses, which in turn induce acute inflammation.
- **Systemic acute-phase response.** IL-1 and TNF (as well as IL-6) induce the systemic acute-phase responses associated with infection or injury, including *fever* (described later in the chapter). They are also implicated in the syndrome of *sepsis*, resulting from disseminated bacterial infection. TNF regulates energy balance by promoting lipid and protein mobilization and by suppressing appetite. Therefore, sustained production of TNF contributes to *cachexia*, a pathologic state characterized by weight loss and anorexia that accompanies some chronic infections and neoplastic diseases.

TNF antagonists have been remarkably effective in the treatment of chronic inflammatory diseases, particularly rheumatoid arthritis and also psoriasis and some types of inflammatory bowel disease. One of the complications of this therapy is that patients become susceptible to mycobacterial infection, reflecting the reduced ability of macrophages to kill intracellular microbes. Although many of the actions of TNF and IL-1 seem overlapping, IL-1 antagonists are not as effective, for reasons that remain

Table 3-6 Cytokines in Inflammation

Cytokine	Principal Sources	Principal Actions in Inflammation
In Acute Inflammation		
TNF	Macrophages, mast cells, T lymphocytes	Stimulates expression of endothelial adhesion molecules and secretion of other cytokines; systemic effects
IL-1	Macrophages, endothelial cells, some epithelial cells	Similar to TNF; greater role in fever
IL-6	Macrophages, other cells	Systemic effects (acute phase response)
Chemokines	Macrophages, endothelial cells, T lymphocytes, mast cells, other cell types	Recruitment of leukocytes to sites of inflammation; migration of cells in normal tissues
IL-17	T lymphocytes	Recruitment of neutrophils and monocytes
In Chronic Inflammation		
IL-12	Dendritic cells, macrophages	Increased production of IFN- γ
IFN- γ	T lymphocytes, NK cells	Activation of macrophages (increased ability to kill microbes and tumor cells)
IL-17	T lymphocytes	Recruitment of neutrophils and monocytes

IFN- γ , Interferon- γ ; IL-1, interleukin-1; NK cells, natural killer cells; TNF, tumor necrosis factor.

The most important cytokines involved in inflammatory reactions are listed. Many other cytokines may play lesser roles in inflammation. There is also considerable overlap between the cytokines involved in acute and chronic inflammation. Specifically, all the cytokines listed under acute inflammation may also contribute to chronic inflammatory reactions.

Figure 3-11 Major roles of cytokines in acute inflammation. PDGF, Platelet-derived growth factor; PGE, prostaglandin E; PGI, prostaglandin I.

obscure. Also, blocking either cytokine has no effect on the outcome of sepsis, perhaps because other cytokines contribute to this serious systemic inflammatory reaction.

Chemokines

Chemokines are a family of small (8 to 10 kD) proteins that act primarily as chemoattractants for specific types of leukocytes. About 40 different chemokines and 20 different receptors for chemokines have been identified. They are classified into four major groups, according to the arrangement of cysteine (C) residues in the proteins:

- *C-X-C chemokines* have one amino acid residue separating the first two of the four conserved cysteine residues. These chemokines act primarily on neutrophils. IL-8 is typical of this group. It is secreted by activated macrophages, endothelial cells, and other cell types, and causes activation and chemotaxis of neutrophils, with limited activity on monocytes and eosinophils. Its most important inducers are microbial products and other cytokines, mainly IL-1 and TNF.
- *C-C chemokines* have the first two conserved cysteine residues adjacent. The C-C chemokines, which include monocyte chemoattractant protein (MCP-1), eotaxin, macrophage inflammatory protein-1 α (MIP-1 α), and RANTES (regulated and normal T-cell expressed and secreted), generally attract monocytes, eosinophils, basophils and lymphocytes, but are not as potent chemoattractants for neutrophils. Although most of the chemokines in this class have overlapping actions, eotaxin selectively recruits eosinophils.
- *C chemokines* lack the first and third of the four conserved cysteines. The C chemokines (e.g., lymphotactin) are relatively specific for lymphocytes.

- *CX₃C chemokines* contain three amino acids between the two cysteines. The only known member of this class is called *fractalkine*. This chemokine exists in two forms: a cell surface-bound protein induced on endothelial cells by inflammatory cytokines that promotes strong adhesion of monocytes and T cells, and a soluble form, derived by proteolysis of the membrane-bound protein, that has potent chemoattractant activity for the same cells.

Chemokines mediate their activities by binding to seven-transmembrane G protein-coupled receptors. These receptors (called CXCR or CCR, for C-X-C or C-C chemokine receptors) usually exhibit overlapping ligand specificities, and leukocytes generally express more than one receptor type. As discussed in [Chapter 6](#), certain chemokine receptors (CXCR-4, CCR-5) act as coreceptors for a viral envelope glycoprotein of human immunodeficiency virus (HIV), the cause of AIDS, and are thus involved in binding and entry of the virus into cells.

Chemokines may be displayed at high concentrations attached to proteoglycans on the surface of endothelial cells and in the extracellular matrix. They have two main functions:

- **In acute inflammation.** *Inflammatory chemokines* are the ones whose production is induced by microbes and other stimuli. These chemokines stimulate leukocyte attachment to endothelium by acting on leukocytes to increase the affinity of integrins, and they stimulate migration (chemotaxis) of leukocytes in tissues to the site of infection or tissue damage.
- **Maintenance of tissue architecture.** Some chemokines are produced constitutively in tissues and are sometimes called *homeostatic chemokines*. These organize

Figure 3-12 The activation and functions of the complement system. Activation of complement by different pathways leads to cleavage of C3. The functions of the complement system are mediated by breakdown products of C3 and other complement proteins, and by the membrane attack complex (MAC).

various cell types in different anatomic regions of the tissues, such as T and B lymphocytes in discrete areas of the spleen and lymph nodes (Chapter 6).

Although the role of chemokines in inflammation is well established, it has proved difficult to develop antagonists that block the activities of these proteins.

Other Cytokines in Acute Inflammation

The list of cytokines implicated in inflammation is huge and constantly growing. In addition to the ones described earlier, two that have received considerable recent interest are IL-6, made by macrophages and other cells, which is involved in local and systemic reactions, and IL-17, produced mainly by T lymphocytes, which promotes neutrophil recruitment. Antagonists against both are approved or have shown impressive efficacy in the treatment of inflammatory diseases. Type I interferons, whose normal function is to inhibit viral replication, contribute to some of the systemic manifestations of inflammation. Cytokines also play key roles in chronic inflammation; these are described later in the chapter.

Complement System

The complement system is a collection of soluble proteins and membrane receptors that function mainly in host defense against microbes and in pathologic inflammatory reactions. The system consists of more than 20 proteins, some of which are numbered C1 through C9. This system functions in both innate and adaptive immunity for defense against microbial pathogens. In the process of complement activation, several cleavage products of complement proteins are elaborated that cause increased vascular permeability, chemotaxis, and opsonization. The

activation and functions of complement are outlined in Figure 3-12.

Complement proteins are present in inactive forms in the plasma, and many of them are activated to become proteolytic enzymes that degrade other complement proteins, thus forming an enzymatic cascade capable of tremendous amplification. The critical step in complement activation is the proteolysis of the third (and most abundant) component, C3. **Cleavage of C3 can occur by one of three pathways:**

- The *classical pathway*, which is triggered by fixation of C1 to antibody (IgM or IgG) that has combined with antigen
- The *alternative pathway*, which can be triggered by microbial surface molecules (e.g., endotoxin, or LPS), complex polysaccharides, cobra venom, and other substances, in the absence of antibody
- The *lectin pathway*, in which plasma mannose-binding lectin binds to carbohydrates on microbes and directly activates C1.

All three pathways of complement activation lead to the formation of an active enzyme called the C3 convertase, which splits C3 into two functionally distinct fragments, C3a and C3b. C3a is released, and C3b becomes covalently attached to the cell or molecule where complement is being activated. More C3b then binds to the previously generated fragments to form *C5 convertase*, which cleaves C5 to release C5a and leave C5b attached to the cell surface. C5b binds the late components (C6-C9), culminating in the formation of the membrane attack complex (MAC, composed of multiple C9 molecules).

The complement system has three main functions (Fig. 3-12):

- **Inflammation.** *C3a*, *C5a*, and, to a lesser extent, *C4a* are cleavage products of the corresponding complement components that stimulate histamine release from mast cells and thereby increase vascular permeability and cause vasodilation. They are called *anaphylatoxins* because they have effects similar to those of mast cell mediators that are involved in the reaction called *anaphylaxis* (Chapter 6). *C5a* is also a chemotactic agent for neutrophils, monocytes, eosinophils, and basophils. In addition, *C5a* activates the lipoxygenase pathway of AA metabolism in neutrophils and monocytes, causing further release of inflammatory mediators.
- **Opsonization and phagocytosis.** *C3b* and its cleavage product *iC3b* (inactive *C3b*), when fixed to a microbial cell wall, act as opsonins and promote phagocytosis by neutrophils and macrophages, which bear cell surface receptors for the complement fragments.
- **Cell lysis.** The deposition of the MAC on cells makes these cells permeable to water and ions and results in death (lysis) of the cells. This role of complement is important mainly for the killing of microbes with thin cell walls, such as *Neisseria* bacteria, and deficiency of the terminal components of complement predisposes to *Neisseria* infections.

The activation of complement is tightly controlled by cell-associated and circulating regulatory proteins. Different regulatory proteins inhibit the production of active complement fragments or remove fragments that deposit on cells. These regulators are expressed on normal host cells and are thus designed to prevent healthy tissues from being injured at sites of complement activation. Regulatory proteins can be overwhelmed when large amounts of complement are deposited on host cells and in tissues, as happens in autoimmune diseases, in which individuals produce complement-fixing antibodies against their own cell and tissue antigens (Chapter 6). The most important of these regulatory proteins are the following:

- **C1 inhibitor (C1 INH)** blocks the activation of C1, the first protein of the classical complement pathway. Inherited deficiency of this inhibitor is the cause of *hereditary angioedema*.
- **Decay accelerating factor (DAF)** and **CD59** are two proteins that are linked to plasma membranes by a glycosphosphatidyl (GPI) anchor. DAF prevents formation of C3 convertases and CD59 inhibits formation of the membrane attack complex. An acquired deficiency of the enzyme that creates GPI anchors leads to deficiency of these regulators and excessive complement activation and lysis of red cells (which are sensitive to complement-mediated cell lysis) in the disease called *paroxysmal nocturnal hemoglobinuria (PNH)* (Chapter 14).
- Other complement regulatory proteins proteolytically cleave active complement components.

The complement system contributes to disease in several ways. The activation of complement by antibodies or antigen-antibody complexes deposited on host cells and tissues is an important mechanism of cell and tissue injury (Chapter 6). Inherited deficiencies of complement proteins cause increased susceptibility to infections (Chapter 6), and, as mentioned earlier, deficiencies of regulatory

proteins cause a variety of disorders, such as macular degeneration and hemolytic uremic syndrome, resulting from excessive complement activation.

Other Mediators of Inflammation

Platelet-Activating Factor (PAF)

PAF is a phospholipid-derived mediator that was discovered as a factor that caused platelet aggregation, but it is now known to have multiple inflammatory effects. A variety of cell types, including platelets themselves, basophils, mast cells, neutrophils, macrophages, and endothelial cells, can elaborate PAF, in both secreted and cell-bound forms. In addition to platelet aggregation, PAF causes vasoconstriction and bronchoconstriction, and at low concentrations it induces vasodilation and increased venular permeability. In the 1990s there was great interest in PAF as a mediator of inflammation, but trials of PAF antagonists in various inflammatory diseases have been disappointing.

Products of Coagulation

Studies done more than 50 years ago suggested that inhibiting coagulation reduced the inflammatory reaction to some microbes, leading to the idea that coagulation and inflammation are linked processes. This concept was supported by the discovery of protease-activated receptors (PARs), which are activated by thrombin (the protease that cleaves fibrinogen to produce fibrin, which forms the clot), and are expressed on platelets and leukocytes. It is, however, likely that the major role of the PARs is in platelet activation during clotting (Chapter 4). In fact, it is difficult to dissociate clotting and inflammation, since virtually all forms of tissue injury that lead to clotting also induce inflammation, and inflammation causes changes in endothelial cells that increase the likelihood of abnormal clotting (thrombosis, described in Chapter 4). However, whether the products of coagulation, per se, have a key role in stimulating inflammation is still not established.

Kinins

Kinins are vasoactive peptides derived from plasma proteins, called *kininogens*, by the action of specific proteases called kallikreins. The enzyme kallikrein cleaves a plasma glycoprotein precursor, high-molecular-weight kininogen, to produce *bradykinin*. **Bradykinin increases vascular permeability and causes contraction of smooth muscle, dilation of blood vessels, and pain when injected into the skin.** These effects are similar to those of histamine. The action of bradykinin is short-lived, because it is quickly inactivated by an enzyme called kininase. Bradykinin has been implicated as a mediator in some forms of allergic reaction, such as anaphylaxis (Chapter 6).

Neuropeptides

Neuropeptides are secreted by sensory nerves and various leukocytes, and may play a role in the initiation and regulation of inflammatory responses. These small peptides, such as substance P and neurokinin A, are produced in the central and peripheral nervous systems. Nerve fibers containing substance P are prominent in the lung and gastrointestinal tract. Substance P has many biologic functions, including the transmission of pain signals, regulation of

Table 3-7 Role of Mediators in Different Reactions of Inflammation

Reaction of Inflammation	Principal Mediators
Vasodilation	Histamine Prostaglandins

blood pressure, stimulation of hormone secretion by endocrine cells, and increasing vascular permeability.

When Lewis discovered the role of histamine in inflammation, one mediator was thought to be enough. Now, we are wallowing in them! Yet, from this large compendium, it is likely that a few mediators are most important for the reactions of acute inflammation *in vivo*, and these are summarized in Table 3-7. The redundancy of the mediators and their actions ensures that this protective response remains robust and is not readily subverted.

KEY CONCEPTS

Actions of the Principal Mediators of Inflammation

- Vasoactive amines, mainly histamine: vasodilation and increased vascular permeability
- Arachidonic acid metabolites (prostaglandins and leukotrienes): several forms exist and are involved in vascular reactions, leukocyte chemotaxis, and other reactions of inflammation; antagonized by lipoxins
- Cytokines: proteins produced by many cell types; usually act at short range; mediate multiple effects, mainly in leukocyte recruitment and migration; principal ones in acute inflammation are TNF, IL-1, and chemokines
- Complement proteins: Activation of the complement system by microbes or antibodies leads to the generation of multiple breakdown products, which are responsible for leukocyte chemotaxis, opsonization, and phagocytosis of microbes and other particles, and cell killing
- Kinins: produced by proteolytic cleavage of precursors; mediate vascular reaction, pain

Morphologic Patterns of Acute Inflammation

The morphologic hallmarks of acute inflammatory reactions are dilation of small blood vessels and accumulation of leukocytes and fluid in the extravascular tissue. However, special morphologic patterns are often

superimposed on these general features, depending on the severity of the reaction, its specific cause, and the particular tissue and site involved. The importance of recognizing the gross and microscopic patterns is that they often provide valuable clues about the underlying cause.

Serous Inflammation

Serous inflammation is marked by the exudation of cell-poor fluid into spaces created by cell injury or into body cavities lined by the peritoneum, pleura, or pericardium. Typically, the fluid in serous inflammation is not infected by destructive organisms and does not contain large numbers of leukocytes (which tend to produce purulent inflammation, described later). In body cavities the fluid may be derived from the plasma (as a result of increased vascular permeability) or from the secretions of mesothelial cells (as a result of local irritation); accumulation of fluid in these cavities is called an *effusion*. (Effusions also occur in noninflammatory conditions, such as reduced blood outflow in heart failure, or reduced plasma protein levels in some kidney and liver diseases.) The skin blister resulting from a burn or viral infection represents accumulation of serous fluid within or immediately beneath the damaged epidermis of the skin (Fig. 3-13).

Fibrinous Inflammation

With greater increase in vascular permeability, large molecules such as fibrinogen pass out of the blood, and fibrin is formed and deposited in the extracellular space. **A fibrinous exudate develops when the vascular leaks are large or there is a local procoagulant stimulus** (e.g., cancer cells). A fibrinous exudate is characteristic of inflammation in the lining of body cavities, such as the meninges, pericardium (Fig. 3-14A), and pleura. Histologically, fibrin appears as an eosinophilic meshwork of threads or sometimes as an amorphous coagulum (Fig. 3-14B). Fibrinous exudates may be dissolved by fibrinolysis and cleared by macrophages. If the fibrin is not removed, over time it may stimulate the ingrowth of fibroblasts and blood vessels and thus lead to scarring. Conversion of the fibrinous exudate to scar tissue (*organization*) within the pericardial sac leads to opaque fibrous thickening of the pericardium and

Figure 3-13 Serous inflammation. Low-power view of a cross-section of a skin blister showing the epidermis separated from the dermis by a focal collection of serous effusion.

epicardium in the area of exudation and, if the fibrosis is extensive, obliteration of the pericardial space.

Purulent (Suppurative) Inflammation, Abscess

Purulent inflammation is characterized by the production of pus, an exudate consisting of neutrophils, the liquefied debris of necrotic cells, and edema fluid. The most frequent cause of purulent (also called *suppurative*) inflammation is infection with bacteria that cause liquefactive tissue necrosis, such as staphylococci; these pathogens are referred to as *pyogenic* (pus-producing) bacteria. A common example of an acute suppurative inflammation is acute appendicitis. **Abscesses are localized collections of purulent inflammatory tissue** caused by suppuration buried in a tissue, an organ, or a confined space. They are produced by seeding of pyogenic bacteria into a tissue (Fig. 3-15). Abscesses have a central region that appears as a mass of necrotic leukocytes and tissue cells. There is usually a zone of preserved neutrophils around this necrotic focus, and outside this region there may be vascular dilation and parenchymal and fibroblastic proliferation, indicating chronic inflammation and repair. In time the abscess may

become walled off and ultimately replaced by connective tissue.

Ulcers

An ulcer is a local defect, or excavation, of the surface of an organ or tissue that is produced by the sloughing (shedding) of inflamed necrotic tissue (Fig. 3-16). Ulceration can occur only when tissue necrosis and resultant inflammation exist on or near a surface. It is most commonly encountered in (1) the mucosa of the mouth, stomach, intestines, or genitourinary tract, and (2) the skin and subcutaneous tissue of the lower extremities in older persons who have circulatory disturbances that predispose to extensive ischemic necrosis.

Ulcerations are best exemplified by peptic ulcer of the stomach or duodenum, in which acute and chronic inflammation coexist. During the acute stage there is intense polymorphonuclear infiltration and vascular dilation in the margins of the defect. With chronicity, the margins and base of the ulcer develop fibroblastic proliferation, scarring, and the accumulation of lymphocytes, macrophages, and plasma cells.

Outcomes of Acute Inflammation

Although, as might be expected, many variables may modify the basic process of inflammation, including the nature and intensity of the injury, the site and tissue affected, and the responsiveness of the host, **all acute inflammatory reactions typically have one of three outcomes** (Fig. 3-17):

- **Complete resolution.** In a perfect world, all inflammatory reactions, once they have succeeded in eliminating the offending agent, should end with restoration of the site of acute inflammation to normal. This is called

resolution and is the usual outcome when the injury is limited or short-lived or when there has been little tissue destruction and the damaged parenchymal cells can regenerate. Resolution involves removal of cellular debris and microbes by macrophages, and resorption of edema fluid by lymphatics.

- **Healing by connective tissue replacement (scarring, or fibrosis).** This occurs after substantial tissue destruction, when the inflammatory injury involves tissues that are incapable of regeneration, or when there is abundant fibrin exudation in tissue or in serous cavities (pleura, peritoneum) that cannot be adequately cleared. In all

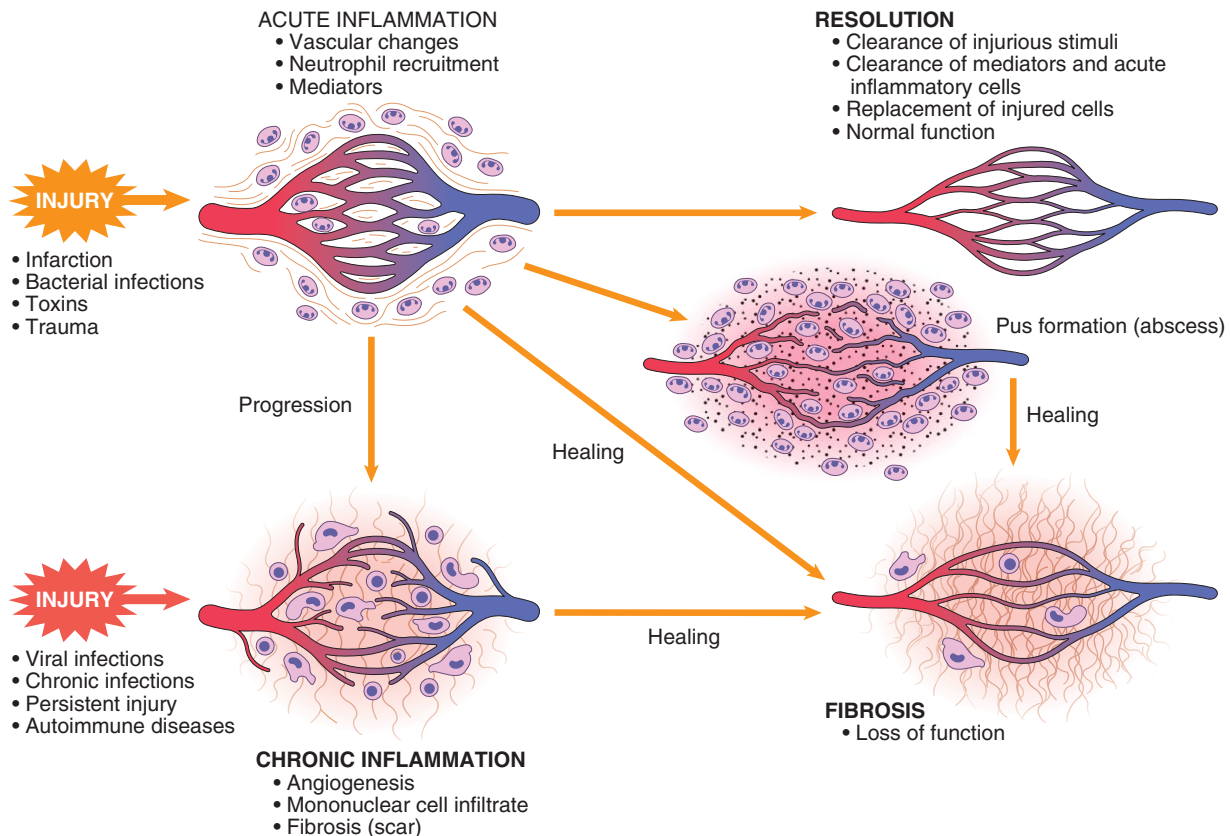

Figure 3-17 Outcomes of acute inflammation: resolution, healing by fibrosis, or chronic inflammation. The components of the various reactions and their functional outcomes are listed.

these situations, connective tissue grows into the area of damage or exudate, converting it into a mass of fibrous tissue, a process also called *organization*.

- Progression of the response to **chronic inflammation** (discussed later). Acute to chronic transition occurs when the acute inflammatory response cannot be resolved, as a result of either the persistence of the injurious agent or some interference with the normal process of healing.

Summary of Acute Inflammation

Now that we have described the components, mediators, and pathologic manifestations of acute inflammatory responses, it is useful to summarize the main features of a typical response of this type. When a host encounters an injurious agent, such as an infectious microbe or dead cells, phagocytes that reside in all tissues try to eliminate these agents. At the same time, phagocytes and other host cells react to the presence of the foreign or abnormal substance by liberating cytokines, lipid messengers, and other mediators of inflammation. Some of these mediators act on small blood vessels in the vicinity and promote the efflux of plasma and the recruitment of circulating leukocytes to the site where the offending agent is located. The recruited leukocytes are activated by the injurious agent and by locally produced mediators, and the activated leukocytes try to remove the offending agent by phagocytosis. As the injurious agent is eliminated and anti-inflammatory mechanisms become active, the process subsides and the host returns to a normal state of health. If the injurious agent cannot be quickly eliminated, the result may be chronic inflammation.

The vascular and cellular reactions account for the signs and symptoms of the inflammatory response. The increased blood flow to the injured area and increased vascular permeability lead to the accumulation of extravascular fluid rich in plasma proteins, known as *edema*. The redness (*rubor*), warmth (*calor*), and swelling (*tumor*) of acute inflammation are caused by the increased blood flow and edema. Circulating leukocytes, initially predominantly neutrophils, adhere to the endothelium via adhesion molecules, traverse the endothelium, and migrate to the site of injury under the influence of chemotactic agents. Leukocytes that are activated by the offending agent and by endogenous mediators may release toxic metabolites and proteases extracellularly, causing tissue damage. During the damage, and in part as a result of the liberation of prostaglandins, neuropeptides, and cytokines, one of the local symptoms is pain (*dolor*).

Chronic Inflammation

Chronic inflammation is a response of prolonged duration (weeks or months) in which inflammation, tissue injury and attempts at repair coexist, in varying combinations. It may follow acute inflammation, as described earlier, or chronic inflammation may begin insidiously, as a low-grade, smoldering response without any manifestations of a preceding acute reaction.

Causes of Chronic Inflammation

Chronic inflammation arises in the following settings:

- **Persistent infections** by microorganisms that are difficult to eradicate, such as mycobacteria and certain viruses, fungi, and parasites. These organisms often evoke an immune reaction called *delayed-type hypersensitivity* (Chapter 6). The inflammatory response sometimes takes a specific pattern called a *granulomatous reaction* (discussed later). In other cases, an unresolved acute inflammation may evolve into chronic inflammation, as may occur in acute bacterial infection of the lung that progresses to a chronic lung abscess.
- **Hypersensitivity diseases.** Chronic inflammation plays an important role in a group of diseases that are caused by excessive and inappropriate activation of the immune system. Under certain conditions immune reactions develop against the individual's own tissues, leading to *autoimmune diseases* (Chapter 6). In these diseases, autoantigens evoke a self-perpetuating immune reaction that results in chronic tissue damage and inflammation; examples of such diseases are rheumatoid arthritis and multiple sclerosis. In other cases, chronic inflammation is the result of unregulated immune responses against microbes, as in inflammatory bowel disease. Immune responses against common environmental substances are the cause of *allergic diseases*, such as bronchial asthma (Chapter 6). Because these autoimmune and allergic reactions are inappropriately triggered against antigens that are normally harmless, the reactions serve no useful purpose and only cause disease. Such diseases may show morphologic patterns of mixed acute and chronic inflammation because they are characterized by repeated bouts of inflammation. Fibrosis may dominate the late stages.
- **Prolonged exposure to potentially toxic agents, either exogenous or endogenous.** An example of an exogenous agent is particulate silica, a nondegradable inanimate material that, when inhaled for prolonged periods, results in an inflammatory lung disease called *silicosis* (Chapter 15). *Atherosclerosis* (Chapter 11) is thought to be a chronic inflammatory process of the arterial wall induced, at least in part, by excessive production and tissue deposition of endogenous cholesterol and other lipids.
- Some forms of chronic inflammation may be important in the pathogenesis of diseases that are not conventionally thought of as inflammatory disorders. These include neurodegenerative diseases such as Alzheimer disease, metabolic syndrome and the associated type 2 diabetes, and certain cancers in which inflammatory reactions promote tumor development. The role of inflammation in these conditions is discussed in the relevant chapters.

Morphologic Features

In contrast to acute inflammation, which is manifested by vascular changes, edema, and predominantly neutrophilic infiltration, **chronic inflammation is characterized by:**

- **Infiltration with mononuclear cells**, which include macrophages, lymphocytes, and plasma cells (Fig. 3-18)

Figure 3-18 **A**, Chronic inflammation in the lung, showing all three characteristic histologic features: (1) collection of chronic inflammatory cells (*), (2) destruction of parenchyma (normal alveoli are replaced by spaces lined by cuboidal epithelium, *arrowheads*), and (3) replacement by connective tissue (fibrosis, *arrows*). **B**, In contrast, in acute inflammation of the lung (acute bronchopneumonia), neutrophils fill the alveolar spaces and blood vessels are congested.

- **Tissue destruction**, induced by the persistent offending agent or by the inflammatory cells
- **Attempts at healing** by connective tissue replacement of damaged tissue, accomplished by *angiogenesis* (proliferation of small blood vessels) and, in particular, *fibrosis*

Because angiogenesis and fibrosis are also components of wound healing and repair, they are discussed later, in the context of tissue repair.

Cells and Mediators of Chronic Inflammation

The combination of leukocyte infiltration, tissue damage, and fibrosis that characterize chronic inflammation is the result of the local activation of several cell types and the production of mediators.

Role of Macrophages

The dominant cells in most chronic inflammatory reactions are macrophages, which contribute to the reaction by secreting cytokines and growth factors that act on various cells, by destroying foreign invaders and tissues, and by activating other cells, notably T lymphocytes.

Macrophages are professional phagocytes that act as filters for particulate matter, microbes, and senescent cells. They also function as effector cells that eliminate microbes in cellular and humoral immune responses (Chapter 6). But they serve many other roles in inflammation and repair. Here we review the basic biology of macrophages, including their development and functional responses.

Macrophages are tissue cells derived from hematopoietic stem cells in the bone marrow and from progenitors in the embryonic yolk sac and fetal liver during early development (Fig. 3-19). Circulating cells of this lineage are known as *monocytes*. Macrophages are normally diffusely scattered in most connective tissues. In addition, they are found in specific locations in organs such as the liver (where they are called Kupffer cells), spleen and lymph nodes (called sinus histiocytes), central nervous system (microglial cells), and lungs (alveolar macrophages). Together these cells comprise the *mononuclear phagocyte system*, also known by the older (and inaccurate) name of reticuloendothelial system.

Committed progenitors in the bone marrow give rise to monocytes, which enter the blood, migrate into various tissues and differentiate into macrophages. This is typical of macrophages at sites of inflammation and in some tissues such as the skin and intestinal tract. The half-life of blood monocytes is about 1 day, whereas the life span of tissue macrophages is several months or years. Most tissue resident macrophages, such as microglia, Kupffer cells, alveolar macrophages and macrophages in the spleen and connective tissues, may arise from yolk sac or fetal liver very early in embryogenesis, populate the tissues, stay for long periods in the steady state, and are replenished mainly by proliferation of resident cells. As discussed earlier, in inflammatory reactions, monocytes begin to emigrate into extravascular tissues quite early, and within 48 hours they may constitute the predominant cell type. Extravasation of monocytes is governed by the same factors that are involved in neutrophil emigration, that is, adhesion molecules and chemical mediators with chemotactic and activating properties.

There are two major pathways of macrophage activation, called *classical* and *alternative* (Fig. 3-20). The stimuli that activate macrophages by these pathways, and the functions of the activated cells, are quite different.

- **Classical macrophage activation** may be induced by microbial products such as endotoxin, which engage TLRs and other sensors; by T cell-derived signals, importantly the cytokine IFN- γ , in immune responses; or by foreign substances including crystals and particulate matter. Classically activated (also called M1) macrophages produce NO and ROS and upregulate lysosomal enzymes, all of which enhance their ability to kill ingested organisms, and secrete cytokines that stimulate inflammation. These macrophages are important in host defense against microbes and in many inflammatory reactions. As discussed earlier in the context of acute inflammation and leukocyte activation, the same activated cells are capable of injuring normal tissues.
- **Alternative macrophage activation** is induced by cytokines other than IFN- γ , such as IL-4 and IL-13, produced by T lymphocytes and other cells. These macrophages

Figure 3-19 Maturation of mononuclear phagocytes. **A**, In the steady state, some tissue macrophages, including microglia and alveolar macrophages, may be derived from embryonic precursors and populate the tissues. The development of macrophages from hematopoietic precursors and monocytes may be more prominent when tissue macrophages need to be increased or replenished, as after injury and during inflammation. **B**, The morphology of a monocyte and activated macrophage.

are not actively microbicidal and the cytokines may actually inhibit the classical activation pathway; instead, the principal function of alternatively activated (M2) macrophages is in tissue repair. They secrete growth factors that promote angiogenesis, activate fibroblasts, and stimulate collagen synthesis. It seems plausible that

in response to most injurious stimuli, the first activation pathway is the classical one, designed to destroy the offending agents, and this is followed by alternative activation, which initiates tissue repair. However, such a precise sequence is not well documented in most inflammatory reactions.

Figure 3-20 Classical and alternative macrophage activation. Different stimuli activate monocytes/macrophages to develop into functionally distinct populations. Classically activated macrophages are induced by microbial products and cytokines, particularly IFN- γ . They phagocytose and destroy microbes and dead tissues and can potentiate inflammatory reactions. Alternatively activated macrophages are induced by other cytokines and are important in tissue repair and the resolution of inflammation.

The products of activated macrophages eliminate injurious agents such as microbes and initiate the process of repair, but are also responsible for much of the tissue injury in chronic inflammation. Several functions of macrophages are central to the development and persistence of chronic inflammation and the accompanying tissue injury.

- Macrophages, like the other type of phagocyte, the neutrophils, **ingest and eliminate microbes and dead tissues**.
- Macrophages **initiate the process of tissue repair** and are involved in scar formation and fibrosis. These processes are discussed later in the chapter.
- Macrophages **secrete mediators of inflammation**, such as cytokines (TNF, IL-1, chemokines, and others) and eicosanoids. Thus, macrophages are central to the initiation and propagation of inflammatory reactions.
- Macrophages **display antigens to T lymphocytes and respond to signals from T cells**, thus setting up a feedback loop that is essential for defense against many microbes by cell-mediated immune responses. These interactions are described further in the discussion of the role of lymphocytes in chronic inflammation, below, and in more detail in [Chapter 6](#) where cell-mediated immunity is considered.

Their impressive arsenal of mediators makes macrophages powerful allies in the body's defense against unwanted invaders, but the same weaponry can also induce considerable tissue destruction when macrophages are inappropriately or excessively activated. It is because of these activities of macrophages that tissue destruction is one of the hallmarks of chronic inflammation.

In some instances, if the irritant is eliminated, macrophages eventually disappear (either dying off or making their way into the lymphatics and lymph nodes). In others, macrophage accumulation persists, as a result of continuous recruitment from the circulation and local proliferation at the site of inflammation.

Role of Lymphocytes

Microbes and other environmental antigens activate T and B lymphocytes, which amplify and propagate chronic inflammation. Although the major function of these lymphocytes is as the mediators of adaptive immunity, which provides defense against infectious pathogens ([Chapter 6](#)), these cells are often present in chronic inflammation and when they are activated, the inflammation tends to be persistent and severe. Some of the strongest chronic inflammatory reactions, such as granulomatous inflammation, described later, are dependent on lymphocyte responses. Lymphocytes may be the dominant population in the chronic inflammation seen in autoimmune and other hypersensitivity diseases.

Antigen-stimulated (effector and memory) T and B lymphocytes use various adhesion molecule pairs (selectins, integrins and their ligands) and chemokines to migrate into inflammatory sites. Cytokines from activated macrophages, mainly TNF, IL-1, and chemokines, promote leukocyte recruitment, setting the stage for persistence of the inflammatory response.

By virtue of their ability to secrete cytokines, CD4+ T lymphocytes promote inflammation and influence the

nature of the inflammatory reaction. These T cells greatly amplify the early inflammatory reaction that is induced by recognition of microbes and dead cells as part of innate immunity. There are three subsets of CD4+ T cells that secrete different types of cytokines and elicit different types of inflammation.

- T_H1 cells produce the cytokine IFN- γ , which activates macrophages by the classical pathway.
- T_H2 cells secrete IL-4, IL-5, and IL-13, which recruit and activate eosinophils and are responsible for the alternative pathway of macrophage activation.
- T_H17 cells secrete IL-17 and other cytokines, which induce the secretion of chemokines responsible for recruiting neutrophils (and monocytes) into the reaction.

Both T_H1 and T_H17 cells are involved in defense against many types of bacteria and viruses and in autoimmune diseases. T_H2 cells are important in defense against helminthic parasites and in allergic inflammation. These T cell subsets and their functions are described in more detail in [Chapter 6](#).

Lymphocytes and macrophages interact in a bidirectional way, and these interactions play an important role in propagating chronic inflammation ([Fig. 3-21](#)). Macrophages display antigens to T cells, express membrane molecules (called costimulators), and produce cytokines (IL-12 and others) that stimulate T-cell responses ([Chapter 6](#)). Activated T lymphocytes, in turn, produce cytokines, described earlier, which recruit and activate macrophages, promoting more antigen presentation and cytokine secretion. The result is a cycle of cellular reactions that fuel and sustain chronic inflammation.

Activated B lymphocytes and antibody-producing plasma cells are often present at sites of chronic inflammation. The antibodies may be specific for persistent foreign or self antigens in the inflammatory site or against altered tissue components. However, the specificity and even the importance of antibodies in most chronic inflammatory disorders are unclear.

In some chronic inflammatory reactions, the accumulated lymphocytes, antigen-presenting cells, and plasma cells cluster together to form lymphoid tissues resembling lymph nodes. These are called *tertiary lymphoid organs*; this type of *lymphoid organogenesis* is often seen in the synovium of patients with long-standing rheumatoid arthritis and in the thyroid in Hashimoto thyroiditis. It has been postulated that the local formation of lymphoid organs may perpetuate the immune reaction, but the significance of these structures is not established.

Other Cells in Chronic Inflammation

Other cell types may be prominent in chronic inflammation induced by particular stimuli.

- **Eosinophils** are abundant in immune reactions mediated by IgE and in parasitic infections ([Fig. 3-22](#)). Their recruitment is driven by adhesion molecules similar to those used by neutrophils, and by specific chemokines (e.g., eotaxin) derived from leukocytes and epithelial cells. Eosinophils have granules that contain *major basic protein*, a highly cationic protein that is toxic to parasites but also causes lysis of mammalian epithelial cells. This

Figure 3-21 Macrophage-lymphocyte interactions in chronic inflammation. Activated T cells produce cytokines that recruit macrophages (TNF, IL-17, chemokines) and others that activate macrophages (IFN- γ). Activated macrophages in turn stimulate T cells by presenting antigens and via cytokines such as IL-12.

is why eosinophils are of benefit in controlling parasitic infections, yet they also contribute to tissue damage in immune reactions such as allergies (Chapter 6).

- **Mast cells** are widely distributed in connective tissues and participate in both acute and chronic inflammatory reactions. Mast cells express on their surface the receptor (Fc ϵ RI) that binds the Fc portion of IgE antibody. In immediate hypersensitivity reactions, IgE antibodies bound to the cells' Fc receptors specifically recognize antigen, and the cells degranulate and release mediators, such as histamine and prostaglandins (Chapter 6). This type of response occurs during allergic reactions to foods, insect venom, or drugs, sometimes with catastrophic results (e.g., anaphylactic shock). Mast cells are also present in chronic inflammatory reactions, and because they secrete a plethora of cytokines, they may promote inflammatory reactions in different situations.
- Although **neutrophils** are characteristic of acute inflammation, many forms of chronic inflammation, lasting for months, continue to show large numbers of neutrophils, induced either by persistent microbes or by mediators produced by activated macrophages and

T lymphocytes. In chronic bacterial infection of bone (osteomyelitis), a neutrophilic exudate can persist for many months. Neutrophils are also important in the chronic damage induced in lungs by smoking and other irritant stimuli (Chapter 15). This pattern of inflammation has been called *acute on chronic*.

Granulomatous Inflammation

Granulomatous inflammation is a form of chronic inflammation characterized by collections of activated macrophages, often with T lymphocytes, and sometimes associated with central necrosis. Granuloma formation is a cellular attempt to contain an offending agent that is difficult to eradicate. In this attempt there is often strong activation of T lymphocytes leading to macrophage activation, which can cause injury to normal tissues. The activated macrophages may develop abundant cytoplasm and begin to resemble epithelial cells, and are called *epithelioid cells*. Some activated macrophages may fuse, forming multinucleate *giant cells*.

There are two types of granulomas, which differ in their pathogenesis.

- **Foreign body granulomas** are incited by relatively inert foreign bodies, in the absence of T cell-mediated immune responses. Typically, foreign body granulomas form around materials such as talc (associated with intravenous drug abuse) (Chapter 9), sutures, or other fibers that are large enough to preclude phagocytosis by a macrophage and do not incite any specific inflammatory or immune response. Epithelioid cells and giant cells are apposed to the surface of the foreign body. The foreign material can usually be identified in the center of the granuloma, particularly if viewed with polarized light, in which it appears refractile.
- **Immune granulomas** are caused by a variety of agents that are capable of inducing a persistent T cell-mediated immune response. This type of immune response produces granulomas usually when the inciting agent is difficult to eradicate, such as a persistent microbe or a self antigen. In such responses, macrophages activate

Figure 3-22 A focus of inflammation containing numerous eosinophils.

T cells to produce cytokines, such as IL-2, which activates other T cells, perpetuating the response, and IFN- γ , which activates the macrophages. It is not established which macrophage-activating cytokines (IL-4 or IFN- γ) transform the cells into epithelioid cells and multinucleate giant cells.

MORPHOLOGY

In the usual hematoxylin and eosin preparations (Fig. 3-23), the activated macrophages in granulomas have pink granular cytoplasm with indistinct cell boundaries and are called **epithelioid cells** because of their resemblance to epithelia. The aggregates of epithelioid macrophages are surrounded by a collar of lymphocytes. Older granulomas may have a rim of fibroblasts and connective tissue. Frequently, but not invariably, multinucleated **giant cells** 40 to 50 μm in diameter are found in granulomas; these are called Langhans giant cells. They consist of a large mass of cytoplasm and many nuclei, and they derive from the fusion of multiple activated macrophages. In granulomas associated with certain infectious organisms (most classically *Mycobacterium tuberculosis*), a combination of hypoxia and free radical-mediated injury leads to a central zone of necrosis. Grossly, this has a granular, cheesy appearance and is therefore called **caseous necrosis**. Microscopically, this necrotic material appears as amorphous, structureless, eosinophilic, granular debris, with complete loss of cellular details. The granulomas in Crohn disease, sarcoidosis, and foreign body reactions tend to not have necrotic centers and are said to be *noncaseating*. Healing of granulomas is accompanied by fibrosis that may be extensive.

Granulomas are encountered in certain specific pathologic states; recognition of the granulomatous pattern is important because of the limited number of conditions (some life-threatening) that cause it (Table 3-8). In the setting of persistent T-cell responses to certain microbes (e.g., *M. tuberculosis*, *Treponema pallidum*, or fungi), T cell-derived cytokines are responsible for chronic macrophage activation and granuloma formation. Granulomas may also develop in some immune-mediated inflammatory

Figure 3-23 Typical tuberculous granuloma showing an area of central necrosis surrounded by multiple Langhans-type giant cells, epithelioid cells, and lymphocytes.

Table 3-8 Examples of Diseases with Granulomatous Inflammation

Disease	Cause	Tissue Reaction
Tuberculosis	<i>Mycobacterium tuberculosis</i>	Caseating granuloma (tubercle): focus of activated macrophages (epithelioid cells), rimmed by fibroblasts, lymphocytes, histiocytes, occasional Langhans giant cells; central necrosis with amorphous granular debris; acid-fast bacilli
Leprosy	<i>Mycobacterium leprae</i>	Acid-fast bacilli in macrophages; noncaseating granulomas
Syphilis	<i>Treponema pallidum</i>	Gumma: microscopic to grossly visible lesion, enclosing wall of histiocytes; plasma cell infiltrate; central cells are necrotic without loss of cellular outline
Cat-scratch disease	Gram-negative bacillus	Rounded or stellate granuloma containing central granular debris and recognizable neutrophils; giant cells uncommon
Sarcoidosis	Unknown etiology	Noncaseating granulomas with abundant activated macrophages
Crohn disease (inflammatory bowel disease)	Immune reaction against intestinal bacteria, possibly self antigens	Occasional noncaseating granulomas in the wall of the intestine, with dense chronic inflammatory infiltrate

diseases, notably Crohn disease, which is one type of inflammatory bowel disease and an important cause of granulomatous inflammation in the United States, and in a disease of unknown etiology called *sarcoidosis*. **Tuberculosis is the prototype of a granulomatous disease caused by infection and should always be excluded as the cause when granulomas are identified.** In this disease the granuloma is referred to as a *tubercle*. The morphologic patterns in the various granulomatous diseases may be sufficiently different to allow reasonably accurate diagnosis by an experienced pathologist (see Table 3-8); however, there are so many atypical presentations that it is always necessary to identify the specific etiologic agent by special stains for organisms (e.g., acid-fast stains for tubercle bacilli), by culture methods (e.g., in tuberculosis and fungal diseases), by molecular techniques (e.g., the polymerase chain reaction in tuberculosis), and by serologic studies (e.g., in syphilis).

KEY CONCEPTS

Chronic Inflammation

- Chronic inflammation is a prolonged host response to persistent stimuli.
- It is caused by microbes that resist elimination, immune responses against self and environmental antigens, and some toxic substances (e.g., silica); underlies many medically important diseases.
- It is characterized by coexisting inflammation, tissue injury, attempted repair by scarring, and immune response.

- The cellular infiltrate consists of macrophages, lymphocytes, plasma cells, and other leukocytes.
- It is mediated by cytokines produced by macrophages and lymphocytes (notably T lymphocytes); bidirectional interactions between these cells tend to amplify and prolong the inflammatory reaction.
- Granulomatous inflammation is a pattern of chronic inflammation induced by T cell and macrophage activation in response to an agent that is resistant to eradication.

Systemic Effects of Inflammation

Inflammation, even if it is localized, is associated with cytokine-induced systemic reactions that are collectively called the acute-phase response. Anyone who has suffered through a severe bout of a viral illness (e.g., influenza) has experienced the systemic manifestations of acute inflammation. These changes are reactions to cytokines whose production is stimulated by bacterial products such as LPS and by other inflammatory stimuli. **The cytokines TNF, IL-1, and IL-6 are important mediators of the acute-phase reaction; other cytokines, notably type I interferons, also contribute to the reaction.**

The acute-phase response consists of several clinical and pathologic changes:

- **Fever**, characterized by an elevation of body temperature, usually by 1° to 4°C, is one of the most prominent manifestations of the acute-phase response, especially when inflammation is associated with infection. Substances that induce fever are called *pyrogens*. The increase in body temperature is caused by prostaglandins that are produced in the vascular and perivascular cells of the hypothalamus. Bacterial products, such as LPS (called *exogenous pyrogens*), stimulate leukocytes to release cytokines such as IL-1 and TNF (called *endogenous pyrogens*) that increase the enzymes (cyclooxygenases) that convert AA into prostaglandins. In the hypothalamus, the prostaglandins, especially PGE₂, stimulate the production of neurotransmitters that reset the temperature set point at a higher level. NSAIDs, including aspirin, reduce fever by inhibiting prostaglandin synthesis. An elevated body temperature has been shown to help amphibians ward off microbial infections, and it is assumed that fever is a protective host response in mammals as well, although the mechanism is unknown. One hypothesis is that fever may induce heat shock proteins that enhance lymphocyte responses to microbial antigens.
 - **Acute-phase proteins** are plasma proteins, mostly synthesized in the liver, whose plasma concentrations may increase several hundred-fold as part of the response to inflammatory stimuli. Three of the best-known of these proteins are C-reactive protein (CRP), fibrinogen, and serum amyloid A (SAA) protein. Synthesis of these molecules in hepatocytes is stimulated by cytokines, especially IL-6 (for CRP and fibrinogen) and IL-1 or TNF (for SAA). Many acute-phase proteins, such as CRP and SAA, bind to microbial cell walls, and they may act as opsonins and fix complement. They also bind chromatin, possibly aiding in clearing necrotic cell nuclei.
- Fibrinogen binds to red cells and causes them to form stacks (rouleaux) that sediment more rapidly at unit gravity than do individual red cells. This is the basis for measuring the *erythrocyte sedimentation rate* as a simple test for an inflammatory response caused by any stimulus. Acute-phase proteins have beneficial effects during acute inflammation, but prolonged production of these proteins (especially SAA) in states of chronic inflammation causes *secondary amyloidosis* (Chapter 6). Elevated serum levels of CRP have been proposed as a marker for increased risk of myocardial infarction in patients with coronary artery disease. It is postulated that inflammation involving atherosclerotic plaques in the coronary arteries may predispose to thrombosis and subsequent infarction. Another peptide whose production is increased in the acute-phase response is the iron-regulating peptide *hepcidin*. Chronically elevated plasma concentrations of hepcidin reduce the availability of iron and are responsible for the *anemia* associated with chronic inflammation (Chapter 14).
- **Leukocytosis** is a common feature of inflammatory reactions, especially those induced by bacterial infections. The leukocyte count usually climbs to 15,000 or 20,000 cells/mL, but sometimes it may reach extraordinarily high levels of 40,000 to 100,000 cells/mL. These extreme elevations are referred to as *leukemoid reactions*, because they are similar to the white cell counts observed in leukemia and have to be distinguished from leukemia. The leukocytosis occurs initially because of accelerated release of cells from the bone marrow postmitotic reserve pool (caused by cytokines, including TNF and IL-1) and is therefore associated with a rise in the number of more immature neutrophils in the blood, referred to as a *left shift*. Prolonged infection also induces proliferation of precursors in the bone marrow, caused by increased production of colony-stimulating factors. Thus, the bone marrow output of leukocytes is increased to compensate for the loss of these cells in the inflammatory reaction. (See also the discussion of leukocytosis in Chapter 13.) Most bacterial infections induce an increase in the blood neutrophil count, called *neutrophilia*. Viral infections, such as infectious mononucleosis, mumps, and German measles, cause an absolute increase in the number of lymphocytes (*lymphocytosis*). In some allergies and parasitic infestations, there is an increase in the absolute number of eosinophils, creating an *eosinophilia*. Certain infections (typhoid fever and infections caused by some viruses, rickettsiae, and certain protozoa) are associated with a decreased number of circulating white cells (*leukopenia*).
 - Other manifestations of the acute-phase response include increased pulse and blood pressure; decreased sweating, mainly because of redirection of blood flow from cutaneous to deep vascular beds, to minimize heat loss through the skin; rigors (shivering), chills (search for warmth), anorexia, somnolence, and malaise, probably because of the actions of cytokines on brain cells.
 - In severe bacterial infections (*sepsis*), the large amounts of bacteria and their products in the blood stimulate the production of enormous quantities of several cytokines, notably TNF and IL-1. High blood levels of cytokines cause various widespread clinical manifestations such

as disseminated intravascular coagulation, hypotensive shock, and metabolic disturbances including insulin resistance and hyperglycemia. This clinical triad is known as *septic shock*; it is discussed in more detail in Chapter 4.

KEY CONCEPTS

Systemic Effects of Inflammation

- **Fever:** cytokines (TNF, IL-1) stimulate production of prostaglandins in hypothalamus
- **Production of acute-phase proteins:** C-reactive protein, others; synthesis stimulated by cytokines (IL-6, others) acting on liver cells
- **Leukocytosis:** cytokines (colony-stimulating factors) stimulate production of leukocytes from precursors in the bone marrow
- **In some severe infections, septic shock:** fall in blood pressure, disseminated intravascular coagulation, metabolic abnormalities; induced by high levels of TNF and other cytokines

Excessive inflammation is the underlying cause of many human diseases, described throughout this book. Conversely, defective inflammation is responsible for increased susceptibility to infections. The most common cause of defective inflammation is leukocyte deficiency resulting from replacement of the bone marrow by leukemias and metastatic tumors, and suppression of the marrow by therapies for cancer and graft rejection. Inherited genetic abnormalities of leukocyte adhesion and microbicidal function are rare but very informative; these are described in Chapter 6, in the context of immunodeficiency diseases. Deficiencies of the complement system are mentioned earlier and are described further in Chapter 6.

We next consider the process of *repair*, which is a healing response to tissue destruction caused by inflammatory or non-inflammatory causes.

Tissue Repair

Overview of Tissue Repair

Repair, sometimes called healing, refers to the restoration of tissue architecture and function after an injury. (By convention, the term *repair* is often used for parenchymal and connective tissues and *healing* for surface epithelia, but these distinctions are not based on biology and we use the terms interchangeably.) Critical to the survival of an organism is the ability to repair the damage caused by toxic insults and inflammation. Hence, the inflammatory response to microbes and injured tissues not only serves to eliminate these dangers but also sets into motion the process of repair.

Repair of damaged tissues occurs by two types of reactions: regeneration by proliferation of residual (uninjured) cells and maturation of tissue stem cells, and the deposition of connective tissue to form a scar (Fig. 3-24).

- **Regeneration.** Some tissues are able to replace the damaged components and essentially return to a normal state; this process is called *regeneration*. Regeneration

Figure 3-24 Mechanisms of tissue repair: regeneration and scar formation. Following mild injury, which damages the epithelium but not the underlying tissue, resolution occurs by regeneration, but after more severe injury with damage to the connective tissue, repair is by scar formation.

occurs by proliferation of cells that survive the injury and retain the capacity to proliferate, for example, in the rapidly dividing epithelia of the skin and intestines, and in some parenchymal organs, notably the liver. In other cases, tissue stem cells may contribute to the restoration of damaged tissues. However, mammals have a limited capacity to regenerate damaged tissues and organs, and only some components of most tissues are able to fully restore themselves.

- **Connective tissue deposition (scar formation).** If the injured tissues are incapable of complete restitution, or if the supporting structures of the tissue are severely damaged, repair occurs by the laying down of connective (fibrous) tissue, a process that may result in scar formation. Although the fibrous scar is not normal, it provides enough structural stability that the injured tissue is usually able to function. The term *fibrosis* is most often used to describe the extensive deposition of collagen that occurs in the lungs, liver, kidney, and other organs as a consequence of chronic inflammation, or in the myocardium after extensive ischemic necrosis (infarction). If fibrosis develops in a tissue space occupied by an inflammatory exudate, it is called *organization* (as in organizing pneumonia affecting the lung).

After many common types of injury, both regeneration and scar formation contribute in varying degrees to the ultimate repair. Both processes involve the proliferation of various cells, and close interactions between cells and the extracellular matrix (ECM). We first discuss the general

mechanisms of cellular proliferation and regeneration, and then the salient features of regeneration and healing by scar formation, and conclude with a description of cutaneous wound healing and fibrosis (scarring) in parenchymal organs as illustrations of the repair process.

Cell and Tissue Regeneration

The regeneration of injured cells and tissues involves cell proliferation, which is driven by growth factors and is critically dependent on the integrity of the extracellular matrix, and by the development of mature cells from stem cells. Before describing examples of repair by regeneration, the general principles of cell proliferation are discussed.

Cell Proliferation: Signals and Control Mechanisms

Several cell types proliferate during tissue repair. These include the remnants of the injured tissue (which attempt to restore normal structure), vascular endothelial cells (to create new vessels that provide the nutrients needed for the repair process), and fibroblasts (the source of the fibrous tissue that forms the scar to fill defects that cannot be corrected by regeneration).

The ability of tissues to repair themselves is determined, in part, by their intrinsic proliferative capacity. Based on this criterion, the tissues of the body are divided into three groups.

- **Labile (continuously dividing) tissues.** Cells of these tissues are continuously being lost and replaced by maturation from tissue stem cells and by proliferation of mature cells. Labile cells include hematopoietic cells in the bone marrow and the majority of surface epithelia, such as the stratified squamous epithelia of the skin, oral cavity, vagina, and cervix; the cuboidal epithelia of the ducts draining exocrine organs (e.g., salivary glands, pancreas, biliary tract); the columnar epithelium of the gastrointestinal tract, uterus, and fallopian tubes; and the transitional epithelium of the urinary tract. These tissues can readily regenerate after injury as long as the pool of stem cells is preserved.
- **Stable tissues.** Cells of these tissues are quiescent (in the G_0 stage of the cell cycle) and have only minimal proliferative activity in their normal state. However, these cells are capable of dividing in response to injury or loss of tissue mass. Stable cells constitute the parenchyma of most solid tissues, such as liver, kidney, and pancreas. They also include endothelial cells, fibroblasts, and smooth muscle cells; the proliferation of these cells is particularly important in wound healing. With the exception of liver, stable tissues have a limited capacity to regenerate after injury.
- **Permanent tissues.** The cells of these tissues are considered to be terminally differentiated and nonproliferative in postnatal life. The majority of neurons and cardiac muscle cells belong to this category. Thus, injury to the brain or heart is irreversible and results in a scar, because neurons and cardiac myocytes cannot regenerate. Limited stem cell replication and differentiation occur in some areas of the adult brain, and there is some evidence that heart muscle cells may proliferate after myocardial necrosis. Nevertheless, whatever proliferative

capacity may exist in these tissues, it is insufficient to produce tissue regeneration after injury. Skeletal muscle is usually classified as a permanent tissue, but satellite cells attached to the endomysial sheath provide some regenerative capacity for muscle. In permanent tissues, repair is typically dominated by scar formation.

Although it is believed that most mature tissues contain variable proportions of continuously dividing cells, quiescent cells that can return to the cell cycle, and nondividing cells, it is actually difficult to quantify the proportions of these cells in any tissue. Also, we now realize that cell proliferation is only one pathway of regeneration and that stem cells contribute to this process in important ways.

Cell proliferation is driven by signals provided by growth factors and from the extracellular matrix. Many different growth factors have been described; some act on multiple cell types and others are cell-selective (Chapter 1, Table 1-1). Growth factors are typically produced by cells near the site of damage. The most important sources of these growth factors are macrophages that are activated by the tissue injury, but epithelial and stromal cells also produce some of these factors. Several growth factors bind to ECM proteins and are displayed at high concentrations. All growth factors activate signaling pathways that ultimately induce the production of proteins that are involved in driving cells through the cell cycle and other proteins that release blocks on the cell cycle (checkpoints) (Chapter 1). In addition to responding to growth factors, cells use integrins to bind to ECM proteins, and signals from the integrins can also stimulate cell proliferation.

In the process of regeneration, proliferation of residual cells is supplemented by development of mature cells from stem cells. In Chapter 1 we introduced the major types of stem cells. In adults, the most important stem cells for regeneration after injury are tissue stem cells. These stem cells live in specialized niches, and it is believed that injury triggers signals in these niches that activate quiescent stem cells to proliferate and differentiate into mature cells that repopulate the injured tissue.

Mechanisms of Tissue Regeneration

The importance of regeneration in the replacement of injured tissues varies in different types of tissues and with the severity of injury.

- In labile tissues, such as the epithelia of the intestinal tract and skin, injured cells are rapidly replaced by proliferation of residual cells and differentiation of tissue stem cells provided the underlying basement membrane is intact. The growth factors involved in these processes are not defined. Loss of blood cells is corrected by proliferation of hematopoietic stem cells in the bone marrow and other tissues, driven by growth factors called colony-stimulating factors (CSFs), which are produced in response to the reduced numbers of blood cells.
- Tissue regeneration can occur in parenchymal organs with stable cell populations, but with the exception of the liver, this is usually a limited process. Pancreas, adrenal, thyroid, and lung have some regenerative capacity. The surgical removal of a kidney elicits in the remaining kidney a compensatory response that

consists of both hypertrophy and hyperplasia of proximal duct cells. The mechanisms underlying this response are not understood, but likely involve local production of growth factors and interactions of cells with the ECM. The extraordinary capacity of the liver to regenerate has made it a valuable model for studying this process, as described below.

Restoration of normal tissue structure can occur only if the residual tissue is structurally intact, as after partial surgical resection. By contrast, if the entire tissue is damaged by infection or inflammation, regeneration is incomplete and is accompanied by scarring. For example, extensive destruction of the liver with collapse of the reticulin framework, as occurs in a liver abscess, leads to scar formation even though the remaining liver cells have the capacity to regenerate.

Liver Regeneration

The human liver has a remarkable capacity to regenerate, as demonstrated by its growth after partial hepatectomy, which may be performed for tumor resection or for living-donor hepatic transplantation. The mythologic image of liver regeneration is the regrowth of the liver of Prometheus, which was eaten every day by an eagle sent by Zeus as punishment for stealing the secret of fire, and grew back overnight. The reality, although less dramatic, is still quite impressive.

Regeneration of the liver occurs by two major mechanisms: proliferation of remaining hepatocytes and repopulation from progenitor cells. Which mechanism plays the dominant role depends on the nature of the injury.

- **Proliferation of hepatocytes following partial hepatectomy.** In humans, resection of up to 90% of the liver can be corrected by proliferation of the residual hepatocytes. This classic model of tissue regeneration has been used experimentally to study the initiation and control of the process.

Hepatocyte proliferation in the regenerating liver is triggered by the combined actions of cytokines and polypeptide growth factors. The process occurs in distinct stages (Fig. 3-25). In the first, or *priming*, phase, cytokines such as IL-6 are produced mainly by Kupffer cells and act on hepatocytes to make the parenchymal cells competent to receive and respond to growth factor signals. In the second, or *growth factor*, phase, growth factors such as HGF and TGF- α , produced by many cell types, act on primed hepatocytes to stimulate cell metabolism and entry of the cells into the cell cycle. Because hepatocytes are quiescent cells, it takes them several hours to enter the cell cycle, progress from G₀ to G₁, and reach the S phase of DNA replication. Almost all hepatocytes replicate during liver regeneration after partial hepatectomy. The wave of hepatocyte replication is followed by replication of nonparenchymal cells (Kupffer cells, endothelial cells, and stellate cells). During the phase of hepatocyte replication, more than 70 genes are activated; these include genes encoding transcription factors, cell cycle regulators, regulators of energy metabolism, and many others. In the final, *termination*, phase, hepatocytes return to quiescence. The nature of the stop signals is poorly understood;

Figure 3-25 Liver regeneration by proliferation of hepatocytes. Following partial hepatectomy, the liver regenerates by proliferation of surviving cells. The process occurs in stages, including priming, followed by growth factor-induced proliferation. The main signals involved in these steps are shown. Once the mass of the liver is restored, the proliferation is terminated (not shown).

antiproliferative cytokines of the TGF- β family are likely involved.

- **Liver regeneration from progenitor cells.** In situations where the proliferative capacity of hepatocytes is impaired, such as after chronic liver injury or inflammation, progenitor cells in the liver contribute to repopulation. In rodents, these progenitor cells have been called *oval cells* because of the shape of their nuclei. Some of these progenitor cells reside in specialized niches called *canals of Hering*, where bile canaliculi connect with larger bile ducts. The signals that drive proliferation of progenitor cells and their differentiation into mature hepatocytes are topics of active investigation.

KEY CONCEPTS

Repair by Regeneration

- Tissues are classified as labile, stable, and permanent, according to the proliferative capacity of their cells.
- Continuously dividing tissues (labile tissues) contain stem cells that differentiate to replenish lost cells and maintain tissue homeostasis.
- Cell proliferation is controlled by the cell cycle, and is stimulated by growth factors and interactions of cells with the extracellular matrix.
- Regeneration of the liver is a classic example of repair by regeneration. It is triggered by cytokines and growth factors produced in response to loss of liver mass and inflammation. In different situations, regeneration may occur by proliferation of surviving hepatocytes or repopulation from progenitor cells.

Repair by Connective Tissue Deposition

If repair cannot be accomplished by regeneration alone it occurs by replacement of the injured cells with connective tissue, leading to the formation of a scar, or by a combination of regeneration of some residual cells and scar formation. As discussed earlier, scarring may happen

if the tissue injury is severe or chronic and results in damage to parenchymal cells and epithelia as well as to the connective tissue framework, or if nondividing cells are injured. In contrast to regeneration, which involves the restitution of tissue components, scar formation is a response that “patches” rather than restores the tissue. The term *scar* is most often used in connection to *wound healing* in the skin, but may also be used to describe the replacement of parenchymal cells in any tissue by collagen, as in the heart after myocardial infarction.

Steps in Scar Formation

Repair by connective tissue deposition consists of sequential processes that follow tissue injury and the inflammatory response (Fig. 3-26):

- **Angiogenesis** is the formation of new blood vessels, which supply nutrients and oxygen needed to support the repair process. Newly formed vessels are leaky because of incomplete interendothelial junctions and because VEGF, the growth factor that drives angiogenesis, increases vascular permeability. This leakiness accounts in part for the edema that may persist in healing wounds long after the acute inflammatory response has resolved.
- **Formation of granulation tissue.** Migration and proliferation of fibroblasts and deposition of loose connective tissue, together with the vessels and interspersed leukocytes, form *granulation tissue*. The term *granulation tissue* derives from its pink, soft, granular gross appearance, such as that seen beneath the scab of a skin wound. Its histologic appearance is characterized by proliferation of fibroblasts and new thin-walled, delicate capillaries (angiogenesis), in a loose extracellular matrix, often with admixed inflammatory cells, mainly macrophages (Fig. 3-27A). Granulation tissue progressively invades the site of injury; the amount of granulation tissue that is formed depends on the size of the tissue deficit created by the wound and the intensity of inflammation.
- **Remodeling of connective tissue.** Maturation and reorganization of the connective tissue (remodeling) produce the stable fibrous *scar*. The amount of connective tissue increases in the granulation tissue, eventually resulting

Figure 3-26 Steps in repair by scar formation. Injury to a tissue, such as muscle (which has limited regenerative capacity), first induces inflammation, which clears dead cells and microbes, if any. This is followed by the formation of vascularized granulation tissue and then the deposition of extracellular matrix to form the scar.

Figure 3-27 **A**, Granulation tissue showing numerous blood vessels, edema, and a loose extracellular matrix containing occasional inflammatory cells. Collagen is stained blue by the trichrome stain; minimal mature collagen can be seen at this point. **B**, Trichrome stain of mature scar, showing dense collagen, with only scattered vascular channels.

in the formation of a scar (Fig. 3-27B), which may remodel over time.

Macrophages play a central role in repair by clearing offending agents and dead tissue, providing growth factors for the proliferation of various cells, and secreting cytokines that stimulate fibroblast proliferation and connective tissue synthesis and deposition. The macrophages that are involved in repair are mostly of the alternatively activated (M2) type. It is not clear how the classically activated macrophages that dominate during inflammation, and are involved in getting rid of microbes and dead tissues, are gradually replaced by alternatively activated macrophages that serve to terminate inflammation and induce repair.

Repair begins within 24 hours of injury by the emigration of fibroblasts and the induction of fibroblast and endothelial cell proliferation. By 3 to 5 days, the specialized granulation tissue that is characteristic of healing is apparent.

We next describe the steps in the formation of granulation tissue and the scar.

Angiogenesis

Angiogenesis is the process of new blood vessel development from existing vessels. It is critical in healing at sites of injury, in the development of collateral circulations at sites of ischemia, and in allowing tumors to increase in size beyond the constraints of their original blood supply. Much work has been done to understand the mechanisms underlying angiogenesis, and therapies to either augment the process (e.g., to improve blood flow to a heart ravaged by coronary atherosclerosis) or inhibit it (to frustrate tumor growth or block pathologic vessel growth such as in diabetic retinopathy) are being developed.

Angiogenesis involves sprouting of new vessels from existing ones, and consists of the following steps (Fig. 3-28):

- Vasodilation in response to nitric oxide and increased permeability induced by vascular endothelial growth factor (VEGF)
- Separation of pericytes from the abluminal surface and breakdown of the basement membrane to allow formation of a vessel sprout
- Migration of endothelial cells toward the area of tissue injury
- Proliferation of endothelial cells just behind the leading front (“tip”) of migrating cells
- Remodeling into capillary tubes
- Recruitment of periendothelial cells (pericytes for small capillaries and smooth muscle cells for larger vessels) to form the mature vessel
- Suppression of endothelial proliferation and migration and deposition of the basement membrane.

The process of angiogenesis involves several signaling pathways, cell-cell interactions, ECM proteins, and tissue enzymes.

- **Growth factors.** *Vascular endothelial growth factors (VEGFs)*, mainly VEGF-A (Chapter 1), stimulates both migration and proliferation of endothelial cells, thus initiating the process of capillary sprouting in

Figure 3-28 Angiogenesis. In tissue repair, angiogenesis occurs mainly by sprouting of new vessels. The steps in the process, and the major signals involved, are illustrated. The newly formed vessel joins up with other vessels (not shown) to form the new vascular bed.

angiogenesis. It promotes vasodilation by stimulating the production of NO and contributes to the formation of the vascular lumen. *Fibroblast growth factors (FGFs)*, mainly FGF-2, stimulates the proliferation of endothelial cells. It also promotes the migration of macrophages and fibroblasts to the damaged area, and stimulates epithelial cell migration to cover epidermal wounds. *Angiopoietins 1 and 2 (Ang 1 and Ang 2)* are growth factors that play a role in angiogenesis and the structural maturation of new vessels. Newly formed vessels need to be stabilized by the recruitment of pericytes and smooth muscle cells and by the deposition of connective tissue. Ang1 interacts with a tyrosine kinase receptor on endothelial cells called Tie2. The growth factors PDGF and TGF- β also participate in the stabilization process: PDGF recruits smooth muscle cells and TGF- β suppresses endothelial proliferation and migration, and enhances the production of ECM proteins.

- **Notch signaling.** Through “cross-talk” with VEGF, the Notch signaling pathway regulates the sprouting and branching of new vessels and thus ensures that the new vessels that are formed have the proper spacing to effectively supply the healing tissue with blood.

- **ECM proteins** participate in the process of vessel sprouting in angiogenesis, largely through interactions with integrin receptors in endothelial cells and by providing the scaffold for vessel growth.
- **Enzymes** in the ECM, notably the matrix metalloproteinases (MMPs), degrade the ECM to permit remodeling and extension of the vascular tube.

Deposition of Connective Tissue

The laying down of connective tissue occurs in two steps: (1) migration and proliferation of fibroblasts into the site of injury and (2) deposition of ECM proteins produced by these cells. These processes are orchestrated by locally produced cytokines and growth factors, including PDGF, FGF-2, and TGF- β . The major sources of these factors are inflammatory cells, particularly alternatively activated (M2) macrophages, which are present at sites of injury and in granulation tissue. Sites of inflammation are also rich in mast cells, and in the appropriate chemotactic milieu lymphocytes may also be present. Each of these can secrete cytokines and growth factors that contribute to fibroblast proliferation and activation.

Transforming growth factor- β (TGF- β) is the most important cytokine for the synthesis and deposition of connective tissue proteins. It is produced by most of the cells in granulation tissue, including alternatively activated macrophages. The levels of TGF- β in tissues are primarily regulated not by the transcription of the gene but by the posttranscriptional activation of latent TGF- β , the rate of secretion of the active molecule, and factors in the ECM, notably integrins, that enhance or diminish TGF- β activity. TGF- β stimulates fibroblast migration and proliferation, increased synthesis of collagen and fibronectin, and decreased degradation of ECM due to inhibition of metalloproteinases. TGF- β is involved not only in scar formation after injury but also in the development of fibrosis in lung, liver, and kidneys that follows chronic inflammation. TGF- β is also an antiinflammatory cytokine that serves to limit and terminate inflammatory responses. It does this by inhibiting lymphocyte proliferation and the activity of other leukocytes.

As healing progresses, the number of proliferating fibroblasts and new vessels decreases; however, the fibroblasts progressively assume a more synthetic phenotype, and hence there is increased deposition of ECM. Collagen synthesis, in particular, is critical to the development of strength in a healing wound site. As described later, collagen synthesis by fibroblasts begins early in wound healing (days 3 to 5) and continues for several weeks, depending on the size of the wound. Net collagen accumulation, however, depends not only on increased synthesis but also on diminished collagen degradation (discussed later). Ultimately, the granulation tissue evolves into a scar composed of largely inactive, spindle-shaped fibroblasts, dense collagen, fragments of elastic tissue, and other ECM components (Fig. 3-27B). As the scar matures, there is progressive vascular regression, which eventually transforms the highly vascularized granulation tissue into a pale, largely avascular scar. Some of the fibroblasts also acquire features of smooth muscle cells, including the presence of actin filaments, and are called *myofibroblasts*. These cells contribute to the contraction of the scar over time.

Remodeling of Connective Tissue

The outcome of the repair process is influenced by a balance between synthesis and degradation of ECM proteins. After its deposition, the connective tissue in the scar continues to be modified and remodeled. The degradation of collagens and other ECM components is accomplished by a family of *matrix metalloproteinases (MMPs)*, so called because they are dependent on metal ions (e.g., zinc) for their activity. MMPs should be distinguished from neutrophil elastase, cathepsin G, plasmin, and other serine proteinases that can also degrade ECM but are not metalloenzymes. MMPs include interstitial collagenases, which cleave fibrillar collagen (MMP-1, -2 and -3); gelatinases (MMP-2 and 9), which degrade amorphous collagen and fibronectin; and stromelysins (MMP-3, -10, and -11), which degrade a variety of ECM constituents, including proteoglycans, laminin, fibronectin, and amorphous collagen.

MMPs are produced by a variety of cell types (fibroblasts, macrophages, neutrophils, synovial cells, and some epithelial cells), and their synthesis and secretion are regulated by growth factors, cytokines, and other agents. The activity of the MMPs is tightly controlled. They are produced as inactive precursors (zymogens) that must be first activated; this is accomplished by proteases (e.g., plasmin) likely to be present only at sites of injury. In addition, activated collagenases can be rapidly inhibited by specific tissue inhibitors of metalloproteinases (TIMPs), produced by most mesenchymal cells. Thus, during scar formation, MMPs are activated to remodel the deposited ECM and then their activity is shut down by the TIMPs.

A family of enzymes related to MMPs is called ADAM (a disintegrin and metalloproteinase). ADAMs are anchored to the plasma membrane and cleave and release extracellular domains of cell-associated cytokines and growth factors, such as TNF, TGF- β , and members of the EGF family.

KEY CONCEPTS

Repair by Scar Formation

- Tissues are repaired by replacement with connective tissue and scar formation if the injured tissue is not capable of proliferation or if the structural framework is damaged and cannot support regeneration.
- The main components of connective tissue repair are angiogenesis, migration and proliferation of fibroblasts, collagen synthesis, and connective tissue remodeling.
- Repair by connective tissue starts with the formation of granulation tissue and culminates in the laying down of fibrous tissue.
- Multiple growth factors stimulate the proliferation of the cell types involved in repair.
- TGF- β is a potent fibrogenic agent; ECM deposition depends on the balance between fibrogenic agents, metalloproteinases (MMPs) that digest ECM, and the tissue inhibitors of MMPs (TIMPs).

Factors That Influence Tissue Repair

Tissue repair may be altered by a variety of influences, frequently reducing the quality or adequacy of the reparative process. Variables that modify healing may be extrin-

sic (e.g., infection) or intrinsic to the injured tissue, and systemic or local:

- **Infection** is clinically one of the most important causes of delay in healing; it prolongs inflammation and potentially increases the local tissue injury.
- **Diabetes** is a metabolic disease that compromises tissue repair for many reasons (Chapter 24), and is one of the most important systemic causes of abnormal wound healing.
- **Nutritional status** has profound effects on repair; protein deficiency, for example, and particularly vitamin C deficiency, inhibits collagen synthesis and retards healing.
- **Glucocorticoids (steroids)** have well-documented anti-inflammatory effects, and their administration may result in weakness of the scar due to inhibition of TGF- β production and diminished fibrosis. In some instances, however, the anti-inflammatory effects of glucocorticoids are desirable. For example, in corneal infections, glucocorticoids are sometimes prescribed (along with antibiotics) to reduce the likelihood of opacity that may result from collagen deposition.
- **Mechanical factors** such as increased local pressure or torsion may cause wounds to pull apart, or dehisce.
- **Poor perfusion**, due either to arteriosclerosis and diabetes or to obstructed venous drainage (e.g., in varicose veins), also impairs healing.
- **Foreign bodies** such as fragments of steel, glass, or even bone impede healing.
- **The type and extent of tissue injury** affects the subsequent repair. Complete restoration can occur only in tissues composed of stable and labile cells; even then, extensive injury will probably result in incomplete tissue regeneration and at least partial loss of function. Injury to tissues composed of permanent cells must inevitably result in scarring with, at most, attempts at functional compensation by the remaining viable elements. Such is the case with healing of a myocardial infarct.
- The **location of the injury** and the character of the tissue in which the injury occurs are also important. For example, inflammation arising in tissue spaces (e.g., pleural, peritoneal, synovial cavities) develops extensive exudates. Subsequent repair may occur by digestion of the exudate, initiated by the proteolytic enzymes of leukocytes and resorption of the liquefied exudate. This is called *resolution*, and in the absence of cellular necrosis, normal tissue architecture is generally restored. However, in the setting of larger accumulations, the exudate undergoes organization: granulation tissue grows into the exudate, and a fibrous scar ultimately forms.

Selected Clinical Examples of Tissue Repair and Fibrosis

So far, we have discussed the general principles and mechanisms of repair by regeneration and scar formation. In this section we describe two clinically significant types of repair—the healing of skin wounds (cutaneous wound healing) and fibrosis in injured parenchymal organs.

Healing of Skin Wounds

This is a process that involves both epithelial regeneration and the formation of connective tissue scar and is thus illustrative of the general principles that apply to healing in all tissues.

Based on the nature and size of the wound, the healing of skin wounds is said to occur by first or second intention.

Healing by First Intention

When the injury involves only the epithelial layer, the principal mechanism of repair is epithelial regeneration, also called *primary union* or *healing by first intention*. One of the simplest examples of this type of wound repair is the healing of a clean, uninfected surgical incision approximated by surgical sutures (Fig. 3-29). The incision causes only focal disruption of epithelial basement membrane continuity and death of relatively few epithelial and connective tissue cells. The repair consists of three connected processes: *inflammation*, *proliferation* of epithelial and other cells, and *maturation* of the connective tissue scar.

- Wounding causes the rapid activation of coagulation pathways, which results in the formation of a blood clot on the wound surface (Chapter 4). In addition to entrapped red cells, the clot contains fibrin, fibronectin, and complement proteins. The clot serves to stop bleeding and acts as a scaffold for migrating cells, which are attracted by growth factors, cytokines, and chemokines released into the area. Release of VEGF leads to increased vessel permeability and edema. As dehydration occurs at the external surface of the clot, a scab covering the wound is formed.
- Within 24 hours, neutrophils are seen at the incision margin, migrating toward the fibrin clot. They release proteolytic enzymes that begin to clear the debris. Basal cells at the cut edge of the epidermis begin to show increased mitotic activity. Within 24 to 48 hours, epithelial cells from both edges have begun to migrate and proliferate along the dermis, depositing basement membrane components as they progress. The cells meet in the midline beneath the surface scab, yielding a thin but continuous epithelial layer that closes the wound.
- By day 3, neutrophils have been largely replaced by macrophages, and granulation tissue progressively invades the incision space. As mentioned earlier, macrophages are key cellular constituents of tissue repair, clearing extracellular debris, fibrin, and other foreign material, and promoting angiogenesis and ECM deposition. Collagen fibers are now evident at the incision margins. Epithelial cell proliferation continues, forming a covering approaching the normal thickness of the epidermis.
- By day 5, neovascularization reaches its peak as granulation tissue fills the incisional space. These new vessels are leaky, allowing the passage of plasma proteins and fluid into the extravascular space. Thus, new granulation tissue is often edematous. Migration of fibroblasts to the site of injury is driven by chemokines, TNF, PDGF, TGF- β , and FGF. Their subsequent proliferation is triggered by multiple growth factors, including PDGF, EGF, TGF- β , and FGF, and the cytokines IL-1 and

Figure 3-29 Steps in wound healing by first intention (left) and second intention (right). In the latter, note the large amount of granulation tissue and wound contraction.

TNF. Macrophages are the main source for these factors, although other inflammatory cells and platelets may also produce them. The fibroblasts produce ECM proteins, and collagen fibrils become more abundant and begin to bridge the incision. The epidermis recovers its normal thickness as differentiation of surface cells yields a mature epidermal architecture with surface keratinization.

- During the second week, there is continued collagen accumulation and fibroblast proliferation. The leukocyte infiltrate, edema, and increased vascularity are substantially diminished. The process of “blanching” begins, accomplished by increasing collagen deposition within the incisional scar and the regression of vascular channels.

- By the end of the first month, the scar comprises a cellular connective tissue largely devoid of inflammatory cells and covered by an essentially normal epidermis. However, the dermal appendages destroyed in the line of the incision are permanently lost. The tensile strength of the wound increases with time, as described later.

Healing by Second Intention

When cell or tissue loss is more extensive, such as in large wounds, abscesses, ulceration, and ischemic necrosis (infarction) in parenchymal organs, the repair process involves a combination of regeneration and scarring. In healing of skin wounds by *second intention*, also known as healing by *secondary union* (Figs. 3-29 and 3-30), the

Figure 3-30 Healing of skin ulcers. **A**, Pressure ulcer of the skin, commonly found in diabetic patients. The histologic slides show a skin ulcer with a large gap between the edges of the lesion (**B**), a thin layer of epidermal reepithelialization and extensive granulation tissue formation in the dermis (**C**), and continuing reepithelialization of the epidermis and wound contraction (**D**). (Courtesy Z. Argenyi, MD, University of Washington, Seattle, Wash.)

inflammatory reaction is more intense, there is development of abundant granulation tissue, accumulation of ECM and formation of a large scar, and wound contraction by the action of myofibroblasts.

Secondary healing differs from primary healing in several respects:

- In wounds causing large tissue deficits, the fibrin clot is larger, and there is more exudate and necrotic debris in the wounded area. Inflammation is more intense because large tissue defects have a greater volume of necrotic debris, exudate, and fibrin that must be removed. Consequently, large defects have a greater potential for secondary, inflammation-mediated, injury.
- Much larger amounts of granulation tissue are formed. Larger defects require a greater volume of granulation tissue to fill in the gaps and provide the underlying framework for the regrowth of tissue epithelium. A greater volume of granulation tissue generally results in a greater mass of scar tissue.
- At first a provisional matrix containing fibrin, plasma fibronectin, and type III collagen is formed, but in about 2 weeks this is replaced by a matrix composed primarily of type I collagen. Ultimately, the original granulation tissue scaffold is converted into a pale, avascular scar, composed of spindle-shaped fibroblasts, dense collagen, fragments of elastic tissue, and other ECM components. The dermal appendages that have been

destroyed in the line of the incision are permanently lost. The epidermis recovers its normal thickness and architecture. By the end of the first month, the scar is made up of acellular connective tissue devoid of inflammatory infiltrate, covered by intact epidermis.

- Wound contraction generally occurs in large surface wounds. The contraction helps to close the wound by decreasing the gap between its dermal edges and by reducing the wound surface area. Hence, it is an important feature in healing by secondary union. The initial steps of wound contraction involve the formation, at the edge of the wound, of a network of *myofibroblasts*, which are modified fibroblasts exhibiting many of the ultrastructural and functional features of contractile smooth muscle cells. Within 6 weeks, large skin defects may be reduced to 5% to 10% of their original size, largely by contraction.

Wound Strength

Carefully sutured wounds have approximately 70% of the strength of normal skin, largely because of the placement of sutures. When sutures are removed, usually at 1 week, wound strength is approximately 10% of that of unwounded skin, but this increases rapidly over the next 4 weeks. The recovery of tensile strength results from the excess of collagen synthesis over collagen degradation during the first 2 months of healing, and, at later times, from structural

modifications of collagen fibers (cross-linking, increased fiber size) after collagen synthesis ceases. Wound strength reaches approximately 70% to 80% of normal by 3 months but usually does not substantially improve beyond that point.

Fibrosis in Parenchymal Organs

Deposition of collagen is part of normal wound healing. The term *fibrosis* is used to denote the excessive deposition of collagen and other ECM components in a tissue. As already mentioned, the terms *scar* and *fibrosis* are used interchangeably, but *fibrosis* most often refers to the abnormal deposition of collagen that occurs in internal organs in chronic diseases. The basic mechanisms of fibrosis are the same as those of scar formation in the skin during tissue repair. Fibrosis is a pathologic process induced by persistent injurious stimuli such as chronic infections and immunologic reactions, and is typically associated with loss of tissue (Fig. 3-31). It may be responsible for substantial organ dysfunction and even organ failure.

Figure 3-31 Mechanisms of fibrosis. Persistent tissue injury leads to chronic inflammation and loss of tissue architecture. Cytokines produced by macrophages and other leukocytes stimulate the migration and proliferation of fibroblasts and myfibroblasts and the deposition of collagen and other extracellular matrix proteins. The net result is replacement of normal tissue by fibrosis.

As discussed earlier, the major cytokine involved in fibrosis is TGF- β . The mechanisms that lead to the activation of TGF- β in fibrosis are not precisely known, but cell death by necrosis or apoptosis and the production of reactive oxygen species seem to be important triggers of the activation, regardless of the tissue. Similarly, the cells that produce collagen under TGF- β stimulation may vary depending on the tissue. In most organs, such as in lung and kidney, myofibroblasts are the main source of collagen, but stellate cells are the major collagen producers in liver cirrhosis.

Fibrotic disorders include diverse chronic and debilitating diseases such as liver cirrhosis, systemic sclerosis (scleroderma), fibrosing diseases of the lung (idiopathic pulmonary fibrosis, pneumoconioses, and drug-, radiation-induced pulmonary fibrosis), end-stage kidney disease, and constrictive pericarditis. These conditions are discussed in the appropriate chapters throughout the book. Because of the tremendous functional impairment caused by fibrosis in these conditions, there is great interest in the development of antifibrotic drugs.

Abnormalities in Tissue Repair

Complications in tissue repair can arise from abnormalities in any of the basic components of the process, including deficient scar formation, excessive formation of the repair components, and formation of contractures.

- Inadequate formation of granulation tissue or formation of a scar can lead to two types of complications: wound dehiscence and ulceration.** Dehiscence or rupture of a wound, although not common, occurs most frequently after abdominal surgery and is due to increased abdominal pressure. Vomiting, coughing, or ileus can generate mechanical stress on the abdominal wound. Wounds can ulcerate because of inadequate vascularization during healing. For example, lower extremity wounds in individuals with atherosclerotic peripheral vascular disease typically ulcerate (Chapter 11). Nonhealing wounds also form in areas devoid of sensation. These neuropathic ulcers are occasionally seen in patients with diabetic peripheral neuropathy (Chapters 24 and 27).
- Excessive formation of the components of the repair process can give rise to hypertrophic scars and keloids.** The accumulation of excessive amounts of collagen may give rise to a raised scar known as a *hypertrophic scar*; if the scar tissue grows beyond the boundaries of the original wound and does not regress, it is called a *keloid* (Fig. 3-32). Keloid formation seems to be an individual predisposition, and for unknown reasons this aberration is somewhat more common in African Americans. Hypertrophic scars generally develop after thermal or traumatic injury that involves the deep layers of the dermis.
- Exuberant granulation** is another deviation in wound healing consisting of the formation of excessive amounts of granulation tissue, which protrudes above the level of the surrounding skin and blocks reepithelialization (this process has been called, with more literary fervor, *proud flesh*). Excessive granulation must be removed by cautery or surgical excision to permit restoration of the

Figure 3-32 Keloid. **A**, Excess collagen deposition in the skin forming a raised scar known as *keloid*. **B**, Note the thick connective tissue deposition in the dermis. (**A**, From Murphy GF, Herzberg AJ: Atlas of Dermatopathology. Philadelphia, WB Saunders, 1996, p 219; **B**, Courtesy Z. Argenyi, MD, University of Washington, Seattle, Wash.)

continuity of the epithelium. Fortunately rarely, incisional scars or traumatic injuries may be followed by exuberant proliferation of fibroblasts and other connective tissue elements that may, in fact, recur after excision. Called *desmoids*, or *aggressive fibromatoses*, these neoplasms lie in the interface between benign and malignant (though low-grade) tumors.

- **Contraction** in the size of a wound is an important part of the normal healing process. An exaggeration of this process gives rise to contracture and results in deformities of the wound and the surrounding tissues. Contractures are particularly prone to develop on the palms, the soles, and the anterior aspect of the thorax. Contractures are commonly seen after serious burns and can compromise the movement of joints.

KEY CONCEPTS

Cutaneous Wound Healing and Pathologic Aspects of Repair

- The main phases of cutaneous wound healing are inflammation, formation of granulation tissue, and ECM remodeling.
- Cutaneous wounds can heal by primary union (first intention) or secondary union (secondary intention); secondary healing involves more extensive scarring and wound contraction.
- Wound healing can be altered by many conditions, particularly infection and diabetes; the type, volume, and location of the injury are important factors that influence the healing process.
- Excessive production of ECM can cause keloids in the skin.
- Persistent stimulation of collagen synthesis in chronic inflammatory diseases leads to fibrosis of the tissue, often with extensive loss of the tissue and functional impairment.

Cardiovascular disease is the most important cause of morbidity and mortality in Western society. In 2008, it was estimated that 83 million people in the United States had one or more forms of cardiovascular disease, accounting for 35% to 40% of deaths. These diseases primarily affect one of the three major components of the cardiovascular system: the heart, the blood vessels, and the blood itself, which is composed of water, salts, a wide variety of proteins, elements that regulate clotting (the coagulation factors and platelets), and other formed elements (red cells and white cells). For simplicity, disorders that affect each component of the cardiovascular system are considered separately, recognizing that disturbances affecting one component often lead to adaptations and abnormalities involving others. Herein, we focus on disorders of hemodynamics (edema, effusions, congestion, and shock), provide an overview of disorders of abnormal bleeding and clotting (thrombosis), and discuss the various forms of embolism. Diseases that primarily affect the blood vessels and the heart are discussed in [Chapters 11](#) and [12](#), respectively, while specific bleeding disorders are covered in greater detail in [Chapter 14](#).

Edema and Effusions

Disorders that perturb cardiovascular, renal, or hepatic function are often marked by the accumulation of fluid in

tissues (edema) or body cavities (effusions). Under normal circumstances, the tendency of vascular hydrostatic pressure to push water and salts out of capillaries into the interstitial space is nearly balanced by the tendency of plasma colloid osmotic pressure to pull water and salts back into vessels. There is usually a small net movement of fluid into the interstitium, but this drains into lymphatic vessels and ultimately returns to the bloodstream via the thoracic duct, keeping the tissues “dry” ([Fig. 4-1](#)). **Elevated hydrostatic pressure or diminished colloid osmotic pressure disrupts this balance and results in increased movement of fluid out of vessels.** If the net rate of fluid movement exceeds the rate of lymphatic drainage, fluid accumulates. Within tissues the result is *edema*, and if a serosal surface is involved, fluid may accumulate within the adjacent body cavity as an *effusion*.

Edema fluids and effusions may be *inflammatory* or *noninflammatory* ([Table 4-1](#)). Inflammation-related edema and effusions are discussed in detail in [Chapter 3](#). These protein-rich *exudates* accumulate due to increases in vascular permeability caused by inflammatory mediators. Usually, inflammation-associated edema is localized to one or a few tissues, but in systemic inflammatory states, such as sepsis, that produce widespread endothelial injury and dysfunction, generalized edema may appear, often with severe consequences (discussed later). In contrast, noninflammatory edema and effusions are protein-poor fluids called *transudates*. Noninflammatory edema and effusions are common in many diseases, including heart failure, liver failure, renal disease, and severe nutritional disorders ([Fig. 4-2](#)). We will now discuss the various causes of edema.

*The contributions of Dr. Richard N Mitchell to this chapter over the past many editions are gratefully acknowledged.

Increased Hydrostatic Pressure

Increases in hydrostatic pressure are mainly caused by disorders that impair venous return. If the impairment is localized (e.g., a deep venous thrombosis [DVT] in a lower extremity), then the resulting edema is confined to the affected part. Conditions leading to systemic increases in venous pressure (e.g., congestive heart failure, Chapter 12) are understandably associated with more widespread edema.

Reduced Plasma Osmotic Pressure

Under normal circumstances albumin accounts for almost half of the total plasma protein; it follows that conditions leading to inadequate synthesis or increased loss of albumin from the circulation are common causes of reduced plasma oncotic pressure. Reduced albumin synthesis occurs mainly in severe liver diseases (e.g., end-stage cirrhosis, Chapter 18) and protein malnutrition (Chapter 9). An important cause of albumin loss is the nephrotic syndrome (Chapter 20), in which albumin leaks into the urine through abnormally permeable glomerular capillaries. Regardless of cause, reduced plasma osmotic pressure leads in a stepwise fashion to edema, reduced intravascular volume, renal hypoperfusion, and secondary hyperaldosteronism. Not only does the ensuing salt and water

Figure 4-1 Factors influencing fluid movement across capillary walls. Normally, hydrostatic and osmotic forces are nearly balanced so that there is little net movement of fluid out of vessels. Many different pathologic disorders (Table 4-1) are associated with increases in capillary hydrostatic pressure or decreases in plasma osmotic pressure that lead to the extravasation of fluid into tissues. Lymphatic vessels remove much of the excess fluid, but if the capacity for lymphatic drainage is exceeded, tissue edema results.

retention by the kidney fail to correct the plasma volume deficit, but it also exacerbates the edema, because the primary defect—a low plasma protein level—persists.

Sodium and Water Retention

Increased salt retention—with obligate retention of associated water—causes both increased hydrostatic pressure (due to intravascular fluid volume expansion) and diminished vascular colloid osmotic pressure (due to dilution). Salt retention occurs whenever renal function is compromised, such as in primary kidney disorders and in cardiovascular disorders that decrease renal perfusion. One of the most important causes of renal hypoperfusion is congestive heart failure, which (like hypoproteinemia) results in the activation of the renin-angiotensin-aldosterone axis. In early heart failure, this response is beneficial, as the retention of sodium and water and other adaptations, including increased vascular tone and elevated levels of antidiuretic hormone, improve cardiac output and restore normal renal perfusion. However, as heart failure worsens and cardiac output diminishes, the retained fluid merely increases the hydrostatic pressure, leading to edema and effusions.

Lymphatic Obstruction

Trauma, fibrosis, invasive tumors, and infectious agents can all disrupt lymphatic vessels and impair the clearance of interstitial fluid, resulting in lymphedema in the affected part of the body. A dramatic example is seen in parasitic *filariasis*, in which the organism induces obstructive fibrosis of lymphatic channels and lymph nodes. This may result in edema of the external genitalia and lower limbs that is so massive as to earn the appellation *elephantiasis*. Severe edema of the upper extremity may also complicate surgical removal and/or irradiation of the breast and associated axillary lymph nodes in patients with breast cancer.

Table 4-1 Pathophysiologic Categories of Edema

Increased Hydrostatic Pressure
Impaired Venous Return
Congestive heart failure
Constrictive pericarditis
Ascites (liver cirrhosis)
Venous obstruction or compression
Thrombosis
External pressure (e.g., mass)
Lower extremity inactivity with prolonged dependency
Arteriolar Dilation
Heat
Neurohumoral dysregulation
Reduced Plasma Osmotic Pressure (Hypoproteinemia)
Protein-losing glomerulopathies (nephrotic syndrome)
Liver cirrhosis (ascites)
Malnutrition
Protein-losing gastroenteropathy
Lymphatic Obstruction
Inflammatory
Neoplastic
Postsurgical
Postirradiation
Sodium Retention
Excessive salt intake with renal insufficiency
Increased tubular reabsorption of sodium
Renal hypoperfusion
Increased renin-angiotensin-aldosterone secretion
Inflammation
Acute inflammation
Chronic inflammation
Angiogenesis

Modified from Leaf A, Cotran RS. Renal pathophysiology, 3rd ed. New York, Oxford University Press, 1985, p 146.

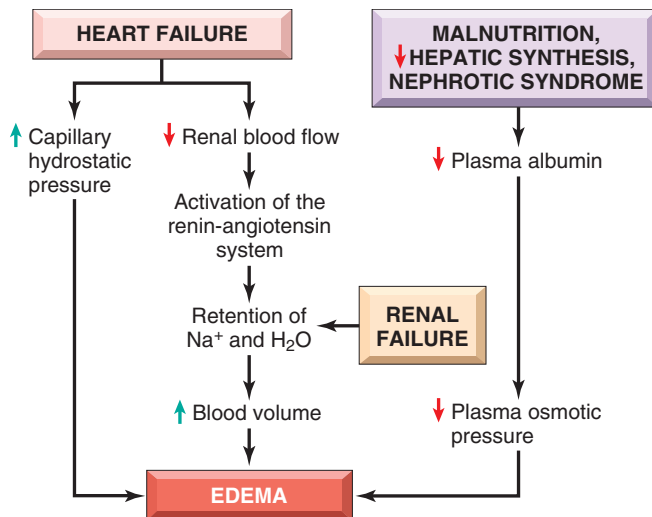

Figure 4-2 Mechanisms of systemic edema in heart failure, renal failure, malnutrition, hepatic failure, and nephrotic syndrome.

MORPHOLOGY

Edema is easily recognized grossly; microscopically, it is appreciated as clearing and separation of the extracellular matrix and subtle cell swelling. Any organ or tissue can be involved, but edema is most commonly seen in subcutaneous tissues, the lungs, and the brain. **Subcutaneous edema** can be diffuse or more conspicuous in regions with high hydrostatic pressures. Its distribution is often influenced by gravity (e.g., it appears in the legs when standing and the sacrum when recumbent), a feature termed **dependent edema**. Finger pressure over markedly edematous subcutaneous tissue displaces the interstitial fluid and leaves a depression, a sign called **pitting edema**.

Edema resulting from **renal dysfunction** often appears initially in parts of the body containing loose connective tissue, such as the eyelids; **periorbital edema** is thus a characteristic finding in severe renal disease. With **pulmonary edema**, the lungs are often two to three times their normal weight, and sectioning yields frothy, blood-tinged fluid—a mixture of air, edema, and extravasated red cells. **Brain edema** can be localized or generalized depending on the nature and extent of the pathologic process or injury. The swollen brain exhibits narrowed sulci and distended gyri, which are compressed by the unyielding skull (Chapter 28).

Effusions involving the pleural cavity (**hydrothorax**), the pericardial cavity (**hydropericardium**), or the peritoneal cavity (**hydroperitoneum** or **ascites**) are common in a wide range of clinical settings. Transudative effusions are typically protein-poor, translucent and straw colored; an exception are peritoneal effusions caused by lymphatic blockage (chylous effusion), which may be milky due to the presence of lipids absorbed from the gut. In contrast, exudative effusions are protein-rich and often cloudy due to the presence of white cells.

Clinical Features

The consequences of edema range from merely annoying to rapidly fatal. *Subcutaneous edema* is important primarily because it signals potential underlying cardiac or renal disease; however, when significant, it can also impair wound healing or the clearance of infections. *Pulmonary*

edema is a common clinical problem that is most frequently seen in the setting of left ventricular failure; it can also occur with renal failure, acute respiratory distress syndrome (Chapter 15), and pulmonary inflammation or infection. Not only does fluid collect in the alveolar septa around capillaries and impede oxygen diffusion, but edema fluid in the alveolar spaces also creates a favorable environment for bacterial infection. *Pulmonary effusions* often accompany edema in the lungs and can further compromise gas exchange by compressing the underlying pulmonary parenchyma. *Peritoneal effusions (ascites)* resulting most commonly from portal hypertension are prone to seeding by bacteria, leading to serious and sometimes fatal infections. *Brain edema* is life threatening; if severe, brain substance can *herniate* (extrude) through the foramen magnum, or the brain stem vascular supply can be compressed. Either condition can injure the medullary centers and cause death (Chapter 28).

KEY CONCEPTS

Edema

Edema is the result of the movement of fluid from the vasculature into the interstitial spaces; the fluid may be protein-poor (*transudate*) or protein-rich (*exudate*).

Edema may be caused by:

- Increased hydrostatic pressure (e.g., heart failure)
- Decreased colloid osmotic pressure caused by reduced plasma albumin, either due to decreased synthesis (e.g., liver disease, protein malnutrition) or to increased loss (e.g., nephrotic syndrome)
- Increased vascular permeability (e.g., inflammation), which is usually localized but may occur throughout the body in severe systemic inflammatory states such as sepsis
- Lymphatic obstruction (e.g., infection or neoplasia)
- Sodium and water retention (e.g., renal failure)

Hyperemia and Congestion

Hyperemia and congestion both stem from increased blood volumes within tissues, but have different underlying mechanisms and consequences. *Hyperemia* is an active process in which arteriolar dilation (e.g., at sites of inflammation or in skeletal muscle during exercise) leads to increased blood flow. Affected tissues turn red (*erythema*) because of increased delivery of oxygenated blood. *Congestion* is a passive process resulting from reduced outflow of blood from a tissue. It can be systemic, as in cardiac failure, or localized, as in isolated venous obstruction.

As a result of increased hydrostatic pressures, congestion commonly leads to edema. In long-standing *chronic passive congestion*, the associated chronic hypoxia may result in ischemic tissue injury and scarring. In chronically congested tissues, capillary rupture can also produce small hemorrhagic foci; subsequent catabolism of extravasated red cells can leave residual telltale clusters of hemosiderin-laden macrophages.

Figure 4-3 Liver with chronic passive congestion and hemorrhagic necrosis. **A**, Central areas are red and slightly depressed compared with the surrounding tan viable parenchyma, forming a “nutmeg liver” pattern (so-called because it resembles the cut surface of a nutmeg). **B**, Centrilobular necrosis with degenerating hepatocytes and hemorrhage. (Courtesy Dr. James Crawford, Department of Pathology, University of Florida, Gainesville, Fla.)

MORPHOLOGY

Congested tissues take on a dusky reddish-blue color (*cyanosis*) due to red cell stasis and the presence of deoxygenated hemoglobin. Microscopically, **acute pulmonary congestion** exhibits engorged alveolar capillaries, alveolar septal edema, and focal intraalveolar hemorrhage. In **chronic pulmonary congestion**, which is often caused by congestive heart failure, the septa are thickened and fibrotic, and the alveoli often contain numerous hemosiderin-laden macrophages called **heart failure cells**. In **acute hepatic congestion**, the central vein and sinusoids are distended. Because the centrilobular area is at the distal end of the hepatic blood supply, centrilobular hepatocytes may undergo ischemic necrosis while the periportal hepatocytes—better oxygenated because of proximity to hepatic arterioles—may only develop fatty change. In **chronic passive hepatic congestion**, the centrilobular regions are grossly red-brown and slightly depressed (because of cell death) and are accentuated against the surrounding zones of uncongested tan liver (**nutmeg liver**) (Fig. 4-3A). Microscopically, there is centrilobular hemorrhage, hemosiderin-laden macrophages, and variable degrees of hepatocyte dropout and necrosis (Fig. 4-3B).

Hemostasis, Hemorrhagic Disorders, and Thrombosis

Hemostasis can be defined simply as the process by which blood clots form at sites of vascular injury. Hemostasis is essential for life and is deranged to varying degrees in a broad range of disorders, which can be divided into two groups. In *hemorrhagic disorders*, characterized by excessive bleeding, hemostatic mechanisms are either blunted or insufficient to prevent abnormal blood loss. By contrast, in *thrombotic disorders* blood clots (often referred to as *thrombi*) form within intact blood vessels or within the chambers of the heart. As is discussed in Chapters 11 and 12, thrombosis has a central role in the most common and clinically important forms of cardiovascular disease.

While useful, it must be recognized that this division between bleeding and thrombotic disorders sometimes breaks down, in that generalized activation of clotting sometimes paradoxically produces bleeding due to the consumption of coagulation factors, as in *disseminated intravascular coagulation (DIC)*. To provide context for understanding

disorders of bleeding and clotting, this discussion begins with normal hemostasis, focusing on the contribution of platelets, coagulation factors, and endothelium.

Hemostasis

Hemostasis is a precisely orchestrated process involving platelets, clotting factors, and endothelium that occurs at the site of vascular injury and culminates in the formation of a blood clot, which serves to prevent or limit the extent of bleeding. The general sequence of events leading to hemostasis at a site of vascular injury is shown in Figure 4-4.

- *Arteriolar vasoconstriction* occurs immediately and markedly reduces blood flow to the injured area (Fig. 4-4A). It is mediated by reflex neurogenic mechanisms and augmented by the local secretion of factors such as *endothelin*, a potent endothelium-derived vasoconstrictor. This effect is transient, however, and bleeding would resume if not for activation of platelets and coagulation factors.
- *Primary hemostasis: the formation of the platelet plug.* Disruption of the endothelium exposes subendothelial von Willebrand factor (vWF) and collagen, which promote platelet adherence and activation. Activation of platelets results in a dramatic shape change (from small rounded discs to flat plates with spiky protrusions that markedly increased surface area), as well as the release of secretory granules. Within minutes the secreted products recruit additional platelets, which undergo *aggregation* to form a *primary hemostatic plug* (Fig. 4-4B).
- *Secondary hemostasis: deposition of fibrin.* *Tissue factor* is also exposed at the site of injury. Tissue factor is a membrane-bound procoagulant glycoprotein that is normally expressed by subendothelial cells in the vessel wall, such as smooth muscle cells and fibroblasts. Tissue factor binds and activates factor VII (see later), setting in motion a cascade of reactions that culminates in *thrombin* generation. Thrombin cleaves circulating fibrinogen into insoluble *fibrin*, creating a fibrin meshwork, and also is a potent activator of platelets, leading to additional platelet aggregation at the site of injury. This sequence, referred to as *secondary hemostasis*, consolidates the initial platelet plug (Fig. 4-4C).
- *Clot stabilization and resorption.* Polymerized fibrin and platelet aggregates undergo contraction to form a solid,

Figure 4-4 Normal hemostasis. **A**, After vascular injury, local neurohumoral factors induce a transient vasoconstriction. **B**, Platelets bind via glycoprotein Ib (GpIb) receptors to von Willebrand factor (vWF) on exposed extracellular matrix (ECM) and are activated, undergoing a shape change and granule release. Released adenosine diphosphate (ADP) and thromboxane A_2 (TxA_2) induce additional platelet aggregation through platelet GpIIb/IIIa receptor binding to fibrinogen, and form the *primary* hemostatic plug. **C**, Local activation of the coagulation cascade (involving tissue factor and platelet phospholipids) results in fibrin polymerization, “cementing” the platelets into a definitive *secondary* hemostatic plug. **D**, Counterregulatory mechanisms, mediated by tissue plasminogen activator (t-PA, a fibrinolytic product) and thrombomodulin, confine the hemostatic process to the site of injury.

permanent plug that prevents further hemorrhage. At this stage, counterregulatory mechanisms (e.g., *tissue plasminogen activator*, *t-PA*) are set into motion that limit clotting to the site of injury (Fig. 4-4D) and eventually lead to clot resorption and tissue repair.

The following sections discuss the roles of the platelets, coagulation factors, and endothelium in hemostasis in greater detail.

Platelets

Platelets play a critical role in hemostasis by forming the primary plug that initially seals vascular defects and by providing a surface that binds and concentrates activated coagulation factors. Platelets are disc-shaped anucleate cell fragments that are shed from megakaryocytes in the bone marrow into the bloodstream. Their function depends on several glycoprotein receptors, a contractile cytoskeleton, and two types of cytoplasmic granules. α -*Granules* have the adhesion molecule P-selectin on their membranes (Chapter 3) and contain proteins involved in coagulation, such as fibrinogen, coagulation factor V, and vWF, as well as protein factors that may be involved in wound healing, such as fibronectin, platelet factor 4 (a heparin-binding chemokine), platelet-derived growth factor (PDGF), and transforming growth factor- β . *Dense* (or δ) *granules* contain adenosine diphosphate (ADP) and adenosine triphosphate, ionized calcium, serotonin, and epinephrine.

After a traumatic vascular injury, platelets encounter constituents of the subendothelial connective tissue, such as vWF and collagen. On contact with these proteins, platelets undergo a sequence of reactions that culminate in the formation of a platelet plug (Fig. 4-4B).

- *Platelet adhesion* is mediated largely via interactions with vWF, which acts as a bridge between the platelet surface receptor glycoprotein Ib (GpIb) and exposed collagen (Fig. 4-5). Notably, genetic deficiencies of vWF (von Willebrand disease, Chapter 14) or GpIb (Bernard-Soulier syndrome) result in bleeding disorders, attesting to the importance of these factors.
- *Platelets rapidly change shape* following adhesion, being converted from smooth discs to spiky “sea urchins” with greatly increased surface area. This change is accompanied by alterations in *glycoprotein IIb/IIIa* that increase its affinity for fibrinogen (see later), and by the translocation of *negatively charged phospholipids* (particularly phosphatidylserine) to the platelet surface. These phospholipids bind calcium and serve as nucleation sites for the assembly of coagulation factor complexes.
- *Secretion (release reaction) of granule contents* occurs along with changes in shape; these two events are

A. VASOCONSTRICTION

B. PRIMARY HEMOSTASIS

C. SECONDARY HEMOSTASIS

D. THROMBUS AND ANTITHROMBOTIC EVENTS

Figure 4-5 Platelet adhesion and aggregation. Von Willebrand factor functions as an adhesion bridge between subendothelial collagen and the glycoprotein Ib (GpIb) platelet receptor. Aggregation is accomplished by fibrinogen bridging GpIIb-IIIa receptors on different platelets. Congenital deficiencies in the various receptors or bridging molecules lead to the diseases indicated in the colored boxes. ADP, adenosine diphosphate.

often referred to together as *platelet activation*. Platelet activation is triggered by a number of factors, including the coagulation factor thrombin and ADP. Thrombin activates platelets through a special type of G-protein-coupled receptor referred to as a *protease-activated receptor* (PAR), which is switched on by a proteolytic cleavage carried out by thrombin. ADP is a component of dense-body granules; thus, platelet activation and ADP release begets additional rounds of platelet activation, a

phenomenon referred to as *recruitment*. Activated platelets also produce the prostaglandin *thromboxane A₂* (TxA₂), a potent inducer of platelet aggregation. *Aspirin* inhibits platelet aggregation and produces a mild bleeding defect by inhibiting cyclooxygenase, a platelet enzyme that is required for TxA₂ synthesis. Although the phenomenon is less well characterized, it is also suspected that growth factors released from platelets contribute to the repair of the vessel wall following injury.

- *Platelet aggregation* follows their activation. The conformational change in glycoprotein IIb/IIIa that occurs with platelet activation allows binding of fibrinogen, a large bivalent plasma polypeptide that forms bridges between adjacent platelets, leading to their aggregation. Predictably, inherited deficiency of GpIIb-IIIa results in a bleeding disorder called *Glanzmann thrombasthenia*. The initial wave of aggregation is reversible, but concurrent activation of thrombin stabilizes the platelet plug by causing further platelet activation and aggregation, and by promoting irreversible *platelet contraction*. Platelet contraction is dependent on the cytoskeleton and consolidates the aggregated platelets. In parallel, thrombin also converts fibrinogen into insoluble *fibrin*, cementing the platelets in place and creating the definitive *secondary hemostatic plug*. Entrapped red cells and leukocytes are also found in hemostatic plugs, in part due to adherence of leukocytes to P-selectin expressed on activated platelets.

Coagulation Cascade

The **coagulation cascade is series of amplifying enzymatic reactions that leads to the deposition of an insoluble fibrin clot**. As discussed later, the dependency of clot formation on various factors differs in the laboratory in the laboratory test tube and in blood vessels *in vivo* (Fig. 4-6).

Figure 4-6 The coagulation cascade in the laboratory and *in vivo*. **A**, Clotting is initiated in the laboratory by adding phospholipids, calcium, and either a negative charged substance such as glass beads (intrinsic pathway) or a source of tissue factor (extrinsic pathway). **B**, *In vivo*, tissue factor is the major initiator of coagulation, which is amplified by feedback loops involving thrombin (dotted lines). The red polypeptides are inactive factors, the dark green polypeptides are active factors, while the light green polypeptides correspond to cofactors..

Figure 4-7 Schematic illustration of the conversion of factor X to factor Xa via the extrinsic pathway, which in turn converts factor II (prothrombin) to factor IIa (thrombin). The initial reaction complex consists of a proteolytic enzyme (factor VIIa), a substrate (factor X), and a reaction accelerator (tissue factor), all assembled on a platelet phospholipid surface. Calcium ions hold the assembled components together and are essential for the reaction. Activated factor Xa becomes the protease for the second adjacent complex in the coagulation cascade, converting prothrombin substrate (II) to thrombin (IIa) using factor Va as the reaction accelerator.

However, clotting *in vitro* and *in vivo* both follow the same general principles, as follows.

The cascade of reactions in the pathway can be likened to a “dance,” in which coagulation factors are passed from one partner to the next (Fig. 4-7). Each reaction step involves an enzyme (an activated coagulation factor), a substrate (an inactive proenzyme form of a coagulation factor), and a cofactor (a reaction accelerator). These components are assembled on a negatively charged phospholipid surface, which is provided by activated platelets. Assembly of reaction complexes also depends on calcium, which binds to γ -carboxylated glutamic acid residues that are present in factors II, VII, IX, and X. The enzymatic reactions that produce γ -carboxylated glutamic acid use vitamin K as a cofactor and are antagonized by drugs such as coumadin, a widely used anticoagulant.

Based on assays carried out in clinical laboratories, the coagulation cascade has traditionally been divided into the *extrinsic* and *intrinsic* pathways (Fig. 4-6A).

- The *prothrombin time* (PT) assay assesses the function of the proteins in the extrinsic pathway (factors VII, X, V, II, and fibrinogen). In brief, tissue factor, phospholipids, and calcium are added to plasma and the time for a fibrin clot to form is recorded.
- The *partial thromboplastin time* (PTT) assay screens the function of the proteins in the intrinsic pathway (factors XII, XI, IX, VIII, X, V, II, and fibrinogen). In this assay, clotting of plasma is initiated by addition of negative-charged particles (e.g., ground glass) that activate factor XII (Hageman factor) together with phospholipids and calcium, and the time to fibrin clot formation is recorded.

While the PT and PTT assays are of great utility in evaluating coagulation factor function in patients, they fail to recapitulate the events that lead to coagulation *in vivo*. This point is most clearly made by considering

the clinical effects of deficiencies of various coagulation factors. Deficiencies of factors V, VII, VIII, IX, and X are associated with moderate to severe bleeding disorders, and prothrombin deficiency is likely incompatible with life. In contrast, factor XI deficiency is only associated with mild bleeding, and individuals with factor XII deficiency do not bleed and in fact may be susceptible to thrombosis. The paradoxical effect of factor XII deficiency may be explained by involvement of factor XII in the fibrinolysis pathway (discussed later); while there is also some evidence from experimental models suggesting that factor XII may promote thrombosis under certain circumstances, the relevance of these observations to human thrombotic disease remains to be determined.

Based on the effects of various factor deficiencies in humans, it is believed that, *in vivo*, factor VIIa/tissue factor complex is the most important activator of factor IX and that factor IXa/factor VIIIa complex is the most important activator of factor X (Fig. 4-6B). The mild bleeding tendency seen in patients with factor XI deficiency is likely explained by the ability of thrombin to activate factor XI (as well as factors V and VIII), a feedback mechanism that amplifies the coagulation cascade.

Among the coagulation factors, thrombin is the most important, in that its various enzymatic activities control diverse aspects of hemostasis and link clotting to inflammation and repair. Among thrombin’s most important activities are the following:

- *Conversion of fibrinogen into crosslinked fibrin.* Thrombin directly converts soluble fibrinogen into fibrin monomers that polymerize into an insoluble clot, and also amplifies the coagulation process, not only by activating factor XI, but also by activating two critical co-factors, factors V and VIII. It also stabilizes the secondary hemostatic plug by activating factor XIII, which covalently cross-links fibrin.

Figure 4-8 Role of thrombin in hemostasis and cellular activation. Thrombin plays a critical role in generating cross-linked fibrin (by cleaving fibrinogen to fibrin and by activating factor XIII), as well as activating several other coagulation factors (see Fig. 4-6B). Through protease-activated receptors (PARs, see text), thrombin also modulates several cellular activities. It directly induces platelet aggregation and TxA_2 production, and activates endothelial cells, which respond by expressing adhesion molecules and a variety of fibrinolytic (t-PA), vasoactive (NO, PGI_2), and cytokine mediators (e.g., PDGF). Thrombin also directly activates leukocytes. ECM, extracellular matrix; NO, nitric oxide; PDGF, platelet-derived growth factor; PGI_2 , prostacyclin; TxA_2 , thromboxane A_2 ; t-PA, tissue plasminogen activator. See Figure 4-10 for additional anticoagulant activities mediated by thrombin. (Courtesy Shaun Coughlin, MD, PhD, Cardiovascular Research Institute, University of California at San Francisco; modified with permission.)

- **Platelet activation.** Thrombin is a potent inducer of platelet activation and aggregation through its ability to activate PARs, thereby linking platelet function to coagulation.
- **Pro-inflammatory effects.** PARs are also expressed on inflammatory cells, endothelium, and other cell types (Fig. 4-8), and activation of these receptors by thrombin

is believed to mediate proinflammatory effects that contribute to tissue repair and angiogenesis.

- **Anticoagulant effects.** Remarkably, through mechanisms described later, upon encountering normal endothelium thrombin changes from a procoagulant to an anticoagulant. This reversal in function prevents clotting from extending beyond the site of the vascular injury.

Factors That Limit Coagulation. Once initiated, coagulation must be restricted to the site of vascular injury to prevent deleterious consequences. One limiting factor is simple dilution; blood flowing past the site of injury washes out activated coagulation factors, which are rapidly removed by the liver. A second is the requirement for negatively charged phospholipids, which, as mentioned, are mainly provided by platelets that have been activated by contact with subendothelial matrix at sites of vascular injury. However, the most important counterregulatory mechanisms involve factors that are expressed by intact endothelium adjacent to the site of injury (described later).

Activation of the coagulation cascade also sets into motion a *fibrinolytic cascade* that limits the size of the clot and contributes to its later dissolution (Fig. 4-9). Fibrinolysis is largely accomplished through the enzymatic activity of *plasmin*, which breaks down fibrin and interferes with its polymerization. An elevated level of breakdown products of fibrinogen (often called fibrin split products), most notably fibrin-derived *D-dimers*, are a useful clinical markers of several thrombotic states (described later). Plasmin is generated by enzymatic catabolism of the inactive circulating precursor *plasminogen*, either by a factor XII-dependent pathway (possibly explaining the association of factor XII deficiency and thrombosis) or by plasminogen activators. The most important plasminogen activator is t-PA; it is synthesized principally by endothelium and is most active when bound to fibrin. This characteristic makes t-PA a useful therapeutic agent, since its fibrinolytic activity is largely confined to sites of recent thrombosis. Once activated, plasmin is in turn tightly controlled by counterregulatory factors such as α_2 -plasmin inhibitor, a plasma protein that binds and rapidly inhibits free plasmin.

Figure 4-9 The fibrinolytic system, illustrating various plasminogen activators and inhibitors (see text).

Figure 4-10 Anticoagulant activities of normal endothelium. NO, nitric oxide; PGI₂, prostacyclin; t-PA, tissue plasminogen activator; vWF, von Willebrand factor. The thrombin receptor is also called a protease-activated receptor (PAR).

Endothelium

The balance between the anticoagulant and procoagulant activities of endothelium often determines whether clot formation, propagation, or dissolution occurs. As alluded to earlier, normal endothelial cells express a multitude of factors that inhibit the procoagulant activities of platelets and coagulation factors and that augment fibrinolysis (Fig. 4-10). These factors act in concert to prevent thrombosis and to limit clotting to sites of vascular damage. However, if injured or exposed to proinflammatory factors, endothelial cells lose many of their antithrombotic properties. Here, we complete the discussion of hemostasis by focusing on the antithrombotic activities of normal endothelium; we return to the “dark side” of endothelial cells later when discussing thrombosis.

The antithrombotic properties of endothelium can be divided into activities directed at platelets, coagulation factors, and fibrinolysis.

- **Platelet inhibitory effects.** An obvious effect of intact endothelium is to serve as a barrier that shields platelets from subendothelial vWF and collagen. However, normal endothelium also releases a number of factors that inhibit platelet activation and aggregation. Among the most important are *prostacyclin* (PGI₂), *nitric oxide* (NO), and *adenosine diphosphatase*; the latter degrades ADP, already discussed as a potent activator of platelet aggregation. Finally, endothelial cells bind and alter the activity of thrombin, which is one of the most potent activators of platelets.

- **Anticoagulant effects.** Normal endothelium shields coagulation factors from tissue factor in vessel walls and expresses multiple factors that actively oppose coagulation, most notably thrombomodulin, endothelial protein C receptor, heparin-like molecules, and tissue factor pathway inhibitor. *Thrombomodulin* and *endothelial protein C receptor* bind thrombin and protein C, respectively, in a complex on the endothelial cell surface. When bound in this complex, thrombin loses its ability to activate coagulation factors and platelets, and instead cleaves and activates *protein C*, a vitamin K-dependent protease that requires a cofactor, protein S. Activated protein C/protein S complex is a potent inhibitor of coagulation factors Va and VIIIa. *Heparin-like molecules* on the surface of endothelium bind and activate antithrombin III, which then inhibits thrombin and factors IXa, Xa, XIa, and XIIa. The clinical utility of heparin and related drugs is based on their ability to stimulate antithrombin III activity. *Tissue factor pathway inhibitor* (TFPI), like protein C, requires protein S as a cofactor and, as the name implies, binds and inhibits tissue factor/factor VIIa complexes.
- **Fibrinolytic effects.** Normal endothelial cells synthesize t-PA, already discussed, as a key component of the fibrinolytic pathway.

Hemorrhagic Disorders

Disorders associated with abnormal bleeding inevitably stem from primary or secondary defects in vessel walls, platelets, or coagulation factors, all of which must function properly to ensure hemostasis. The presentation of abnormal bleeding varies widely. At one end of the spectrum are massive bleeds associated with ruptures of large vessels such as the aorta or of the heart; these catastrophic events simply overwhelm hemostatic mechanisms and are often fatal. Diseases associated with sudden, massive hemorrhage include aortic dissection in the setting of Marfan syndrome (Chapter 5), and aortic abdominal aneurysm (Chapter 11) and myocardial infarction (Chapter 12) complicated by rupture of the aorta or the heart. At the other end of the spectrum are subtle defects in clotting that only become evident under conditions of hemostatic stress, such as surgery, childbirth, dental procedures, menstruation, or trauma. Among the most common causes of mild bleeding tendencies are inherited defects in von Willebrand factor (Chapter 14), aspirin consumption, and uremia (renal failure); the latter alters platelet function through uncertain mechanisms. Between these extremes lie deficiencies of coagulation factors (the hemophilias, Chapter 14), which are usually inherited and lead to severe bleeding disorders if untreated.

Additional specific examples of disorders associated with abnormal bleeding are discussed throughout the book. The following are general principles related to abnormal bleeding and its consequences.

- **Defects of primary hemostasis (platelet defects or von Willebrand disease)** often present with small bleeds in skin or mucosal membranes. These bleeds typically take the form of petechiae, minute 1- to 2-mm hemorrhages (Fig. 4-11A), or *purpura*, which are slightly larger

Figure 4-11 **A**, Punctate petechial hemorrhages of the colonic mucosa, a consequence of thrombocytopenia. **B**, Fatal intracerebral bleed.

(≥ 3 mm) than petechiae. It is believed that the capillaries of the mucosa and skin are particularly prone to rupture following minor trauma and that under normal circumstances platelets seal these defects virtually immediately. Mucosal bleeding associated with defects in primary hemostasis may also take the form of epistaxis (nosebleeds), gastrointestinal bleeding, or excessive menstruation (menorrhagia). A feared complication of very low platelet counts (*thrombocytopenia*) is intracerebral hemorrhage, which may be fatal.

- *Defects of secondary hemostasis (coagulation factor defects)* often present with bleeds into soft tissues (e.g., muscle) or joints. Bleeding into joints (*hemarthrosis*) following minor trauma is particularly characteristic of hemophilia (Chapter 14). It is unknown why severe defects in secondary hemostasis present with this peculiar pattern of bleeding; as with severe platelet defects, intracranial hemorrhage, sometimes fatal, may also occur.
- *Generalized defects involving small vessels* often present with “palpable purpura” and ecchymoses. *Ecchymoses* (sometimes simply called bruises) are hemorrhages of 1 to 2 cm in size. In both purpura and ecchymoses, the volume of extravasated blood is sufficient to create a palpable mass of blood known as a *hematoma*. Purpura and ecchymoses are particularly characteristic of systemic disorders that disrupt small blood vessels (e.g., vasculitis, Chapter 11) or that lead to blood vessel fragility (e.g., amyloidosis, Chapter 6; scurvy, Chapter 9).

The clinical significance of hemorrhage depends on the volume of the bleed, the rate at which it occurs, and its location. Rapid loss of up to 20% of the blood volume may have little impact in healthy adults; greater losses, however, can cause *hemorrhagic (hypovolemic) shock* (discussed later). Bleeding that is trivial in the subcutaneous tissues can cause death if located in the brain (Fig. 4-11B); because the skull is unyielding, intracranial hemorrhage may increase intracranial pressure to a level that compromises the blood supply or causes herniation of the brainstem (Chapter 28). Finally, chronic or recurrent external blood loss (e.g., peptic ulcer or menstrual bleeding) causes iron loss and can lead to an iron deficiency anemia. In contrast, when red cells are retained (e.g., hemorrhage into body cavities or tissues), iron is recovered and recycled for use in the synthesis of hemoglobin.

Thrombosis

The primary abnormalities that lead to thrombosis are (1) **endothelial injury**, (2) **stasis or turbulent blood flow**, and (3) **hypercoagulability of the blood (the so-called Virchow triad)** (Fig. 4-12). Thrombosis is one of the scourges of modern man, because it underlies the most serious and common forms of cardiovascular disease. Here, the focus is on its causes and consequences; its role in cardiovascular disorders is discussed in detail in Chapters 11 and 12.

Endothelial Injury

Endothelial injury leading to platelet activation almost inevitably underlies thrombus formation in the heart and the arterial circulation, where the high rates of blood flow impede clot formation. Notably, cardiac and arterial clots are typically rich in platelets, and it is believed that platelet adherence and activation is a necessary prerequisite for thrombus formation under high shear stress, such as exists

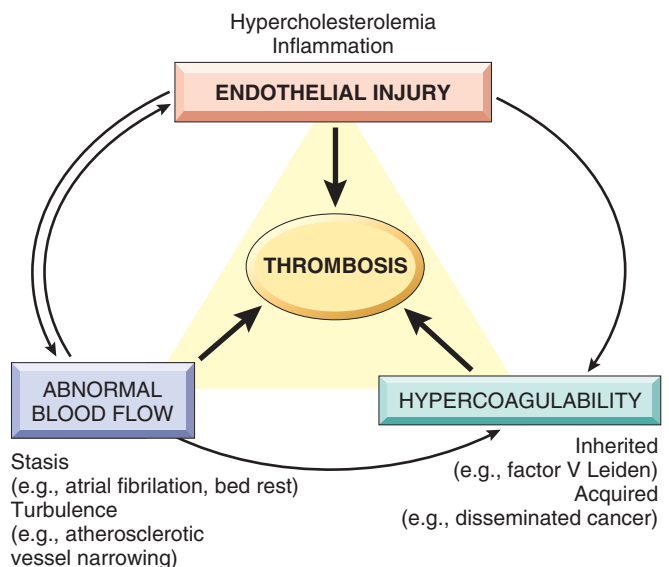

Figure 4-12 The Virchow triad in thrombosis. Endothelial integrity is the most important factor. Injury to endothelial cells can alter local blood flow and affect coagulability. Abnormal blood flow (stasis or turbulence), in turn, can cause endothelial injury. These factors may promote thrombosis independently or in combination.

in arteries. This insight provides part of the reasoning behind the use of aspirin and other platelet inhibitors in coronary artery disease and acute myocardial infarction.

Obviously, severe endothelial injury may trigger thrombosis by exposing vWF and tissue factor. However, inflammation and other noxious stimuli also promote thrombosis by shifting the pattern of gene expression in endothelium to one that is “prothrombotic.” This change is sometimes referred to as *endothelial activation* or *dysfunction* and can be produced by diverse exposures, including physical injury, infectious agents, abnormal blood flow, inflammatory mediators, metabolic abnormalities, such as hypercholesterolemia or homocystinemia, and toxins absorbed from cigarette smoke. Endothelial activation is believed to have an important role in triggering arterial thrombotic events.

The role of endothelial cell activation and dysfunction in arterial thrombosis is discussed in detail in [Chapters 11](#) and [12](#). Here it suffices to mention several of the major prothrombotic alterations:

- **Procoagulant changes.** Endothelial cells activated by cytokines downregulate the expression of *thrombomodulin*, already described as a key modulator of thrombin activity. This may result in sustained activation of thrombin, which can in turn stimulate platelets and augment inflammation through PARs expressed on platelets and inflammatory cells. In addition, inflamed endothelium also downregulates the expression of other anticoagulants, such as protein C and tissue factor protein inhibitor, changes that further promote a procoagulant state.
- **Antifibrinolytic effects.** Activated endothelial cells secrete *plasminogen activator inhibitors* (PAIs), which limit fibrinolysis, and downregulate the expression of t-PA, alterations that also favor the development of thrombi.

Alterations in Normal Blood Flow

Turbulence contributes to arterial and cardiac thrombosis by causing endothelial injury or dysfunction, as well as by forming countercurrents that contribute to local pockets of stasis. *Stasis* is a major contributor in the development of venous thrombi. Normal blood flow is *laminar* such that the platelets (and other blood cellular elements) flow centrally in the vessel lumen, separated from endothelium by a slower moving layer of plasma. Stasis and turbulence therefore:

- Promote endothelial activation, enhancing procoagulant activity and leukocyte adhesion, in part through flow-induced changes in the expression of adhesion molecules and pro-inflammatory factors
- Disrupt laminar flow and bring platelets into contact with the endothelium
- Prevent washout and dilution of activated clotting factors by fresh flowing blood and the inflow of clotting factor inhibitors

Altered blood flow contributes to thrombosis in several clinical settings. Ulcerated atherosclerotic plaques not only expose subendothelial vWF and tissue factor but also cause turbulence. Aortic and arterial dilations called *aneurysms* result in local stasis and are therefore fertile sites for thrombosis ([Chapter 11](#)). Acute myocardial infarctions result in areas of noncontractile myocardium and sometimes in cardiac aneurysms; both are associated with stasis and

flow abnormalities that promote the formation of cardiac mural thrombi ([Chapter 12](#)). Rheumatic mitral valve stenosis results in left atrial dilation; in conjunction with atrial fibrillation, a dilated atrium is a site of profound stasis and a prime location for thrombosis ([Chapter 12](#)). *Hyperviscosity* (such as is seen with polycythemia vera; [Chapter 13](#)) increases resistance to flow and causes small vessel stasis, and the deformed red cells in *sickle cell anemia* ([Chapter 14](#)) impede blood flow through small vessels, with the resulting stasis also predisposing to thrombosis.

Hypercoagulability

Hypercoagulability (also called thrombophilia) can be loosely defined as any disorder of the blood that predisposes to thrombosis. Hypercoagulability has a particularly important role in venous thrombosis and can be divided into *primary* (genetic) and *secondary* (acquired) disorders ([Table 4-2](#)). Of the inherited causes of hypercoagulability, point mutations in the factor V gene and prothrombin gene are the most common.

- Approximately 2% to 15% of Caucasians carry a single-nucleotide mutation in factor V that is called the *factor V Leiden*, after the city in The Netherlands where it was discovered. Among individuals with recurrent DVT, the frequency of this mutation is considerably higher, approaching 60%. The mutation results in a glutamine

Table 4-2 Hypercoagulable States

Primary (Genetic)
Common
Factor V mutation (Arg to Glu substitution in amino acid residue 506 leading to resistance to activated protein C; factor V Leiden)
Prothrombin mutation (G20210A noncoding sequence variant leading to increased prothrombin levels)
Increased levels of factors VIII, IX, XI, or fibrinogen (genetics unknown)
Rare
Antithrombin III deficiency
Protein C deficiency
Protein S deficiency
Very Rare
Fibrinolysis defects
Homozygous homocystinuria (deficiency of cystathione β -synthetase)
Secondary (Acquired)
High Risk for Thrombosis
Prolonged bed rest or immobilization
Myocardial infarction
Atrial fibrillation
Tissue injury (surgery, fracture, burn)
Cancer
Prosthetic cardiac valves
Disseminated intravascular coagulation
Heparin-induced thrombocytopenia
Antiphospholipid antibody syndrome
Lower Risk for Thrombosis
Cardiomyopathy
Nephrotic syndrome
Hyperestrogenic states (pregnancy and postpartum)
Oral contraceptive use
Sickle cell anemia
Smoking

to arginine substitution at amino acid residue 506 that renders factor V resistant to cleavage and inactivation by protein C. As a result, an important antithrombotic counterregulatory pathway is lost (Fig. 4-10). Indeed, heterozygotes have a five-fold increased relative risk of venous thrombosis, and homozygotes have a 50-fold increase.

- A single nucleotide change (G20210A) in the 3'-untranslated region of the *prothrombin* gene is another common mutation (1% to 2% of the population) associated with hypercoagulability. It leads to elevated prothrombin levels and an almost three-fold increased risk of venous thrombosis.
- Elevated levels of *homocysteine* contribute to arterial and venous thrombosis, as well as the development of atherosclerosis (Chapter 11). The prothrombotic effects of homocysteine may be due to thioester linkages formed between homocysteine metabolites and a variety of proteins, including fibrinogen. Marked elevations of homocysteine may be caused by an inherited deficiency of cystathione β -synthetase.
- Rare inherited causes of primary hypercoagulability include deficiencies of anticoagulants such as antithrombin III, protein C, or protein S; affected individuals typically present with venous thrombosis and recurrent thromboembolism beginning in adolescence or early adulthood.

The most common thrombophilic genotypes found in various populations (heterozygosity for factor V Leiden and heterozygosity for the prothrombin G20210A variant) impart only a moderately increased risk of thrombosis; most individuals with these genotypes, when otherwise healthy, are free of thrombotic complications. However, factor V and prothrombin mutations are frequent enough that homozygosity and compound heterozygosity are not rare, and such genotypes are associated with greater risk. Moreover, individuals with such mutations have a significantly increased frequency of venous thrombosis in the setting of other acquired risk factors (e.g., pregnancy or prolonged bed rest). Thus, factor V Leiden heterozygosity may trigger DVT when combined with enforced inactivity, such as during prolonged airplane travel. Consequently, **inherited causes of hypercoagulability must be considered in patients younger than age 50 years who present with thrombosis—even when acquired risk factors are present.**

Unlike hereditary disorders, the pathogenesis of *acquired thrombophilia* is frequently multifactorial (Table 4-2). In some cases (e.g., cardiac failure or trauma), stasis or vascular injury may be most important. Hypercoagulability due to oral contraceptive use or the hyperestrogenic state of pregnancy is probably caused by increased hepatic synthesis of coagulation factors and reduced anticoagulant synthesis. In disseminated cancers, release of various procoagulants from tumors predisposes to thrombosis. The hypercoagulability seen with advancing age may be due to reduced endothelial PGI₂ production. Smoking and obesity promote hypercoagulability by unknown mechanisms.

Among the acquired thrombophilic states, the heparin-induced thrombocytopenia and the antiphospholipid antibody syndromes are particularly important clinical problems that deserve special mention.

Heparin-Induced Thrombocytopenia (HIT) Syndrome

HIT occurs following the administration of *unfractionated heparin*, which may induce the appearance of antibodies that recognize complexes of heparin and platelet factor 4 on the surface of platelets (Chapter 14), as well as complexes of heparin-like molecules and platelet factor 4-like proteins on endothelial cells. Binding of these antibodies to platelets results in their activation, aggregation, and consumption (hence the *thrombocytopenia* in the syndrome name). This effect on platelets and endothelial damage induced by antibody binding combine to produce a *prothrombotic state*, even in the face of heparin administration and low platelet counts. Low-molecular-weight heparin preparations induce HIT less frequently, and other classes of anticoagulants such as direct inhibitors of factor X and thrombin may also obviate the risk.

Antiphospholipid Antibody Syndrome

This syndrome (previously called the lupus anticoagulant syndrome) has protean clinical manifestations, including recurrent thromboses, repeated miscarriages, cardiac valve vegetations, and thrombocytopenia. Depending on the vascular bed involved, the clinical presentations can include pulmonary embolism (PE) (following lower extremity venous thrombosis), pulmonary hypertension (from recurrent subclinical pulmonary emboli), stroke, bowel infarction, or renovascular hypertension. Fetal loss does not appear to be explained by thrombosis, but rather seems to stem from antibody-mediated interference with the growth and differentiation of trophoblasts, leading to a failure of placentation. Antiphospholipid antibody syndrome is also a cause of renal microangiopathy, resulting in renal failure associated with multiple capillary and arterial thromboses (Chapter 20).

The name antiphospholipid antibody syndrome is misleading, as it is believed that the most important pathologic effects are mediated through binding of the antibodies to epitopes on proteins that are somehow induced or “unveiled” by phospholipids. Transfer of antiphospholipid antibodies to rodents can induce thrombosis, clearly indicating their pathogenicity, but the precise mechanisms remain uncertain. Suspected antibody targets include β 2-glycoprotein I, a plasma protein that associates with the surfaces of endothelial cells and trophoblasts, and thrombin. In vivo, it is suspected that these antibodies bind to these and perhaps other proteins, thereby inducing a hypercoagulable state through uncertain mechanisms. However, in vitro, the antibodies interfere with phospholipids and thus inhibit coagulation. The antibodies also frequently give a false-positive serologic test for syphilis because the antigen in the standard assay is embedded in cardiolipin.

Antiphospholipid antibody syndrome has primary and secondary forms. Individuals with a well-defined autoimmune disease, such as systemic lupus erythematosus (Chapter 6), are designated as having *secondary antiphospholipid syndrome* (hence the earlier term *lupus anticoagulant syndrome*). In *primary antiphospholipid syndrome*, patients exhibit only the manifestations of a hypercoagulable state and lack evidence of other autoimmune disorders; occasionally, it appears following exposure to certain drugs or infections. Therapy involves anticoagulation and

immunosuppression. Although antiphospholipid antibodies are clearly associated with thrombotic diatheses, they have also been identified in 5% to 15% of apparently normal individuals, implying that they are necessary but not sufficient to cause the full-blown syndrome.

MORPHOLOGY

Thrombi can develop anywhere in the cardiovascular system and vary in size and shape depending on the involved site and the underlying cause. Arterial or cardiac thrombi usually begin at sites of turbulence or endothelial injury, whereas venous thrombi characteristically occur at sites of stasis. Thrombi are focally attached to the underlying vascular surface, particularly at the point of initiation. From here, arterial thrombi tend to grow retrograde, while venous thrombi extend in the direction of blood flow; thus both propagate toward the heart. The propagating portion of a thrombus is often poorly attached and therefore prone to fragmentation and embolization.

Thrombi often have grossly and microscopically apparent laminations called **lines of Zahn**, which are pale platelet and fibrin deposits alternating with darker red cell-rich layers. Such laminations signify that a thrombus has formed in flowing blood; their presence can therefore distinguish antemortem clots from the bland nonlaminated clots that occur postmortem (see later).

Thrombi occurring in heart chambers or in the aortic lumen are designated **mural thrombi**. Abnormal myocardial contraction (arrhythmias, dilated cardiomyopathy, or myocardial infarction) or endomyocardial injury (myocarditis or catheter trauma) promotes cardiac mural thrombi (Fig. 4-13A), while ulcerated atherosclerotic plaque and aneurysmal dilation are the precursors of aortic thrombi (Fig. 4-13B).

Arterial thrombi are frequently **occlusive**; the most common sites in decreasing order of frequency are the coronary, cerebral, and femoral arteries. They typically consist of a friable meshwork of platelets, fibrin, red cells, and degenerating leukocytes. Although these are usually superimposed on a ruptured atherosclerotic plaque, other vascular injuries (vasculitis, trauma) may be the underlying cause.

Venous thrombosis (phlebothrombosis) is almost invariably occlusive, with the thrombus forming a long luminal cast. Because these thrombi form in the sluggish venous circulation,

they tend to contain more enmeshed red cells (and relatively few platelets) and are therefore known as **red**, or **stasis**, **thrombi**. Venous thrombi are firm, are focally attached to the vessel wall, and contain lines of Zahn, features that help distinguish them from postmortem clots (see later). The veins of the lower extremities are most commonly involved (90% of cases); however, upper extremities, periprostatic plexus, or the ovarian and periuterine veins can also develop venous thrombi. Under special circumstances, they can also occur in the dural sinuses, portal vein, or hepatic vein.

Postmortem clots can sometimes be mistaken for antemortem venous thrombi. However, clots that form after death are gelatinous and have a dark red dependent portion where red cells have settled by gravity and a yellow “chicken fat” upper portion, and are usually not attached to the underlying vessel wall.

Thrombi on heart valves are called **vegetations**. Bloodborne bacteria or fungi can adhere to previously damaged valves (e.g., due to rheumatic heart disease) or can directly cause valve damage; in either case, endothelial injury and disturbed blood flow can induce the formation of large thrombotic masses (**infective endocarditis**; Chapter 12). Sterile vegetations can also develop on noninfected valves in persons with hypercoagulable states, so-called **nonbacterial thrombotic endocarditis** (Chapter 12). Less commonly, sterile verrucous endocarditis (**Libman-Sacks endocarditis**) can occur in the setting of systemic lupus erythematosus (Chapter 6).

Fate of the Thrombus

If a patient survives the initial thrombosis, in the ensuing days to weeks thrombi undergo some combination of the following four events:

- **Propagation.** Thrombi accumulate additional platelets and fibrin (discussed earlier).
- **Embolization.** Thrombi dislodge and travel to other sites in the vasculature (discussed later).
- **Dissolution.** Dissolution is the result of fibrinolysis, which can lead to the rapid shrinkage and total disappearance of recent thrombi. In contrast, the extensive fibrin deposition and cross-linking in older thrombi renders them more resistant to lysis. This distinction explains why therapeutic administration of fibrinolytic

Figure 4-13 Mural thrombi. **A**, Thrombus in the left and right ventricular apices (arrows), overlying white fibrous scar. **B**, Laminated thrombus in a dilated abdominal aortic aneurysm (denoted by asterisks). Numerous friable mural thrombi are also superimposed on advanced atherosclerotic lesions of the more proximal aorta (left side of picture).

Figure 4-14 Low-power view of a thrombosed artery stained for elastic tissue. The original lumen is delineated by the internal elastic lamina (arrows) and is totally filled with organized thrombus, now punctuated by several recanalized endothelium-lined channels (white spaces).

agents such as t-PA (e.g., in the setting of acute coronary thrombosis) is generally effective only when given during the first few hours of a thrombotic event.

- **Organization and recanalization.** Older thrombi become organized by the ingrowth of endothelial cells, smooth muscle cells, and fibroblasts (Fig. 4-14). Capillary channels eventually form that reestablish the continuity of the original lumen, albeit to a variable degree. Continued recanalization may convert a thrombus into a smaller mass of connective tissue that becomes incorporated into the vessel wall. Eventually, with remodeling and contraction of the mesenchymal elements, only a fibrous lump may remain to mark the original thrombus.

Occasionally the centers of thrombi undergo enzymatic digestion, presumably as a result of the release of lysosomal enzymes from trapped leukocytes and platelets. In the setting of bacteremia, such thrombi may become infected, producing an inflammatory mass that erodes and weakens the vessel wall. If unchecked, this may result in a mycotic aneurysm (Chapter 11).

Clinical Features

Thrombi come to clinical attention when they obstruct arteries or veins, or give rise to emboli. The clinical presentation depends on the involved site. Venous thrombi can cause painful congestion and edema distal to an obstruction, but are mainly of concern due to their tendency to embolize to the lungs (see later). Conversely, although arterial thrombi can also embolize and cause downstream infarctions, the chief clinical problem is more often related to occlusion of a critical vessel (e.g., a coronary or cerebral artery), which can have serious or fatal consequences.

Venous Thrombosis (Phlebothrombosis). Most venous thrombi occur in the superficial or deep veins of the leg. Superficial venous thrombi typically occur in the saphenous veins in the setting of varicosities. Such thrombi can cause local congestion, swelling, pain, and tenderness, but

rarely embolize. Nevertheless, the associated edema and impaired venous drainage predispose the overlying skin to the development of infections and ulcers (*varicose ulcers*). Deep venous thrombosis (DVT) involving one of the large leg veins—at or above the knee (e.g., the popliteal, femoral, and iliac veins)—is more serious because such thrombi more often embolize to the lungs and give rise to pulmonary infarction (see later and Chapter 15). Although DVTs may cause local pain and edema due to venous obstruction, these symptoms are often absent due to the opening of venous collateral channels. Consequently, DVTs are asymptomatic in approximately 50% of affected individuals and are recognized only in retrospect after embolization.

Lower extremity DVTs are often associated with hypercoagulable states, as described earlier (Table 4-2). Common predisposing factors include bed rest and immobilization (because they reduce the milking action of the leg muscles, resulting in stasis), and congestive heart failure (also a cause of impaired venous return). Trauma, surgery, and burns not only immobilize a person but are also associated with vascular insults, procoagulant release from injured tissues, increased hepatic synthesis of coagulation factors, and decreased t-PA production. Many elements contribute to the thrombotic diathesis of pregnancy, including decreased venous return from leg veins and systemic hypercoagulability associated with the hormonal changes of late pregnancy and the postpartum period. Tumor-associated inflammation and coagulation factors (tissue factor, factor VIII), as well as procoagulants (e.g., mucin) released from tumor cells, all contribute to the increased risk of thromboembolism in disseminated cancers, so-called *migratory thrombophlebitis* or *Trousseau syndrome*. Regardless of the specific clinical setting, advanced age also increases the risk of DVT.

Arterial and Cardiac Thrombosis. *Atherosclerosis* is a major cause of arterial thromboses because it is associated with loss of endothelial integrity and with abnormal blood flow (Fig. 4-13B). Myocardial infarction can predispose to cardiac mural thrombi by causing dyskinetic myocardial contraction and endocardial injury (Fig. 4-13A), and rheumatic heart disease may engender atrial mural thrombi by causing atrial dilation and fibrillation. Both cardiac and aortic mural thrombi are prone to embolization. Although any tissue can be affected, the brain, kidneys, and spleen are particularly likely targets because of their rich blood supply.

KEY CONCEPTS

Thrombosis

- Thrombus development usually is related to one or more components of the Virchow triad:
 - Endothelial injury (e.g., by toxins, hypertension, inflammation, or metabolic products) associated with endothelial activation and changes in endothelial gene expression that favor coagulation
 - Abnormal blood flow—stasis or turbulence (e.g., due to aneurysms, atherosclerotic plaque)

- Hypercoagulability, either primary (e.g., factor V Leiden, increased prothrombin synthesis, antithrombin III deficiency) or secondary (e.g., bed rest, tissue damage, malignancy, or development of antiphospholipid antibodies [antiphospholipid antibody syndrome]) or antibodies against platelet factor IV/heparin complexes [heparin-induced thrombocytopenia])
- Thrombi may propagate, resolve, become organized, or embolize.
- Thrombosis causes tissue injury by local vascular occlusion or by distal embolization.

Disseminated Intravascular Coagulation

DIC is not a specific disease but rather a complication of a large number of conditions associated with systemic activation of thrombin. Disorders ranging from obstetric complications to advanced malignancy can be complicated by DIC, which leads to widespread formation of thrombi in the microcirculation. These microvascular thrombi can cause diffuse circulatory insufficiency and organ dysfunction, particularly of the brain, lungs, heart, and kidneys. To complicate matters, the runaway thrombosis “uses up” platelets and coagulation factors (hence the synonym *consumptive coagulopathy*) and often activates fibrinolytic mechanisms. Thus, symptoms initially related to thrombosis can evolve into a bleeding catastrophe, such as hemorrhagic stroke or hypovolemic shock. DIC is discussed in greater detail along with other bleeding diatheses in [Chapter 14](#).

Embolism

An embolus is a detached intravascular solid, liquid, or gaseous mass that is carried by the blood from its point of origin to a distant site, where it often causes tissue dysfunction or infarction. The vast majority of emboli are dislodged thrombi, hence the term *thromboembolism*. Other rare emboli are composed of fat droplets, nitrogen bubbles, atherosclerotic debris (*cholesterol emboli*), tumor fragments, bone marrow, or even foreign bodies. Emboli travel through the blood until they encounter vessels too small to permit further passage, causing partial or complete vascular occlusion. Depending on where they originate, emboli can lodge anywhere in the vascular tree; as discussed later, the clinical consequences vary widely depending on the size and the position of the lodged embolus, as well as the vascular bed that is impacted.

Pulmonary Embolism

Pulmonary emboli originate from deep venous thromboses and are the most common form of thromboembolic disease. Pulmonary embolism (PE) has had a fairly stable incidence since the 1970s of roughly 2 to 4 per 1000 hospitalized patients in the United States, although the numbers vary depending on the mix of patient age and diagnosis (i.e., surgery, pregnancy, and malignancy all increase the risk). PE causes about 100,000 deaths per year in the United States. In more than 95% of cases, PEs originate from leg DVTs.

Figure 4-15 Embolus from a lower extremity deep venous thrombosis, lodged at a pulmonary artery branchpoint.

Fragmented thrombi from DVTs are carried through progressively larger veins and the right side of the heart before slamming into the pulmonary arterial vasculature. Depending on the size of the embolus, it can occlude the main pulmonary artery, straddle the pulmonary artery bifurcation (*saddle embolus*), or pass out into the smaller, branching arteries ([Fig. 4-15](#)). Frequently there are multiple emboli, occurring either sequentially or simultaneously as a shower of smaller emboli from a single large mass; in general, **the patient who has had one PE is at high risk for more**. Rarely, a venous embolus passes through an interatrial or interventricular defect and gains access to the systemic arterial circulation (*paradoxical embolism*). A more complete discussion of PEs is presented in [Chapter 15](#); the following is an overview of the major functional consequences of pulmonary emboli.

- Most pulmonary emboli (60% to 80%) are clinically silent because they are small. With time they become organized and are incorporated into the vascular wall; in some cases organization of the thromboembolus leaves behind a delicate, bridging fibrous *web*.
- Sudden death, right heart failure (*cor pulmonale*), or cardiovascular collapse occurs when emboli obstruct 60% or more of the pulmonary circulation.
- Embolic obstruction of medium-sized arteries with subsequent vascular rupture can result in pulmonary hemorrhage but usually does not cause pulmonary infarction. This is because the lung is supplied by both the pulmonary arteries and the bronchial arteries, and the intact bronchial circulation is usually sufficient to perfuse the affected area. Understandably, if the bronchial arterial flow is compromised (e.g., by left-sided cardiac failure), infarction may occur.
- Embolic obstruction of small end-arteriolar pulmonary branches often does produce hemorrhage or infarction.
- Multiple emboli over time may cause pulmonary hypertension and right ventricular failure.

Systemic Thromboembolism

Most systemic emboli (80%) arise from intracardiac mural thrombi, two thirds of which are associated with left ventricular wall infarcts and another one fourth with

left atrial dilation and fibrillation. The remainder originates from aortic aneurysms, atherosclerotic plaques, valvular vegetations, or venous thrombi (paradoxical emboli); 10% to 15% are of unknown origin. In contrast to venous emboli, the vast majority of which lodge in the lung, arterial emboli can travel to a wide variety of sites; the point of arrest depends on the source and the relative amount of blood flow that downstream tissues receive. Most come to rest in the lower extremities (75%) or the brain (10%), but other tissues, including the intestines, kidneys, spleen, and upper extremities, may be involved on occasion. The consequences of systemic emboli depend on the vulnerability of the affected tissues to ischemia, the caliber of the occluded vessel, and whether a collateral blood supply exists; in general, however, the outcome is tissue infarction.

Fat and Marrow Embolism

Microscopic fat globules—sometimes with associated hematopoietic bone marrow—can be found in the pulmonary vasculature after fractures of long bones or, rarely, in the setting of soft tissue trauma and burns. Presumably these injuries rupture vascular sinusoids in the marrow or small venules, allowing marrow or adipose tissue to herniate into the vascular space and travel to the lung. Fat and marrow emboli are very common incidental findings after vigorous cardiopulmonary resuscitation and are probably of no clinical consequence. Indeed, fat embolism occurs in some 90% of individuals with severe skeletal injuries (Fig. 4-16), but less than 10% of such patients have any clinical findings.

Fat embolism syndrome is the term applied to the minority of patients who become symptomatic. It is characterized by pulmonary insufficiency, neurologic symptoms, anemia, and thrombocytopenia, and is fatal in about 5% to 15% of cases. Typically, 1 to 3 days after injury there is a sudden onset of tachypnea, dyspnea, and tachycardia; irritability and restlessness can progress to delirium or coma. Thrombocytopenia is attributed to platelet adhesion to fat globules and subsequent aggregation or splenic sequestration; anemia can result from similar red cell aggregation

Figure 4-16 Bone marrow embolus in the pulmonary circulation. The cellular elements on the left side of the embolus are hematopoietic cells, while the cleared vacuoles represent marrow fat. The relatively uniform red area on the right of the embolus is an early organizing thrombus.

and/or hemolysis. A diffuse petechial rash (seen in 20% to 50% of cases) is related to rapid onset of thrombocytopenia and can be a useful diagnostic feature.

The pathogenesis of fat emboli syndrome probably involves both mechanical obstruction and biochemical injury. Fat microemboli and associated red cell and platelet aggregates can occlude the pulmonary and cerebral microvasculature. Release of free fatty acids from the fat globules exacerbates the situation by causing local toxic injury to endothelium, and platelet activation and granulocyte recruitment (with free radical, protease, and eicosanoid release) complete the vascular assault. Because lipids are dissolved out of tissue preparations by the solvents routinely used in paraffin embedding, the microscopic demonstration of fat microglobules typically requires specialized techniques, including frozen sections and stains for fat.

Air Embolism

Gas bubbles within the circulation can coalesce to form frothy masses that obstruct vascular flow and cause distal ischemic injury. For example, a very small volume of air trapped in a coronary artery during bypass surgery, or introduced into the cerebral circulation by neurosurgery in the “sitting position,” can occlude flow with dire consequences. A larger volume of air, generally more than 100 cc, is necessary to produce a clinical effect in the pulmonary circulation; unless care is taken, this volume of air can be inadvertently introduced during obstetric or laparoscopic procedures, or as a consequence of chest wall injury.

A particular form of gas embolism, called *decompression sickness*, occurs when individuals experience sudden decreases in atmospheric pressure. Scuba and deep sea divers, underwater construction workers, and individuals in unpressurized aircraft in rapid ascent are all at risk. When air is breathed at high pressure (e.g., during a deep sea dive), increased amounts of gas (particularly nitrogen) are dissolved in the blood and tissues. If the diver then ascends (depressurizes) too rapidly, the nitrogen comes out of solution in the tissues and the blood.

The rapid formation of gas bubbles within skeletal muscles and supporting tissues in and about joints is responsible for the painful condition called *the bends* (so named in the 1880s because it was noted that those afflicted characteristically arched their backs in a manner reminiscent of a then-popular women’s fashion pose called the Grecian bend). In the lungs, gas bubbles in the vasculature cause edema, hemorrhage, and focal atelectasis or emphysema, leading to a form of respiratory distress called *the chokes*. A more chronic form of decompression sickness is called *caisson disease* (named for the pressurized vessels used in bridge construction; workers in these vessels suffered both acute and chronic forms of decompression sickness). In caisson disease, persistence of gas emboli in the skeletal system leads to multiple foci of ischemic necrosis; the more common sites are the femoral heads, tibia, and humeri.

Individuals affected by acute decompression sickness are treated by being placed in a chamber under sufficiently high pressure to force the gas bubbles back into solution. Subsequent slow decompression permits gradual

resorption and exhalation of the gases, which prevents the obstructive bubbles from reforming.

Amniotic Fluid Embolism

Amniotic fluid embolism is the fifth most common cause of maternal mortality worldwide; it accounts for roughly 10% of maternal deaths in the United States and results in permanent neurologic deficit in as many as 85% of survivors. Amniotic fluid embolism is an ominous complication of labor and the immediate postpartum period. Although the incidence is only approximately 1 in 40,000 deliveries, the mortality rate is up to 80%. The onset is characterized by sudden severe dyspnea, cyanosis, and shock, followed by neurologic impairment ranging from headache to seizures and coma. If the patient survives the initial crisis, pulmonary edema typically develops, frequently accompanied by disseminated intravascular coagulation. Note that these features differ from those observed with pulmonary embolism from a deep venous thrombosis; in fact, much of the morbidity and mortality in amniotic fluid embolism may stem from the biochemical activation of coagulation factors and components of the innate immune system by substances in the amniotic fluid, rather than the mechanical obstruction of pulmonary vessels by amniotic debris.

The underlying cause is the infusion of amniotic fluid or fetal tissue into the maternal circulation via a tear in the placental membranes or rupture of uterine veins. Classic findings at autopsy include the presence of squamous cells shed from fetal skin, lanugo hair, fat from vernix caseosa, and mucin derived from the fetal respiratory or gastrointestinal tract in the maternal pulmonary microvasculature (Fig. 4-17). Other findings include marked pulmonary edema, *diffuse alveolar damage* (Chapter 15), and the presence of fibrin thrombi in many vascular beds due to disseminated intravascular coagulation.

Figure 4-17 Amniotic fluid embolism. Two small pulmonary arterioles are packed with laminated swirls of fetal squamous cells. There is marked edema and congestion. Elsewhere the lung contained small organizing thrombi consistent with disseminated intravascular coagulation. (Courtesy Dr. Beth Schwartz, Baltimore, Md.)

KEY CONCEPTS

Embolism

- An embolus is a solid, liquid, or gaseous mass carried by the blood to a site distant from its origin; most are dislodged thrombi.
- Pulmonary emboli derive primarily from lower extremity deep vein thrombi; their effects depend mainly on the size of the embolus and the location in which it lodges. Consequences may include right-sided heart failure, pulmonary hemorrhage, pulmonary infarction, or sudden death.
- Systemic emboli derive primarily from cardiac mural or valvular thrombi, aortic aneurysms, or atherosclerotic plaques; whether an embolus causes tissue infarction depends on the site of embolization and the presence or absence of collateral circulation.

Infarction

An infarct is an area of ischemic necrosis caused by occlusion of either the arterial supply or the venous drainage. Tissue infarction is a common and extremely important cause of clinical illness. Roughly 40% of all deaths in the United States are caused by cardiovascular disease, and most of these are attributable to myocardial or cerebral infarction. Pulmonary infarction is also a common complication in many clinical settings, bowel infarction is frequently fatal, and ischemic necrosis of the extremities (*gangrene*) is a serious problem in the diabetic population.

Arterial thrombosis or arterial embolism underlies the vast majority of infarctions. Less common causes of arterial obstruction leading to infarction include local vasospasm, hemorrhage into an atheromatous plaque, or extrinsic vessel compression (e.g., by tumor). Other uncommon causes of tissue infarction include torsion of a vessel (e.g., in testicular torsion or bowel volvulus), traumatic vascular rupture, or vascular compromise by edema (e.g., *anterior compartment syndrome*) or by entrapment in a hernia sac. Although venous thrombosis can cause infarction, the more common outcome is just congestion; in this setting, bypass channels rapidly open and permit vascular outflow, which then improves arterial inflow. Infarcts caused by venous thrombosis are thus more likely in organs with a single efferent vein (e.g., testis and ovary).

MORPHOLOGY

Infarcts are classified according to color and the presence or absence of infection; they are either red (hemorrhagic) or white (anemic) and may be septic or bland.

- **Red infarcts** (Fig. 4-18A) occur (1) with venous occlusions (e.g., testicular torsion, Chapter 19), (2) in loose, spongy tissues (e.g., lung) where blood can collect in the infarcted zone, (3) in tissues with dual circulations (e.g., lung and small intestine) that allow blood to flow from an unobstructed parallel supply into a necrotic zone, (4) in tissues previously

Figure 4-18 Red and white infarcts. **A**, Hemorrhagic, roughly wedge-shaped pulmonary red infarct. **B**, Sharply demarcated white infarct in the spleen.

congested by sluggish venous outflow, and (5) when flow is reestablished to a site of previous arterial occlusion and necrosis (e.g., following angioplasty of an arterial obstruction).

- **White infarcts** (Fig. 4-18B) occur with arterial occlusions in solid organs with end-arterial circulation (e.g., heart, spleen, and kidney), and where tissue density limits the seepage of blood from adjoining capillary beds into the necrotic area.

Infarcts tend to be wedge-shaped, with the occluded vessel at the apex and the periphery of the organ forming the base (Fig. 4-18); when the base is a serosal surface there may be an overlying fibrinous exudate resulting from an acute inflammatory response to mediators release from injured and necrotic cells. Fresh infarcts are poorly defined and slightly hemorrhagic, but over a few days the margins tend to become better defined by a narrow rim of congestion attributable to inflammation. With further passage of time, infarcts resulting from arterial occlusions in organs without a dual blood supply typically become progressively paler and more sharply defined (Fig. 4-18B). In comparison, in the lung hemorrhagic infarcts are the rule (Fig. 4-18A). Extravasated red cells in hemorrhagic infarcts are phagocytosed by macrophages, which convert heme iron into hemosiderin; small amounts do not grossly impart any appreciable color to the tissue, but extensive hemorrhage can leave a firm, brown hemosiderin-rich residuum.

The dominant histologic characteristic of infarction is **ischemic coagulative necrosis** (Chapter 2). Importantly, if the vascular occlusion has occurred shortly (minutes to hours) before the death of the person, histologic changes may be absent; it takes 4 to 12 hours for the dead tissue to show microscopic evidence of frank necrosis. Acute inflammation is present along the margins of infarcts within a few hours and is usually well defined within 1 to 2 days. Eventually a reparative response begins in the preserved margins (Chapter 3). In stable or labile tissues, parenchymal regeneration can occur at the periphery where underlying stromal architecture is preserved. However, most infarcts are ultimately replaced by scar (Fig. 4-19). The brain is an exception to these generalizations, in that central nervous system infarction results in **liquefactive necrosis** (Chapter 2).

Septic infarctions occur when infected cardiac valve vegetations embolize or when microbes seed necrotic tissue. In these cases the infarct is converted into an *abscess*, with a correspondingly greater inflammatory response (Chapter 3). The eventual sequence of organization, however, follows the pattern already described.

Factors That Influence Development of an Infarct. A vascular occlusion can cause effects ranging from virtually nothing to tissue dysfunction and necrosis sufficient to result in death. The variables that influence the outcome of vascular occlusion are the following:

- **Anatomy of the vascular supply.** The availability of an alternative blood supply is the most important determinant of whether vessel occlusion will cause tissue damage. As mentioned, the lungs have a dual pulmonary and bronchial artery blood supply that protects against thromboembolism-induced infarction. Similarly, the liver, with its dual hepatic artery and portal vein circulation, and the hand and forearm, with their dual radial and ulnar arterial supply, are all relatively resistant to infarction. In contrast, renal and splenic circulations are end-arterial, and vascular obstruction generally causes tissue death.
- **Rate of occlusion.** Slowly developing occlusions are less likely to cause infarction, because they provide time for development of collateral pathways of perfusion. For example, small interarteriolar anastomoses—normally with minimal functional flow—interconnect the three major coronary arteries in the heart. If one of the coronaries is occluded slowly (i.e., by an encroaching atherosclerotic plaque), flow within this *collateral circulation* may increase sufficiently to prevent infarction, even though the larger coronary artery is eventually occluded.
- **Tissue vulnerability to hypoxia.** Neurons undergo irreversible damage when deprived of their blood supply for only 3 to 4 minutes. Myocardial cells, although hardier than neurons, are also quite sensitive and die after only 20 to 30 minutes of ischemia (although, as mentioned, changes in the appearance of the dead cells take 4-12 hours to develop). In contrast, fibroblasts within myocardium remain viable even after many hours of ischemia (Chapter 12).

Figure 4-19 Remote kidney infarct replaced by a large fibrotic scar.

- *Hypoxemia*. Understandably, abnormally low blood O₂ content (regardless of cause) increases both the likelihood and extent of infarction.

KEY CONCEPTS

Infarction

- Infarcts are areas of ischemic necrosis most commonly caused by arterial occlusion (typically due to thrombosis or embolization); venous outflow obstruction is a less frequent cause.
- Infarcts caused by venous occlusion or occurring in spongy tissues with dual blood supply and where blood can collect typically are hemorrhagic (red); those caused by arterial occlusion in compact tissues typically are pale (white).
- Whether or not vascular occlusion causes tissue infarction is influenced by collateral blood supplies, the rate at which an obstruction develops, intrinsic tissue susceptibility to ischemic injury, and blood oxygenation.

Shock

Shock is a state in which diminished cardiac output or reduced effective circulating blood volume impairs tissue perfusion and leads to cellular hypoxia. At the outset the cellular injury is reversible; however, prolonged shock eventually leads to irreversible tissue injury and is often fatal. Shock may complicate severe hemorrhage, extensive trauma or burns, myocardial infarction, pulmonary embolism, and microbial sepsis. Its causes fall into three general categories (Table 4-3):

- *Cardiogenic shock* results from low cardiac output due to myocardial pump failure. This can be due to intrinsic myocardial damage (infarction), ventricular arrhythmias, extrinsic compression (cardiac tamponade; Chapter 11), or outflow obstruction (e.g., pulmonary embolism).
- *Hypovolemic shock* results from low cardiac output due to low blood volume, such as can occur with massive hemorrhage or fluid loss from severe burns.
- *Shock associated with systemic inflammation* may be triggered by a variety of insults, particularly microbial infections, burns, trauma, and or pancreatitis. The common pathogenic feature is a massive outpouring of inflammatory mediators from innate and adaptive immune cells that produce arterial vasodilation, vascular leakage, and venous blood pooling. These cardiovascular abnormalities result in tissue hypoperfusion,

cellular hypoxia, and metabolic derangements that lead to organ dysfunction and, if severe and persistent, organ failure and death. It should be noted that diverse triggers of shock (microbial and non-microbial) associated with inflammation produce a similar set of clinical findings, which are referred to as the *systemic inflammatory response syndrome*. The pathogenesis of shock caused by microbial infection (*septic shock*) is discussed in detail below.

Less commonly, shock can occur in the setting of an anesthetic accident or a spinal cord injury (*neurogenic shock*), or an IgE-mediated hypersensitivity reaction (*anaphylactic shock*, Chapter 6). In both of these forms of shock, acute vasodilation leads to hypotension and tissue hypoperfusion.

Pathogenesis of Septic Shock

With a mortality rate exceeding 20%, septic shock ranks first among the causes of death in intensive care units and accounts for over 200,000 lost lives each year in the United States. Its incidence is rising, ironically due to improvements in life support for critically ill patients, as well as the growing ranks of immunocompromised hosts (due to chemotherapy, immunosuppression, advanced age or HIV infection) and the increasing prevalence of multidrug resistant organisms in the hospital setting. Septic shock is most frequently triggered by gram-positive bacterial infections, followed by gram-negative bacteria and fungi. Hence, an older synonym, “endotoxic shock”, is no longer appropriate.

The ability of diverse microorganisms to cause septic shock is consistent with the idea that a variety of microbial constituents can trigger the process. As you will recall from Chapter 3, macrophages, neutrophils, dendritic cells, endothelial cells, and soluble components of the innate immune system (e.g., complement) recognize and are activated by several substances derived from microorganisms. Once activated, these cells and factors initiate a number of inflammatory responses that interact in a complex, incompletely understood fashion to produce septic shock and multiorgan dysfunction (Fig. 4-20).

Factors believed to play major roles in the pathophysiology of septic shock include the following:

- *Inflammatory and counter-inflammatory responses*. In sepsis, various microbial cell wall constituents engage receptors on cells of the innate immune system,

Table 4-3 Three Major Types of Shock

Type of Shock	Clinical Example	Principal Mechanisms
Cardiogenic	Myocardial infarction Ventricular rupture Arrhythmia Cardiac tamponade Pulmonary embolism	Failure of myocardial pump resulting from intrinsic myocardial damage, extrinsic compression, or obstruction to outflow
Hypovolemic	Fluid loss (e.g., hemorrhage, vomiting, diarrhea, burns, or trauma)	Inadequate blood or plasma volume
Shock associated with systemic inflammation	Overwhelming microbial infections (bacterial and fungal) Superantigens (e.g., toxic shock syndrome) Trauma, burns, pancreatitis	Activation of cytokine cascades; peripheral vasodilation and pooling of blood; endothelial activation/injury; leukocyte-induced damage, disseminated intravascular coagulation

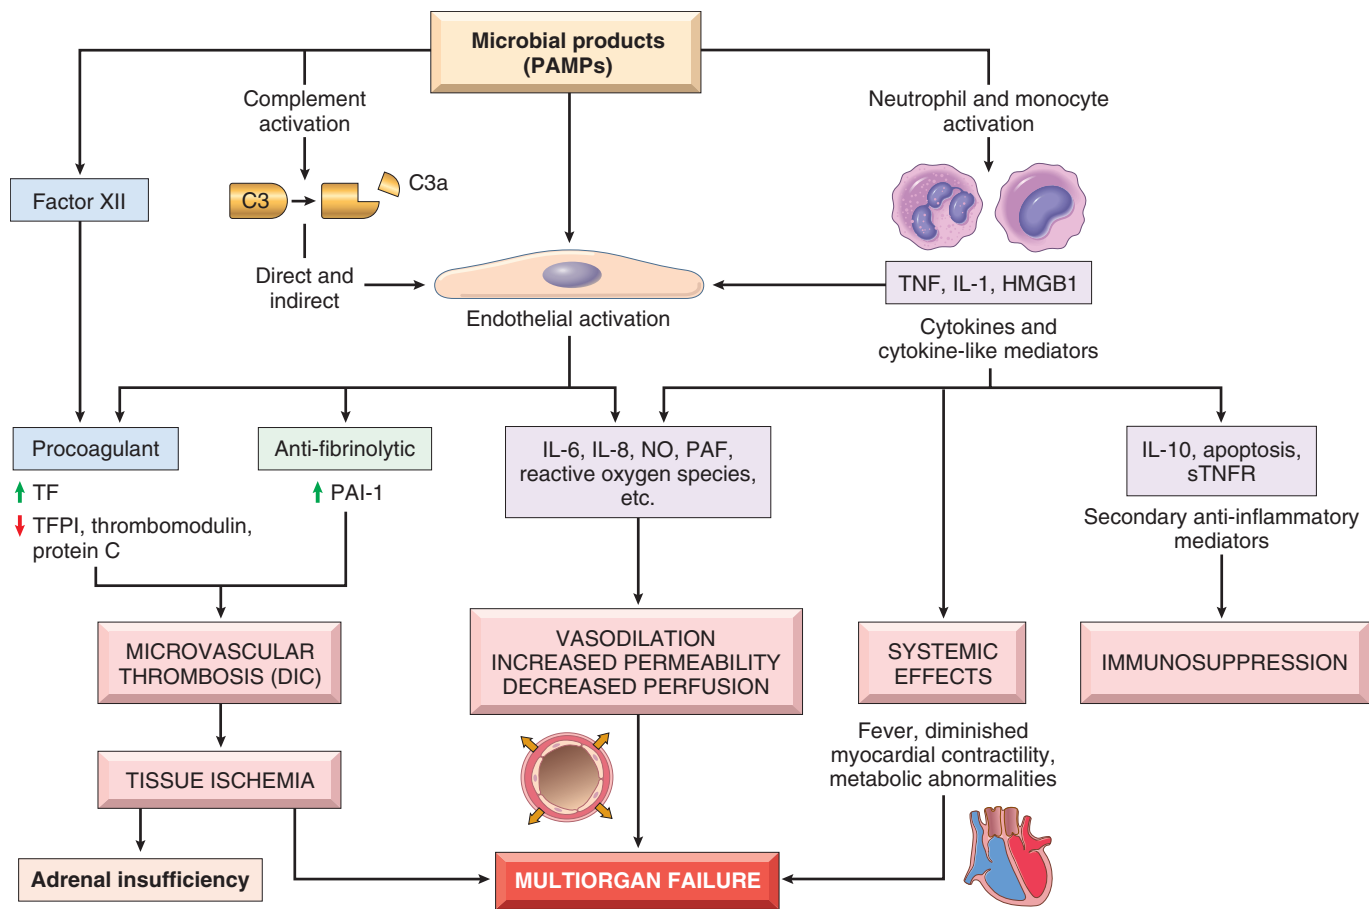

Figure 4-20 Major pathogenic pathways in septic shock. Microbial products (PAMPs, or pathogen-associated molecular patterns) activate endothelial cells and cellular and humoral elements of the innate immune system, initiating a cascade of events that lead to end-stage multiorgan failure. Additional details are given in the text. DIC, Disseminated vascular coagulation; HMGB1, high mobility group box 1 protein; NO, nitric oxide; PAF, platelet activating factor; PAI-1, plasminogen activator inhibitor 1; TF, tissue factor; TFPI, tissue factor pathway inhibitor.

triggering pro-inflammatory responses. Likely initiators of inflammation in sepsis are signaling pathways that lie downstream of *Toll-like receptors* (TLRs, [Chapter 3](#)), which you will recall recognize a host of microbe-derived substances containing so-called pathogen-associated molecular patterns (PAMPs), as well as G-protein coupled receptors that detect bacterial peptides, and nucleotide oligomerization domain proteins 1 and 2 [NOD1, NOD2]). Upon activation, innate immune cells produce TNF, IL-1, IFN- γ , IL-12, and IL-18, as well as other inflammatory mediators such as high mobility group box 1 protein (HMGB1). Reactive oxygen species and lipid mediators such as prostaglandins and platelet activating factor (PAF) are also elaborated. These effector molecules induce endothelial cells (and other cell types) to upregulate adhesion molecule expression and further stimulate cytokine and chemokine production. The *complement cascade* is also activated by microbial components, both directly and through the proteolytic activity of plasmin ([Chapter 3](#)), resulting in the production of anaphylotoxins (C3a, C5a), chemotactic fragments (C5a), and opsonins (C3b), all of which contribute to the pro-inflammatory state. In addition, microbial components can activate coagulation directly through factor XII and indirectly through altered endothelial function (discussed below). The accompanying

widespread activation of thrombin may further augment inflammation by triggering protease-activated receptors (PARs) on inflammatory cells.

The hyperinflammatory state initiated by sepsis also activates counter-regulatory immunosuppressive mechanisms, which may involve both innate and adaptive immune cells. As a result, septic patients may oscillate between hyperinflammatory and immunosuppressed states during their clinical course. Proposed mechanisms for the immune suppression include a shift from pro-inflammatory (T_H1) to anti-inflammatory (T_H2) cytokines ([Chapter 6](#)), production of anti-inflammatory mediators (e.g., soluble TNF receptor, IL-1 receptor antagonist, and IL-10), lymphocyte apoptosis, the immunosuppressive effects of apoptotic cells, and the induction of cellular anergy.

- **Endothelial activation and injury.** The pro-inflammatory state and endothelial cell activation associated with sepsis leads to widespread vascular leakage and tissue edema, which have deleterious effects on both nutrient delivery and waste removal. One effect of inflammatory cytokines is to loosen endothelial cell tight junctions, making vessels leaky and resulting in the accumulation of protein-rich edema throughout the body. This alteration impedes tissue perfusion and may be exacerbated by attempts to support the patient with

intravenous fluids. Activated endothelium also upregulates production of nitric oxide (NO) and other vasoactive inflammatory mediators (e.g., C3a, C5a, and PAF), which may contribute to vascular smooth muscle relaxation and systemic hypotension.

- *Induction of a procoagulant state.* The derangement in coagulation is sufficient to produce the formidable complication of disseminated intravascular coagulation in up to half of septic patients. Sepsis alters the expression of many factors so as to favor coagulation. Pro-inflammatory cytokines increase tissue factor production by monocytes and possibly endothelial cells as well, and decrease the production of endothelial anti-coagulant factors, such as tissue factor pathway inhibitor, thrombomodulin, and protein C (see Fig. 4-6 and Fig. 4-8). They also dampen fibrinolysis by increasing plasminogen activator inhibitor-1 expression (see Fig. 4-6B and Fig. 4-8). The vascular leak and tissue edema decrease blood flow at the level of small vessels, producing stasis and diminishing the washout of activated coagulation factors. Acting in concert, these effects lead to systemic activation of thrombin and the deposition of fibrin-rich thrombi in small vessels, often throughout the body, further compromising tissue perfusion. In full-blown disseminated intravascular coagulation, the consumption of coagulation factors and platelets is so great that deficiencies of these factors appear, leading to concomitant bleeding and hemorrhage (Chapter 14).
- *Metabolic abnormalities.* Septic patients exhibit insulin resistance and hyperglycemia. Cytokines such as TNF and IL-1, stress-induced hormones (such as glucagon, growth hormone, and glucocorticoids), and catecholamines all drive gluconeogenesis. At the same time, the pro-inflammatory cytokines suppress insulin release while simultaneously promoting insulin resistance in the liver and other tissues, likely by impairing the surface expression of GLUT-4, a glucose transporter. Hyperglycemia decreases neutrophil function—thereby suppressing bactericidal activity—and causes increased adhesion molecule expression on endothelial cells. Although sepsis is initially associated with an acute surge in glucocorticoid production, this phase may be followed by adrenal insufficiency and a functional deficit of glucocorticoids. This may stem from depression of the synthetic capacity of intact adrenal glands or frank adrenal necrosis due to disseminated intravascular dissemination (*Waterhouse-Friderichsen syndrome*, Chapter 25). Finally, cellular hypoxia and diminished oxidative phosphorylation leads to increased lactate production and lactic acidosis.
- *Organ dysfunction.* Systemic hypotension, interstitial edema, and small vessel thrombosis all decrease the delivery of oxygen and nutrients to the tissues, which fail to properly utilize those nutrients that are delivered due to cellular hypoxia. High levels of cytokines and secondary mediators diminish myocardial contractility and cardiac output, and increased vascular permeability and endothelial injury can lead to the *acute respiratory distress syndrome* (Chapter 15). Ultimately, these factors may conspire to cause the failure of multiple organs, particularly the kidneys, liver, lungs, and heart, culminating in death.

The severity and outcome of septic shock are likely dependent upon the extent and virulence of the infection; the immune status of the host; the presence of other comorbid conditions; and the pattern and level of mediator production. The multiplicity of factors and the complexity of the interactions that underlie sepsis explain why most attempts to intervene therapeutically with antagonists of specific mediators have failed to be effective and may even have had deleterious effects in some cases. The standard of care remains antibiotics to treat the underlying infection and intravenous fluids, pressors and supplemental oxygen to maintain blood pressure and limit tissue hypoxia. Suffice it to say that even in the best of clinical centers, septic shock remains an obstinate clinical challenge.

It is worth mentioning here that an additional group of secreted bacterial proteins called *superantigens* also cause a syndrome similar to septic shock (e.g., *toxic shock syndrome*). Superantigens are polyclonal T-lymphocyte activators that induce the release of high levels of cytokines that result in a variety of clinical manifestations, ranging from a diffuse rash to vasodilation, hypotension, shock, and death.

Stages of Shock

Shock is a progressive disorder that, if uncorrected, leads to death. The exact mechanism(s) of death from sepsis are still unclear; aside from increased lymphocyte and enterocyte apoptosis there is only minimal cell death, and patients rarely have refractory hypotension, suggesting that organ failure secondary to edema and the attendant tissue hypoxia has a central role. For hypovolemic and cardiogenic shock, however, the pathways to death are reasonably well understood. Unless the insult is massive and rapidly lethal (e.g., a massive hemorrhage from a ruptured aortic aneurysm), shock in those settings tends to evolve through three general (albeit somewhat artificial) phases:

- An initial *nonprogressive phase* during which reflex compensatory mechanisms are activated and perfusion of vital organs is maintained
- A *progressive stage* characterized by tissue hypoperfusion and onset of worsening circulatory and metabolic imbalances, including lactic acidosis
- An *irreversible stage* that sets in after the body has incurred cellular and tissue injury so severe that even if the hemodynamic defects are corrected, survival is not possible

In the early nonprogressive phase of shock, a variety of *neurohumoral mechanisms* help to maintain cardiac output and blood pressure. These include baroreceptor reflexes, catecholamine release, activation of the renin-angiotensin axis, ADH release, and generalized sympathetic stimulation. The net effect is *tachycardia*, *peripheral vasoconstriction*, and *renal conservation of fluid*. Cutaneous vasoconstriction, for example, is responsible for the characteristic coolness and pallor of the skin in well-developed shock (although septic shock can initially cause cutaneous *vasodilation* and thus present with warm, flushed skin). Coronary and cerebral vessels are less sensitive to the sympathetic response and thus maintain relatively normal caliber, blood flow, and oxygen delivery.

If the underlying causes are not corrected, shock passes imperceptibly to the progressive phase, during which there

is widespread tissue hypoxia. In the setting of persistent oxygen deficit, intracellular aerobic respiration is replaced by anaerobic glycolysis with excessive production of lactic acid. The resulting lactic acidosis lowers the tissue pH and blunts the vasomotor response; arterioles dilate, and blood begins to pool in the microcirculation. Peripheral pooling not only worsens the cardiac output, but also puts endothelial cells at risk for developing anoxic injury with subsequent disseminated intravascular coagulation. With widespread tissue hypoxia, vital organs are affected and begin to fail.

In severe cases, the process eventually enters an irreversible stage. Widespread cell injury is reflected in lysosomal enzyme leakage, further aggravating the shock state. If ischemic bowel allows intestinal flora to enter the circulation, bacteremic septic shock may be superimposed. At this point the patient may develop anuria as a result of acute tubular necrosis and renal failure (Chapter 20), and despite heroic measures the downward clinical spiral almost inevitably culminates in death.

MORPHOLOGY

The cellular and tissue changes induced by cardiogenic or hypovolemic shock are essentially those of hypoxic injury (Chapter 2); changes can manifest in any tissue although they are particularly evident in brain, heart, lungs, kidneys, adrenals, and gastrointestinal tract. The **adrenal** changes in shock are those seen in all forms of stress; essentially there is cortical cell lipid depletion. This does not reflect adrenal exhaustion but rather conversion of the relatively inactive vacuolated cells to metabolically active cells that utilize stored lipids for the synthesis of steroids. The **kidneys** typically exhibit acute tubular necrosis (Chapter 20). The **lungs** are seldom affected in pure hypovolemic shock, because they are somewhat resistant to hypoxic injury. However, when shock is caused by sepsis or trauma, **diffuse alveolar damage** (Chapter 15) may develop, the so-called shock lung. In septic shock, the development of disseminated intravascular coagulation leads to widespread deposition of fibrin-rich microthrombi, particularly in the brain, heart, lungs, kidney, adrenal glands, and gastrointestinal tract. The consumption of platelets and coagulation factors also often leads to the appearance of petechial hemorrhages on serosal surface and the skin.

With the exception of neuronal and myocyte ischemic loss, virtually all of these tissues may revert to normal if the individual survives. Unfortunately, most patients with irreversible changes due to severe shock die before the tissues can recover.

Clinical Consequences. The clinical manifestations of shock depend on the precipitating insult. In hypovolemic and cardiogenic shock the patient presents with hypotension; a weak, rapid pulse; tachypnea; and cool, clammy, cyanotic skin. In septic shock the skin may initially be warm and flushed because of peripheral vasodilation. The initial threat to life stems from the underlying catastrophe that precipitated the shock (e.g., myocardial infarct, severe hemorrhage, or sepsis). Rapidly, however, shock begets cardiac, cerebral, and pulmonary dysfunction, and eventually electrolyte disturbances and metabolic acidosis exacerbate the dire state of the patient further. Individuals who survive the initial complications may enter a second phase

dominated by renal insufficiency and marked by a progressive fall in urine output as well as severe fluid and electrolyte imbalances. Coagulopathy frequently complicates shock, particularly when the cause is sepsis or trauma, and can have serious or even fatal consequences, particularly in patients with severe disseminated intravascular coagulation.

The prognosis varies with the origin of shock and its duration. Thus, greater than 90% of young, otherwise healthy patients with hypovolemic shock survive with appropriate management; in comparison, septic shock, or cardiogenic shock associated with extensive myocardial infarction, are associated with substantially worse mortality rates, even with state-of-the-art care.

KEY CONCEPTS

Shock

- Shock is defined as a state of systemic tissue hypoperfusion due to reduced cardiac output and/or reduced effective circulating blood volume.
- The major types of shock are cardiogenic (e.g., myocardial infarction), hypovolemic (e.g., blood loss), and shock associated with systemic inflammatory responses (e.g., in the setting of severe infections); acute spinal or brain injuries and severe hypersensitivity reactions can also cause neurogenic and anaphylactic shock, respectively
- Shock of any form can lead to hypoxic tissue injury if not corrected.
- Septic shock is caused by the host response to bacterial, viral or fungal infections; it is a systemic inflammatory condition characterized by endothelial cell activation, tissue edema, disseminated intravascular coagulation, and metabolic derangements that often lead to organ failure and death.

Genes and Human Diseases

In [chapter 1](#) we discussed the architecture of the normal human genome. Here we build upon that knowledge to discuss the genetic basis of human diseases.

Genetic disorders are far more common than is widely appreciated. The lifetime frequency of genetic diseases is estimated to be 670 per 1000. Furthermore, the genetic diseases encountered in medical practice represent only the tip of the iceberg, that is, those with less extreme genotypic errors that permit full embryonic development and live birth. It is estimated that 50% of spontaneous abortuses during the early months of gestation have a

demonstrable chromosomal abnormality; there are, in addition, numerous smaller detectable errors and many other genetic lesions that are only now coming into view thanks to advances in DNA sequencing. About 1% of all newborn infants possess a gross chromosomal abnormality, and serious disease with a significant genetic component develops in approximately 5% of individuals younger than age 25 years. How many more mutations remain hidden?

Before discussing specific aberrations that may cause genetic diseases, it is useful to summarize the genetic contribution to human disease. Human genetic disorders can be broadly classified into three categories:

- **Disorders related to mutations in single genes with large effects.** These mutations cause the disease or predispose to the disease and with some exceptions, like hemoglobinopathies, are typically not present in normal population. Such mutations and their associated disorders are highly penetrant, meaning that the presence of the mutation is associated with the disease in a large proportion of individuals. Because these diseases are caused by single gene mutations, they usually follow the classic Mendelian pattern of inheritance and are also referred to as Mendelian disorders. A few important exceptions to this rule are noted later.

Study of single genes and mutations with large effects has been extremely informative in medicine since a great deal of what is known about several physiologic pathways (e.g., cholesterol transport, chloride secretion) has been learned from analysis of single gene disorders. Although informative, these disorders are generally rare unless they are maintained in a population by strong selective forces (e.g., sickle cell anemia in areas where malaria is endemic, [Chapter 14](#)).

- **Chromosomal disorders.** These arise from structural or numerical alteration in the autosomes and sex chromosomes. Like monogenic disease they are uncommon but associated with high penetrance.
- **Complex multigenic disorders.** These are far more common than diseases in the previous two categories. They are caused by interactions between multiple variant forms of genes and environmental factors. Such variations in genes are common within the population and are also called *polymorphisms*. Each such variant gene confers a small increase in disease risk, and no single susceptibility gene is necessary or sufficient to produce the disease. It is only when several such polymorphisms are present in an individual that disease occurs, hence the term *multigenic* or *polygenic*. Thus, unlike mutant genes with large effects that are highly penetrant and give rise to Mendelian disorders, each polymorphism has a small effect and is of low penetrance. Since environmental interactions are important in the pathogenesis of these diseases, they are also called multifactorial disorders. In this category are some of the most common diseases that afflict humans, including atherosclerosis, diabetes mellitus, hypertension, and autoimmune diseases. Even normal traits such as height and weight are governed by polymorphisms in several genes.

The following discussion describes mutations that affect single genes, which underlie Mendelian disorders, followed by transmission patterns and selected samples of single gene disorders.

Mutations

A mutation is defined as a permanent change in the DNA. Mutations that affect germ cells are transmitted to the progeny and can give rise to inherited diseases. Mutations that arise in somatic cells understandably do not cause hereditary diseases but are important in the genesis of cancers and some congenital malformations.

General principles relating to the effects of gene mutations follow.

- **Point mutations within coding sequences.** A point mutation is a change in which a single base is substituted with a different base. It may alter the code in a triplet of bases and lead to the replacement of one amino acid by another in the gene product. Because these mutations alter the meaning of the sequence of the encoded protein, they are often termed *missense mutations*. If the substituted amino acid is biochemically similar to the original, typically it causes little change in the function of the protein and the mutation is called a “conservative” missense mutation. On the other hand, a “nonconservative” missense mutation replaces the normal amino acid with a biochemically different one. An excellent example of this type is the sickle mutation affecting the β -globin chain of hemoglobin ([Chapter 14](#)). Here the nucleotide triplet CTC (or GAG in mRNA), which encodes glutamic acid, is changed to CAC (or GUG in mRNA), which encodes valine. This single amino acid substitution alters the physicochemical properties of hemoglobin, giving rise to sickle cell anemia. Besides producing an amino acid substitution, a point mutation may change an amino acid codon to a chain terminator, or *stop codon* (*nonsense mutation*). Taking again the example of β -globin, a point mutation affecting the codon for glutamine (CAG) creates a stop codon (UAG) if U is substituted for C ([Fig. 5-1](#)). This change leads to premature termination of β -globin gene translation, and the short peptide that is produced is rapidly degraded. The resulting deficiency of β -globin chains can give rise to a severe form of anemia called β^0 -thalassemia ([Chapter 14](#)).
- **Mutations within noncoding sequences.** Deleterious effects may also result from mutations that do not involve the exons. Recall that transcription of DNA is initiated and regulated by promoter and enhancer sequences ([Chapter 1](#)). Point mutations or deletions involving these regulatory sequences may interfere with binding of transcription factors and thus lead to a marked reduction in or total lack of transcription. Such is the case in certain forms of hereditary anemias called thalassemias ([Chapter 14](#)). In addition, point mutations within introns may lead to defective splicing of intervening sequences. This, in turn, interferes with normal processing of the initial mRNA transcripts and results in a failure to form mature mRNA. Therefore, translation cannot take place, and the gene product is not synthesized.

Figure 5-1 Nonsense mutation leading to premature chain termination. Partial mRNA sequence of the β -globin chain of hemoglobin showing codons for amino acids 38 to 40. A point mutation (C \rightarrow U) in codon 39 changes a glutamine (Gln) codon to a stop codon, and hence protein synthesis stops at amino acid 38.

Figure 5-2 Three-base deletion in the common cystic fibrosis (CF) allele results in synthesis of a protein that lacks amino acid 508 (phenylalanine). Because the deletion is a multiple of three, this is not a frameshift mutation. (From Thompson MW, et al: Thompson and Thompson Genetics in Medicine, 5th ed. Philadelphia, WB Saunders, 1991, p 135.)

- **Deletions and insertions.** Small deletions or insertions involving the coding sequence can have two possible effects on the encoded protein. If the number of base pairs involved is three or a multiple of three, the reading frame will remain intact, and an abnormal protein lacking or gaining one or more amino acids will be synthesized (Fig. 5-2). If the number of affected coding bases is not a multiple of three, this will result in an alteration of the reading frame of the DNA strand, producing what is referred to as a frameshift mutation (Figs. 5-3 and 5-4). Typically, the result is the incorporation of a variable number of incorrect amino acids followed by truncation resulting from a premature stop codon.
- **Trinucleotide-repeat mutations.** Trinucleotide-repeat mutations belong to a special category of genetic anomaly. These mutations are characterized by amplification of a sequence of three nucleotides. Although the specific nucleotide sequence that undergoes amplification differs in various disorders, almost all affected sequences share the nucleotides guanine (G) and cytosine (C). For example, in fragile X syndrome, prototypical of this category of disorders, there are 250 to 4000 tandem repeats of the sequence CGG within a gene called *familial mental retardation 1 (FMR1)*. In normal populations the number of repeats is small, averaging 29. Such expansions of the trinucleotide sequences prevent normal expression of the *FMR1* gene, thus giving rise to mental retardation. Another *distinguishing feature of trinucleotide-repeat mutations is that they are dynamic* (i.e., the degree of amplification increases during gametogenesis). These features, discussed in greater detail later, influence the pattern of inheritance and the phenotypic manifestations of the diseases caused by this class of mutation.

To summarize, mutations can interfere with gene expression at various levels. Transcription may be suppressed

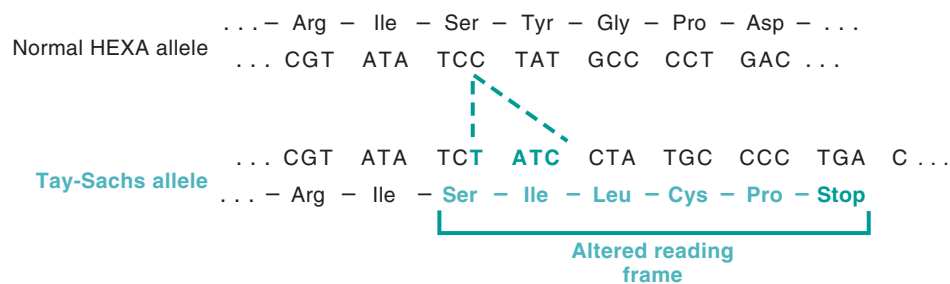

Figure 5-4 Four-base insertion in the hexosaminidase A gene, leading to a frameshift mutation. This mutation is the major cause of Tay-Sachs disease in Ashkenazi Jews. (From Nussbaum RL, et al: Thompson and Thompson Genetics in Medicine, 6th ed. Philadelphia, WB Saunders, 2001, p 212.)

Figure 5-3 Single-base deletion at the ABO (glycosyltransferase) locus, leading to a frameshift mutation responsible for the O allele. (From Thompson MW, et al. Thompson and Thompson Genetics in Medicine, 5th ed. Philadelphia, WB Saunders, 1991, p 134.)

by gene deletions and point mutations involving promoter sequences. Abnormal mRNA processing may result from mutations affecting introns or splice junctions or both. Translation is affected if a nonsense mutation creates a stop codon (chain termination mutation) within an exon. Finally, some pathogenic point mutations may lead to expression of normal amounts of a dysfunctional protein.

Against this background, we now turn our attention to the three major categories of genetic disorders: (1) disorders related to mutant genes of large effect, (2) diseases with multifactorial inheritance, and (3) chromosomal disorders. To these three well-known categories must be added a heterogeneous group of *single-gene disorders with nonclassic patterns of inheritance*. This group includes disorders resulting from triplet-repeat mutations, those arising from mutations in mitochondrial DNA (mtDNA), and those in which the transmission is influenced by genomic imprinting or gonadal mosaicism. Diseases within this group are caused by mutations in single genes, but they do not follow the Mendelian pattern of inheritance. These are discussed later in this chapter.

It is beyond the scope of this book to review normal human genetics. Some fundamentals of DNA structure and regulation of gene expressions were described in [Chapter 1](#). It is important here to clarify several commonly used terms—*hereditary*, *familial*, and *congenital*. Hereditary disorders, by definition, are derived from one's parents and are transmitted in the germ line through the generations and therefore are familial. The term *congenital* simply implies "born with." Some congenital diseases are not genetic; for example, congenital syphilis. Not all genetic diseases are congenital; individuals with Huntington disease, for example, begin to manifest their condition only after their 20s or 30s.

Mendelian Disorders

Virtually all Mendelian disorders are the result of mutations in single genes that have large effects. It is not necessary to detail Mendel's laws here, since every student in biology, and possibly every garden pea, has learned about them at an early age. Only some comments of medical relevance are made.

It is estimated that every individual is a carrier of five to eight deleterious genes, a number originally estimated from studies of populations that appears to be borne out by genomic sequencing of normal individuals. Most of these are recessive and therefore do not have serious phenotypic effects. About 80% to 85% of these mutations are familial. The remainder represents new mutations acquired *de novo* by an affected individual.

Some autosomal mutations produce partial expression in the heterozygote and full expression in the homozygote. Sickle cell anemia is caused by substitution of normal hemoglobin (HbA) by hemoglobin S (HbS). When an individual is homozygous for the mutant gene, all the hemoglobin is of the abnormal, HbS, type, and even with normal saturation of oxygen the disorder is fully expressed (i.e., sickling deformity of all red cells and hemolytic anemia). In the heterozygote, only a proportion of the hemoglobin is HbS (the remainder being HbA), and therefore red cell sickling occurs only under unusual circumstances, such as exposure to lowered oxygen tension. This is referred to as the *sickle cell trait* to differentiate it from full-blown sickle cell anemia.

Although Mendelian traits are usually described as dominant or recessive, in some cases both of the alleles of a gene pair contribute to the phenotype—a condition called *codominance*. Histocompatibility and blood group antigens are good examples of codominant inheritance.

A single mutant gene may lead to many end effects, termed *pleiotropism*; conversely, mutations at several genetic loci may produce the same trait (*genetic heterogeneity*). Sickle cell anemia is an example of pleiotropism. In this hereditary disorder not only does the point mutation in the gene give rise to HbS, which predisposes the red cells to hemolysis, but also the abnormal red cells tend to cause a logjam in small vessels, inducing, for example, splenic fibrosis, organ infarcts, and bone changes. The numerous differing end-organ derangements are all related to the primary defect in hemoglobin synthesis. On the other hand, profound childhood deafness, an apparently homogeneous clinical entity, results from many different types of autosomal recessive mutations. Recognition of genetic heterogeneity not only is important in genetic counseling but also is relevant in the understanding of the pathogenesis of some common disorders, such as diabetes mellitus.

Transmission Patterns of Single-Gene Disorders

Mutations involving single genes typically follow one of three patterns of inheritance: autosomal dominant, autosomal recessive, and X-linked. The general rules that govern the transmission of single-gene disorders are well known; only a few salient features are summarized. Single-gene disorders with nonclassic patterns of inheritance are described later.

Autosomal Dominant Disorders

Autosomal dominant disorders are manifested in the heterozygous state, so at least one parent of an index case is usually affected; both males and females are affected, and both can transmit the condition. When an affected person marries an unaffected one, every child has one chance in two of having the disease. In addition to these basic rules, autosomal dominant conditions are characterized by the following:

- *With every autosomal dominant disorder, some proportion of patients do not have affected parents.* Such patients owe their disorder to new mutations involving either the egg or the sperm from which they were derived. Their siblings are neither affected nor at increased risk for disease development. The proportion of patients who develop the disease as a result of a new mutation is related to the effect of the disease on reproductive capability. If a disease markedly reduces reproductive fitness, most cases would be expected to result from new mutations. Many new mutations seem to occur in germ cells of relatively older fathers.
- *Clinical features can be modified by variations in penetrance and expressivity.* Some individuals inherit the mutant gene but are phenotypically normal. This is referred to as *incomplete penetrance*. Penetrance is expressed in mathematical terms. Thus, 50% penetrance indicates that 50% of those who carry the gene express the trait. In contrast to penetrance, if a trait is seen in all individuals carrying the mutant gene but is expressed differently among individuals, the phenomenon is called *variable expressivity*. For example, manifestations of neurofibromatosis type 1 range from brownish spots on the skin to multiple skin tumors and skeletal deformities. The mechanisms underlying incomplete penetrance and variable expressivity are not fully understood, but they most likely result from effects of other genes or environmental factors that modify the phenotypic expression of the mutant allele. For example, the phenotype of a patient with sickle cell anemia (resulting from mutation at the β -globin locus) is influenced by the genotype at the α -globin locus, because the latter influences the total amount of hemoglobin made (Chapter 14). The influence of environmental factors is exemplified by individuals heterozygous for familial hypercholesterolemia. The expression of the disease in the form of atherosclerosis is conditioned by the dietary intake of lipids.
- In many conditions the age at onset is delayed; symptoms and signs may not appear until adulthood (as in Huntington disease).

The biochemical mechanisms of autosomal dominant disorders depend upon the nature of the mutation and the type of protein affected. Most mutations lead to the reduced production of a gene product or give rise to a dysfunctional or inactive protein. Whether such a mutation gives rise to dominant or recessive disease depends on whether the remaining copy of the gene is capable of compensating for the loss. Thus, understanding the reasons why particular loss-of-function mutations give rise to dominant vs. recessive disease patterns requires an understanding of the biology. Many autosomal dominant

diseases arising from deleterious mutations fall into one of a few familiar patterns:

1. *Those involved in regulation of complex metabolic pathways that are subject to feedback inhibition.* Membrane receptors such as the low-density lipoprotein (LDL) receptor provide one such example; in familial hypercholesterolemia, discussed later, a 50% loss of LDL receptors results in a secondary elevation of cholesterol that, in turn, predisposes to atherosclerosis in affected heterozygotes.
2. *Key structural proteins, such as collagen and cytoskeletal elements of the red cell membrane* (e.g., spectrin). The biochemical mechanisms by which a 50% reduction in the amounts of such proteins results in an abnormal phenotype are not fully understood. In some cases, especially when the gene encodes one subunit of a multimeric protein, the product of the mutant allele can interfere with the assembly of a functionally normal multimer. For example, the collagen molecule is a trimer in which the three collagen chains are arranged in a helical configuration. Each of the three collagen chains in the helix must be normal for the assembly and stability of the collagen molecule. Even with a single mutant collagen chain, normal collagen trimers cannot be formed, and hence there is a marked deficiency of collagen. In this instance the mutant allele is called *dominant negative*, because it impairs the function of a normal allele. This effect is illustrated by some forms of osteogenesis imperfecta, characterized by marked deficiency of collagen and severe skeletal abnormalities (Chapter 26).

Less common than loss-of-function mutations are *gain-of-function* mutations, which can take two forms. Some mutations result in an increase in a protein's normal function, for example, excessive enzymatic activity. In other cases, mutations impart a wholly new activity completely unrelated to the affected protein's normal function. The transmission of disorders produced by gain-of-function mutations is almost always autosomal dominant, as illustrated by Huntington disease (Chapter 28). In this disease the trinucleotide-repeat mutation affecting the Huntington gene (see later) gives rise to an abnormal protein, called *huntingtin*, that is toxic to neurons, and hence even heterozygotes develop a neurologic deficit.

Table 5-1 lists common autosomal dominant disorders. Many are discussed more logically in other chapters. A few conditions not considered elsewhere are discussed later in this chapter to illustrate important principles.

Autosomal Recessive Disorders

Autosomal recessive traits make up the largest category of Mendelian disorders. They occur when both alleles at a given gene locus are mutated. These disorders are characterized by the following features: (1) The trait does not usually affect the parents of the affected individual, but siblings may show the disease; (2) siblings have one chance in four of having the trait (i.e., the recurrence risk is 25% for each birth); and (3) if the mutant gene occurs with a low frequency in the population, there is a strong likelihood that the affected individual (proband) is the product of a consanguineous marriage. The following features generally apply to most autosomal recessive disorders and distinguish them from autosomal dominant diseases:

Table 5-1 Autosomal Dominant Disorders

System	Disorder
Nervous	Huntington disease Neurofibromatosis Myotonic dystrophy Tuberous sclerosis
Urinary	Polycystic kidney disease
Gastrointestinal	Familial polyposis coli
Hematopoietic	Hereditary spherocytosis von Willebrand disease
Skeletal	Marfan syndrome* Ehlers-Danlos syndrome (some variants)* Osteogenesis imperfecta Achondroplasia
Metabolic	Familial hypercholesterolemia* Acute intermittent porphyria

*Discussed in this chapter. Other disorders listed are discussed in appropriate chapters in the book.

- The expression of the defect tends to be more uniform than in autosomal dominant disorders.
- Complete penetrance is common.
- Onset is frequently early in life.
- Although new mutations associated with recessive disorders do occur, they are rarely detected clinically. Since the individual with a new mutation is an asymptomatic heterozygote, several generations may pass before the descendants of such a person mate with other heterozygotes and produce affected offspring.
- Many of the mutated genes encode enzymes. In heterozygotes, equal amounts of normal and defective enzyme are synthesized. Usually the natural "margin of safety" ensures that cells with half the usual complement of the enzyme function normally.

Autosomal recessive disorders include almost all inborn errors of metabolism. The various consequences of enzyme deficiencies are discussed later. The more common of these conditions are listed in Table 5-2. Most are presented elsewhere; a few prototypes are discussed later in this chapter.

Table 5-2 Autosomal Recessive Disorders

System	Disorder
Metabolic	Cystic fibrosis Phenylketonuria Galactosemia Homocystinuria Lysosomal storage diseases* α_1 -Antitrypsin deficiency Wilson disease Hemochromatosis Glycogen storage diseases*
Hematopoietic	Sickle cell anemia Thalassemias
Endocrine	Congenital adrenal hyperplasia
Skeletal	Ehlers-Danlos syndrome (some variants)* Alkaptonuria*
Nervous	Neurogenic muscular atrophies Friedreich ataxia Spinal muscular atrophy

*Discussed in this chapter. Many others are discussed elsewhere in the text.

X-Linked Disorders

All sex-linked disorders are X-linked, and almost all are recessive. Several genes are located in the “male-specific region of Y”; all of these are related to spermatogenesis. Males with mutations affecting the Y-linked genes are usually infertile, and hence there is no Y-linked inheritance. As discussed later, a few additional genes with homologues on the X chromosome have been mapped to the Y chromosome, but only a few rare disorders resulting from mutations in such genes have been described.

X-linked recessive inheritance accounts for a small number of well-defined clinical conditions. The Y chromosome, for the most part, is not homologous to the X, and so mutant genes on the X do not have corresponding alleles on the Y. Thus, the male is said to be *hemizygous* for X-linked mutant genes, so these disorders are expressed in the male. Other features that characterize these disorders are as follows:

- An affected male does not transmit the disorder to his sons, but all daughters are carriers. Sons of heterozygous women have, of course, one chance in two of receiving the mutant gene.
- The heterozygous female usually does not express the full phenotypic change because of the paired normal allele. Because of the random inactivation of one of the X chromosomes in the female, however, females have a variable proportion of cells in which the mutant X chromosome is active. Thus, it is remotely possible for the normal allele to be inactivated in most cells, permitting full expression of heterozygous X-linked conditions in the female. Much more commonly, the normal allele is inactivated in only some of the cells, and thus the heterozygous female expresses the disorder partially. An illustrative condition is *glucose-6-phosphate dehydrogenase (G6PD) deficiency*. Transmitted on the X chromosome, this enzyme deficiency, which predisposes to red cell hemolysis in patients receiving certain types of drugs (Chapter 14), is expressed principally in males. In the female, a proportion of the red cells may be derived from precursors with inactivation of the normal allele. Such red cells are at the same risk for undergoing hemolysis as are the red cells in the hemizygous male. Thus, the female is not only a carrier of this trait but also is susceptible to drug-induced hemolytic reactions. Because the proportion of defective red cells in heterozygous females depends on the random inactivation of one of the X chromosomes, however, the severity of the hemolytic reaction is almost always less in heterozygous women than in hemizygous men. Most of the X-linked conditions listed in Table 5-3 are covered elsewhere in the text.

There are only a few X-linked dominant conditions. They are caused by dominant disease-associated alleles on the X chromosome. These disorders are transmitted by an affected heterozygous female to half her sons and half her daughters and by an affected male parent to all his daughters but none of his sons, if the female parent is unaffected. Vitamin D-resistant rickets is an example of this type of inheritance.

Table 5-3 X-Linked Recessive Disorders

System	Disease
Musculoskeletal	Duchenne muscular dystrophy
Blood	Hemophilia A and B Chronic granulomatous disease Glucose-6-phosphate dehydrogenase deficiency
Immune	Agammaglobulinemia Wiskott-Aldrich syndrome
Metabolic	Diabetes insipidus Lesch-Nyhan syndrome
Nervous	Fragile X syndrome*

*Discussed in this chapter. Others are discussed in appropriate chapters in the text.

KEY CONCEPTS

Transmission Patterns of Single-Gene Disorders

- **Autosomal dominant disorders** are characterized by expression in heterozygous state; they affect males and females equally, and both sexes can transmit the disorder.
- Enzyme proteins are not affected in autosomal dominant disorders; instead, receptors and structural proteins are involved.
- **Autosomal recessive diseases** occur when both copies of a gene are mutated; enzyme proteins are frequently involved. Males and females are affected equally.
- **X-linked disorders** are transmitted by heterozygous females to their sons, who manifest the disease. Female carriers usually are protected because of random inactivation of one X chromosome.

Biochemical and Molecular Basis of Single-Gene (Mendelian) Disorders

Mendelian disorders result from alterations involving single genes. The genetic defect may lead to the formation of an abnormal protein or a reduction in the output of the gene product. Virtually any type of protein may be affected in single-gene disorders and by a variety of mechanisms (Table 5-4). To some extent the pattern of inheritance of the disease is related to the kind of protein affected by the mutation. For this discussion, the mechanisms involved in single-gene disorders can be classified into four categories: (1) *enzyme defects and their consequences*; (2) *defects in membrane receptors and transport systems*; (3) *alterations in the structure, function, or quantity of nonenzyme proteins*; and (4) *mutations resulting in unusual reactions to drugs*.

Enzyme Defects and Their Consequences

Mutations may result in the synthesis of an enzyme with reduced activity or a reduced amount of a normal enzyme. In either case, the consequence is a metabolic block. Figure 5-5 provides an example of an enzyme reaction in which the substrate is converted by intracellular enzymes, denoted as 1, 2, and 3, into an end product through intermediates 1 and 2. In this model the final product exerts feedback control on enzyme 1. A minor pathway producing small quantities of M1 and M2 also exists. The biochemical

Table 5-4 Biochemical and Molecular Basis of Some Mendelian Disorders

Protein Type/ Function	Example	Molecular Lesion	Disease
Enzyme	Phenylalanine hydroxylase	Splice-site mutation: reduced amount	Phenylketonuria
	Hexosaminidase	Splice-site mutation or frameshift mutation with stop codon: reduced amount	Tay-Sachs disease
	Adenosine deaminase	Point mutations: abnormal protein with reduced activity	Severe combined immunodeficiency
Enzyme inhibitor	α_1 -Antitrypsin	Missense mutations: impaired secretion from liver to serum	Emphysema and liver disease
Receptor	Low-density lipoprotein receptor	Deletions, point mutations: reduction of synthesis, transport to cell surface, or binding to low-density lipoprotein	Familial hypercholesterolemia
	Vitamin D receptor	Point mutations: failure of normal signaling	Vitamin D-resistant rickets
Transport Oxygen	Hemoglobin	Deletions: reduced amount	α -Thalassemia
		Defective mRNA processing: reduced amount	β -Thalassemia
Ion channels	Cystic fibrosis transmembrane conductance regulator	Point mutations: abnormal structure	Sickle cell anemia
		Deletions and other mutations: nonfunctional or misfolded proteins	Cystic fibrosis
Structural Extracellular	Collagen	Deletions or point mutations cause reduced amount of normal collagen or normal amounts of defective collagen	Osteogenesis imperfecta; Ehlers-Danlos syndromes
		Missense mutations	Marfan syndrome
Cell membrane	Fibrillin Dystrophin Spectrin, ankyrin, or protein 4.1	Deletion with reduced synthesis	Duchenne/Becker muscular dystrophy
		Heterogeneous	Hereditary spherocytosis
Hemostasis	Factor VIII	Deletions, insertions, nonsense mutations, and others: reduced synthesis or abnormal factor VIII	Hemophilia A
Growth regulation	Rb protein	Deletions	Hereditary retinoblastoma
	Neurofibromin	Heterogeneous	Neurofibromatosis type 1

consequences of an enzyme defect in such a reaction may lead to three major consequences:

- *Accumulation of the substrate*, depending on the site of block, may be accompanied by accumulation of one or both intermediates. Moreover, an increased concentration of intermediate 2 may stimulate the minor pathway and thus lead to an excess of M1 and M2. Under these conditions tissue injury may result if the precursor, the intermediates, or the products of alternative minor pathways are toxic in high concentrations. For example, in galactosemia, the deficiency of galactose-1-phosphate uridylyltransferase (Chapter 10) leads to

Figure 5-5 A possible metabolic pathway in which a substrate is converted to an end product by a series of enzyme reactions. M1, M2, products of a minor pathway.

the accumulation of galactose and consequent tissue damage. Excessive accumulation of complex substrates within the lysosomes as a result of deficiency of degradative enzymes is responsible for a group of diseases generally referred to as *lysosomal storage diseases*.

- *An enzyme defect can lead to a metabolic block and a decreased amount of end product* that may be necessary for normal function. For example, a deficiency of melanin may result from lack of tyrosinase, which is necessary for the biosynthesis of melanin from its precursor, tyrosine, resulting in the clinical condition called *albinism*. If the end product is a feedback inhibitor of the enzymes involved in the early reactions (in Fig. 5-5 it is shown that the product inhibits enzyme 1), the deficiency of the end product may permit overproduction of intermediates and their catabolic products, some of which may be injurious at high concentrations. A prime example of a disease with such an underlying mechanism is the Lesch-Nyhan syndrome (Chapter 26).
- *Failure to inactivate a tissue-damaging substrate* is best exemplified by α_1 -antitrypsin deficiency. Individuals who have an inherited deficiency of serum α_1 -antitrypsin are unable to inactivate neutrophil elastase in their lungs. Unchecked activity of this protease leads to destruction of elastin in the walls of lung alveoli, leading eventually to pulmonary emphysema (Chapter 15).

Defects in Receptors and Transport Systems

As we discussed in chapter 1, biologically active substances have to be actively transported across the cell membrane. In some cases transport is achieved by

receptor-mediated endocytosis. A genetic defect in a receptor-mediated transport system is exemplified by familial hypercholesterolemia, in which reduced synthesis or function of LDL receptors leads to defective transport of LDL into the cells and secondarily to excessive cholesterol synthesis by complex intermediary mechanisms. In cystic fibrosis the transport system for chloride ions in exocrine glands, sweat ducts, lungs, and pancreas is defective. By mechanisms not fully understood, impaired chloride transport leads to serious injury to the lungs and pancreas (Chapter 10).

Alterations in Structure, Function, or Quantity of Nonenzyme Proteins

Genetic defects resulting in alterations of nonenzyme proteins often have widespread secondary effects, as exemplified by sickle cell disease. The hemoglobinopathies, sickle cell disease being one, all of which are characterized by defects in the structure of the globin molecule, best exemplify this category. In contrast to the hemoglobinopathies, the thalassemias result from mutations in globin genes that affect the amount of globin chains synthesized. Thalassemias are associated with reduced amounts of structurally normal α -globin or β -globin chains (Chapter 14). Other examples of genetic disorders involving defective structural proteins include collagen, spectrin, and dystrophin, giving rise to osteogenesis imperfecta (Chapter 26), hereditary spherocytosis (Chapter 14), and muscular dystrophies (Chapter 27), respectively.

Genetically Determined Adverse Reactions to Drugs

Certain genetically determined enzyme deficiencies are unmasked only after exposure of the affected individual to certain drugs. This special area of genetics, called *pharmacogenetics*, is of considerable clinical importance. The classic example of drug-induced injury in the genetically susceptible individual is associated with a deficiency of the enzyme G6PD. Under normal conditions glucose-6 phosphate-dehydrogenase (G6PD) deficiency does not result in disease, but on administration, for example, of the antimalarial drug primaquine, a severe hemolytic anemia results (Chapter 14). In recent years an increasing number of polymorphisms of genes encoding drug-metabolizing enzymes, transporters, and receptors have been identified. In some cases these genetic factors have major impact on drug sensitivity and adverse reactions. It is hoped that advances in pharmacogenetics will lead to patient-tailored therapy, an example of “personalized medicine.”

With this overview of the biochemical basis of single-gene disorders, we now consider selected examples grouped according to the underlying defect.

Disorders Associated with Defects in Structural Proteins

Several diseases caused by mutations in genes that encode structural proteins are listed in Table 5-4. Many are discussed elsewhere in the text. Only Marfan syndrome and Ehlers-Danlos syndromes (EDSs) are discussed here, because they affect connective tissue and hence involve multiple organ systems.

Marfan Syndrome

Marfan syndrome is a disorder of connective tissues, manifested principally by changes in the skeleton, eyes, and cardiovascular system. Its prevalence is estimated to be 1 in 5000. Approximately 70% to 85% of cases are familial and transmitted by autosomal dominant inheritance. The remainder are sporadic and arise from new mutations.

Pathogenesis. Marfan syndrome results from an inherited defect in an extracellular glycoprotein called *fibrillin-1*. There are two fundamental mechanisms by which loss of fibrillin leads to the clinical manifestations of Marfan syndrome: loss of structural support in microfibril rich connective tissue and excessive activation of TGF- β signaling. Each of these is discussed below.

- Fibrillin is the major component of microfibrils found in the extracellular matrix (Chapter 1). These fibrils provide a scaffolding on which tropoelastin is deposited to form elastic fibers. Although microfibrils are widely distributed in the body, they are particularly abundant in the aorta, ligaments, and the ciliary zonules that support the lens; these tissues are prominently affected in Marfan syndrome. Fibrillin occurs in two homologous forms, fibrillin-1 and fibrillin-2, encoded by two separate genes, *FBN1* and *FBN2*, mapped on chromosomes 15q21.1 and 5q23.31, respectively. Mutations of *FBN1* underlie Marfan syndrome; mutations of the related *FBN2* gene are less common, and they give rise to *congenital contractural arachnodactyly*, an autosomal dominant disorder characterized by skeletal abnormalities. Mutational analysis has revealed more than 600 distinct mutations of the *FBN1* gene in individuals with Marfan syndrome. Most of these are missense mutations that give rise to abnormal fibrillin-1. These can inhibit polymerization of fibrillin fibers (dominant negative effect). Alternatively, the reduction of fibrillin content below a certain threshold weakens the connective tissue (haploinsufficiency).
- While many clinical manifestations of Marfan syndrome can be explained by changes in the mechanical properties of the extracellular matrix resulting from abnormalities of fibrillin, several others such as bone overgrowth and myxoid changes in mitral valves cannot be attributed to changes in tissue elasticity. Recent studies indicate that loss of microfibrils gives rise to abnormal and excessive activation of transforming growth factor- β (TGF- β), since normal microfibrils sequester TGF- β and thus control the bioavailability of this cytokine. Excessive TGF- β signaling has deleterious effects on vascular smooth muscle development and it also increases the activity of metalloproteases, causing loss of extracellular matrix. This schema is supported by two sets of observations. First, in a small number of individuals with clinical features of Marfan syndrome (MFS2), there are no mutations in *FBN1* but instead gain-of-function mutations in genes that encode TGF- β receptors. Second, in mouse models of Marfan syndrome generated by mutations in *Fbn1*, administration of antibodies to TGF- β prevents alterations in the aorta and mitral valves.

MORPHOLOGY

Skeletal abnormalities are the most striking feature of Marfan syndrome. Typically the patient is unusually tall with exceptionally long extremities and long, tapering fingers and toes. The joint ligaments in the hands and feet are lax, suggesting that the patient is double-jointed; typically the thumb can be hyperextended back to the wrist. The head is commonly dolichocephalic (long-headed) with bossing of the frontal eminences and prominent supraorbital ridges. A variety of spinal deformities may appear, including kyphosis, scoliosis, or rotation or slipping of the dorsal or lumbar vertebrae. The chest is classically deformed, presenting either pectus excavatum (deeply depressed sternum) or a pigeon-breast deformity.

The **ocular changes** take many forms. Most characteristic is bilateral subluxation or dislocation (usually outward and upward) of the lens, referred to as ectopia lentis. This abnormality is so uncommon in persons who do not have this disease that the finding of bilateral ectopia lentis should raise the suspicion of Marfan syndrome.

Cardiovascular lesions are the most life-threatening features of this disorder. The two most common lesions are mitral valve prolapse and, of greater importance, dilation of the ascending aorta due to cystic medionecrosis. Histologically the changes in the media are virtually identical to those found in cystic medionecrosis not related to Marfan syndrome (Chapter 12). Loss of medial support results in progressive dilation of the aortic valve ring and the root of the aorta, giving rise to severe aortic incompetence. In addition, excessive TGF- β signaling in the adventitia may also contribute to aortic dilation. Weakening of the media predisposes to an intimal tear, which may initiate an intramural hematoma that cleaves the layers of the media to produce **aortic dissection**. After cleaving the aortic layers for considerable distances, sometimes back to the root of the aorta or down to the iliac arteries, the hemorrhage often ruptures through the aortic wall. Such a calamity is the cause of death in 30% to 45% of these individuals.

Clinical Features. Although mitral valve lesions are more frequent, they are clinically less important than aortic lesions. Loss of connective tissue support in the mitral valve leaflets makes them soft and billowy, creating a so-called floppy valve (Chapter 12). Valvular lesions, along with lengthening of the chordae tendineae, frequently give rise to mitral regurgitation. Similar changes may affect the tricuspid and, rarely, the aortic valves. Echocardiography greatly enhances the ability to detect the cardiovascular abnormalities and is therefore extremely valuable in the diagnosis of Marfan syndrome. The great majority of deaths are caused by rupture of aortic dissections, followed in importance by cardiac failure.

While the lesions just described typify Marfan syndrome, it must be emphasized that there is great variation in the clinical expression of this genetic disorder. Patients with prominent eye or cardiovascular changes may have few skeletal abnormalities, whereas others with striking changes in body habitus have no eye changes. Although variability in clinical expression may be seen within a family, interfamilial variability is much more common and extensive. Because of such variations, the clinical diagnosis of Marfan syndrome is currently based on the so called “revised Ghent criteria.” These take into account family history, cardinal clinical signs in the absence of family history, and presence or absence of fibrillin mutation. In general, major involvement of two of the four organ systems (skeletal, cardiovascular, ocular, and skin) and minor involvement of another organ is required for diagnosis.

The variable expression of the Marfan defect is best explained on the basis of the many different mutations that affect the fibrillin locus, which number more than 600. This genetic heterogeneity also poses formidable challenges in the diagnosis of Marfan syndrome. The evolving high throughput sequencing technologies discussed later in this chapter may overcome this problem in the future.

The mainstay of the medical treatment is administration of β blockers which likely act by reducing heart rate and aortic wall stress. In animal models inhibition of TGF- β action by use of specific antibodies has been found useful. Since lifelong use of such antibodies in humans is not feasible, other strategies to block TGF- β signaling are being tested. Blockade of angiotensin type 2 receptors accomplishes this effect in humans and several preliminary studies are very promising.

Ehlers-Danlos Syndromes (EDS)

EDSs comprise a clinically and genetically heterogeneous group of disorders that result from some defect in the synthesis or structure of fibrillar collagen. Other disorders resulting from mutations affecting collagen synthesis include osteogenesis imperfecta (Chapter 26), Alport syndrome (Chapter 20), and epidermolysis bullosa (Chapter 25).

Biosynthesis of collagen is a complex process (Chapter 1) that can be disturbed by genetic errors that may affect any one of the numerous structural collagen genes or enzymes necessary for posttranscriptional modifications of collagen. Hence, the mode of inheritance of EDS encompasses all three Mendelian patterns. On the basis of clinical and molecular characteristics, six variants of EDS have been recognized. These are listed in Table 5-5. It is beyond the scope of this book to discuss each variant individually; instead, the important clinical features common to most

Table 5-5 Classification of Ehlers-Danlos Syndromes

EDS Type*	Clinical Findings	Inheritance	Gene Defects
Classic (I/II)	Skin and joint hypermobility, atrophic scars, easy bruising	Autosomal dominant	<i>COL5A1</i> , <i>COL5A2</i>
Hypermobility (III)	Joint hypermobility, pain, dislocations	Autosomal dominant	Unknown
Vascular (IV)	Thin skin, arterial or uterine rupture, bruising, small joint hyperextensibility	Autosomal dominant	<i>COL3A1</i>
Kyphoscoliosis (VI)	Hypotonia, joint laxity, congenital scoliosis, ocular fragility	Autosomal recessive	Lysyl hydroxylase
Arthrochalasia (VIIa,b)	Severe joint hypermobility, skin changes (mild), scoliosis, bruising	Autosomal dominant	<i>COL1A1</i> , <i>COL1A2</i>
Dermatosparaxis (VIIc)	Severe skin fragility, cutis laxa, bruising	Autosomal recessive	Procollagen <i>N</i> -peptidase

*EDS types were previously classified by Roman numerals. Parentheses show previous numerical equivalents.

variants are summarized and clinical manifestations are correlated with the underlying molecular defects in collagen synthesis or structure.

As might be expected, tissues rich in collagen, such as skin, ligaments, and joints, are frequently involved in most variants of EDS. Because the abnormal collagen fibers lack adequate tensile strength, *skin is hyperextensible, and the joints are hypermobile*. These features permit grotesque contortions, such as bending the thumb backward to touch the forearm and bending the knee forward to create almost a right angle. It is believed that most contortionists have one of the EDSs. A predisposition to joint dislocation, however, is one of the prices paid for this virtuosity. *The skin is extraordinarily stretchable, extremely fragile, and vulnerable to trauma*. Minor injuries produce gaping defects, and surgical repair or intervention is accomplished with great difficulty because of the lack of normal tensile strength. *The basic defect in connective tissue may lead to serious internal complications*. These include rupture of the colon and large arteries (vascular EDS), ocular fragility with rupture of cornea and retinal detachment (kyphoscoliosis EDS), and diaphragmatic hernia (classic EDS).

The biochemical and molecular bases of these abnormalities are known in several forms of EDS. These are described briefly, because they offer some insights into the perplexing clinical heterogeneity of EDS. Perhaps the best characterized is the *kyphoscoliosis type, the most common autosomal recessive form of EDS*. It results from mutations in the gene encoding lysyl hydroxylase, an enzyme necessary for hydroxylation of lysine residues during collagen synthesis. Affected patients have markedly reduced levels of this enzyme. Because hydroxylysine is essential for the cross-linking of collagen fibers, a deficiency of lysyl hydroxylase results in the synthesis of collagen that lacks normal structural stability.

The *vascular type of EDS results from abnormalities of type III collagen*. This form is genetically heterogeneous, because at least three distinct types of mutations affecting the *COL3A1* gene encoding collagen type III can give rise to this variant. Some affect the rate of synthesis of pro- $\alpha 1$ (III) chains, others affect the secretion of type III procollagen, and still others lead to the synthesis of structurally abnormal type III collagen. Some mutant alleles behave as dominant negatives (see discussion under “[Autosomal Dominant Disorders](#)”) and thus produce severe phenotypic effects. These molecular studies provide a rational basis for the pattern of transmission and clinical features that are characteristic of this variant. First, because vascular-type EDS results from mutations involving a structural protein (rather than an enzyme protein), an autosomal dominant pattern of inheritance would be expected. Second, because blood vessels and intestines are known to be rich in collagen type III, an abnormality of this collagen is consistent with severe structural defects (e.g., vulnerability to spontaneous rupture) in these organs.

In two forms of EDS—arthrochalasia type and dermatosparaxis type—the fundamental defect is in the conversion of type I procollagen to collagen. This step in collagen synthesis involves cleavage of noncollagen peptides at the N terminus and C terminus of the procollagen molecule. This is accomplished by N-terminal-specific and C-terminal-specific peptidases. The defect in the conversion of procollagen to collagen in the arthrochalasia type

has been traced to mutations that affect one of the two type I collagen genes, *COL1A1* and *COL1A2*. As a result, structurally abnormal pro- $\alpha 1$ (I) or pro- $\alpha 2$ (I) chains that resist cleavage of N-terminal peptides are formed. In patients with a single mutant allele, only 50% of the type I collagen chains are abnormal, but because these chains interfere with the formation of normal collagen helices, heterozygotes manifest the disease. In contrast, the related dermatosparaxis type is caused by mutations in the procollagen-N-peptidase genes, essential for the cleavage of collagens. Because in this case the disease is caused by an enzyme deficiency, it follows an autosomal recessive form of inheritance.

Finally, in *classic type of EDS*, molecular analysis suggests that genes other than those that encode collagen may also be involved. In 30% to 50% of these cases, mutations in the genes for type V collagen (*COL5A1* and *COL5A2*) have been detected. Surprisingly, in the remaining cases, no other collagen gene abnormalities have been found despite clinical features typical of EDS. It is suspected that in some cases genetic defects that affect the biosynthesis of other extracellular matrix molecules that influence collagen synthesis indirectly may be involved. One example is an EDS-like condition caused by mutation in tenascin-X, a large multimeric protein, that affects the synthesis and fibril formation of type VI and type I collagens.

To summarize, the common thread in EDS is some abnormality of collagen. These disorders, however, are extremely heterogeneous. At the molecular level, a variety of defects, varying from mutations involving structural genes for collagen to those involving enzymes that are responsible for posttranscriptional modifications of mRNA, have been detected. Such molecular heterogeneity results in the expression of EDS as a clinically variable disorder with several patterns of inheritance.

KEY CONCEPTS

Marfan Syndrome

- Marfan syndrome is caused by a mutation in the *FBN1* gene encoding fibrillin, which is required for structural integrity of connective tissues and regulation of TGF- β signaling.
- The major tissues affected are the skeleton, eyes, and cardiovascular system.
- Clinical features may include tall stature, long fingers, bilateral subluxation of lens, mitral valve prolapse, aortic aneurysm, and aortic dissection.
- Clinical trials with drugs that inhibit TGF- β signaling such as angiotensin receptor blockers are ongoing, as these have been shown to improve aortic and cardiac function in mouse models.

Ehlers-Danlos Syndromes

- There are six variants of Ehlers-Danlos syndromes, all characterized by defects in collagen synthesis or assembly. Each of the variants is caused by a distinct mutation involving one of several collagen genes or genes that encode other ECM proteins like tenascin-X.
- Clinical features may include fragile, hyperextensible skin vulnerable to trauma, hypermobile joints, and ruptures involving colon, cornea, or large arteries. Wound healing is poor.

Disorders Associated with Defects in Receptor Proteins

Familial Hypercholesterolemia

Familial hypercholesterolemia is a “receptor disease” that is the consequence of a mutation in the gene encoding the receptor for LDL, which is involved in the transport and metabolism of cholesterol. As a consequence of receptor abnormalities there is a loss of feedback control and elevated levels of cholesterol that induce premature atherosclerosis, leading to a greatly increased risk of myocardial infarction.

Familial hypercholesterolemia is one of the most frequently occurring Mendelian disorders. Heterozygotes with one mutant gene, representing about 1 in 500 individuals, have from birth a two-fold to three-fold elevation of plasma cholesterol level, leading to tendinous xanthomas and premature atherosclerosis in adult life (Chapter 11). Homozygotes, having a double dose of the mutant gene, are much more severely affected and may have five-fold to six-fold elevations in plasma cholesterol levels. Skin xanthomas and coronary, cerebral, and peripheral vascular atherosclerosis may develop in these individuals at an early age. Myocardial infarction may occur before age 20 years. Large-scale studies have found that familial hypercholesterolemia is present in 3% to 6% of survivors of myocardial infarction.

Normal Process of Cholesterol Metabolism and Transport

Approximately 7% of the body’s cholesterol circulates in the plasma, predominantly in the form of LDL. As might be expected, the amount of plasma cholesterol is influenced by its synthesis and catabolism, and the liver plays a crucial role in both these processes (Fig. 5-6). The first step in this complex sequence is the secretion of very-low-density lipoproteins (VLDLs) by the liver into the bloodstream. VLDL particles are rich in triglycerides, but they contain lesser amounts of cholesteryl esters. When a VLDL particle reaches the capillaries of adipose tissue or muscle, it is cleaved by lipoprotein lipase, a process that extracts most of the triglycerides. The resulting molecule, called *intermediate-density lipoprotein (IDL)*, is reduced in triglyceride content and enriched in cholesteryl esters, but it retains two of the three apoproteins (B-100 and E) present in the parent VLDL particle (Fig. 5-6). After release from the capillary endothelium, the IDL particles have one of two fates. Approximately 50% of newly formed IDL is rapidly taken up by the liver by receptor-mediated transport. The receptor responsible for the binding of IDL to the liver cell membrane recognizes both apoprotein B-100 and apoprotein E. It is called the *LDL receptor*, however, because it is also involved in the hepatic clearance of LDL (described later). In the liver cells, IDL is recycled to generate VLDL. The IDL particles not taken up by the liver are subjected to further metabolic processing that removes most of the remaining triglycerides and apoprotein E, yielding cholesterol-rich LDL particles. *IDL is the immediate and major source of plasma LDL.* There seem to be two mechanisms for removal of LDL from plasma, one mediated by an LDL receptor and the other by a receptor for oxidized LDL (scavenger receptor), described later.

Figure 5-6 Low-density lipoprotein (LDL) metabolism and the role of the liver in its synthesis and clearance. Lipolysis of very-low-density lipoprotein (VLDL) by lipoprotein lipase in the capillaries releases triglycerides, which are then stored in fat cells and used as a source of energy in skeletal muscles. See text for explanation of abbreviations used.

Although many cell types, including fibroblasts, lymphocytes, smooth muscle cells, hepatocytes, and adrenocortical cells, possess high-affinity LDL receptors, approximately 70% of the plasma LDL is cleared by the liver, using a quite sophisticated transport process (Fig. 5-7). The first step involves binding of LDL to cell surface receptors, which are clustered in specialized regions of the plasma membrane called *coated pits* (Chapter 1). After binding, the coated pits containing the receptor-bound LDL are internalized by invagination to form coated vesicles, after which they migrate within the cell to fuse with the lysosomes. Here the LDL dissociates from the receptor, which is recycled to the surface. In the lysosomes the LDL molecule is enzymatically degraded; the apoprotein part is hydrolyzed to amino acids, whereas the cholesteryl esters are broken down to free cholesterol. This free cholesterol, in turn, crosses the lysosomal membrane to enter the cytoplasm, where it is used for membrane synthesis and as a regulator of cholesterol homeostasis. The exit of cholesterol from the lysosomes requires the action of two proteins, called NPC1 and NPC2 (see “[Niemann-Pick Disease Type C](#)”). Three separate processes are affected by the released intracellular cholesterol, as follows:

- Cholesterol *suppresses* cholesterol synthesis within the cell by inhibiting the activity of the enzyme 3-hydroxy-3-methylglutaryl coenzyme A (HMG CoA) reductase,

Figure 5-7 The LDL receptor pathway and regulation of cholesterol metabolism.

which is the rate-limiting enzyme in the synthetic pathway.

- Cholesterol *activates* the enzyme acyl-coenzyme A: cholesterol acyltransferase, favoring esterification and storage of excess cholesterol.
- Cholesterol *suppresses* the synthesis of LDL receptors, thus protecting the cells from excessive accumulation of cholesterol.

As mentioned earlier, familial hypercholesterolemia results from mutations in the gene encoding the receptor for LDL. Heterozygotes with familial hypercholesterolemia possess only 50% of the normal number of high-affinity LDL receptors, because they have only one normal gene. As a result of this defect in transport, the catabolism of LDL by the receptor-dependent pathways is impaired, and the plasma level of LDL increases approximately two-fold. Homozygotes have virtually no normal LDL receptors in their cells and have much higher levels of circulating LDL. In addition to defective LDL clearance, both the homozygotes and heterozygotes have increased synthesis of LDL. The mechanism of increased synthesis that contributes to hypercholesterolemia also results from a lack of LDL receptors (Fig. 5-6). IDL, the immediate precursor of plasma LDL, also uses hepatic LDL receptors (apoprotein B-100 and E receptors) for its transport into the liver. In familial hypercholesterolemia, impaired IDL transport into the liver secondarily diverts a greater proportion of plasma IDL into the precursor pool for plasma LDL.

The transport of LDL via the scavenger receptor seems to occur at least in part into the cells of the mononuclear phagocyte system. Monocytes and macrophages have receptors for chemically altered (e.g., acetylated or oxidized) LDL. Normally the amount of LDL transported along this scavenger receptor pathway is less than that mediated by the LDL receptor-dependent mechanisms. In the face of hypercholesterolemia, however, there is a marked increase in the scavenger receptor-mediated traffic of LDL cholesterol into the cells of the mononuclear phagocyte system and possibly the vascular walls (Chapter 11). This increase is responsible for the appearance of xanthomas and contributes to the pathogenesis of premature atherosclerosis.

The molecular genetics of familial hypercholesterolemia is extremely complex. More than 900 mutations involving the LDL receptor gene, including insertions, deletions, and missense and nonsense mutations, have been identified. These can be classified into five groups (Fig. 5-8): *Class I mutations* are relatively uncommon and lead to a complete failure of synthesis of the receptor protein (null allele). *Class II mutations* are fairly common; they encode receptor proteins that accumulate in the endoplasmic reticulum because their folding defects make it impossible for them to be transported to the Golgi complex. *Class III mutations* affect the LDL-binding domain of the receptor; the encoded proteins reach the cell surface but fail to bind LDL or do so poorly. *Class IV mutations* encode proteins that are synthesized and transported to the cell surface efficiently.

Figure 5-8 Classification of LDL receptor mutations based on abnormal function of the mutant protein. These mutations disrupt the receptor's synthesis in the endoplasmic reticulum, transport to the Golgi complex, binding of apoprotein ligands, clustering in coated pits, and recycling in endosomes. Each class is heterogeneous at the DNA level. (Modified with permission from Hobbs HH, et al: The LDL receptor locus in familial hypercholesterolemia: mutational analysis of a membrane protein. *Annu Rev Genet* 24:133-170, 1990. © 1990 by Annual Reviews.)

They bind LDL normally, but they fail to localize in coated pits, and hence the bound LDL is not internalized. *Class V mutations* encode proteins that are expressed on the cell surface, can bind LDL, and can be internalized; however, the pH-dependent dissociation of the receptor and the bound LDL fails to occur. Such receptors are trapped in the endosome, where they are degraded, and hence they fail to recycle to the cell surface.

The discovery of the critical role of LDL receptors in cholesterol homeostasis has led to the rational design of drugs that lower plasma cholesterol by increasing the number of LDL receptors. One strategy is based on the ability of certain drugs (statins) to suppress intracellular cholesterol synthesis by inhibiting the enzyme HMG CoA reductase. This, in turn, allows greater synthesis of LDL receptors (Fig. 5-8). Statins have been widely and successfully used for secondary prevention of ischemic heart disease. They exemplify rational design of drugs based on an understanding of pathophysiology.

KEY CONCEPTS

Familial Hypercholesterolemia

- Familial hypercholesterolemia is an autosomal dominant disorder caused by mutations in the gene encoding the LDL receptor.
- Patients develop hypercholesterolemia as a consequence of impaired transport of LDL into the cells.

- In heterozygotes, elevated serum cholesterol greatly increases the risk of atherosclerosis and resultant coronary artery disease; homozygotes have an even greater increase in serum cholesterol and a higher frequency of ischemic heart disease. Cholesterol also deposits along tendon sheaths to produce xanthomas.

Disorders Associated with Defects in Enzymes

Lysosomal Storage Diseases

Lysosomes are key components of the "intracellular digestive tract." They contain a battery of hydrolytic enzymes, which have two special properties. First, they function in the acidic milieu of the lysosomes. Second, these enzymes constitute a special category of secretory proteins that are destined not for the extracellular fluids but for intracellular organelles. This latter characteristic requires special processing within the Golgi apparatus, which merits brief discussion.

Similar to all other secretory proteins, lysosomal enzymes (or *acid hydrolases*, as they are sometimes called) are synthesized in the endoplasmic reticulum and transported to the Golgi apparatus. Within the Golgi complex they undergo a variety of posttranslational modifications including the attachment of terminal mannose-6-phosphate groups to some of the oligosaccharide side chains. The phosphorylated mannose residues serve as an "address label" that is recognized by specific receptors found on the inner surface of the Golgi membrane. Lysosomal enzymes bind these receptors and are thereby segregated from the numerous other secretory proteins within the Golgi. Subsequently, small transport vesicles containing the receptor-bound enzymes are pinched off from the Golgi and proceed to fuse with the lysosomes. Thus, the enzymes are targeted to their intracellular abode, and the vesicles are shuttled back to the Golgi (Fig. 5-9). As indicated later, genetically determined errors in this remarkable sorting mechanism may give rise to one form of lysosomal storage disease.

The lysosomal enzymes catalyze the breakdown of a variety of complex macromolecules. These large molecules may be derived from the metabolic turnover of intracellular organelles (autophagy), or they may be acquired from outside the cells by phagocytosis (heterophagy). An inherited deficiency of a functional lysosomal enzyme gives rise to two pathologic consequences (Fig. 5-10):

- Catabolism of the substrate of the missing enzyme remains incomplete, leading to the accumulation of the partially degraded insoluble metabolite within the lysosomes. This is called "primary accumulation". Stuffed with incompletely digested macromolecules, lysosomes become large and numerous enough to interfere with normal cell functions.
- Since lysosomal function is also essential for autophagy, impaired autophagy gives rise to "secondary accumulation" of autophagic substrates such as polyubiquitinated proteins and old and effete mitochondria. The absence of this quality control mechanism causes accumulation of dysfunctional mitochondria with poor calcium buffering capacity and altered membrane potentials. This can trigger generation of free radicals and apoptosis.

Figure 5-9 Synthesis and intracellular transport of lysosomal enzymes.

While details are still lacking it is clear that defects in autophagy are common in lysosomal storage diseases and play an important role in tissue damage.

There are three general approaches to the treatment of lysosomal storage diseases. The most obvious is enzyme replacement therapy, currently in use for several of these diseases. Another approach, the “substrate reduction therapy,” is based on the premise that if the substrate to be degraded by the lysosomal enzyme can be reduced, the residual enzyme activity may be sufficient to catabolize it and prevent accumulation. A more recent strategy is based on the understanding of the molecular basis of enzyme deficiency. In many disorders, exemplified by Gaucher disease, the enzyme activity is low because the mutant proteins are unstable and prone to misfolding, and hence degraded in the endoplasmic reticulum. In such diseases an exogenous competitive inhibitor of the enzyme can, paradoxically, bind to the mutant enzyme and act as the “folding template” that assists proper folding of the enzyme and thus prevents its degradation. Such *molecular chaperone therapy* is under active investigation.

Several distinctive and separable conditions are included among the lysosomal storage diseases (Table 5-6). In general, the distribution of the stored material, and hence the organs affected, is determined by two interrelated factors: (1) the tissue where most of the material to be degraded is found and (2) the location where most of the degradation normally occurs. For example, brain is rich in gangliosides, and hence defective hydrolysis of gangliosides, as occurs in GM₁ and GM₂ gangliosidoses, results primarily in accumulation within neurons and consequent neurologic symptoms. Defects in degradation of mucopolysaccharides affect virtually every organ, because mucopolysaccharides are widely distributed in the body. Because cells of the mononuclear phagocyte system are especially rich in lysosomes and are involved in the

Figure 5-10 Pathogenesis of lysosomal storage diseases. In the example shown, a complex substrate is normally degraded by a series of lysosomal enzymes (A, B, and C) into soluble end products. If there is a deficiency or malfunction of one of the enzymes (e.g., B), catabolism is incomplete and insoluble intermediates accumulate in the lysosomes. In addition to this primary storage, secondary storage and toxic effects result from defective autophagy.

Table 5-6 Lysosomal Storage Diseases

Disease	Enzyme Deficiency	Major Accumulating Metabolites
Glycogenosis	Type 2—Pompe disease α -1,4-Glucosidase (lysosomal glucosidase)	Glycogen
Sphingolipidoses		
G_{M1} gangliosidosis Type 1—infantile, generalized Type 2—juvenile	G_{M1} ganglioside β -galactosidase	G_{M1} ganglioside, galactose-containing oligosaccharides
G_{M2} gangliosidosis Tay-Sachs disease Sandhoff disease G_{M2} gangliosidosis variant AB	Hexosaminidase, α subunit Hexosaminidase, β subunit Ganglioside activator protein	G_{M2} ganglioside G_{M2} ganglioside, globoside G_{M2} ganglioside
Sulfatidoses		
Metachromatic leukodystrophy Multiple sulfatase deficiency	Arylsulfatase A Arylsulfatase A, B, C; steroid sulfatase; iduronate sulfatase; heparan <i>N</i> -sulfatase	Sulfatide Sulfatide, steroid sulfate, heparan sulfate, dermatan sulfate
Krabbe disease Fabry disease Gaucher disease Niemann-Pick disease: types A and B	Galactosylceramidase α -Galactosidase A Glucocerebrosidase Sphingomyelinase	Galactocerebroside Ceramide trihexoside Glucocerebroside Sphingomyelin
Mucopolysaccharidoses (MPSs)		
MPS I H (Hurler) MPS II (Hunter)	α -L-Iduronidase L-Iduronosulfate sulfatase	Dermatan sulfate, heparan sulfate
Mucolipidoses (MLs)		
I-cell disease (ML II) and pseudo-Hurler polydystrophy	Deficiency of phosphorylating enzymes essential for the formation of mannose-6-phosphate recognition marker; acid hydrolases lacking the recognition marker cannot be targeted to the lysosomes but are secreted extracellularly	Mucopolysaccharide, glycolipid
Other diseases of complex carbohydrates		
Fucosidosis Mannosidosis Aspartylglycosaminuria	α -Fucosidase α -Mannosidase Aspartylglycosamine amide hydrolase	Fucose-containing sphingolipids and glycoprotein fragments Mannose-containing oligosaccharides Aspartyl-2-deoxy-2-acetamido-glycosylamine
Other lysosomal storage diseases		
Wolman disease Acid phosphate deficiency	Acid lipase Lysosomal acid phosphatase	Cholesterol esters, triglycerides Phosphate esters

degradation of a variety of substrates, organs rich in phagocytic cells, such as the spleen and liver, are frequently enlarged in several forms of lysosomal storage disorders. The ever-expanding number of lysosomal storage diseases can be divided into rational categories based on the biochemical nature of the accumulated metabolite, thus creating such subgroups as the *glycogenoses*, *sphingolipidoses* (*lipidoses*), *mucopolysaccharidoses* (*MPSs*), and *mucolipidoses* (Table 5-6). Only the most common disorders are considered here.

Tay-Sachs Disease (G_{M2} Gangliosidosis: Hexosaminidase α -Subunit Deficiency)

G_{M2} gangliosidoses are a group of three lysosomal storage diseases caused by an inability to catabolize G_{M2} gangliosides. Degradation of G_{M2} gangliosides requires three polypeptides encoded by three distinct genes. The phenotypic effects of mutations affecting these genes are fairly similar, because they result from accumulation of G_{M2} gangliosides. The underlying enzyme defect, however, is different for each. Tay-Sachs disease, the most common form of G_{M2} gangliosidosis, results from mutations in the α -subunit locus on chromosome 15 that cause a severe deficiency of hexosaminidase A. This disease is especially prevalent among Jews, particularly among those of Eastern European (Ashkenazic) origin, in whom a carrier rate of 1 in 30 has been reported.

MORPHOLOGY

The hexosaminidase A is absent from virtually all the tissues, so G_{M2} ganglioside accumulates in many tissues (e.g., heart, liver, spleen, nervous system), but the **involvement of neurons in the central and autonomic nervous systems and retina dominates the clinical picture**. On histologic examination, the neurons are ballooned with cytoplasmic vacuoles, each representing a markedly distended lysosome filled with gangliosides (Fig. 5-11A). Stains for fat such as oil red O and Sudan black B are positive. With the electron microscope, several types of **cytoplasmic inclusions** can be visualized, the most prominent being whorled configurations within lysosomes composed of onion-skin layers of membranes (Fig. 5-11B). In time there is progressive destruction of neurons, proliferation of microglia, and accumulation of complex lipids in phagocytes within the brain substance. A similar process occurs in the cerebellum as well as in neurons throughout the basal ganglia, brain stem, spinal cord, and dorsal root ganglia and in the neurons of the autonomic nervous system. The ganglion cells in the retina are similarly swollen with G_{M2} ganglioside, particularly at the margins of the macula. A **cherry-red spot thus appears in the macula**, representing accentuation of the normal color of the macular choroid contrasted with the pallor produced by the swollen ganglion cells in the remainder of the retina (Chapter 29). This finding is characteristic of Tay-Sachs disease and other storage disorders affecting the neurons.

Figure 5-11 Ganglion cells in Tay-Sachs disease. **A**, Under the light microscope, a large neuron has obvious lipid vacuolation. **B**, A portion of a neuron under the electron microscope shows prominent lysosomes with whorled configurations. Part of the nucleus is shown above. (**A**, Courtesy of Dr. Arthur Weinberg, Department of Pathology, University of Texas Southwestern Medical Center, Dallas, TX. **B**, Electron micrograph courtesy of Dr. Joe Rutledge, University of Texas Southwestern Medical Center, Dallas, TX.)

Clinical Features. The affected infants appear normal at birth but begin to manifest signs and symptoms at about age 6 months. There is relentless motor and mental deterioration, beginning with motor incoordination, mental obtundation leading to muscular flaccidity, blindness, and increasing dementia. Sometime during the early course of the disease, the characteristic, but not pathognomonic, cherry-red spot appears in the macula of the eye in almost all patients. Over the span of 1 or 2 years a complete vegetative state is reached, followed by death at age 2 to 3 years. More than 100 mutations have been described in the α -subunit gene; most affect protein folding. Such misfolded proteins trigger the “unfolded protein” response (Chapter 1) leading to apoptosis. These findings have given rise to the possibility of chaperone therapy of Tay-Sachs disease.

Antenatal diagnosis and carrier detection are possible by enzyme assays and DNA-based analysis. The clinical features of the two other forms of G_{M2} gangliosidosis, Sandhoff disease, resulting from β -subunit defect, and G_{M2} activator deficiency, are similar to those of Tay-Sachs disease.

Niemann-Pick Disease Types A and B

Niemann-Pick disease types A and B are two related disorders that are characterized by lysosomal accumulation of sphingomyelin due to an inherited deficiency of sphingomyelinase. Type A is a severe infantile form with extensive neurologic involvement, marked visceral accumulations of sphingomyelin, and progressive wasting and early death within the first 3 years of life. In contrast, type B disease patients have organomegaly but generally no central nervous system involvement. They usually survive into adulthood. As with Tay-Sachs disease, Niemann-Pick disease types A and B are common in Ashkenazi Jews. The gene for acid sphingomyelinase maps to chromosome 11p15.4 and is one of the imprinted genes that is preferentially expressed from the maternal chromosome as a result of epigenetic silencing of the paternal gene (discussed later). Although, this disease is typically inherited as an autosomal recessive, those heterozygotes who inherit the

mutant allele from the mother can develop Nieman Pick Disease. More than 100 mutations have been found in the acid sphingomyelinase gene and there seems to be a correlation between the type of mutation, the severity of enzyme deficiency, and the phenotype.

MORPHOLOGY

In the classic infantile type A variant, a missense mutation causes almost complete deficiency of sphingomyelinase. Sphingomyelin is a ubiquitous component of cellular (including organellar) membranes, and so the enzyme deficiency blocks degradation of the lipid, resulting in its progressive accumulation within lysosomes, particularly within cells of the mononuclear phagocyte system. **Affected cells become enlarged, sometimes to 90 μm in diameter, due to the distention of lysosomes with sphingomyelin and cholesterol.** Innumerable small vacuoles of relatively uniform size are created, imparting foaminess to the cytoplasm (Fig. 5-12). In frozen sections of fresh tissue, the vacuoles stain for fat. Electron microscopy confirms that the vacuoles are engorged secondary lysosomes that often contain membranous cytoplasmic bodies resembling concentric lamellated myelin figures, sometimes called “zebra” bodies.

The lipid-laden phagocytic foam cells are widely distributed in the spleen, liver, lymph nodes, bone marrow, tonsils, gastrointestinal tract, and lungs. **The involvement of the spleen generally produces massive enlargement,** sometimes to ten times its normal weight, but the hepatomegaly is usually not quite so striking. The lymph nodes are generally moderately to markedly enlarged throughout the body.

Involvement of the brain and eye deserves special mention. In the brain, the gyri are shrunken and the sulci widened. The neuronal involvement is diffuse, affecting all parts of the nervous system. **Vacuolation and ballooning of neurons** constitute the dominant histologic change, which in time leads to cell death and loss of brain substance. A **retinal cherry-red spot** similar to that seen in Tay-Sachs disease is present in about one third to one half of affected individuals.

Figure 5-12 Niemann-Pick disease in liver. The hepatocytes and Kupffer cells have a foamy, vacuolated appearance due to deposition of lipids. (Courtesy of Dr. Arthur Weinberg, Department of Pathology, University of Texas Southwestern Medical Center, Dallas, TX.)

Clinical manifestations in type A disease may be present at birth and almost invariably become evident by age 6 months. Infants typically have a protuberant abdomen because of the hepatosplenomegaly. Once the manifestations appear, they are followed by progressive failure to thrive, vomiting, fever, and generalized lymphadenopathy as well as progressive deterioration of psychomotor function. Death comes, usually within the first or second year of life.

The diagnosis is established by biochemical assays for sphingomyelinase activity in liver or bone marrow biopsy. Individuals affected with types A and B as well as carriers can be detected by DNA analysis.

Niemann-Pick Disease Type C

Although previously considered to be related to types A and B, Niemann-Pick disease type C (NPC) is distinct at the biochemical and genetic levels and is more common than types A and B combined. Mutations in two related genes, *NPC1* and *NPC2*, can give rise to NPC, with *NPC1* being responsible for 95% of cases. Unlike most other storage diseases, NPC is due to a primary defect in non-enzymatic lipid transport. *NPC1* is membrane bound whereas *NPC2* is soluble. Both are involved in the transport of free cholesterol from the lysosomes to the cytoplasm. NPC is clinically heterogeneous. It may present as hydrops fetalis and stillbirth, as neonatal hepatitis, or, most commonly, as a chronic form characterized by progressive neurologic damage. The latter presents in childhood and is marked by ataxia, vertical supranuclear gaze palsy, dystonia, dysarthria, and psychomotor regression.

Gaucher Disease

Gaucher disease refers to a cluster of autosomal recessive disorders resulting from mutations in the gene encoding glucocerebrosidase. It is the most common lysosomal storage disorder. The affected gene encodes glucocerebrosidase, an enzyme that normally cleaves the glucose residue from ceramide. As a result of the enzyme defect, glucocerebroside accumulates principally in phagocytes but in some subtypes also in the central nervous system. Glucocerebrosides are continually formed from the catabo-

lism of glycolipids derived mainly from the cell membranes of senescent leukocytes and red cells. It is clear now that the pathologic changes in Gaucher disease are caused not just by the burden of storage material but also by activation of macrophages and the consequent secretion of cytokines such as IL-1, IL-6, and tumor necrosis factor (TNF).

Three clinical subtypes of Gaucher disease have been distinguished.

- The most common, accounting for 99% of cases, is called type I, or the chronic nonneuropathic form. In this type, storage of glucocerebrosides is limited to the mononuclear phagocytes throughout the body without involving the brain. Splenic and skeletal involvements dominate this pattern of the disease. It is found principally in Jews of European stock. Individuals with this disorder have reduced but detectable levels of glucocerebrosidase activity. Longevity is shortened but not markedly.
- Type II, or acute neuronopathic Gaucher disease, is the infantile acute cerebral pattern. This form has no predilection for Jews. In these patients there is virtually no detectable glucocerebrosidase activity in the tissues. Hepatosplenomegaly is also seen in this form of Gaucher disease, but the clinical picture is dominated by progressive central nervous system involvement, leading to death at an early age.
- A third pattern, type III, is intermediate between types I and II. These patients have the systemic involvement characteristic of type I but have progressive central nervous system disease that usually begins in adolescence or early adulthood.

MORPHOLOGY

Glucocerebrosides accumulate in massive amounts within phagocytic cells throughout the body in all forms of Gaucher disease. The **distended phagocytic cells, known as Gaucher cells, are found in the spleen, liver, bone marrow, lymph nodes, tonsils, thymus, and Peyer patches.** Similar cells may be found in both the alveolar septa and the air spaces in the lung. In contrast to other lipid storage diseases, Gaucher cells rarely appear vacuolated but instead have a fibrillary type of cytoplasm likened to crumpled tissue paper (Fig. 5-13). Gaucher cells are often enlarged, sometimes up to 100 μm in diameter, and have one or more dark, eccentrically placed nuclei. Periodic acid-Schiff staining is usually intensely positive. With the electron microscope **the fibrillary cytoplasm can be resolved as elongated, distended lysosomes,** containing the stored lipid in stacks of bilayers.

In type I disease, the **spleen is enlarged, sometimes up to 10 kg.** The lymphadenopathy is mild to moderate and is body-wide. The accumulation of Gaucher cells in the bone marrow occurs in 70% to 100% of cases of type I Gaucher disease. It produces areas of **bone erosion** that are sometimes small but in other cases sufficiently large to give rise to pathologic fractures. Bone destruction occurs due to the secretion of cytokines by activated macrophages. In patients with cerebral involvement, Gaucher cells are seen in the Virchow-Robin spaces, and arterioles are surrounded by swollen adventitial cells. There is no storage of lipids in the neurons, yet

Figure 5-13 Gaucher disease involving the bone marrow. Gaucher cells (**A**, Wright stain; **B**, Hematoxylin and eosin) are plump macrophages that characteristically have the appearance in the cytoplasm of crumpled tissue paper due to accumulation of glucocerebroside. (Courtesy of Dr. John Anastasi, Department of Pathology, University of Chicago, Chicago, IL.)

neurons appear shriveled and are progressively destroyed. It is suspected that the lipids that accumulate in the phagocytic cells around blood vessels secrete cytokines that damage nearby neurons.

Clinical Features. The clinical course of Gaucher disease depends on the clinical subtype. In type I, symptoms and signs first appear in adult life and are related to splenomegaly or bone involvement. Most commonly there is pancytopenia or thrombocytopenia secondary to hypersplenism. Pathologic fractures and bone pain occur if there has been extensive expansion of the marrow space. Although the disease is progressive in the adult, it is compatible with long life. In types II and III, central nervous system dysfunction, convulsions, and progressive mental deterioration dominate, although organs such as the liver, spleen, and lymph nodes are also affected. The diagnosis of homozygotes can be made by measurement of glucocerebrosidase activity in peripheral blood leukocytes or in

extracts of cultured skin fibroblasts. In principle, heterozygotes can be identified by detection of mutations. However, because more than 150 mutations in the glucocerebroside gene can cause Gaucher disease, currently it is not possible to use a single genetic test. However, with rapid advances in next generation sequencing (discussed later), it is likely that a comprehensive molecular diagnostic test for carriers will soon be developed.

Replacement therapy with recombinant enzymes is the mainstay for treatment of Gaucher disease; it is effective, and those with type I disease can expect normal life expectancy with this form of treatment. However, such therapy is extremely expensive. Because the fundamental defect resides in mononuclear phagocytic cells originating from marrow stem cells, allogeneic hematopoietic stem cell transplantation can be curative. Other work is directed toward correction of the enzyme defect by transfer of the normal glucocerebrosidase gene into the patient's hematopoietic stem cells. Substrate reduction therapy with inhibitors of glucosylceramide synthetase is also being evaluated.

Mucopolysaccharidoses (MPS)

The MPSs are a group of closely related syndromes that result from genetically determined deficiencies of enzymes involved in the degradation of mucopolysaccharides (glycosaminoglycans). Chemically, mucopolysaccharides are long-chain complex carbohydrates that are linked with proteins to form proteoglycans. They are abundant in the ground substance of connective tissue. The glycosaminoglycans that accumulate in MPSs are dermatan sulfate, heparan sulfate, keratan sulfate, and chondroitin sulfate. The enzymes involved in the degradation of these molecules cleave terminal sugars from the polysaccharide chains disposed along a polypeptide or core protein. In the absence of enzymes, these chains accumulate within lysosomes in various tissues and organs of the body.

Several clinical variants of MPS, classified numerically from MPS I to MPS VII, have been described, each resulting from the deficiency of one specific enzyme. All the MPSs except one are inherited as autosomal recessive traits; the exception, *Hunter syndrome*, is an X-linked recessive trait. Within a given group (e.g., MPS I, characterized by a deficiency of α -L-iduronidase), subgroups exist that result from different mutant alleles at the same genetic locus. Thus, the severity of enzyme deficiency and the clinical picture even within subgroups are often different.

In general, MPSs are progressive disorders, characterized by *coarse facial features, clouding of the cornea, joint stiffness, and mental retardation*. Urinary excretion of the accumulated mucopolysaccharides is often increased.

MORPHOLOGY

The accumulated **mucopolysaccharides are generally found in mononuclear phagocytic cells, endothelial cells, intimal smooth muscle cells, and fibroblasts** throughout the body. Common sites of involvement are thus the spleen, liver, bone marrow, lymph nodes, blood vessels, and heart.

Microscopically, affected cells are distended and have apparent clearing of the cytoplasm to create so-called balloon cells.

Under the electron microscope, the clear cytoplasm can be resolved as numerous minute vacuoles. These are swollen lysosomes containing a finely granular periodic acid–Schiff–positive material that can be identified biochemically as mucopolysaccharide. Similar lysosomal changes are found in the neurons of those syndromes characterized by central nervous system involvement. In addition, however, some of the lysosomes in neurons are replaced by lamellated zebra bodies similar to those seen in Niemann–Pick disease. **Hepatosplenomegaly, skeletal deformities, valvular lesions, and subendothelial arterial deposits, particularly in the coronary arteries, and lesions in the brain are common threads that run through all of the MPSs.** In many of the more protracted syndromes, coronary subendothelial lesions lead to myocardial ischemia. Thus, myocardial infarction and cardiac decompensation are important causes of death.

Clinical Features. Of the seven recognized variants, only two well-characterized syndromes are described briefly here. *Hurler syndrome*, also called MPS I-H, results from a deficiency of α -L-iduronidase. It is one of the most severe forms of MPS. Affected children appear normal at birth but develop hepatosplenomegaly by age 6 to 24 months. Their growth is retarded, and, as in other forms of MPS, they develop coarse facial features and skeletal deformities. Death occurs by age 6 to 10 years and is often due to cardiovascular complications. *Hunter syndrome*, also called MPS II, differs from Hurler syndrome in mode of inheritance (X-linked), absence of corneal clouding, and milder clinical course.

KEY CONCEPTS

Lysosomal Storage Diseases

Inherited mutations leading to defective lysosomal enzyme functions gives rise to accumulation and storage of complex substrates in the lysosomes and defects in autophagy resulting in cellular injury.

- **Tay-Sachs disease** is caused by an inability to metabolize G_{M2} gangliosides due to lack of the α subunit of lysosomal hexosaminidase. G_{M2} gangliosides accumulate in the central nervous system and cause severe mental retardation, blindness, motor weakness, and death by 2 to 3 years of age.
- **Niemann-Pick disease types A and B** are caused by a deficiency of sphingomyelinase. In the more severe type A variant, accumulation of sphingomyelin in the nervous system results in neuronal damage. Lipid also is stored in phagocytes within the liver, spleen, bone marrow, and lymph nodes, causing their enlargement. In type B, neuronal damage is not present.
- **Niemann-Pick disease type C** is caused by a defect in cholesterol transport and resultant accumulation of cholesterol and gangliosides in the nervous system. Affected children most commonly exhibit ataxia, dysarthria, and psychomotor regression.
- **Gaucher disease** results from lack of the lysosomal enzyme glucocerebrosidase and accumulation of glucocerebroside in mononuclear phagocytic cells. In the most common, type I variant, affected phagocytes become

enlarged (Gaucher cells) and accumulate in liver, spleen, and bone marrow, causing hepatosplenomegaly and bone erosion. Types II and III are characterized by variable neuronal involvement.

- **Mucopolysaccharidoses** result in accumulation of mucopolysaccharides in many tissues including liver, spleen, heart, blood vessels, brain, cornea, and joints. Affected patients in all forms have coarse facial features. Manifestations of Hurler syndrome include corneal clouding, coronary arterial and valvular deposits, and death in childhood. Hunter syndrome is associated with a milder clinical course.

Glycogen Storage Diseases (Glycogenoses)

The glycogen storage diseases result from a hereditary deficiency of one of the enzymes involved in the synthesis or sequential degradation of glycogen. Depending on the tissue or organ distribution of the specific enzyme in the normal state, glycogen storage in these disorders may be limited to a few tissues, may be more widespread while not affecting all tissues, or may be systemic in distribution.

The significance of a specific enzyme deficiency is best understood from the perspective of the normal metabolism of glycogen (Fig. 5-14). Glycogen is a storage form of glucose. Glycogen synthesis begins with the conversion of glucose to glucose-6-phosphate by the action of a hexokinase (glucokinase). A phosphoglucomutase then transforms the glucose-6-phosphate to glucose-1-phosphate, which, in turn, is converted to uridine diphosphoglucose. A highly branched, large polymer is then built (molecular weight as high as 100 million), containing as many as 10,000 glucose molecules linked together by α -1,4-glycoside bonds. The glycogen chain and branches continue to be elongated by the addition of glucose molecules mediated by glycogen synthetases. During degradation, distinct phosphorylases in the liver and muscle split glucose-1-phosphate from the glycogen until about four glucose residues remain on each branch, leaving a branched oligosaccharide called *limit dextrin*. This can be further degraded only by the debranching enzyme. In addition to these major pathways, glycogen is also degraded in the lysosomes by acid maltase. If the lysosomes are deficient in this enzyme, the glycogen contained within them is not accessible to degradation by cytoplasmic enzymes such as phosphorylases.

On the basis of specific enzyme deficiencies and the resultant clinical pictures, glycogenoses have traditionally been divided into a dozen or so syndromes designated by roman numerals, and the list continues to grow. On the basis of pathophysiology glycogenoses can be divided into three major subgroups (Table 5-7):

- **Hepatic forms.** The liver is a key player in glycogen metabolism. It contains enzymes that synthesize glycogen for storage and ultimately break it down into free glucose, which is then released into the blood. An inherited deficiency of hepatic enzymes that are involved in glycogen degradation therefore leads not only to the storage of glycogen in the liver but also to a reduction in blood glucose concentrations (hypoglycemia) (Fig. 5-15). Deficiency of the enzyme glucose-6-phosphatase

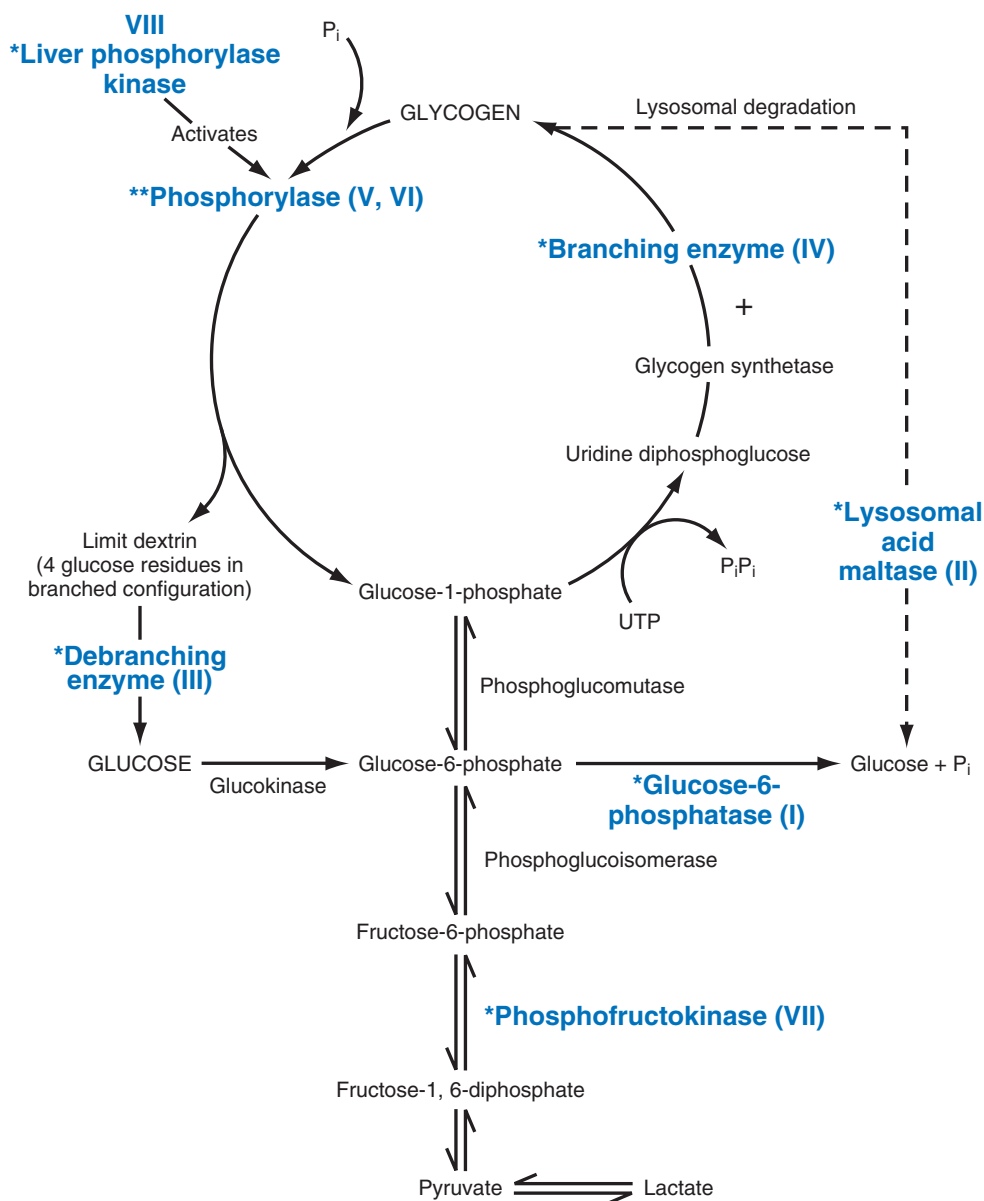

Figure 5-14 Pathways of glycogen metabolism. Asterisks mark the enzyme deficiencies associated with glycogen storage diseases. Roman numerals indicate the type of glycogen storage disease associated with the given enzyme deficiency. Types V and VI result from deficiencies of muscle and liver phosphorylases, respectively. (Modified from Hers H, et al: Glycogen storage diseases. In Scriver CR, et al [eds]: *The Metabolic Basis of Inherited Disease*, 6th ed. New York, McGraw-Hill, 1989, p 425.)

(von Gierke disease, or type I glycogenosis) is a prime example of the hepatic-hypoglycemic form of glycogen storage disease (Table 5-7). Other examples include deficiencies of liver phosphorylase and debranching enzyme, both involved in the breakdown of glycogen (Fig. 5-15). In all these disorders glycogen is stored in many organs, but *hepatic enlargement and hypoglycemia dominate the clinical picture*.

- *Myopathic forms*. In the skeletal muscles, as opposed to the liver, glycogen is used predominantly as a source of energy during physical activity. ATP is generated by glycolysis, which leads ultimately to the formation of lactate (Fig. 5-16). If the enzymes that fuel the glycolytic pathway are deficient, glycogen storage occurs in the muscles and is associated with muscular weakness due to impaired energy production. Examples in

this category include deficiencies of muscle phosphorylase (McArdle disease, or type V glycogenosis), muscle phosphofructokinase (type VII glycogen storage disease), and several others. *Typically, individuals with the myopathic forms present with muscle cramps after exercise and lactate levels in the blood fail to rise after exercise due to a block in glycolysis*.

- *Glycogen storage diseases associated with (1) deficiency of α -glucosidase (acid maltase) and (2) lack of branching enzyme* do not fit into the hepatic or myopathic categories. They are associated with glycogen storage in many organs and death early in life. Acid maltase is a lysosomal enzyme, and hence its deficiency leads to lysosomal storage of glycogen (type II glycogenosis, or *Pompe disease*) in all organs, but *cardiomegaly is the most prominent feature* (Fig. 5-16).

Table 5-7 Principal Subgroups of Glycogenoses

Clinicopathologic Category	Specific Type	Enzyme Deficiency	Morphologic Changes	Clinical Features
Hepatic type	Hepatorenal—von Gierke disease (type I)	Glucose-6-phosphatase	Hepatomegaly—intracytoplasmic accumulations of glycogen and small amounts of lipid; intranuclear glycogen Renomegaly—intracytoplasmic accumulations of glycogen in cortical tubular epithelial cells	In untreated patients: failure to thrive, stunted growth, hepatomegaly, and renomegaly Hypoglycemia due to failure of glucose mobilization, often leading to convulsions Hyperlipidemia and hyperuricemia resulting from deranged glucose metabolism; many patients develop gout and skin xanthomas Bleeding tendency due to platelet dysfunction With treatment: Most survive and develop late complications (e.g., hepatic adenomas)
Myopathic type	McArdle disease (type V)	Muscle phosphorylase	Skeletal muscle only—accumulations of glycogen predominant in subsarcolemmal location	Painful cramps associated with strenuous exercise; myoglobinuria occurs in 50% of cases; onset in adulthood (>20 years); muscular exercise fails to raise lactate level in venous blood; serum creatine kinase always elevated; compatible with normal longevity
Miscellaneous types	Generalized glycogenosis—Pompe disease (type II)	Lysosomal glucosidase (acid maltase)	Mild hepatomegaly—ballooning of lysosomes with glycogen, creating lacy cytoplasmic pattern Cardiomegaly—glycogen within sarcoplasm as well as membrane-bound Skeletal muscle—similar to changes in heart	Massive cardiomegaly, muscle hypotonia, and cardiorespiratory failure within 2 years; a milder adult form with only skeletal muscle involvement, presenting with chronic myopathy; enzyme replacement therapy available

Figure 5-15 **A**, Normal glycogen metabolism in the liver and skeletal muscles. **B**, Effects of an inherited deficiency of hepatic enzymes involved in glycogen metabolism. **C**, Consequences of a genetic deficiency in the enzymes that metabolize glycogen in skeletal muscles.

KEY CONCEPTS

Glycogen Storage Diseases

- Inherited deficiency of enzymes involved in glycogen metabolism can result in storage of normal or abnormal forms of glycogen, predominantly in liver or muscles, but also in other tissues as well.
- In the **hepatic form** (von Gierke disease), liver cells store glycogen because of a lack of hepatic glucose-6-phosphatase. There are several **myopathic forms**, including McArdle disease, in which muscle phosphorylase lack gives rise to storage in skeletal muscles and cramps after exercise. In **Pompe disease** there is lack of lysosomal acid maltase, and all organs are affected, but heart involvement is predominant.

Disorders Associated with Defects in Proteins That Regulate Cell Growth

Normal growth and differentiation of cells are regulated by two classes of genes; proto-oncogenes and tumor suppressor genes, whose products promote or restrain cell growth (Chapter 7). It is now well established that mutations in these two classes of genes are important in the pathogenesis of tumors. In the vast majority of cases, cancer-causing mutations affect somatic cells and hence are not passed in the germ line. In approximately 5% of all cancers, however, mutations transmitted through the germ line contribute to the development of cancer. Most familial cancers are inherited in an autosomal dominant fashion, but a few recessive disorders have also been described. This subject is discussed in Chapter 7. Specific forms of familial tumors are described in various chapters.

(Courtesy of Dr. Trace Worrell, Department of Pathology, University of Texas Southwestern Medical Center, Dallas, TX.)

Complex Multigenic Disorders

As discussed previously, such disorders are caused by interactions between variant forms of genes and environmental factors. A gene that has at least two alleles, each of which occurs at a frequency of at least 1% in the population, is polymorphic, and each variant allele is referred to as a polymorphism. According to the common disease/common variant hypothesis, complex genetic disorders occur when many polymorphisms, each with a modest effect and low penetrance, are co-inherited. Two additional facts that have emerged from studies of common complex disorders, such as type 1 diabetes, are:

- While complex disorders result from the collective inheritance of many polymorphisms, different polymorphisms vary in significance. For example, of the 20 to 30 genes implicated in type 1 diabetes, six to seven are most important, and a few HLA-alleles contribute more than 50% of the risk (Chapter 24).
- Some polymorphisms are common to multiple diseases of the same type, while others are disease specific. This is best illustrated in immune-mediated inflammatory diseases (Chapter 6).

Several normal phenotypic characteristics are governed by multifactorial inheritance, such as hair color, eye color, skin color, height, and intelligence. These characteristics show a continuous variation in population groups, producing the standard bell-shaped curve of distribution. Environmental influences, however, significantly modify the phenotypic expression of complex traits. For example, type 2 diabetes mellitus has many of the features of a multifactorial disorder. It is well recognized that individuals often first manifest this disease after weight gain. Thus, obesity as well as other environmental influences unmasks the diabetic genetic trait. Nutritional influences may cause even monozygous twins to achieve different heights. The culturally deprived child cannot achieve his or her full intellectual capacity.

Assigning a disease to this mode of inheritance must be done with caution. It depends on many factors but first on familial clustering and the exclusion of Mendelian and chromosomal modes of transmission. A range of levels of severity of a disease is suggestive of a complex multigenic disorder, but, as pointed out earlier, variable expressivity and reduced penetrance of single mutant genes may also account for this phenomenon. Because of these problems, sometimes it is difficult to distinguish between Mendelian and multifactorial disease.

Chromosomal Disorders

Normal Karyotype

As you will remember, human somatic cells contain 46 chromosomes; these comprise 22 homologous pairs of autosomes and two sex chromosomes, XX in the female and XY in the male. The study of chromosomes—*karyotyping*—is the basic tool of the cytogeneticist. The usual procedure to examine chromosomes is to arrest dividing cells in metaphase with mitotic spindle inhibitors (e.g., *N*-diacetyl-*N*-methylcolchicine [Colcemid]) and then to stain the chromosomes. In a metaphase spread, the individual chromosomes take the form of two chromatids connected at the centromere. A karyotype is obtained by arranging each pair of autosomes according to length, followed by sex chromosomes.

A variety of staining methods have been developed that allow identification of individual chromosomes on the basis of a distinctive and reliable pattern of alternating light and dark bands. The one most commonly used involves a Giemsa stain and is hence called *G banding*. A normal male karyotype with G banding is illustrated in Figure 5-17. With standard G banding, approximately 400 to 800 bands per haploid set can be detected. The resolution obtained by banding can be markedly improved by obtaining the cells in prophase. The individual chromosomes appear markedly elongated, and as many as 1500 bands

Figure 5-17 G-banded karyotype from a normal male (46,XY). Also shown is the banding pattern of the X-chromosome with nomenclature of arms, regions, bands, and sub-bands. (Courtesy of Dr. Stuart Schwartz, Department of Pathology, University of Chicago, Chicago, IL.)

per karyotype can be recognized. The use of these banding techniques permits certain identification of each chromosome and roughly delineates breakpoints and other gross alterations (described later).

Commonly Used Cytogenetic Terminology

Karyotypes are usually described using a shorthand system of notations in the following order: total number of chromosomes is given first, followed by the sex chromosome complement, and finally the description of abnormalities in ascending numerical order. For example, a male with trisomy 21 is designated 47,XY,+21. Notations denoting structural alterations of chromosomes and their corresponding abnormalities are described later.

The short arm of a chromosome is designated *p* (for *petit*), and the long arm is referred to as *q* (the next letter of the alphabet). In a banded karyotype, each arm of the chromosome is divided into two or more regions bordered by prominent bands. The regions are numbered (e.g., 1, 2, 3) from the centromere outward. Each region is further subdivided into bands and sub-bands, and these are ordered numerically as well (Fig. 5-17). Thus, the notation *Xp21.2* refers to a chromosomal segment located on the short arm of the X chromosome, in region 2, band 1, and sub-band 2.

Structural Abnormalities of Chromosomes

The aberrations underlying cytogenetic disorders may take the form of an abnormal number of chromosomes or alterations in the structure of one or more chromosomes. The normal chromosome complement is expressed

as 46,XX for the female and 46,XY for the male. Any exact multiple of the haploid number of chromosomes (23) is called *euploid*. If an error occurs in meiosis or mitosis and a cell acquires a chromosome complement that is not an exact multiple of 23, it is referred to as *aneuploidy*. The usual causes for aneuploidy are *nondisjunction* and *anaphase lag*. When nondisjunction occurs during gametogenesis, the gametes formed have either an extra chromosome ($n + 1$) or one less chromosome ($n - 1$). Fertilization of such gametes by normal gametes results in two types of zygotes—trisomic ($2n + 1$) or monosomic ($2n - 1$). In anaphase lag, one homologous chromosome in meiosis or one chromatid in mitosis lags behind and is left out of the cell nucleus. The result is one normal cell and one cell with monosomy. As seen subsequently, monosomy or trisomy involving the sex chromosomes, or even more bizarre aberrations, are compatible with life and are usually associated with variable degrees of phenotypic abnormalities. **Monosomy involving an autosome generally causes loss of too much genetic information to permit live birth or even embryogenesis, but several autosomal trisomies do permit survival.** With the exception of trisomy 21, all yield severely handicapped infants who almost invariably die at an early age.

Occasionally, *mitotic errors in early development give rise to two or more populations of cells with different chromosomal complement, in the same individual*, a condition referred to as *mosaicism*. Mosaicism can result from mitotic errors during the cleavage of the fertilized ovum or in somatic cells. Mosaicism affecting the sex chromosomes is relatively common. In the division of the fertilized ovum, an error may lead to one of the daughter cells receiving three sex

chromosomes, whereas the other receives only one, yielding, for example, a 45,X/47,XXX mosaic. All descendant cells derived from each of these precursors thus have either a 47,XXX complement or a 45,X complement. Such a patient is a mosaic variant of Turner syndrome, with the extent of phenotypic expression dependent on the number and distribution of the 45,X cells.

Autosomal mosaicism seems to be much less common than that involving the sex chromosomes. An error in an early mitotic division affecting the autosomes usually leads to a nonviable mosaic due to autosomal monosomy. Rarely, the nonviable cell population is lost during embryogenesis, yielding a viable mosaic (e.g., 46,XY/47,XY,+21). Such a patient is a trisomy 21 mosaic with variable expression of Down syndrome, depending on the proportion of cells containing the trisomy.

A second category of chromosomal aberrations is associated with changes in the structure of chromosomes. To be visible by routine banding techniques, a fairly large amount of DNA (approximately 2 to 4 million base pairs), containing many genes, must be involved. The resolution is much higher with fluorescence in situ hybridization (FISH), which can detect changes as small as kilobases. Structural changes in chromosomes usually result from chromosome breakage followed by loss or rearrangement of material. In the next section the more common forms of alterations in chromosome structure and the notations used to signify them are reviewed.

Deletion refers to loss of a portion of a chromosome (Fig. 5-18). Most deletions are interstitial, but rarely terminal deletions may occur. Interstitial deletions occur when there are two breaks within a chromosome arm, followed by loss of the chromosomal material between the breaks and fusion of the broken ends. One can specify in which regions

and at what bands the breaks have occurred. For example, 46,XY,del(16)(p11.2p13.1) describes breakpoints in the short arm of chromosome 16 at 16p11.2 and 16p13.1 with loss of material between breaks. Terminal deletions result from a single break in a chromosome arm, producing a fragment with no centromere, which is then lost at the next cell division, and a chromosome bearing a deletion. The end of the chromosome is protected by acquiring telomeric sequences.

A *ring chromosome* is a special form of deletion. It is produced when a break occurs at both ends of a chromosome with fusion of the damaged ends (Fig. 5-18). If significant genetic material is lost, phenotypic abnormalities result. This might be expressed as 46,XY,r(14). Ring chromosomes do not behave normally in meiosis or mitosis and usually result in serious consequences.

Inversion refers to a rearrangement that involves two breaks within a single chromosome with reincorporation of the inverted, intervening segment (Fig. 5-18). An inversion involving only one arm of the chromosome is known as *paracentric*. If the breaks are on opposite sides of the centromere, it is known as *pericentric*. Inversions are often fully compatible with normal development.

Isochromosome formation results when one arm of a chromosome is lost and the remaining arm is duplicated, resulting in a chromosome consisting of two short arms only or of two long arms (Fig. 5-18). An isochromosome has morphologically identical genetic information in both arms. The most common isochromosome present in live births involves the long arm of the X and is designated *i(X)(q10)*. The Xq isochromosome is associated with monosomy for genes on the short arm of X and with trisomy for genes on the long arm of X.

In a *translocation*, a segment of one chromosome is transferred to another (Fig. 5-18). In one form, called *balanced*

Figure 5-18 Types of chromosomal rearrangements.

reciprocal translocation, there are single breaks in each of two chromosomes, with exchange of material. A balanced reciprocal translocation between the long arm of chromosome 2 and the short arm of chromosome 5 would be written $46,XX,t(2;5)(q31;p14)$. This individual has 46 chromosomes with altered morphology of one of the chromosomes 2 and one of the chromosomes 5. Because there has been no loss of genetic material, the individual is likely to be phenotypically normal. A balanced translocation carrier, however, is at increased risk for producing abnormal gametes. For example, in the case cited earlier, a gamete containing one normal chromosome 2 and a translocated chromosome 5 may be formed. Such a gamete would be unbalanced because it would not contain the normal complement of genetic material. Subsequent fertilization by a normal gamete would lead to the formation of an abnormal (unbalanced) zygote, resulting in spontaneous abortion or birth of a malformed child. The other important pattern of translocation is called a *robertsonian translocation* (or centric fusion), a translocation between two acrocentric chromosomes. Typically the breaks occur close to the centromeres of each chromosome. Transfer of the segments then leads to one very large chromosome and one extremely small one. Usually the small product is lost (Fig. 5-18); however, because it carries only highly redundant genes (e.g., ribosomal RNA genes), this loss is compatible with a normal phenotype. Robertsonian translocation between two chromosomes is encountered in 1 in 1000 apparently normal individuals. The significance of this form of translocation also lies in the production of abnormal progeny, as discussed later with Down syndrome.

Many more numerical and structural chromosomal aberrations are described in specialized texts, and more and more abnormal karyotypes are being identified in disease. As pointed out earlier, the clinically detected chromosome disorders represent only the “tip of the iceberg.” It is estimated that approximately 7.5% of all conceptions have a chromosomal abnormality, most of which are not compatible with survival or live birth. Even in live-born infants the frequency is approximately 0.5% to 1.0%. It is beyond the scope of this book to discuss most of the clinically recognizable chromosomal disorders. Hence, we focus attention on those few that are most common.

Cytogenetic Disorders Involving Autosomes

Trisomy 21 (Down Syndrome)

Down syndrome is the most common of the chromosomal disorders and is a major cause of mental retardation. In the United States the incidence in newborns is about 1 in 700. Approximately 95% of affected individuals have trisomy 21, so their chromosome count is 47. FISH with chromosome 21-specific probes reveals the extra copy of chromosome 21 in such cases (Fig. 5-19). Most others have normal chromosome numbers, but the extra chromosomal material is present as a translocation. As mentioned earlier, the most common cause of trisomy and therefore of Down syndrome is meiotic nondisjunction. The parents of such children have a normal karyotype and are normal in all respects.

Maternal age has a strong influence on the incidence of trisomy 21. It occurs once in 1550 live births in women

Figure 5-19 Fluorescence in situ hybridization analysis of an interphase nucleus using locus-specific probes to chromosome 13 (green) and chromosome 21 (red), revealing three red signals consistent with trisomy 21. (Courtesy of Dr. Stuart Schwartz, Department of Pathology, University of Chicago, Chicago, IL.)

under age 20, in contrast to 1 in 25 live births for mothers older than age 45. The correlation with maternal age suggested that most cases the meiotic nondisjunction of chromosome 21 occurs in the ovum. Indeed, studies in which DNA polymorphisms were used to trace the parental origin of chromosome 21 have revealed that in 95% of the cases with trisomy 21 the extra chromosome is of maternal origin. Although many hypotheses have been advanced, the reason for the increased susceptibility of the ovum to nondisjunction remains unknown.

In about 4% of cases of Down syndrome, the extra chromosomal material derives from the presence of a robertsonian translocation of the long arm of chromosome 21 to another acrocentric chromosome (e.g., 22 or 14). Because the fertilized ovum already possesses two normal autosomes 21, the translocated material provides the same triple gene dosage as in trisomy 21. Such cases are frequently (but not always) familial, and the translocated chromosome is inherited from one of the parents (usually the mother), who is a carrier of a robertsonian translocation, for example, a mother with karyotype $45,XX,der(14;21)(q10;q10)$. In cells with robertsonian translocations, the genetic material normally found on two pairs of chromosomes is distributed among only three chromosomes. This affects chromosome pairing during meiosis, and as a result the gametes have a high probability of being aneuploid.

Approximately 1% of Down syndrome patients are mosaics, having a mixture of cells with 46 or 47 chromosomes. This mosaicism results from mitotic nondisjunction of chromosome 21 during an early stage of embryogenesis. Symptoms in such cases are variable and milder, depending on the proportion of abnormal cells. Clearly, in cases of translocation or mosaic Down syndrome, maternal age is of no importance.

The diagnostic clinical features of this condition—flat facial profile, oblique palpebral fissures, and epicanthic folds (Fig. 5-20)—are usually readily evident, even at

Figure 5-20 Clinical features and karyotypes of selected autosomal trisomies.

birth. Down syndrome is a leading cause of severe mental retardation; approximately 80% of those afflicted have an IQ of 25 to 50. While intellectually disadvantaged, these children typically have a gentle, shy manner and often seem more content with life than their normal siblings. It should be pointed out that some mosaics with Down syndrome have mild phenotypic changes and may even have normal or near-normal intelligence. In addition to the phenotypic abnormalities and the mental retardation already noted, some other clinical features are worthy of note.

- *Approximately 40% of the patients have congenital heart disease*, most commonly defects of the endocardial cushion, including ostium primum, atrial septal defects, atrioventricular valve malformations, and ventricular septal defects. Cardiac problems are responsible for the majority of the deaths in infancy and early childhood. Several other congenital malformations, including atresias of the esophagus and small bowel, are also common.
- *Children with trisomy 21 have a 10-fold to 20-fold increased risk of developing acute leukemia.* Both acute lymphoblastic leukemias and acute myeloid leukemias occur. The latter, most commonly, is acute megakaryoblastic leukemia.
- Virtually all patients with trisomy 21 older than age 40 develop *neuropathologic changes* characteristic of Alzheimer disease, a degenerative disorder of the brain.
- Patients with Down syndrome have *abnormal immune responses that predispose them to serious infections*, particularly of the lungs, and to thyroid autoimmunity. Although several abnormalities, affecting mainly T-cell functions, have been reported, the basis of immunologic disturbances is not clear.

Despite all these problems, improved medical care has increased the longevity of individuals with trisomy 21. Currently the median age at death is 47 years (up from 25 years in 1983).

Although the karyotype and clinical features of trisomy 21 have been known for decades, little is known about the molecular basis of Down syndrome. Based on study of humans with partial trisomy of chromosome 21 and mouse models of trisomy, the critical region of human chromosome 21 that is involved in the pathogenesis has been identified. Based on these studies, several gene clusters, each of which is predicted to participate in the same biologic pathway, have been implicated. For example, 16 genes are involved in the mitochondrial energy pathway; several are likely to influence central nervous system development and one group is involved in folate metabolism. It is not known how each of these groups of genes is related to Down syndrome. The gene dosage hypothesis assumes that the phenotypic features of the trisomy 21 are related to overexpression of genes. In reality only about 37% of the genes on chromosomes 21 are overexpressed by 150%, whereas others have variable degrees of changes in expression. Further complexity in defining the specific genes involved in the pathogenesis of Down syndrome is related to the presence of several miRNA genes on chromosome 21 that can shut down translation of genes that map elsewhere in the genome. Thus, despite the availability of the gene map of chromosome 21, the progress in understanding the molecular basis of Down syndrome remains slow.

Much progress is being made in the molecular diagnosis of Down syndrome prenatally. Approximately 5% to 10% of the total cell free DNA in maternal blood is derived from the fetus and can be identified by polymorphic genetic markers. By using next generation sequencing the gene dosage of chromosome 21 linked genes in fetal DNA can be determined with great precision. This is emerging as a powerful noninvasive method for prenatal diagnosis of trisomy 21 as well as other trisomies.

Other Trisomies

A variety of other trisomies involving chromosomes 8, 9, 13, 18, and 22 have been described. Only trisomy 18 (Edwards syndrome) and trisomy 13 (Patau syndrome) are common enough to merit brief mention here. As noted in [Figure 5-20](#), they share several karyotypic and clinical features with trisomy 21. Thus, most cases result from meiotic nondisjunction and therefore carry a complete extra copy of chromosome 13 or 18. As in Down syndrome, an association with increased maternal age is also noted. In contrast to trisomy 21, however, the malformations are much more severe and wide ranging. As a result, only rarely do infants survive beyond the first year of life. Most succumb within a few weeks to months.

Chromosome 22q11.2 Deletion Syndrome

Chromosome 22q11.2 deletion syndrome encompasses a spectrum of disorders that result from a small deletion of band q11.2 on the long arm of chromosome 22. The syndrome is fairly common, occurring in as many as 1 in 4000 births, but it is often missed because of variable clinical features. These include *congenital heart defects, abnormalities of the palate, facial dysmorphism, developmental delay, and variable degrees of T-cell immunodeficiency and hypocalcemia*. Previously, these clinical features were considered to represent two different disorders—*DiGeorge syndrome* and *velocardiofacial syndrome*.

Patients with DiGeorge syndrome have thymic hypoplasia, with resultant T-cell immunodeficiency ([Chapter 6](#)), parathyroid hypoplasia giving rise to hypocalcemia, a variety of cardiac malformations affecting the outflow tract, and mild facial anomalies. The clinical features of the so-called velocardiofacial syndrome include facial dysmorphism (prominent nose, retrognathia), cleft palate, cardiovascular anomalies, and learning disabilities. Less frequently, these patients also have immunodeficiency.

Until recently the overlapping clinical features of these two conditions (e.g., cardiac malformations, facial dysmorphism) were not appreciated; it was only after these two apparently unrelated syndromes were found to be associated with a similar cytogenetic abnormality that the clinical overlap came into focus. Recent studies indicate that, in addition to the numerous structural malformations, individuals with the 22q11.2 deletion syndrome are at a particularly high risk for psychotic illnesses, such as *schizophrenia and bipolar disorders*. In fact, it is estimated that *schizophrenia develops in approximately 25% of adults with this syndrome*. Conversely, deletions of the region can be found in 2% to 3% of individuals with childhood-onset schizophrenia. In addition, attention deficit hyperactivity disorder is seen in 30% to 35% of affected children.

The diagnosis of this condition may be suspected on clinical grounds but can be established only by detection

Figure 5-21 Fluorescence in situ hybridization of both metaphase chromosomes and an interphase cell from a patient with DiGeorge syndrome demonstrating the deletion of a probe that maps to chromosome 22q11.2. The 22q11.2 probe is in red, and the control probe, localized to 22q, is in green. The metaphase spread shows one chromosome 22 with both a green signal (control probe) and a red signal (from the 22q11.2 probe). The other chromosome 22 shows only hybridization with the control probe (green), but no red 22q11.2 signal since there is a deletion on this chromosome. The interphase cell also shows a hybridization pattern consistent with a deletion of chromosome 22q11.2. (Courtesy of Dr. Stuart Schwartz, Department of Pathology, University of Chicago, Chicago, IL.)

of the deletion by FISH (Fig. 5-21). By this test, approximately 90% of those previously diagnosed as having DiGeorge syndrome and 80% of those with the velocardiofacial syndrome have a deletion of 22q11.2. Thirty percent of individuals with conotruncal cardiac defects but no other features of this syndrome also reveal deletions of the same chromosomal region.

The molecular basis of this syndrome is not fully understood. The deleted region is large (approximately 1.5 megabases) and includes many genes. The clinical heterogeneity, with predominant immunodeficiency in some cases (DiGeorge syndrome) and predominant dysmorphism and cardiac malformations in other cases, probably reflects the variable position and size of the deleted segment from this genetic region. Approximately 30 candidate genes have been mapped to the deleted region. Among these, *TBX1*, a T-box transcription factor is most closely associated with the phenotypic features of this syndrome. This gene is expressed in the pharyngeal mesenchyme and endodermal pouch from which facial structures, thymus, and parathyroid are derived. The targets of *TBX1* include *PAX9*, a gene that controls the development of the palate, parathyroids, and thymus. Clearly there are other genes that contribute to the behavioral and psychiatric disorders that remain to be identified.

KEY CONCEPTS

Cytogenetic Disorders Involving Autosomes

- **Down syndrome** is associated with an extra copy of genes on chromosome 21, most commonly due to trisomy 21 and less frequently from translocation of extra chromo-

somal material from chromosome 21 to other chromosomes or from mosaicism.

- Patients with Down syndrome have severe mental retardation, flat facial profile, epicanthic folds, cardiac malformations, higher risk of leukemia and infections, and premature development of Alzheimer disease.
- Deletion of genes at chromosomal locus 22q11.2 gives rise to malformations affecting the face, heart, thymus, and parathyroids. The resulting disorders are recognized as
 - **DiGeorge syndrome** (thymic hypoplasia with diminished T-cell immunity and parathyroid hypoplasia with hypocalcemia) and
 - **Velocardiofacial syndrome** (congenital heart disease involving outflow tracts, facial dysmorphism, and developmental delay).

Cytogenetic Disorders Involving Sex Chromosomes

Genetic diseases associated with changes involving the sex chromosomes are far more common than those related to autosomal aberrations. Furthermore, imbalances (excess or loss) of sex chromosomes are much better tolerated than are similar imbalances of autosomes. In large part, this latitude relates to two factors that are peculiar to the sex chromosomes: (1) lyonization or inactivation of all but one X chromosome and (2) the modest amount of genetic material carried by the Y chromosome. These features are discussed briefly in relation to sex chromosomal disorders.

In 1961, Lyon outlined the idea of X-inactivation, now commonly known as the Lyon hypothesis. It states that (1) *only one of the X chromosomes is genetically active*, (2) *the other X of either maternal or paternal origin undergoes heteropyknosis and is rendered inactive*, (3) *inactivation of either the maternal or paternal X occurs at random among all the cells of the blastocyst on or about day 5.5 of embryonic life*, and (4) *inactivation of the same X chromosome persists in all the cells derived from each precursor cell*. Thus, the great preponderance of normal females are in reality mosaics and have two populations of cells, one with an inactivated maternal X and the other with an inactivated paternal X. Herein lies the explanation of why females have the same dosage of X-linked active genes as have males. The inactive X can be seen in the interphase nucleus as a darkly staining small mass in contact with the nuclear membrane known as the Barr body, or X chromatin. The molecular basis of X inactivation involves a unique gene called *XIST*, whose product is a long noncoding RNA (Chapter 1) that is retained in the nucleus, where it “coats” the X chromosome that it is transcribed from and initiates a gene-silencing process by chromatin modification and DNA methylation. The *XIST* allele is switched off in the active X.

Although it was initially thought that all the genes on the inactive X are “switched off,” more recent studies have revealed that many genes escape X inactivation. Molecular studies suggest that 21% of genes on Xp, and a smaller number (3%) on Xq escape X inactivation. At least some of the genes that are expressed from both X chromosomes are important for normal growth and development. This notion is supported by the fact that patients with monosomy of

the X chromosome (Turner syndrome: 45,X) have severe somatic and gonadal abnormalities. If a single dose of X-linked genes were sufficient, no detrimental effect would be expected in such cases. Furthermore, although one X chromosome is inactivated in all cells during embryogenesis, it is selectively reactivated in oogonia before the first meiotic division. Thus, it seems that both X chromosomes are required for normal oogenesis.

With respect to the Y chromosome, it is well known that this chromosome is both necessary and sufficient for male development. **Regardless of the number of X chromosomes, the presence of a single Y determines the male sex.** The gene that dictates testicular development (*SRY*: sex-determining region Y gene) is located on its distal short arm. For quite some time this was considered to be the only gene of significance on the Y chromosome. Recent studies of the Y chromosome, however, have yielded a rich harvest of gene families in the so-called “male-specific Y,” or MSY region encoding at least 75 protein coding genes. All of these are believed to be testes-specific and are involved in spermatogenesis. In keeping with this, all Y chromosome deletions are associated with azoospermia. The following features are common to all sex chromosome disorders.

- In general, sex chromosome disorders cause subtle, chronic problems relating to sexual development and fertility.
- Sex chromosome disorders are often difficult to diagnose at birth, and many are first recognized at the time of puberty.
- In general, the greater the number of X chromosomes, in both male and female, the greater the likelihood of mental retardation.

The two most important disorders arising in aberrations of sex chromosomes are described briefly here.

Klinefelter Syndrome

Klinefelter syndrome is best defined as male hypogonadism that occurs when there are two or more X chromosomes and one or more Y chromosomes. It is one of the most frequent forms of genetic disease involving the sex chromosomes as well as one of the most common causes of hypogonadism in the male. The incidence of this condition is approximately 1 in 660 live male births.

Klinefelter syndrome can rarely be diagnosed before puberty, particularly because the testicular abnormality does not develop before early puberty. Most patients have a distinctive body habitus with an increase in length between the soles and the pubic bone, which creates the appearance of an elongated body. Also characteristic are eunuchoid body habitus with abnormally long legs; small atrophic testes often associated with a small penis; and lack of such secondary male characteristics as deep voice, beard, and male distribution of pubic hair. Gynecomastia may be present. The mean IQ is somewhat lower than normal, but mental retardation is uncommon. There is increased incidence of type 2 diabetes and the metabolic syndrome that gives rise to insulin resistance. Curiously, mitral valve prolapse is seen in about 50% of adults with Klinefelter syndrome. There is also an increased incidence of osteoporosis and fractures due to sex hormonal imbalance.

It should be evident that the clinical features of this condition are variable, the only consistent finding being hypogonadism. Plasma gonadotropin concentrations,

particularly follicle-stimulating hormone, are consistently elevated, whereas testosterone levels are variably reduced. Mean plasma estradiol levels are elevated by an as yet unknown mechanism. The ratio of estrogens and testosterone determines the degree of feminization in individual cases.

Klinefelter syndrome is an important genetic cause of reduced spermatogenesis and male infertility. In some patients the testicular tubules are totally atrophied and replaced by pink, hyaline, collagenous ghosts. In others, apparently normal tubules are interspersed with atrophic tubules. In some patients all tubules are primitive and appear embryonic, consisting of cords of cells that never developed a lumen or progressed to mature spermatogenesis. Leydig cells appear prominent, as a result of the atrophy and crowding of the tubules and elevation of gonadotropin concentrations.

Patients with Klinefelter syndrome have a higher risk for breast cancer (20 times more common than in normal males), extragonadal germ cell tumors, and autoimmune diseases such as systemic lupus erythematosus.

The classic pattern of Klinefelter syndrome is associated with a 47,XXY karyotype (90% of cases). This complement of chromosomes results from nondisjunction during the meiotic divisions in the germ cells of one of the parents. Maternal and paternal nondisjunction at the first meiotic division are roughly equally involved. There is no phenotypic difference between those who receive the extra X chromosome from their father and those who receive it from their mother. Maternal age is increased in the cases associated with errors in oogenesis. In addition to this classic karyotype, approximately 15% of patients with Klinefelter syndrome have been found to have a variety of mosaic patterns, most of them being 46,XY/47,XXY. Other patterns are 47,XXY/48,XXX and variations on this theme.

As is the case with normal females, all but one X chromosome undergoes inactivation in patients with Klinefelter syndrome. Why then, do the patients with this disorder have hypogonadism and associated features? The explanation for this lies in genes on the X chromosome that escape lyonization and in the pattern of X inactivation.

- One pathogenic mechanism is related to uneven dosage compensation during X-inactivation. In some cases about 15% of the X-linked genes escape inactivation. Thus, there is an extra dose of these genes compared to normal males in whom only one copy of X is active, and it appears that “overexpression” of one or more of these genes leads to hypogonadism.
- A second mechanism involves the gene encoding the androgen receptor, through which testosterone mediates its effects. The androgen receptor gene maps to the X chromosome and contains highly polymorphic CAG (trinucleotide) repeats. The functional response of the receptor to any particular dose of androgen is dictated, in part, by the number of CAG repeats, as receptors with shorter CAG repeats are more sensitive to androgens than those with long CAG repeats. In persons with Klinefelter syndrome, the X chromosome bearing the androgen receptor allele with the shortest CAG repeat is preferentially inactivated. In XXY males with low testosterone levels, expression of androgen receptors with long CAG repeats exacerbates the hypogonadism and

appears to account for certain aspects of the phenotype, such as small penis size.

Turner Syndrome

Turner syndrome results from complete or partial monosomy of the X chromosome and is characterized primarily by hypogonadism in phenotypic females. It is the most common sex chromosome abnormality in females, affecting about 1 in 2500 live-born females.

With routine cytogenetic methods, three types of karyotypic abnormalities are seen in individuals with Turner syndrome.

- *Approximately 57% are missing an entire X chromosome, resulting in a 45,X karyotype.* Of the remaining 43%, approximately one third (approximately 14%) have structural abnormalities of the X chromosomes, and two thirds (approximately 29%) are mosaics.
- *The common feature of the structural abnormalities is to produce partial monosomy of the X chromosome.* In order of frequency, the structural abnormalities of the X chromosome include (1) an isochromosome of the long arm, 46,X,i(X)(q10) resulting in the loss of the short arm; (2) deletion of portions of both long and short arms, resulting in the formation of a ring chromosome, 46,X,r(X); and (3) deletion of portions of the short or long arm, 46X,del(Xq) or 46X,del(Xp).
- *The mosaic patients have a 45,X cell population along with one or more karyotypically normal or abnormal cell types.* Examples of karyotypes that mosaic Turner females may have are the following: (1) 45,X/46,XX; (2) 45,X/46,XY; (3) 45,X/47,XXX; or (4) 45,X/46,X,i(X)(q10). Studies suggest that the prevalence of mosaicism in Turner syndrome may be much higher than the 30% detected by conventional cytogenetic studies. With the use of more sensitive techniques, the prevalence of mosaic Turner syndrome increases to 75%. Because 99% of conceptuses with an apparent 45,X karyotype are nonviable, many authorities believe that there are no truly nonmosaic Turner syndrome patients. While this issue remains controversial, it is important to appreciate the karyotypic heterogeneity associated with Turner syndrome, because it is responsible for significant variations in phenotype. In patients in whom the proportion of 45,X cells is high, the phenotypic changes are more severe than in those who have readily detectable mosaicism. The latter may have an almost normal appearance and may present only with primary amenorrhea.

Five percent to 10% of patients with Turner syndrome have Y chromosome sequences either as a complete Y chromosome (e.g., 45,X/46,XY karyotype) or as fragments of Y chromosomes translocated on other chromosomes. These patients are at a higher risk for development of a gonadal tumor (gonadoblastoma).

The most severely affected patients generally present during infancy with edema of the dorsum of the hand and foot due to lymph stasis, and sometimes *swelling of the nape of the neck*. The latter is related to markedly distended lymphatic channels, producing a so-called cystic hygroma (Chapter 10). As these infants develop, the swellings subside but often leave bilateral *neck webbing* and persistent looseness of skin on the back of the neck. *Congenital heart disease* is also common, affecting 25% to 50% of patients.

Left-sided cardiovascular abnormalities, particularly preductal coarctation of the aorta and bicuspid aortic valve, are seen most frequently. *Cardiovascular abnormalities are the most important cause of increased mortality in children with Turner syndrome.*

The principal clinical features in the adolescent and adult are illustrated in Figure 5-22. At puberty there is *failure to develop normal secondary sex characteristics*. The genitalia remain infantile, breast development is inadequate, and there is little pubic hair. The mental status of these patients is usually normal, but subtle defects in non-verbal, visual-spatial information processing have been noted. Of particular importance in establishing the diagnosis in the adult is the shortness of stature (rarely exceeding 150 cm in height) and amenorrhea. *Turner syndrome is the single most important cause of primary amenorrhea*, accounting for approximately one third of the cases. For reasons not clear, approximately 50% of patients develop autoantibodies that react with the thyroid gland, and up to half of these develop clinically manifest hypothyroidism. Equally mysterious is the presence of glucose intolerance, obesity, and insulin resistance in a minority of patients. The last mentioned is significant, because therapy with growth hormone, commonly used in these patients, worsens insulin resistance.

The molecular pathogenesis of Turner syndrome is not completely understood, but studies have begun to shed some light. In approximately 75% of cases the X-chromosome is maternal in origin, thus suggesting that there is an abnormality in paternal gametogenesis. As mentioned earlier, both X chromosomes are active during oogenesis and are essential for normal development of the ovaries. During normal fetal development, ovaries contain as many as 7 million oocytes. The oocytes gradually disappear so that by menarche their numbers have dwindled to a mere 400,000, and when menopause occurs fewer than 10,000 remain. In Turner syndrome, fetal ovaries develop normally early in embryogenesis, but the absence of the second X chromosome leads to an accelerated loss of oocytes, which is complete by age 2 years. In a sense, therefore, “menopause occurs before menarche,” and the ovaries are reduced to atrophic fibrous strands, devoid of ova and follicles (*streak ovaries*). Because patients with Turner syndrome also have other (nongonadal) abnormalities, it follows that some genes for normal growth and development of somatic tissues must also reside on the X chromosome. Among the genes involved in the Turner phenotype is the short stature homeobox (*SHOX*) gene at Xp22.33. This is one of several genes that remain active in both X chromosomes and has an active homologue on the short arm of the Y chromosome. Thus, both normal males and females have two copies of this gene. Haploinsufficiency of *SHOX* gives rise to short stature. Indeed, deletions of the *SHOX* gene are noted in 2% to 5% of otherwise normal children with short stature. In keeping with its role as a critical regulator of growth, the *SHOX* gene is expressed during fetal life in the growth plates of several long bones including the radius, ulna, tibia, and fibula. It is also expressed in the first and second pharyngeal arches. Just as the loss of *SHOX* is always associated with short stature, excess copies of this gene are associated with tall stature. Whereas haploinsufficiency of *SHOX* can explain growth deficit in Turner syndrome, it cannot explain other clinical

Figure 5-22 Clinical features and karyotypes of Turner syndrome.

features such as cardiac malformations and endocrine abnormalities. Clearly several other genes located on the X chromosome are also involved.

Hermaphroditism and Pseudohermaphroditism

The problem of sexual ambiguity is exceedingly complex, and only limited observations are possible here; for more details, reference should be made to specialized sources. It will be no surprise to medical students that the sex of an individual can be defined on several levels. *Genetic sex* is determined by the presence or absence of a Y chromosome. No matter how many X chromosomes are present, a single Y chromosome dictates testicular development and the genetic male gender. The initially indifferent gonads of both the male and the female embryos have an inherent tendency to feminize, unless influenced by Y chromosome-dependent masculinizing factors. *Gonadal sex* is based on the histologic characteristics of the gonads. *Ductal sex* depends on the presence of derivatives of the müllerian or wolffian ducts. *Phenotypic, or genital, sex* is based on the appearance of the external genitalia. Sexual ambiguity is present whenever there is disagreement among these various criteria for determining sex.

The term true hermaphrodite implies the presence of both ovarian and testicular tissue. In contrast, a pseudohermaphrodite represents a disagreement between the phenotypic and gonadal sex (i.e., a female pseudohermaphrodite has ovaries but male external genitalia; a male

pseudohermaphrodite has testicular tissue but female-type genitalia). The genetic bases of these conditions are quite variable and beyond the scope of our discussion here.

KEY CONCEPTS

Cytogenetic Disorders Involving Sex Chromosomes

- In females, one X chromosome, maternal or paternal, is randomly inactivated during development (Lyon hypothesis).
- In **Klinefelter syndrome**, there are two or more X chromosomes with one Y chromosome as a result of nondisjunction of sex chromosomes. Patients have testicular atrophy, sterility, reduced body hair, gynecomastia, and eunuchoid body habitus. It is the most common cause of male sterility.
- In **Turner syndrome**, there is partial or complete monosomy of genes on the short arm of the X chromosome, most commonly due to absence of one X chromosome (45,X) and less commonly from mosaicism, or from deletions involving the short arm of the X chromosome. Short stature, webbing of the neck, cubitus valgus, cardiovascular malformations, amenorrhea, lack of secondary sex characteristics, and fibrotic ovaries are typical clinical features.

Single-Gene Disorders with Nonclassic Inheritance

It has become increasingly evident that transmission of certain single-gene disorders does not follow classic Mendelian principles. This group of disorders can be classified into four categories:

- Diseases caused by trinucleotide-repeat mutations
- Disorders caused by mutations in mitochondrial genes
- Disorders associated with genomic imprinting
- Disorders associated with gonadal mosaicism

Clinical and molecular features of some single-gene diseases that exemplify nonclassic patterns of inheritance are described next.

Diseases Caused by Trinucleotide-Repeat Mutations

Expansion of trineucleotide repeats is an important genetic cause of human disease, particularly neurodegenerative disorders. The discovery in 1991 of expanding trinucleotide repeats as a cause of fragile X syndrome was a landmark in human genetics. Since then the origins of about 40 human diseases (Table 5-8) have been traced to unstable nucleotide repeats, and the number continues to grow. Some general principles that apply to these diseases are as follows:

- The causative mutations are associated with the expansion of a stretch of trinucleotides that usually share the nucleotides G and C. In all cases the DNA is unstable, and an expansion of the repeats above a certain threshold impairs gene function in various ways, discussed later. In recent years diseases associated with unstable

tetra-, penta-, and hexa- nucleotides have also been found establishing this as a fundamental mechanism of neuromuscular diseases.

- The proclivity to expand depends strongly on the sex of the transmitting parent. In the fragile X syndrome, expansions occur during oogenesis, whereas in Huntington disease they occur during spermatogenesis.
- There are three key mechanisms by which unstable repeats cause diseases: (1) *Loss of function* of the affected gene, typically by transcription silencing, as in fragile X syndrome. In such cases the repeats are generally in non-coding part of the gene (2) *A toxic gain of function* by alterations of protein structure as in Huntington disease and spinocerebellar ataxias. In such cases the expansions occur in the coding regions of the genes. (3) *A toxic gain of function mediated by mRNA* as is seen in fragile X tremor-ataxia syndrome. As in fragile X syndrome, the noncoding parts of the gene are affected (Fig. 5-23).

The pathogenetic mechanisms underlying disorders caused by mutations that affect coding regions seem to be distinct from those in which the expansions affect non-coding regions. The former usually involve CAG repeats coding for polyglutamine tracts in the corresponding proteins. Such “polyglutamine diseases” are characterized by progressive neurodegeneration, typically striking in midlife. Polyglutamine expansions lead to toxic gain of function, whereby the abnormal protein may interfere with the function of the normal protein (a dominant negative activity) or acquire a novel pathophysiologic toxic activity. The precise mechanisms by which expanded polyglutamine proteins cause disease is not fully understood. In most cases the proteins are misfolded and tend to aggregate; the aggregates may suppress transcription of other genes, cause mitochondrial dysfunction, or trigger the unfolded-protein stress response and apoptosis (Chapter 1). A

Table 5-8 Examples of Trinucleotide-Repeat Disorders

Disease	Gene	Locus	Protein	Repeat	No. of Repeats	
					Normal	Disease
Expansions Affecting Noncoding Regions						
Fragile X syndrome	<i>FMRI (FRAXA)</i>	Xq27.3	FMR-1 protein (FMRP)	CGG	6-55	55-200 (pre); >230 (full)
Friedreich ataxia	<i>FXN</i>	9q21.1	Frxataxin	GAA	7-34	34-80 (pre); >100 (full)
Myotonic dystrophy	<i>DMPK</i>	19q13.3	Myotonic dystrophy protein kinase (DMPK)	CTG	5-37	34-80 (pre); >100 (full)
Expansions Affecting Coding Regions						
Spinobulbar muscular atrophy (Kennedy disease)	<i>AR</i>	Xq12	Androgen receptor (AR)	CAG	9-36	38-62

morphologic hallmark of these diseases is the accumulation of aggregated mutant proteins in large intranuclear inclusions. While formation of aggregates is common to many “polyglutamine disease,” evidence of a direct toxic role of aggregates is not universal. In fact some observers believe that aggregation may be protective by sequestration of the misfolded protein. Other models of pathogenicity implicate downstream effects mediated by proteolytic fragments of the polyglutamine fragment. Much more needs to be learned before therapeutic strategies can be developed.

Fragile X Syndrome and Fragile X Tremor/Ataxia

Fragile X syndrome is the prototype of diseases in which the mutation is characterized by a long repeating sequence of three nucleotides. Although the specific nucleotide sequence that undergoes amplification differs in the 20 or so disorders included in this group, in most cases the affected sequences share the nucleotides guanine (G) and cytosine (C). The ensuing discussion considers the clinical features and inheritance pattern of the fragile-X syndrome, followed by the causative molecular lesion. The remaining disorders in this group are discussed elsewhere in this text. Although distinct diseases, fragile X syndrome and fragile X tremor/ataxia share common features and so are discussed together.

Fragile X syndrome is the second most common genetic cause of mental retardation after Down syndrome. It is caused by a trinucleotide mutation in the familial mental retardation-1 (FMR1) gene. Fragile-X-syndrome has a frequency of 1 in 1550 for affected males and 1 in 8000 for affected females and is characterized by an inducible cytogenetic abnormality in the X chromosome within which the *FMR1* gene maps. The cytogenetic alteration was discovered as a discontinuity of staining or as a constriction in the long arm of the X chromosome when cells are cultured in a folate-deficient medium. Because it appears that the chromosome is “broken” at this locale, it was named as a *fragile site* (Fig. 5-24). There are more than 100 “fragile sites” in the human genome of unknown significance; many are present in normal individuals.

In fragile X syndrome, the affected males are *mentally retarded*, with an IQ in the range of 20 to 60. They express a characteristic physical phenotype that includes a *long face with a large mandible, large everted ears, and large testicles (macro-orchidism)*. Hyperextensible joints, a high arched palate, and mitral valve prolapse noted in some patients

mimic a connective tissue disorder. These and other physical abnormalities described in this condition, however, are not always present and, in some cases, are quite subtle. *The most distinctive feature is macro-orchidism, which is observed in at least 90% of affected postpubertal males.*

As with all X-linked diseases, fragile X syndrome affects males. Analysis of several pedigrees, however, reveals some patterns of transmission not typically associated with other X-linked recessive disorders (Fig. 5-25). These include the following:

- **Carrier males:** Approximately 20% of males who, by pedigree analysis and by molecular tests, are known to carry a fragile X mutation are clinically and cytogenetically normal. Because carrier males transmit the trait through all their phenotypically normal daughters to affected grandchildren, they are called *normal transmitting males*.
- **Affected females:** 30% to 50% of carrier females are affected (i.e., mentally retarded), a number much higher than that in other X-linked recessive disorders.
- **Risk of phenotypic effects:** Risk depends on the position of the individual in the pedigree. For example, brothers of transmitting males are at a 9% risk of having mental retardation, whereas grandsons of transmitting males incur a 40% risk.
- **Anticipation:** This refers to the observation that clinical features of fragile X syndrome worsen with each successive generation, as if the mutation becomes increasingly deleterious as it is transmitted from a man to his grandsons and great-grandsons.

Figure 5-24 Fragile X seen as discontinuity of staining. (Courtesy of Dr. Patricia Howard-Peebles, University of Texas Southwestern Medical Center, Dallas, TX.)

Figure 5-25 Fragile X pedigree. Note that in the first generation all sons are normal and all females are carriers. During oogenesis in the carrier female, pre-mutation expands to full mutation; hence, in the next generation all males who inherit the X with full mutation are affected. However, only 50% of females who inherit the full mutation are affected, and only mildly. (Courtesy of Dr. Nancy Schneider, Department of Pathology, University of Texas Southwestern Medical Center, Dallas, TX.)

The first breakthrough in resolving these perplexing observations came when linkage studies localized the mutation responsible for this disease to Xq27.3, within the cytogenetically abnormal region. Within this region lies the *FMR1* gene, characterized by multiple tandem repeats of the nucleotide sequence CGG in its 5' untranslated region. In the normal population, the number of CGG repeats is small, ranging from 6 to 55 (average, 29). The presence of clinical symptoms and a cytogenetically detectable fragile site is related to the amplification of the CGG repeats. Thus, normal transmitting males and carrier females carry 55 to 200 CGG repeats. Expansions of this size are called *premutations*. In contrast, affected individuals have an extremely large expansion of the repeat region (200 to 4000 repeats, or *full mutations*). Full mutations are believed to arise by further amplification of the CGG repeats seen in premutations. How this process takes place is quite peculiar. Carrier males transmit the repeats to their progeny with small changes in repeat number. When the premutation is passed on by a carrier female, however, there is a high probability of a dramatic amplification of the CGG repeats, leading to mental retardation in most male offspring and 50% of female offspring. Thus, *it seems that during the process of oogenesis, but not spermatogenesis, premutations can be converted to mutations by triplet-repeat amplification*. This explains the unusual inheritance pattern; that is, the likelihood of mental retardation is much higher in grandsons than in brothers of transmitting males because grandsons incur the risk of inheriting a premutation from their grandfather that is amplified to a "full mutation" in their mothers' ova. By comparison, brothers of

transmitting males, being "higher up" in the pedigree, are less likely to have a full mutation. These molecular details also provide a satisfactory explanation of anticipation—a phenomenon observed by clinical geneticists but not believed by molecular geneticists until triplet-repeat mutations were identified. Why only 50% of the females with the full mutation are clinically affected is not clear. Presumably in those that are clinically affected there is unfavorable lyonization (i.e., there is a higher frequency of cells in which the X chromosome carrying the mutation is active).

The molecular basis of mental retardation and other somatic changes is related to a loss of function of the familial mental retardation protein (FMRP). As mentioned earlier, the normal *FMR1* gene contains up to 55 CGG repeats in its 5' untranslated region. When the trinucleotide repeats in the *FMR1* gene exceed approximately 230, the DNA of the entire 5' region of the gene becomes abnormally methylated. Methylation also extends upstream into the promoter region of the gene, resulting in transcriptional suppression of *FMR1*. The resulting absence of FMRP is believed to cause the phenotypic changes.

FMRP is a widely expressed cytoplasmic protein, most abundant in the brain and testis, the two organs most affected in this disease. Its proposed functions are the following:

- *FMRP selectively binds mRNAs associated with polysomes and regulates their intracellular transport to dendrites.* FMRP binds to approximately 4% of mammalian brain mRNAs. Unlike other cells, in neurons protein synthesis

Figure 5-26 A model for the action of familial mental retardation protein (FMRP) in neurons. (Adapted from Hin P, Warren ST: New insights into fragile X syndrome: from molecules to neurobehavior. *Trends Biochem Sci* 28:152, 2003.)

occurs both in the perinuclear cytoplasm and in dendritic spines. Newly made FMRP translocates to the nucleus, where it assembles into a complex containing specific mRNA transcripts. The FMRP-mRNA complexes are then exported to the cytoplasm, from where they are trafficked near neuronal synapses (Fig. 5-26). As would be anticipated, only mRNAs encoding proteins that regulate synaptic function are subject to shuttling by FMRP.

- *FMRP is a translation regulator.* At synaptic junctions FMRP suppresses protein synthesis from the bound mRNAs in response to signaling through group I metabotropic glutamate receptors (mGlu-R). Thus a reduction in FMRP in the fragile X syndrome results in increased translation of the bound mRNAs at the synaptic junctions. Such imbalance in turn causes permanent changes in synaptic activity and ultimately mental retardation.

Although demonstration of an abnormal karyotype led to the identification of this disorder, PCR-based detection of the repeats is now the method of choice for diagnosis.

Fragile X Tremor/Ataxia. Although initially assumed to be innocuous, CGG premutations in the *FMR1* gene can cause a disease that is phenotypically different from fragile X syndrome through a distinct mechanism involving a toxic “gain-of-function”. A decade after the discovery that CGG repeat expansions cause fragile X syndrome, it became clear that approximately 20% of females carrying the premutation (carrier females) have premature ovarian failure (before the age of 40 years), and more than 50% of premutation-carrying males (transmitting males) exhibit a progressive neurodegenerative syndrome starting in their sixth decade. This syndrome, referred to as *fragile X tremor/*

ataxia, is characterized by intention tremors and cerebellar ataxia and may progress to parkinsonism.

How do premutations cause disease? In these patients, the *FMR1* gene instead of being methylated and silenced continues to be transcribed. CGG-containing *FMR1* mRNAs so formed are “toxic.” They accumulate in the nucleus and form intranuclear inclusions. In this process the aggregated mRNA recruits RNA-binding proteins. Perhaps sequestration of these proteins at abnormal locations leads to events that are toxic to the cell. In recent years, abnormal RNAs with toxic gain of function as a mechanism of tissue injury have also been implicated in certain myotonic muscular dystrophies.

KEY CONCEPTS

Fragile X Syndrome

- Pathologic amplification of trinucleotide repeats causes loss-of-function (fragile X syndrome) or gain-of-function mutations (Huntington disease). Most such mutations produce neurodegenerative disorders.
- Fragile X syndrome results from loss of *FMR1* gene function and is characterized by mental retardation, macroorchidism, and abnormal facial features.
- In the normal population, there are about 29–55 CGG repeats in the *FMR1* gene. The genomes of carrier males and females contain premutations with 55 to 200 CGG repeats that can expand to 4000 repeats (full mutations) during oogenesis. When full mutations are transmitted to progeny, fragile X syndrome occurs.
- Fragile X tremor/ataxia due to expression of a *FMR1* gene bearing a premutation develops in some males and females. The accumulation of corresponding mRNA in the nucleus binds and sequesters certain proteins that are essential for normal neuronal functions.

Mutations in Mitochondrial Genes—Leber Hereditary Optic Neuropathy

The vast majority of genes are located on chromosomes in the cell nucleus and are inherited in classical Mendelian fashion. There exist several mitochondrial genes, however, that are inherited in quite a different manner. A feature unique to mtDNA is *maternal inheritance*. This peculiarity exists because ova contain numerous mitochondria within their abundant cytoplasm, whereas spermatozoa contain few, if any. Hence, the mtDNA complement of the zygote is derived entirely from the ovum. Thus, mothers transmit mtDNA to all their offspring, male and female; however, daughters but not sons transmit the DNA further to their progeny (Fig. 5-27). Several other features apply to mitochondrial inheritance. They are as follows:

- Human mtDNA contains 37 genes, of which 22 are transcribed into transfer RNAs and two into ribosomal RNAs. The remaining 13 genes encode subunits of the respiratory chain enzymes. Because mtDNA encodes enzymes involved in oxidative phosphorylation, mutations affecting these genes exert their deleterious effects primarily on the organs most dependent on oxidative phosphorylation such as the central nervous system, skeletal muscle, cardiac muscle, liver, and kidneys.

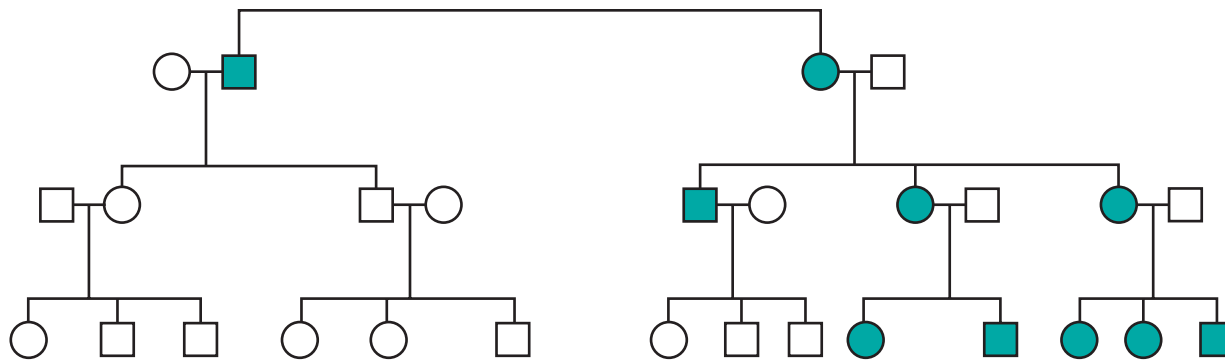

Figure 5-27 Pedigree of Leber hereditary optic neuropathy, a disorder caused by mutation in mitochondrial DNA. Note that all progeny of an affected male (shaded squares) are normal, but all children, male and female, of the affected female (shaded circles) manifest disease to a variable degree as discussed in the text.

- Each mitochondrion contains thousands of copies of mtDNA, and, typically, deleterious mutations of mtDNA affect some but not all of these copies. Thus, tissues and, indeed, individuals may harbor both wild-type and mutant mtDNA, a situation called *heteroplasmy*. A minimum number of mutant mtDNA must be present in a cell or tissue before oxidative dysfunction gives rise to disease. This is called the “threshold effect.” Not surprisingly, the threshold is reached most easily in the metabolically active tissues listed earlier.
- During cell division, mitochondria and their contained DNA are randomly distributed to the daughter cells. Thus, when a cell containing normal and mutant mtDNA divides, the proportion of the normal and mutant mtDNA in daughter cells is extremely variable. Therefore, the expression of disorders resulting from mutations in mtDNA is quite variable.

Diseases associated with mitochondrial inheritance are rare and, as mentioned earlier, many of them affect the neuromuscular system. *Leber hereditary optic neuropathy* is a prototype of this type of disorder. It is a neurodegenerative disease that manifests as a progressive bilateral loss of central vision. Visual impairment is first noted between ages 15 and 35, leading eventually to blindness. Cardiac conduction defects and minor neurologic manifestations have also been observed in some families.

Genomic Imprinting

We all inherit two copies of each autosomal gene, carried on homologous maternal and paternal chromosomes. In the past, it had been assumed that there is no functional difference between the alleles derived from the mother or the father. Studies over the past two decades have provided definite evidence that, at least with respect to some genes, important functional differences exist between the paternal allele and the maternal allele. These differences result from an epigenetic process called *imprinting*. In most cases, imprinting selectively inactivates either the maternal or paternal allele. Thus, *maternal imprinting* refers to transcriptional silencing of the maternal allele, whereas *paternal imprinting* implies that the paternal allele is inactivated.

Imprinting occurs in the ovum or the sperm, before fertilization, and then is stably transmitted to all somatic cells through mitosis. As with other instances of epigenetic

regulation, imprinting is associated with differential patterns of DNA methylation at CG nucleotides. Other mechanisms include histone H4 deacetylation and methylation (Chapter 1). Regardless of the mechanism, it is believed that such marking of paternal and maternal chromosomes occurs during gametogenesis, and thus it seems that from the moment of conception some chromosomes remember where they came from. The exact number of imprinted genes is not known; estimates range from 200 to 600. Although imprinted genes may occur in isolation, more commonly they are found in groups that are regulated by common *cis*-acting elements called imprinting control regions. Genomic imprinting is best illustrated by considering two uncommon genetic disorders: Prader-Willi syndrome and Angelman syndrome which were originally believed to be unrelated until the genetic lesions responsible for them were mapped to the very same location. They are described next.

Prader-Willi Syndrome and Angelman Syndrome

Prader-Willi syndrome is characterized by mental retardation, short stature, hypotonia, profound hyperphagia, obesity, small hands and feet, and hypogonadism. In 65% to 70% of cases, an interstitial deletion of band q12 in the long arm of chromosome 15, $\text{del}(15)(\text{q}11.2\text{q}13)$, can be detected. In most cases the breakpoints are the same, causing a 5-Mb deletion. *It is striking that in all cases the deletion affects the paternally derived chromosome 15.* In contrast with the Prader-Willi syndrome, patients with the phenotypically distinct Angelman syndrome are *born with a deletion of the same chromosomal region derived from their mothers. Patients with Angelman syndrome are also mentally retarded, but in addition they present with ataxic gait, seizures, and inappropriate laughter.* Because of their laughter and ataxia, they have been referred to as “happy puppets.” A comparison of these two syndromes clearly demonstrates the *parent-of-origin* effects on gene function.

The molecular basis of these two syndromes lies in the genomic imprinting (Fig. 5-28). Three mechanisms are involved:

- **Deletions.** It is known that a gene or set of genes on maternal chromosome 15q12 is imprinted (and hence silenced), and thus the only functional allele(s) are provided by the paternal chromosome. When these are lost as a result of a deletion, the person develops

Figure 5-28 Diagrammatic representation of Prader-Willi and Angelman syndromes.

Prader-Willi syndrome. Conversely, a distinct gene that also maps to the same region of chromosome 15 is imprinted on the paternal chromosome. Only the maternally derived allele of this gene is normally active. Deletion of this maternal gene on chromosome 15 gives rise to the Angelman syndrome. Deletions account for about 70% cases.

- *Uniparental disomy.* Molecular studies of cytogenetically normal patients with the Prader-Willi syndrome (i.e., those without the deletion) have revealed that they have two maternal copies of chromosome 15. Inheritance of both chromosomes of a pair from one parent is called *uniparental disomy*. The net effect is the same (i.e., the person does not have a functional set of genes from the [nonimprinted] paternal chromosomes 15). Angelman syndrome, as might be expected, can also result from uniparental disomy of paternal chromosome 15. This is the second most common mechanism responsible for 20% to 25% cases.
- *Defective imprinting.* In a small minority of patients (1% to 4%), there is an imprinting defect. In some patients with Prader-Willi syndrome, the paternal chromosome carries the maternal imprint and conversely in Angelman syndrome the maternal chromosome carries the paternal imprint (hence there are no functional alleles).

The genetic basis of these two imprinting disorders is now being unraveled.

- In the Angelman syndrome, the affected gene is a ubiquitin ligase that is involved in catalyzing the transfer of activated ubiquitin to target protein substrates. The gene, called *UBE3A*, maps within the 15q12 region, is

imprinted on the paternal chromosome, and is expressed from the maternal allele primarily in specific regions of the brain. The imprinting is tissue-specific in that *UBE3A* is expressed from both alleles in most tissues.

- In contrast to Angelman syndrome, no single gene has been implicated in Prader-Willi syndrome. Instead, a series of genes located in the 15q11.2-q13 interval (which are imprinted on the maternal chromosome and expressed from the paternal chromosome) are believed to be involved. These include the SNORP family of genes that encode small nucleolar RNAs which are involved in modifications of ribosomal RNAs. Loss of SNORP functions is believed to contribute to Prader-Willi syndrome.

Molecular diagnosis of these syndromes is based on assessment of methylation status of marker genes and FISH. The importance of imprinting is not restricted to rare chromosomal disorders. Parent-of-origin effects have been identified in a variety of inherited diseases, such as Huntington disease and myotonic dystrophy and in tumorigenesis.

KEY CONCEPTS

Genomic Imprinting

- Imprinting involves transcriptional silencing of the paternal or maternal copies of certain genes during gametogenesis. For such genes, only one functional copy exists in the individual. Loss of the functional (not imprinted) allele by deletion gives rise to diseases.

- In **Prader-Willi syndrome**, deletion of band q12 on long arm of paternal chromosome 15 occurs. Genes in this region of maternal chromosome 15 are imprinted so there is complete loss of their functions. Patients have mental retardation, short stature, hypotonia, hyperphagia, small hands and feet, and hypogonadism.
- In **Angelman syndrome** there is deletion of the same region from the maternal chromosome. Since genes on the corresponding region of paternal chromosome 15 are imprinted, these patients have mental retardation, ataxia, seizures, and inappropriate laughter.

Gonadal Mosaicism

It was mentioned earlier that with every autosomal dominant disorder some patients do not have affected parents. In such patients the disorder results from a new mutation in the egg or the sperm from which they were derived; as such, their siblings are neither affected nor at increased risk for development of the disease. This is not always the case, however. *In some autosomal dominant disorders, exemplified by osteogenesis imperfecta, phenotypically normal parents have more than one affected child.* This clearly violates the laws of Mendelian inheritance. Studies indicate that gonadal mosaicism may be responsible for such unusual pedigrees. Such mosaicism results from a mutation that occurs postzygotically during early (embryonic) development. If the mutation affects only cells destined to form the gonads, the gametes carry the mutation, but the somatic cells of the individual are completely normal. A phenotypically normal parent who has gonadal mosaicism can transmit the disease-causing mutation to the offspring through their mutated gametes. Because the progenitor cells of the gametes carry the mutation, there is a possibility that more than one child of such a parent would be affected. Obviously the likelihood of such an occurrence depends on the proportion of germ cells carrying the mutation.

Molecular Genetic Diagnosis

The nascent field of molecular diagnostics emerged in the latter half of the twentieth century, with the application of low throughput approaches such as conventional karyotyping for recognition of cytogenetic disorders (e.g., Down syndrome) and DNA-based assays such as Southern blotting for the diagnosis of Huntington disease. Over time, a steady stream of technologic breakthroughs has led to ever-increasing capabilities, including notably the development of Sanger DNA sequencing in 1977 and polymerase chain reaction (PCR) in 1983. Used together, these two techniques allowed the routine sequencing of any known segment of DNA, both rapidly accelerating research and providing a straightforward avenue for targeted diagnostics development.

Today, with the completion of the Human Genome Project and with newer and more powerful techniques for genetic and genomic analysis, nucleic acid-based testing is beginning to take a central role in the diagnosis and management of many diseases. Molecular diagnostic

techniques have found application in virtually all areas of medicine, and their adoption continues to accelerate.

While an exhaustive discussion of molecular diagnostics is beyond the scope of this book, many of the better known approaches are highlighted in the ensuing sections. It is important to emphasize that, regardless of the technique used, human genetic markers can be either constitutional (i.e., present in each and every cell of the affected person, as with a *CFTR* mutation in a patient with cystic fibrosis) or somatic (i.e., restricted to specific tissue types or lesions, as with mutations in the *KRAS* gene in a variety of human cancers). In suspected infections, the goal is to detect and quantify nucleic acids that are specific to the infectious agent, which may be confined to particular cells or body sites. These considerations determine the nature of the sample used for the assay (e.g., peripheral blood cells, tumor tissue, nasopharyngeal swab).

Diagnostic Methods and Indications for Testing

There are a truly dizzying number of both techniques and indications for performing molecular genetic diagnostic tests on patient specimens, both for inherited and acquired genetic anomalies. The burden of choice can often be problematic, both for molecular pathologists who design tests as well as for clinicians who need to choose the optimal test for their patients.

Laboratory Considerations

On the laboratory side, pathologists focus on the sensitivity, specificity, accuracy, and reproducibility of different methods, as well as practical factors like cost, labor, reliability, and turn-around time. To choose the appropriate diagnostic technique, it is critical to first understand the spectrum of genetic anomalies that are responsible for the disease in the patient population under study. Disease-causing genetic anomalies range in size from single base substitutions up to gains or losses of entire chromosomes, and may vary widely in frequency among ethnic groups. Proper test design requires careful consideration of these factors. For example, standard cystic fibrosis testing for the 23 most common point mutations and small deletions (≤ 3 base pairs) in the *CFTR* gene has a sensitivity of 94% in Ashkenazi Jews, but identifies less than 50% of affected patients in Asian populations. In cases with negative standard test results and a high clinical suspicion, further tests are needed, such as extensive sequencing that covers all 27 exons of the *CFTR* gene. But even sequencing assays may miss large (kilobase scale) deletions involving one or more exons, which require a different test methodology. Issues like this arise quite frequently in genetic testing, and close communication between primary care clinicians, medical genetics specialists, and diagnosticians is often required in order to select the optimal test strategy in difficult cases.

Indications for Analysis of Inherited Genetic Alterations

Testing for inherited alterations may be required at any age, depending on clinical presentation, although in general most testing is performed during the prenatal or postnatal/childhood periods. Mendelian disorders that have been linked to specific genes number in the thousands, and definitive diagnosis for most of them is possible

by direct sequencing. Some disorders, most with recessive inheritance, are associated with a limited number of recurrent mutations. Many others, especially those with dominant inheritance, are caused by mutations scattered throughout the responsible gene and represent a considerable diagnostic challenge.

Prenatal testing should be offered for all fetuses at risk for a cytogenetic abnormality. Possible indications include:

- Advanced maternal age
- A parent known to carry a balanced chromosomal rearrangement (because these greatly increase the frequency of abnormal chromosome segregation during meiosis and the risk of aneuploidy in the fertilized ovum)
- Fetal anomalies observed on ultrasound
- Routine maternal blood screening, indicating an increased risk of Down syndrome or another trisomy

Prenatal testing may also be considered for children at known risk for many other genetic disorders (e.g., cystic fibrosis, spinal muscular atrophy) using targeted analysis based on familial mutations or family history. At present it is usually performed on cells obtained by amniocentesis, chorionic villus biopsy, or umbilical cord blood. However, as much as 10% of the free DNA in a pregnant mother's blood is of fetal origin, and new technologies are opening the door to an era of noninvasive prenatal diagnostics utilizing this source of DNA.

Beyond prenatal testing, parents known to be at risk for having a child with a genetic disorder can choose to have genetic testing performed on embryos created *in vitro* prior to uterine implantation, eliminating the chance of generational transmission of a familial disease.

Following birth, testing is ideally done as soon as the possibility of constitutional genetic disease arises. It is most commonly performed on peripheral blood DNA and is targeted based on clinical suspicion. In newborns or children, indications may be as follows:

- Multiple congenital anomalies
- Suspicion of a metabolic syndrome
- Unexplained mental retardation and/or developmental delay
- Suspected aneuploidy (e.g., features of Down syndrome) or other syndromic chromosomal abnormality (e.g., deletions, inversions)
- Suspected monogenic disease, whether previously described or unknown

In older patients, testing logically becomes more focused toward genetic diseases that manifest at later stages of life. Again, the possibilities are vast, but the more common indications include:

- Inherited cancer syndromes (triggered by either family history or an unusual cancer presentation)
- Atypically mild monogenic disease (e.g., attenuated cystic fibrosis)
- Neurodegenerative disorders (e.g., familial Alzheimer disease, Huntington disease)

Indications for Analysis of Acquired Genetic Alterations

In this era of molecularly targeted therapies it is becoming increasingly important to identify nucleic acid sequences

or aberrations that are specific for acquired diseases (e.g., cancer and infectious disease). The technical approaches are the same as those used for germ line Mendelian disorders, and the common indications include:

- Diagnosis and management of cancer (see also [Chapter 7](#))
 - Detection of tumor-specific acquired mutations and cytogenetic alterations that are the hallmarks of specific tumors (e.g., *BCR-ABL* fusion genes in chronic myelogenous leukemia, or CML)
 - Determination of clonality as an indicator of a neoplastic condition
 - The identification of specific genetic alterations that can direct therapeutic choices (e.g., HER2 [official name *ERBB2*] amplification in breast cancer or EGFR [official name *ERBB1*] mutations in lung cancer)
 - Determination of treatment efficacy (e.g., minimal residual disease detection of *BCR-ABL* by PCR in CML)
 - Detection of drug-resistant secondary mutations in malignancies treated with genetically tailored therapeutics
- Diagnosis and management of infectious disease (see also [Chapter 8](#))
 - Detection of microorganism-specific genetic material for definitive diagnosis (e.g., HIV, mycobacteria, human papillomavirus, herpesvirus in central nervous system)
 - The identification of specific genetic alterations in the genomes of microbes that are associated with drug resistance
 - Determination of treatment efficacy (e.g., assessment of viral loads in HIV, Epstein-Barr virus, and hepatitis C virus infection)

PCR and Detection of DNA Sequence Alterations

PCR analysis, which involves the synthesis of relatively short DNA fragments from a DNA template, has been a mainstay of molecular diagnostics for the last few decades. By using appropriate heat-stable DNA polymerases and thermal cycling, the target DNA (usually less than 1000 base pairs) lying between designed primer sites is exponentially amplified from as little as one original copy, greatly simplifying secondary sequence analysis. Many options exist for subsequent analysis, each with different strengths and weaknesses:

- *Sanger sequencing.* Here, the amplified DNA is mixed with a DNA polymerase, a DNA primer, nucleotides, and four dead-end (di-deoxy terminator) nucleotides (A, T, G, and C) labeled with different fluorescent tags. The ensuing reaction produces a series of DNA molecules of all possible lengths up to a kilobase or so, each labeled with a tag that corresponds to the base at which the reaction stopped due to incorporation of one of the terminator nucleotides. After size separation by capillary electrophoresis, the exact sequence can be "read" and compared with the normal sequence to detect the presence of mutations. Many applications of Sanger

sequencing (and other PCR-based approaches) are starting to give way to next generation sequencing (discussed later), particularly when analysis of large genes or multiple genes is required. Still, 36 years after its Nobel-worthy invention by Frederick Sanger, Sanger sequencing is still considered the “gold standard” for sequence determination.

- **Pyrosequencing:** This approach takes advantage of the release of pyrophosphate when a nucleotide is incorporated into a growing DNA strand. Like Sanger sequencing, it is performed on PCR products using a single sequencing primer, but instead of terminator nucleotides it involves cycling individual nucleotides (A, C, T, or G) one at a time into the reaction. If one or more nucleotides are incorporated into the growing strand of DNA, pyrophosphate is released and participates in a secondary reaction involving luciferase that produces light, which is measured by a photo detector. Pyrosequencing is most often used when testing for particular sequence variants and is more sensitive than Sanger sequencing, allowing for detection of as little as 5% mutated alleles in a background of normal alleles. For this reason, it may be used to analyze DNA obtained from cancer biopsies, in which tumor cells are often “contaminated” with large numbers of admixed stromal cells.
- **Single-base primer extension.** This is a useful approach for identifying mutations at a specific nucleotide position (e.g., an oncogenic mutation in codon 600 of the *BRAF* gene). An interrogating sequencing primer is added to the PCR product, which binds just one base upstream of the target. Differently colored terminator fluorescent nucleotides are also added (corresponding to the normal and variant bases), and a single base polymerase extension is performed. The relative amounts of normal/variant fluorescence are then detected (Fig. 5-29). Like pyrosequencing, this technique is very sensitive, down to approximately 1% to 2% mutated alleles, with the obvious disadvantage of only producing one base pair of sequence data.
- **Restriction fragment length analysis.** This simple approach takes advantage of the digestion of DNA with endonucleases known as restriction enzymes that recognize and cut DNA at specific sequences. If the specific mutation is known to affect a restriction site, then the amplified PCR product may be digested, and the normal and mutant PCR products will yield fragments of different sizes. These can be identified as different bands following electrophoresis. Needless to say, this approach is considerably less comprehensive than direct sequencing but remains useful for molecular diagnosis when the causal mutation always occurs at an invariant nucleotide position.
- **Amplicon length analysis.** Mutations that affect the length of DNA (e.g., deletions or expansions) can be easily detected by PCR. As discussed earlier, several diseases, such as the fragile X syndrome, are associated with alterations in trinucleotide repeats. Figure 5-30 reveals how PCR analysis can be used to detect this mutation. Two primers that flank the region containing the trinucleotide repeats at the 5' end of the *FMR1* gene are used to amplify the intervening sequences. Because

Figure 5-29 Single-base extension analysis of a PCR product, using a primer to interrogate a single base position. Nucleotides complementary to the mutant and wild-type bases at the queried position are labeled with different fluorophores, such that incorporation yields fluorescent signals of varying intensity based on the ratio of mutant to wild-type DNA present.

- there are large differences in the number of repeats, the size of the PCR products obtained from the DNA of normal individuals, or those with a premutation, is quite different and can be easily distinguished by gel electrophoresis. An important caveat is that this technique will fail if a trinucleotide repeat expansion is so large that it is beyond the amplification capacity of conventional PCR, a situation that is commonly seen in some trinucleotide repeat disorders. In such a case, Southern blot analysis of genomic DNA must be performed (see “Southern Blotting”).
- **Real-time PCR.** A variety of PCR-based technologies that use fluorophore indicators can detect and quantify the presence of particular nucleic acid sequences in “real time” (i.e., during the exponential phase of DNA amplification rather than post-PCR). It is most often used to monitor the frequency of cancer cells bearing characteristic genetic lesions in the blood or in tissues (e.g., the level of *BCR-ABL* fusion gene sequences in patients with CML), or the infectious load of certain viruses (e.g., HIV, EBV). It can also be used to detect somatic point mutations in oncogenes such as *KRAS* and *BRAF*, an approach that has the advantage of avoiding the need for post-PCR analysis.

Molecular Analysis of Genomic Alterations

A significant number of genetic lesions involve large deletions, duplications, or more complex rearrangements that are not easily assayed using standard PCR methods. Such genomic-scale alterations can be studied using a variety of hybridization-based techniques.

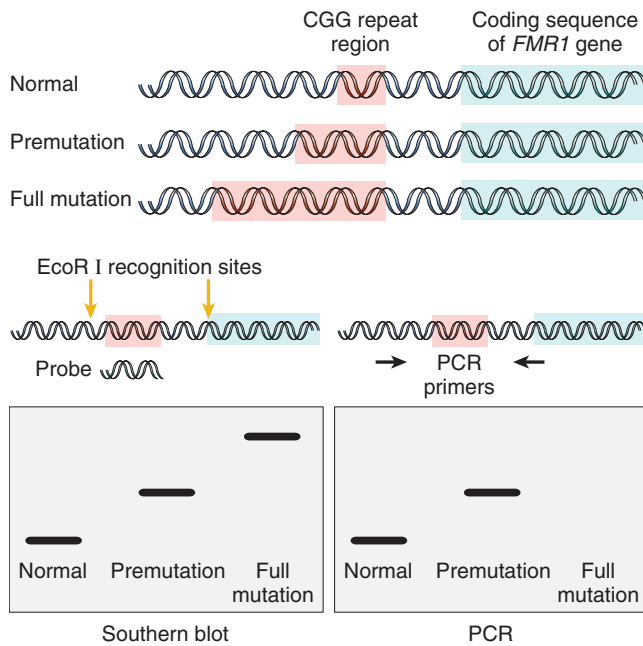

Figure 5-30 Diagnostic application of PCR and Southern blot analysis in fragile X syndrome. With PCR the differences in the size of CGG repeats between normal and premutation give rise to products of different sizes and mobility. With a full mutation, the region between the primers is too large to be amplified by conventional PCR. In Southern blot analysis the DNA is cut by enzymes that flank the CGG repeat region, and is then probed with a complementary DNA that binds to the affected part of the gene. A single small band is seen in normal males, a band of higher molecular weight in males with premutation, and a very large (usually diffuse) band in those with the full mutation.

Fluorescence in Situ Hybridization (FISH)

FISH uses DNA probes that recognize sequences specific to particular chromosomal regions. As part of the Human Genome Project, large libraries of bacterial artificial chromosomes that span the entire human genome were created. The human DNA inserts in these clones are on the order of 100,000-200,000 base pairs. These DNA clones are labeled with fluorescent dyes and applied to metaphase chromosome spreads or interphase nuclei that are pretreated so as to “melt” the genomic DNA. The probe hybridizes to its homologous genomic sequence and thus labels a specific chromosomal region that can be visualized under a fluorescent microscope. The ability of FISH to circumvent the need for dividing cells is invaluable when a rapid diagnosis is warranted (e.g., when deciding to treat a patient with acute myeloid leukemia with retinoic acid, which is only effective in a particular subtype with a chromosomal translocation involving the retinoic acid receptor gene [Chapter 13]). FISH can be performed on prenatal samples, peripheral blood cells, touch preparations from cancer biopsies, and even fixed archival tissue sections. FISH is used to detect numeric abnormalities of chromosomes (aneuploidy) (Fig. 5-19); subtle microdeletions (Fig. 5-20) or complex translocations that are not demonstrable by routine karyotyping; and gene amplification (e.g., *HER2* in breast cancer or *NMYC* amplification in neuroblastomas). Chromosome painting is an extension of FISH, whereby probes are prepared that span entire chromosomes. The

number of chromosomes that can be detected simultaneously by chromosome painting is limited by the availability of fluorescent dyes that emit different wavelengths of visible light. This limitation has been overcome by the introduction of spectral karyotyping (also called multicolor FISH). Use of different mixtures of five fluorochromes in probes that are specific for each chromosome permits visualization of entire human genome. So powerful is spectral karyotyping that it might well be called “spectacular karyotyping.”

Multiplex Ligation-Dependent Probe Amplification (MLPA)

MLPA blends DNA hybridization, DNA ligation, and PCR amplification to detect deletions and duplications of any size, including anomalies that are too large to be detected by PCR and too small to be identified by FISH. Briefly, each MLPA reaction uses a pair of probes that can hybridize side-by-side to one strand of the target DNA. Once bound, the probes are covalently joined via a ligase reaction. In addition to the target sequence, the probes also contain additional sequences at their ends that can be used as primer sequences in a PCR. The ligated probes thus create a template that can then be amplified by PCR. Quantification of the amplified DNA yields highly accurate information regarding the original amount of genetic starting material at the particular probe location (e.g., a probe at the site of a heterozygous deletion will produce only a 50% signal). Because it involves PCR amplification, MLPA can be performed on very small amounts of genomic DNA, and because each probe-set can be designed with identical primer sequences, many probe-sets can be applied and amplified in one reaction tube. Looking back to the cystic fibrosis example presented earlier, an MLPA probe-set covering the genomic coordinates corresponding to each of the 27 exons of the *CFTR* gene can readily detect deletions affecting one or more exons that would escape identification by PCR and conventional DNA sequencing.

Southern Blotting

Changes in the structure of specific loci can be detected by Southern blotting, which involves hybridization of radiolabeled sequence-specific probes to genomic DNA that has been first digested with a restriction enzyme and separated by gel electrophoresis. The probe usually detects one germ line band in normal individuals, and a different size band depending on the genetic anomaly. With the advent of FISH, MLPA, and microarray technology, Southern blotting is rarely used but remains useful in the detection of certain large-trinucleotide-expansion diseases, including the fragile X syndrome (Fig. 5-30).

Cytogenomic Array Technology

FISH requires prior knowledge of the one or few specific chromosomal regions suspected of being altered in the test sample. However, **genomic abnormalities can also be detected without prior knowledge by using microarray technology to perform a global genomic survey.** First generation platforms were designed for comparative genomic hybridization (CGH), while newer platforms incorporate SNP genotyping approaches, offering multiple benefits.

Array-Based Comparative Genomic Hybridization (Array CGH). In array CGH, the test DNA and a reference

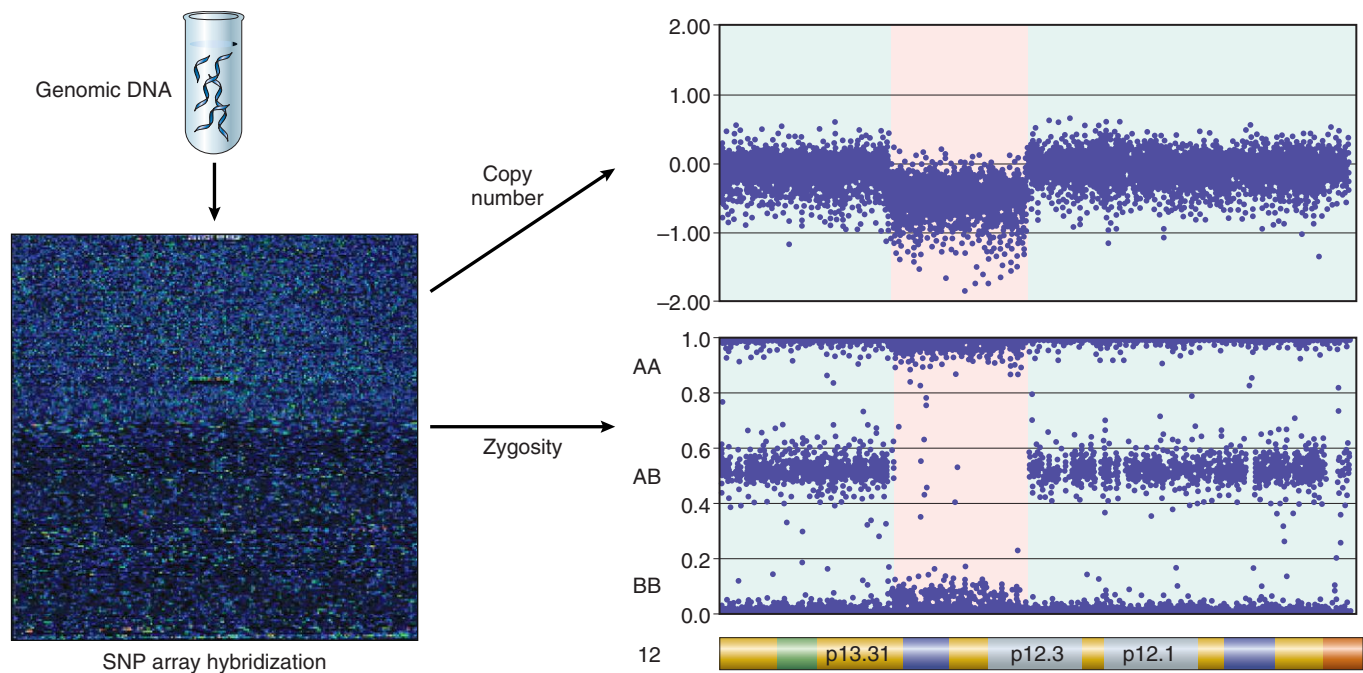

Figure 5-31 Analysis of copy number variation via SNP cytogenomic array. Genomic DNA is labeled and hybridized to an array containing potentially millions of probe spots. Copy number is determined by overall intensity and genotype is determined by allelic ratio. The example shown is the p arm of chromosome 12 in a pediatric leukemia. Here, the normal areas (green) show neutral (diploid) DNA content and the zygoty plot shows the expected ratio of AA, AB, and BB SNP genotypes. The anomalous area (red) shows decreased overall intensity, and the zygoty plot shows absence of the mixed AB genotype, indicating a full heterozygous deletion. (Modified from Paulsson K, et al: Genetic landscape of high hyperdiploid childhood acute lymphoblastic leukemia. *PNAS* 107(50):21719-24, 2010.)

(normal) DNA are labeled with two different fluorescent dyes. The differentially labeled samples are then co-hybridized to an array spotted with DNA probes that span the human genome at regularly spaced intervals, and usually cover all 22 autosomes and the sex chromosomes. At each chromosomal probe location, the binding of the labeled DNA from the two samples is compared. If the two samples are equal (i.e., the test sample is diploid), then all spots on the array will fluoresce yellow (the result of an equal admixture of green and red dyes). In contrast, if the test sample shows even a focal deletion or duplication, the probe spots corresponding to it will show skewing toward red or green (depending on gain or loss of material), allowing highly accurate determinations of copy number variants across the genome.

SNP Genotyping Arrays. Newer types of genomic arrays are based on a similar concept, but some or all of the probes are designed to identify single nucleotide polymorphism (SNP) sites genome-wide, which provides a number of advantages. As discussed earlier in [Chapter 1](#), SNPs are the most common type of DNA polymorphism, occurring approximately every 1000 nucleotides throughout the genome (e.g., in exons, introns, and regulatory sequences). SNPs serve as both a physical landmark within the genome and as a genetic marker whose transmission can be followed from parent to child.

There are several testing platforms using different methodologies that allow SNPs to be analyzed genome-wide on arrays; details of these methods are beyond the scope of this discussion. Like CGH probes, these methods involving SNPs can be used to make copy number variations (CNV)

calls, but by discriminating between SNP alleles at each particular location they also provide zygoty data ([Fig. 5-31](#)). The current generation of SNP arrays is quite comprehensive, with the largest containing greater than 4 million SNP probes. As a result, this technology is the mainstay of genome wide association studies (GWAS, described later).

In the clinical laboratory, SNP arrays are routinely used to uncover copy number abnormalities in pediatric patients when the karyotype is normal but a structural chromosomal abnormality is still suspected. Common indications include congenital abnormalities, dysmorphic features, developmental delay and autism. Here, the SNP data also proves useful. Typically, in areas of normal diploid copy number, the SNP results are roughly evenly split between homozygous and heterozygous calls. However, in anomalies such as uniparental disomy (e.g., in certain cases of Prader-Willi/Angelman syndromes), despite diploid copy number, the SNP calls in the affected region are all homozygous. SNP data can also help uncover other anomalies, such as mosaicism, which produces complex but distinctive skewing of zygoty plots.

Polymorphic Markers and Molecular Diagnosis

Clinical detection of disease-specific mutations is possible only if the gene responsible for the disorder is known and its sequence has been identified. If the exact nature of the genetic aberration is not known, or if testing for the primary defect is technically challenging or unfeasible, diagnostic labs can take advantage of the phenomenon of *linkage*. In humans, two DNA loci even 100,000 base pairs apart on

Figure 5-32 DNA polymorphisms resulting from a variable number of CA repeats. The three alleles produce PCR products of different sizes, thus identifying their origins from specific chromosomes. In the example depicted, allele C is linked to a mutation responsible for autosomal dominant polycystic kidney disease (PKD). Application of this to detect progeny carrying the disease-related gene (red symbols) is illustrated in one hypothetical pedigree. Males (squares); females (circles).

the same chromosome are almost certain to cosegregate during meiosis, due to the extremely low chance of a crossover event happening between them. Thus, the closer two loci are, the safer it is to assume that they will travel together in family pedigrees. In the event of a challenging or unknown pathogenic allele, a diagnostics lab can instead choose simply to examine nearby marker loci in the context of the family pedigree, as a surrogate approach. **The two types of genetic polymorphisms most useful for linkage analysis are SNPs (described earlier) and repeat-length polymorphisms known as minisatellite and microsatellite repeats.**

Human DNA contains short repetitive sequences of DNA giving rise to what are called repeat-length polymorphisms. These polymorphisms are often subdivided on the basis of their length into microsatellite repeats and minisatellite repeats. Microsatellites are usually less than 1 kilobase and are characterized by a repeat size of 2 to 6 base pairs. Minisatellite repeats, by comparison, are larger (1 to 3 kilobases), and the repeat motif is usually 15 to 70 base pairs. It is important to recall that the number of repeats, both in microsatellites and minisatellites, is extremely variable within a given population, and hence these stretches of DNA can be used quite effectively to establish genetic identity for linkage analysis. Microsatellites and the smaller minisatellites can be readily distinguished by using PCR primers that flank the repeat region. [Figure 5-32](#) depicts the application of microsatellite linkage analysis to the *PKD1* gene (historically very difficult to sequence) for the familial diagnosis of adult polycystic kidney disease. It can be seen that the longest microsatellite allele is linked in the family to the disease allele and can be used to track transmission.

Assays to detect genetic polymorphisms are also important in many other areas of medicine, including in the determination of relatedness and identity in transplantation, cancer genetics, paternity testing, and forensic medicine. Since microsatellite markers are scattered throughout the human genome and have such a high level of polymorphism, they are ideal for differentiating between two individuals and to follow transmission of the marker from parent to child. Panels of microsatellite marker PCR assays have been extensively validated and are now routinely used for determining paternity and for criminal investigations. Since PCR can be performed even with

highly degraded biologic samples, DNA technology is critical in forensic identifications. The same assays are regularly applied to the detection and quantification of transplant chimerism in allogeneic hematopoietic stem cell transplant patients, by looking for relative amounts of both donor- and host-specific microsatellite markers in host blood and blood cell subsets.

Polymorphisms and Genome-Wide Analyses

Beyond the clinic, linkage-based analysis has a long and storied history as a critical tool for discovery in the research laboratory. Many Mendelian diseases (including cystic fibrosis) were originally localized to candidate chromosomal locations using family pedigrees, testing a variety of candidate marker loci in a search for linkage disequilibrium, followed by subsequent refinement and testing of new nearby markers. Linkage studies have been similarly invaluable for identifying genes responsible for various phenotypes in laboratory animal models. However, similar analyses of complex (multifactorial) disorders have been unsuccessful since conventional linkage studies lack the statistical power to detect variants with small effects and low penetrance, which are thought to contribute to complex disorders.

To address this problem, researchers have utilized SNP genotyping array technology to perform large-scale linkage studies of complex diseases (e.g., type 2 diabetes, hypertension), which are termed genome wide association studies (GWAS). **In GWAS, large cohorts of patients with and without a disease (rather than families) are examined across the entire genome for common genetic variants or polymorphisms that are overrepresented in patients with the disease.** This identifies regions of the genome that contain a variant gene or genes that confer disease susceptibility and provides a springboard for further targeted research to find the true causative factor.

In addition to polygenic diseases, GWASs also have led to the identification of genetic loci that modulate common quantitative traits in humans, such as height, body mass, hair and eye color, and bone density. There has been much dispute about the value of GWAS studies, with criticisms often focusing on their underlying hypothesis that common disease risk could be explained by examining associations with common genetic variants. In support of that criticism, the combined relative risk from the associated variants that

have been discovered falls well short of estimates of genetic inheritance predicted by twin studies, for example it may be that the missing risk factors will prove to be rare genetic variants that are more difficult to study, and have yet to be identified.

Epigenetic Alterations

Epigenetics is defined as the study of heritable chemical modification of DNA or chromatin that does not alter the DNA sequence itself. Examples of such modification include the methylation of DNA, and the methylation and acetylation of histones (Chapter 1). Our understanding of these types of molecular alterations is rapidly growing, and it is clear that epigenetic modifications are critical for normal human development—including the regulation of tissue-specific gene expression, X chromosome inactivation, and imprinting, as well as for understanding of the cellular perturbations in the aging and cancer.

Gene expression frequently correlates with the level of methylation of DNA, usually of cytosines specifically in CG dinucleotide-rich promoter regions known as CpG islands. As discussed earlier in the section on **genomic imprinting**, increased methylation of these loci is associated with decreased gene expression and is accompanied by concomitant specific patterns of histone methylation and acetylation. An ever increasing number of disease states warrant analysis of promoter methylation—for example, in the diagnosis of fragile X syndrome, in which hypermethylation results in *FMR1* silencing. Methylation analysis is also essential in the diagnosis of Prader-Willi and Angelman syndromes.

Since traditional Sanger sequencing alone cannot detect DNA methylation, other techniques have been developed to uncover these chemical modifications. One common approach is to treat genomic DNA with sodium bisulfite, a chemical that converts unmethylated cytosine to uracil, which acts like thymine in downstream reactions. Methylated cytosines are protected from modification and remain unchanged. After treatment, it is then straightforward to discriminate the unmethylated (modified) DNA from the methylated (unmodified) DNA on the basis of sequence analysis.

RNA Analysis

Because DNA exerts its effects on the cell through RNA expression and mature mRNA contains the coding sequences of all expressed genes, RNA can substitute for DNA in a wide range of diagnostic applications. From a practical standpoint, however, DNA-based diagnosis is usually preferred, since DNA is much more stable. Nonetheless, RNA analysis is critical in several areas of molecular diagnostics. The most important application is the detection and quantification of RNA viruses such as HIV and hepatitis C virus. Furthermore, mRNA expression profiling (described for breast cancer in Chapter 23) is emerging as an important tool for molecular stratification of tumors. In some instances cancer cells bearing particular chromosomal translocations are detected with greater sensitivity by analyzing mRNA (e.g., the *BCR-ABL* fusion transcript in CML). The principal reason for this is that most translocations occur in scattered locations within particular introns, which can be very large, beyond the capacity of

conventional PCR amplification. Since introns are removed by splicing during the formation of mRNA, PCR analysis is possible if RNA is first converted to cDNA by reverse transcriptase. Real-time PCR performed on cDNA is the method of choice for monitoring residual disease in patients with CML and certain other hematologic malignancies (Chapter 13).

Next-Generation Sequencing

Next-generation sequencing (NGS) is a term used to describe several newer DNA sequencing technologies that are capable of producing large amounts of sequence data in a massively parallel manner. These technologies, developed over the past decade, have already revolutionized biomedical research, and they are now beginning to have a similar impact on molecular diagnostics. The factors propelling rapid adoption of NGS are both price and performance: NGS allows us to perform previously impossible analyses at extremely low relative cost.

The fundamental factor that sets NGS apart from traditional Sanger sequencing is its input sample requirements. Whereas Sanger sequencing requires a single, simple, homogenous template DNA (usually either a specific PCR product or prepared plasmid), NGS has no such requirement: any DNA from almost any source can be used. Because Sanger sequencing essentially provides an “average” result for a DNA sample, samples with extreme sequence heterogeneity amongst input DNA molecules produce uninterpretable results. NGS instruments, in contrast, are well suited to heterogeneous DNA samples due to the application of these common basic processes (Fig. 5-33):

- **Spatial separation.** At the beginning of the procedure, individual input DNA molecules are physically isolated from each other in space. The specifics of this process are platform-dependent.
- **Local amplification.** After separation, the individual DNA molecules are amplified in situ using a limited number of PCR cycles. Amplification is necessary so that sufficient signal can be generated to ensure detection and accuracy.
- **Parallel sequencing.** The amplified DNA molecules are simultaneously sequenced by the addition of polymerases and other reagents, with each spatially separated and amplified original molecule yielding a “read” corresponding to its sequence. Sequence reads from NGS instruments are generally short, approximately less than 500 bp.

Bioinformatics

NGS instruments can generate a staggering amount of sequence data. For example one newer instrument is capable of analyzing over 500 million individual DNA clusters and producing 180 billion base pairs or more of sequence in a little more than a day. This is enough to produce a high-quality sequence spanning an entire human genome. The downstream analysis necessary to make sense of these enormous data sets is sufficiently complex that specialized training in bioinformatics is frequently needed to ensure its proper interpretation.

Bioinformatic computational pipelines can vary tremendously based on particular applications and sample types,

Figure 5-33 Principle of next-generation sequencing. Several alternative approaches currently are available for “NextGen” sequencing, and one of the more commonly used platforms is illustrated. **A**, Short fragments of genomic DNA (“template”) between 100 and 500 base pairs in length are immobilized on a solid phase platform such as a glass slide, using universal capture primers that are complementary to adapters that have previously been added to ends of the template fragments. The addition of fluorescently labeled complementary nucleotides, one per template DNA per cycle, occurs in a “massively parallel” fashion, at millions of templates immobilized on the solid phase at the same time. A four-color imaging camera captures the fluorescence emanating from each template location (corresponding to the specific incorporated nucleotide), following which the fluorescent dye is cleaved and washed away, and the entire cycle is repeated. **B**, Powerful computational programs can decipher the images to generate sequences complementary to the template DNA at the end of one “run,” and these sequences are then mapped back to the reference genomic sequence in order to identify alterations. (Reproduced with permission from Metzker M: Sequencing technologies—the next generation. *Nat Rev Genet* 11:31-46, 2010, © Nature Publishing Group.)

and a detailed discussion is beyond the scope of this text. However, it is worth describing the basic steps necessary to process this type of data in a generic human DNA context:

- **Alignment.** Alignment is the process by which the sequencing reads from a sample (which are individually uninformative) are mapped onto the appropriate reference genome, where they can be viewed and interpreted in context.
- **Variant calling.** This process involves “walking” across the reference genome and evaluating all of the sequence data that mapped to each position and comparing it with the reference sequence. The more reads that cover a particular location (sequencing depth), the more likely that a variant will be detected if present. If a locus shows sufficient evidence of a difference from the reference sequence, a variant call will be made.
- **Variant annotation and interpretation.** Called variants can be annotated with various sources of information (e.g., gene names, coding changes and protein effects predictions, SNP IDs, information from databases of both benign and pathogenic variants, clinical information). In the clinical laboratory the data may then be ready for interpretation and reporting.

Clinical Applications of NGS DNA Sequencing

As discussed, any DNA sample can be analyzed by NGS. However, the DNA needs to first be prepared for sequencing, and the choice of technique determines what data

will be collected. In order to allow for binding and focal amplification on the instrument, input DNA must be in the form of small segments (<500 bp) with instrument-compatible linker oligonucleotide sequences incorporated at the ends. For whole genome sequencing this often involves automated genomic DNA fragmentation followed by ligation of adapter oligonucleotides. The final product is termed a *library*. There are many methods for NGS library preparation from genomic DNA, depending on the question and desired result. Currently in the clinical labs, most applications of NGS are targeted toward constitutional genetic disease and cancer diagnostics, using a few different basic approaches:

- **Targeted sequencing.** Most clinical laboratory NGS tests today fall in this category. With targeted sequencing just one gene or a panel of genes minimizes sequencing costs as well as the time and expense required for manual interpretation and clinical reporting. Sample preparation can be performed either by subselecting relevant clones from a whole genome library via custom complementary probes or by alternate preparations from genomic DNA, such as multiplex PCR. Single gene assays are more common for constitutional testing, and many laboratories that previously performed costly whole gene analyses by Sanger sequencing (i.e., comprehensive *CFTR* sequencing) are now moving those assays to NGS platforms. Analysis of large panels of genes (up to 100 or more) was previously unfeasible, but is now a commonplace approach for children with

common genetic diseases, such as cardiomyopathy and congenital deafness. In cancer testing, gene panels are being widely adopted to perform detailed tumor profiling. Each tumor has a unique set of somatic mutations, and these assays aim to detect as many treatable or prognostic mutations as possible to offer individually tailored patient care. Currently available panels vary widely in size, from a few dozen genes up to nearly a thousand. For cancer, targeted testing allows for high-depth sequencing at low cost, helpful for detecting clinically relevant mutations present at low allelic percentage due to tumor or sample heterogeneity.

- **Whole exome sequencing (WES).** Exome sequencing is really just a type of targeted sequencing. It uses hundreds of thousands of custom probes to pull out the roughly 1.5% of the genome that consists of protein-encoding exons. At a time when whole genome sequencing is still costly, WES enables a broad survey for protein coding mutations (which are responsible for as much as 80% of Mendelian disease) at significantly reduced cost. This has led to some wonderful success stories, allowing physicians to deliver answers and even therapies for children with orphan diseases who had suffered through prolonged and unsuccessful diagnostic odysseys. WES is also used in oncology to perform a very broad analysis, mostly in the research setting but also in some clinical laboratories.
- **Whole genome sequencing (WGS).** Whole genome sequencing is the most comprehensive type of DNA analysis that can be performed on an individual. However, current costs and informatic challenges still preclude its routine use in clinical practice. Indications for use in medical genetics are mostly limited to cases where exome sequencing has failed to provide an answer but the clinical suspicion of genetic disease remains high. For cancer applications, WGS is the only NGS application that can detect novel structural rearrangements (e.g., insertions, deletions, translocations) that may be clinically relevant. Because of associated costs, WGS is generally performed to lower sequencing depth than either targeted panels or exomes, and may suffer from a lack of statistical power to detect low percentage mutations in heterogeneous tumor samples.

The choice of approach is mainly a function of sequencing cost and interpretive workload. Interpreting NGS clinical assays can be laborious, with considerable effort required to research the potential relevance of novel, suspicious variants. These interpretive challenges should lessen over time with improvements to variant databases.

Future Applications

Because NGS can be used to detect genetic anomalies of essentially any size scale, from SNPs to very large rearrangements and even aneuploidy, almost all of today's genetic diagnostic tests could in principle be supplanted by NGS. This includes RNA analysis, because NGS-based analysis of the transcriptome (RNA-seq) is straightforward. As costs continue to drop, it is reasonable to expect NGS to occupy an increasingly prominent place in the diagnostics lab. Additionally, NGS holds promise for application into novel areas, including microbiome analysis and blood screening for early markers of diseases,

including cancer. Continuing technologic advances may even extend the applications further. Already third generation (or "single molecule" or "next next generation") technologies are emerging that can rapidly sequence single molecules in parallel without the need for focal amplification, and these could soon have an impact in the clinical laboratory.

Amyloidosis 258

The immune system is vital for survival, because it protects us from infectious pathogens that abound in the environment. Predictably, immune deficiencies render individuals easy prey to infections. But the immune system is itself capable of causing tissue injury and disease. Examples of disorders caused by immune responses include *allergies* and reactions against an individual's own tissues and cells (*autoimmunity*).

This chapter is devoted to diseases caused by too little immunity or too much immunologic reactivity. We also consider amyloidosis, a disease in which an abnormal protein, derived in some cases from fragments of immunoglobulins, is deposited in tissues. First, we review some of the important features of normal immune responses, to provide a foundation for understanding the abnormalities that give rise to immunologic diseases.

The Normal Immune Response

The classic definition of *immunity* is protection from infectious pathogens, and the normal immune response is best understood in this context. The mechanisms of defense against microbes fall into two broad categories (Fig. 6-1). *Innate immunity* (also called natural, or native, immunity) refers to the mechanisms that are ready to react to infections even before they occur, and that have evolved to specifically recognize and combat microbes. *Adaptive immunity* (also called acquired, or specific, immunity) consists of mechanisms that are stimulated by ("adapt to") microbes and are capable of recognizing microbial and nonmicrobial substances. Innate immunity is the first line

of defense. It is mediated by cells and molecules that recognize products of microbes and dead cells and induce rapid protective host reactions. Adaptive immunity develops later, after exposure to microbes and other foreign substances, and is even more powerful than innate immunity in combating infections. By convention, the term *immune response* usually refers to adaptive immunity.

Innate Immunity

Innate immunity is always present, ready to provide defense against microbes and to eliminate damaged cells.

The receptors and components of innate immunity have evolved to serve these purposes. Innate immunity functions in stages: recognition of microbes and damaged cells, activation of various mechanisms, and elimination of the unwanted substances.

Components of Innate Immunity

The major components of innate immunity are epithelial barriers that block entry of microbes, phagocytic cells (mainly neutrophils and macrophages), dendritic cells, natural killer (NK) cells, and several plasma proteins, including the proteins of the complement system.

- *Epithelia* of the skin and gastrointestinal and respiratory tracts provide mechanical barriers to the entry of microbes from the external environment. Epithelial cells also produce antimicrobial molecules such as defensins, and lymphocytes located in the epithelia combat microbes at these sites. If microbes do breach epithelial boundaries, other defense mechanisms are called in.

Figure 6-1 The principal mechanisms of innate immunity and adaptive immunity. NK cells, Natural killer cells.

- *Monocytes* and *neutrophils* are phagocytes in the blood that can rapidly be recruited to any site of infection; monocytes that enter the tissues and mature are called *macrophages*. All tissues contain resident macrophages, the professional phagocytes of the body. These cells not only sense the presence of microbes and other offending agents, but also ingest (phagocytose) these invaders and destroy them. Because macrophages are the dominant cells of chronic inflammation, we described them in more detail in [Chapter 3](#) in the discussion of chronic inflammation.
- *Dendritic cells* are a specialized cell population present in epithelia, lymphoid organs, and most tissues. They capture protein antigens and display peptides for recognition by T lymphocytes. In addition to their antigen presenting function, dendritic cells are endowed with a rich collection of receptors that sense microbes and cell damage and stimulate the secretion of cytokines, mediators that play critical roles in inflammation and anti-viral defense. Thus, dendritic cells are involved in the initiation of innate immune responses, but, unlike macrophages, they are not key participants in the destruction of microbes and other offending agents.
- *Natural killer cells* provide early protection against many viruses and intracellular bacteria; their properties and functions are described later.
- Several other cell types can sense and react to microbes. These include *mast cells*, which are capable of producing many mediators of inflammation (discussed later), and even epithelial and endothelial cells.
- It has recently been recognized that cells with the appearance of lymphocytes but with features more like the cells of innate immunity may contribute to the early defense against microbes. These *innate lymphoid cells* are described later, when the properties and functions of lymphocytes are discussed.
- In addition to these cells, several soluble proteins play important roles in innate immunity. The proteins of the *complement system*, which were described in [Chapter 3](#), are plasma proteins that are activated by microbes using the alternative and lectin pathways in innate immune responses; in adaptive immunity it is activated by antibodies using the classical pathway. Other circulating proteins of innate immunity are mannose-binding lectin and C-reactive protein, both of which coat microbes and promote phagocytosis. Lung surfactant is also a component of innate immunity, providing protection against inhaled microbes.

Cellular Receptors for Microbes, Products of Damaged Cells, and Foreign Substances

Cells that participate in innate immunity are capable of recognizing certain microbial components that are shared among related microbes and are often essential for infectivity (and thus cannot be mutated to allow the microbes to evade the defense mechanisms). These microbial structures are called *pathogen-associated molecular patterns*. Leukocytes also recognize molecules released by injured and necrotic cells, which are called *damage-associated molecular patterns*. Collectively, the cellular receptors that recognize these molecules are often called *pattern recognition receptors*.

Figure 6-2 Cellular receptors for microbes and products of cell injury. Phagocytes, dendritic cells, and many types of epithelial cells express different classes of receptors that sense the presence of microbes and dead cells. Toll-like receptors (TLRs) located in different cellular compartments, as well as other cytoplasmic and plasma membrane receptors, recognize products of different classes of microbes. The four major classes of innate immune receptors are TLRs, NOD-like receptors in the cytosol (NLRs), C-type lectin receptors (CLRs), and RIG-like receptors for viral nucleic acids (RLRs).

Pattern recognition receptors are located in all the cellular compartments where microbes may be present: plasma membrane receptors detect extracellular microbes, endosomal receptors detect ingested microbes, and cytosolic receptors detect microbes in the cytoplasm (Fig. 6-2). Several classes of these receptors have been identified.

Toll-Like Receptors. The best known of the pattern recognition receptors are the Toll-like receptors (TLRs), whose founding member, *Toll*, was discovered in *Drosophila*. A family of related proteins was later shown to be essential for host defense against microbes. There are 10 TLRs in mammals, and each recognizes a different set of microbial molecules. The TLRs are present in the plasma membrane and endosomal vesicles (Fig. 6-2). All these receptors signal by a common pathway that culminates in the activation of two sets of transcription factors: (1) *NF- κ B*, which stimulates the synthesis and secretion of cytokines and the expression of adhesion molecules, both of which are critical for the recruitment and activation of leukocytes ([Chapter 3](#)), and (2) *interferon regulatory factors (IRFs)*, which stimulate the production of the antiviral cytokines, type I interferons. Germline loss-of-function mutations affecting TLRs and their signaling pathways are associated with rare but serious immunodeficiency syndromes, described later in the chapter.

Figure 6-3 The inflammasome. The inflammasome is a protein complex that recognizes products of dead cells and some microbes and induces the secretion of biologically active interleukin 1. The inflammasome consists of a sensor protein (a leucine-rich protein called NLRP3), an adapter, and the enzyme caspase-1, which is converted from an inactive to an active form.

NOD-Like Receptors and the Inflammasome. NOD-like receptors (NLRs) are cytosolic receptors named after the founding member NOD-2. They recognize a wide variety of substances, including products of necrotic cells (e.g., uric acid and released ATP), ion disturbances (e.g., loss of K⁺), and some microbial products. How this family of sensors is capable of detecting so many, quite diverse, signs of danger or damage is not known. Several of the NLRs signal via a cytosolic multiprotein complex called the *inflammasome*, which activates an enzyme (caspase-1) that cleaves a precursor form of the cytokine interleukin-1 (IL-1) to generate the biologically active form (Fig. 6-3). As is discussed later, IL-1 is a mediator of inflammation that recruits leukocytes and induces fever. Gain-of-function mutations in one of the NLRs result in periodic fever syndromes, called *autoinflammatory syndromes* (to be distinguished from autoimmune diseases, which result from T and B lymphocyte reactions against self antigens). The autoinflammatory syndromes respond very well to treatment with IL-1 antagonists. The NLR-inflammasome pathway may also play a role in many common disorders. For example, recognition of urate crystals by a class of NLRs underlies the inflammation associated with gout. These receptors may also be capable of detecting lipids and cholesterol crystals

that are deposited in abnormally large amounts in tissues, and the resulting inflammation may contribute to obesity-associated type 2 diabetes and atherosclerosis, respectively.

Other Receptors for Microbial Products. *C-type lectin receptors* (CLRs) expressed on the plasma membrane of macrophages and dendritic cells detect fungal glycans and elicit inflammatory reactions to fungi. *RIG-like receptors* (RLRs), named after the founding member RIG-I, are located in the cytosol of most cell types and detect nucleic acids of viruses that replicate in the cytoplasm of infected cells. These receptors stimulate the production of antiviral cytokines. *G protein-coupled receptors* on neutrophils, macrophages, and most other types of leukocytes recognize short bacterial peptides containing *N*-formylmethionyl residues. Because all bacterial proteins and few mammalian proteins (only those synthesized within mitochondria) are initiated by *N*-formylmethionine, this receptor enables neutrophils to detect bacterial proteins and stimulate chemotactic responses of the cells. *Mannose receptors* recognize microbial sugars (which often contain terminal mannose residues, unlike mammalian glycoproteins) and induce phagocytosis of the microbes.

Reactions of Innate Immunity

The innate immune system provides host defense by two main reactions.

- **Inflammation.** Cytokines and products of complement activation, as well as other mediators, are produced during innate immune reactions and trigger the vascular and cellular components of inflammation. The recruited leukocytes destroy microbes and ingest and eliminate damaged cells. This reaction is described in [Chapter 3](#).
- **Antiviral defense.** Type I interferons produced in response to viruses act on infected and uninfected cells and activate enzymes that degrade viral nucleic acids and inhibit viral replication, inducing what has been called an *antiviral state*.
- In addition to these defensive functions, innate immunity provides the danger signals that stimulate the subsequent more powerful adaptive immune response. The nature of some of these signals is described later.

Innate immunity, unlike adaptive immunity, does not have memory or fine antigen specificity. It is estimated that innate immunity uses about 100 different receptors to recognize 1,000 molecular patterns. In contrast, adaptive immunity uses two types of receptors (antibodies and T-cell receptors, described later), each with millions of variations, to recognize millions of antigens.

Adaptive Immunity

The adaptive immune system consists of lymphocytes and their products, including antibodies. The lymphocytes of adaptive immunity use highly diverse receptors to recognize a vast array of foreign substances. In the remainder of this introductory section we focus on lymphocytes and the reactions of the adaptive immune system.

Figure 6-4 The principal classes of lymphocytes and their functions. B and T lymphocytes are cells of adaptive immunity and natural killer (NK) cells are cells of innate immunity. Several more classes of lymphocytes have been identified, including NK-T cells and so-called innate lymphoid cells (ILCs); the functions of these cells are not established.

There are two types of adaptive immunity: *humoral immunity*, which protects against extracellular microbes and their toxins, and *cell-mediated (or cellular) immunity*, which is responsible for defense against intracellular microbes. Humoral immunity is mediated by B (bone marrow–derived) lymphocytes and their secreted products, *antibodies* (also called *immunoglobulins*, Ig), and cellular immunity is mediated by T (thymus-derived) lymphocytes. Both classes of lymphocytes express highly specific receptors for a wide variety of substances, which are called *antigens*.

Cells of the Immune System

Although T and B lymphocytes and their subsets are morphologically unimpressive and appear quite similar to one another, they are actually remarkably heterogeneous and specialized in molecular properties and functions. The major classes of lymphocytes and their functions are

illustrated in [Figure 6-4](#). Lymphocytes and other cells involved in immune responses are not fixed in particular tissues (as are cells in most of the organs of the body) but constantly circulate among lymphoid and other tissues via the blood and the lymphatic circulation. This feature promotes immune surveillance by allowing lymphocytes to home to any site of infection. In lymphoid organs, different classes of lymphocytes are anatomically segregated in such a way that they interact with one another only when stimulated to do so by encounters with antigens and other stimuli. Mature lymphocytes that have not encountered the antigen for which they are specific are said to be *naive* (immunologically inexperienced). After they are activated by recognition of antigens and other signals described later, lymphocytes differentiate into *effector cells*, which perform the function of eliminating microbes, and *memory cells*, which live in a state of heightened awareness and are able to react rapidly and strongly to combat the microbe in case it returns. The process of lymphocyte differentiation

into effector and memory cells is summarized later. We start with a consideration of the diversity of lymphocytes.

Lymphocyte Diversity

Lymphocytes specific for a large number of antigens exist before exposure to antigen, and when an antigen enters, it selectively activates the antigen-specific cells. This fundamental concept is called *clonal selection*. According to this hypothesis, lymphocytes express specific receptors for antigens and mature into functionally competent cells before exposure to antigen. Lymphocytes of the same specificity are said to constitute a *clone*; all the members of one clone express identical antigen receptors, which are different from the receptors in all other clones. There are about 10^{12} lymphocytes in a healthy adult, and it is estimated that these are capable of recognizing 10^7 to 10^9 different antigens. It follows that the number of cells specific for any one antigen is very small, probably less than 1 in 100,000 to 1 in 1 million lymphocytes. It is remarkable that so few cells with a particular specificity can accomplish the difficult task of combating various microbes; as discussed later, the immune system has developed many mechanisms for optimizing reactions to microbial antigens. It is also remarkable that the system is capable of producing so many receptors, far more than could be individually encoded in the genome. The mechanisms by which this happens are now well understood, and have many interesting clinical implications.

Antigen receptor diversity is generated by somatic recombination of the genes that encode the receptor proteins. All cells of the body, including lymphocyte progenitors, contain antigen receptor genes in the germline (inherited) configuration, in which the genes encoding these receptors consist of spatially separated segments that cannot be expressed as proteins. During lymphocyte maturation (in the thymus for T cells and the bone marrow for B cells), these gene segments recombine in random sets and variations are introduced at the sites of recombination, forming many different genes that can be transcribed and translated into functional antigen receptors. The enzyme in developing lymphocytes that mediates recombination of these gene segments is the product of *RAG-1* and *RAG-2* (recombination activating genes); inherited defects in *RAG* proteins result in a failure to generate mature lymphocytes. It is important to note that germline antigen receptor genes are present in all cells in the body, but only T and B cells contain recombined (also called rearranged) antigen receptor genes (the T-cell receptor [TCR] in T cells and immunoglobulin [Ig] in B cells). Hence, the presence of recombined TCR or Ig genes, which can be demonstrated by molecular analysis, is a marker of T- or B-lineage cells. Furthermore, because each T or B cell and its clonal progeny have a unique DNA rearrangement (and hence a unique antigen receptor), it is possible to distinguish polyclonal (nonneoplastic) lymphocyte proliferations from monoclonal (neoplastic) lymphoid tumors. Thus, **analysis of antigen receptor gene rearrangements is a valuable assay for detecting tumors derived from lymphocytes** (Chapter 13).

T Lymphocytes

There are three major populations of T cells, which serve distinct functions. **Helper T lymphocytes stimulate**

B lymphocytes to make antibodies and activate other leukocytes (e.g., phagocytes) to destroy microbes; cytotoxic T lymphocytes (CTLs) kill infected cells; and regulatory T lymphocytes limit immune responses and prevent reactions against self antigens.

T lymphocytes develop in the thymus from precursors that arise from hematopoietic stem cells. Mature T cells are found in the blood, where they constitute 60% to 70% of lymphocytes, and in T-cell zones of peripheral lymphoid organs (described later). Each T cell recognizes a specific cell-bound antigen by means of an antigen-specific TCR. In approximately 95% of T cells, the TCR consists of a disulfide-linked heterodimer made up of an α and a β polypeptide chain (Fig. 6-5), each having a variable (antigen-binding) region and a constant region. **The $\alpha\beta$ TCR recognizes peptide antigens that are presented by major histocompatibility complex (MHC) molecules on the surfaces of antigen-presenting cells.** By limiting the specificity of T cells for peptides displayed by cell surface MHC molecules, called *MHC restriction*, the immune system ensures that T cells see only cell-associated antigens (e.g., those derived from microbes in cells or from proteins ingested by cells).

Each TCR is noncovalently linked to six polypeptide chains, which form the CD3 complex and the ζ chain dimer (Fig. 6-5). The CD3 and ζ proteins are invariant (i.e., identical) in all T cells. They are involved in the transduction of signals into the T cell that are triggered by binding of

Figure 6-5 The T-cell receptor (TCR) complex and other molecules involved in T-cell activation. The TCR heterodimer, consisting of an α and a β chain, recognizes antigen (in the form of peptide-MHC complexes expressed on antigen-presenting cells, or APCs), and the linked CD3 complex and ζ chains initiate activating signals. CD4 and CD28 are also involved in T-cell activation. (Note that some T cells express CD8 and not CD4; these molecules serve analogous roles.) The sizes of the molecules are not drawn to scale. MHC, Major histocompatibility complex.

antigen to the TCR. Together with the TCR, these proteins form the *TCR complex*.

A small population of mature T cells expresses another type of TCR composed of γ and δ polypeptide chains. The $\gamma\delta$ TCR recognizes peptides, lipids, and small molecules, without a requirement for display by MHC proteins. $\gamma\delta$ T cells tend to aggregate at epithelial surfaces, such as the skin and mucosa of the gastrointestinal and urogenital tracts, suggesting that these cells are sentinels that protect against microbes that try to enter through epithelia. However, the functions of $\gamma\delta$ T cells are not established. Another small subset of T cells expresses markers that are also found on NK cells; these cells are called NK-T cells. NK-T cells express a very limited diversity of TCRs, and they recognize glycolipids that are displayed by the MHC-like molecule CD1. The functions of NK-T cells are also not well defined.

In addition to CD3 and ζ proteins, T cells express several other proteins that assist the TCR complex in functional responses. These include CD4, CD8, CD28, and integrins. CD4 and CD8 are expressed on two mutually exclusive subsets of $\alpha\beta$ T cells. Approximately 60% of mature T cells are CD4+ and about 30% are CD8+. Most CD4+ T cells function as cytokine-secreting helper cells that assist macrophages and B lymphocytes to combat infections. Most CD8+ cells function as cytotoxic (killer) T lymphocytes (CTLs) to destroy host cells harboring microbes. CD4 and CD8 serve as *coreceptors* in T-cell activation, so called because they recognize a part of the same ligand that the antigen receptor sees. During antigen recognition, CD4 molecules bind to class II MHC molecules that are displaying antigen (Fig. 6-5), and CD8 molecules bind to class I MHC molecules, and the CD4 or CD8 coreceptor initiates signals that are necessary for activation of the T cells. Because of this requirement for coreceptors, CD4+ helper T cells can recognize and respond to antigen displayed only by class II MHC molecules, whereas CD8+ cytotoxic T cells recognize cell-bound antigens only in association with class I MHC molecules; this segregation is described later. Integrins are adhesion molecules that promote the attachment of T-cells to APCs.

To respond, T cells have to recognize not only antigen-MHC complexes but additional signals provided by antigen-presenting cells. This process, in which CD28 plays an important role, is described later, when the steps in cell-mediated immune responses are summarized.

B Lymphocytes

B lymphocytes are the only cells in the body capable of producing antibody molecules, the mediators of humoral immunity. B lymphocytes develop from precursors in the bone marrow. Mature B cells constitute 10% to 20% of the circulating peripheral lymphocyte population and are also present in peripheral lymphoid tissues such as lymph nodes, spleen, and mucosa-associated lymphoid tissues. B cells recognize antigen via the B-cell antigen receptor complex. Membrane-bound antibodies of the IgM and IgD isotypes, present on the surface of all mature, naive B cells, are the antigen-binding component of the B-cell receptor complex (Fig. 6-6). After stimulation by antigen and other signals (described later), B cells develop into *plasma cells*, veritable protein factories for antibodies. It is estimated that a single plasma cell can secrete hundreds to thousands

Figure 6-6 Structure of antibodies and the B-cell antigen receptor. **A**, The B-cell antigen receptor complex is composed of membrane immunoglobulin M (IgM; or IgD, not shown), which recognizes antigens, and the associated signaling proteins Ig α and Ig β . CD21 is a receptor for a complement component that also promotes B-cell activation. **B**, Crystal structure of a secreted IgG molecule, showing the arrangement of the variable (V) and constant (C) regions of the heavy (H) and light (L) chains. (Courtesy Dr. Alex McPherson, University of California, Irvine, Calif.)

of antibody molecules per second, a remarkable measure of the power of the immune response for combating pathogens. Antibody-secreting cells are also detected in human peripheral blood; these are called *plasmablasts*.

In addition to membrane Ig, the B-cell antigen receptor complex contains a heterodimer of two invariant proteins called Ig α and Ig β . Similar to the CD3 and ζ proteins of the TCR complex, Ig α (CD79a) and Ig β (CD79b) are essential for signal transduction through the antigen receptor. B cells also express several other molecules that are essential for their responses. These include the type 2 complement receptor (CR2, or CD21), which recognizes complement products generated during innate immune responses to microbes, and CD40, which receives signals from helper T cells. CR2 is also used by the Epstein-Barr virus (EBV) as a receptor to enter and infect B cells.

Dendritic Cells

Dendritic cells (sometimes called *interdigitating dendritic cells*) are the most important antigen-presenting cells for initiating T-cell responses against protein antigens. These

cells have numerous fine cytoplasmic processes that resemble dendrites, from which they derive their name. Several features of dendritic cells account for their key role in antigen presentation. First, these cells are located at the right place to capture antigens—under epithelia, the common site of entry of microbes and foreign antigens, and in the interstitia of all tissues, where antigens may be produced. Immature dendritic cells within the epidermis are called *Langerhans cells*. Second, dendritic cells express many receptors for capturing and responding to microbes (and other antigens), including TLRs and lectins. Third, in response to microbes, dendritic cells are recruited to the T-cell zones of lymphoid organs, where they are ideally located to present antigens to T cells. Fourth, dendritic cells express high levels of MHC and other molecules needed for presenting antigens to and activating T cells.

A second type of cell with dendritic morphology is present in the germinal centers of lymphoid follicles in the spleen and lymph nodes and is called the *follicular dendritic cell*. These cells bear Fc receptors for IgG and receptors for C3b and can trap antigen bound to antibodies or complement proteins. Such cells play a role in humoral immune responses by presenting antigens to B cells and selecting the B cells that have the highest affinity for the antigen, thus improving the quality of the antibody produced.

Macrophages

Macrophages are a part of the mononuclear phagocyte system; their origin, differentiation, and role in inflammation are discussed in [Chapter 3](#). Here, their important functions in the induction and effector phases of adaptive immune responses are discussed.

- Macrophages that have phagocytosed microbes and protein antigens process the antigens and present peptide fragments to T cells. Thus, macrophages function as antigen-presenting cells in T-cell activation.
- Macrophages are key effector cells in certain forms of cell-mediated immunity, the reaction that serves to eliminate intracellular microbes. In this type of response, T cells activate macrophages and enhance their ability to kill ingested microbes (discussed later).
- Macrophages also participate in the effector phase of humoral immunity. As discussed in [Chapter 3](#), macrophages efficiently phagocytose and destroy microbes that are opsonized (coated) by IgG or C3b.

Natural Killer Cells

The function of NK cells is to destroy irreversibly stressed and abnormal cells, such as virus-infected cells and tumor cells. NK cells make up approximately 5% to 10% of peripheral blood lymphocytes. They do not express TCRs or Ig. Morphologically, NK cells are somewhat larger than small lymphocytes, and they contain abundant azurophilic granules. NK cells are endowed with the ability to kill a variety of virus-infected cells and tumor cells, without prior exposure to or activation by these microbes or tumors. This ability makes NK cells an early line of defense against viral infections and, perhaps, some tumors. Two cell surface molecules, CD16 and CD56, are commonly used to identify NK cells. CD16 is an Fc receptor for IgG, and it confers on NK cells the ability to lyse IgG-coated target cells. This phenomenon is known as *antibody-dependent*

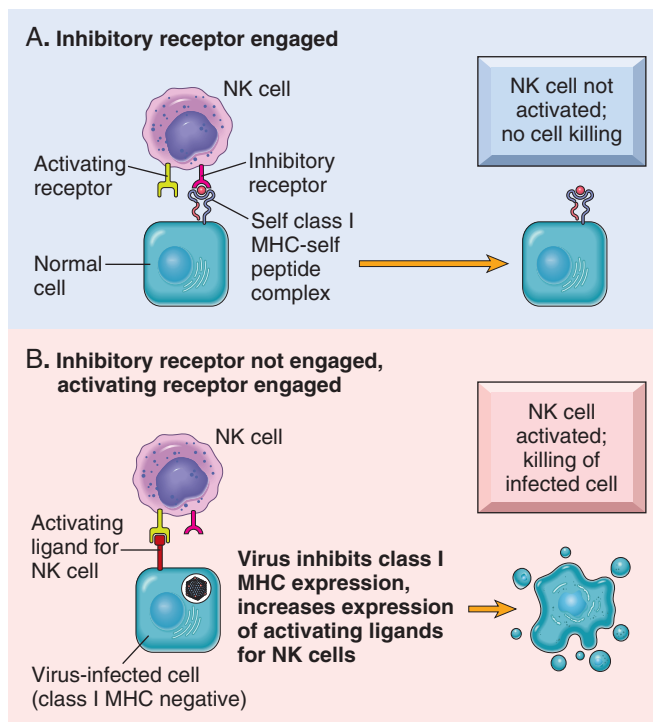

Figure 6-7 Activating and inhibitory receptors of natural killer (NK) cells. **A**, Healthy cells express self class I MHC molecules, which are recognized by inhibitory receptors, thus ensuring that NK cells do not attack normal cells. Note that healthy cells may express ligands for activating receptors (not shown) or may not express such ligands (as shown), but they do not activate NK cells because they engage the inhibitory receptors. **B**, In infected and stressed cells, class I MHC expression is reduced so that the inhibitory receptors are not engaged, and ligands for activating receptors are expressed. The result is that NK cells are activated and the infected cells are killed.

cell-mediated cytotoxicity (ADCC). The function of CD56 is not known.

The functional activity of NK cells is regulated by a balance between signals from activating and inhibitory receptors (Fig. 6-7). There are many types of activating receptors, of which the NKG2D family is the best characterized. The NKG2D receptors recognize surface molecules that are induced by various kinds of stress, such as infection and DNA damage. NK cell inhibitory receptors recognize self class I MHC molecules, which are expressed on all healthy cells. The inhibitory receptors prevent NK cells from killing normal cells. Virus infection or neoplastic transformation often enhances expression of ligands for activating receptors and at the same time reduces the expression of class I MHC molecules. As a result the balance is tilted toward activation, and the infected or tumor cell is killed.

NK cells also secrete cytokines such as interferon- γ (IFN- γ), which activates macrophages to destroy ingested microbes, and thus NK cells provide early defense against intracellular microbial infections. The activity of NK cells is regulated by many cytokines, including the interleukins IL-2, IL-15, and IL-12. IL-2 and IL-15 stimulate proliferation of NK cells, whereas IL-12 activates killing and secretion of IFN- γ .

Innate Lymphoid Cells (ILCs)

Recent studies have identified populations of lymphocytes that lack TCRs but produce cytokines similar to those that are made by T cells. NK cells are considered the first defined ILC. Different subsets of ILCs produce IFN- γ , IL-5, IL-17, and IL-22. The functions that have been attributed to ILCs include:

- Early defense against infections
- Recognition and elimination of stressed cells (so-called stress surveillance)
- Shaping the later adaptive immune response, by providing cytokines that influence the differentiation of T lymphocytes.

Interest in these cells has been spurred by the hypothesis that they are early participants in inflammatory diseases, primarily as a source of cytokines. However, much remains to be learned about the functions and roles of these cells in normal and pathologic immune responses.

Tissues of the Immune System

The tissues of the immune system consist of the *generative* (also called *primary*, or *central*) lymphoid organs, in which T and B lymphocytes mature and become competent to respond to antigens, and the *peripheral* (or *secondary*) lymphoid organs, in which adaptive immune responses to microbes are initiated.

Generative Lymphoid Organs

The principal generative lymphoid organs are the thymus, where T cells develop, and the bone marrow, the site of production of all blood cells and where B lymphocytes mature. These organs are described in [Chapter 13](#).

Peripheral Lymphoid Organs

The peripheral lymphoid organs—lymph nodes, spleen, and the mucosal and cutaneous lymphoid tissues—are organized to concentrate antigens, antigen-presenting cells, and lymphocytes in a way that optimizes interactions among these cells and the development of adaptive immune responses.

- *Lymph nodes* are nodular aggregates of lymphoid tissues located along lymphatic channels throughout the body ([Fig. 6-8](#)). As lymph slowly suffuses through lymph nodes, antigen-presenting cells in the nodes are able to sample the antigens of microbes that may enter through epithelia into tissues and are carried in the lymph. In addition, dendritic cells pick up and transport antigens of microbes from epithelia and tissues via lymphatic vessels to the lymph nodes. Thus, the antigens of microbes that enter through epithelia or colonize tissues become concentrated in draining lymph nodes.
- The *spleen* is an abdominal organ that serves the same role in immune responses to bloodborne antigen as the lymph nodes do in responses to lymph-borne antigens. Blood entering the spleen flows through a network of sinusoids. Bloodborne antigens are trapped by dendritic cells and macrophages in the spleen.
- The cutaneous and mucosal lymphoid systems are located under the epithelia of the skin and the gastrointestinal and respiratory tracts, respectively. They

respond to antigens that enter through breaches in the epithelium. Pharyngeal tonsils and Peyer's patches of the intestine are two anatomically defined mucosal lymphoid tissues. At any time, more than half the body's lymphocytes are in the mucosal tissues (reflecting the large size of these tissues), and many of these are memory cells.

Within the peripheral lymphoid organs, T lymphocytes and B lymphocytes are segregated into different regions (Fig. 6-8). In lymph nodes the B cells are concentrated in discrete structures, called *follicles*, located around the periphery, or cortex, of each node. If the B cells in a follicle have recently responded to an antigen, this follicle may contain a central region called a *germinal center*. The T lymphocytes are concentrated in the paracortex, adjacent to the follicles. The follicles contain the follicular dendritic cells that are involved in the activation of B cells, and the paracortex contains the dendritic cells that present antigens to T lymphocytes. In the spleen, T lymphocytes are concentrated in periarteriolar lymphoid sheaths surrounding small arterioles, and B cells reside in the follicles.

Lymphocyte Recirculation

Lymphocytes constantly recirculate between tissues and home to particular sites; naive lymphocytes traverse the peripheral lymphoid organs where immune responses are initiated, and effector lymphocytes migrate to sites of infection and inflammation. This process of lymphocyte recirculation is most important for T cells, because naive T cells have to circulate through the peripheral lymphoid organs where antigens are concentrated and effector T cells have to locate and eliminate microbes at any site of infection. In contrast, plasma cells remain in lymphoid organs and the bone marrow and do not need to migrate to sites of infection because they secrete antibodies that are carried to distant tissues.

Major Histocompatibility Complex (MHC) Molecules: The Peptide Display System of Adaptive Immunity

The function of MHC molecules is to display peptide fragments of protein antigens for recognition by antigen-specific T cells. Because MHC molecules are fundamental to the recognition of antigens by T cells and are linked to many autoimmune diseases, it is important to briefly review the structure and function of these molecules. MHC molecules were discovered as products of genes that evoke rejection of transplanted organs, and their name derives from their role in determining tissue compatibility between individuals. In humans the MHC molecules are called *human leukocyte antigens* (HLA) because they were initially detected on leukocytes by the binding of antibodies. The genes encoding HLA molecules are clustered on a small segment of chromosome 6 (Fig. 6-9). The HLA system is highly polymorphic, meaning that there are many alleles of MHC genes (in the thousands) in humans and each individual's HLA alleles differ from those inherited by most other individuals in the population. This, as we see subsequently, constitutes a formidable barrier in organ transplantation.

On the basis of their structure, cellular distribution and function, MHC gene products are classified into two major classes.

- **Class I MHC molecules** are expressed on all nucleated cells and platelets. They are heterodimers consisting of a polymorphic α , or heavy, chain (44-kD) linked non-covalently to a smaller (12-kD) nonpolymorphic protein called β_2 -microglobulin. The α chains are encoded by three genes, designated *HLA-A*, *HLA-B*, and *HLA-C*, that lie close to one another in the MHC locus (Fig. 6-9). The extracellular region of the α chain is divided into three domains: α_1 , α_2 , and α_3 . The α_1 and α_2 domains form a cleft, or groove, where peptides bind. The polymorphic amino acid residues line the sides and the base of the peptide-binding groove, explaining why different class I alleles bind different peptides.

Class I MHC molecules display peptides that are derived from proteins, such as viral and tumor antigens, that are located in the cytoplasm and usually produced in the cell, and class I-associated peptides are recognized by CD8+ T lymphocytes. Cytoplasmic proteins are degraded in proteasomes and peptides are transported into the endoplasmic reticulum (ER) where the peptides bind to newly synthesized class I molecules. Peptide-loaded MHC molecules associate with β_2 -microglobulin to form a stable trimer that is transported to the cell surface. The nonpolymorphic α_3 domain of class I MHC molecules has a binding site for CD8, and therefore the peptide-class I complexes are recognized by CD8+ T cells, which function as CTLs. In this interaction, the TCR recognizes the MHC-peptide complex, and the CD8 molecule, acting as a coreceptor, binds to the class I heavy chain. Since CD8+ T cells recognize peptides only if presented as a complex with class I MHC molecules, CD8+ T cells are said to be *class I MHC-restricted*. Because one of the important functions of CD8+ CTLs is to eliminate viruses, which may infect any nucleated cell, and tumors, which may arise from any nucleated cell, it makes good sense that all nucleated cells express class I HLA molecules and can be surveyed by CD8+ T cells.

- **Class II MHC molecules** are encoded in a region called *HLA-D*, which has three subregions: *HLA-DP*, *HLA-DQ*, and *HLA-DR*. Each class II molecule is a heterodimer consisting of a noncovalently associated α chain and β chain, both of which are polymorphic. The extracellular portions of the α and β chains both have two domains designated α_1 and α_2 , and β_1 and β_2 . Crystal structure of class II molecules has revealed that, similar to class I molecules, they have peptide-binding clefts facing outward (Fig. 6-9). This cleft is formed by an interaction of the α_1 and β_1 domains, and it is in this portion that most class II alleles differ. Thus, as with class I molecules, polymorphism of class II molecules is associated with differential binding of antigenic peptides.

Class II MHC molecules present antigens that are internalized into vesicles, and are typically derived from extracellular microbes and soluble proteins. The internalized proteins are proteolytically digested in endosomes or lysosomes. Peptides resulting from proteolytic cleavage then associate with class II heterodimers in the vesicles, and the stable peptide-MHC

Figure 6-9 The human leukocyte antigen (HLA) complex and the structure of HLA molecules. **A**, The location of genes in the HLA complex. The relative locations, sizes, and distances between genes are not to scale. Genes that encode several proteins involved in antigen processing (the TAP transporter, components of the proteasome, and HLA-DM) are located in the class II region (not shown). **B**, Schematic diagrams and crystal structures of class I and class II HLA molecules. (Crystal structures are courtesy Dr. P. Bjorkman, California Institute of Technology, Pasadena, Calif.)

complexes are transported to the cell surface. The class II β_2 domain has a binding site for CD4, and therefore, the class II-peptide complex is recognized by CD4⁺ T cells, which function as helper cells. In this interaction, the CD4 molecule acts as the coreceptor. Because CD4⁺ T cells can recognize antigens only in the context of self class II molecules, they are referred to as *class II MHC-restricted*. In contrast to class I molecules, class II MHC molecules are mainly expressed on cells that present ingested antigens and respond to T-cell help (macrophages, B lymphocytes, and dendritic cells).

- The MHC locus also contains genes that encode some complement components and the cytokines tumor necrosis factor (TNF) and lymphotoxin, as well as some proteins that have no apparent role in the immune system.

The combination of HLA alleles in each individual is called the *HLA haplotype*. Any given individual inherits one set of HLA genes from each parent and thus typically expresses two different molecules for every locus. Because of the polymorphism of the HLA genes, virtually innumerable combinations of molecules exist in the population, and each individual expresses an MHC profile on his or her cell surface that is different from the haplotypes of most other individuals. It is believed that this polymorphism evolved to ensure that at least some individuals in a species would

be able to display any microbial peptide and thus provide protection against any infection. This polymorphism also means that no two individuals (other than identical twins) are likely to express the same MHC molecules, and therefore grafts exchanged between these individuals are recognized as foreign and attacked by the immune system.

MHC molecules play several key roles in regulating T cell-mediated immune responses. First, because different antigenic peptides bind to different MHC molecules, it follows that an individual mounts an immune response against a protein antigen only if he or she inherits the genes for those MHC molecules that can bind peptides derived from the antigen and present it to T cells. The consequences of inheriting a given MHC (e.g., class II) gene depend on the nature of the antigen bound by the class II molecule. For example, if the antigen is a peptide from ragweed pollen, the individual who expresses class II molecules capable of binding the antigen would be genetically prone to allergic reactions against pollen. In contrast, an inherited capacity to bind a bacterial peptide may provide resistance to the infection by evoking a protective antibody response. Second, by segregating cytoplasmic and internalized antigens, MHC molecules ensure that the correct immune response is mounted against different microbes—CTL-mediated killing of cells harboring cytoplasmic microbes, and helper T cell-mediated antibody and macrophage activation to combat extracellular microbes.

Interest in HLA molecules was spurred by the realization, in the 1960s and 1970s, that **a number of autoimmune and other diseases are associated with the inheritance of particular HLA alleles**. These associations are discussed when the pathogenesis of autoimmune diseases is considered later in the chapter.

Cytokines: Messenger Molecules of the Immune System

The induction and regulation of immune responses involve multiple interactions among lymphocytes, dendritic cells, macrophages, other inflammatory cells (e.g., neutrophils), and endothelial cells. Some of these interactions depend on cell-to-cell contact; however, **many cellular interactions and functions of leukocytes are mediated by secreted proteins called cytokines**. Molecularly defined cytokines are called *interleukins*, because they mediate communications between leukocytes. Most cytokines have a wide spectrum of effects, and some are produced by several different cell types. The majority of these cytokines act on the cells that produce them (*autocrine* actions) or on neighboring cells (*paracrine*) and rarely at a distance (*endocrine*).

Cytokines contribute to different types of immune responses.

- In innate immune responses, cytokines are produced rapidly after encounter with microbes and other stimuli, and function to induce inflammation and inhibit virus replication. These cytokines include TNF, IL-1, IL-12, type I IFNs, IFN- γ , and chemokines (Chapter 3). Their major sources are macrophages, dendritic cells, and NK cells, but endothelial and epithelial cells can also produce them.
- In adaptive immune responses, cytokines are produced principally by CD4+ T lymphocytes activated by antigen and other signals, and function to promote lymphocyte proliferation and differentiation and to activate effector cells. The main ones in this group are IL-2, IL-4, IL-5, IL-17, and IFN- γ ; their roles in immune responses are described later. Some cytokines serve mainly to limit and terminate immune responses; these include TGF- β and IL-10.
- Some cytokines stimulate hematopoiesis and are called *colony-stimulating factors* because they are assayed by their ability to stimulate formation of blood cell colonies from bone marrow progenitors (Chapter 13). Their functions are to increase leukocyte numbers during immune and inflammatory responses, and to replace leukocytes that are consumed during such responses. They are produced by marrow stromal cells, T lymphocytes, macrophages, and other cells. Examples include the colony-stimulating factors (CSFs) such as GM-CSF, and IL-7.

The knowledge gained about cytokines has numerous practical therapeutic applications. Inhibiting cytokine production or actions is an approach for controlling the harmful effects of inflammation and tissue-damaging immune reactions. Patients with rheumatoid arthritis often show dramatic responses to TNF antagonists, an elegant example of rationally designed and molecularly targeted therapy. Many other cytokine antagonists are

now approved for the treatment of various inflammatory disorders. Conversely, administration of cytokines is used to boost reactions that are normally dependent on these proteins, such as hematopoiesis and defense against some viruses. An important therapeutic application of cytokines is to mobilize and recruit stem cells from bone marrow to peripheral blood; the cells are then collected from the blood for stem cell transplantation.

Overview of Lymphocyte Activation and Immune Responses

All adaptive immune responses develop in steps, consisting of: antigen recognition, activation of specific lymphocytes to proliferate and differentiate into effector and memory cells, elimination of the antigen, and decline of the response, with memory cells being the long-lived survivors. The major events in each step are summarized later; these general principles apply to protective responses against microbes as well as pathologic responses that injure the host.

Display and Recognition of Antigens

Microbes and other foreign antigens can enter anywhere in the body. It is obviously impossible for lymphocytes of every specificity to patrol every possible portal of antigen entry. In fact, antigens are captured and concentrated in lymphoid organs through which lymphocytes circulate, thus increasing the likelihood of lymphocytes finding the antigen they recognize. Microbes and their protein antigens are captured by dendritic cells that are resident in epithelia and tissues. These cells carry their antigenic cargo to draining lymph nodes (Fig. 6-10). Here the antigens are processed and displayed complexed with MHC molecules on the cell surface, where the antigens are recognized by T cells.

B lymphocytes use their antigen receptors (membrane-bound antibody molecules) to recognize antigens of many different chemical types, including proteins, polysaccharides, and lipids.

Even before the antigens of a microbe are recognized by T and B lymphocytes, the microbe elicits an innate immune response through recognition by pattern recognition receptors; this encounter is the first line of defense and also serves to activate adaptive immunity. In the case of immunization with a protein antigen, microbial mimics, called *adjuvants*, are given with the antigen and these stimulate innate immune responses. During the innate response the microbe or adjuvant activates antigen-presenting cells to express molecules called *costimulators* and to secrete cytokines that stimulate the proliferation and differentiation of T lymphocytes. The principal costimulators for T cells are the B7 proteins (CD80 and CD86) that are expressed on antigen-presenting cells and are recognized by the CD28 receptor on naive T cells. Thus, antigen (“signal 1”) and costimulatory molecules produced during innate immune responses to microbes (“signal 2”) function cooperatively to activate antigen-specific lymphocytes (Fig. 6-5). The requirement for microbe-triggered signal 2 ensures that the adaptive immune response is induced by microbes and not by harmless substances. In immune responses to tumors and transplants, “signal 2” may be provided by substances

Figure 6-10 Cell-mediated immunity. Dendritic cells (DCs) capture microbial antigens from epithelia and tissues and transport the antigens to lymph nodes. During this process, the DCs mature, and express high levels of MHC molecules and costimulators. Naive T cells recognize MHC-associated peptide antigens displayed on DCs. The T cells are activated to proliferate and to differentiate into effector and memory cells, which migrate to sites of infection and serve various functions in cell-mediated immunity. CD4⁺ effector T cells of the T_H1 subset recognize the antigens of microbes ingested by phagocytes, and activate the phagocytes to kill the microbes; other subsets of effector cells enhance leukocyte recruitment and stimulate different types of immune responses. CD8⁺ cytotoxic T lymphocytes (CTLs) kill infected cells harboring microbes in the cytoplasm. Some activated T cells remain in the lymphoid organs and help B cells to produce antibodies, and some T cells differentiate into long-lived memory cells (not shown). APC, Antigen-presenting cell.

released from necrotic cells (the “damage-associated molecular patterns” mentioned earlier).

The reactions and functions of T and B lymphocytes differ in important ways and are best considered separately.

Cell-Mediated Immunity: Activation of T Lymphocytes and Elimination of Intracellular Microbes

Naive T lymphocytes are activated by antigen and costimulators in peripheral lymphoid organs, and proliferate and differentiate into effector cells that migrate to any site where the antigen (microbe) is present (Fig. 6-10). One of

the earliest responses of CD4⁺ helper T cells is secretion of the cytokine IL-2 and expression of high-affinity receptors for IL-2. IL-2 is a growth factor that acts on these T lymphocytes and stimulates their proliferation, leading to an increase in the number of antigen-specific lymphocytes. The functions of helper T cells are mediated by the combined actions of CD40-ligand (CD40L) and cytokines. When CD4⁺ helper T cells recognize antigens being displayed by macrophages or B lymphocytes, the T cells express CD40L, which engages CD40 on the macrophages or B cells and activates these cells.

Some of the activated CD4⁺ T cells differentiate into effector cells that secrete different sets of cytokines and

Major cytokines produced	IFN- γ	IL-4, IL-5, IL-13	IL-17, IL-22
Cytokines that induce this subset	IFN- γ , IL-12	IL-4	TGF- β , IL-6, IL-1, IL-23
Immunological reactions triggered	Macrophage activation, stimulation of IgG antibody production	Stimulation of IgE production, activation of mast cells and eosinophils	Recruitment of neutrophils, monocytes
Host defense against	Intracellular microbes	Helminthic parasites	Extracellular bacteria, fungi
Role in disease	Autoimmune and other chronic inflammatory diseases (such as IBD, psoriasis, granulomatous inflammation)	Allergies	Autoimmune and other chronic inflammatory diseases (such as IBD, psoriasis, MS)

Figure 6-11 Subsets of helper T (T_H) cells. In response to stimuli (mainly cytokines) present at the time of antigen recognition, naive CD4+ T cells may differentiate into populations of effector cells that produce distinct sets of cytokines and perform different functions. The dominant immune reactions elicited by each subset, and its role in host defense and immunologic diseases, are summarized. These populations may be capable of converting from one to another. Some activated T cells produce multiple cytokines and do not fall into a distinct subset. IBD, inflammatory bowel disease; MS, multiple sclerosis.

perform different functions (Fig. 6-11). Cells of the T_H1 subset secrete the cytokine IFN- γ , which is a potent macrophage activator. The combination of CD40- and IFN- γ -mediated activation results in “classical” macrophage activation (Chapter 3), leading to the induction of microbicidal substances in macrophages and the destruction of ingested microbes. T_H2 cells produce IL-4, which stimulates B cells to differentiate into IgE-secreting plasma cells, and IL-5, which activates eosinophils. Eosinophils and mast cells bind to IgE-coated microbes such as helminthic parasites, and function to eliminate helminths. T_H2 cells also induce the “alternative” pathway of macrophage activation, which is associated with tissue repair and fibrosis (Chapter 3). T_H17 cells, so called because the signature cytokine of these cells is IL-17, recruit neutrophils and monocytes, which destroy some extracellular bacteria and fungi and are involved in some inflammatory diseases.

Activated CD8+ T lymphocytes differentiate into CTLs that kill cells harboring microbes in the cytoplasm. By destroying the infected cells, CTLs eliminate the reservoirs of infection.

Humoral Immunity: Activation of B Lymphocytes and Elimination of Extracellular Microbes

Upon activation, B lymphocytes proliferate and then differentiate into plasma cells that secrete different classes of antibodies with distinct functions (Fig. 6-12). Antibody responses to most protein antigens require T cell help and are said to be *T-dependent*. In these responses, B cells ingest protein antigens into vesicles, degrade them, and display peptides bound to class II MHC molecules for recognition by helper T cells. The helper T cells are activated and express CD40L and secrete cytokines, which work together

to stimulate the B cells. Many polysaccharide and lipid antigens cannot be recognized by T cells but have multiple identical antigenic determinants (epitopes) that are able to engage many antigen receptor molecules on each B cell and initiate the process of B-cell activation; these responses are said to be *T-independent*. T-independent responses are relatively simple, whereas T-dependent responses show features such as immunoglobulin isotype switching and affinity maturation (described below), which require T cell help and make the responses more varied and sophisticated.

Each plasma cell is derived from an antigen-stimulated B cell and secretes antibodies that recognize the same antigen that was bound to the BCR and initiated the response. Polysaccharides and lipids stimulate secretion mainly of IgM antibody. Protein antigens, by virtue of CD40L- and cytokine-mediated helper T-cell actions, induce the production of antibodies of different classes, or isotypes (IgG, IgA, IgE). *Isotype switching* is induced by cytokines including IFN- γ and IL-4. Helper T cells also stimulate the production of antibodies with high affinities for the antigen. This process, called *affinity maturation*, improves the quality of the humoral immune response. Isotype switching and affinity maturation occur mainly in germinal centers, which are formed by proliferating B cells, especially in helper T cell-dependent responses to protein antigens. Some activated B cells migrate into follicles and form germinal centers, which are the major sites of isotype switching and affinity maturation. The helper T-cells that stimulate these processes in B lymphocytes migrate to and reside in the germinal centers and are called *follicular helper T cells* (T_{FH}).

The humoral immune response combats microbes in many ways (Fig. 6-12). Antibodies bind to microbes and prevent them from infecting cells, thus neutralizing the

Figure 6-12 Humoral immunity. Naive B lymphocytes recognize antigens, and under the influence of T_H cells and other stimuli (not shown), the B cells are activated to proliferate and to differentiate into antibody-secreting plasma cells. Some of the activated B cells undergo heavy-chain class switching and affinity maturation, and some become long-lived memory cells. Antibodies of different heavy-chain classes (isotypes) perform different effector functions, shown on the right. Note that the antibodies shown are IgG; these and IgM activate complement; and the specialized functions of IgA (mucosal immunity) and IgE (mast cell and eosinophil activation) are not shown.

microbes. IgG antibodies coat (*opsonize*) microbes and target them for phagocytosis, since phagocytes (neutrophils and macrophages) express receptors for the Fc tails of IgG. IgG and IgM activate the complement system by the classical pathway, and complement products promote phagocytosis and destruction of microbes. Some antibodies serve special roles at particular anatomic sites. IgA is secreted from mucosal epithelia and neutralizes microbes in the lumens of the respiratory and gastrointestinal tracts (and other mucosal tissues). IgG is actively transported across the placenta and protects the newborn until the immune system becomes mature. IgE and eosinophils cooperate to kill parasites, mainly by release of eosinophil granule contents that are toxic to the worms. As mentioned above, T_H2 cytokines stimulate the production of IgE and activate eosinophils, and thus the response to helminths is orchestrated by T_H2 cells.

Most circulating IgG antibodies have half-lives of about 3 weeks. Some antibody-secreting plasma cells, particularly those that are generated in germinal centers, migrate to the bone marrow and live for months or even years, continuously producing antibodies during this time.

Decline of Immune Responses and Immunologic Memory

The majority of effector lymphocytes induced by an infectious pathogen die by apoptosis after the microbe is eliminated, thus returning the immune system to its resting state. The initial activation of lymphocytes also generates long-lived *memory cells*, which may survive for years after the infection. Memory cells are an expanded pool of antigen-specific lymphocytes (more numerous than the naive cells specific for any antigen that are present before

encounter with that antigen), and they respond faster and more effectively when reexposed to the antigen than do naive cells. This is why the generation of memory cells is an important goal of vaccination.

KEY CONCEPTS

The Normal Immune Response: Cells, Tissues, Receptors, Mediators, and Overview

- The innate immune system uses several families of receptors, notably the Toll-like receptors, to recognize molecules present in various types of microbes and produced by damaged cells.
- Lymphocytes are the mediators of adaptive immunity and the only cells that produce specific and diverse receptors for antigens.
- T (thymus-derived) lymphocytes express antigen receptors called T cell receptors (TCRs) that recognize peptide fragments of protein antigens that are displayed by MHC molecules on the surface of antigen-presenting cells.
- B (bone marrow-derived) lymphocytes express membrane-bound antibodies that recognize a wide variety of antigens. B cells are activated to become plasma cells, which secrete antibodies.
- Natural killer (NK) cells kill cells that are infected by some microbes, or are stressed and damaged beyond repair. NK cells express inhibitory receptors that recognize MHC molecules that are normally expressed on healthy cells, and are thus prevented from killing normal cells.
- Antigen-presenting cells (APCs) capture microbes and other antigens, transport them to lymphoid organs, and

display them for recognition by lymphocytes. The most efficient APCs are dendritic cells, which live in epithelia and most tissues.

- The cells of the immune system are organized in tissues, some of which are the sites of production of mature lymphocytes (the generative lymphoid organs, the bone marrow and thymus), and others are the sites of immune responses (the peripheral lymphoid organs, including lymph nodes, spleen, and mucosal lymphoid tissues).
- The early reaction to microbes is mediated by the mechanisms of innate immunity, which are ready to respond to microbes. These mechanisms include epithelial barriers, phagocytes, NK cells, and plasma proteins, for example, of the complement system. The reaction of innate immunity is often manifested as inflammation. Innate immunity, unlike adaptive immunity, does not have fine antigen specificity or memory.
- The defense reactions of adaptive immunity develop slowly, but are more potent and specialized.
- Microbes and other foreign antigens are captured by dendritic cells and transported to lymph nodes, where the antigens are recognized by naïve lymphocytes. The lymphocytes are activated to proliferate and differentiate into effector and memory cells.
- Cell-mediated immunity is the reaction of T lymphocytes, designed to combat cell-associated microbes (e.g., phagocytosed microbes and microbes in the cytoplasm of infected cells). Humoral immunity is mediated by antibodies and is effective against extracellular microbes (in the circulation and mucosal lumens).
- CD4+ helper T cells help B cells to make antibodies, activate macrophages to destroy ingested microbes, stimulate recruitment of leukocytes, and regulate all immune responses to protein antigens. The functions of CD4+ T cells are mediated by secreted proteins called cytokines. CD8+ cytotoxic T lymphocytes kill cells that express antigens in the cytoplasm that are seen as foreign (e.g., virus-infected and tumor cells) and can also produce cytokines.
- Antibodies secreted by plasma cells neutralize microbes and block their infectivity, and promote the phagocytosis and destruction of pathogens. Antibodies also confer passive immunity to neonates.

The brief outline of basic immunology presented here provides a foundation for considering the diseases of the immune system. We first discuss the immune reactions that cause injury, called *hypersensitivity* reactions, and then disorders caused by the failure of tolerance to self antigens, called *autoimmune disorders*, and the rejection of transplants. This is followed by diseases caused by a defective immune system, called *immunodeficiency diseases*. We close with a consideration of *amyloidosis*, a disorder that is often associated with immune and inflammatory diseases.

Hypersensitivity: Immunologically Mediated Tissue Injury

Injurious immune reactions, called *hypersensitivity*, are the basis of the pathology associated with immunologic

diseases. This term arose from the idea that individuals who have been previously exposed to an antigen manifest detectable reactions to that antigen and are therefore said to be *sensitized*. Hypersensitivity implies an excessive or harmful reaction to antigen. There are several important general features of hypersensitivity disorders.

- **Hypersensitivity reactions can be elicited by exogenous environmental antigens (microbial and nonmicrobial) or endogenous self antigens.** Humans live in an environment teeming with substances capable of eliciting immune responses. Exogenous antigens include those in dust, pollens, foods, drugs, microbes, and various chemicals. The immune responses against such exogenous antigens may take a variety of forms, ranging from annoying but trivial discomforts, such as itching of the skin, to potentially fatal diseases, such as bronchial asthma and anaphylaxis. Some of the most common reactions to environmental antigens cause the group of diseases known as *allergy*. Immune responses against self, or autologous, antigens, result in *autoimmune diseases*.
- **Hypersensitivity usually results from an imbalance between the effector mechanisms of immune responses and the control mechanisms that serve to normally limit such responses.** In fact, in many hypersensitivity diseases, it is suspected that the underlying cause is a failure of normal regulation. We will return to this concept when we consider autoimmunity.
- **The development of hypersensitivity diseases (both allergic and autoimmune) is often associated with the inheritance of particular susceptibility genes.** HLA genes and many non-HLA genes have been implicated in different diseases; specific examples will be described in the context of the diseases.
- **The mechanisms of tissue injury in hypersensitivity reactions are the same as the effector mechanisms of defense against infectious pathogens.** The problem in hypersensitivity is that these reactions are poorly controlled, excessive, or misdirected (e.g., against normally harmless environmental and self antigens).

Classification of Hypersensitivity Diseases

Hypersensitivity diseases can be classified on the basis of the immunologic mechanism that mediates the disease (Table 6-1). This classification is of value in distinguishing the manner in which the immune response causes tissue injury and disease, and the accompanying pathologic and clinical manifestations. However, it is now increasingly recognized that multiple mechanisms may be operative in any one hypersensitivity disease. The main types of hypersensitivity reactions are the following:

- **In immediate hypersensitivity (type I hypersensitivity), the injury is caused by T_H2 cells, IgE antibodies, and mast cells and other leukocytes.** Mast cells release mediators that act on vessels and smooth muscle and proinflammatory cytokines that recruit inflammatory cells.
- **In antibody-mediated disorders (type II hypersensitivity), secreted IgG and IgM antibodies injure cells by promoting their phagocytosis or lysis and injure tissues by inducing inflammation.** Antibodies may also

Table 6-1 Mechanisms of Hypersensitivity Reactions

Type	Immune Mechanisms	Histopathologic Lesions	Prototypical Disorders
Immediate (type I) hypersensitivity	Production of IgE antibody → immediate release of vasoactive amines and other mediators from mast cells; later recruitment of inflammatory cells	Vascular dilation, edema, smooth muscle contraction, mucus production, tissue injury, inflammation	Anaphylaxis; allergies; bronchial asthma (atopic forms)
Antibody-mediated (type II) hypersensitivity	Production of IgG, IgM → binds to antigen on target cell or tissue → phagocytosis or lysis of target cell by activated complement or Fc receptors; recruitment of leukocytes	Phagocytosis and lysis of cells; inflammation; in some diseases, functional derangements without cell or tissue injury	Autoimmune hemolytic anemia; Goodpasture syndrome
Immune complex-mediated (type III) hypersensitivity	Deposition of antigen-antibody complexes → complement activation → recruitment of leukocytes by complement products and Fc receptors → release of enzymes and other toxic molecules	Inflammation, necrotizing vasculitis (fibrinoid necrosis)	Systemic lupus erythematosus; some forms of glomerulonephritis; serum sickness; Arthus reaction
Cell-mediated (type IV) hypersensitivity	Activated T lymphocytes → (1) release of cytokines, inflammation and macrophage activation; (2) T cell-mediated cytotoxicity	Perivascular cellular infiltrates; edema; granuloma formation; cell destruction	Contact dermatitis; multiple sclerosis; type 1 diabetes; tuberculosis

Ig, Immunoglobulin.

interfere with cellular functions and cause disease without tissue injury.

- **In immune complex-mediated disorders (type III hypersensitivity), IgG and IgM antibodies bind antigens usually in the circulation, and the antigen-antibody complexes deposit in tissues and induce inflammation.** The leukocytes that are recruited (neutrophils and monocytes) produce tissue damage by release of lysosomal enzymes and generation of toxic free radicals.
- **In cell-mediated immune disorders (type IV hypersensitivity), sensitized T lymphocytes (T_H1 and T_H17 cells and CTLs) are the cause of the tissue injury.** T_H2 cells induce lesions that are part of immediate hypersensitivity reactions and are not considered a form of type IV hypersensitivity.

Immediate (Type I) Hypersensitivity

Immediate, or type I, hypersensitivity is a rapid immunologic reaction occurring in a previously sensitized

individual that is triggered by the binding of an antigen to IgE antibody on the surface of mast cells. These reactions are often called *allergy*, and the antigens that elicit them are *allergens*. Immediate hypersensitivity may occur as a systemic disorder or as a local reaction. The systemic reaction most often follows injection of an antigen into a sensitized individual (e.g., by a bee sting), but can also follow antigen ingestion (e.g., peanut allergens). Sometimes, within minutes the patient goes into a state of shock, which may be fatal. Local reactions are diverse and vary depending on the portal of entry of the allergen. They may take the form of localized cutaneous rash or blisters (skin allergy, hives), nasal and conjunctival discharge (allergic rhinitis and conjunctivitis), hay fever, bronchial asthma, or allergic gastroenteritis (food allergy).

Many local type I hypersensitivity reactions have two well-defined phases (Fig. 6-13). The *immediate reaction* is characterized by vasodilation, vascular leakage, and depending on the location, smooth muscle spasm or glandular secretions. These changes usually become evident within minutes after exposure to an allergen and tend to

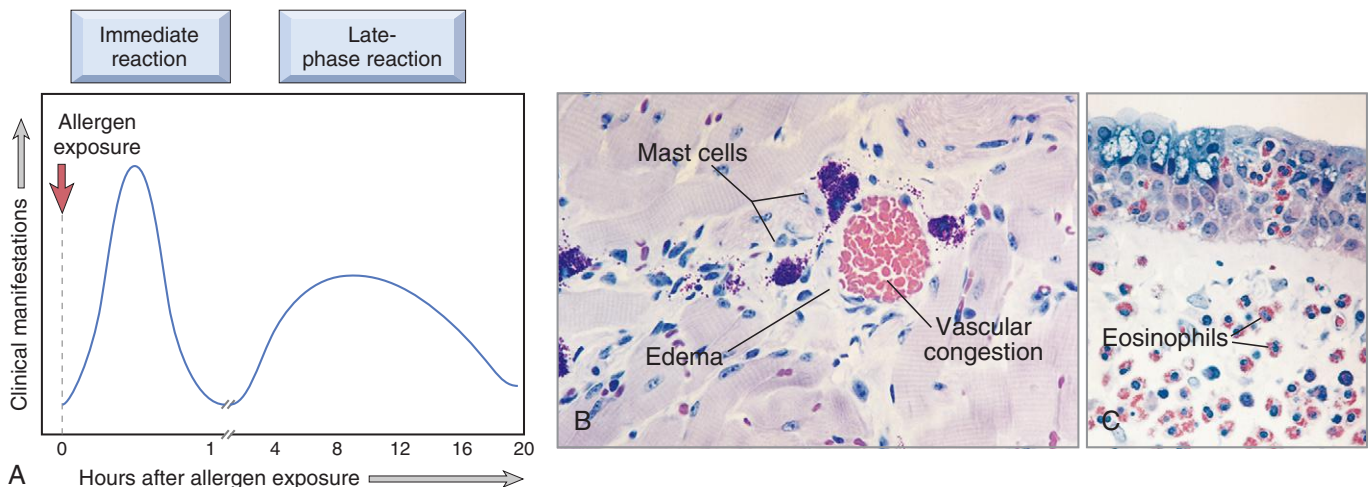

Figure 6-13 Phases of immediate hypersensitivity reactions. **A**, Kinetics of the immediate and late-phase reactions. The immediate vascular and smooth muscle reaction to allergen develops within minutes after challenge (allergen exposure in a previously sensitized individual), and the late-phase reaction develops 2 to 24 hours later. The immediate reaction (**B**) is characterized by vasodilation, congestion, and edema, and the late-phase reaction (**C**) is characterized by an inflammatory infiltrate rich in eosinophils, neutrophils, and T cells. (Courtesy Dr. Daniel Friend, Department of Pathology, Brigham and Women's Hospital, Boston, Mass.)

subside in a few hours. In many instances (e.g., allergic rhinitis and bronchial asthma), a second, *late-phase reaction* sets in 2 to 24 hours later without additional exposure to antigen and may last for several days. This late-phase reaction is characterized by infiltration of tissues with eosinophils, neutrophils, basophils, monocytes, and CD4+ T cells, as well as tissue destruction, typically in the form of mucosal epithelial cell damage.

Most immediate hypersensitivity disorders are caused by excessive T_H2 responses and these cells play a central role by stimulating IgE production and promoting inflammation. These T_H2 -mediated disorders show a characteristic sequence of events (Fig. 6-14), described next.

Activation of T_H2 Cells and Production of IgE Antibody

The first step in the generation of T_H2 cells is the presentation of the antigen to naive CD4+ helper T cells, probably by dendritic cells that capture the antigen from its site of entry. For reasons that are still not understood, only some environmental antigens elicit strong T_H2 responses and thus serve as allergens. In response to antigen and other stimuli, including cytokines such as IL-4 produced at the local site, the T cells differentiate into T_H2 cells. The newly minted T_H2 cells produce a number of cytokines upon subsequent encounter with the antigen; as mentioned earlier, the signature cytokines of this subset are IL-4, IL-5, and IL-13. IL-4 acts on B cells to stimulate class switching to IgE and promotes the development of additional T_H2 cells. IL-5 is involved in the development and activation of eosinophils, which are important effectors of type I hypersensitivity (discussed later). IL-13 enhances IgE production and acts on epithelial cells to stimulate mucus secretion. In addition, T_H2 cells (as well as mast cells and epithelial cells) produce chemokines that attract more T_H2 cells, as well as other leukocytes, to the reaction site.

Sensitization and Activation of Mast Cells

Because mast cells are central to the development of immediate hypersensitivity, we first review some of their salient characteristics. *Mast cells* are bone marrow-derived cells that are widely distributed in the tissues. They are abundant near blood vessels and nerves and in subepithelial tissues, which explains why local immediate hypersensitivity reactions often occur at these sites. Mast cells have cytoplasmic membrane-bound granules that contain a variety of biologically active mediators, described later. The granules also contain acidic proteoglycans that bind basic dyes such as toluidine blue. (*Mast* in German refers to fattening of animals, and the name of these cells came from the erroneous belief that their granules fed the tissue where the cells were located.) As is detailed next, mast cells (and their circulating counterpart, basophils) are activated by the cross-linking of high-affinity IgE Fc receptors; in addition, mast cells may also be triggered by several other stimuli, such as complement components C5a and C3a (called *anaphylatoxins* because they elicit reactions that mimic anaphylaxis), both of which act by binding to receptors on the mast cell membrane. Other mast cell secretagogues include some chemokines (e.g., IL-8), drugs such as codeine and morphine, adenosine, melittin (present in bee venom), and physical stimuli (e.g., heat, cold, sunlight). Basophils are similar to mast cells in many respects, including the presence of cell surface IgE Fc receptors as well as

Figure 6-14 Sequence of events in immediate (type I) hypersensitivity. Immediate hypersensitivity reactions are initiated by the introduction of an allergen, which stimulates T_H2 responses and IgE production in genetically susceptible individuals. IgE binds to Fc receptors (Fc ϵ RI) on mast cells, and subsequent exposure to the allergen activates the mast cells to secrete the mediators that are responsible for the pathologic manifestations of immediate hypersensitivity. See text for abbreviations.

cytoplasmic granules. In contrast to mast cells, however, basophils are not normally present in tissues but rather circulate in the blood in extremely small numbers. Similar to other granulocytes, basophils can be recruited to inflammatory sites.

Mast cells and basophils express a high-affinity receptor, called FcεRI, which is specific for the Fc portion of IgE and therefore avidly binds IgE antibodies. IgE-coated mast cells are said to be *sensitized*, because they are sensitive to subsequent encounter with the specific antigen. **When a mast cell, armed with IgE antibodies previously produced in response to an antigen, is exposed to the same antigen, the cell is activated, leading eventually to the release of an arsenal of powerful mediators responsible for the clinical features of immediate hypersensitivity reactions.** In the first step in the sequence of mast cell activation, the antigen binds to the IgE antibodies previously attached to the mast cells. Multivalent antigens bind to and cross-link adjacent IgE antibodies. The underlying Fcε receptors are brought together, and this activates signal transduction pathways from the cytoplasmic portion of the receptors. These signals lead to the production of mediators that are responsible for the initial, sometimes explosive, symptoms of immediate hypersensitivity, and they also set into motion the events that lead to the late-phase reaction.

Mediators of Immediate Hypersensitivity

Mast cell activation leads to degranulation, with the discharge of preformed (primary) mediators that are stored in the granules, and de novo synthesis and release of secondary mediators, including lipid products and cytokines (Fig. 6-15).

Preformed Mediators. Mediators contained within mast cell granules are the first to be released and can be divided into three categories:

- **Vasoactive amines.** The most important mast cell-derived amine is *histamine* (Chapter 3). Histamine causes intense smooth muscle contraction, increased vascular permeability, and increased mucus secretion by nasal, bronchial, and gastric glands.
- **Enzymes.** These are contained in the granule matrix and include neutral proteases (chymase, tryptase) and several acid hydrolases. The enzymes cause tissue damage and lead to the generation of kinins and activated components of complement (e.g., C3a) by acting on their precursor proteins.
- **Proteoglycans.** These include heparin, a well-known anticoagulant, and chondroitin sulfate. The proteoglycans serve to package and store the amines in the granules.

Lipid Mediators. The major *lipid mediators* are arachidonic acid-derived products (Chapter 3). Reactions in the mast cell membranes lead to activation of phospholipase A₂, an enzyme that converts membrane phospholipids to *arachidonic acid*. This is the parent compound from which leukotrienes and prostaglandins are produced by the 5-lipoxygenase and cyclooxygenase pathways, respectively.

- **Leukotrienes.** Leukotrienes C₄ and D₄ are the most potent vasoactive and spasmogenic agents known. On a molar basis, they are several thousand times more active than histamine in increasing vascular permeability and causing bronchial smooth muscle contraction. Leukotriene B₄ is highly chemotactic for neutrophils, eosinophils, and monocytes.

Figure 6-15 Mast cell mediators. Upon activation, mast cells release various classes of mediators that are responsible for the immediate and late-phase reactions. PAF, Platelet-activating factor.

- **Prostaglandin D₂.** This is the most abundant mediator produced in mast cells by the cyclooxygenase pathway. It causes intense bronchospasm as well as increased mucus secretion.
- **Platelet-activating factor (PAF).** PAF (Chapter 3) is a lipid mediator produced by some mast cell populations but it is not derived from arachidonic acid. It causes platelet aggregation, release of histamine, bronchospasm, increased vascular permeability, and vasodilation. Its role in immediate hypersensitivity reactions is not well established.

Cytokines. Mast cells are sources of many cytokines, which may play an important role at several stages of immediate hypersensitivity reactions. The cytokines include: TNF, IL-1, and chemokines, which promote leukocyte recruitment (typical of the late-phase reaction); IL-4, which amplifies the T_H2 response; and numerous others. The inflammatory cells that are recruited by mast cell-derived TNF and chemokines are additional sources of cytokines and of histamine-releasing factors that cause further mast cell degranulation.

These mediators are responsible for the manifestations of immediate hypersensitivity reactions. Some, such as histamine and leukotrienes, are released rapidly from sensitized mast cells and are responsible for the intense

immediate reactions characterized by edema, mucus secretion, and smooth muscle spasm; others, exemplified by cytokines, including chemokines, set the stage for the late-phase response by recruiting additional leukocytes. Not only do these inflammatory cells release additional waves of mediators (including cytokines), but they also cause epithelial cell damage. Epithelial cells themselves are not passive bystanders in this reaction; they can also produce soluble mediators, such as chemokines.

Late-Phase Reaction

In the late-phase reaction, leukocytes are recruited that amplify and sustain the inflammatory response without additional exposure to the triggering antigen. *Eosinophils* are often an abundant leukocyte population in these reactions (Fig. 6-13C). They are recruited to sites of immediate hypersensitivity by chemokines, such as eotaxin, and others that may be produced by epithelial cells, T_H2 cells, and mast cells. The T_H2 cytokine IL-5 is the most potent eosinophil-activating cytokine known. Upon activation, eosinophils liberate proteolytic enzymes as well as two unique proteins called major basic protein and eosinophil cationic protein, which damage tissues. It is now believed that the late-phase reaction is a major cause of symptoms in some type I hypersensitivity disorders, such as allergic asthma. Therefore, treatment of these diseases requires the use of broad-spectrum antiinflammatory drugs, such as steroids, rather than anti-histamine drugs, which are of benefit in the immediate reaction as occurs in allergic rhinitis (hay fever).

Development of Allergies

Susceptibility to immediate hypersensitivity reactions is genetically determined. An increased propensity to develop immediate hypersensitivity reactions is called *atopy*. Atopic individuals tend to have higher serum IgE levels and more IL-4-producing T_H2 cells than does the general population. A positive family history of allergy is found in 50% of atopic individuals. The basis of familial predisposition is not clear, but studies in patients with asthma reveal linkage to polymorphisms in several genes. Some of these genes are located in the chromosome 5q31 region; these include genes encoding the cytokines IL-3, IL-4, IL-5, IL-9, IL-13, and GM-CSF. This locus has attracted great attention because of the known roles of many of these cytokines in the allergic reaction, but how the disease-associated polymorphisms influence the development of allergies is not known. Linkage has also been noted to 6p, close to the HLA complex, suggesting that the inheritance of certain HLA alleles permits reactivity to certain allergens.

Environmental factors are also important in the development of allergic diseases. Exposure to environmental pollutants, which is common in industrialized societies, is an important predisposing factor for allergy. In fact, it is known that dogs and cats diverged from humans about 95 million years ago and chimpanzees only about 4-5 million years ago, suggesting that chimps share more genes with us than do dogs and cats. Nevertheless, dogs and cats, who live in the same environment as humans, develop allergies and chimps do not. This simple observation suggests that environmental factors may be more important in the development of allergic disease than genetics. Viral

infections of the airways are important triggers for bronchial asthma, an allergic disease affecting the lungs (Chapter 15). Bacterial skin infections are strongly associated with atopic dermatitis.

It is estimated that 20% to 30% of immediate hypersensitivity reactions are triggered by non-antigenic stimuli such as temperature extremes and exercise, and do not involve T_H2 cells or IgE; such reactions are sometimes called *nonatopic allergy*. It is believed that in these cases mast cells are abnormally sensitive to activation by various nonimmune stimuli.

The incidence of many allergic diseases is increasing in developed countries, and seems to be related to a decrease in infections during early life. These observations have led to an idea, sometimes called the *hygiene hypothesis*, that early childhood and even prenatal exposure to microbial antigens educates the immune system in such a way that subsequent pathologic responses against common environmental allergens are prevented. Thus, too much hygiene in childhood may increase allergies later in life. This hypothesis, however, is difficult to prove, and the underlying mechanisms are not defined.

With this consideration of the basic mechanisms of type I hypersensitivity, we turn to some clinically important examples of IgE-mediated disease. These reactions can lead to a wide spectrum of injury and clinical manifestations (Table 6-2).

Systemic Anaphylaxis

Systemic anaphylaxis is characterized by vascular shock, widespread edema, and difficulty in breathing. It may occur in sensitized individuals in hospital settings after administration of foreign proteins (e.g., antisera), hormones, enzymes, polysaccharides, and drugs (e.g., the antibiotic penicillin), or in the community setting following exposure to food allergens (e.g., peanuts, shellfish) or insect toxins (e.g., those in bee venom). Extremely small doses of antigen may trigger anaphylaxis, for example, the tiny amounts used in skin testing for various forms of allergies. Because of the risk of severe allergic reactions to minute quantities of peanuts, U.S. agencies are considering a ban on peanut snacks served in the confined quarters of commercial airplanes. Within minutes after exposure, itching, hives, and skin erythema appear, followed shortly thereafter by a striking contraction of respiratory bronchioles and respiratory distress. Laryngeal edema results in hoarseness and further compromises breathing. Vomiting, abdominal

Table 6-2 Examples of Disorders Caused by Immediate Hypersensitivity

Clinical Syndrome	Clinical and Pathologic Manifestations
Anaphylaxis (may be caused by drugs, bee sting, food)	Fall in blood pressure (shock) cause by vascular dilation; airway obstruction due to laryngeal edema
Bronchial asthma	Airway obstruction caused by bronchial smooth muscle hyperactivity; inflammation and tissue injury caused by late-phase reaction
Allergic rhinitis, sinusitis (hay fever)	Increased mucus secretion; inflammation of upper airways, sinuses
Food allergies	Increased peristalsis due to contraction of intestinal muscles

cramps, diarrhea, and laryngeal obstruction follow, and the patient may go into shock and even die within the hour. The risk of anaphylaxis must be borne in mind when certain therapeutic agents are administered. Although patients at risk can generally be identified by a previous history of some form of allergy, the absence of such a history does not preclude the possibility of an anaphylactic reaction.

Local Immediate Hypersensitivity Reactions

About 10% to 20% of the population suffers from allergies involving localized reactions to common environmental allergens, such as pollen, animal dander, house dust, foods, and the like. Specific diseases include urticaria, allergic rhinitis (hay fever), bronchial asthma, and food allergies; these are discussed elsewhere in this text.

KEY CONCEPTS

Immediate (Type I) Hypersensitivity

- These are also called allergic reactions, or allergies
- They are induced by environmental antigens (allergens) that stimulate strong T_H2 responses and IgE production in genetically susceptible individuals
- IgE coats mast cells by binding to Fcε receptors; reexposure to the allergen leads to cross-linking of the IgE and FcεRI, activation of mast cells, and release of mediators.
- The principal mediators are histamine, proteases, and other granule contents, prostaglandins and leukotrienes, and cytokines.
- The mediators are responsible for the immediate vascular and smooth muscle reactions and the late-phase reaction (inflammation).
- The clinical manifestations may be local or systemic, and range from mildly annoying rhinitis to fatal anaphylaxis.

Antibody-Mediated (Type II) Hypersensitivity

Antibodies that react with antigens present on cell surfaces or in the extracellular matrix cause disease by destroying these cells, triggering inflammation, or interfering with normal functions. The antibodies may be specific for normal cell or tissue antigens (*autoantibodies*) or for exogenous antigens, such as chemical or microbial proteins, that bind to a cell surface or tissue matrix. The antibody-dependent mechanisms that cause tissue injury and disease are illustrated in [Figure 6-16](#) and described next. These reactions are the cause of several important diseases ([Table 6-3](#)).

Opsonization and Phagocytosis

Phagocytosis is largely responsible for depletion of cells coated with antibodies. Cells opsonized by IgG antibodies are recognized by phagocyte Fc receptors, which are specific for the Fc portions of some IgG subclasses. In addition, when IgM or IgG antibodies are deposited on the surfaces of cells, they may activate the complement system by the classical pathway. Complement activation generates by-products, mainly C3b and C4b, which are deposited on the surfaces of the cells and recognized by phagocytes that express receptors for these proteins. The net result is

phagocytosis of the opsonized cells and their destruction ([Fig. 6-16A](#)). Complement activation on cells also leads to the formation of the membrane attack complex, which disrupts membrane integrity by “drilling holes” through the lipid bilayer, thereby causing osmotic lysis of the cells. This mechanism of killing is probably effective only with cells that have thin cell walls, such as *Neisseria* bacteria.

Antibody-mediated destruction of cells may occur by another process called *antibody-dependent cellular cytotoxicity* (ADCC). Cells that are coated with IgG antibody are killed by a variety of effector cells, mainly NK cells and macrophages, which bind to the target by their receptors for the Fc fragment of IgG, and cell lysis proceeds without phagocytosis. The contribution of ADCC to common hypersensitivity diseases is uncertain.

Clinically, antibody-mediated cell destruction and phagocytosis occur in the following situations: (1) transfusion reactions, in which cells from an incompatible donor react with and are opsonized by preformed antibody in the host ([Chapter 14](#)); (2) hemolytic disease of the newborn (erythroblastosis fetalis), in which there is an antigenic difference between the mother and the fetus, and IgG antierythrocyte antibodies from the mother cross the placenta and cause destruction of fetal red cells ([Chapter 10](#)); (3) autoimmune hemolytic anemia, agranulocytosis, and thrombocytopenia, in which individuals produce antibodies to their own blood cells, which are then destroyed ([Chapter 14](#)); and (4) certain drug reactions, in which a drug acts as a “hapten” by attaching to plasma membrane proteins of red cells and antibodies are produced against the drug-protein complex.

Inflammation

When antibodies deposit in fixed tissues, such as basement membranes and extracellular matrix, the resultant injury is due to inflammation. The deposited antibodies activate complement, generating by-products, including chemotactic agents (mainly C5a), which direct the migration of polymorphonuclear leukocytes and monocytes, and anaphylatoxins (C3a and C5a), which increase vascular permeability ([Fig. 6-16B](#)). The leukocytes are activated by engagement of their C3b and Fc receptors. This results in the production of other substances that damage tissues, such as lysosomal enzymes, including proteases capable of digesting basement membrane, collagen, elastin, and cartilage, and reactive oxygen species.

Antibody-mediated inflammation is the mechanism responsible for tissue injury in some forms of *glomerulonephritis*, *vascular rejection* in organ grafts, and other disorders ([Table 6-3](#)).

Cellular Dysfunction

In some cases, antibodies directed against cell surface receptors impair or dysregulate function without causing cell injury or inflammation ([Fig. 6-16C](#)). For example, in *myasthenia gravis*, antibodies reactive with acetylcholine receptors in the motor end plates of skeletal muscles block neuromuscular transmission and therefore cause muscle weakness. The converse (i.e., antibody-mediated stimulation of cell function) is the basis of *Graves disease*. In this disorder, antibodies against the thyroid-stimulating hormone receptor on thyroid epithelial cells stimulate the cells, resulting in hyperthyroidism.

Figure 6-16 Mechanisms of antibody-mediated injury. **A**, Opsonization of cells by antibodies and complement components and ingestion by phagocytes. **B**, Inflammation induced by antibody binding to Fc receptors of leukocytes and by complement breakdown products. **C**, Antireceptor antibodies disturb the normal function of receptors. In these examples, antibodies to the acetylcholine (ACh) receptor impair neuromuscular transmission in myasthenia gravis, and antibodies against the thyroid-stimulating hormone (TSH) receptor activate thyroid cells in Graves disease.

Table 6-3 Examples of Antibody-Mediated Diseases (Type II Hypersensitivity)

Disease	Target Antigen	Mechanisms of Disease	Clinicopathologic Manifestations
Autoimmune hemolytic anemia	Red cell membrane proteins (Rh blood group antigens, I antigen)	Opsonization and phagocytosis of red cells	Hemolysis, anemia
Autoimmune thrombocytopenic purpura	Platelet membrane proteins (GpIIb : IIIa integrin)	Opsonization and phagocytosis of platelets	Bleeding
Pemphigus vulgaris	Proteins in intercellular junctions of epidermal cells (epidermal cadherin)	Antibody-mediated activation of proteases, disruption of intercellular adhesions	Skin vesicles (bullae)
Vasculitis caused by ANCA	Neutrophil granule proteins, presumably released from activated neutrophils	Neutrophil degranulation and inflammation	Vasculitis
Goodpasture syndrome	Noncollagenous protein in basement membranes of kidney glomeruli and lung alveoli	Complement- and Fc receptor-mediated inflammation	Nephritis, lung hemorrhage
Acute rheumatic fever	Streptococcal cell wall antigen; antibody cross-reacts with myocardial antigen	Inflammation, macrophage activation	Myocarditis, arthritis
Myasthenia gravis	Acetylcholine receptor	Antibody inhibits acetylcholine binding, down-modulates receptors	Muscle weakness, paralysis
Graves disease (hyperthyroidism)	TSH receptor	Antibody-mediated stimulation of TSH receptors	Hyperthyroidism
Insulin-resistant diabetes	Insulin receptor	Antibody inhibits binding of insulin	Hyperglycemia, ketoacidosis
Pernicious anemia	Intrinsic factor of gastric parietal cells	Neutralization of intrinsic factor, decreased absorption of vitamin B ₁₂	Abnormal erythropoiesis, anemia

ANCA, Antineutrophil cytoplasmic antibodies; TSH, thyroid-stimulating hormone.

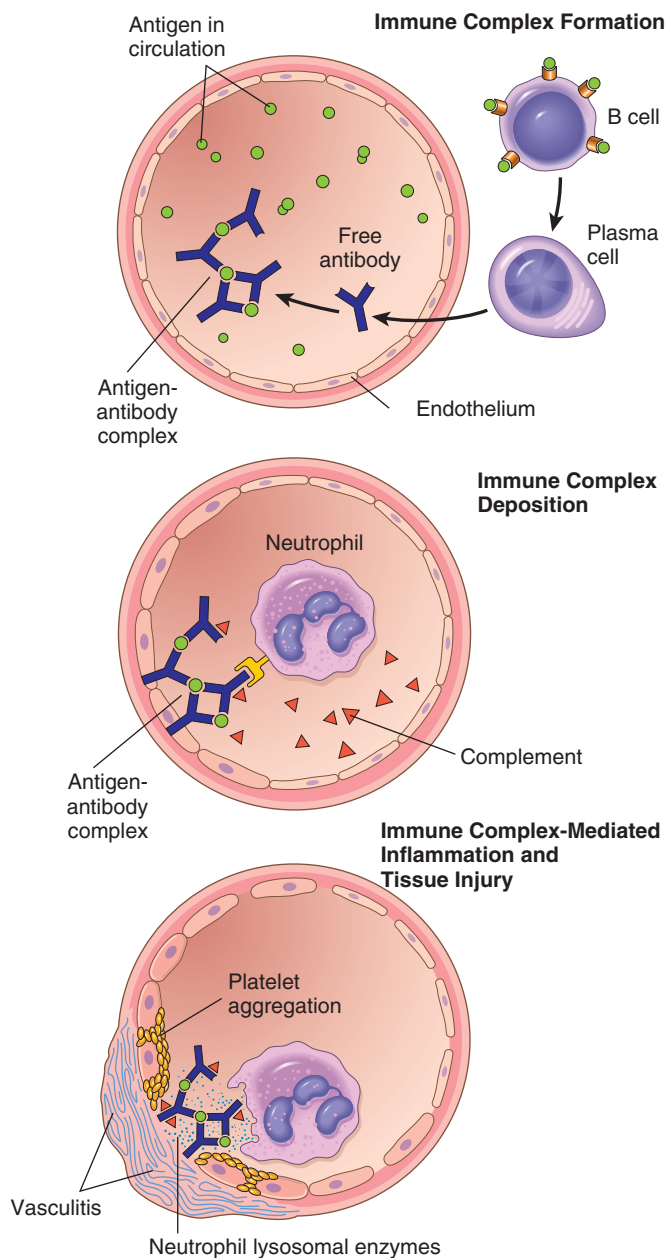

Figure 6-17 Immune complex disease. The sequential phases in the induction of systemic immune complex-mediated diseases (type III hypersensitivity).

Immune Complex–Mediated (Type III) Hypersensitivity

Antigen-antibody complexes produce tissue damage mainly by eliciting inflammation at the sites of deposition. The pathologic reaction is usually initiated when antigen combines with antibody in the circulation, creating immune complexes that typically deposit in vessel walls. Less frequently, the complexes may be formed at sites where antigen has been “planted” previously (called *in situ* immune complexes). The antigens that form immune complexes may be *exogenous*, such as a foreign protein that is injected or produced by an infectious microbe, or *endogenous*, if the individual produces antibody against self antigens (autoimmunity). Examples of immune complex disorders and the antigens involved are listed in [Table 6-4](#). Immune complex-mediated diseases tend to be *systemic*, but often preferentially involve the kidney (glomerulonephritis), joints (arthritis), and small blood vessels (vasculitis), all of which are common sites of immune complex deposition.

Systemic Immune Complex Disease

Acute serum sickness is the prototype of a systemic immune complex disease; it was once a frequent sequela to the administration of large amounts of foreign serum (e.g., serum from immunized horses used for protection against diphtheria). In modern times the disease is infrequent, and usually seen in individuals who receive antibodies from other individuals or species. Nevertheless, it is an informative model that has taught us a great deal about systemic immune complex disorders.

The pathogenesis of systemic immune complex disease can be divided into three phases ([Fig. 6-17](#)).

- 1. Formation of immune complexes.** The introduction of a protein antigen triggers an immune response that results in the formation of antibodies, typically about a week after the injection of the protein. These antibodies are secreted into the blood, where they react with the antigen still present in the circulation and form antigen-antibody complexes.
- 2. Deposition of immune complexes.** In the next phase the circulating antigen-antibody complexes are deposited in various tissues. The factors that determine whether immune complex formation will lead to tissue deposition and disease are not fully understood, but the major influences seem to be the characteristics of the complexes and local vascular alterations. In general, complexes that are of medium size, formed in slight antigen excess, are the most pathogenic. Organs where

Table 6-4 Examples of Immune Complex–Mediated Diseases

Disease	Antigen Involved	Clinicopathologic Manifestations
Systemic lupus erythematosus	Nuclear antigens (circulating or “planted” in kidney)	Nephritis, skin lesions, arthritis, others
Poststreptococcal glomerulonephritis	Streptococcal cell wall antigen(s); may be “planted” in glomerular basement membrane	Nephritis
Polyarteritis nodosa	Hepatitis B virus antigens in some cases	Systemic vasculitis
Reactive arthritis	Bacterial antigens (e.g., <i>Yersinia</i>)	Acute arthritis
Serum sickness	Various proteins, e.g., foreign serum protein (horse antithymocyte globulin)	Arthritis, vasculitis, nephritis
Arthus reaction (experimental)	Various foreign proteins	Cutaneous vasculitis

blood is filtered at high pressure to form other fluids, like urine and synovial fluid, are sites where immune complexes become concentrated and tend to deposit; hence, immune complex disease often affects glomeruli and joints.

3. **Inflammation and tissue injury.** Once immune complexes are deposited in the tissues, they initiate an acute inflammatory reaction. During this phase (approximately 10 days after antigen administration), clinical features such as fever, urticaria, joint pains (arthralgias), lymph node enlargement, and proteinuria appear. Wherever complexes deposit the tissue damage is similar. The mechanisms of inflammation and injury were discussed above, in the discussion of antibody-mediated injury. The resultant inflammatory lesion is termed *vasculitis* if it occurs in blood vessels, *glomerulonephritis* if it occurs in renal glomeruli, *arthritis* if it occurs in the joints, and so on.

It is clear that complement-fixing antibodies (i.e., IgG and IgM) and antibodies that bind to leukocyte Fc receptors (some subclasses of IgG) induce the pathologic lesions of immune complex disorders. The important role of complement in the pathogenesis of the tissue injury is supported by the observations that complement proteins can be detected at the site of injury and, during the active phase of the disease, consumption of complement leads to a decrease in serum levels of C3. In fact, serum C3 levels can, in some cases, be used to monitor disease activity.

MORPHOLOGY

The principal morphologic manifestation of immune complex injury is acute vasculitis, associated with necrosis of the vessel wall and intense neutrophilic infiltration. The necrotic tissue and deposits of immune complexes, complement, and plasma protein appear as a smudgy eosinophilic area of tissue destruction, an appearance termed **fibrinoid necrosis** (see Fig. 2-15). When deposited in the kidney, the complexes can be seen on immunofluorescence microscopy as granular lumpy deposits of immunoglobulin and complement and on electron microscopy as electron-dense deposits along the glomerular basement membrane (see Figs. 6-31 and 6-32).

If the disease results from a single large exposure to antigen, such as *acute serum sickness*, the lesions tend to resolve as a result of catabolism of the immune complexes. A form of *chronic serum sickness* results from repeated or prolonged exposure to an antigen. This occurs in several diseases, such as systemic lupus erythematosus (SLE), which is associated with persistent antibody responses to autoantigens. In many diseases, the morphologic changes and other findings suggest immune complex deposition but the inciting antigens are unknown. Included in this category are membranous glomerulonephritis and several vasculitides.

Local Immune Complex Disease (Arthus Reaction)

The *Arthus reaction* is a localized area of tissue necrosis resulting from acute immune complex vasculitis, usually elicited in the skin. The reaction can be produced experimentally by intracutaneous injection of antigen in a previously immunized animal that contains circulating

antibodies against the antigen. As the antigen diffuses into the vascular wall, it binds the preformed antibody, and large immune complexes are formed locally. These complexes precipitate in the vessel walls and cause fibrinoid necrosis, and superimposed thrombosis worsens the ischemic injury.

KEY CONCEPTS

Pathogenesis of Diseases Caused by Antibodies and Immune Complexes

- Antibodies can coat (opsonize) cells, with or without complement proteins, and target these cells for phagocytosis by phagocytes (macrophages), which express receptors for the Fc tails of IgG and for complement proteins. The result is depletion of the opsonized cells.
- Antibodies and immune complexes may deposit in tissues or blood vessels, and elicit an acute inflammatory reaction by activating complement, with release of breakdown products, or by engaging Fc receptors of leukocytes. The inflammatory reaction causes tissue injury.
- Antibodies can bind to cell surface receptors or other essential molecules and cause functional derangements (either inhibition or unregulated activation) without cell injury.

T Cell–Mediated (Type IV) Hypersensitivity

The cell-mediated type of hypersensitivity is caused by inflammation resulting from cytokines produced by CD4+ T cells and cell killing by CD8+ T cells (Fig. 6-18). CD4+ T cell–mediated hypersensitivity induced by environmental and self antigens is the cause of many chronic inflammatory diseases, including autoimmune diseases (Table 6-5). CD8+ cells may also be involved in some of these autoimmune diseases and may be the dominant effector cells in certain reactions, especially those that follow viral infections.

CD4+ T Cell–Mediated Inflammation

In CD4+ T cell–mediated hypersensitivity reactions, cytokines produced by the T cells induce inflammation that may be chronic and destructive. The prototype of T cell–mediated inflammation is *delayed-type hypersensitivity (DTH)*, a tissue reaction to antigens given to immune individuals. In this reaction, an antigen administered into the skin of a previously immunized individual results in a detectable cutaneous reaction within 24 to 48 hours (hence the term *delayed*, in contrast to immediate hypersensitivity). Both T_H1 and T_H17 cells contribute to organ-specific diseases in which inflammation is a prominent aspect of the pathology. The inflammatory reaction associated with T_H1 cells is dominated by activated macrophages, and that triggered by T_H17 cells has a greater neutrophil component.

The inflammatory reactions stimulated by CD4+ T cells can be divided into sequential stages.

Activation of CD4+ T Cells. As described earlier, naive CD4+ T cells recognize peptides displayed by dendritic cells and secrete IL-2, which functions as an autocrine growth factor to stimulate proliferation of the antigen-responsive T cells. The subsequent differentiation of

Figure 6-18 Mechanisms of T cell-mediated (type IV) hypersensitivity reactions. **A**, CD4+ T_H1 cells (and sometimes CD8+ T cells, not shown) respond to tissue antigens by secreting cytokines that stimulate inflammation and activate phagocytes, leading to tissue injury. CD4+ T_H17 cells contribute to inflammation by recruiting neutrophils (and, to a lesser extent, monocytes). **B**, In some diseases, CD8+ cytotoxic T lymphocytes (CTLs) directly kill tissue cells. APC, Antigen-presenting cell.

antigen-stimulated T cells to T_H1 or T_H17 cells is driven by the cytokines produced by APCs at the time of T-cell activation. In some situations the APCs (dendritic cells and macrophages) produce IL-12, which induces differentiation of CD4+ T cells to the T_H1 subset. IFN- γ produced by these effector cells promotes further T_H1 development, thus amplifying the reaction. If the APCs produce inflammatory cytokines such as IL-1, IL-6, and a close relative of IL-12 called IL-23, these stimulate differentiation of T cells to the T_H17 subset. Some of the differentiated effector cells enter the circulation and may remain in the memory pool of T cells for long periods, sometimes years.

Responses of Differentiated Effector T Cells. Upon repeat exposure to an antigen, T_H1 cells secrete cytokines, mainly IFN- γ , which are responsible for many of the manifestations of delayed-type hypersensitivity. IFN- γ -activated (“classically activated”) macrophages are altered in several ways: their ability to phagocytose and kill microorganisms is markedly augmented; they express more class II MHC molecules on the surface, thus facilitating further antigen presentation; they secrete TNF, IL-1, and chemokines, which promote inflammation (Chapter 3); and they produce more IL-12, thereby amplifying the T_H1 response. Thus, activated macrophages serve to eliminate the offending

Table 6-5 T Cell-Mediated Diseases

Disease	Specificity of Pathogenic T Cells	Principal Mechanisms of Tissue Injury	Clinicopathologic Manifestations
Rheumatoid arthritis	Collagen? Citrullinated self proteins?	Inflammation mediated by T _H 17 (and T _H 1?) cytokines; role of antibodies and immune complexes?	Chronic arthritis with inflammation, destruction of articular cartilage
Multiple sclerosis	Protein antigens in myelin (e.g., myelin basic protein)	Inflammation mediated by T _H 1 and T _H 17 cytokines, myelin destruction by activated macrophages	Demyelination in CNS with perivascular inflammation; paralysis,
Type 1 diabetes mellitus	Antigens of pancreatic islet β cells (insulin, glutamic acid decarboxylase, others)	T cell-mediated inflammation, destruction of islet cells by CTLs	Insulinitis (chronic inflammation in islets), destruction of β cells; diabetes
Inflammatory bowel disease	Enteric bacteria; self antigens?	Inflammation mediated by T _H 1 and T _H 17 cytokines	Chronic intestinal inflammation, obstruction
Psoriasis	Unknown	Inflammation mediated mainly by T _H 17 cytokines	Destructive plaques in the skin
Contact sensitivity	Various environmental chemicals (e.g., urushiol from poison ivy or poison oak)	Inflammation mediated by T _H 1 (and T _H 17?) cytokines	Epidermal necrosis, dermal inflammation, causing skin rash and blisters

Examples of human T cell-mediated diseases are listed. In many cases, the specificity of the T cells and the mechanisms of tissue injury are inferred based on the similarity with experimental animal models of the diseases.

antigen; if the activation is sustained, continued inflammation and tissue injury result.

Activated T_H17 cells secrete IL-17, IL-22, chemokines, and several other cytokines. Collectively, these cytokines recruit neutrophils and monocytes to the reaction, thus promoting inflammation. T_H17 cells also produce IL-21, which amplifies the T_H17 response.

Clinical Examples of CD4+ T Cell–Mediated Inflammatory Reactions. The classic example of DTH is the *tuberculin reaction*, which is produced by the intracutaneous injection of purified protein derivative (PPD, also called tuberculin), a protein-containing antigen of the tubercle bacillus. In a previously sensitized individual, reddening and induration of the site appear in 8 to 12 hours, reach a peak in 24 to 72 hours, and thereafter slowly subside. Morphologically, delayed-type hypersensitivity is characterized by the accumulation of mononuclear cells, mainly CD4+ T cells and macrophages, around venules, producing perivascular “cuffing” (Fig. 6-19). In fully developed lesions, the venules show marked endothelial hypertrophy, reflecting cytokine-mediated endothelial activation.

With certain persistent or nondegradable antigens, such as tubercle bacilli colonizing the lungs or other tissues, the infiltrate is dominated by macrophages over a period of 2 or 3 weeks. With sustained activation, macrophages often undergo a morphologic transformation into *epithelioid cells*, large epithelium-like cells with abundant cytoplasm. A microscopic aggregation of epithelioid cells, usually surrounded by a collar of lymphocytes, is referred to as a *granuloma* (Fig. 6-20A). This pattern of inflammation, called *granulomatous inflammation* (Chapter 3), is typically associated with strong T_H1 -cell activation and high-level production of cytokines such as IFN- γ (Fig. 6-20B). It can also be caused by indigestible foreign bodies, which activate macrophages without eliciting an adaptive immune response.

Contact dermatitis is a common example of tissue injury resulting from DTH reactions. It may be evoked by contact

Figure 6-19 Delayed hypersensitivity reaction in the skin. **A**, Perivascular accumulation (“cuffing”) of mononuclear inflammatory cells (lymphocytes and macrophages), with associated dermal edema and fibrin deposition. **B**, Immunoperoxidase staining reveals a predominantly perivascular cellular infiltrate that marks positively with anti-CD4 antibodies. (Courtesy Dr. Louis Picker, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas.)

Figure 6-20 Granulomatous inflammation. **A**, A section of a lymph node shows several granulomas, each made up of an aggregate of epithelioid cells and surrounded by lymphocytes. The granuloma in the center shows several multinucleate giant cells. **B**, The events that give rise to the formation of granulomas in type IV hypersensitivity reactions, illustrating the role of T_H1 cytokines. In some granulomas (e.g., in schistosomiasis), T_H2 cells contribute to the lesions. The role of T_H17 cells in granuloma formation is not known. (**A**, Courtesy Dr. Trace Worrell, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas.)

with urushiol, the antigenic component of poison ivy or poison oak, and presents as a vesicular dermatitis. It is thought that in these reactions, the environmental chemical binds to and structurally modifies some self proteins and peptides derived from these modified proteins are recognized by T cells and elicit the reaction. Chemicals may also modify HLA molecules, making them appear foreign to T cells. The same mechanism is responsible for most *drug reactions*, among the most common immunologic reactions

of humans. In these reactions, the drug (often a reactive chemical) alters self proteins, including MHC molecules, and the “neoantigens” are recognized as foreign by T cells, leading to cytokine production and inflammation. These often manifest as skin rashes.

CD4+ T cell-mediated inflammation is the basis of tissue injury in many organ-specific and systemic autoimmune diseases, such as rheumatoid arthritis and multiple sclerosis, as well as diseases probably caused by uncontrolled reactions to bacterial commensals, such as inflammatory bowel disease (Table 6-5).

CD8+ T Cell-Mediated Cytotoxicity

In this type of T cell-mediated reaction, CD8+ CTLs kill antigen-expressing target cells. Tissue destruction by CTLs may be an important component of some T cell-mediated diseases, such as type 1 diabetes. CTLs directed against cell surface histocompatibility antigens play an important role in graft rejection, to be discussed later. They also play a role in reactions against viruses. In a virus-infected cell, viral peptides are displayed by class I MHC molecules and the complex is recognized by the TCR of CD8+ T lymphocytes. The killing of infected cells leads to the elimination of the infection, but in some cases it is responsible for cell damage that accompanies the infection (e.g., in viral hepatitis). Tumor-associated antigens are also presented on the cell surface, and CTLs are involved in the host response to transformed cells (Chapter 7).

The principal mechanism of T cell-mediated killing of targets involves *perforins* and *granzymes*, preformed mediators contained in the lysosome-like granules of CTLs. CTLs that recognize the target cells secrete a complex consisting of perforin, granzymes, and other proteins which enters target cells by endocytosis. In the target cell cytoplasm, perforin facilitates the release of the granzymes from the complex. Granzymes are proteases that cleave and activate caspases, which induce apoptosis of the target cells (Chapter 2). Activated CTLs also express Fas ligand, a molecule with homology to TNF, which can bind to Fas expressed on target cells and trigger apoptosis.

CD8+ T cells also produce cytokines, notably IFN- γ , and are involved in inflammatory reactions resembling DTH, especially following virus infections and exposure to some contact sensitizing agents.

KEY CONCEPTS

Mechanisms of T Cell-Mediated Hypersensitivity Reactions

- Cytokine-mediated inflammation: CD4+ T cells are activated by exposure to a protein antigen and differentiate into T_H1 and T_H17 effector cells. Subsequent exposure to the antigen results in the secretion of cytokines. IFN- γ activates macrophages to produce substances that cause tissue damage and promote fibrosis, and IL-17 and other cytokines recruit leukocytes, thus promoting inflammation.
- The classical T cell-mediated inflammatory reaction is delayed type hypersensitivity.
- T cell-mediated cytotoxicity: CD8+ cytotoxic T lymphocytes (CTLs) specific for an antigen recognize cells expressing the target antigen and kill these cells. CD8+ T cells also secrete IFN- γ .

Now that we have described how the immune system can cause tissue damage, we turn to diseases in which normal control mechanisms fail. The prototypes of such diseases are autoimmune disorders, which are the result of failure of tolerance to self antigens.

Autoimmune Diseases

Immune reactions against self antigens—*autoimmunity*—are an important cause of certain diseases in humans, estimated to affect at least 1% to 2% of the US population. A growing number of diseases have been attributed to autoimmunity (Table 6-6). It should be noted, however, that the mere presence of autoantibodies does not indicate an autoimmune disease exists. Autoantibodies can be found in the serum of apparently normal individuals, particularly in older age groups. Furthermore, innocuous autoantibodies are sometimes produced after damage to tissues and may serve a physiologic role in the removal of tissue breakdown products. How, then, does one define *pathologic autoimmunity*? Ideally, at least three requirements should be met before a disorder is categorized as truly caused by autoimmunity: (1) the presence of an immune reaction specific for some self antigen or self tissue; (2) evidence that such a reaction is not secondary to tissue damage but is of primary pathogenic significance; and (3) the absence of another well-defined cause of the disease. Similarity with experimental models of proven autoimmunity is also often used to support this mechanism in human diseases. Disorders in which chronic inflammation is a prominent component are sometimes grouped under *immune-mediated inflammatory diseases*; these may be autoimmune, or the immune

Table 6-6 Autoimmune Diseases

Organ-Specific	Systemic
Diseases Mediated by Antibodies	
Autoimmune hemolytic anemia	Systemic lupus erythematosus
Autoimmune thrombocytopenia	
Autoimmune atrophic gastritis of pernicious anemia	
Myasthenia gravis	
Graves disease	
Goodpasture syndrome	
Diseases Mediated by T Cells*	
Type 1 diabetes mellitus	Rheumatoid arthritis
Multiple sclerosis	Systemic sclerosis (scleroderma) [†] Sjögren syndrome [†]
Diseases Postulated to Be Autoimmune	
Inflammatory bowel diseases (Crohn disease, ulcerative colitis) [‡]	
Primary biliary cirrhosis [†]	Polyarteritis nodosa [†]
Autoimmune (chronic active) hepatitis	Inflammatory myopathies [†]

*A role for T cells has been demonstrated in these disorders, but antibodies may also be involved in tissue injury.

[†]An autoimmune basis of these disorders is suspected but the supporting evidence is not strong.

[‡]These disorders may result from excessive immune responses to commensal enteric microbes, autoimmunity, or a combination of the two.

Figure 6-21 Mechanisms of immunologic tolerance to self antigens. The principal mechanisms of central and peripheral self-tolerance in T and B cells are illustrated. APC, Antigen-presenting cell.

response may be directed against normally harmless microbes such as gut commensal bacteria.

The clinical manifestations of autoimmune disorders are extremely varied. On one end are conditions in which the immune responses are directed against a single organ or tissue, resulting in *organ-specific disease*, and on the other end are diseases in which the autoimmune reactions are against widespread antigens, resulting in *systemic* or *generalized disease*. Examples of organ-specific autoimmune diseases are type 1 diabetes mellitus, in which the autoreactive T cells and antibodies are specific for β cells of the pancreatic islets, and multiple sclerosis, in which autoreactive T cells react against central nervous system myelin. The best example of systemic autoimmune disease is SLE, in which a diversity of antibodies directed against DNA, platelets, red cells, and protein-phospholipid complexes result in widespread lesions throughout the body. In the middle of the spectrum falls Goodpasture syndrome, in which antibodies to basement membranes of lung and kidney induce lesions in these organs.

It is obvious that autoimmunity results from the loss of self-tolerance, and the question arises as to how this happens. Before we look for answers to this question, we review the mechanisms of immunologic tolerance to self antigens.

Immunologic Tolerance

Immunologic tolerance is the phenomenon of unresponsiveness to an antigen induced by exposure of lymphocytes to that antigen. *Self-tolerance* refers to lack of responsiveness to an individual's own antigens, and it

underlies our ability to live in harmony with our cells and tissues. Because the antigen receptors of lymphocytes are generated by somatic recombination of genes in a random fashion, lymphocytes with receptors capable of recognizing self antigens are generated constantly, and these cells have to be eliminated or inactivated as soon as they recognize self antigens, to prevent them from causing harm.

The mechanisms of self-tolerance can be broadly classified into two groups: central tolerance and peripheral tolerance (Fig. 6-21). Each of these is considered briefly.

Central Tolerance

In this process, immature self-reactive T and B lymphocyte clones that recognize self antigens during their maturation in the central (or generative) lymphoid organs (the thymus for T cells and the bone marrow for B cells) are killed or rendered harmless. The mechanisms of central tolerance in T and B cells show some similarities and differences.

- In developing T cells, random somatic gene rearrangements generate diverse TCRs. Such antigen-independent TCR generation produces many lymphocytes that express high-affinity receptors for self antigens. When immature lymphocytes encounter the antigens in the thymus, many of the cells die by apoptosis. This process, called *negative selection* or *deletion*, is responsible for eliminating self-reactive lymphocytes from the T-cell pool. A wide variety of autologous protein antigens, including antigens thought to be restricted to peripheral tissues, are processed and presented by thymic antigen-presenting cells in association with self MHC molecules and can, therefore, be recognized by potentially

self-reactive T cells. A protein called AIRE (autoimmune regulator) stimulates expression of some “peripheral tissue-restricted” self antigens in the thymus and is thus critical for deletion of immature T cells specific for these antigens. Mutations in the *AIRE* gene are the cause of an autoimmune polyendocrinopathy (Chapter 24). In the CD4+ T-cell lineage, some of the cells that see self antigens in the thymus do not die but develop into regulatory T cells (described later).

- When developing B cells strongly recognize self antigens in the bone marrow, many of the cells reactivate the machinery of antigen receptor gene rearrangement and begin to express new antigen receptors, not specific for self antigens. This process is called *receptor editing*; it is estimated that a quarter to half of all B cells in the body may have undergone receptor editing during their maturation. If receptor editing does not occur, the self-reactive cells undergo apoptosis, thus purging potentially dangerous lymphocytes from the mature pool.

Central tolerance, however, is imperfect. Not all self antigens may be present in the thymus, and hence T cells bearing receptors for such autoantigens escape into the periphery. There is similar “slippage” in the B-cell system. Self-reactive lymphocytes that escape negative selection can inflict tissue injury unless they are deleted or muzzled in the peripheral tissues.

Peripheral Tolerance

Several mechanisms silence potentially autoreactive T and B cells in peripheral tissues; these are best defined for T cells. These mechanisms include the following:

- **Anergy. Lymphocytes that recognize self antigens may be rendered functionally unresponsive, a phenomenon called anergy.** We discussed earlier that activation of antigen-specific T cells requires two signals: recognition of peptide antigen in association with self MHC molecules on the surface of APCs and a set of costimulatory signals (“second signals”) from APCs. These second signals are provided by certain T cell-associated molecules, such as CD28, that bind to their ligands (the costimulators B7-1 and B7-2) on APCs. If the antigen is presented to T cells without adequate levels of costimulators, the cells become anergic. Because costimulatory molecules are not expressed or are weakly expressed on resting dendritic cells in normal tissues, the encounter between autoreactive T cells and their specific self antigens displayed by these dendritic cells may lead to anergy. Several mechanisms of T-cell anergy have been demonstrated in various experimental systems. One of these, which has clinical implications, is that T cells that recognize self antigens receive an inhibitory signal from receptors that are structurally homologous to CD28 but serve the opposite functions. Two of these inhibitory receptors are CTLA-4, which (like CD28) binds to B7 molecules, and PD-1, which binds to two ligands that are expressed on a wide variety of cells. Because CTLA-4 has higher affinity for B7 molecules than does CD28, CTLA-4 may be preferentially engaged when the levels of B7 are low, as when APCs are presenting self antigens. Conversely, microbial products elicit innate immune reactions, during which B7 levels on APCs increase and

the low-affinity receptor CD28 is engaged more. Thus, the affinities of the activating and inhibitory receptors and the level of expression of B7 may determine the outcome of T cell antigen recognition. The importance of these inhibitory mechanisms has been established by the finding that mice in which the gene encoding CTLA-4 or PD-1 is knocked out develop autoimmune diseases. Furthermore, polymorphisms in the *CTLA4* gene are associated with some autoimmune endocrine diseases in humans. Interestingly, some tumors and viruses may use the same pathways of immune regulation to evade immune attack. This realization has led to the development of antibodies that block CTLA-4 and PD-1 for tumor immunotherapy—by removing the brakes on the immune response, these antibodies promote responses against tumors.

Anergy also affects mature B cells in peripheral tissues. It is believed that if B cells encounter self antigen in peripheral tissues, especially in the absence of specific helper T cells, the B cells become unable to respond to subsequent antigenic stimulation and may be excluded from lymphoid follicles, resulting in their death. B lymphocytes also express inhibitory receptors that may play a role in limiting their activation and preventing responses to self antigens.

- **Suppression by regulatory T cells. A population of T cells called *regulatory T cells* functions to prevent immune reactions against self antigens.** Regulatory T cells develop mainly in the thymus, as a result of recognition of self antigens (Fig. 6-21), but they may also be induced in peripheral lymphoid tissues. The best-defined regulatory T cells are CD4+ cells that express high levels of CD25, the α chain of the IL-2 receptor, and a transcription factor of the forkhead family, called FOXP3. Both IL-2 and FOXP3 are required for the development and maintenance of functional CD4+ regulatory T cells. Mutations in *FOXP3* result in severe autoimmunity in humans and mice; in humans these mutations are the cause of a systemic autoimmune disease called *IPEX* (an acronym for immune dysregulation, polyendocrinopathy, enteropathy, X-linked). In mice knockout of the gene encoding IL-2 or the IL-2 receptor α or β chain also results in severe multi-organ autoimmunity, because IL-2 is essential for the maintenance of regulatory T cells. Recent genome-wide association studies have revealed that polymorphisms in the *CD25* gene are associated with multiple sclerosis and other autoimmune diseases, raising the possibility of a regulatory T-cell defect contributing to these diseases. The mechanisms by which regulatory T cells suppress immune responses are not fully defined, but their inhibitory activity may be mediated in part by the secretion of immunosuppressive cytokines such as IL-10 and TGF- β , which inhibit lymphocyte activation and effector functions. Regulatory T cells also express CTLA-4, which may bind to B7 molecules on APCs and reduce their ability to activate T cells via CD28.

Regulatory T cells may play a role in the acceptance of the fetus. Placental mammals face a unique challenge because the developing fetus expresses paternal antigens that are foreign to the mother yet have to be tolerated. There is emerging evidence that regulatory T cells

prevent immune reactions against fetal antigens that are inherited from the father and therefore foreign to the mother. In line with this idea, during evolution, placentation appeared simultaneously with the ability to stably express the Foxp3 transcription factor. Experiments in mice have shown that fetal antigens induce long-lived Foxp3⁺ regulatory T cells, and depletion of these cells results in fetal loss. There is great interest in determining the contribution of regulatory T cells in human pregnancy and possible defects in these cells as the basis for recurrent spontaneous abortions.

- Deletion by apoptosis.** T cells that recognize self antigens may receive signals that promote their death by apoptosis. Two mechanisms of deletion of mature T cells have been proposed, based mainly on studies in mice. It is postulated that if T cells recognize self antigens, they may express a pro-apoptotic member of the Bcl family, called Bim, without antiapoptotic members of the family like Bcl-2 and Bcl-x (whose induction requires the full set of signals for lymphocyte activation). Unopposed Bim triggers apoptosis by the mitochondrial pathway (Chapter 2). A second mechanism of activation-induced death of CD4⁺ T cells and B cells involves the Fas-Fas ligand system. Lymphocytes as well as many other cells express the death receptor Fas (CD95), a member of the TNF-receptor family. Fas ligand (FasL), a membrane protein that is structurally homologous to the cytokine TNF, is expressed mainly on activated T lymphocytes. The engagement of Fas by FasL induces apoptosis of activated T cells (Chapter 2). It is postulated that if self antigens engage antigen receptors of self-reactive T cells, Fas and FasL are co-expressed, leading to elimination of the cells via Fas-mediated apoptosis. Self-reactive B cells may also be deleted by FasL on T cells engaging Fas on the B cells. The importance of this mechanism in the peripheral deletion of autoreactive lymphocytes is highlighted by two mice that are natural mutants of Fas or FasL. These mice develop an autoimmune disease somewhat resembling human SLE, associated with generalized lymphoproliferation. In humans a similar disease is caused by mutations in the *FAS* gene; it is called the *autoimmune lymphoproliferative syndrome (ALPS)*.

Some antigens are hidden (sequestered) from the immune system, because the tissues in which these antigens are located do not communicate with the blood and lymph. As a result, self antigens in these tissues fail to elicit immune responses and are essentially ignored by the immune system. This is believed to be the case for the testis, eye, and brain, all of which are called *immune-privileged sites* because it is difficult to induce immune responses to antigens introduced into these sites. If the antigens of these tissues are released, for example, as a consequence of trauma or infection, the result may be an immune response that leads to prolonged tissue inflammation and injury. This is the postulated mechanism for post-traumatic orchitis and uveitis.

Mechanisms of Autoimmunity: General Principles

The immune system normally exists in an equilibrium in which lymphocyte activation, which is required for defense

Figure 6-22 Pathogenesis of autoimmunity. Autoimmunity results from multiple factors, including susceptibility genes that may interfere with self-tolerance and environmental triggers (such as infections, tissue injury, and inflammation) that promote lymphocyte entry into tissues, activation of self-reactive lymphocytes, and tissue damage.

against pathogens, is balanced by the mechanisms of tolerance, which prevent reactions against self antigens. The underlying cause of autoimmune diseases is the failure of tolerance, which allows responses to develop against self antigens. Understanding why tolerance fails in these diseases is an important goal of immunologists.

Autoimmunity arises from a combination of the inheritance of susceptibility genes, which may contribute to the breakdown of self-tolerance, and environmental triggers, such as infections and tissue damage, which promote the activation of self-reactive lymphocytes (Fig. 6-22). The genetics, as well as the gene-environment interactions, are complex and difficult to dissect, because of which much remains unknown about the enigma of autoimmunity. Nevertheless, some interesting clues have begun to emerge with the development of better technologies for defining genetic susceptibility and for studying patients.

It is thought that susceptibility genes and environmental triggers induce a number of changes that contribute to the development of autoimmunity:

- Defective tolerance or regulation.** Fundamental to the development of autoimmune diseases is a failure of the

mechanisms that maintain self-tolerance. As discussed later, some clues about how these mechanisms might be disrupted have come from the analysis of patients with rare inherited autoimmune disorders and from gene knockout mice that develop autoimmune lesions. However, despite the advances in understanding mechanisms of immune tolerance and regulation, it is not known why these may become defective in the majority of common autoimmune diseases.

- **Abnormal display of self antigens.** Abnormalities may include increased expression and persistence of self antigens that are normally cleared, or structural changes in these antigens resulting from enzymatic modifications or from cellular stress or injury. If these changes lead to the display of antigenic epitopes that are not expressed normally, the immune system may not be tolerant to these epitopes, thus allowing anti-self responses to develop.
- **Inflammation or an initial innate immune response.** As discussed earlier, the innate immune response is a strong stimulus for the subsequent activation of lymphocytes and the generation of adaptive immune responses. Microbes or cell injury may elicit local inflammatory reactions resembling innate immune responses, and these may be critical inducers of the autoimmune disease.

Although these are appealing hypotheses, which of these abnormalities actually play a role in a specific autoimmune disease in humans remains largely a matter of speculation.

Role of Susceptibility Genes

Most autoimmune diseases are complex multigenic disorders. It has been known for decades that autoimmunity has a genetic component. The incidence of many autoimmune diseases is greater in twins of affected individuals than in the general population, and greater in monozygotic than in dizygotic twins, proof that genetics contributes to the development of these disorders.

Association of HLA Alleles with Disease. Among the genes known to be associated with autoimmunity, the greatest contribution is that of HLA genes (Table 6-7). The most striking of these associations is between ankylosing spondylitis and *HLA-B27*; individuals who inherit this class I HLA allele have a 100-200 fold greater chance (odds ratio, or relative risk) of developing the disease compared with those who do not carry *HLA-B27*. Many autoimmune diseases are associated with different class II HLA alleles. Although it is reasonable to postulate that these associations reflect the ability of some HLA molecules to display self peptides, it has been difficult to show that disease-associated HLA molecules do so any better or worse than molecules that are not associated with autoimmunity. Thus, the mechanisms underlying these disease associations remain poorly understood. It is also important to understand that different HLA alleles may contribute to a disease but their presence is not, by itself, the cause of any disease. Thus, in the example of *HLA-B27*, the vast majority of individuals who inherit this allele never develop ankylosing spondylitis.

Table 6-7 Association of HLA Alleles and Inflammatory Diseases

Disease	HLA allele	Odds Ratio [†]
Rheumatoid arthritis (anti-CCP Ab positive) [‡]	DRB1, 1 SE allele [§]	4
	DRB1, 2 SE alleles	12
Type 1 diabetes	DRB1*0301-DQA1*0501-DQB1*0201 haplotype	4
	DRB1*0401-DQA1*0301-DQB1*0302 haplotype	8
	DRB1*0301/0401 haplotype heterozygotes	35
Multiple sclerosis	DRB1*1501	3
Systemic lupus erythematosus	DRB1*0301	2
	DRB1*1501	1.3
Ankylosing spondylitis	B*27 (mainly B*2705 and B*2702)	100-200
Celiac disease	DQA1*0501-DQB1*0201 haplotype	7

[†]The odds ratio reflects approximate values of increased risk of the disease associated with the inheritance of particular HLA alleles. The data are from European-derived populations.

[‡]Anti-CCP Ab = antibodies directed against cyclic citrullinated peptides. Data are from patients who test positive for these antibodies in the serum.

[§]SE refers to shared epitope, so called because the susceptibility alleles map to one region of the DRB1 protein (positions 70-74).

Courtesy Dr. Michelle Fernando, Imperial College London.

In addition to autoimmune diseases, some inherited errors of metabolism, such as 21-hydroxylase deficiency and hereditary hemochromatosis, are also associated with particular HLA alleles (*HLA-BW47* and *HLA-A*, respectively). However, in these cases, the mutated genes causing 21-hydroxylase deficiency and hereditary hemochromatosis happen by chance to be located in the MHC locus, and the linked HLA alleles are innocent bystanders that are not culpable in either of these diseases.

Association of Non-MHC Genes with Autoimmune Diseases. Genome-wide association studies and family studies have shown that multiple non-MHC genes are associated with various autoimmune diseases (Table 6-8). Some of these genes are disease-specific, but many of the associations are seen in multiple disorders, suggesting that the products of these genes affect general mechanisms of immune regulation and self-tolerance. Three recently described genetic associations are especially interesting.

- Polymorphisms in a gene called *PTPN22*, which encodes a protein tyrosine phosphatase, are associated with rheumatoid arthritis, type 1 diabetes, and several other autoimmune diseases. Because these disorders have a fairly high prevalence (especially rheumatoid arthritis), *PTPN22* is said to be the gene that is most frequently implicated in autoimmunity. It is postulated that the disease-associated variants encode a phosphatase that is functionally defective and is thus unable to fully control the activity of tyrosine kinases, which are involved in many responses of lymphocytes and other cells. The net result is excessive lymphocyte activation.
- Polymorphisms in the gene for *NOD2* are associated with Crohn disease, a form of inflammatory bowel disease, especially in certain ethnic populations. *NOD2*, a member of the NOD-like receptor (NLR) family (discussed earlier), is a cytoplasmic sensor of microbes that is expressed in intestinal epithelial and other cells. According to one hypothesis, the disease-associated

Table 6-8 Selected Non-HLA Genes Associated with Autoimmune Diseases

Putative Gene Involved	Diseases	Postulated Function of Encoded Protein and Role of Mutation/Polymorphism in Disease
Genes involved in immune regulation:		
<i>PTPN22</i>	RA, T1D, IBD	Protein tyrosine phosphatase, may affect signaling in lymphocytes and may alter negative selection or activation of self-reactive T cells
<i>IL23R</i>	IBD, PS, AS	Receptor for the T _H 17-inducing cytokine IL-23; may alter differentiation of CD4+ T cells into pathogenic T _H 17 effector cells
<i>CTLA4</i>	T1D, RA	Inhibits T cell responses by terminating activation and promoting activity of regulatory T cells; may interfere with self-tolerance
<i>IL2RA</i>	MS, T1D	α chain of the receptor for IL-2, which is a growth and survival factor for activated and regulatory T cells; may affect development of effector cells and/or regulation of immune responses
Genes involved in immune responses to microbes:		
<i>NOD2</i>	IBD	Cytoplasmic sensor of bacteria expressed in Paneth and other intestinal epithelial cells; may control resistance to gut commensal bacteria
<i>ATG16</i>	IBD	Involved in autophagy; possible role in defense against microbes and maintenance of epithelial barrier function
<i>IRF5, IFIH1</i>	SLE	Role in type I interferon production; type I IFN is involved in the pathogenesis of SLE (see text)

AS, Ankylosing spondylitis; IBD, inflammatory bowel disease; MS, multiple sclerosis; PS, psoriasis; RA, rheumatoid arthritis; SLE, systemic lupus erythematosus.

The probable linkage of these genes with various autoimmune diseases has been defined by genome-wide association studies (GWAS) and other methods for studying disease-associated polymorphisms.

Adapted from Zenewicz LA, Abraham C, Flavell RA, Cho JH: Unraveling the genetics of autoimmunity. *Cell* 2010;140:791.

variant is ineffective at sensing gut microbes, including commensal bacteria, resulting in entry of and chronic inflammatory responses against these normally well-tolerated organisms.

- Polymorphisms in the genes encoding the *IL-2 receptor* (*CD25*) and *IL-7 receptor* α chains are associated with multiple sclerosis and other autoimmune diseases. These cytokines may control the maintenance of regulatory T cells.

Many other polymorphisms have been described in particular autoimmune diseases, and we will mention some of these when we describe specific disorders. Although these genetic associations are beginning to reveal interesting clues about pathogenesis, the links between the genes, functions of their encoded proteins, and the diseases remain to be established.

We have previously mentioned that in mice and humans, gene knockouts and natural mutations affecting several individual genes result in autoimmunity. These genes include *AIRE*, *CTLA4*, *PD1*, *FAS*, *FASL*, and *IL2* and its receptor *CD25*. In addition, B cells express an Fc receptor that recognizes IgG antibodies bound to antigens and switches off further antibody production (a normal negative-feedback mechanism). Knockout of this receptor results in autoimmunity, presumably because the B cells can no longer be controlled. These examples provide valuable information about pathways of self-tolerance and immune regulation, but the diseases caused by these single gene mutations are rare and mutations in these genes are not the cause of most common autoimmune disorders.

Role of Infections

Autoimmune reactions may be triggered by infections.

Two mechanisms have been postulated to explain the link between infections and autoimmunity (Fig. 6-23). First, infections may upregulate the expression of costimulators on APCs. If these cells are presenting self antigens, the result may be a breakdown of anergy and activation of T cells specific for the self antigens. Second, some microbes

may express antigens that have the same amino acid sequences as self antigens. Immune responses against the microbial antigens may result in the activation of self-reactive lymphocytes. This phenomenon is called *molecular mimicry*. A clear example of such mimicry is rheumatic heart disease, in which antibodies against streptococcal proteins cross-react with myocardial proteins and cause myocarditis (Chapter 12). More subtle molecular mimicry may be involved in classic autoimmune diseases as well.

Microbes may induce other abnormalities that promote autoimmune reactions. Some viruses, such as Epstein-Barr virus (EBV) and HIV, cause polyclonal B-cell activation, which may result in production of autoantibodies. The tissue injury that is common in infections may release self antigens and structurally alter these antigens so that they are able to activate T cells that would not be tolerant to these new, modified antigens. Infections may induce the production of cytokines that recruit lymphocytes, including potentially self-reactive lymphocytes, to sites of self antigens.

Infections may protect against some autoimmune diseases. Although the role of infections in triggering autoimmunity has received a great deal of attention, recent epidemiologic studies suggest that the incidence of autoimmune diseases is increasing in developed countries as infections are better controlled. In some animal models (e.g., of type 1 diabetes) infections greatly reduce the incidence of disease. The underlying mechanisms are unclear; one possibility is that infections promote low-level IL-2 production, and this is essential for maintaining regulatory T cells.

Recently, there has been great interest in the idea that the normal gut and skin microbiome influences the development of autoimmunity. It is possible that different non-pathogenic microbes affect the relative proportions of effector and regulatory T cells, and shape the host response towards or away from aberrant activation. However, it is still not clear which microbes actually contribute to specific diseases in humans, or if the microbiome can be manipulated to prevent or treat these disorders.

Figure 6-23 Postulated role of infections in autoimmunity. Infections may promote activation of self-reactive lymphocytes by inducing the expression of costimulators (A), or microbial antigens may mimic self antigens and activate self-reactive lymphocytes as a cross-reaction (B).

KEY CONCEPTS

Immunologic Tolerance and Autoimmunity

- Tolerance (unresponsiveness) to self antigens is a fundamental property of the immune system, and breakdown of tolerance is the basis of autoimmune diseases.
- Central tolerance: immature lymphocytes that recognize self antigens in the central (generative) lymphoid organs are killed by apoptosis; in the B-cell lineage, some of the self-reactive lymphocytes switch to new antigen receptors that are not self-reactive.
- Peripheral tolerance: mature lymphocytes that recognize self antigens in peripheral tissues become functionally inactive (anergic), or are suppressed by regulatory T lymphocytes, or die by apoptosis.
- The factors that lead to a failure of self-tolerance and the development of autoimmunity include (1) inheritance of susceptibility genes that may disrupt different tolerance pathways, and (2) infections and tissue injury that may expose self antigens and activate APCs and lymphocytes in the tissues.
- Autoimmune diseases are usually chronic and progressive, and the type of tissue injury is determined by the nature of the dominant immune response.

General Features of Autoimmune Diseases

Diseases caused by autoimmunity have some important general features.

- Autoimmune diseases tend to be chronic, sometimes with relapses and remissions, and the damage is often

progressive. One reason for the chronicity is that the immune system contains many intrinsic amplification loops that allow small numbers of antigen-specific lymphocytes to accomplish their task of eradicating complex infections. When the response is inappropriately directed against self tissues, the same amplification mechanisms exacerbate and prolong the injury. Another reason for the persistence and progression of autoimmune disease is the phenomenon of *epitope spreading*, in which an immune response against one self antigen causes tissue damage, releasing other antigens, and resulting in the activation of lymphocytes by these newly encountered epitopes.

- **The clinical and pathologic manifestations of an autoimmune disease are determined by the nature of the underlying immune response.** Some of these diseases are caused by autoantibodies, whose formation may be associated with dysregulated germinal center reactions. Most chronic inflammatory diseases are caused by abnormal and excessive T_H1 and T_H17 responses; examples of these diseases include psoriasis, multiple sclerosis, and some types of inflammatory bowel disease. $CD8^+$ CTLs contribute to killing of cells, such as islet β cells in type 1 diabetes. In some autoimmune diseases, such as rheumatoid arthritis, both antibodies and T cell-mediated inflammation may be involved.

With this background we can proceed to a discussion of specific autoimmune diseases. Table 6-6 lists both systemic and organ-specific autoimmune disorders. The systemic diseases tend to involve blood vessels and connective tissues, and therefore, they are often called *collagen vascular diseases* or *connective tissue diseases*. Our focus here is on selected systemic autoimmune diseases; organ-specific disorders are covered elsewhere in the book.

Systemic Lupus Erythematosus (SLE)

SLE is an autoimmune disease involving multiple organs, characterized by a vast array of autoantibodies, particularly antinuclear antibodies (ANAs), in which injury is caused mainly by deposition of immune complexes and binding of antibodies to various cells and tissues. The disease may be acute or insidious in its onset, and is typically a chronic, remitting and relapsing, often febrile, illness. Injury to the skin, joints, kidney, and serosal membranes is prominent. Virtually every other organ in the body, however, may also be affected. The clinical presentation of SLE is so variable that the American College of Rheumatology has established a complex set of criteria for this disorder, which is helpful for clinicians and for the design and assessment of clinical trials (Table 6-9). However, the disease is very heterogeneous, and any patient may present with any number of these clinical features. SLE is a fairly common disease, with a prevalence that may be as high as 1 in 2500 in certain populations. Similar to many autoimmune diseases, SLE predominantly affects women, with a frequency of 1 in 700 among women of childbearing age and a female-to-male ratio of 9:1 during the reproductive age group of 17 through 55 years. By comparison, the female-to-male ratio is only 2:1 for disease developing during childhood or after the age of 65. The prevalence of the disease is 2- to 3-fold higher in blacks and Hispanics than in whites. Although SLE often presents in the 20s and 30s, it may manifest at any age, even in early childhood.

Spectrum of Autoantibodies in SLE

The hallmark of SLE is the production of autoantibodies. Some antibodies recognize diverse nuclear and cytoplasmic components of the cell that are neither organ- nor species-specific, and others are directed against cell surface antigens of blood cells. Apart from their value in the diagnosis and management of patients with SLE, these autoantibodies are of major pathogenetic significance, as, for example, in the immune complex-mediated glomerulonephritis so typical of this disease. Autoantibodies are found in many diseases in addition to SLE, and antibodies of different specificities tend to be associated with different autoimmune disorders (Table 6-10).

Antinuclear antibodies (ANAs). These are directed against nuclear antigens and can be grouped into four categories: (1) antibodies to DNA, (2) antibodies to histones, (3) antibodies to nonhistone proteins bound to RNA, and (4) antibodies to nucleolar antigens. Table 6-10 lists several ANAs and their association with SLE as well as with other autoimmune diseases to be discussed later. The most widely used method for detecting ANAs is indirect immunofluorescence, which can identify antibodies that bind to a variety of nuclear antigens, including DNA, RNA, and proteins (collectively called *generic ANAs*). The pattern of nuclear fluorescence suggests the type of antibody present in the patient's serum. Four basic patterns are recognized (Fig. 6-24):

Table 6-9 1997 Revised Criteria for Classification of Systemic Lupus Erythematosus*

Criterion	Definition
1. Malar rash	Fixed erythema, flat or raised, over the malar eminences, tending to spare the nasolabial folds
2. Discoid rash	Erythematous raised patches with adherent keratotic scaling and follicular plugging; atrophic scarring may occur in older lesions
3. Photosensitivity	Rash as a result of unusual reaction to sunlight, by patient history or physician observation
4. Oral ulcers	Oral or nasopharyngeal ulceration, usually painless, observed by a physician
5. Arthritis	Nonerosive arthritis involving two or more peripheral joints, characterized by tenderness, swelling, or effusion
6. Serositis	Pleuritis—convincing history of pleuritic pain or rub heard by a physician or evidence of pleural effusion, or Pericarditis—documented by electrocardiogram or rub or evidence of pericardial effusion
7. Renal disorder	Persistent proteinuria >0.5 g/dL or >3 if quantitation not performed or Cellular casts—may be red blood cell, hemoglobin, granular, tubular, or mixed
8. Neurologic disorder	Seizures—in the absence of offending drugs or known metabolic derangements (e.g., uremia, ketoacidosis, or electrolyte imbalance), or Psychosis—in the absence of offending drugs or known metabolic derangements (e.g., uremia, ketoacidosis, or electrolyte imbalance)
9. Hematologic disorder	Hemolytic anemia—with reticulocytosis, or Leukopenia— $<4.0 \times 10^9$ cells/L (4000 cells/mm ³) total on two or more occasions, or Lymphopenia— $<1.5 \times 10^9$ cells/L (1500 cells/mm ³) on two or more occasions, or Thrombocytopenia— $<100 \times 10^9$ cells/L (100 $\times 10^3$ cells/mm ³) in the absence of offending drugs
10. Immunologic disorder	Anti-DNA antibody to native DNA in abnormal titer, or Anti-Sm—presence of antibody to Sm nuclear antigen, or Positive finding of antiphospholipid antibodies based on (1) an abnormal serum level of IgG or IgM anticardiolipin antibodies, (2) a positive test for lupus anticoagulant using a standard test, or (3) a false-positive serologic test for syphilis known to be positive for at least 6 months and confirmed by negative <i>Treponema pallidum</i> immobilization or fluorescent treponemal antibody absorption test
11. Antinuclear antibody	An abnormal titer of antinuclear antibody by immunofluorescence or an equivalent assay at any point in time and in the absence of drugs known to be associated with drug-induced lupus syndrome

*This classification, based on 11 criteria, was proposed for the purpose of identifying patients in clinical studies. A person is said to have SLE if any four or more of the 11 criteria are present, serially or simultaneously, during any period of observation.

From Tan EM, et al: The revised criteria for the classification of systemic lupus erythematosus. *Arthritis Rheum* 1982;25:1271; and Hochberg MC: Updating the American College of Rheumatology revised criteria for the classification of systemic lupus erythematosus. *Arthritis Rheum* 1997;40:1725.

Table 6-10 Autoantibodies in Systemic Autoimmune Diseases

Disease	Specificity of Autoantibody	% Positive	Association with Specific Disease Features
Systemic lupus erythematosus (SLE)	Double-stranded DNA	40-60	Nephritis; specific for SLE
	U1-RNP	30-40	
	Smith (Sm) antigen (core protein of small RNP particles)	20-30	Specific for SLE
	Ro (SS-A)/La (SS-B) nucleoproteins	30-50	Congenital heart block; neonatal lupus
	Phospholipid-protein complexes (anti-PL)	30-40	Antiphospholipid syndrome (in ~10% of SLE patients)
	Multiple nuclear antigens ("generic ANAs")	95-100	Found in other autoimmune diseases, not specific.
Systemic sclerosis	DNA topoisomerase 1	30-70	Diffuse skin disease, lung disease; specific for systemic sclerosis
	Centromeric proteins (CENPs) A, B, C	20-40	Limited skin disease, ischemic digital loss, pulmonary hypertension
	RNA polymerase III	15-20	Acute onset, scleroderma renal crisis, cancer
Sjögren syndrome	Ro/SS-A	70-95	
	La/SS-B		
Autoimmune myositis	Histidyl aminoacyl-tRNA synthetase, Jo1	25	Interstitial lung disease, Raynaud phenomenon
	Mi-2 nuclear antigen	5-10	Dermatomyositis, skin rash
	MDA5 (cytoplasmic receptor for viral RNA)	20-35 (Japanese)	Vascular skin lesions, interstitial lung disease
	TIF1 γ nuclear protein	15-20	Dermatomyositis, cancer
Rheumatoid arthritis	CCP (cyclic citrullinated peptides); various citrullinated proteins	60-80	Specific for rheumatoid arthritis
	Rheumatoid factor (not specific)	60-70	

Listed autoantibodies are associated with high frequencies with particular diseases. "Generic" antinuclear antibodies (ANAs), which may react against many nuclear antigens, are positive in a large fraction of patients with SLE but are also positive in other autoimmune diseases. % positive refers to the approximate % of patients who test positive for each antibody. The table was compiled with the help of Dr. Antony Rosen, Johns Hopkins University.

- *Homogeneous or diffuse nuclear staining* usually reflects antibodies to chromatin, histones, and, occasionally, double-stranded DNA.
- *Rim or peripheral staining* patterns are most often indicative of antibodies to double-stranded DNA and sometimes to nuclear envelope proteins.
- *Speckled pattern* refers to the presence of uniform or variable-sized speckles. This is one of the most commonly observed patterns of fluorescence and therefore the least specific. It reflects the presence of antibodies to non-DNA nuclear constituents such as Sm antigen, ribonucleoprotein, and SS-A and SS-B reactive antigens.
- *Nucleolar pattern* refers to the presence of a few discrete spots of fluorescence within the nucleus and represents antibodies to RNA. This pattern is reported most often in patients with systemic sclerosis.
- *Centromeric pattern.* Patients with systemic sclerosis often contain antibodies specific for centromeres, which give rise to this pattern.

The fluorescence patterns are not absolutely specific for the type of antibody, and because many autoantibodies may be present, combinations of patterns are frequent. Concerns have been raised about the sensitivity and subjective nature of this assay, and attempts are ongoing to replace it with ELISA for specific nuclear and other antigens. Nevertheless, the staining pattern is considered of diagnostic value, and the test remains in use. **Antibodies to double-stranded DNA and the so-called Smith (Sm) antigen are virtually diagnostic of SLE.**

Other Autoantibodies. In addition to ANAs, lupus patients have a host of other autoantibodies. Some are directed against blood cells, such as red cells, platelets, and lymphocytes; others react with proteins in complex with phospholipids. *Antiphospholipid antibodies* are present in 30% to

40% of lupus patients. They are actually directed against epitopes of plasma proteins that are revealed when the proteins are in complex with phospholipids. Included among these proteins are prothrombin, annexin V, β_2 -glycoprotein I, protein S, and protein C. Antibodies against the phospholipid- β_2 -glycoprotein complex also bind to cardiolipin antigen, used in syphilis serology, and therefore lupus patients may have a false-positive test result for syphilis. Some of these antibodies interfere with *in vitro* clotting tests, such as partial thromboplastin time. Therefore, these antibodies are sometimes referred to as *lupus anticoagulant*. Despite the observed clotting delays *in vitro*, however, patients with antiphospholipid antibodies have complications related to excessive clotting (a *hypercoagulable state*), such as thrombosis ([Chapter 4](#)).

Etiology and Pathogenesis of SLE

The fundamental defect in SLE is a failure of the mechanisms that maintain self-tolerance. Although what causes this failure of self-tolerance remains unknown, as is true of most autoimmune diseases, both genetic and environmental factors play a role.

Genetic Factors. SLE is a genetically complex disease with contributions from MHC and multiple non-MHC genes. Many lines of evidence support a genetic predisposition.

- Family members of patients have an increased risk of developing SLE. As many as 20% of clinically unaffected first-degree relatives of SLE patients reveal autoantibodies and other immunoregulatory abnormalities.
- There is a higher rate of concordance (>20%) in monozygotic twins when compared with dizygotic twins (1% to 3%).
- Studies of HLA associations support the concept that MHC genes regulate production of particular

Figure 6-24 Staining patterns of antinuclear antibodies. **A**, Homogeneous or diffuse staining of nuclei is typical of antibodies reactive with dsDNA, nucleosomes and histones, and is common in SLE. **B**, Speckled pattern is seen with antibodies against various nuclear antigens, including Sm and RNPs. **C**, The pattern of staining of anti-centromere antibodies is seen in some cases of systemic sclerosis, Sjogren syndrome, and other diseases. **D**, Nucleolar pattern is typical of antibodies against nucleolar proteins. (Images reproduced from Wiik AS, et al, *J. Autoimm.* 35:276, 2010, with permission.)

autoantibodies. Specific alleles of the *HLA-DQ* locus have been linked to the production of anti-double-stranded DNA, anti-Sm, and antiphospholipid antibodies, although the relative risk is small.

- Some lupus patients have inherited deficiencies of early complement components, such as C2, C4, or C1q. Lack of complement may impair removal of circulating immune complexes by the mononuclear phagocyte system, thus favoring tissue deposition. Knockout mice lacking C4 or certain complement receptors are also prone to develop lupus-like autoimmunity. Various mechanisms have been invoked, including failure to clear immune complexes and loss of B-cell self-tolerance. It has also been proposed that deficiency of C1q results in defective phagocytic clearance of apoptotic cells. Many cells normally undergo apoptosis, and if they are not cleared their nuclear components may elicit immune responses.
- Genome-wide association studies have identified several genetic loci that may be associated with the disease. Many of these loci encode proteins involved in

lymphocyte signaling and interferon responses, both of which may play a role in lupus pathogenesis, as discussed later. The relative risk for each locus is small, and even taken together these loci account for 20% or less of the genetic predisposition, suggesting an important role for environmental factors, discussed later.

Immunologic Factors. Recent studies in animal models and patients have revealed several immunologic aberrations that collectively may result in the persistence and uncontrolled activation of self-reactive lymphocytes.

- **Failure of self-tolerance in B cells** results from defective elimination of self-reactive B cells in the bone marrow or defects in peripheral tolerance mechanisms.
- **CD4+ helper T cells** specific for nucleosomal antigens also escape tolerance and contribute to the production of high-affinity pathogenic autoantibodies. The autoantibodies in SLE show characteristics of T cell-dependent antibodies produced in germinal centers, and increased

numbers of follicular helper T cells have been detected in the blood of SLE patients.

- **TLR engagement by nuclear DNA and RNA** contained in immune complexes may activate B lymphocytes. These TLRs function normally to sense microbial products, including nucleic acids. Thus, B cells specific for nuclear antigens may get second signals from TLRs and may be activated, resulting in increased production of antinuclear autoantibodies.
- **Type I interferons** play a role in lymphocyte activation in SLE. High levels of circulating type I interferons and a molecular signature in blood cells suggesting exposure to these cytokines has been reported in SLE patients and correlates with disease severity. Type I interferons are antiviral cytokines that are normally produced during innate immune responses to viruses. It may be that nucleic acids engage TLRs on dendritic cells and stimulate the production of interferons. In other words, self nucleic acids mimic their microbial counterparts. How interferons contribute to the development of SLE is unclear; these cytokines may activate dendritic cells and B cells and promote T_H1 responses, all of which may stimulate the production of pathogenic autoantibodies.
- Other cytokines that may play a role in unregulated B-cell activation include the TNF family member BAFF, which promotes survival of B cells. In some patients and animal models, increased production of BAFF has been reported, prompting attempts to block the cytokine or its receptor as therapy for SLE.

Environmental Factors. There are many indications that environmental factors must also be involved in the pathogenesis of SLE.

- **Exposure to ultraviolet (UV) light** exacerbates the disease in many individuals. UV irradiation may induce apoptosis in cells and may alter the DNA in such a way that it becomes immunogenic, perhaps because of enhanced recognition by TLRs. In addition, UV light may modulate the immune response, for example, by stimulating keratinocytes to produce IL-1, a cytokine known to promote inflammation.
- The **gender bias** of SLE is partly attributable to actions of sex hormones and partly related to genes on the X chromosome, independent of hormone effects.
- **Drugs** such as hydralazine, procainamide, and D-penicillamine can induce an SLE-like response in humans.

A Model for the Pathogenesis of SLE. It is clear from this discussion that the immunologic abnormalities in SLE—both documented and postulated—are varied and complex. Nevertheless, an attempt can be made to synthesize results from human studies and animal models into a hypothetical model of the pathogenesis of SLE (Fig. 6-25). UV irradiation and other environmental insults lead to the apoptosis of cells. Inadequate clearance of the nuclei of these cells results in a large burden of nuclear antigens. Underlying abnormalities in B and T lymphocytes are responsible for defective tolerance, because of which self-reactive lymphocytes survive and remain functional. These lymphocytes are stimulated by nuclear self antigens, and

Figure 6-25 Model for the pathogenesis of systemic lupus erythematosus. In this hypothetical model, susceptibility genes interfere with the maintenance of self-tolerance and external triggers lead to persistence of nuclear antigens. The result is an antibody response against self nuclear antigens, which is amplified by the action of nucleic acids on dendritic cells (DCs) and B cells, and the production of type 1 interferons. TLRs, Toll-like receptors.

antibodies are produced against the antigens. Complexes of the antigens and antibodies bind to Fc receptors on B cells and dendritic cells, and may be internalized. The nucleic acid components engage TLRs and stimulate B cells to produce more autoantibodies. TLR stimuli also activate dendritic cells to produce interferons and other cytokines, which further enhance the immune response and cause more apoptosis. The net result is a cycle of antigen release and immune activation resulting in the production of high-affinity autoantibodies.

Mechanism of Tissue Injury. Different autoantibodies are the cause of most of the lesions of SLE.

- **Most of the systemic lesions are caused by immune complexes (type III hypersensitivity).** DNA-anti-DNA complexes can be detected in the glomeruli and small blood vessels. Low levels of serum complement

(secondary to consumption of complement proteins) and granular deposits of complement and immunoglobulins in the glomeruli further support the immune complex nature of the disease. T cell infiltrates are also frequently seen in the kidneys, but the role of these cells in tissue damage is not established.

- **Autoantibodies specific for red cells, white cells, and platelets opsonize these cells and promote their phagocytosis and lysis.** There is no evidence that ANAs, which are involved in immune complex formation, can penetrate intact cells. If cell nuclei are exposed, however, the ANAs can bind to them. In tissues, nuclei of damaged cells react with ANAs, lose their chromatin pattern, and become homogeneous, to produce so-called LE bodies or hematoxylin bodies. Related to this phenomenon is the *LE cell*, which is readily seen when blood is agitated in vitro. The LE cell is any phagocytic leukocyte (blood neutrophil or macrophage) that has engulfed the denatured nucleus of an injured cell. The demonstration of LE cells in vitro was used in the past as a test for SLE. With new techniques for detection of ANAs, however, this test is now largely of historical interest. Sometimes, LE cells are found in pericardial or pleural effusions in patients.
- **Antiphospholipid antibody syndrome.** Patients with antiphospholipid antibodies may develop venous and arterial thromboses, which may be associated with recurrent spontaneous miscarriages and focal cerebral or ocular ischemia. This constellation of clinical features, in association with lupus, is referred to as the *secondary antiphospholipid antibody syndrome*. The mechanisms of thrombosis are not defined, and antibodies against clotting factors, platelets and endothelial cells have all been proposed as being responsible for thrombosis ([Chapter 4](#)). Some patients develop these autoantibodies and the clinical syndrome without associated SLE. They are said to have the *primary antiphospholipid antibody syndrome* ([Chapter 4](#)).
- The neuropsychiatric manifestations of SLE have been attributed to antibodies that react with neurons or receptors for various neurotransmitters and cross the blood brain barrier. However, this is not established and mechanisms involving other immune factors, such as cytokines, may also underlie the cognitive dysfunction and other CNS abnormalities that are associated with SLE.

MORPHOLOGY

The morphologic changes in SLE are extremely variable. The frequency of individual organ involvement is shown in [Table 6-11](#). The most characteristic lesions result from immune complex deposition in blood vessels, kidneys, connective tissue, and skin.

Blood Vessels. An acute necrotizing vasculitis involving capillaries, small arteries and arterioles may be present in any tissue. The arteritis is characterized by fibrinoid deposits in the vessel walls. In chronic stages, vessels undergo fibrous thickening with luminal narrowing.

Kidney. Up to 50% of SLE patients have clinically significant renal involvement. All of the glomerular lesions described later

Table 6-11 Clinical and Pathologic Manifestations of Systemic Lupus Erythematosus

Clinical Manifestation	Prevalence in Patients (%)*
Hematologic	100
Arthritis, arthralgia or myalgia	80-90
Skin	85
Fever	55-85
Fatigue	80-100
Weight loss	60
Renal	50-70
Neuropsychiatric	25-35
Pleuritis	45
Pericarditis	25
Gastrointestinal	20
Raynaud phenomenon	15-40
Ocular	5-15
Peripheral neuropathy	15

*Percentages are approximate and may vary with age, ethnicity, and other factors. Table compiled with the assistance of Dr. Meenakshi Jolly, Rush Medical Center, Chicago.

are the result of deposition of immune complexes that are regularly present in the mesangium or along the entire basement membrane and sometimes throughout the glomerulus. Both in situ formation and deposition of preformed circulating immune complexes may contribute to the injury, but the reason for the wide spectrum of histopathologic lesions (and clinical manifestations) in patients with lupus nephritis remains uncertain.

The kidney virtually always shows some evidence of renal abnormality if examined by electron microscopy and immunofluorescence. According to the currently accepted classification, six patterns of glomerular disease are seen in SLE. It should be noted that there is some overlap within these classes and over time lesions may evolve from one class to another. Thus, the exact percentage of patients with each of the six classes of lesions is difficult to determine. Suffice it to say that Class I is the least common and class IV is the most common pattern.

- **Minimal mesangial lupus nephritis** (class I) is very uncommon, and is characterized by immune complex deposition in the mesangium, identified by immunofluorescence and by electron microscopy, but without structural changes by light microscopy.
- **Mesangial proliferative lupus nephritis** (class II) is characterized by mesangial cell proliferation, often accompanied by accumulation of mesangial matrix, and granular mesangial deposits of immunoglobulin and complement without involvement of glomerular capillaries.
- **Focal lupus nephritis** (class III) is defined by involvement of fewer than 50% of all glomeruli. The lesions may be segmental (affecting only a portion of the glomerulus) or global (involving the entire glomerulus). Affected glomeruli may exhibit swelling and proliferation of endothelial and mesangial cells associated with leukocyte accumulation, capillary necrosis, and hyaline thrombi. There is also often extracapillary proliferation associated with focal necrosis and crescent formation ([Fig. 6-26A](#)). The clinical presentation ranges from mild hematuria and proteinuria to acute renal insufficiency. Red cell casts in the urine are common when the disease is active. Some patients progress to diffuse glomerulonephritis.

Figure 6-26 Lupus nephritis. **A**, Focal proliferative glomerulonephritis, with two focal necrotizing lesions at the 11 o'clock and 2 o'clock positions (H&E stain). Extracapillary proliferation is not prominent in this case. **B**, Diffuse proliferative glomerulonephritis. Note the marked increase in cellularity throughout the glomerulus (H&E stain). **C**, Lupus nephritis showing a glomerulus with several "wire loop" lesions representing extensive subendothelial deposits of immune complexes (periodic acid-Schiff stain). **D**, Electron micrograph of a renal glomerular capillary loop from a patient with SLE nephritis. Subendothelial dense deposits (*arrowheads*) correspond to "wire loops" seen by light microscopy. B (*with arrow*) refers to the basement membrane. **E**, Deposition of IgG antibody in a granular pattern, detected by immunofluorescence. B, Basement membrane; End, endothelium; Ep, epithelial cell with foot processes; Mes, mesangium; RBC, red blood cell in capillary lumen; US, urinary space. (**A-C**, Courtesy Dr. Helmut Rennke, Department of Pathology, Brigham and Women's Hospital, Boston, Mass. **D**, Courtesy Dr. Edwin Eigenbrodt, Department of Pathology, University of Texas, Southwestern Medical School, Dallas, Texas. **E**, Courtesy Dr. Jean Olson, Department of Pathology, University of California, San Francisco, Calif.)

The active (or proliferative) inflammatory lesions can heal completely or lead to chronic global or segmental glomerular scarring.

- **Diffuse lupus nephritis** (class IV) is the most common and severe form of lupus nephritis. The lesions are similar to those in class III, but differ in extent; typically, in class IV nephritis half or more of the glomeruli are affected. As in class III, the lesions may be segmental or global and on the basis of this, it can be subclassified as Class IV segmental (IV-S) or Class IV global (IV-G). Involved glomeruli show proliferation of endothelial, mesangial and epithelial cells (Fig. 6-26B), with the latter producing cellular crescents that fill Bowman's space (Chapter 20). Subendothelial immune complex deposits may create a circumferential thickening of the capillary wall, forming "wire loop" structures on light microscopy (Fig. 6-26C). Immune complexes can be readily detected by electron microscopy (Fig. 6-26D) and immunofluorescence (Fig. 6-26E). Lesions may progress to scarring of glomeruli. Patients with diffuse glomerulonephritis are usually symptomatic, showing hematuria as well as proteinuria. Hypertension and mild to severe renal insufficiency are also common.
- **Membranous lupus nephritis** (class V) is characterized by diffuse thickening of the capillary walls due to deposition of subepithelial immune complexes, similar to idiopathic membranous nephropathy, described in Chapter 20. The immune complexes are usually accompanied by increased production of basement membrane-like material. This lesion is usually accompanied by severe proteinuria or nephrotic syndrome, and may occur concurrently with focal or diffuse lupus nephritis.
- **Advanced sclerosing lupus nephritis** (class VI) is characterized by sclerosis of more than 90% of the glomeruli, and represents end-stage renal disease.
- Changes in the interstitium and tubules are frequently present in lupus nephritis patients. Rarely, **tubulointerstitial lesions** may be the dominant abnormality. Discrete immune complexes similar to those in glomeruli are present in the tubular or peritubular capillary basement membranes in many lupus nephritis patients, but the clinical significance of these extraglomerular deposits is not established. Often, there are well-organized B-cell follicles in the interstitium, with plasma cells that may be sources of autoantibodies.

Skin. Characteristic erythema affects the face along the bridge of the nose and cheeks (the "butterfly" rash) in approximately 50% of patients, but a similar rash may also be seen on the extremities and trunk. Urticaria, bullae, maculopapular lesions, and ulcerations also occur. Exposure to sunlight incites or accentuates the erythema. Histologically the involved areas show vacuolar degeneration of the basal layer of the epidermis (Fig. 6-27A). In the dermis, there is variable edema and perivascular inflammation. Vasculitis with fibrinoid necrosis may be prominent. Immunofluorescence microscopy shows deposition of immunoglobulin and complement along the dermoepidermal junction (Fig. 6-27B), which may also be present in uninvolved skin. This finding is not diagnostic of SLE and is sometimes seen in scleroderma or dermatomyositis.

Joints. Joint involvement is typically a nonerosive synovitis with little deformity, which contrasts with rheumatoid arthritis.

Central Nervous System. Neuropsychiatric symptoms of SLE have often been ascribed to acute vasculitis, but

Figure 6-27 Systemic lupus erythematosus involving the skin. **A**, An H&E-stained section shows liquefactive degeneration of the basal layer of the epidermis and edema at the dermoepidermal junction. **B**, An immunofluorescence micrograph stained for IgG reveals deposits of Ig along the dermoepidermal junction. (A, Courtesy Dr. Jag Bhawan, Boston University School of Medicine, Boston, Mass. B, Courtesy Dr. Richard Sontheimer, Department of Dermatology, University of Texas Southwestern Medical School, Dallas, Texas.)

in histologic studies of the nervous system in such patients significant vasculitis is rarely present. Instead, noninflammatory occlusion of small vessels by intimal proliferation is sometimes noted, which may be due to endothelial damage by autoantibodies or immune complexes.

Pericarditis and Other Serosal Cavity Involvement.

Inflammation of the serosal lining membranes may be acute, subacute, or chronic. During the acute phases, the mesothelial surfaces are sometimes covered with fibrinous exudate. Later they become thickened, opaque, and coated with a shaggy fibrous tissue that may lead to partial or total obliteration of the serosal cavity. Pleural and pericardial effusions may be present.

Cardiovascular system involvement may manifest as damage to any layer of the heart. Symptomatic or asymptomatic pericardial involvement is present in up to 50% of patients. Myocarditis, or mononuclear cell infiltration, is less common and may cause resting tachycardia and electrocardiographic abnormalities. Valvular abnormalities, primarily of the mitral and aortic valves, manifest as diffuse leaflet thickening that may be associated with dysfunction (stenosis and/or regurgitation). Valvular (or so-called Libman-Sacks) endocarditis was more common prior to the widespread use of steroids. This nonbacterial verrucous endocarditis takes the form of single or multiple 1- to 3-mm warty deposits on any heart valve, distinctively on either surface of the leaflets (Fig. 6-28). By comparison, the

Figure 6-28 Libman-Sacks endocarditis of the mitral valve in lupus erythematosus. The vegetations attached to the margin of the thickened valve leaflet are indicated by arrows. (Courtesy Dr. Fred Schoen, Department of Pathology, Brigham and Women's Hospital, Boston, Mass.)

vegetations in infective endocarditis are considerably larger, and those in rheumatic heart disease (Chapter 12) are smaller and confined to the lines of closure of the valve leaflets.

An increasing number of patients have clinical evidence of coronary artery disease (angina, myocardial infarction) owing to coronary atherosclerosis. This complication is particularly notable in young patients with long-standing disease, and especially prevalent in those who have been treated with corticosteroids. The pathogenesis of accelerated coronary atherosclerosis is unclear but is probably multifactorial. Risk factors for atherosclerosis, including hypertension, obesity, and hyperlipidemia, are more commonly present in SLE patients than in the population at large. In addition, immune complexes and antiphospholipid antibodies may cause endothelial damage and promote atherosclerosis.

Spleen. Splenomegaly, capsular thickening, and follicular hyperplasia are common features. Central penicillary arteries may show concentric intimal and smooth muscle cell hyperplasia, producing so-called onion-skin lesions.

Lungs. In addition to pleuritis and pleural effusions, which are present in almost 50% of patients, in some cases, there is chronic interstitial fibrosis and secondary pulmonary hypertension. None of these changes is specific for SLE.

Other Organs and Tissues. LE, or hematoxylin, bodies in the bone marrow or other organs are strongly indicative of SLE. Lymph nodes may be enlarged with hyperplastic follicles or even demonstrate necrotizing lymphadenitis.

Clinical Features. SLE is a multisystem disease that is highly variable in its clinical presentation, and its diagnosis relies on a constellation of clinical, serologic, and morphologic changes (Table 6-9). Typically, the patient is a young

woman with some, but not necessarily all, of the following features: a butterfly rash over the face, fever, pain but no deformity in one or more peripheral joints (feet, ankles, knees, hips, fingers, wrists, elbows, shoulders), pleuritic chest pain, and photosensitivity. In many patients, however, the presentation of SLE is subtle and puzzling, taking forms such as a febrile illness of unknown origin, abnormal urinary findings, or joint disease masquerading as rheumatoid arthritis or rheumatic fever. “Generic” ANAs, detected by immunofluorescence assays, are found in virtually 100% of patients, but these are not specific for SLE. A variety of clinical findings may point toward renal involvement, including hematuria, red cell casts, proteinuria, and in some cases the classic nephrotic syndrome (Chapter 20). Laboratory evidence of some hematologic derangement is seen in virtually every case, but in some patients anemia or thrombocytopenia may be the presenting manifestation as well as the dominant clinical problem. In still others, mental aberrations, including psychosis or convulsions, or coronary artery disease may be prominent clinical problems. Patients with SLE are also prone to infections, presumably because of their underlying immune dysfunction and treatment with immunosuppressive drugs.

The course of the disease is variable and unpredictable. Rare acute cases result in death within weeks to months. More often, with appropriate therapy, the disease is characterized by flare-ups and remissions spanning a period of years or even decades. During acute flare-ups, increased formation of immune complexes results in complement activation, often leading to hypocomplementemia. Disease flares are usually treated with corticosteroids or other immunosuppressive drugs. Even without therapy, in some patients the disease may run an indolent course with relatively mild manifestations, such as skin changes and mild hematuria, for years. The outcome has improved significantly, and an approximately 90% 5-year and 80% 10-year survival can be expected. The most common causes of death are renal failure and intercurrent infections. Coronary artery disease is also becoming an important cause of death. Patients treated with steroids and immunosuppressive drugs incur the usual risks associated with such therapy.

As mentioned earlier, involvement of skin along with multisystem disease is fairly common in SLE. The following sections describe two syndromes in which the cutaneous involvement is the exclusive or most prominent feature.

Chronic Discoid Lupus Erythematosus. Chronic discoid lupus erythematosus is a disease in which the skin manifestations may mimic SLE, but systemic manifestations are rare. It is characterized by the presence of skin plaques showing varying degrees of edema, erythema, scaliness, follicular plugging, and skin atrophy surrounded by an elevated erythematous border. The face and scalp are usually affected, but widely disseminated lesions occasionally occur. The disease is usually confined to the skin, but 5% to 10% of patients with discoid lupus erythematosus develop multisystem manifestations after many years. Conversely, some patients with SLE may have prominent discoid lesions in the skin. Approximately 35% of patients show a positive test for generic ANAs, but antibodies

to double-stranded DNA are rarely present. Immunofluorescence studies of skin biopsy specimens show deposition of immunoglobulin and C3 at the dermoepidermal junction similar to that in SLE.

Subacute Cutaneous Lupus Erythematosus. This condition also presents with predominant skin involvement and can be distinguished from chronic discoid lupus erythematosus by several criteria. The skin rash in this disease tends to be widespread, superficial, and nonscarring, although scarring lesions may occur in some patients. Most patients have mild systemic symptoms consistent with SLE. Furthermore, there is a strong association with antibodies to the SS-A antigen and with the *HLA-DR3* genotype. Thus, the term *subacute cutaneous lupus erythematosus* seems to define a group intermediate between SLE and lupus erythematosus localized only to skin.

Drug-Induced Lupus Erythematosus

A lupus erythematosus-like syndrome may develop in patients receiving a variety of drugs, including hydralazine, procainamide, isoniazid, and D-penicillamine, to name only a few. Somewhat surprisingly, anti-TNF therapy, which is effective in rheumatoid arthritis and other autoimmune diseases, can also cause drug-induced lupus. Many of these drugs are associated with the development of ANAs, but most patients do not have symptoms of lupus erythematosus. For example, 80% of patients receiving procainamide test positive for ANAs, but only one third of these manifest clinical symptoms, such as arthralgias, fever, and serositis. Although multiple organs are affected, renal and central nervous system involvement is distinctly uncommon. There are serologic and genetic differences from classic SLE, as well. Antibodies specific for double-stranded DNA are rare, but there is an extremely high frequency of antibodies specific for histones. Persons with the *HLA-DR4* allele are at a greater risk of developing a lupus erythematosus-like syndrome after administration of hydralazine, whereas those with *HLA-DR6* (but not *DR4*) are at high risk with procainamide. The disease remits after withdrawal of the offending drug.

KEY CONCEPTS

Systemic Lupus Erythematosus

- SLE is a systemic autoimmune disease caused by autoantibodies produced against numerous self antigens and the formation of immune complexes.
- The major autoantibodies, and the ones responsible for the formation of circulating immune complexes, are directed against nuclear antigens. Other autoantibodies react with erythrocytes, platelets, and various complexes of phospholipids with proteins.
- Disease manifestations include nephritis, skin lesions and arthritis (caused by the deposition of immune complexes), and hematologic and neurologic abnormalities.
- The underlying cause of the breakdown in self-tolerance in SLE is unknown; it may include excess or persistence of nuclear antigens, multiple inherited susceptibility genes, and environmental triggers (e.g., UV irradiation, which results in cellular apoptosis and release of nuclear proteins).

Rheumatoid Arthritis

Rheumatoid arthritis is a chronic inflammatory disease that affects primarily the joints but may involve extra-articular tissues such as the skin, blood vessels, lungs, and heart. Abundant evidence supports the autoimmune nature of the disease. Because the principal manifestations of the disease are in the joints, it is discussed in [Chapter 26](#).

Sjögren Syndrome

Sjögren syndrome is a chronic disease characterized by dry eyes (*keratoconjunctivitis sicca*) and dry mouth (*xerostomia*) resulting from immunologically mediated destruction of the lacrimal and salivary glands. It occurs as an isolated disorder (primary form), also known as the sicca syndrome, or more often in association with another autoimmune disease (secondary form). Among the associated disorders, rheumatoid arthritis is the most common, but some patients have SLE, polymyositis, scleroderma, vasculitis, mixed connective tissue disease, or thyroiditis.

Etiology and Pathogenesis

The characteristic decrease in tears and saliva (*sicca syndrome*) is the result of lymphocytic infiltration and fibrosis of the lacrimal and salivary glands. The infiltrate contains predominantly activated CD4+ helper T cells and some B cells, including plasma cells. About 75% of patients have rheumatoid factor (an antibody reactive with self IgG) whether or not coexisting rheumatoid arthritis is present. ANAs are detected in 50% to 80% of patients by immunofluorescence assay. A host of other organ-specific and non-organ-specific antibodies have also been identified. Most important, however, are antibodies directed against two ribonucleoprotein antigens, SS-A (Ro) and SS-B (La) ([Table 6-10](#)), which can be detected in as many as 90% of patients by sensitive techniques. These antibodies are thus considered serologic markers of the disease. Patients with high titers of antibodies to SS-A are more likely to have early disease onset, longer disease duration, and extraglandular manifestations, such as cutaneous vasculitis and nephritis. These autoantibodies are also present in a smaller percentage of patients with SLE and hence are not diagnostic of Sjögren syndrome.

As with other autoimmune diseases, Sjögren syndrome shows some association, albeit weak, with certain HLA alleles. Studies of whites and blacks suggest linkage of the primary form with *HLA-B8*, *HLA-DR3*, and *DRW52* as well as *HLA-DQA1* and *HLA-DQB1* loci; in patients with anti-SS-A or anti-SS-B antibodies, specific alleles of *HLA-DQA1* and *HLA-DQB1* are frequent. This suggests that, as in SLE, inheritance of certain class II molecules predisposes to the development of particular autoantibodies.

Although the pathogenesis of Sjögren syndrome remains obscure, aberrant T-cell and B-cell activation are both implicated. The initiating trigger may be a viral infection of the salivary glands, which causes local cell death and release of tissue self antigens. In genetically susceptible individuals, CD4+ T cells and B cells specific for these self antigens may have escaped tolerance and are able to react. The result is inflammation, tissue damage, and, eventually, fibrosis. However, the role of particular cytokines or T cell

subsets in the development of the lesions is not established. The nature of the autoantigens recognized by these lymphocytes is still mysterious. A cytoskeletal protein called α -fodrin is a candidate autoantigen, but its role in disease development has not been established yet. Sjögren syndrome-like disease is seen in some patients with human T-lymphotropic virus (HTLV), human immunodeficiency virus (HIV) or hepatitis C virus infections, but the link between these viruses and the autoimmune disorder is obscure.

MORPHOLOGY

As mentioned earlier, **lacrimal and salivary glands are the major targets of the disease**, although other exocrine glands, including those lining the respiratory and gastrointestinal tracts and the vagina, may also be involved. The earliest histologic finding in both the major and the minor salivary glands is periductal and perivascular lymphocytic infiltration. Eventually the lymphocytic infiltrate becomes extensive (Fig. 6-29), and in the larger salivary glands lymphoid follicles with germinal centers may be seen. The ductal lining epithelial cells may show hyperplasia, thus obstructing the ducts. Later there is atrophy of the acini, fibrosis, and hyalinization; still later in the course atrophy and replacement of parenchyma with fat are seen. In some cases the lymphoid infiltrate may be so intense as to give the appearance of a lymphoma. Indeed, these patients are at high risk for development of B-cell lymphomas, and molecular assessments of clonality may be necessary to distinguish intense reactive chronic inflammation from early involvement by lymphoma.

The lack of tears leads to drying of the corneal epithelium, which becomes inflamed, eroded, and ulcerated; the oral mucosa may atrophy, with inflammatory fissuring and ulceration; and dryness and crusting of the nose may lead to ulcerations and even perforation of the nasal septum.

Clinical Features. Sjögren syndrome occurs most commonly in women between the ages of 50 and 60. As might be expected, symptoms result from inflammatory destruction of the exocrine glands. The *keratoconjunctivitis* produces blurring of vision, burning, and itching, and

thick secretions accumulate in the conjunctival sac. The *xerostomia* results in difficulty in swallowing solid foods, a decrease in the ability to taste, cracks and fissures in the mouth, and dryness of the buccal mucosa. Parotid gland enlargement is present in half the patients; dryness of the nasal mucosa, epistaxis, recurrent bronchitis, and pneumonitis are other symptoms. Manifestations of *extraglandular disease* are seen in one third of patients and include synovitis, diffuse pulmonary fibrosis, and peripheral neuropathy. These are more common in patients with high titers of antibodies specific for SS-A. In contrast to SLE, glomerular lesions are extremely rare in Sjögren syndrome. Defects of tubular function, however, including renal tubular acidosis, uricosuria, and phosphaturia, are often seen and are associated histologically with tubulointerstitial nephritis (Chapter 20). About 60% of patients have another accompanying autoimmune disorder, such as rheumatoid arthritis, and these patients also have the symptoms and signs of that disorder.

The combination of lacrimal and salivary gland inflammatory involvement was once called *Mikulicz disease*. The name has now been replaced by *Mikulicz syndrome*, broadened to include lacrimal and salivary gland enlargement from any cause, including sarcoidosis, lymphoma, and other tumors. *Biopsy of the lip (to examine minor salivary glands) is essential for the diagnosis of Sjögren syndrome.*

The lymph nodes of patients with Sjögren syndrome are often hyperplastic, but the most intense lymphocytic response is seen in the tissues that are the focal point of the autoimmune response, particularly the salivary and lacrimal glands. In early stages of the disease, this immune infiltrate consists of a mixture of polyclonal T and B cells. However, if the reaction continues unabated there is a strong tendency over time for individual clones within the population of B cells to gain a growth advantage, presumably because of the acquisition of somatic mutations. Emergence of a dominant B-cell clone is usually indicative of the development of a marginal zone lymphoma, a specific type of B-cell malignancy that often arises in the setting of chronic lymphocytic inflammation. About 5% of Sjögren patients develop lymphoma, an incidence that is 40-fold greater than normal. Certain other autoimmune disorders (e.g., Hashimoto thyroiditis) are also associated

Figure 6-29 Sjögren syndrome. **A**, Enlargement of the salivary gland. **B**, Intense lymphocytic and plasma cell infiltration with ductal epithelial hyperplasia in a salivary gland. with a high risk of marginal zone lymphoma (Chapter 13), which typically arises within the organ or tissue that is the target of the autoimmune inflammation.

KEY CONCEPTS

Sjögren Syndrome

- Sjögren syndrome is an inflammatory disease that affects primarily the salivary and lacrimal glands, causing dryness of the mouth and eyes.
- The disease is believed to be caused by an autoimmune T-cell reaction against an unknown self antigen expressed in these glands, or immune reactions against the antigens of a virus that infects the tissues.

Systemic Sclerosis (Scleroderma)

Systemic sclerosis is characterized by: (1) chronic inflammation thought to be the result of autoimmunity, (2) widespread damage to small blood vessels, and (3) progressive interstitial and perivascular fibrosis in the skin and multiple organs. Although the term *scleroderma* is ingrained in clinical medicine, this disease is better named *systemic sclerosis* because it is characterized by excessive fibrosis throughout the body. The skin is most commonly affected, but the gastrointestinal tract, kidneys, heart, muscles, and lungs also are frequently involved. In some patients the disease seems to remain confined to the skin for many years, but in the majority it progresses to visceral involvement with death from renal failure, cardiac failure, pulmonary insufficiency, or intestinal malabsorption. The clinical heterogeneity of systemic sclerosis has been recognized by classifying the disease into two major categories: *diffuse scleroderma*, characterized by widespread skin involvement at onset, with rapid progression and early visceral involvement; and *limited scleroderma*, in which the skin involvement is often confined to fingers, forearms, and face. Visceral involvement occurs late; hence, the clinical course is relatively benign. Some patients with the limited disease also develop a combination of calcinosis,

Raynaud phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasia, called the *CREST syndrome*. Several other variants and related conditions, such as eosinophilic fasciitis, occur far less frequently and are not described here.

Etiology and Pathogenesis

The cause of systemic sclerosis is not known, but the **disease likely results from three interrelated processes—autoimmune responses, vascular damage, and collagen deposition** (Fig. 6-30).

- **Autoimmunity.** It is proposed that CD4+ T cells responding to an as yet unidentified antigen accumulate in the skin and release cytokines that activate inflammatory cells and fibroblasts. Although inflammatory infiltrates are typically sparse in the skin of patients with systemic sclerosis, activated CD4+ T cells can be found in many patients, and T_H2 cells have been isolated from the skin. Several cytokines produced by these T cells, including TGF- β and IL-13, can stimulate transcription of genes that encode collagen and other extracellular matrix proteins (e.g., fibronectin) in fibroblasts. Other cytokines recruit leukocytes and propagate the chronic inflammation.

There is also evidence for inappropriate activation of humoral immunity, and the presence of various autoantibodies, notably ANAs, provides diagnostic and prognostic information. The role of these ANAs in the pathogenesis of the disease is unclear; it has been postulated that some of these antibodies may stimulate fibrosis, but the evidence in support of this idea is not convincing.

- **Vascular damage. Microvascular disease is consistently present early in the course of systemic sclerosis and may be the initial lesion.** Intimal proliferation is evident in the digital arteries of patients with systemic sclerosis. Capillary dilation with leaking, as well as destruction, is also common. Nailfold capillary loops are distorted early in the course of disease, and later they disappear. Telltale signs of endothelial activation and

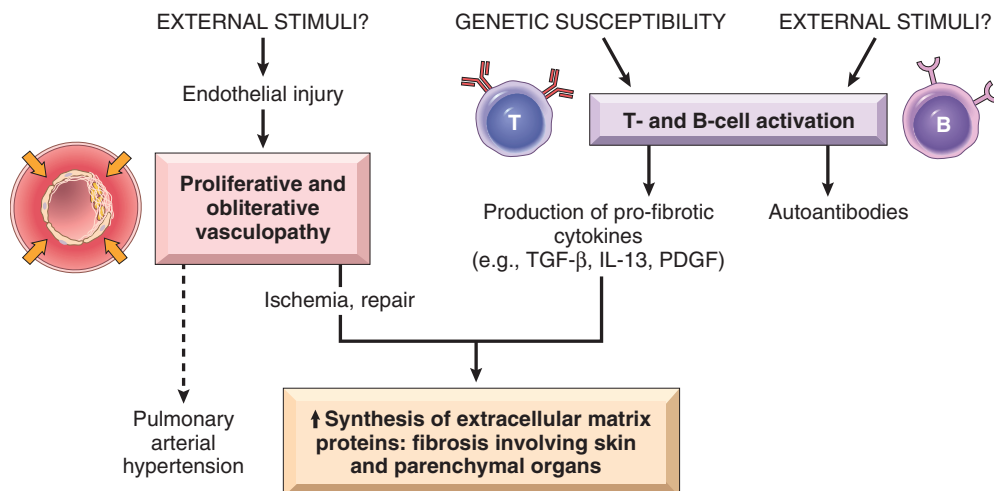

Figure 6-30 A model for the pathogenesis of systemic sclerosis. Unknown external stimuli cause vascular abnormalities and immune activation in genetically susceptible individuals, and both contribute to the excessive fibrosis.

injury (e.g., increased levels of von Willebrand factor) and increased platelet activation (increased percentage of circulating platelet aggregates) have also been noted. However, what causes the vascular injury is not known; it could be the initiating event or the result of chronic inflammation, with mediators released by inflammatory cells inflicting damage on microvascular endothelium. Repeated cycles of endothelial injury followed by platelet aggregation lead to release of platelet and endothelial factors (e.g., PDGF, TGF- β) that trigger perivascular fibrosis. Vascular smooth muscle cells also show abnormalities, such as increased expression of adrenergic receptors. Eventually, widespread narrowing of the microvasculature leads to ischemic injury and scarring.

- **Fibrosis.** The progressive fibrosis characteristic of the disease may be the culmination of multiple abnormalities, including the accumulation of alternatively activated macrophages, actions of fibrogenic cytokines produced by infiltrating leukocytes, hyperresponsiveness of fibroblasts to these cytokines, and scarring following upon ischemic damage caused by the vascular lesions. There is some evidence that fibroblasts from patients with systemic sclerosis have an intrinsic abnormality that causes them to produce excessive amounts of collagen, which is structurally normal. This idea is based on studies with cultured fibroblasts, and whether or how this abnormality relates to pathogenesis *in vivo* is unknown.

MORPHOLOGY

Virtually all organs can be involved in systemic sclerosis. Prominent changes occur in the skin, alimentary tract, musculoskeletal system, and kidney, but lesions also are often present in the blood vessels, heart, lungs, and peripheral nerves.

Skin. A great majority of patients have diffuse, sclerotic atrophy of the skin, which usually begins in the fingers and distal regions of the upper extremities and extends proximally to involve the upper arms, shoulders, neck, and face. Histologically, there are edema and perivascular infiltrates containing CD4+ T cells, together with swelling and degeneration of collagen fibers, which become eosinophilic. Capillaries and small arteries (150 to 500 μm in diameter) may show thickening of the basal lamina, endothelial cell damage, and partial occlusion. With progression of the disease, there is increasing fibrosis of the dermis, which becomes tightly bound to the subcutaneous structures. There is marked increase of compact collagen in the dermis, usually with thinning of the epidermis, loss of rete pegs, atrophy of the dermal appendages, and hyaline thickening of the walls of dermal arterioles and capillaries (Fig. 6-31B). Focal and sometimes diffuse subcutaneous calcifications may develop, especially in patients with the CREST syndrome. In advanced stages the fingers take on a tapered, clawlike appearance with limitation of motion in the joints, and the face becomes a drawn mask. Loss of blood supply may lead to cutaneous ulcerations and to atrophic changes in the terminal phalanges (Fig. 6-31C). Sometimes the tips of the fingers undergo autoamputation.

Alimentary Tract. The alimentary tract is affected in approximately 90% of patients. Progressive atrophy and collagenous fibrous replacement of the muscularis may develop at any level

of the gut but are most severe in the esophagus. The lower two thirds of the esophagus often develops a rubber-hose-like inflexibility. The associated dysfunction of the lower esophageal sphincter gives rise to gastroesophageal reflux and its complications, including Barrett metaplasia (Chapter 17) and strictures. The mucosa is thinned and may be ulcerated, and there is excessive collagenization of the lamina propria and submucosa. Loss of villi and microvilli in the small bowel is the anatomic basis for the malabsorption syndrome sometimes encountered.

Musculoskeletal System. Inflammation of the synovium, associated with hypertrophy and hyperplasia of the synovial soft tissues, is common in the early stages; fibrosis later ensues. These changes are reminiscent of rheumatoid arthritis, but joint destruction is not common in systemic sclerosis. In a small subset of patients (approximately 10%), inflammatory myositis indistinguishable from polymyositis may develop.

Kidneys. Renal abnormalities occur in two-thirds of patients with systemic sclerosis. The most prominent are the vascular lesions. Interlobular arteries show intimal thickening as a result of deposition of mucinous or finely collagenous material, which stains histochemically for glycoprotein and acid mucopolysaccharides. There is also concentric proliferation of intimal cells. These changes may resemble those seen in malignant hypertension, but in scleroderma the alterations are restricted to vessels 150 to 500 μm in diameter and are not always associated with hypertension. Hypertension, however, does occur in 30% of patients with scleroderma, and in 20% it takes an ominously rapid, downhill course (malignant hypertension). In hypertensive patients, vascular alterations are more pronounced and are often associated with fibrinoid necrosis involving the arterioles together with thrombosis and infarction. Such patients often die of renal failure, which accounts for about 50% of deaths in persons with this disease. There are no specific glomerular changes.

Lungs. The lungs are involved in more than 50% of individuals with systemic sclerosis. This involvement may manifest as pulmonary hypertension and interstitial fibrosis. Pulmonary vasospasm, secondary to pulmonary vascular endothelial dysfunction, is considered important in the pathogenesis of pulmonary hypertension. Pulmonary fibrosis, when present, is indistinguishable from that seen in idiopathic pulmonary fibrosis (Chapter 15).

Heart. Pericarditis with effusion, myocardial fibrosis, and thickening of intramyocardial arterioles occur in one third of the patients. Clinical impairment by myocardial involvement, however, is less common.

Clinical Features. Systemic sclerosis has a female-to-male ratio of 3:1, with a peak incidence in the 50- to 60-year age group. Although systemic sclerosis shares many features with SLE, rheumatoid arthritis (Chapter 26), and polymyositis (Chapter 27), its distinctive features are the striking cutaneous changes, notably skin thickening. *Raynaud phenomenon*, manifested as episodic vasoconstriction of the arteries and arterioles of the extremities, is seen in virtually all patients and precedes other symptoms in 70% of cases. *Dysphagia* attributable to esophageal fibrosis and its resultant hypomotility are present in more than 50% of patients. Eventually, destruction of the esophageal wall leads to

Figure 6-31 Systemic sclerosis. **A**, Normal skin. **B**, Skin biopsy from a patient with systemic sclerosis. Note the extensive deposition of dense collagen in the dermis with virtual absence of appendages (e.g., hair follicles) and foci of inflammation (arrow). **C**, The extensive subcutaneous fibrosis has virtually immobilized the fingers, creating a clawlike flexion deformity. Loss of blood supply has led to cutaneous ulcerations. (**C**, Courtesy Dr. Richard Sontheimer, Department of Dermatology, University of Texas Southwestern Medical School, Dallas, Texas.)

atony and dilation, especially at its lower end. Abdominal pain, intestinal obstruction, or malabsorption syndrome with weight loss and anemia reflect involvement of the small intestine. Respiratory difficulties caused by the pulmonary fibrosis may result in right-sided cardiac dysfunction, and myocardial fibrosis may cause either arrhythmias or cardiac failure. Mild proteinuria occurs in as many as 30% of patients, but rarely is the proteinuria severe enough to cause a nephrotic syndrome. The most ominous manifestation is malignant hypertension (Chapter 11), with the subsequent development of fatal renal failure, but in its absence progression of the disease may be slow. The disease tends to be more severe in blacks, especially black women. As treatment of the renal crises has improved, pulmonary disease has become the major cause of death in systemic sclerosis.

Virtually all patients have ANAs that react with a variety of nuclear antigens. Two ANAs strongly associated with systemic sclerosis have been described. One of these, directed against *DNA topoisomerase I* (anti-Scl 70), is highly specific. Depending on the ethnic group and the assay, it is present in 10% to 20% of patients with diffuse systemic

sclerosis. Patients who have this antibody are more likely to have pulmonary fibrosis and peripheral vascular disease. The other, an *anticentromere antibody*, is found in 20% to 30% of patients, who tend to have the CREST syndrome. Patients with this syndrome have relatively limited involvement of skin, often confined to fingers, forearms, and face, and calcification of the subcutaneous tissues. Involvement of the viscera, including esophageal lesions, pulmonary hypertension, and biliary cirrhosis, may not occur at all or occur late. In general these patients live longer than those with systemic sclerosis with diffuse visceral involvement at the outset.

KEY CONCEPTS

Systemic Sclerosis

- Systemic sclerosis (commonly called scleroderma) is characterized by progressive fibrosis involving the skin, gastrointestinal tract, and other tissues.

- Fibrosis may be the result of activation of fibroblasts by cytokines produced by T cells, but what triggers T-cell responses is unknown.
- Endothelial injury and microvascular disease are commonly present in the lesions of systemic sclerosis, perhaps causing chronic ischemia, but the pathogenesis of vascular injury is not known.

Inflammatory Myopathies

Inflammatory myopathies comprise an uncommon, heterogeneous group of disorders characterized by injury and inflammation of mainly the skeletal muscles, which are probably immunologically mediated. Three distinct disorders, *dermatomyositis*, *polymyositis*, and *inclusion-body myositis*, are included in this category. These may occur alone or with other immune-mediated diseases, particularly systemic sclerosis. These diseases are described in [Chapter 27](#).

Mixed Connective Tissue Disease

The term *mixed connective tissue disease* is used to describe a disease with clinical features that are a mixture of the features of SLE, systemic sclerosis, and polymyositis. The disease is characterized serologically by high titers of antibodies to ribonucleoprotein particle-containing U1 ribonucleoprotein. Typically, mixed connective tissue disease presents with synovitis of the fingers, Raynaud phenomenon and mild myositis, but renal involvement is modest and there is a good response to corticosteroids, at least in the short term. Because the clinical features overlap with other diseases, it has been suggested that mixed connective tissue disease is not a distinct entity but that different patients represent subsets of SLE, systemic sclerosis, and polymyositis. The disease can, over time, evolve into classic SLE or systemic sclerosis. However, a subset of patients do not evolve into other diseases and the salutary response to steroids is not universal, suggesting that there may be an entity of mixed connective tissue disease distinct from other autoimmune diseases. Serious complications of mixed connective tissue disease include pulmonary hypertension, interstitial lung disease, and renal disease.

Polyarteritis Nodosa and Other Vasculitides

Polyarteritis nodosa belongs to a group of diseases characterized by necrotizing inflammation of the walls of blood vessels and showing strong evidence of an immunologic pathogenetic mechanism. The general term *noninfectious vasculitis* differentiates these conditions from those due to direct infection of the blood vessel wall (such as occurs in the wall of an abscess) and serves to emphasize that any type of vessel may be involved—arteries, arterioles, veins, or capillaries.

Noninfectious vasculitis is encountered in many clinical settings. A detailed classification and description of vasculitides is presented in [Chapter 11](#), where the immunologic mechanisms are also discussed.

IgG4-Related Disease

IgG4-related disease (IgG4-RD) is a newly recognized constellation of disorders characterized by tissue infiltrates dominated by IgG4 antibody-producing plasma cells and lymphocytes, particularly T cells, storiform fibrosis, obliterative phlebitis, and usually increased serum IgG4. Although recognized only recently when extra-pancreatic manifestations were identified in patients with autoimmune pancreatitis, IgG4-related disease has now been described in virtually every organ system: the biliary tree, salivary glands, periorbital tissues, kidneys, lungs, lymph nodes, meninges, aorta, breast, prostate, thyroid, pericardium, and skin. Many medical conditions long viewed as confined to single organs are part of the IgG4-RD spectrum. These include Mikulicz syndrome (enlargement and fibrosis of salivary and lacrimal glands), Riedel thyroiditis, idiopathic retroperitoneal fibrosis, autoimmune pancreatitis, and inflammatory pseudotumors of the orbit, lungs, and kidneys, to name a few. The disease most often affects middle-aged and older men.

The pathogenesis of this condition is not understood, and although IgG4 production in lesions is a hallmark of the disease it is not known if this antibody type contributes to the pathology. The key role of B cells is supported by initial clinical trials in which depletion of B cells by anti-B cell reagents such as rituximab provided clinical benefit. It is unclear if the disease is truly autoimmune in nature, and no target autoantigens have been identified.

Rejection of Tissue Transplants

Transplant rejection is discussed here because it involves several of the immunologic reactions that underlie immune-mediated inflammatory diseases. A major barrier to transplantation is the process of *rejection*, in which the recipient's immune system recognizes the graft as being foreign and attacks it.

Mechanisms of Recognition and Rejection of Allografts

Rejection is a process in which T lymphocytes and antibodies produced against graft antigens react against and destroy tissue grafts. We next discuss how donor antigens from the graft are recognized by lymphocytes in the recipient and how the lymphocytes and their products destroy the graft.

Recognition of Graft Alloantigens by T and B Lymphocytes

The major antigenic differences between a donor and recipient that result in rejection of transplants are differences in HLA alleles. Grafts exchanged between individuals of the same species (the usual clinical situation) are called *allografts*, and grafts from one species to another (still an experimental procedure) are called *xenografts*. Because HLA genes are highly polymorphic, there are always some differences between individuals (except, of course, identical twins). Following transplantation, the recipient's T cells recognize donor antigens from the graft (the allogeneic

Figure 6-32 Recognition of alloantigens in organ grafts. **A**, In the direct pathway, donor class I and class II MHC antigens on antigen-presenting cells in the graft (along with costimulators, not shown) are recognized by host CD8+ cytotoxic T cells and CD4+ helper T cells, respectively. CD4+ cells proliferate and produce cytokines (e.g., IFN- γ), which induce tissue damage by a local inflammatory reaction. CD8+ T cells responding to graft antigens differentiate into CTLs that kill graft cells. **B**, In the indirect pathway graft antigens are picked up, processed, and displayed by host APCs and activate CD4+ T cells, which damage the graft by an inflammatory reaction and stimulate B lymphocytes to produce antibodies. An example of the reaction to kidney allografts is shown, but the same principles are applicable to all solid organ grafts.

antigens, or alloantigens) by two pathways, called *direct* and *indirect* (Fig. 6-32).

- Direct pathway of allorecognition.** In the direct pathway, T cells of the transplant recipient recognize allogeneic (donor) MHC molecules on the surface of APCs in the graft. It is believed that dendritic cells carried in the donor organs are the most important APCs for initiating the antigraft response, because they not only express high levels of class I and II MHC molecules but also are endowed with costimulatory molecules (e.g., B7-1 and B7-2). The T cells of the host encounter the donor dendritic cells either within the grafted organ or after the dendritic cells migrate to the draining lymph nodes. CD8+ T cells recognize class I MHC molecules and differentiate into active CTLs. CD4+ helper T cells recognize allogeneic class II molecules and proliferate and differentiate into T_{H1} (and possibly T_{H17}) effector cells. The direct recognition of allogeneic MHC molecules seems paradoxical to the rules of self MHC restriction: If T cells normally are

restricted to recognizing foreign peptides displayed by self MHC molecules, why should these T cells recognize foreign MHC? The probable explanation is that allogeneic MHC molecules, with their bound peptides, resemble, or mimic, the self MHC–foreign peptide complexes that are recognized by self MHC–restricted T cells. In other words, recognition of allogeneic MHC molecules is a cross-reaction of T cells selected to recognize self MHC plus foreign peptides.

- Indirect pathway of allorecognition.** In the indirect pathway, recipient T lymphocytes recognize MHC antigens of the graft donor after they are presented by the recipient's own APCs. This process involves the uptake and processing of MHC molecules from the grafted organ by host APCs. The peptides derived from the donor tissue are presented by the host's own MHC molecules, like any other foreign peptide. Thus, the indirect pathway is similar to the physiologic processing and presentation of other foreign (e.g., microbial) antigens. The indirect pathway generates CD4+ T cells that enter

the graft and recognize graft antigens being displayed by host APCs that have also entered the graft, and the result is a delayed hypersensitivity type of inflammatory reaction. However, CD8⁺ CTLs that may be generated by the indirect pathway cannot kill graft cells, because these CTLs recognize graft antigens presented by the host's APCs and cannot recognize the graft cells directly. Therefore, when T cells react to a graft by the indirect pathway, the principal mechanism of cellular rejection may be T-cell cytokine production and inflammation.

The frequency of T cells that can recognize the foreign antigens in a graft is much higher than the frequency of T cells specific for any microbe. For this reason, immune responses to allografts are stronger than responses to pathogens. Predictably, these strong reactions can destroy grafts rapidly, and their control requires powerful immunosuppressive agents.

B lymphocytes also recognize antigens in the graft, including HLA and other antigens that differ between donor and recipient. The activation of these B cells typically requires T cell help.

T Cell–Mediated Reactions

The critical role of T cells in transplant rejection has been documented in humans and in experimental animals. T cells can contribute to both acute and chronic rejection.

- **Acute cellular rejection**, also called *acute T cell–mediated rejection*, is most commonly seen within the initial months after transplantation and is heralded by clinical and biochemical signs of organ failure. It was thought that direct killing of graft cells by CD8⁺ CTLs is a major component of the reaction. However, more recent studies have established that an important component of this process is an inflammatory reaction in the graft triggered by cytokines secreted by activated CD4⁺ T cells. The inflammation results in increased vascular permeability and local accumulation of mononuclear cells (lymphocytes and macrophages), and graft injury is caused by the activated macrophages.
- T cells also contribute to **chronic rejection**, in which lymphocytes reacting against alloantigens in the vessel wall secrete cytokines that induce local inflammation and may stimulate the proliferation of vascular endothelial and smooth muscle cells.

Antibody-Mediated Reactions

Although T cells are pivotal in the rejection of organ transplants, antibodies produced against alloantigens in the graft are also important mediators of rejection. Antibody-mediated reactions can take three forms.

- **Hyperacute rejection occurs when preformed antidonor antibodies are present in the circulation of the recipient.** Such antibodies may be present in a recipient who has previously rejected a transplant. Multiparous women who develop antibodies against paternal HLA antigens shed from the fetus may have preformed antibodies that will react with grafts taken from their husbands or children, or even from unrelated individuals who share HLA alleles with the husbands. Prior

blood transfusions can also lead to presensitization, because platelets and white blood cells are rich in HLA antigens and donors and recipients are usually not HLA-identical. Hyperacute rejection was a concern in the early days of kidney transplantation, but with the current practice of cross-matching, that is, testing recipient's serum for antibodies against donor's cells, it is no longer a significant clinical problem.

- **Acute antibody-mediated rejection** is caused by antidonor antibodies produced after transplantation. In recipients not previously sensitized to transplantation antigens, exposure to the class I and class II HLA antigens of the donor graft, as well as other antigens that differ between donor and recipient, may evoke antibodies. The antibodies formed by the recipient may cause injury by several mechanisms, including complement-dependent cytotoxicity, inflammation, and antibody-dependent cell-mediated cytotoxicity. The initial target of these antibodies in rejection seems to be the graft vasculature.
- **Chronic antibody-mediated rejection** usually develops insidiously, without preceding acute rejection, and primarily affects vascular components. Antibodies are detected in the circulation but are not readily identified within the graft. The mechanisms of the vascular lesions are not well understood.

Rejection of Kidney Grafts

Because kidneys were the first solid organs to be transplanted and more kidneys have been transplanted than any other organ, much of our understanding of the clinical and pathologic aspects of solid-organ transplantation is based on studies of renal allografts.

MORPHOLOGY

On the basis of the morphology and the underlying mechanism, rejection reactions are classified as hyperacute, acute, and chronic. The morphologic changes in these patterns are described later as they relate to renal transplants. Similar changes may occur in any other vascularized organ transplant and are discussed in relevant chapters.

Hyperacute Rejection

This form of rejection occurs within minutes or hours after transplantation. A hyperacutely rejecting kidney rapidly becomes cyanotic, mottled, and flaccid, and may excrete a mere few drops of bloody urine. Immunoglobulin and complement are deposited in the vessel wall, causing endothelial injury and fibrin-platelet thrombi (Fig. 6-33). Neutrophils rapidly accumulate within arterioles, glomeruli, and peritubular capillaries. As these changes become diffuse and intense, the glomeruli undergo thrombotic occlusion of the capillaries, and fibrinoid necrosis occurs in arterial walls. The kidney cortex then undergoes outright necrosis (infarction), and such nonfunctioning kidneys have to be removed.

Acute Rejection

This may occur within days of transplantation in the untreated recipient or may appear suddenly months or even years later, after immunosuppression is tapered or terminated. In any

Figure 6-33 Hyperacute rejection. Hyperacute rejection of a kidney allograft showing platelet and fibrin thrombi, early neutrophil infiltration, and severe ischemic injury in a glomerulus.

one patient, cellular or humoral immune mechanisms may predominate.

- **Acute cellular (T cell-mediated) rejection.** Histologically, acute T cell-mediated rejection may be seen as two patterns.
 - In the **tubulointerstitial pattern** (sometimes called type I), there is extensive interstitial inflammation with infiltration of tubules, referred to as **tubulitis**, associated with focal tubular injury (Fig. 6-34A). As might be expected, immunohistochemical staining reveals both CD4+ and CD8+ T lymphocytes, which express markers of activated T cells, such as the α chain of the IL-2 receptor.
 - The **vascular pattern** shows inflammation of vessels (**endotheliitis**, type II) (Fig. 6-34B), sometimes with necrosis of vascular walls (type III). The affected vessels have swollen endothelial cells, and at places the lymphocytes can be seen between the endothelium and the vessel wall. The recognition of cellular rejection is important because, in the absence of an accompanying humoral rejection, patients respond well to immunosuppressive therapy.
- **Acute antibody-mediated rejection** is manifested mainly by damage to glomeruli and small blood vessels. Typically, the lesions consist of inflammation of glomeruli and peritubular capillaries, associated with deposition of the complement breakdown product C4d, which is produced during activation of the complement system by the antibody-dependent classical pathway (Fig. 6-35). Small vessels may also show focal thrombosis.

Cyclosporine, an immunosuppressive drug, is also nephrotoxic, and hence the histologic changes resulting from cyclosporine therapy (e.g., arteriolar hyaline deposits) may be superimposed.

Chronic Rejection

In recent years acute rejection has been largely controlled by immunosuppressive therapy, and chronic rejection has emerged as an increasingly frequent cause of graft failure. Patients with chronic rejection present clinically with progressive renal failure manifested by a rise in serum creatinine over a period of 4 to 6 months. Chronic rejection is dominated by vascular changes,

which include (1) intimal thickening with inflammation, (2) glomerulopathy, with duplication of the basement membrane, likely secondary to chronic endothelial injury, and (3) peritubular capillaritis with multilayering of peritubular capillary basement membranes (Fig. 6-36). Interstitial fibrosis and tubular atrophy with loss of renal parenchyma may occur secondary to the vascular lesions. Chronically rejecting kidneys usually have interstitial mononuclear cell infiltrates, including NK cells and plasma cells.

Methods of Increasing Graft Survival

The value of HLA matching between donor and recipient varies in different solid-organ transplants. In kidney transplants, there is substantial benefit if all the polymorphic HLA alleles are matched (both inherited alleles of *HLA-A*, *-B*, and *DR*). However, HLA matching is usually not even done for transplants of liver, heart, and lungs, because other considerations, such as anatomic compatibility, severity of the underlying illness, and the need to minimize the time of organ storage, override the potential benefits of HLA matching.

Except for identical twins, who obviously express the same histocompatibility antigens, *immunosuppressive therapy* is a practical necessity in all other donor-recipient

Figure 6-34 Acute T cell-mediated (cellular) rejection of a kidney allograft. **A**, Inflammatory cells in the interstitium and between epithelial cells of the tubules (tubulitis). **B**, Rejection vasculitis, with inflammatory cells attacking and undermining the endothelium (endotheliitis). combinations. Immunosuppressive drugs in current use include steroids (which reduce inflammation), mycophenolate mofetil (which inhibits lymphocyte proliferation), and tacrolimus (FK506). Tacrolimus, like its predecessor cyclosporine, is an inhibitor of the phosphatase calcineurin, which is required for activation of a transcription factor called nuclear factor of activated T cells (NFAT). NFAT stimulates transcription of cytokine genes, in particular, the gene that encodes IL-2. Thus, Tacrolimus inhibits T cell functions. Additional drugs that are used to treat rejection include T cell- and B cell-depleting antibodies, and pooled intravenous IgG (IVIg), which suppresses inflammation by unknown mechanisms. Plasmapheresis is used in cases of severe antibody-mediated rejection. Another, more recent, strategy for reducing antigrraft immune responses

is to prevent host T cells from receiving costimulatory signals from dendritic cells during the initial phase of sensitization. This can be accomplished by interrupting the interaction between the B7 molecules on the dendritic cells of the graft donor with the CD28 receptors on host T cells, for example, by administration of proteins that bind to B7 costimulators.

Although immunosuppression prolongs graft survival, it carries its own risks. The price paid in the form of increased susceptibility to opportunistic infections is not small. One of the most frequent infectious complications is reactivation of *polyoma virus*. The virus establishes latent infection of epithelial cells in the lower genitourinary tract of healthy individuals, and upon immunosuppression, it is reactivated, infects renal tubules, and may even cause graft

Figure 6-36 Chronic rejection of a kidney allograft. **A**, Transplant glomerulopathy, the characteristic manifestation of chronic antibody-mediated rejection. The glomerulus shows inflammatory cells within the capillary loops (glomerulitis), accumulation of mesangial matrix, and duplication of the capillary basement membrane. **B**, Interstitial fibrosis and tubular atrophy. In this trichrome stain, the blue area (asterisk) shows fibrosis, contrasted with the normal kidney on the top right. At the bottom right is an artery showing prominent arteriosclerosis. failure. These patients are also at increased risk for developing EBV-induced lymphomas, human papillomavirus-induced squamous cell carcinomas, and Kaposi sarcoma (Chapter 11), all probably the result of reactivation of latent viral infections because of diminished host defenses. To circumvent the untoward effects of immunosuppression, much effort is being devoted to induce donor-specific tolerance in graft recipients. For instance, giving donor cells to graft recipients may prevent reactions to the graft, perhaps because the donor inoculum contains cells, such as immature dendritic cells, that induce tolerance to the donor antigens. This approach may result in long-term *mixed chimerism*, in which the recipient lives with the injected donor cells. Other strategies being tested include injecting regulatory T cells, and blocking the costimulatory signals that are required for lymphocyte activation, as mentioned above.

Transplantation of Other Solid Organs

In addition to the kidney, a variety of organs, such as the liver (Chapter 18), heart (Chapter 12), lungs, and pancreas, are also transplanted. The rejection reaction against liver transplants is not as vigorous as might be expected from the degree of HLA disparity. The molecular basis of this “privilege” is not understood.

Transplantation of Hematopoietic Stem Cells

Use of hematopoietic stem cell (HSC) transplants for hematologic malignancies, bone marrow failure syndromes (such as aplastic anemia), and disorders caused by inherited HSC defects (such as sickle cell anemia, thalassemia, and immunodeficiency states) is increasing in number each year. Transplantation of genetically “reengineered” hematopoietic stem cells obtained from affected patients may also be useful for somatic cell gene therapy, and is being evaluated in some immunodeficiencies. Historically, HSCs were obtained from the bone marrow, but now they usually are harvested from peripheral blood after they are mobilized from the bone marrow by administration of hematopoietic growth factors, or from the umbilical cord blood of newborn infants, a rich source of HSCs. In most of the conditions in which HSC transplantation is indicated, the recipient is irradiated or treated with high doses of chemotherapy to destroy the immune system (and sometimes, cancer cells) and to “open up” niches in the microenvironment of the marrow that nurture HSCs, thus allowing the transplanted HSCs to engraft. Several features distinguish HSC transplants from solid-organ transplants. Two problems that are unique to HSC transplantation are graft-versus-host disease (GVHD) and immunodeficiency.

GVHD occurs when immunologically competent cells or their precursors are transplanted into immunologically crippled recipients, and the transferred cells recognize alloantigens in the host and attack host tissues. It is seen most commonly in the setting of HSC transplantation but, rarely, may occur following transplantation of solid organs rich in lymphoid cells (e.g., the liver) or transfusion of unirradiated blood. When immune-compromised recipients receive HSC preparations from allogeneic donors, the immunocompetent T cells present in the donor inoculum recognize the recipient’s HLA antigens as foreign and react

against them. To try to minimize GVHD, HSC transplants are done between donor and recipient that are HLA-matched using precise DNA sequencing-based methods for molecular typing of HLA alleles.

- **Acute GVHD** occurs within days to weeks after allogeneic bone marrow transplantation. Although any organ may be affected, the major clinical manifestations result from involvement of the immune system and epithelia of the skin, liver, and intestines. Involvement of skin in GVHD is manifested by a generalized rash that may lead to desquamation in severe cases. Destruction of small bile ducts gives rise to jaundice, and mucosal ulceration of the gut results in bloody diarrhea. Although tissue injury may be severe, the affected tissues are usually not heavily infiltrated by lymphocytes. It is believed that in addition to direct cytotoxicity by CD8+ T cells, considerable damage is inflicted by cytokines released by the sensitized donor T cells.
- **Chronic GVHD** may follow the acute syndrome or may occur insidiously. These patients have extensive cutaneous injury, with destruction of skin appendages and fibrosis of the dermis. The changes may resemble systemic sclerosis (discussed earlier). Chronic liver disease manifested by cholestatic jaundice is also frequent. Damage to the gastrointestinal tract may cause esophageal strictures. The immune system is devastated, with involution of the thymus and depletion of lymphocytes in the lymph nodes. Not surprisingly, the patients experience recurrent and life-threatening infections. Some patients develop manifestations of autoimmunity, postulated to result from the grafted CD4+ helper T cells reacting with host B cells and stimulating these cells, some of which may be capable of producing autoantibodies.

Because GVHD is mediated by T lymphocytes contained in the transplanted donor cells, depletion of donor T cells before transfusion virtually eliminates the disease. This protocol, however, has proved to be a mixed blessing: GVHD is ameliorated, but the recurrence of tumor in leukemic patients as well as the incidence of graft failures and EBV-related B-cell lymphoma increase. It seems that the multifaceted T cells not only mediate GVHD but also are required for engraftment of the transplanted HSCs, suppression of EBV-infected B-cell clones, and control of leukemia cells. The latter *graft-versus-leukemia* effect can be quite dramatic. In fact, deliberate induction of graft-versus-leukemia effect by infusion of allogeneic T cells is used to treat chronic myelogenous leukemia that has relapsed after HSC transplantation.

Immunodeficiency is a frequent complication of HSC transplantation. The immunodeficiency may be a result of prior treatment, myeloablative preparation for the graft, a delay in repopulation of the recipient’s immune system, and attack on the host’s immune cells by grafted lymphocytes. Affected individuals are profoundly immunosuppressed and are easy prey to infections. Although many different types of organisms may infect patients, infection with cytomegalovirus is particularly important. This usually results from activation of previously silent infection. Cytomegalovirus-induced pneumonitis can be a fatal complication.

KEY CONCEPTS

Recognition and Rejection of Transplants (Allografts)

- The rejection response against solid organ transplants is initiated mainly by host T cells that recognize the foreign HLA antigens of the graft, either directly (on APCs in the graft) or indirectly (after uptake and presentation by host APCs).
- Types and mechanisms of rejection of solid organ grafts:
 - Hyperacute rejection. Preformed antidonor antibodies bind to graft endothelium immediately after transplantation, leading to thrombosis, ischemic damage, and rapid graft failure.
 - Acute cellular rejection. T cells destroy graft parenchyma (and vessels) by cytotoxicity and inflammatory reactions.
 - Acute humoral rejection. Antibodies damage graft vasculature.
 - Chronic rejection. Dominated by arteriosclerosis, this type is caused by T-cell activation and antibodies. The T-cells may secrete cytokines that induce proliferation of vascular smooth muscle cells, and the antibodies cause endothelial injury. The vascular lesions and T-cell reactions cause parenchymal fibrosis.
- Treatment of graft rejection relies on immunosuppressive drugs, which inhibit immune responses against the graft.
- Transplantation of hematopoietic stem cells (HSCs) requires careful matching of donor and recipient and is often complicated by graft-vs-host diseases (GVHD) and immune deficiency.

Immunodeficiency Syndromes

Immunodeficiencies can be divided into **primary** (or **congenital**) immunodeficiency disorders, which are genetically determined, and **secondary** (or **acquired**) immunodeficiencies, which may arise as complications of cancers, infections, malnutrition, or side effects of immunosuppression, irradiation, or chemotherapy for cancer and other diseases. Immunodeficiencies are manifested clinically by increased infections, which may be newly acquired or reactivation of latent infections. The primary immunodeficiency syndromes are accidents of nature that provide valuable insights into some of the critical molecules of the human immune system. Here we briefly discuss the more important and best-defined primary immunodeficiencies, to be followed by a more detailed description of acquired immunodeficiency syndrome (AIDS), the most devastating example of secondary immunodeficiency.

Primary Immunodeficiencies

Most primary immunodeficiency diseases are genetically determined and affect the defense mechanisms of innate immunity (phagocytes, NK cells, or complement) or the humoral and/or cellular arms of adaptive immunity (mediated by B and T lymphocytes, respectively). Although these disorders were once thought to be quite rare, some

form of mild genetic immune deficiency is, in fact, present in many individuals. Most primary immunodeficiencies are detected in infancy, between 6 months and 2 years of life, the telltale signs being susceptibility to recurrent infections. Here we present selected examples of immunodeficiencies, beginning with defects in innate immunity and then defects in the maturation and activation of B and T lymphocytes. We conclude with immune defects associated with some systemic diseases.

Defects in Innate Immunity

Inherited defects in the early innate immune response typically affect leukocyte functions or the complement system, and all lead to increased vulnerability to infections (Table 6-12). Some of the defects whose molecular basis is defined are summarized next.

Defects in Leukocyte Function

- **Inherited defects in leukocyte adhesion.** Individuals with *leukocyte adhesion deficiency type 1* have a defect in the biosynthesis of the β_2 chain shared by the LFA-1 and Mac-1 integrins. *Leukocyte adhesion deficiency type 2* is caused by the absence of sialyl-Lewis X, the fucose-containing ligand for E- and P-selectins, as a result of a defect in a fucosyl transferase, the enzyme that attaches fucose moieties to protein backbones. The major clinical problem in both conditions is recurrent bacterial infections due to inadequate granulocyte function.

Table 6-12 Defects in Innate Immunity

Disease	Defect
Defects in Leukocyte Function	
Leukocyte adhesion deficiency 1	Defective leukocyte adhesion because of mutations in β chain of CD11/CD18 integrins
Leukocyte adhesion deficiency 2	Defective leukocyte adhesion because of mutations in fucosyl transferase required for synthesis of sialylated oligosaccharide (receptor for selectins)
Chédiak-Higashi syndrome	Decreased leukocyte functions because of mutations affecting protein involved in lysosomal membrane traffic
Chronic granulomatous disease	Decreased oxidative burst
X-linked	Phagocyte oxidase (membrane component)
Autosomal recessive	Phagocyte oxidase (cytoplasmic components)
Myeloperoxidase deficiency	Decreased microbial killing because of defective MPO- H_2O_2 system
Defects in the Complement System	
C2, C4 deficiency	Defective classical pathway activation, results in reduced resistance to infection and reduced clearance of immune complexes
C3 deficiency	Defects in all complement functions
Deficiency of complement regulatory proteins	Excessive complement activation; clinical syndromes include angioedema, paroxysmal hemoglobinuria, others

The table lists some of the more common inherited immune deficiencies affecting phagocytic leukocytes and the complement system.

Modified in part from Gallin JI: Disorders of phagocytic cells. In Gallin JI, et al (eds): *Inflammation: Basic Principles and Clinical Correlates*, 2nd ed. New York, Raven Press, 1992, pp 860, 861.

- **Inherited defects in phagolysosome function.** One such disorder is *Chédiak-Higashi syndrome*, an autosomal recessive condition characterized by defective fusion of phagosomes and lysosomes, resulting in defective phagocytes function and susceptibility to infections. The main leukocyte abnormalities are neutropenia (decreased numbers of neutrophils), defective degranulation, and delayed microbial killing. Leukocytes contain giant granules, which can be readily seen in peripheral blood smears and are thought to result from aberrant phagolysosome fusion. In addition, there are abnormalities in melanocytes (leading to albinism), cells of the nervous system (associated with nerve defects), and platelets (causing bleeding disorders). The gene associated with this disorder encodes a large cytosolic protein called LYST, which is believed to regulate lysosomal trafficking.
- **Inherited defects in microbicidal activity.** The importance of oxygen-dependent bactericidal mechanisms is shown by the existence of a group of congenital disorders called *chronic granulomatous disease*, which are characterized by defects in bacterial killing and render patients susceptible to recurrent bacterial infection. Chronic granulomatous disease results from inherited defects in the genes encoding components of *phagocyte oxidase*, the phagolysosomal enzyme that generates superoxide (O_2^-). The most common variants are an X-linked defect in one of the membrane-bound components (gp91phox) and autosomal recessive defects in the genes encoding two of the cytoplasmic components (p47phox and p67phox). The name of this disease comes from the macrophage-rich chronic inflammatory reaction that tries to control the infection when the initial neutrophil defense is inadequate. This often leads to collections of activated macrophages that wall off the microbes, forming granulomas.
- **Defects in TLR signaling.** Rare defects have been described in various TLRs. Defects in TLR3, a receptor for viral RNA, result in recurrent herpes simplex encephalitis, and defects in MyD88, the adaptor protein downstream of multiple TLRs, are associated with destructive bacterial pneumonias. It has been a surprise that these inherited abnormalities present with such restricted clinical phenotypes.
- Deficiency of components of the alternative pathway (properdin and factor D) is rare. It is associated with recurrent pyogenic infections.
- The C3 component of complement is required for both the classical and alternative pathways, and hence a deficiency of this protein results in susceptibility to serious and recurrent pyogenic infections. There is also increased incidence of immune complex-mediated glomerulonephritis; in the absence of complement, immune complex-mediated inflammation is presumably caused by Fc receptor-dependent leukocyte activation.
- The terminal components of complement C5, 6, 7, 8, and 9 are required for the assembly of the membrane attack complex involved in the lysis of organisms. With a deficiency of these late-acting components, there is increased susceptibility to recurrent neisserial (gonococcal and meningococcal) infections; *Neisseria* bacteria have thin cell walls and are especially susceptible to the lytic actions of complement. Some patients inherit a defective form of mannose-binding lectin, the plasma protein that initiates the lectin pathway of complement. These individuals also show increased susceptibility to infections.
- A deficiency of C1 inhibitor (C1 INH) gives rise to *hereditary angioedema*. This autosomal dominant disorder is more common than complement deficiency states. The C1 inhibitor's targets are proteases, specifically C1r and C1s of the complement cascade, factor XII of the coagulation pathway, and the kallikrein system. With deficiency of C1 INH, unregulated activation of kallikrein may lead to increased production of vasoactive peptides such as bradykinin. Although the exact nature of the bioactive compound produced in hereditary angioedema is uncertain, these patients have episodes of edema affecting skin and mucosal surfaces such as the larynx and the gastrointestinal tract. This may result in life-threatening asphyxia or nausea, vomiting, and diarrhea after minor trauma or emotional stress. Acute attacks of hereditary angioedema can be treated with C1 inhibitor concentrates prepared from human plasma.
- Deficiencies of other complement regulatory proteins are the cause of paroxysmal nocturnal hemoglobinuria ([Chapter 14](#)) and some cases of hemolytic uremic syndrome ([Chapter 20](#)).

Deficiencies Affecting the Complement System

Hereditary deficiencies have been described for virtually all components of the complement system and several of the regulators. In addition, one disease, paroxysmal nocturnal hemoglobinuria, is marked by an acquired deficiency of complement regulatory factors.

- Deficiency of C2 is the most common complement protein deficiency. A deficiency of C2 or C4, early components of the classical pathway, is associated with increased bacterial or viral infections. However, many patients have no clinical manifestations, presumably because the alternative complement pathway is adequate for the control of most infections. Surprisingly, in some of these patients, as well as in patients with C1q deficiency, the dominant manifestation is SLE-like autoimmune disease, as discussed earlier.

Defects in Adaptive Immunity

Defects in adaptive immunity are often subclassified on the basis of the primary component involved (i.e., B cells or T cells or both). However, these distinctions are not clear-cut; for instance, T-cell defects almost always lead to impaired antibody synthesis, and hence isolated deficiencies of T cells are often indistinguishable clinically from combined deficiencies of T and B cells. These immunodeficiencies result from abnormalities in lymphocyte maturation or activation. With advances in genetic analyses, the mutations responsible for many of these diseases have now been identified ([Fig. 6-37](#)).

Defects in Lymphocyte Maturation

Genetic deficiencies affecting the maturation of T or B lymphocytes present with abnormalities in cell-mediated or humoral immunity that are of varying severity.

Figure 6-37 Primary immune deficiency diseases. Shown are the principal pathways of lymphocyte development and the blocks in these pathways in selected primary immune deficiency diseases. The affected genes are indicated in parentheses for some of the disorders. ADA, Adenosine deaminase; CD40L, CD40 ligand (also known as CD154); CVID, common variable immunodeficiency; SCID, severe combined immunodeficiency.

Severe Combined Immunodeficiency

Severe combined immunodeficiency (SCID) represents a constellation of genetically distinct syndromes, all having in common defects in both humoral and cell-mediated immune responses. Affected infants present with prominent thrush (oral candidiasis), extensive diaper rash, and failure to thrive. Some patients develop a morbilliform rash shortly after birth because maternal T cells are transferred across the placenta and attack the fetus, causing GVHD. Persons with SCID are extremely susceptible to recurrent, severe infections by a wide range of pathogens, including *Candida albicans*, *Pneumocystis jirovecii*, *Pseudomonas*, cytomegalovirus, varicella, and a whole host of bacteria. Without HSC transplantation, death occurs within the first year of life. Despite the common clinical manifestations, the underlying defects are quite varied in different forms of SCID, and in many cases the genetic lesion is not known. Often, the SCID defect resides in the T-cell compartment, with a secondary impairment of humoral immunity.

X-linked SCID. The most common form, accounting for 50% to 60% of cases, is X-linked, and hence SCID is more common in boys than in girls. The genetic defect in the

X-linked form is a **mutation in the common γ -chain (γ c) subunit of cytokine receptors**. This transmembrane protein is a signal-transducing component of the receptors for IL-2, IL-4, IL-7, IL-9, IL-11, IL-15, and IL-21. IL-7 is required for the survival and proliferation of lymphoid progenitors, particularly T-cell precursors. As a result of defective IL-7 receptor signaling, there is a profound defect in the earliest stages of lymphocyte development, especially T-cell development. T-cell numbers are greatly reduced, and although B cells may be normal in number, antibody synthesis is impaired because of lack of T-cell help. IL-15 is important for the maturation and proliferation of NK cells, and because the common γ chain is a component of the receptor for IL-15, these individuals often have a deficiency of NK cells as well.

Autosomal recessive SCID. The remaining forms of SCID are autosomal recessive disorders. The most common cause of autosomal recessive SCID is a **deficiency of the enzyme adenosine deaminase (ADA)**. Although the mechanisms by which ADA deficiency causes SCID are not entirely clear, it has been proposed that deficiency of ADA leads to accumulation of deoxyadenosine and its derivatives (e.g., deoxy-ATP), which are toxic to rapidly dividing

immature lymphocytes, especially those of the T-cell lineage. Hence there may be a greater reduction in the number of T lymphocytes than of B lymphocytes.

Several other less common causes of autosomal recessive SCID have been identified:

- Mutations in recombinase-activating genes (RAG) or other components of the antigen receptor gene recombination machinery prevent the somatic gene rearrangements that are essential for the assembly of T-cell receptor and Ig genes. This blocks the development of T and B cells.
- An intracellular kinase called Jak3 is essential for signal transduction through the common cytokine receptor γ chain (which is mutated in X-linked SCID, as discussed above). Mutations of Jak3 therefore have the same effects as mutations in the γ chain.
- Several mutations have been described in signaling molecules, including kinases associated with the T-cell antigen receptor and components of calcium channels that are required for entry of calcium and activation of many signaling pathways.

The histologic findings in SCID depend on the underlying defect. In the two most common forms (γ c mutation and ADA deficiency), the thymus is small and devoid of lymphoid cells. In X-linked SCID the thymus contains lobules of undifferentiated epithelial cells resembling fetal thymus, whereas in SCID caused by ADA deficiency, remnants of Hassall's corpuscles can be found. In both diseases, other lymphoid tissues are hypoplastic as well, with marked depletion of T-cell areas and in some cases both T-cell and B-cell zones.

Currently, HSC transplantation is the mainstay of treatment, but X-linked SCID is the first human disease in which gene therapy has been successful. For gene therapy a normal γ c gene is expressed using a viral vector in HSCs taken from patients, and the cells are then transplanted back into the patients. The clinical experience is small, but some patients have shown reconstitution of their immune systems for over a year after therapy. Unfortunately, however, about 20% of these patients have developed T-cell lymphoblastic leukemia, highlighting the dangers of this particular approach to gene therapy. The uncontrolled T-cell proliferation may have been triggered by the activation of oncogenes by the integrated virus together with the growth advantage conferred by the introduced γ c gene. Current trials are using new vectors with safety features built in. Patients with ADA deficiency have also been treated with HSC transplantation and, more recently, with administration of the enzyme or gene therapy involving the introduction of a normal ADA gene into T-cell precursors.

X-Linked Agammaglobulinemia (*Bruton Agammaglobulinemia*)

X-linked agammaglobulinemia is characterized by the failure of B-cell precursors (pro-B cells and pre-B cells) to develop into mature B cells. It is one of the more common forms of primary immunodeficiency. During normal B-cell maturation in the bone marrow, the Ig heavy-chain genes are rearranged first, in pre-B cells, and these

are expressed on the cell surface in association with a "surrogate" light chain, where they deliver signals that induce rearrangement of the Ig light-chain genes and further maturation. This need for Ig-initiated signals is a quality control mechanism that ensures that maturation will proceed only if functional Ig proteins are expressed. X-linked agammaglobulinemia is caused by mutations in a cytoplasmic tyrosine kinase, called *Bruton tyrosine kinase* (*Btk*); the gene that encodes it is located on the long arm of the X chromosome at Xq21.22. Btk is a protein tyrosine kinase that is associated with the Ig receptor complex of pre-B and mature B cells and is needed to transduce signals from the receptor. When it is mutated, the pre-B cell receptor cannot deliver signals, and maturation stops at this stage. Because light chains are not produced, the complete antigen receptor molecule (which contains Ig heavy and light chains) cannot be assembled and transported to the cell membrane.

As an X-linked disease, this disorder is seen almost entirely in males, but sporadic cases have been described in females, possibly caused by mutations in some other genes that function in the same pathway. **The disease usually does not become apparent until about 6 months of age, as maternal immunoglobulins are depleted.** In most cases, recurrent bacterial infections of the respiratory tract, such as acute and chronic pharyngitis, sinusitis, otitis media, bronchitis, and pneumonia, call attention to the underlying immune defect. Almost always the causative organisms are *Haemophilus influenzae*, *Streptococcus pneumoniae*, or *Staphylococcus aureus*. These organisms are normally opsonized by antibodies and cleared by phagocytosis. Because antibodies are important for neutralizing infectious viruses that are present in the bloodstream or mucosal secretions or being passed from cell to cell, individuals with this disease are also susceptible to certain viral infections, especially those caused by enteroviruses, such as echovirus, poliovirus, and coxsackievirus. These viruses infect the gastrointestinal tract, and from here they can disseminate to the nervous system via the blood. Thus, immunization with live poliovirus carries the risk of paralytic poliomyelitis, and echovirus can cause fatal encephalitis. For similar reasons, *Giardia lamblia*, an intestinal protozoan that is normally resisted by secreted IgA, causes persistent infections in persons with this disorder. In general, however, most intracellular viral, fungal, and protozoal infections are handled quite well by the intact T cell-mediated immunity.

The classic form of this disease has the following characteristics:

- B cells are absent or markedly decreased in the circulation, and the serum levels of all classes of immunoglobulins are depressed. Pre-B cells, which express the B-lineage marker CD19 but not membrane Ig, are found in normal numbers in the bone marrow.
- Germinal centers of lymph nodes, Peyer's patches, the appendix, and tonsils are underdeveloped.
- Plasma cells are absent throughout the body.
- T cell-mediated reactions are normal.

Autoimmune diseases, such as arthritis and dermatomyositis, occur in as many as 35% of individuals with this disease, which is paradoxical in association with an immune deficiency. It is likely that these autoimmune

disorders are caused by a breakdown of self-tolerance resulting in autoimmunity, but chronic infections associated with the immune deficiency may play a role in inducing the inflammatory reactions. The treatment of X-linked agammaglobulinemia is replacement therapy with immunoglobulins. In the past, most patients succumbed to infection in infancy or early childhood. Prophylactic intravenous Ig therapy allows most individuals to reach adulthood.

DiGeorge Syndrome (Thymic Hypoplasia)

DiGeorge syndrome is a T-cell deficiency that results from failure of development of the third and fourth pharyngeal pouches. The latter give rise to the thymus, the parathyroids, some of the C cells of the thyroid, and the ultimobranchial body. Thus, individuals with this syndrome have a variable loss of T cell-mediated immunity (resulting from hypoplasia or lack of the thymus), tetany (resulting from lack of the parathyroids), and congenital defects of the heart and great vessels. In addition, the appearance of the mouth, ears, and facies may be abnormal. Absence of cell-mediated immunity is caused by low numbers of T lymphocytes in the blood and lymphoid tissues and poor defense against certain fungal and viral infections. The T-cell zones of lymphoid organs—paracortical areas of the lymph nodes and the periarteriolar sheaths of the spleen—are depleted. Ig levels may be normal or reduced, depending on the severity of the T-cell deficiency.

In many cases, DiGeorge syndrome is not a familial disorder. It results from a deletion that maps to chromosome 22q11. This deletion is seen in more than 50% of patients, and DiGeorge syndrome is now considered a component of the *22q11 deletion syndrome*, discussed in [Chapter 5](#). One gene in the deleted region is *TBX1*, which is required for development of the branchial arch and the great vessels. Notably, *TBX1* is involved by loss-of-function mutations in a few cases of DiGeorge syndrome that lack 22q11 deletions, strongly suggesting that its loss contributes to the observed phenotype.

Other Defects in Lymphocyte Maturation

Many other, rare causes of immunodeficiency resulting from defective lymphocyte maturation have been documented. One of these, the *bare lymphocyte syndrome*, is usually caused by mutations in transcription factors that are required for class II MHC gene expression. Lack of expression of class II MHC molecules prevents the development of CD4+ T cells. CD4+ T cells are involved in cellular immunity and provide help to B cells, and hence class II MHC deficiency results in combined immunodeficiency. Other defects are caused by mutations in antigen receptor chains or signaling molecules involved in T- or B-cell maturation.

Defects in Lymphocyte Activation and Function

With our improving understanding of the molecular pathways in lymphocyte activation and function, there has also been an increasing recognition of immune deficiencies caused by mutations affecting various components of these pathways. Some of the mutations cause well-defined syndromes, and others are rare but informative.

Hyper-IgM Syndrome

In this disorder the affected patients make IgM antibodies but are deficient in their ability to produce IgG, IgA, and IgE antibodies. It is now known that the defect in this disease affects the ability of helper T cells to deliver activating signals to B cells and macrophages. As discussed earlier in the chapter, many of the functions of CD4+ helper T cells require the engagement of CD40 on B cells, macrophages and dendritic cells by CD40L (also called CD154) expressed on antigen-activated T cells. This interaction triggers Ig class switching and affinity maturation in B cells, and stimulates the microbicidal functions of macrophages. Approximately 70% of individuals with hyper-IgM syndrome have the X-linked form of the disease, caused by mutations in the gene encoding CD40L located on Xq26. In the remaining patients the disease is inherited in an autosomal recessive pattern. Most of these patients have loss-of-function mutations involving either CD40 or the enzyme called activation-induced cytidine deaminase (AID), a DNA-editing enzyme that is required for Ig class switching and affinity maturation.

The serum of persons with this syndrome contains normal or elevated levels of IgM but no IgA or IgE and extremely low levels of IgG, although the number of B and T cells is normal. Clinically, patients present with recurrent pyogenic infections, because the level of opsonizing IgG antibodies is low. In addition, those with CD40L mutations are also susceptible to pneumonia caused by the intracellular organism *Pneumocystis jiroveci*, because CD40L-mediated macrophage activation, a key reaction of cell-mediated immunity, is also defective. Occasionally, the IgM antibodies react with blood cells, giving rise to autoimmune hemolytic anemia, thrombocytopenia, and neutropenia. In older patients there may be a proliferation of IgM-producing plasma cells that infiltrates the mucosa of the gastrointestinal tract.

Common Variable Immunodeficiency

This relatively frequent but poorly defined entity encompasses a heterogeneous group of disorders in which the common feature is hypogammaglobulinemia, generally affecting all the antibody classes but sometimes only IgG. The diagnosis of common variable immunodeficiency is based on exclusion of other well-defined causes of decreased antibody production.

Both sporadic and inherited forms of the disease occur. In familial forms there is no single pattern of inheritance. Relatives of such patients have a high incidence of selective IgA deficiency (see later). These studies suggest that at least in some cases, selective IgA deficiency and common variable immunodeficiency may represent different expressions of a common genetic defect in antibody synthesis. In contrast to X-linked agammaglobulinemia, most individuals with common variable immunodeficiency have normal or near-normal numbers of B cells in the blood and lymphoid tissues. These B cells, however, are not able to differentiate into plasma cells.

Both intrinsic B-cell defects and abnormalities in helper T cell-mediated activation of B cells may account for the antibody deficiency in this disease. Families have been reported in which the underlying abnormality is in a receptor for a cytokine called BAFF that promotes the survival and differentiation of B cells, or in a molecule called ICOS

(inducible costimulator) that is homologous to CD28 and is involved in T-cell activation and in interactions between T and B cells. However, the known mutations account for a minority of cases.

The clinical manifestations of common variable immunodeficiency are caused by antibody deficiency, and hence they resemble those of X-linked agammaglobulinemia. The patients typically present with recurrent sinopulmonary pyogenic infections. In addition, about 20% of patients have recurrent herpesvirus infections. Serious enterovirus infections causing meningoencephalitis may also occur. Individuals with this disorder are also prone to the development of persistent diarrhea caused by *G. lamblia*. In contrast to X-linked agammaglobulinemia, common variable immunodeficiency affects both sexes equally, and the onset of symptoms is later, in childhood or adolescence. Histologically the B-cell areas of the lymphoid tissues (i.e., lymphoid follicles in nodes, spleen, and gut) are hyperplastic. The enlargement of B-cell areas may reflect incomplete activation, such that B cells can proliferate in response to antigen but do not produce antibodies.

As in X-linked agammaglobulinemia, these patients have a high frequency of autoimmune diseases (approximately 20%), including rheumatoid arthritis. The risk of lymphoid malignancy is also increased, and an increase in gastric cancer has been reported.

Isolated IgA Deficiency

Isolated IgA deficiency is a common immunodeficiency. In the United States it occurs in about 1 in 600 individuals of European descent. It is far less common in blacks and Asians. Affected individuals have extremely **low levels of both serum and secretory IgA**. It may be familial, or acquired in association with toxoplasmosis, measles, or some other viral infection. The association of IgA deficiency with common variable immunodeficiency was mentioned earlier. Most individuals with this disease are asymptomatic. Because IgA is the major antibody in external secretions, mucosal defenses are weakened, and infections occur in the respiratory, gastrointestinal, and urogenital tracts. Symptomatic patients commonly present with recurrent sinopulmonary infections and diarrhea. Some individuals with IgA deficiency are also deficient in the IgG2 and IgG4 subclasses of IgG. This group of patients is particularly prone to developing infections. In addition, IgA-deficient patients have a high frequency of respiratory tract allergy and a variety of autoimmune diseases, particularly SLE and rheumatoid arthritis. The basis of the increased frequency of autoimmune and allergic diseases is not known. When transfused with blood containing normal IgA, some of these patients develop severe, even fatal, anaphylactic reactions, because the IgA behaves like a foreign antigen (since the patients do not produce it and are not tolerant to it).

The defect in IgA deficiency is impaired differentiation of naive B lymphocytes to IgA-producing plasma cells. The molecular basis of this defect in most patients is unknown. Defects in a receptor for the B cell-activating cytokine, BAFF, have been described in some patients.

X-Linked Lymphoproliferative Syndrome

X-linked lymphoproliferative disease is characterized by an inability to eliminate Epstein-Barr virus (EBV),

eventually leading to fulminant infectious mononucleosis and the development of B-cell tumors. In about 80% of cases, the disease is due to mutations in the gene encoding an adaptor molecule called *SLAM-associated protein (SAP)* that binds to a family of cell surface molecules involved in the activation of NK cells and T and B lymphocytes, including the signaling lymphocyte activation molecule (SLAM). Defects in SAP contribute to attenuated NK and T cell activation and result in increased susceptibility to viral infections. SAP is also required for the development of follicular helper T cells, and because of this defect XLP patients are unable to form germinal centers or produce high affinity antibodies, additional abnormalities that also likely contribute to susceptibility to viral infection. This immunodeficiency is most commonly manifested by severe EBV infection, including severe and sometimes fatal infectious mononucleosis (Chapter 8), but not other viral infections, for reasons that are not clear.

Other Defects in Lymphocyte Activation

Many rare cases of lymphocyte activation defects have been described, affecting antigen receptor signaling and various biochemical pathways. Defects in T_H1 responses are associated with atypical mycobacterial infections and defective T_H17 responses are the cause of chronic mucocutaneous candidiasis as well as bacterial infections of the skin (a disorder called *Job syndrome*).

Immunodeficiencies Associated with Systemic Diseases

In some inherited systemic disorders, immune deficiency is a prominent clinical problem. Two representative examples of such diseases are described next.

Wiskott-Aldrich Syndrome

Wiskott-Aldrich syndrome is an X-linked disease characterized by thrombocytopenia, eczema, and a marked vulnerability to recurrent infection, resulting in early death.

The thymus is morphologically normal, at least early in the course of the disease, but there is progressive loss of T lymphocytes in the peripheral blood and in the T-cell zones (paracortical areas) of the lymph nodes, with variable defects in cellular immunity. Patients do not make antibodies to polysaccharide antigens, and the response to protein antigens is poor. IgM levels in the serum are low, but levels of IgG are usually normal. Paradoxically the levels of IgA and IgE are often elevated. Patients are also prone to developing B-cell lymphomas. The Wiskott-Aldrich syndrome is caused by mutations in the gene encoding *Wiskott-Aldrich syndrome protein (WASP)*, which is located at Xp11.23. WASP belongs to a family of proteins that are believed to link membrane receptors, such as antigen receptors, to cytoskeletal elements. The WASP protein may be involved in cytoskeleton-dependent responses, including cell migration and signal transduction, but the essential functions of this protein in lymphocytes and platelets are unclear. The only treatment is HSC transplantation.

Ataxia Telangiectasia

Ataxia telangiectasia is an autosomal-recessive disorder characterized by abnormal gait (ataxia), vascular malformations (telangiectases), neurologic deficits, increased

incidence of tumors, and immunodeficiency. The immunologic defects are of variable severity and may affect both B and T cells. The most prominent humoral immune abnormalities are defective production of isotype switched antibodies, mainly IgA and IgG2. The T cell defects, which are usually less pronounced, are associated with thymic hypoplasia. Patients experience upper and lower respiratory tract bacterial infections, multiple autoimmune phenomena, and increasingly frequent cancers with advancing age. The gene responsible for this disorder is located on chromosome 11 and encodes a protein called *ATM* (ataxia telangiectasia mutated) that is related structurally to phosphatidylinositol-3 (PI-3) kinase, but is a protein kinase. The ATM protein is a sensor of DNA damage (double-strand breaks) and it activates p53 by phosphorylation, which in turn can activate cell cycle checkpoints and apoptosis in cells with damaged DNA. ATM has also been shown to contribute to the stability of DNA double-strand break complexes during V(D)J recombination. Because of these abnormalities in DNA repair, the generation of antigen receptors may be abnormal. In addition, defective DNA repair may lead to abnormalities in the DNA recombination events that are involved in antibody isotype switching.

KEY CONCEPTS

Primary (Inherited) Immune Deficiency Diseases

- These diseases are caused by inherited mutations in genes involved in lymphocyte maturation or function, or in innate immunity.
- Deficiencies in innate immunity include defects of phagocyte function, complement, and innate immune receptors.
- Some of the common disorders affecting lymphocytes and the adaptive immune response are:
 - X-SCID: failure of T-cell and B-cell maturation; mutation in the common γ chain of a cytokine receptor, leading to failure of IL-7 signaling and defective lymphopoiesis
 - Autosomal recessive SCID: failure of T-cell development, secondary defect in antibody responses; approximately 50% of cases caused by mutation in the gene encoding ADA, leading to accumulation of toxic metabolites during lymphocyte maturation and proliferation
 - X-linked agammaglobulinemia (XLA): failure of B-cell maturation, absence of antibodies; caused by mutations in the *BTK* gene, which encodes B-cell tyrosine kinase, required for maturation signals from the pre-B cell and B-cell receptors
 - Common variable immunodeficiency: defects in antibody production; cause unknown in most cases
 - Selective IgA deficiency: failure of IgA production; cause unknown
 - X-linked hyper-IgM syndrome: failure to produce isotype-switched high-affinity antibodies (IgG, IgA, IgE); mutation in gene encoding CD40L
 - X-linked lymphoproliferative disease (XLP): defect in a signaling molecule causing defective responses against Epstein-Barr virus and lymphoproliferation
- These diseases present clinically with increased susceptibility to infections in early life.

Table 6-13 Causes of Secondary (Acquired) Immunodeficiencies

Cause	Mechanism
Human immunodeficiency virus infection	Depletion of CD4+ helper T cells
Irradiation and chemotherapy treatments for cancer	Decreased bone marrow precursors for all leukocytes
Involvement of bone marrow by cancers (metastases, leukemias)	Reduced site of leukocyte development
Protein-calorie malnutrition	Metabolic derangements inhibit lymphocyte maturation and function
Removal of spleen	Decreased phagocytosis of microbes

Secondary Immunodeficiencies

Secondary (acquired) immune deficiencies may be encountered in individuals with cancer, diabetes and other metabolic diseases, malnutrition, chronic infection, and in persons receiving chemotherapy or radiation therapy for cancer, or immunosuppressive drugs to prevent graft rejection or to treat autoimmune diseases (Table 6-13). As a group, the secondary immune deficiencies are more common than the disorders of primary genetic origin. Some of these secondary immunodeficiency states can be caused by defective lymphocyte maturation (when the bone marrow is damaged by radiation or chemotherapy or involved by tumors, such as leukemias and metastatic cancers), inadequate Ig synthesis (as in malnutrition), or lymphocyte depletion (from drugs or severe infections). The most common secondary immunodeficiency is AIDS, which is described in the next section.

Acquired Immunodeficiency Syndrome (AIDS)

AIDS is a disease caused by the retrovirus human immunodeficiency virus (HIV) and characterized by profound immunosuppression that leads to opportunistic infections, secondary neoplasms, and neurologic manifestations. The magnitude of this modern plague is truly staggering. By the end of 2009 (the last year for which complete US statistics are available), more than a million cases of AIDS had been reported in the United States, where AIDS is the second leading cause of death in men between ages 25 and 44, and the third leading cause of death in women in this age group. Although initially recognized in the United States, AIDS is a global problem. It has now been reported from more than 190 countries around the world, and the pool of HIV-infected persons in Africa and Asia is large and expanding. By the year 2011, HIV had infected 60 million people worldwide, and nearly 30 million adults and children have died of the disease. There are about 34 million people living with HIV, of whom 70% are in Africa and more than 20% in Asia; the prevalence rate of infection in adults in sub-Saharan Africa is more than 8%. It is estimated that 2.5 million people were newly infected with HIV in 2011 and 1.7 million deaths were caused by AIDS. In this dismal scenario, there may be some good news. Because of public health measures, the infection rate seems to be decreasing, and some authorities believe it may have peaked in the late 1990s. Furthermore, improved antiviral therapies have resulted in fewer people dying of the disease. However, these newer treatments are

not readily available in many developing countries, and toxic side effects remain problems. The advent of these drugs raises its own tragic concern; because more people are living with HIV, the risk of spreading the infection will increase if vigilance is relaxed.

The enormous medical and social burden of AIDS has led to an explosion of research aimed at understanding HIV and its remarkable ability to cripple host defenses. The literature on HIV and AIDS is vast. Here we summarize the currently available data on the epidemiology, pathogenesis, and clinical features of HIV infection.

Epidemiology

Epidemiologic studies in the United States have identified five groups of adults at high risk for developing AIDS. The case distribution in these groups is as follows:

- **Homosexual or bisexual men** constitute the largest group, accounting for more than 50% of the reported cases. This includes about 5% who were intravenous drug abusers as well. Transmission of HIV in this category appears to be on the decline: in 2009 about 60% of new cases were attributed to male homosexual contacts.
- **Intravenous drug abusers** with no previous history of homosexuality are the next largest group, representing about 20% of infected individuals and 9% of new cases in 2009.
- **Hemophiliacs**, especially those who received large amounts of factor VIII or factor IX concentrates before 1985, make up about 0.5% of all cases.
- **Recipients of blood and blood components** who are not hemophiliacs but who received transfusions of HIV-infected whole blood or components (e.g., platelets, plasma) account for about 1% of patients. (Organs obtained from HIV-infected donors can also transmit the virus.)
- **Heterosexual contacts** of members of other high-risk groups (chiefly intravenous drug abusers) constitute about 20% of the patient population. About 30% of new cases in 2009 were attributable to heterosexual contact. Heterosexual transmission, although initially of less numerical importance in the United States, is globally the most common mode by which HIV is spread. In the past few years, even in the United States, the rate of increase of heterosexual transmission has outpaced transmission by other means. In sub-Saharan Africa, where the infection rate is estimated to be about 10,000 new cases every day, more than half the infected individuals are women. Spread of the virus is occurring most rapidly in female sex partners of male intravenous drug abusers. As a result, the number of women with AIDS is rising rapidly. In contrast to the experience in the United States, heterosexual transmission has always been the dominant mode of HIV infection in Asia and Africa.
- **HIV infection of the newborn.** The epidemiology of AIDS is quite different in children younger than 13 years. Close to 2% of all AIDS cases occur in this pediatric population, and worldwide more than 500,000 new cases and almost 400,000 deaths were reported in children in 2006. In this group, the vast majority acquired the infection by transmission of the virus from mother to child (discussed later).
- In approximately 5% of cases, the risk factors cannot be determined.

It should be apparent from the preceding discussion that transmission of HIV occurs under conditions that facilitate exchange of blood or body fluids containing the virus or virus-infected cells. **The three major routes of transmission are sexual contact, parenteral inoculation, and passage of the virus from infected mothers to their newborns.**

- **Sexual transmission** is clearly the dominant mode of infection worldwide, accounting for more than 75% of all cases of HIV transmission. Because the majority of infected people in the United States are men who have sex with men, most sexual transmission has occurred among homosexual men. The virus is carried in the semen, and it enters the recipient's body through abrasions in rectal or oral mucosa or by direct contact with mucosal lining cells. Viral transmission occurs in two ways: (1) direct inoculation into the blood vessels breached by trauma and (2) infection of dendritic cells or CD4+ cells within the mucosa. In addition to male-to-male and male-to-female transmission, there is evidence supporting female-to-male transmission.

Sexual transmission of HIV is enhanced by coexisting sexually transmitted diseases, especially those associated with genital ulceration. In this regard, syphilis, chancroid, and herpes are particularly important. Other sexually transmitted diseases, including gonorrhea and chlamydia, are also cofactors for HIV transmission, perhaps because in these genital inflammatory states there is greater concentration of the virus and virus-containing cells in genital fluids, as a result of increased numbers of inflammatory cells in the semen.

- **Parenteral transmission** of HIV has occurred in three groups of individuals: intravenous drug abusers, hemophiliacs who received factor VIII and factor IX concentrates, and random recipients of blood transfusion. Of these three, intravenous drug users constitute by far the largest group. Transmission occurs by sharing of needles, syringes, and other paraphernalia contaminated with HIV-containing blood.

Transmission of HIV by transfusion of blood or blood products, such as lyophilized factor VIII and factor IX concentrates, has been virtually eliminated. This fortunate outcome resulted from increasing use of recombinant clotting factors and from three public health measures: screening of donated blood and plasma for antibody to HIV, stringent purity criteria for factor VIII and factor IX preparations, and screening of donors on the basis of history. However, an extremely small risk of acquiring AIDS through transfusion of seronegative blood persists, because a recently infected individual may be antibody-negative. Currently, this risk is estimated to be 1 in more than 2 million units of blood transfused.

- As alluded to earlier, **mother-to-infant transmission** is the major cause of pediatric AIDS. Infected mothers can transmit the infection to their offspring by three routes: (1) in utero by transplacental spread, (2) during delivery through an infected birth canal, and (3) after birth by ingestion of breast milk. Of these, transmission during

birth (intrapartum) and in the immediate period thereafter (peripartum) is considered to be the most common mode in the United States. The reported transmission rates vary from 7% to 49% in different parts of the world. Higher risk of transmission is associated with high maternal viral load and low CD4+ T-cell counts as well as chorioamnionitis. Fortunately, antiretroviral therapy given to infected pregnant women in the United States has virtually eliminated mother-to-child transmission, but it remains a major source of infection in areas where these treatments are not readily available.

Much concern has arisen in the lay public and among health care workers about spread of HIV infection outside the high-risk groups. Extensive studies indicate that HIV infection cannot be transmitted by casual personal contact in the household, workplace, or school. Spread by insect bites is virtually impossible. Regarding transmission of HIV infection to health care workers, an extremely small but definite risk seems to be present. Seroconversion has been documented after accidental needle-stick injury or exposure of nonintact skin to infected blood in laboratory accidents. After needle-stick accidents, the risk of seroconversion is believed to be about 0.3%, and antiretroviral therapy given within 24 to 48 hours of a needle stick can reduce the risk of infection eightfold. By comparison, approximately 30% of those accidentally exposed to hepatitis B-infected blood become seropositive.

Etiology: The Properties of HIV

HIV is a nontransforming human retrovirus belonging to the lentivirus family. Included in this group are feline immunodeficiency virus, simian immunodeficiency virus, visna virus of sheep, bovine immunodeficiency virus, and the equine infectious anemia virus.

Two genetically different but related forms of HIV, called *HIV-1* and *HIV-2*, have been isolated from patients with AIDS. HIV-1 is the most common type associated with AIDS in the United States, Europe, and Central Africa, whereas HIV-2 causes a similar disease principally in West Africa and India. Specific tests for HIV-2 are available, and blood collected for transfusion is routinely screened for both HIV-1 and HIV-2 seropositivity. The ensuing discussion relates primarily to HIV-1 and diseases caused by it, but the information is generally applicable to HIV-2 as well.

Structure of HIV

Similar to most retroviruses, the HIV-1 virion is spherical and contains an electron-dense, cone-shaped core surrounded by a lipid envelope derived from the host cell membrane (Fig. 6-38). **The virus core contains (1) the major capsid protein p24; (2) nucleocapsid protein p7/p9; (3) two copies of viral genomic RNA; and (4) the three viral enzymes (protease, reverse transcriptase, and integrase).** p24 is the most abundant viral antigen and is detected by an enzyme-linked immunoabsorbent assay that is widely used to diagnose HIV infection. The viral core is surrounded by a matrix protein called p17, which lies underneath the virion envelope. Studding the viral envelope are two viral glycoproteins, gp120 and gp41, which are critical for HIV infection of cells.

The HIV-1 RNA genome contains the *gag*, *pol*, and *env* genes, which are typical of retroviruses (Fig. 6-39). The

Figure 6-38 The structure of the human immune deficiency virus (HIV)-1 virion. The viral particle is covered by a lipid bilayer derived from the host cell and studded with viral glycoproteins gp41 and gp120.

products of the *gag* and *pol* genes are large precursor proteins that are cleaved by the viral protease to yield the mature proteins. In addition to these three standard retroviral genes, HIV contains several other accessory genes, including *tat*, *rev*, *vif*, *nef*, *vpr*, and *vpu*, which regulate the synthesis and assembly of infectious viral particles and the pathogenicity of the virus. For example, the product of the *tat* (transactivator) gene causes a 1000-fold increase in the transcription of viral genes and is critical for virus replication. The functions of other accessory proteins are indicated in Figure 6-39.

Molecular analysis of different HIV-1 isolates has revealed considerable variability in certain parts of the viral genome. Most variations are clustered in particular regions of the envelope glycoproteins. Because the humoral immune response against HIV-1 is targeted against its envelope, such variability poses problems for the development of a single antigen vaccine. On the basis of genetic analysis, HIV-1 can be divided into three subgroups, designated *M* (major), *O* (outlier), and *N* (neither *M* nor *O*). Group *M* viruses are the most common form worldwide, and they are further divided into several subtypes, or clades, designated A through K. Various subtypes differ in their geographic distribution; for example, subtype B is the most common form in western Europe and the United States, whereas subtype E is the most common clade in Thailand. Currently, clade C is the fastest spreading clade worldwide, being present in India, Ethiopia, and Southern Africa.

Pathogenesis of HIV Infection and AIDS

While HIV can infect many tissues, **the two major targets of HIV infection are the immune system and the central nervous system.** The effects of HIV infection on each of these two systems are discussed separately.

Profound immune deficiency, primarily affecting cell-mediated immunity, is the hallmark of AIDS. This results chiefly from infection and subsequent loss of CD4+ T cells

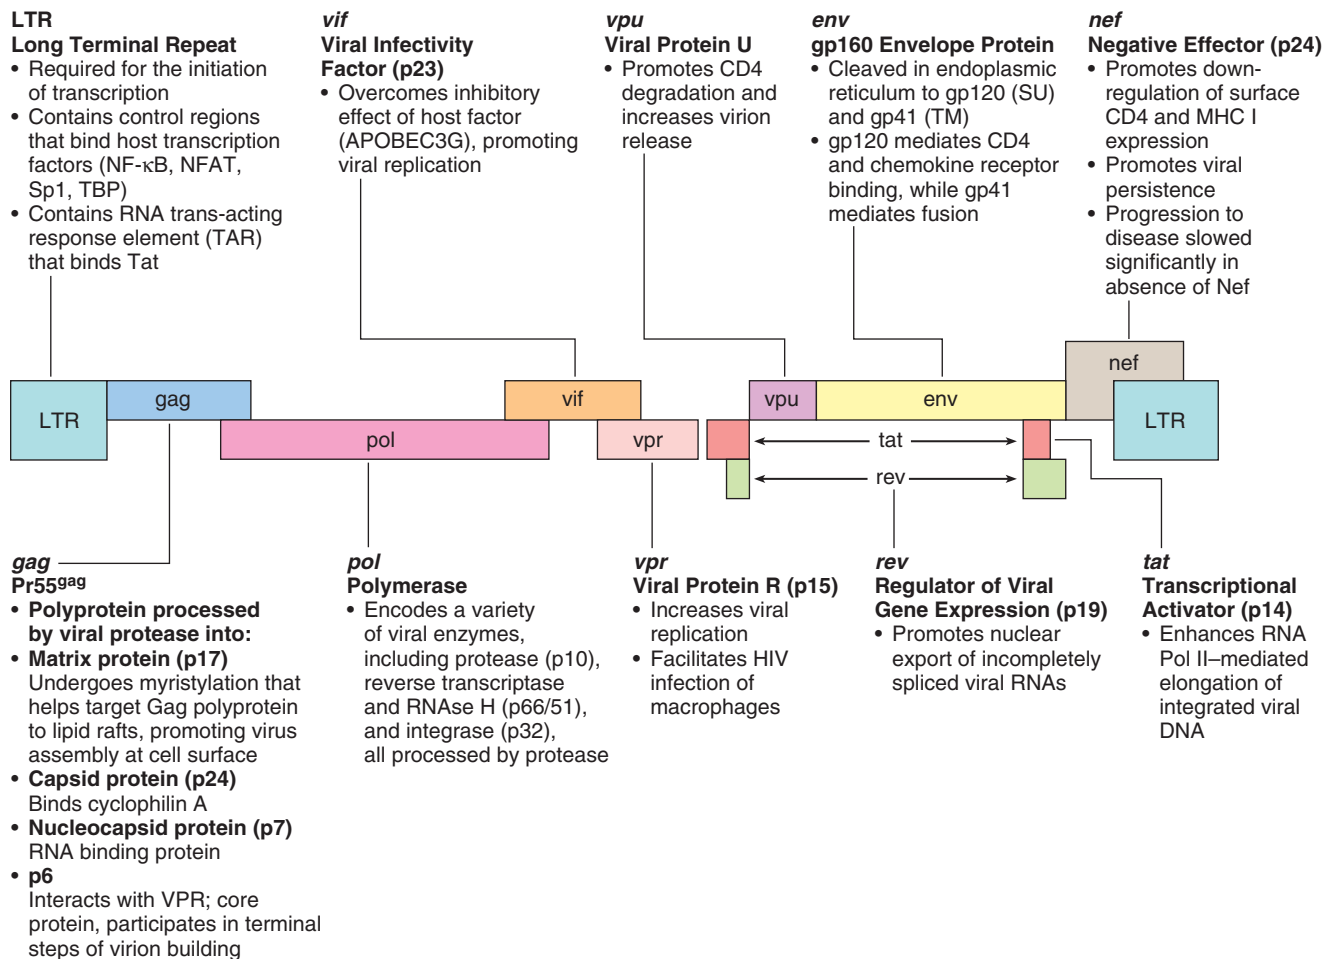

Figure 6-39 The HIV genome. Several viral genes and the functions of the encoded proteins are illustrated. The genes outlined in red are unique to HIV; others are shared by all retroviruses.

as well as impairment in the function of surviving helper T cells. As discussed later, macrophages and dendritic cells are also targets of HIV infection. HIV enters the body through mucosal tissues and blood and first infects T cells as well as dendritic cells and macrophages. The infection becomes established in lymphoid tissues, where the virus may remain latent for long periods. Active viral replication is associated with more infection of cells and progression to AIDS. We first describe the mechanisms involved in viral entry into T cells and macrophages and the replicative cycle of the virus within cells. This is followed by a more detailed review of the interaction between HIV and its cellular targets.

Life Cycle of HIV

The life cycle of HIV consists of infection of cells, integration of the provirus into the host cell genome, activation of viral replication, and production and release of infectious virus (Fig. 6-40). The molecules and mechanisms of each of these steps are understood in considerable detail.

Infection of Cells by HIV

HIV infects cells by using the CD4 molecule as receptor and various chemokine receptors as coreceptors (Fig. 6-40). The requirement for CD4 binding explains the selective tropism of the virus for CD4⁺ T cells and other CD4⁺

cells, particularly monocytes/macrophages and dendritic cells. Binding to CD4 is not sufficient for infection, however. HIV gp120 must also bind to other cell surface molecules (coreceptors) for entry into the cell. Chemokine receptors, particularly CCR5 and CXCR4, serve this role. HIV isolates can be distinguished by their use of these receptors: R5 strains use CCR5, X4 strains use CXCR4, and some strains (R5X4) are dual-tropic. R5 strains preferentially infect cells of the monocyte/macrophage lineage and are thus referred to as M-tropic, whereas X4 strains are T-tropic, preferentially infecting T cells. In approximately 90% of cases, the R5 (M-tropic) type of HIV is the dominant virus found in the blood of acutely infected individuals and early in the course of infection. Over the course of infection, however, T-tropic viruses gradually accumulate; these are especially virulent because T-tropic viruses are capable of infecting many T cells and even thymic T-cell precursors and cause greater T-cell depletion and impairment.

Molecular details of the deadly handshake between HIV glycoproteins and their cell surface receptors have been elucidated and are important to understand because they may provide the basis of anti-HIV therapy. The HIV envelope contains two glycoproteins, surface gp120 noncovalently attached to a transmembrane protein, gp41. **The initial step in infection is the binding of the gp120 envelope glycoprotein to CD4 molecules, which leads to**

Figure 6-40 The life cycle of HIV showing the steps from viral entry to production of infectious virions. (Adapted with permission from Wain-Hobson S: HIV. One on one meets two. Nature 1996;384:117. Copyright 1996, Macmillan Magazines Limited.)

a conformational change that results in the formation of a new recognition site on gp120 for the coreceptors CCR5 or CXCR4. Binding to the coreceptors induces conformational changes in gp41 that result in the exposure of a hydrophobic region called the fusion peptide at the tip of gp41. This peptide inserts into the cell membrane of the target cells (e.g., T cells or macrophages), leading to fusion of the virus with the host cell. After fusion the virus core containing the HIV genome enters the cytoplasm of the cell. The requirement for HIV binding to coreceptors may have important implications for the pathogenesis of AIDS. Chemokines sterically hinder HIV infection of cells in culture by occupying their receptors, and therefore, the level of chemokines in the tissues may influence the efficiency of viral infection *in vivo*. Also, polymorphisms in the gene encoding CCR5 are associated with different susceptibility to HIV infection. About 1% of white Americans inherit two defective copies of the CCR5 gene and are resistant to infection and the development of AIDS associated with R5 HIV isolates. About 20% of individuals

are heterozygous for this protective CCR5 allele; these persons are not protected from AIDS, but the onset of their disease after infection is somewhat delayed. Only rare homozygotes for the mutation have been found in African or East Asian populations.

Viral Replication

Once internalized, the RNA genome of the virus undergoes reverse transcription, leading to the synthesis of double-stranded complementary DNA (cDNA; proviral DNA) (Fig. 6-40). In quiescent T cells, HIV cDNA may remain in the cytoplasm in a linear episomal form. In dividing T cells, the cDNA circularizes, enters the nucleus, and is then integrated into the host genome. After this integration, the provirus may be silent for months or years, a form of latent infection. Alternatively, proviral DNA may be transcribed, with the formation of complete viral particles that bud from the cell membrane. Such productive infection, when associated with extensive viral budding, leads to death of infected cells.

HIV infects memory and activated T cells but is inefficient at productively infecting naive (unactivated) T cells. Naive T cells contain an active form of an enzyme that introduces mutations in the HIV genome. This enzyme has been given the rather cumbersome name APOBEC3G (for apolipoprotein B mRNA-editing, enzyme-catalytic, polypeptide-like 3G). It is a cytidine deaminase that introduces cytosine-to-uracil mutations in the viral DNA that is produced by reverse transcription. These mutations inhibit further DNA replication by mechanisms that are not fully defined. Activation of T cells converts cellular APOBEC3G into an inactive, high-molecular-mass complex, which explains why the virus can replicate in previously activated (e.g., memory) T cells and T-cell lines. HIV has also evolved to counteract this cellular defense mechanism; the viral protein Vif binds to APOBEC3G and promotes its degradation by cellular proteases.

Completion of the viral life cycle in latently infected cells occurs only after cell activation, and in the case of most CD4+ T cells virus activation results in cell lysis. Activation of T cells by antigens or cytokines upregulates several transcription factors, including NF- κ B, which stimulate transcription of genes encoding cytokines such as IL-2 and its receptor. In resting T cells, NF- κ B is held inactive in the cytoplasm in a complex with the I κ B (inhibitor of κ B) protein. Stimulation of cells by antigen or cytokines activates cytoplasmic kinases that phosphorylate I κ B and target it for enzymatic degradation, thus releasing NF- κ B and allowing it to translocate to the nucleus. In the nucleus, NF- κ B binds to sequences within the promoter regions of several genes, including those of cytokines that are expressed in activated T cells. The long-terminal-repeat sequences that flank the HIV genome also contain NF- κ B-binding sites that can be triggered by the same transcription factors. Imagine now a latently infected CD4+ cell that encounters an environmental antigen. Induction of NF- κ B in such a cell (a physiologic response) activates the transcription of HIV proviral DNA (a pathologic outcome) and leads ultimately to the production of virions and to cell lysis. Furthermore, TNF and other cytokines produced by activated macrophages also stimulate NF- κ B activity and thus lead to production of HIV RNA. Thus, it seems that HIV thrives when the host T cells and macrophages are physiologically activated, an act that can be best described as “subversion from within.” Such activation *in vivo* may result from antigenic stimulation by HIV itself or by other infecting microorganisms. HIV-infected people are at increased risk for recurrent exposure to other infections, which lead to increased lymphocyte activation and production of proinflammatory cytokines. These, in turn, stimulate more HIV production, loss of additional CD4+ T cells, and more infection. Thus, it is easy to visualize how in individuals with AIDS a vicious cycle may be set up that culminates in inexorable destruction of the immune system.

Mechanism of T-Cell Depletion in HIV Infection

Loss of CD4+ T cells is mainly because of infection of the cells and the direct cytopathic effects of the replicating virus. In infected individuals, approximately 100 billion new viral particles are produced every day, and 1 to 2 billion CD4+ T cells die each day. Because the frequency of infected cells in the circulation is very low, for many years it was suspected that the immunodeficiency is out of

proportion to the level of infection and cannot be attributed to death of infected cells. In fact, many infected cells may be in mucosal and other peripheral lymphoid organs, and death of these cells is a major cause of the relentless, and eventually profound, cell loss. Also, up to a point the immune system can replace the dying T cells, and hence the rate of T cell loss may appear deceptively low, but as the disease progresses, renewal of CD4+ T cells cannot keep up with their loss. Possible mechanisms by which the virus directly kills infected cells include increased plasma membrane permeability associated with budding of virus particles from the infected cells, and virus replication interfering with protein synthesis.

In addition to direct killing of cells by the virus, other mechanisms may contribute to the loss of T cells. These include:

- Chronic activation of uninfected cells, responding to HIV itself or to infections that are common in individuals with AIDS, leads to apoptosis of these cells by the process of *activation-induced cell death*. Thus, the numbers of CD4+ T cells that die may be considerably more than the numbers of infected cells. The molecular mechanism of this type of cell death is not known.
- Non-cytopathic (abortive) HIV infection activates the inflammasome pathway and leads to a form of cell death that has been called *pyroptosis* (Chapter 2). During this process, inflammatory cytokines and cellular contents are released, thus potentiating recruitment of new cells and increasing the numbers of cells that can be infected. This form of cell death may play an important role in spread of the infection.
- HIV infects cells in lymphoid organs (spleen, lymph nodes, tonsils) and may cause progressive destruction of the architecture and cellular composition of lymphoid tissues.
- Loss of immature precursors of CD4+ T cells can also occur, either by direct infection of thymic progenitor cells or by infection of accessory cells that secrete cytokines essential for CD4+ T-cell maturation.
- Fusion of infected and uninfected cells with formation of syncytia (giant cells) can occur. In tissue culture the gp120 expressed on productively infected cells binds to CD4 molecules on uninfected T cells, followed by cell fusion. Fused cells usually die within a few hours. This property of syncytia formation is generally confined to the T-tropic X4 type of HIV-1. For this reason, this type is often referred to as syncytia-inducing (SI) virus, in contrast to the R5 virus.
- Although marked reduction in CD4+ T cells, a hallmark of AIDS, can account for most of the immunodeficiency late in the course of HIV infection, there is evidence of qualitative defects in T cells even in asymptomatic HIV-infected persons. Reported defects include a reduction in antigen-induced T-cell proliferation, a decrease in T_H1-type responses relative to the T_H2 type, defects in intracellular signaling, and many more. The loss of T_H1 responses results in profound deficiency in cell-mediated immunity, leading to increased susceptibility to infections by viruses and other intracellular microbes. There is also a selective loss of the memory subset of CD4+ helper T cells early in the course of disease, which explains poor recall responses to previously encountered antigens.

Table 6-14 Major Abnormalities of Immune Function in AIDS

Lymphopenia
Predominantly caused by selective loss of the CD4 ⁺ helper T-cell subset
Decreased T-Cell Function In Vivo
Preferential loss of activated and memory T cells
Decreased delayed-type hypersensitivity
Susceptibility to opportunistic infections
Susceptibility to neoplasms
Altered T-Cell Function In Vitro
Decreased proliferative response to mitogens, alloantigens, and soluble antigens
Decreased cytotoxicity
Decreased helper function for B-cell antibody production
Decreased IL-2 and IFN- γ production
Polyclonal B-Cell Activation
Hypergammaglobulinemia and circulating immune complexes
Inability to mount de novo antibody response to new antigens
Poor responses to normal B-cell activation signals in vitro
Altered Monocyte or Macrophage Functions
Decreased chemotaxis and phagocytosis
Decreased class II HLA expression
Diminished capacity to present antigen to T cells
<small>HLA, Human leukocyte antigen; IFN-γ, interferon-γ; IL-2, interleukin-2; TNF, tumor necrosis factor.</small>

Low-level chronic or latent infection of T cells is an important feature of HIV infection. It is widely believed that integrated provirus, without viral gene expression (latent infection), can remain in the cells for months to years. Even with potent antiviral therapy, which practically sterilizes the peripheral blood, latent virus lurks within the CD4⁺ cells (both T cells and macrophages) in the lymph nodes. According to some estimates, 0.05% of CD4⁺ T cells in the lymph nodes are latently infected. Because most of these CD4⁺ T cells are memory cells, they are long-lived, with a life span of months to years, and thus provide a persistent reservoir of virus.

CD4⁺ T cells play a pivotal role in regulating both cellular and humoral immune responses. Therefore, loss of this “master regulator” has ripple effects on virtually every other component of the immune system, as summarized in [Table 6-14](#).

HIV Infection of Non-T Cells

In addition to infection and loss of CD4⁺ T cells, **infection of macrophages and dendritic cells is also important in the pathogenesis of HIV infection**. Similar to T cells, the majority of the macrophages that are infected by HIV are found in the tissues and the number of blood monocytes infected by the virus may be low. In certain tissues, such as the lungs and brain, as many as 10% to 50% of macrophages are infected. Several aspects of HIV infection of macrophages should be emphasized:

- Although cell division is required for nuclear entry and replication of most retroviruses, HIV-1 can infect and multiply in terminally differentiated nondividing macrophages. This property of HIV-1 is dependent on the viral *vpr* gene. The Vpr protein allows nuclear targeting of the HIV preintegration complex through the nuclear pore.

- Infected macrophages bud relatively small amounts of virus from the cell surface, but these cells contain large numbers of virus particles often located in intracellular vacuoles. Even though macrophages allow viral replication, they are quite resistant to the cytopathic effects of HIV, in contrast to CD4⁺ T cells. Thus, macrophages may be reservoirs of infection whose output remains largely protected from host defenses. In late stages of HIV infection, when CD4⁺ T-cell numbers decline greatly, macrophages may be an important site of continued viral replication.
- Macrophages may act as portals of infection. Recall that in more than 90% of cases acute HIV infection is characterized by predominantly circulating M-tropic strains. This finding suggests that the initial infection of macrophages or dendritic cells may be important in the pathogenesis of HIV disease.
- Even uninfected monocytes are reported to have unexplained functional defects that may have important consequences for host defense. These defects include impaired microbicidal activity, decreased chemotaxis, decreased secretion of IL-1, inappropriate secretion of TNF, and poor capacity to present antigens to T cells. Also, even the low number of infected blood monocytes may be vehicles for HIV to be transported to various parts of the body, including the nervous system.

Studies have documented that, in addition to macrophages, two types of dendritic cells are also important targets for the initiation and maintenance of HIV infection: mucosal and follicular dendritic cells. It is thought that **mucosal dendritic cells are infected by the virus and may transport it to regional lymph nodes**, where the virus is transmitted to CD4⁺ T cells. Dendritic cells also express a lectin-like receptor that specifically binds HIV and displays it in an intact, infectious form to T cells, thus promoting infection of the T cells.

Follicular dendritic cells in the germinal centers of lymph nodes are potential reservoirs of HIV. Although some follicular dendritic cells may be susceptible to HIV infection, most virus particles are found on the surface of their dendritic processes. Follicular dendritic cells have receptors for the Fc portion of immunoglobulins, and hence they trap HIV virions coated with anti-HIV antibodies. The antibody-coated virions localized to follicular dendritic cells retain the ability to infect CD4⁺ T cells as they traverse the intricate meshwork formed by the dendritic processes of the follicular dendritic cells.

B Cell Function in HIV Infection. Although much attention has been focused on T cells, macrophages, and dendritic cells because they can be infected by HIV, individuals with AIDS also display profound abnormalities of B-cell function. Paradoxically, there is polyclonal activation of B cells, resulting in germinal center B-cell hyperplasia (particularly early in the disease course), bone marrow plasmacytosis, hypergammaglobulinemia, and formation of circulating immune complexes. This activation may result from multiple interacting factors: reactivation of or reinfection with cytomegalovirus and EBV, both of which are polyclonal B-cell activators, can occur; gp41 itself can promote B-cell growth and differentiation; and HIV-infected macrophages produce increased amounts of IL-6,

which stimulates proliferation of B cells. Despite the presence of spontaneously activated B cells, patients with AIDS are unable to mount antibody responses to newly encountered antigens. This could be due, in part, to lack of T-cell help, but antibody responses against T-independent antigens are also suppressed, and hence there may be other intrinsic defects in B cells as well. Impaired humoral immunity renders these patients prey to disseminated infections caused by encapsulated bacteria, such as *S. pneumoniae* and *H. influenzae*, both of which require antibodies for effective opsonization and clearance.

Pathogenesis of Central Nervous System Involvement

The pathogenesis of neurologic manifestations deserves special mention because, in addition to the lymphoid system, the nervous system is a major target of HIV infection. Macrophages and microglia, cells in the central nervous system that belong to the macrophage lineage, are the predominant cell types in the brain that are infected with HIV. It is believed that HIV is carried into the brain by infected monocytes. In keeping with this, the HIV isolates from the brain are almost exclusively M-tropic. The mechanism of HIV-induced damage of the brain, however, remains obscure. Because neurons are not infected by HIV, and the extent of neuropathologic changes is often less than might be expected from the severity of neurologic symptoms, most workers believe that the neurologic deficit is caused indirectly by viral products and by soluble factors produced by infected microglia. Included among the soluble factors are the usual culprits, such as IL-1, TNF, and IL-6. In addition, nitric oxide induced in neuronal cells by gp41 has been implicated. Direct damage of neurons by soluble HIV gp120 has also been postulated.

Natural History of HIV Infection

Virus typically enters through mucosal epithelia. The subsequent pathologic and clinical manifestations of the infection can be divided into several phases: (1) an acute retroviral syndrome; (2) a middle, chronic phase, in which most individuals are asymptomatic; and (3) clinical AIDS (Figs. 6-41 and 6-42).

Primary Infection, Virus Dissemination, and the Acute Retroviral Syndrome

Acute (early) infection is characterized by infection of memory CD4+ T cells (which express CCR5) in mucosal lymphoid tissues, and death of many infected cells. Because the mucosal tissues are the largest reservoir of T cells in the body, and a major site of residence of memory T cells, this local loss results in considerable depletion of lymphocytes. Few infected cells are detectable in the blood and other tissues. Mucosal infection is often associated with damage to the epithelium, defects in mucosal barrier functions, and translocation of microbes across the epithelium.

Mucosal infection is followed by dissemination of the virus and the development of host immune responses. Dendritic cells in epithelia at sites of virus entry capture the virus and then migrate into the lymph nodes. Once in lymphoid tissues, dendritic cells may pass HIV on to CD4+ T cells through direct cell-cell contact. Within days after the first exposure to HIV, viral replication can be detected in

Figure 6-41 Pathogenesis of HIV-1 infection. The initial infection starts in mucosal tissues, involving mainly memory CD4+ T cells and dendritic cells, and spreads to lymph nodes. Viral replication leads to viremia and widespread seeding of lymphoid tissue. The viremia is controlled by the host immune response, and the patient then enters a phase of clinical latency. During this phase, viral replication in both T cells and macrophages continues unabated, but there is some immune containment of virus (not illustrated). There continues a gradual erosion of CD4+ cells and ultimately, CD4+ T-cell numbers decline, and the patient develops clinical symptoms of full-blown AIDS. CTL, Cytotoxic T lymphocyte.

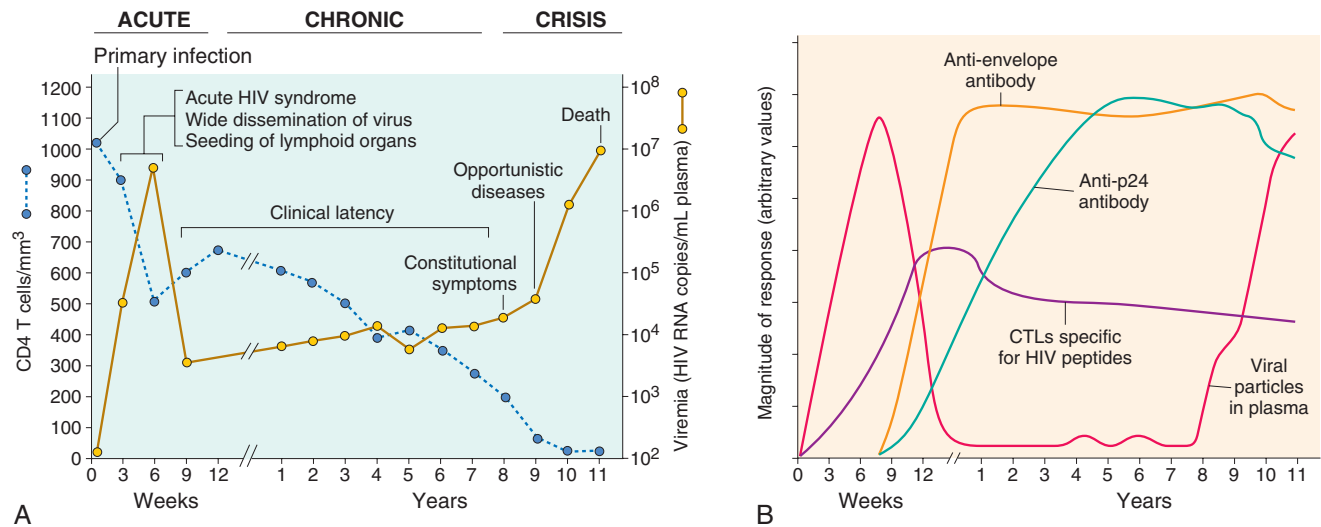

Figure 6-42 Clinical course of HIV infection. **A**, During the early period after primary infection there is dissemination of virus, development of an immune response to HIV, and often an acute viral syndrome. During the period of clinical latency, viral replication continues and the CD4+ T-cell count gradually decreases, until it reaches a critical level below which there is a substantial risk of AIDS-associated diseases. **B**, Immune response to HIV infection. A cytotoxic T lymphocyte (CTL) response to HIV is detectable by 2 to 3 weeks after the initial infection, and it peaks by 9 to 12 weeks. Marked expansion of virus-specific CD8+ T-cell clones occurs during this time, and up to 10% of a patient's CTLs may be HIV specific at 12 weeks. The humoral immune response to HIV peaks at about 12 weeks. (A, Redrawn from Fauci AS, Lane HC: Human immunodeficiency virus disease: AIDS and related conditions. In Fauci AS, et al (eds): Harrison's Principles of Internal Medicine, 14th ed. New York, McGraw-Hill, 1997, p 1791.)

the lymph nodes. This replication leads to viremia, during which high numbers of HIV particles are present in the patient's blood. The virus disseminates throughout the body and infects helper T cells, macrophages, and dendritic cells in peripheral lymphoid tissues.

As the HIV infection spreads, the individual mounts antiviral humoral and cell-mediated immune responses. These responses are evidenced by seroconversion (usually within 3 to 7 weeks of presumed exposure) and by the development of virus-specific CD8+ cytotoxic T cells. HIV-specific CD8+ T cells are detected in the blood at about the time viral titers begin to fall and are most likely responsible for the initial containment of HIV infection. These immune responses partially control the infection and viral production, and such control is reflected by a drop in viremia to low but detectable levels by about 12 weeks after the primary exposure.

The *acute retroviral syndrome* is the clinical presentation of the initial spread of the virus and the host response. It is estimated that 40% to 90% of individuals who acquire a primary infection develop this syndrome. This typically occurs 3 to 6 weeks after infection, and resolves spontaneously in 2 to 4 weeks. Clinically, this phase is associated with a self-limited acute illness with nonspecific symptoms, including sore throat, myalgias, fever, weight loss,

and fatigue, resembling a flulike syndrome. Other clinical features, such as rash, cervical adenopathy, diarrhea, and vomiting, may also occur.

The extent of viremia, measured as HIV-1 RNA levels, in the blood is a useful surrogate marker of HIV disease progression and is of clinical value in the management of people with HIV infection. The viral load at the end of the acute phase reflects the equilibrium reached between the virus and the host response, and in a given patient it may remain fairly stable for several years. This level of steady-state viremia, called the *viral set point*, is a predictor of the rate of decline of CD4+ T cells, and, therefore, progression of HIV disease. In one study, only 8% of patients with a viral load of less than 4350 copies of viral mRNA per microliter of blood progressed to clinical AIDS in 5 years, whereas 62% of those with a viral load of greater than 36,270 copies developed AIDS in the same period.

Because the loss of immune containment is associated with declining CD4+ T-cell counts, the Centers for Disease Control (CDC) classification of HIV infection stratifies three categories on the basis of CD4+ cell counts: CD4+ cells greater than or equal to 500 cells/ μ L, 200 to 499 cells/ μ L, and fewer than 200 cells/ μ L (Table 6-15). For clinical management, blood CD4+ T-cell counts are perhaps the most reliable short-term indicator of disease progression.

Table 6-15 CDC Classification Categories of HIV Infection

Clinical Categories	CD4+ T-Cell Categories		
	1 ≥500 Cells/ μ L	2 200-499 Cells/ μ L	3 <200 Cells/ μ L
A. Asymptomatic, acute (primary) HIV, or persistent generalized lymphadenopathy	A1	A2	A3
B. Symptomatic, not A or C conditions	B1	B2	B3
C. AIDS indicator conditions: including constitutional disease, neurologic disease, or neoplasm			

Data from CDC. Centers for Disease Control and Prevention: 1993 revised classification system and expanded surveillance definition for AIDS among adolescents and adults. MMWR 1992;41(RR-17):1.

For this reason, CD4+ cell counts and not viral load are the primary clinical measurements used to determine when to start antiretroviral therapy.

Chronic Infection: Phase of Clinical Latency

In the next, chronic phase of the disease, lymph nodes and the spleen are sites of continuous HIV replication and cell destruction (Fig. 6-41). During this period of the disease, few or no clinical manifestations of the HIV infection are present. Therefore, this phase of HIV disease is called the clinical latency period. Although the majority of peripheral blood T cells do not harbor the virus, destruction of CD4+ T cells within lymphoid tissues continues during this phase, and the number of circulating blood CD4+ T cells steadily declines. More than 90% of the body's approximately 10^{12} T cells are normally found in lymphoid tissues, and it is estimated that HIV destroys up to 1×10^9 to 2×10^9 CD4+ T cells every day. Early in the course of the disease, the body may continue to make new CD4+ T cells, and therefore CD4+ T cells can be replaced almost as quickly as they are destroyed. At this stage, up to 10% of CD4+ T cells in lymphoid organs may be infected, but the frequency of circulating CD4+ T cells that are infected at any one time may be less than 0.1% of the total CD4+ T cells. Eventually, over a period of years, the continuous cycle of virus infection, T-cell death, and new infection leads to a steady decline in the number of CD4+ T cells in the lymphoid tissues and the circulation.

Concomitant with this loss of CD4+ T cells, host defenses begin to wane, and the proportion of the surviving CD4+ cells infected with HIV increases, as does the viral burden per CD4+ cell. Not unexpectedly, HIV RNA levels increase as the host begins to lose the battle with the virus. How HIV escapes immune control is not entirely clear, but several mechanisms have been proposed. These include destruction of the CD4+ T cells that are critical for effective immunity, antigenic variation, and down-modulation of class I MHC molecules on infected cells so that viral antigens are not recognized by CD8+ CTLs. During this period the virus may evolve and switch from relying solely on CCR5 to enter its target cells to relying on either CXCR4 or both CCR5 and CXCR4. This coreceptor switch is associated with more rapid decline in CD4+ T-cell counts, presumably because of greater infection of T cells.

In this chronic phase of infection, patients are either asymptomatic or develop minor opportunistic infections, such as oral candidiasis (thrush), vaginal candidiasis, herpes zoster, and perhaps mycobacterial tuberculosis (the latter being particularly common in resource-poor regions such as sub-Saharan Africa). Autoimmune thrombocytopenia may also be noted (Chapter 14).

AIDS

The final phase is progression to AIDS, characterized by a breakdown of host defense, a dramatic increase in plasma virus, and severe, life-threatening clinical disease. Typically the patient presents with long-lasting fever (>1 month), fatigue, weight loss, and diarrhea. After a variable period, serious opportunistic infections, secondary neoplasms, or clinical neurologic disease (grouped under the rubric *AIDS indicator diseases*, discussed later) emerge, and the patient is said to have developed AIDS.

In the absence of treatment, most patients with HIV infection progress to AIDS after a chronic phase lasting from 7 to 10 years. Exceptions to this typical course are exemplified by rapid progressors and long-term nonprogressors. In *rapid progressors* the middle, chronic phase is telescoped to 2 to 3 years after primary infection. About 5% to 15% of infected individuals are *long-term nonprogressors*, defined as untreated HIV-1-infected individuals who remain asymptomatic for 10 years or more, with stable CD4+ T-cell counts and low levels of plasma viremia (usually less than 500 viral RNA copies per milliliter). Remarkably, about 1% of infected individuals have undetectable plasma virus (<50-75 RNA copies/mL); these have been called *elite controllers*. Individuals with such an uncommon clinical course have attracted great attention in the hope that studying them may shed light on host and viral factors that influence disease progression. Studies thus far indicate that this group is heterogeneous with respect to the variables that influence the course of the disease. In most cases, the viral isolates do not show qualitative abnormalities, suggesting that the course of the disease cannot be attributed to a "wimpy" virus. In all cases there is evidence of a vigorous anti-HIV immune response, but the immune correlates of protection are still unknown. Some of these individuals have high levels of HIV-specific CD4+ and CD8+ T-cell responses, and these levels are maintained over the course of infection. The inheritance of particular HLA alleles seems to correlate with resistance to disease progression, perhaps reflecting the ability to mount antiviral T cell responses. Further studies, it is hoped, will provide the answers to this and other questions critical to understanding disease progression.

Clinical Features of AIDS

The clinical manifestations of HIV infection can be readily surmised from the foregoing discussion. They range from a mild acute illness to severe disease. Because the salient clinical features of the acute early and chronic middle phases of HIV infection were described earlier, here we summarize the clinical manifestations of the terminal phase, AIDS. At the outset it should be pointed out that the clinical manifestations and opportunistic infections associated with HIV infection may differ in different parts of the world. Also, the course of the disease has been greatly modified by new antiretroviral therapies, and many complications that were once devastating are now infrequent.

In the United States, the typical adult patient with AIDS presents with fever, weight loss, diarrhea, generalized lymphadenopathy, multiple opportunistic infections, neurologic disease, and, in many cases, secondary neoplasms. The infections and neoplasms listed in Table 6-16 are included in the surveillance definition of AIDS.

Opportunistic Infections. Opportunistic infections account for the majority of deaths in untreated patients with AIDS. Many of these infections represent reactivation of latent infections, which are normally kept in check by a robust immune system but are not completely eradicated because the infectious agents have evolved to coexist with their hosts. The actual frequency of infections varies in different regions of the world, and has been markedly reduced by the advent of highly active antiretroviral therapy (HAART), which relies on a combination of three

Table 6-16 AIDS-Defining Opportunistic Infections and Neoplasms Found in Patients with HIV Infection

Infections
Protozoal and Helminthic Infections
Cryptosporidiosis or isosporidiosis (enteritis)
Pneumocystosis (pneumonia or disseminated infection)
Toxoplasmosis (pneumonia or CNS infection)
Fungal Infections
Candidiasis (esophageal, tracheal, or pulmonary)
Cryptococcosis (CNS infection)
Coccidioidomycosis (disseminated)
Histoplasmosis (disseminated)
Bacterial Infections
Mycobacteriosis ("atypical," e.g., <i>Mycobacterium avium-intracellulare</i> , disseminated or extrapulmonary; <i>Mycobacterium tuberculosis</i> , pulmonary or extrapulmonary)
Nocardiosis (pneumonia, meningitis, disseminated)
<i>Salmonella</i> infections, disseminated
Viral Infections
Cytomegalovirus (pulmonary, intestinal, retinitis, or CNS infections)
Herpes simplex virus (localized or disseminated infection)
Varicella-zoster virus (localized or disseminated infection)
Progressive multifocal leukoencephalopathy
Neoplasms
Kaposi sarcoma
Primary lymphoma of brain
Invasive cancer of uterine cervix

CNS, Central nervous system.

or four drugs that block different steps of the HIV life cycle. A brief summary of selected opportunistic infections is provided here.

- Approximately 15% to 30% of untreated HIV-infected people develop pneumonia at some time during the course of the disease, caused by the fungus *Pneumocystis jiroveci* (reactivation of a prior latent infection). Before the advent of HAART, this infection was the presenting feature in about 20% of cases, but the incidence is much less in patients who respond to HAART.
- Many patients present with an opportunistic infection other than *P. jiroveci* pneumonia. Among the most common pathogens are *Candida*, cytomegalovirus, atypical and typical mycobacteria, *Cryptococcus neoformans*, *Toxoplasma gondii*, *Cryptosporidium*, herpes simplex virus, papovaviruses, and *Histoplasma capsulatum*.
- *Candidiasis* is the most common fungal infection in patients with AIDS, and infection of the oral cavity, vagina, and esophagus are its most common clinical manifestations. In asymptomatic HIV-infected individuals oral candidiasis is a sign of immunologic decompensation, and it often heralds the transition to AIDS. Invasive candidiasis is infrequent in patients with AIDS, and it usually occurs when there is drug-induced neutropenia or use of indwelling catheters.
- *Cytomegalovirus* may cause disseminated disease, although, more commonly, it affects the eye and gastrointestinal tract. Chorioretinitis was seen in approximately 25% of patients before the advent of HAART, but this has decreased dramatically after the initiation of HAART. Cytomegalovirus retinitis occurs almost exclusively in patients with CD4+ T cell counts less than 50 per microliter. Gastrointestinal disease, seen in 5% to 10% of cases, manifests as esophagitis and colitis, the latter associated with multiple mucosal ulcerations.
- Disseminated bacterial infection with *atypical mycobacteria* (mainly *Mycobacterium avium-intracellulare*) also occurs late, in the setting of severe immunosuppression. Coincident with the AIDS epidemic, the incidence of tuberculosis has risen dramatically. Worldwide, almost a third of all deaths in AIDS patients are attributable to tuberculosis, but this complication remains uncommon in the United States. Patients with AIDS have reactivation of latent pulmonary disease as well as outbreaks of primary infection. In contrast to infection with atypical mycobacteria, *M. tuberculosis* manifests itself early in the course of AIDS. As with tuberculosis in other settings, the infection may be confined to lungs or may involve multiple organs. The pattern of expression depends on the degree of immunosuppression; dissemination is more common in patients with very low CD4+ T-cell counts. Most worrisome are reports indicating that a growing number of isolates are resistant to multiple antimycobacterial drugs.
- *Cryptococcosis* occurs in about 10% of AIDS patients. As in other settings with immunosuppression, meningitis is the major clinical manifestation of cryptococcosis. *Toxoplasma gondii*, another frequent invader of the central nervous system in AIDS, causes encephalitis and is responsible for 50% of all mass lesions in the central nervous system.
- *JC virus*, a human papovavirus, is another important cause of central nervous system infections in HIV-infected patients. It causes progressive multifocal leukoencephalopathy (Chapter 28). *Herpes simplex virus infection* is manifested by mucocutaneous ulcerations involving the mouth, esophagus, external genitalia, and perianal region. *Persistent diarrhea*, which is common in untreated patients with advanced AIDS, is often caused by infections with protozoans such as *Cryptosporidium*, *Isospora belli*, or microsporidia. These patients have chronic, profuse, watery diarrhea with massive fluid loss. Diarrhea may also result from infection with enteric bacteria, such as *Salmonella* and *Shigella*, as well as *M. avium-intracellulare*.

Tumors. Patients with AIDS have a high incidence of certain tumors, especially *Kaposi sarcoma (KS)*, B-cell lymphoma, cervical cancer in women, and anal cancer in men. It is estimated that 25% to 40% of untreated HIV-infected individuals will eventually develop a malignancy. A common feature of these tumors is that they are caused by oncogenic DNA viruses, specifically Kaposi sarcoma herpesvirus (Kaposi sarcoma), EBV (B-cell lymphoma), and human papillomavirus (cervical and anal carcinoma). Even in healthy people, any of these viruses may establish latent infections that are kept in check by a competent immune system. The increased risk of malignancy in AIDS patients exists mainly because of failure to contain the infections and reactivation of the viruses, as well as decreased immunity against the tumors.

Kaposi Sarcoma. Kaposi sarcoma, a vascular tumor that is otherwise rare in the United States, is the most common

neoplasm in patients with AIDS. The morphology of KS and its occurrence in patients not infected with HIV are discussed in [Chapter 11](#). At the onset of the AIDS epidemic, up to 30% of infected homosexual or bisexual men had KS, but in recent years, with use of HAART there has been a dramatic decline in its incidence. In contrast, in areas of sub-Saharan Africa where HIV infection is both frequent and largely untreated, Kaposi sarcoma is one of the most common tumors.

The lesions of KS are characterized by the proliferation of spindle-shaped cells that express markers of both endothelial cells (vascular or lymphatic) and smooth muscle cells. There is also a profusion of slitlike vascular spaces, suggesting that the lesions may arise from primitive mesenchymal precursors of vascular channels. In addition, KS lesions display chronic inflammatory cell infiltrates. Many of the features of KS suggest that it is not a malignant tumor (despite its ominous name). For instance, spindle cells in many KS lesions are polyclonal or oligoclonal, although more advanced lesions occasionally show monoclonality. The current model of KS pathogenesis is that the spindle cells produce proinflammatory and angiogenic factors, which recruit the inflammatory and neovascular components of the lesion, and the latter components supply signals that aid in spindle cell survival and growth.

There is compelling evidence that KS is caused by the *KS herpesvirus* (KSHV), also called *human herpesvirus 8* (HHV8). Exactly how KSHV infection leads to KS is still unclear. Like other herpesviruses, KSHV establishes latent infection, during which several proteins are produced with potential roles in stimulating spindle cell proliferation and preventing apoptosis. These include a viral homologue of cyclin D and several inhibitors of p53. However, KSHV infection, while necessary for KS development, is not sufficient, and additional cofactors are needed. In the AIDS-related form, that cofactor is clearly HIV. (The relevant cofactors for HIV-negative KS remain unknown.) HIV-mediated immune suppression may aid in widespread dissemination of KSHV in the host.

KSHV infection is not restricted to endothelial cells. The virus is related phylogenetically to the lymphotropic subfamily of herpesviruses (γ -herpesvirus); in keeping with this, its genome is found in B cells of infected subjects.

In fact, KSHV infection is also linked to rare B-cell lymphomas in AIDS patients (called *primary effusion lymphoma*) and to multicentric Castlemann disease, a B-cell lymphoproliferative disorder.

Clinically, AIDS-associated KS is quite different from the sporadic form ([Chapter 11](#)). In HIV-infected individuals the tumor is usually widespread, affecting the skin, mucous membranes, gastrointestinal tract, lymph nodes, and lungs. These tumors also tend to be more aggressive than classic KS.

Lymphomas. Lymphoma occurs at a markedly increased rate in individuals with AIDS, making it one of several AIDS-defining conditions. Roughly 5% of AIDS patients present with lymphoma, and approximately another 5% develop lymphoma during their subsequent course. With the advent of effective antiretroviral therapy, the incidence of lymphoma has fallen substantially in some HIV-infected populations. However, even in the era of retroviral therapy, lymphoma continues to occur in HIV-infected people at an incidence that is at least 10-fold greater than the population average. These epidemiologic findings suggest that the association of lymphoma and HIV infection is only partially explained by T-cell immunodeficiency. Indeed, based on molecular characterization of HIV-associated lymphomas and the epidemiologic considerations above, at least two mechanisms appear to underlie the increased risk of B-cell tumors in HIV infected individuals ([Fig. 6-43](#)).

- Unchecked proliferation of B cells infected with oncogenic herpesviruses in the setting of profound T cell depletion (AIDS).** T-cell immunity is required to restrain the proliferation of B cells infected with oncogenic viruses such as EBV and KSHV. With the appearance of severe T-cell depletion late in the course of HIV infection, this control is lost. As a result AIDS patients are at high risk of developing aggressive B cell lymphomas composed of tumor cells infected by oncogenic viruses, particularly EBV.

By adulthood, most normal individuals are infected by EBV. Once immunity is established, EBV persists in such individuals as a latent infection in approximately 1 in 100,000 B cells, most of which have a memory B-cell

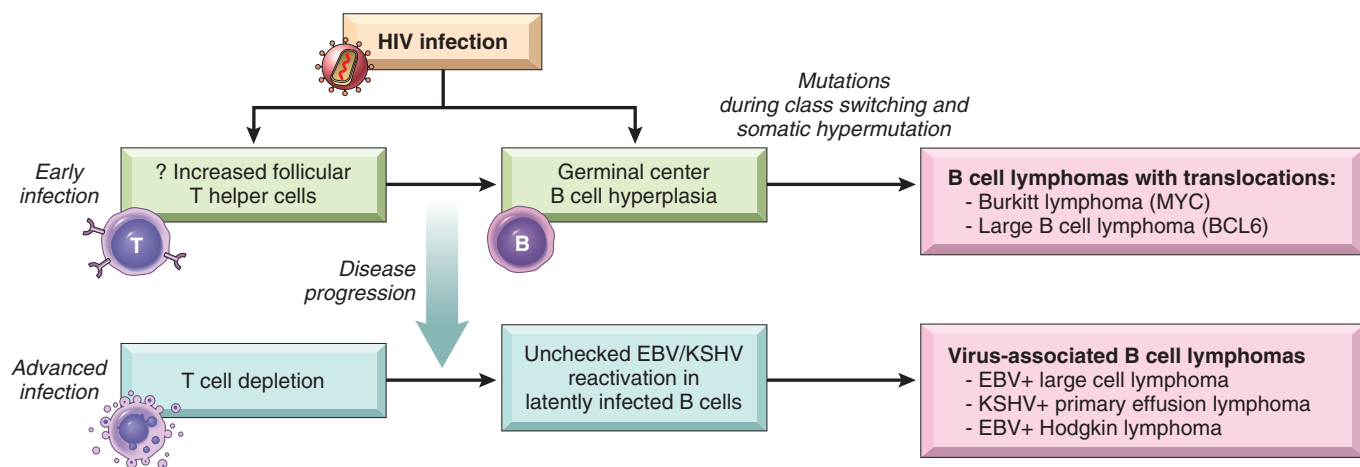

Figure 6-43 A model for the pathogenesis of B-cell lymphomas in HIV infection. HIV infection results in several changes that may cooperate to produce B-cell lymphomas.

phenotype. Activation of such cells, by antigen or by cytokines, reawakens an EBV-encoded program of gene expression that drives B-cell proliferation. Patients with AIDS have high levels of several cytokines, some of which, including IL-6, are growth factors for B cells. These patients are also chronically infected with pathogens that may lead to B-cell stimulation. In the absence of T-cell immunity, these activated, EBV infected clones proliferate and eventually acquire additional somatic mutations, leading to their outgrowth as full-blown EBV-positive B-cell lymphomas. The tumors often occur in extranodal sites, such as the central nervous system, but also the gut, the orbit, and the lungs, and elsewhere. AIDS patients are also prone to rare lymphomas that present as malignant effusions (so-called primary effusion lymphoma), which are remarkable in that the tumor cells are usually coinfecting by both EBV and KSHV, a highly unusual example of cooperativity between two oncogenic viruses.

- **Germinal center B-cell hyperplasia in the setting of early HIV infection.** As mentioned, even in the face of effective antiretroviral therapy, the overall rate of lymphoma in the HIV-infected population remains elevated, even in those with normal CD4+ T-cell counts. As might be anticipated, the majority of the lymphomas that arise in patients with preserved CD4 T-cell counts are not associated with EBV or KSHV. What then explains the continued increased risk of lymphoma? The answer is not known, but it may be related to the profound germinal center B-cell hyperplasia that occurs early in HIV infection. Recall that in germinal centers, B cells diversify their immunoglobulin genes via lesions introduced into their DNA by the enzyme activation-induced deaminase (AID). This process is imperfect, and there is experimental evidence showing that AID can cause mutations in oncogenes implicated in B-cell lymphomagenesis. Of note, the aggressive B cell tumors that arise outside of the setting of full-blown AIDS in HIV-infected individuals, such as Burkitt lymphoma and diffuse large B-cell lymphoma, are often associated with mutations in oncogenes such as *MYC* and *BCL6* that bear the molecular hallmarks of “mistakes” made during attempted immunoglobulin class-switching and somatic hypermutations, two AID-dependent events that occur in germinal center B cells. Thus, the striking germinal center B-cell hyperplasia that occurs early in HIV infection may contribute to lymphomagenesis by simply increasing the number of B cells that are “at-risk” for acquiring potential lymphoma-initiating events.

Several other EBV-related proliferations also merit mention. Hodgkin lymphoma, an unusual B cell tumor associated with a pronounced tissue inflammatory response (Chapter 13), also occurs at increased frequency in HIV-infected individuals. In virtually all instances of HIV-associated Hodgkin lymphoma, the characteristic tumor cells (Reed-Sternberg cells) are infected with EBV. Many (but not all) HIV patients with Hodgkin lymphoma have low CD4 counts at the time of disease presentation. EBV infection also is responsible for oral hairy leukoplakia (white projections on the tongue), which results from EBV-driven squamous cell proliferation of the oral mucosa (Chapter 16).

Other Tumors. In addition to KS and lymphomas, patients with AIDS also have an increased occurrence of carcinoma of the uterine cervix and of anal cancer. This is most likely due to reactivation of latent human papillomavirus (HPV) infection in the setting of immunosuppression. This virus is intimately associated with squamous cell carcinoma of the cervix and its precursor lesions, cervical dysplasia and carcinoma in situ (Chapters 7 and 22). HPV-associated cervical dysplasia is 10 times more common in HIV-infected women as compared with uninfected women attending family planning clinics. Hence it is recommended that gynecologic examination be part of a routine work-up of HIV-infected women.

Central Nervous System Disease. Involvement of the central nervous system is a common and important manifestation of AIDS. Ninety percent of patients demonstrate some form of neurologic involvement at autopsy, and 40% to 60% have clinically apparent neurologic dysfunction. Importantly, in some patients, neurologic manifestations may be the sole or earliest presenting feature of HIV infection. In addition to opportunistic infections and neoplasms, several virally determined neuropathologic changes occur. These include a self-limited meningoencephalitis occurring at the time of seroconversion, aseptic meningitis, vacuolar myelopathy, peripheral neuropathies, and, most commonly, a progressive encephalopathy designated clinically as HIV-associated neurocognitive disorder (Chapter 28).

Effect of Antiretroviral Drug Therapy on the Clinical Course of HIV Infection. The advent of new antiretroviral drugs that target the viral reverse transcriptase, protease, and integrase has changed the clinical face of AIDS. These drugs are given in combination to reduce the emergence of mutants that develop resistance to any one; treatment regimens are commonly called *highly active antiretroviral therapy (HAART)* or *combination antiretroviral therapy*. Over 25 antiretroviral drugs from six distinct drug classes have been developed for the management of HIV infection. When a combination of at least three effective drugs is used in a motivated, compliant patient, HIV replication is reduced to below the level of detection (<50 copies RNA per milliliter) and remains there indefinitely (as long as the patient adheres to therapy). Even when a drug-resistant virus breaks through, there are several second- and third-line options to combat the virus. Once the virus is suppressed, the progressive loss of CD4+ T cells is halted. Over a period of several years the peripheral CD4+ T-cell count slowly increases and often returns to a normal level. With the use of these drugs, in the United States the annual death rate from AIDS has decreased from its peak of 16 to 18 per 100,000 people in 1995-1996 to less than 4 per 100,000. Many AIDS-associated disorders, such as opportunistic infections with *P. jiroveci* and Kaposi sarcoma, are very uncommon now. Effective antiretroviral therapy has reduced the transmission of the virus, especially from infected mothers to newborns. However, because of the reduced mortality, more people are living with HIV, and since they are not virus-free, there is a fear that the risk of spreading the infection may increase if vigilance is relaxed. Indeed, there is compelling evidence that even treated patients who remain asymptomatic, with virtually

undetectable plasma virus for years, develop active infection if they stop the treatment.

Despite these dramatic improvements, several new complications associated with HIV infection and its treatment have emerged. Some patients with advanced disease who are given antiretroviral therapy develop a paradoxical clinical deterioration during the period of recovery of the immune system. This occurs despite increasing CD4+ T-cell counts and decreasing viral load. This disorder has been called the *immune reconstitution inflammatory syndrome*. Its basis is not understood but is postulated to be a poorly regulated host response to the high antigenic burden of persistent microbes. Perhaps a more important complication of long-term HAART pertains to adverse side-effects of the drugs. These include lipoatrophy (loss of facial fat), lipoaccumulation (excess fat deposition centrally), elevated lipids, insulin resistance, peripheral neuropathy, premature cardiovascular kidney and liver disease. Finally, non-AIDS morbidity is far more common than classic AIDS-related morbidity in long-term HAART-treated patients. Major causes of morbidity are cancer, and accelerated cardiovascular, kidney, and liver disease. The mechanism for these non-AIDS related complications is not known, but persistent inflammation and T-cell dysfunction may be playing a role.

MORPHOLOGY

The anatomic changes in the tissues (with the exception of lesions in the brain) are neither specific nor diagnostic. Common pathologic features of AIDS include opportunistic infections, KS, and B cell lymphomas. Most of these lesions are discussed elsewhere, because they also occur in individuals who do not have HIV infection. Lesions in the central nervous system are described in [Chapter 28](#).

Biopsy specimens from enlarged lymph nodes in the early stages of HIV infection reveal a marked hyperplasia of B cell follicles. The follicles are enlarged and often take on unusual, serpiginous shapes. The mantle zones that surround the follicles are attenuated, and the germinal centers impinge on interfollicular T cell areas. This hyperplasia of B cells is the morphologic reflection of the polyclonal B-cell activation and hypergammaglobulinemia seen in HIV-infected individuals.

With disease progression, the frenzy of B-cell proliferation subsides and gives way to a pattern of severe lymphoid involution. The lymph nodes are depleted of lymphocytes, and the organized network of follicular dendritic cells is disrupted. The germinal centers may even become hyalinized. During this advanced stage viral burden in the nodes is reduced, in part because of the disruption of the follicular dendritic cells. These “burnt-out” lymph nodes are atrophic and small and may harbor numerous opportunistic pathogens, often within macrophages. Because of profound immunosuppression, the inflammatory response to infections both in the lymph nodes and at extranodal sites may be sparse or atypical. For example, mycobacteria may not evoke granuloma formation because CD4+ cells are deficient. In the empty-looking lymph nodes and in other organs, the presence of infectious agents may not be readily apparent without special stains. As might be expected, lymphoid involution is not confined to the nodes; in later stages of AIDS, the spleen and thymus also are converted to “wastelands” that are virtually devoid of lymphocytes.

Despite spectacular advances in our understanding of HIV infection, the long-term prognosis of patients with AIDS remains dismal. Although with effective drug therapy the mortality rate has declined in the United States, the treated patients still carry viral DNA in their lymphoid tissues. Can there be a cure with persistent virus? Although a considerable effort has been mounted to develop a vaccine, many hurdles remain to be crossed before vaccine-based prophylaxis becomes a reality. Molecular analyses have revealed an alarming degree of variation in viral isolates from patients; this renders the task of producing a vaccine extremely difficult. Recent efforts have focused on producing antibodies against relatively invariant portions of HIV proteins. The task of developing an effective vaccine is complicated by the fact that the correlates of immune protection are not fully understood. At present, therefore, prevention, public health measures, and antiretroviral drugs remain the mainstays in the fight against AIDS.

KEY CONCEPTS

Pathogenesis and Course of HIV Infection and AIDS

- Virus entry into cells: requires CD4 and co-receptors, which are receptors for chemokines; involves binding of viral gp120 and fusion with the cell mediated by viral gp41 protein; main cellular targets are CD4+ helper T cells, macrophages, and DCs
- Viral replication: provirus genome integrates into host cell DNA; viral gene expression is triggered by stimuli that activate infected cells (e.g., infectious microbes, cytokines produced during normal immune responses)
- Progression of infection: acute infection of mucosal T cells and DCs; viremia with dissemination of virus; latent infection of cells in lymphoid tissue; continuing viral replication and progressive loss of CD4+ T cells
- Mechanisms of immune deficiency:
 - Loss of CD4+ T cells: T-cell death during viral replication and budding (similar to other cytopathic infections); apoptosis as a result of chronic stimulation; decreased thymic output; functional defects
 - Defective macrophage and DC functions
 - Destruction of architecture of lymphoid tissues (late)
- Clinical manifestations of AIDS include opportunistic infections, tumors such as B-cell lymphomas, and CNS abnormalities.

Amyloidosis

Amyloidosis is a condition associated with a number of inherited and inflammatory disorders in which extracellular deposits of fibrillar proteins are responsible for tissue damage and functional compromise. These abnormal fibrils are produced by the aggregation of misfolded proteins (which are soluble in their normal folded configuration). The fibrillar deposits bind a wide variety of proteoglycans and glycosaminoglycans, including heparan sulfate and dermatan sulfate, and plasma proteins, notably serum amyloid P component (SAP). The presence of

abundant charged sugar groups in these adsorbed proteins give the deposits staining characteristics that were thought to resemble starch (amylose). Therefore, the deposits were called *amyloid*, a name that is firmly entrenched despite the realization that the deposits are unrelated to starch.

Amyloid is deposited in the extracellular space in various tissues and organs of the body in a variety of clinical settings. Because amyloid deposition appears insidiously and sometimes mysteriously, its clinical recognition ultimately depends on morphologic identification of this distinctive substance in appropriate biopsy specimens. With the light microscope and hematoxylin and eosin stains, amyloid appears as an amorphous, eosinophilic, hyaline, extracellular substance. *With progressive accumulation, it encroaches on and produces pressure atrophy of adjacent cells.* To differentiate amyloid from other hyaline materials (e.g., collagen, fibrin), a variety of histochemical techniques, described later, are used. Perhaps most widely used is the Congo red stain, which under ordinary light imparts a pink or red color to tissue deposits, but far more striking and specific is the green birefringence of the stained amyloid when observed by polarizing microscopy (see later).

Properties of Amyloid Proteins

Even though all amyloid deposits have a similar appearance and staining characteristics, amyloid is not a single chemical entity. In fact, more than 20 (at last count, 23) different proteins can aggregate and form fibrils with the appearance of amyloid. There are three major and several minor biochemical forms, which are deposited by different pathogenetic mechanisms. Therefore, amyloidosis should not be considered a single disease; rather it is a group of diseases having in common the deposition of similar-appearing proteins. At the heart of the morphologic similarity is the remarkably uniform physical organization of amyloid protein, which we consider first.

Physical Nature of Amyloid. By electron microscopy, all types of amyloid consist of continuous, nonbranching fibrils with a diameter of approximately 7.5 to 10 nm. X-ray crystallography and infrared spectroscopy demonstrate a characteristic cross- β -pleated sheet conformation (Fig. 6-44). This conformation is seen regardless of the clinical setting or chemical composition and is responsible for the distinctive Congo red staining and birefringence of amyloid.

Chemical Nature of Amyloid. Approximately 95% of the amyloid material consists of fibril proteins, the remaining 5% being the P component and other glycoproteins. The three most common forms of amyloid are the following:

- **The AL (amyloid light chain) protein is made up of complete immunoglobulin light chains, the amino-terminal fragments of light chains, or both.** Most of the AL proteins analyzed are composed of λ light chains or their fragments, but κ chains are present in some cases. The amyloid fibril protein of the AL type is produced from free Ig light chains secreted by a monoclonal population of plasma cells, and its deposition is associated with certain forms of plasma cell tumors (Chapter 13).

Figure 6-44 Structure of amyloid. **A**, A schematic diagram of an amyloid fiber showing four fibrils (there can be as many as six in each fiber) wound around one another with regularly spaced binding of the Congo red dye. **B**, Congo red staining shows apple-green birefringence under polarized light, a diagnostic feature of amyloid. **C**, Electron micrograph of 7.5- to 10-nm amyloid fibrils. (From Merlini G, Bellotti V: Molecular mechanisms of amyloidosis. *N Engl J Med* 2003;349:583-596, with permission of the Massachusetts Medical Society.)

- **The AA (amyloid-associated) type of amyloid fibril protein is derived from a unique non-Ig protein made by the liver.** It has a molecular weight of 8500 and consists of 76 amino acid residues. AA fibrils are derived by proteolysis from a larger (12,000 daltons) precursor in the serum called SAA (serum amyloid-associated) protein that is synthesized in the liver and circulates bound to high density lipoproteins. The production of SAA protein is increased in inflammatory states as part of the acute phase response; therefore, this form of amyloidosis is associated with chronic inflammation, and is often called *secondary amyloidosis*.
- **β -amyloid protein ($A\beta$) constitutes the core of cerebral plaques found in Alzheimer disease** as well as the amyloid deposited in walls of cerebral blood vessels in individuals with this disease. The $A\beta$ protein is a 4000-dalton peptide that is derived by proteolysis from a much larger transmembrane glycoprotein, called *amyloid precursor protein*. This form of amyloid is discussed in Chapter 28.

As mentioned, multiple other biochemically distinct proteins can also deposit as amyloid in a variety of clinical settings. Among these rarer causes of amyloidosis, the proteins most often involved are the following:

Figure 6-45 Pathogenesis of amyloidosis, showing the proposed mechanisms underlying deposition of the major forms of amyloid fibrils.

- *Transthyretin (TTR)* is a normal serum protein that binds and transports thyroxine and retinol. Several distinct mutant forms of TTR (and its fragments) are deposited in a group of genetically determined disorders referred to as familial amyloid polyneuropathies. Normal TTR is also deposited in the heart of aged individuals (senile systemic amyloidosis).
- β_2 -microglobulin, a component of MHC class I molecules and a normal serum protein, has been identified as the amyloid fibril subunit ($A\beta_2m$) in amyloidosis that complicates the course of patients on long-term hemodialysis.
- In a minority of cases of prion disease in the central nervous system, the misfolded *prion proteins* aggregate in the extracellular space and acquire the structural and staining characteristics of amyloid protein.
- In addition, other minor components are always present in amyloid. These include serum amyloid P component, proteoglycans, and highly sulfated glycosaminoglycans. Serum amyloid P protein may contribute to amyloid deposition by stabilizing the fibrils and decreasing their clearance.

Pathogenesis and Classification of Amyloidosis

Amyloidosis results from abnormal folding of proteins, which become insoluble, aggregate, and deposit as fibrils in extracellular tissues. Normally, misfolded proteins are degraded intracellularly in proteasomes, or extracellularly by macrophages. It appears that in amyloidosis, these quality control mechanisms fail, leading to accumulation of a misfolded protein outside cells. The proteins that form amyloid fall into two general categories (Fig. 6-45):

(1) normal proteins that have an inherent tendency to fold improperly, associate and form fibrils, and do so when they are produced in increased amounts; and (2) mutant proteins that are prone to misfolding and subsequent aggregation. The mechanisms of deposition of different types of amyloid are discussed below along with classification.

Because a given biochemical form of amyloid (e.g., AA) may be associated with amyloid deposition in diverse clinical settings, we follow a combined biochemical-clinical classification for our discussion (Table 6-17). Amyloid may be *systemic* (generalized), involving several organ systems, or it may be *localized*, when deposits are limited to a single organ, such as the heart.

On clinical grounds, the systemic, or generalized, pattern is subclassified into *primary amyloidosis*, when it is associated with some plasma cell disorder, or *secondary amyloidosis*, when it occurs as a complication of an underlying chronic inflammatory or tissue-destructive process. *Hereditary* or *familial amyloidosis* constitutes a separate, albeit heterogeneous group, with several distinctive patterns of organ involvement.

Primary Amyloidosis: Plasma Cell Disorders Associated with Amyloidosis. Amyloid in this category is usually systemic in distribution and is of the AL type. With approximately 2000 to 3000 new cases every year in the United States, this is the most common form of amyloidosis. In all cases, the disorder is caused by a clonal proliferation of plasma cells that synthesize an Ig that is prone to form amyloid due to its intrinsic physiochemical properties. Best defined is the occurrence of systemic amyloidosis in 5% to 15% of individuals with multiple myeloma, a plasma-cell

Table 6-17 Classification of Amyloidosis

Clinicopathologic Category	Associated Diseases	Major Fibril Protein	Chemically Related Precursor Protein
Systemic (Generalized) Amyloidosis			
Immunocyte dyscrasias with amyloidosis (primary amyloidosis)	Multiple myeloma and other monoclonal plasma cell proliferations	AL	Immunoglobulin light chains, chiefly λ type
Reactive systemic amyloidosis (secondary amyloidosis)	Chronic inflammatory conditions	AA	SAA
Hemodialysis-associated amyloidosis	Chronic renal failure	β_2 m	β_2 -microglobulin
Hereditary Amyloidosis			
Familial Mediterranean fever		AA	SAA
Familial amyloidotic neuropathies (several types)		ATTR	Transthyretin
Systemic senile amyloidosis		ATTR	Transthyretin
Localized Amyloidosis			
Senile cerebral	Alzheimer disease	A β	APP
Endocrine	Type 2 diabetes		
Medullary carcinoma of thyroid		A Cal	Calcitonin
Islets of Langerhans		AIAPP	Islet amyloid peptide
Isolated atrial amyloidosis		AANF	Atrial natriuretic factor

tumor characterized by multiple osteolytic lesions throughout the skeletal system (Chapter 13). The malignant plasma cells synthesize abnormal amounts of a single Ig (monoclonal gammopathy), producing an M (myeloma) protein spike on serum electrophoresis. In addition to the synthesis of whole Ig molecules, the malignant plasma cells often secrete free, unpaired κ or λ light chains (referred to as *Bence-Jones protein*). These may be found in the serum, and due to their small molecular size, Bence-Jones proteins are excreted and concentrated in the urine. In primary amyloidosis, the free light chains are not only present in serum and urine but are also deposited in tissues as amyloid. It should be noted, however, that the great majority of myeloma patients who have free light chains in serum and urine do not develop amyloidosis. Clearly, not all free light chains are equally likely to produce amyloid, and it is believed that the *amyloidogenic potential* of any particular light chain is largely determined by its specific amino acid sequence.

Most persons with AL amyloid do not have classic multiple myeloma or any other overt B-cell neoplasm; such cases have been traditionally classified as primary amyloidosis, because their clinical features derive from the effects of amyloid deposition without any other associated disease. In virtually all such cases, however, monoclonal immunoglobulins or free light chains, or both, can be found in the serum or urine. Most of these patients also have a modest increase in the number of plasma cells in the bone marrow, which presumably secrete the precursors of AL protein. Thus, these patients have an underlying monoclonal proliferation of plasma cells (*monoclonal gammopathy*) in which production of an abnormal protein, rather than production of tumor masses, is the predominant manifestation.

Reactive Systemic Amyloidosis. The amyloid deposits in this pattern are systemic in distribution and are composed of AA protein. This category was previously referred to as *secondary amyloidosis* because it is secondary to an

associated inflammatory condition. At one time, tuberculosis, bronchiectasis, and chronic osteomyelitis were the most important underlying conditions, but with the advent of effective antimicrobial chemotherapy the importance of these conditions has diminished. More commonly now, reactive systemic amyloidosis complicates rheumatoid arthritis, other connective tissue disorders such as ankylosing spondylitis, and inflammatory bowel disease, particularly Crohn disease and ulcerative colitis. Among these the most frequent associated condition is rheumatoid arthritis. Amyloidosis is reported to occur in approximately 3% of patients with rheumatoid arthritis and is clinically significant in one half of those affected. Heroin abusers who inject the drug subcutaneously also have a high occurrence rate of generalized AA amyloidosis. The chronic skin infections associated with “skin-popping” of narcotics seem to be responsible for the amyloidosis. Reactive systemic amyloidosis may also occur in association with solid tumors, the most common being renal cell carcinoma and Hodgkin lymphoma.

In this form of amyloidosis, SAA synthesis by liver cells is stimulated by cytokines such as IL-6 and IL-1 that are produced during inflammation; thus, long-standing inflammation leads to a sustained elevation of SAA levels. However, increased production of SAA by itself is not sufficient for the deposition of amyloid. There are two possible explanations for this. According to one view, SAA is normally degraded to soluble end products by the action of monocyte-derived enzymes. Conceivably, individuals who develop amyloidosis have an enzyme defect that results in incomplete breakdown of SAA, thus generating insoluble AA molecules. Alternatively, a genetically determined structural abnormality in the SAA molecule may render it resistant to degradation by macrophages.

Heredofamilial Amyloidosis. A variety of familial forms of amyloidosis have been described. Most of them are rare and occur in limited geographic areas. The most common and best studied is an autosomal recessive

condition called *familial Mediterranean fever*. This is an “autoinflammatory” syndrome associated with excessive production of the cytokine IL-1 in response to inflammatory stimuli. It is characterized clinically by attacks of fever accompanied by inflammation of serosal surfaces, including peritoneum, pleura, and synovial membrane. The gene for familial Mediterranean fever encodes a protein called *pyrin* (for its relation to fever), which is one of a complex of proteins that regulate inflammatory reactions via the production of proinflammatory cytokines (Chapter 3). This disorder is encountered largely in individuals of Armenian, Sephardic Jewish, and Arabic origins. It is sometimes associated with widespread amyloidosis. The amyloid fibril proteins are made up of AA proteins, suggesting that this form of amyloidosis is related to the recurrent bouts of inflammation.

In contrast to familial Mediterranean fever, a group of autosomal dominant familial disorders is characterized by deposition of amyloid predominantly in peripheral and autonomic nerves. These familial amyloidotic polyneuropathies have been described in different parts of the world. As mentioned before, in all of these genetic disorders, the fibrils are made up of mutant TTRs. In these disorders, TTRs are deposited as amyloid fibrils because genetically determined alterations of structure appear to render the TTRs prone to misfolding and aggregation, and resistant to proteolysis.

Hemodialysis-Associated Amyloidosis. Patients on long-term hemodialysis for renal failure can develop amyloidosis as a result of deposition of β_2 -microglobulin. This protein is present in high concentrations in the serum of persons with renal disease and in the past, it was retained in the circulation because it could not be filtered through dialysis membranes. Patients sometimes presented with carpal tunnel syndrome because of β_2 -microglobulin deposition. With new dialysis filters, the incidence of this complication has decreased substantially.

Localized Amyloidosis. Sometimes, amyloid deposits are limited to a single organ or tissue without involvement of any other site in the body. The deposits may produce grossly detectable nodular masses or be evident only on microscopic examination. Nodular deposits of amyloid are most often encountered in the lung, larynx, skin, urinary bladder, tongue, and the region about the eye. Frequently, there are infiltrates of lymphocytes and plasma cells in the periphery of these amyloid masses. At least in some cases, the amyloid consists of AL protein and may therefore represent a localized form of plasma cell-derived amyloid.

Endocrine Amyloid. Microscopic deposits of localized amyloid may be found in certain endocrine tumors, such as medullary carcinoma of the thyroid gland, islet tumors of the pancreas, pheochromocytomas, and undifferentiated carcinomas of the stomach, and in the islets of Langerhans in individuals with type 2 diabetes mellitus. In these settings the amyloidogenic proteins seem to be derived either from polypeptide hormones (e.g., medullary carcinoma) or from unique proteins (e.g., islet amyloid polypeptide). In medullary carcinomas of the thyroid, the presence of amyloid is an essential diagnostic feature.

Amyloid of Aging. Several well-documented forms of amyloid deposition occur with aging. *Senile systemic amyloidosis* refers to the systemic deposition of amyloid in elderly patients (usually in their 70s and 80s). Because of the dominant involvement and related dysfunction of the heart, this form was previously called *senile cardiac amyloidosis*. Those who are symptomatic present with a restrictive cardiomyopathy and arrhythmias (Chapter 12). The amyloid in this form is derived from normal TTR. In addition to the sporadic senile systemic amyloidosis, another form, affecting predominantly the heart, that results from the deposition of a mutant form of TTR has also been recognized. Approximately 4% of the black population in the United States expresses this mutant form of TTR, and cardiomyopathy has been identified in both homozygous and heterozygous patients. The precise prevalence of patients with this mutation who develop clinically manifest cardiac disease is not known.

MORPHOLOGY

There are no consistent or distinctive patterns of organ or tissue distribution of amyloid deposits in any of the categories cited. Nonetheless, a few generalizations can be made. In amyloidosis secondary to chronic inflammatory disorders, kidneys, liver, spleen, lymph nodes, adrenals, and thyroid, as well as many other tissues, are typically affected. Although amyloidosis associated with plasma cell proliferations cannot reliably be distinguished from the secondary form by its organ distribution, it more often involves the heart, gastrointestinal tract, respiratory tract, peripheral nerves, skin, and tongue. The localization of amyloid deposits in the hereditary syndromes is varied. In familial Mediterranean fever the amyloidosis may be widespread, involving the kidneys, blood vessels, spleen, respiratory tract, and (rarely) liver. The localization of amyloid in the remaining hereditary syndromes can be inferred from the designation of these entities.

Whatever the clinical disorder, the amyloidosis may or may not be apparent on macroscopic examination. When amyloid accumulates in larger amounts, the organ is frequently enlarged and the tissue appears gray with a waxy, firm consistency. **Histologically, the amyloid deposition is always extracellular and begins between cells**, often closely adjacent to basement membranes (Fig. 6-46A). As the amyloid accumulates, it encroaches on the cells, in time surrounding and destroying them. In the form associated with plasma cell proliferation, perivascular and vascular deposits are common.

The histologic diagnosis of amyloid is based almost entirely on its staining characteristics. The most common staining technique uses the dye Congo red, which under ordinary light imparts a pink or red color to amyloid deposits. Under polarized light the Congo red-stained amyloid shows so-called apple-green birefringence (Fig. 6-46B). This reaction is shared by all forms of amyloid and is caused by the crossed β -pleated configuration of amyloid fibrils. Confirmation can be obtained by electron microscopy, which reveals amorphous nonoriented thin fibrils. AA, AL, and ATTR types of amyloid can also be distinguished by specific immunohistochemical staining.

Figure 6-46 Amyloidosis. **A**, A section of the liver stained with Congo red reveals pink-red deposits of amyloid in the walls of blood vessels and along sinusoids. **B**, Note the yellow-green birefringence of the deposits when observed by polarizing microscope. (Courtesy Dr. Trace Worrell and Sandy Hinton, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas.)

The pattern of organ involvement in different clinical forms of amyloidosis is variable.

Kidney. Amyloidosis of the kidney is the most common and potentially the most serious form of organ involvement. Grossly, the kidneys may be of normal size and color, or, in advanced cases, they may be shrunken because of ischemia caused by vascular narrowing induced by the deposition of amyloid within arterial and arteriolar walls.

Histologically, the amyloid is deposited primarily in the glomeruli, but the interstitial peritubular tissue, arteries, and arterioles are also affected. The glomerular deposits first appear as subtle thickenings of the mesangial matrix, accompanied usually by uneven widening of the basement membranes of the glomerular capillaries. In time the mesangial depositions and the deposits along the basement membranes cause capillary narrowing and distortion of the glomerular vascular tuft. With progression of the glomerular amyloidosis, the capillary lumens are obliterated, and the obsolescent glomerulus is flooded by confluent masses or interlacing broad ribbons of amyloid (Fig. 6-47).

Spleen. Amyloidosis of the spleen may be inapparent grossly or may cause moderate to marked splenomegaly (up to 800 g). For completely mysterious reasons, one of two patterns

Figure 6-47 Amyloidosis of the kidney. The glomerular architecture is almost totally obliterated by the massive accumulation of amyloid.

of deposition is seen. In one, the deposits are largely limited to the splenic follicles, producing tapioca-like granules on gross inspection, designated sago spleen. In the other pattern, the amyloid involves the walls of the splenic sinusoids and connective tissue framework in the red pulp. Fusion of the early deposits gives rise to large, maplike areas of amyloidosis, creating what has been designated lardaceous spleen.

Liver. The deposits may be inapparent grossly or may cause moderate to marked hepatomegaly. Amyloid appears first in the space of Disse and then progressively encroaches on adjacent hepatic parenchymal cells and sinusoids (Fig. 6-46). In time, deformity, pressure atrophy, and disappearance of hepatocytes occur, causing total replacement of large areas of liver parenchyma. Vascular involvement and deposits in Kupffer cells are frequent. Normal liver function is usually preserved despite sometimes quite severe involvement of the liver.

Heart. Amyloidosis of the heart (Chapter 12) may occur in any form of systemic amyloidosis. It is also the major organ involved in senile systemic amyloidosis. The heart may be enlarged and firm, but more often it shows no significant changes on gross inspection. Histologically the deposits begin as focal subendocardial accumulations and within the myocardium between the muscle fibers. Expansion of these myocardial deposits eventually causes pressure atrophy of myocardial fibers. When the amyloid deposits are subendocardial, the conduction system may be damaged, accounting for the electrocardiographic abnormalities noted in some patients.

Other Organs. Nodular depositions in the tongue may cause macroglossia, giving rise to the designation tumor-forming amyloid of the tongue. The respiratory tract may be involved focally or diffusely from the larynx down to the smallest bronchioles. As mentioned earlier, a distinct form of amyloid is found in the brains of patients with Alzheimer disease. It may be present in so-called plaques as well as blood vessels (Chapter 28). Amyloidosis of peripheral and autonomic nerves is a feature of several familial amyloidotic neuropathies. Depositions of amyloid in patients on long-term hemodialysis are most prominent in the carpal ligament of the wrist, resulting in compression of the median nerve (carpal tunnel syndrome). These patients may also have extensive amyloid deposition in the joints.

Clinical Features. Amyloidosis may be found as an unsuspected anatomic change, having produced no clinical manifestations, or it may cause serious clinical problems and even death. The symptoms depend on the magnitude of the deposits and on the sites or organs affected. Clinical manifestations at first are often entirely nonspecific, such as weakness, weight loss, light-headedness, or syncope. Somewhat more specific findings appear later and most often relate to renal, cardiac, and gastrointestinal involvement.

Renal involvement gives rise to proteinuria that may be severe enough to cause the nephrotic syndrome (Chapter 20). Progressive obliteration of glomeruli in advanced cases ultimately leads to renal failure and uremia. Renal failure is a common cause of death. *Cardiac amyloidosis* may present as an insidious congestive heart failure. The most serious aspects of cardiac amyloidosis are conduction disturbances and arrhythmias, which may prove fatal. Occasionally, cardiac amyloidosis produces a restrictive pattern of cardiomyopathy and masquerades as chronic constrictive pericarditis (Chapter 12). *Gastrointestinal amyloidosis* may be entirely asymptomatic, or it may present in a variety of ways. Amyloidosis of the tongue may cause sufficient enlargement and inelasticity to hamper speech and swallowing. Depositions in the stomach and intestine may lead to malabsorption, diarrhea, and disturbances in digestion. *Vascular amyloidosis* causes vascular fragility that may lead to bleeding, sometimes massive, that can occur spontaneously or following seemingly trivial trauma. Additionally, in some cases AL amyloid binds and inactivates factor X, a critical coagulation factor, leading to a life-threatening bleeding disorder.

The diagnosis of amyloidosis depends on the histologic demonstration of amyloid deposits in tissues. The most common sites biopsied are the kidney, when renal manifestations are present, or rectal or gingival tissues in patients suspected of having systemic amyloidosis. Examination of abdominal fat aspirates stained with Congo red can also be used for the diagnosis of systemic amyloidosis. The test is quite specific, but its sensitivity is low. In suspected cases of AL amyloidosis, serum and urine protein electrophoresis and immunoelectrophoresis should be performed. Bone marrow aspirates in such cases often show monoclonal plasmacytosis, even in the absence of overt multiple myeloma. Scintigraphy with radiolabeled serum amyloid P (SAP) component is a rapid and specific test, since SAP binds to the amyloid deposits and reveals their presence. It also gives a measure of the extent of amyloidosis and can be used to follow patients undergoing treatment.

The prognosis for individuals with generalized amyloidosis is poor. Those with AL amyloidosis (not including multiple myeloma) have a median survival of 2 years after diagnosis. Persons with myeloma-associated amyloidosis have an even poorer prognosis. The outlook for individuals with reactive systemic amyloidosis is somewhat better and depends to some extent on the control of the underlying condition. Resorption of amyloid after treatment of the associated condition has been reported, but this is a rare occurrence. New therapeutic strategies aimed at correcting protein misfolding and inhibiting fibrillogenesis are being developed.

KEY CONCEPTS

Amyloidosis

- Amyloidosis is a disorder characterized by the extracellular deposits of misfolded proteins that aggregate to form insoluble fibrils.
- The deposition of these proteins may result from: excessive production of proteins that are prone to misfolding and aggregation; mutations that produce proteins that cannot fold properly and tend to aggregate; defective or incomplete proteolytic degradation of extracellular proteins.
- Amyloidosis may be localized or systemic. It is seen in association with a variety of primary disorders, including monoclonal B-cell proliferations (in which the amyloid deposits consist of immunoglobulin light chains); chronic inflammatory diseases such as rheumatoid arthritis (deposits of amyloid A protein, derived from an acute-phase protein produced in inflammation); Alzheimer disease (amyloid β protein); familial conditions in which the amyloid deposits consist of mutants of normal proteins (e.g., transthyretin in familial amyloid polyneuropathies); amyloidosis associated with dialysis (deposits of β_2 -microglobulin, whose clearance is defective).
- Amyloid deposits cause tissue injury and impair normal function by causing pressure on cells and tissues. They do not evoke an inflammatory response.

--	---	---

Cancer is the second leading cause of death in the United States; only cardiovascular diseases exact a higher toll. Even more agonizing than the mortality rate is the emotional and physical suffering inflicted by cancers. Patients and the public often ask, “When will there be a cure for this scourge?” The answer to this simple question is difficult, because cancer is not one disease but many disorders with widely different natural histories and responses to treatments. Some cancers, such as Hodgkin lymphoma, are curable, whereas others, such as pancreatic adenocarcinoma, are virtually always fatal. The only hope for controlling cancer lies in learning more about its causes and pathogenesis. Fortunately, great strides have been made in understanding its molecular basis and some good news has emerged: cancer mortality for both men and

women in the United States declined during the last decade of the twentieth century and has continued its downward course in the twenty-first.

In this chapter, we describe the vocabulary of tumor biology and pathology and then review the morphologic characteristics that define neoplasia and allow benign and malignant tumors to be identified and distinguished. Also reviewed is the epidemiology of cancer, which provides a measure of the impact of cancer on human populations as well as clues to its environmental causes, insights that have led to effective prevention campaigns against certain cancers. Building on this foundation, we then discuss the biologic properties of tumors and the molecular basis of carcinogenesis, emphasizing the critical role that genetic alterations play in the development of neoplasia.

Finally, we turn to cancer diagnosis, focusing on new technologies that are helping to direct the use of cancer drugs that are targeted at particular molecular lesions. Throughout, we give examples of new analytic methods and therapies that are not only changing our approach to cancer treatment but also providing new insights into cancer pathophysiology.

Nomenclature

Neoplasia means “new growth,” and a new growth is called a *neoplasm*. *Tumor* originally applied to the swelling caused by inflammation, but the nonneoplastic usage of tumor has almost vanished; thus, the term is now equated with neoplasm. *Oncology* (Greek *oncos* = tumor) is the study of tumors or neoplasms.

Although all physicians know what they mean when they use the term *neoplasm*, it has been surprisingly difficult to develop an accurate definition. In the pre-molecular era, the eminent British oncologist Willis came closest: “A neoplasm is an abnormal mass of tissue, the growth of which exceeds and is uncoordinated with that of the normal tissues and persists in the same excessive manner after cessation of the stimuli which evoked the change.” In the modern era, a neoplasm can be defined as a disorder of cell growth that is triggered by a series of acquired mutations affecting a single cell and its clonal progeny. As discussed later, the causative mutations give the neoplastic cells a survival and growth advantage, resulting in excessive proliferation that is independent of physiologic growth signals (autonomous).

All tumors have two basic components: (1) neoplastic cells that constitute the tumor *parenchyma* and (2) *reactive stroma* made up of connective tissue, blood vessels, and variable numbers of cells of the adaptive and innate immune system. The classification of tumors and their biologic behavior are based primarily on the parenchymal component, but their growth and spread are critically dependent on their stroma. In some tumors, connective tissue is scant and so the neoplasm is soft and fleshy. In other cases, the parenchymal cells stimulate the formation of an abundant collagenous stroma, referred to as *desmoplasia*. Some desmoplastic tumors—for example, some cancers of the female breast—are stony hard or *scirrhous*.

Benign Tumors. A tumor is said to be *benign* when its gross and microscopic appearances are considered relatively innocent, implying that it will remain localized, will not spread to other sites, and is amenable to local surgical removal; understandably, the patient generally survives. However, “benign” tumors may cause significant morbidity and are sometimes even fatal.

In general, benign tumors are designated by attaching the suffix *-oma* to the name of the cell type from which the tumor originates. Tumors of mesenchymal cells generally follow this rule. For example, a benign tumor arising in fibrous tissue is called a *fibroma*, whereas a benign cartilaginous tumor is a *chondroma*. In contrast, the nomenclature of benign epithelial tumors is more complex; some are classified based on their cells of origin, others on microscopic pattern, and still others on their macroscopic architecture.

Adenoma is applied to benign epithelial neoplasms derived from glands, although they may or may not form glandular structures. On this basis, a benign epithelial neoplasm that arises from renal tubular cells growing in the form of numerous tightly clustered small glands is termed an *adenoma*, as is a heterogeneous mass of adrenal cortical cells growing as a solid sheet. Benign epithelial neoplasms producing microscopically or macroscopically visible fingerlike or warty projections from epithelial surfaces are referred to as *papillomas*. Those that form large cystic masses, such as in the ovary, are referred to as *cystadenomas*. Some tumors produce papillary patterns that protrude into cystic spaces and are called papillary cystadenomas. When a neoplasm—benign or malignant—produces a macroscopically visible projection above a mucosal surface and projects, for example, into the gastric or colonic lumen, it is termed a *polyp*. If the polyp has glandular tissue, it is called an adenomatous polyp (Fig. 7-1).

Malignant Tumors. Malignant tumors are collectively referred to as *cancers*, derived from the Latin word for crab, because they tend to adhere to any part that they seize on in an obstinate manner. **Malignant tumors can invade and destroy adjacent structures and spread to distant sites (metastasize) to cause death.** Not all cancers pursue so deadly a course. Some are discovered early enough to be excised surgically or are treated successfully with chemotherapy or radiation, but the designation *malignant* always raises a red flag.

The nomenclature of malignant tumors essentially follows the same schema used for benign neoplasms, with certain additions. Malignant tumors arising in solid mesenchymal tissues are usually called *sarcomas* (Greek *sar* = fleshy; e.g., fibrosarcoma, chondrosarcoma, leiomyosarcoma, and rhabdomyosarcoma), whereas those arising from blood-forming cells are designated *leukemias* (literally, white blood) or *lymphomas* (tumors of lymphocytes or their precursors). Malignant neoplasms of epithelial cell origin, derived from any of the three germ layers, are called *carcinomas*. Thus, cancers arising in the ectodermally derived epidermis, the mesodermally derived renal tubules, and the endodermally derived lining of the gastrointestinal tract are all termed carcinomas. Carcinomas may be further qualified. *Squamous cell carcinoma* denotes a cancer in which the tumor cells resemble stratified squamous epithelium, and *adenocarcinoma* denotes a lesion in which the neoplastic epithelial cells grow in a glandular pattern. Sometimes the tissue or organ of origin can be identified and is added as a descriptor, as in renal cell adenocarcinoma or bronchogenic squamous cell carcinoma. Not infrequently, a cancer is composed of cells of unknown tissue origin, and must be designated merely as an undifferentiated malignant tumor.

Mixed Tumors. In most benign and malignant neoplasms, all of the parenchymal cells closely resemble one another. Infrequently, however, divergent differentiation of a single neoplastic clone creates a *mixed tumor*, such as the mixed tumor of salivary gland. These tumors contain epithelial components scattered within a myxoid stroma that may contain islands of cartilage or bone (Fig. 7-2). All of these elements arise from a single clone capable of capable of

Figure 7-1 Colonic polyp. **A**, An adenomatous (glandular) polyp is projecting into the colonic lumen and is attached to the mucosa by a distinct stalk. **B**, Gross appearance of several colonic polyps.

producing both epithelial and myoepithelial cells; thus, the preferred designation of this neoplasm is *pleomorphic adenoma*. The great majority of neoplasms, even mixed tumors, are composed of cells from a single germ layer. An exception is a tumor called a *teratoma*, which contains recognizable mature or immature cells or tissues belonging to more than one germ cell layer (and sometimes all three). Teratoma originates from totipotential germ cells that are normally present in the ovary and testis and sometimes also found in abnormal midline embryonic rests. Such cells can differentiate into any of the cell types found in the adult body and so, not surprisingly, may give rise to neoplasms that contain, in a helter-skelter fashion, bone, epithelium, muscle, fat, nerve, and other tissues. A particularly common pattern is seen in the *ovarian cystic teratoma (dermoid cyst)*, which differentiates principally along ectodermal lines to create a cystic tumor lined by skin replete with hair, sebaceous glands, and tooth structures (Fig. 7-3).

The nomenclature of the more common types of tumors is presented in Table 7-1. It is evident from this list that there are some inappropriate but deeply entrenched usages. For instance, benign-sounding designations such as lymphoma, melanoma, mesothelioma, and seminoma are used for certain malignant neoplasms. It is also important to recognize that ominous sounding terms are applied to some trivial lesions. *Hamartomas* are disorganized but benign masses composed of cells indigenous to the involved site. Once thought to be a developmental malformation unworthy of the -oma designation, many in fact have clonal chromosomal aberrations that are acquired through somatic mutations and on this basis are now considered neoplasms. *Choristoma* is the term applied to a heterotopic rest of cells. For example, a small nodule of well-developed and normally organized pancreatic tissue may be found in

the submucosa of the stomach, duodenum, or small intestine. The term *choristoma*, suggesting a neoplasm, imparts a gravity to these lesions that is far beyond their actual significance.

Characteristics of Benign and Malignant Neoplasms

Nothing is more important to the individual with a tumor than being told “It is benign,” and so the differentiation

Figure 7-2 This mixed tumor of the parotid gland contains epithelial cells forming ducts and myxoid stroma that resemble cartilage. (Courtesy Dr. Trace Worrell, University of Texas Southwestern Medical School, Dallas, Texas.)

Figure 7-3 **A**, Gross appearance of an opened cystic teratoma of the ovary. Note the presence of hair, sebaceous material, and tooth. **B**, A microscopic view of a similar tumor shows skin, sebaceous glands, fat cells, and a tract of neural tissue (*arrow*).

between benign and malignant tumors is one of the most important distinctions a pathologist can make. Although an innocent face may mask an ugly nature, in general, benign and malignant tumors can be distinguished on the basis of a number of histologic and anatomic features, (described below). Malignant tumors also tend to grow more rapidly than benign tumors, but there are so many exceptions that growth rate is not a very useful discriminator between benignity and malignancy. In fact, even cancers

exhibit remarkably varied growth rates, from slow-growing tumors associated with survival for years, often without treatment, to rapidly growing tumors that may be lethal within months or weeks.

Differentiation and Anaplasia

Differentiation refers to the extent to which neoplastic parenchymal cells resemble the corresponding normal

Table 7-1 Nomenclature of Tumors

Tissue of Origin	Benign	Malignant	Tissue of Origin	Benign	Malignant
Composed of one parenchymal cell type			Tumors of Epithelial Origin (cont'd)		
Tumors of Mesenchymal Origin			Epithelial lining of glands or ducts	Adenoma Papilloma Cystadenoma	Adenocarcinoma Papillary carcinomas Cystadenocarcinoma
Connective tissue and derivatives	Fibroma Lipoma Chondroma Osteoma	Fibrosarcoma Liposarcoma Chondrosarcoma Osteogenic sarcoma	Respiratory passages	Bronchial adenoma	Bronchogenic carcinoma
Vessels and surface coverings			Renal epithelium	Renal tubular adenoma	Renal cell carcinoma
Blood vessels	Hemangioma	Angiosarcoma	Liver cells	Hepatic adenoma	Hepatocellular carcinoma
Lymph vessels	Lymphangioma	Lymphangiosarcoma	Urinary tract epithelium (transitional)	Transitional cell papilloma	Transitional cell carcinoma
Mesothelium	Benign fibrous tumor	Mesothelioma	Placental epithelium	Hydatidiform mole	Choriocarcinoma
Brain coverings	Meningioma	Invasive meningioma	Testicular epithelium (germ cells)		Seminoma Embryonal carcinoma
Blood Cells and Related Cells			Tumors of Melanocytes	Nevus	Malignant melanoma
Hematopoietic cells		Leukemias	More than one neoplastic cell type—mixed tumors, usually derived from one germ cell layer		
Lymphoid tissue		Lymphomas	Salivary glands	Pleomorphic adenoma (mixed tumor of salivary origin)	Malignant mixed tumor of salivary gland origin
Muscle			Renal anlage		Wilms tumor
Smooth	Leiomyoma	Leiomyosarcoma	More than one neoplastic cell type derived from more than one germ cell layer—teratogenous		
Striated	Rhabdomyoma	Rhabdomyosarcoma	Totipotent cells in gonads or in embryonic rests	Mature teratoma, dermoid cyst	Immature teratoma, teratocarcinoma
Tumors of Epithelial Origin					
Stratified squamous	Squamous cell papilloma	Squamous cell carcinoma			
Basal cells of skin or adnexa		Basal cell carcinoma			

Figure 7-4 Leiomyoma of the uterus. This benign, well-differentiated tumor contains interlacing bundles of neoplastic smooth muscle cells that are virtually identical in appearance to normal smooth muscle cells in the myometrium.

Figure 7-6 Malignant tumor (adenocarcinoma) of the colon. Note that compared with the well-formed and normal-looking glands characteristic of a benign tumor (Fig. 7-5), the cancerous glands are irregular in shape and size and do not resemble the normal colonic glands. This tumor is considered differentiated because gland formation is seen. The malignant glands have invaded the muscular layer of the colon. (Courtesy Dr. Trace Worrell, University of Texas Southwestern Medical School, Dallas, Texas.)

parenchymal cells, both morphologically and functionally; lack of differentiation is called *anaplasia*. In general, benign tumors are well differentiated (Figs. 7-4 and 7-5). The neoplastic cell in a tumor of benign adipocytes—a lipoma—so closely resembles normal adipocytes that it may be impossible to recognize the tumor by microscopic examination of individual cells. Only the growth of these cells into a discrete mass discloses the neoplastic nature of the lesion. One may get so close to the tree that one loses sight of the forest. In well-differentiated benign tumors, mitoses are usually rare and are of normal configuration.

In contrast, while malignant neoplasms exhibit a wide range of parenchymal cell differentiation, most exhibit morphologic alterations that betray their malignant nature (Fig. 7-6). There are exceptions, however. At one end of the spectrum, certain well-differentiated adenocarcinomas of the thyroid, for example, form normal-appearing

follicles, and some squamous cell carcinomas contain cells that appear identical to normal squamous epithelial cells (Fig. 7-7). Thus, the morphologic distinction between well-differentiated malignant tumors and benign tumors may be quite subtle. At the other end of the spectrum lie tumors exhibiting little or no evidence of differentiation (Fig. 7-8). In between the two extremes lie tumors that are loosely referred to as moderately well differentiated.

Malignant neoplasms that are composed of poorly differentiated cells are said to be *anaplastic*. Lack of differentiation, or *anaplasia*, is considered a hallmark of malignancy. The term *anaplasia* means “to form backward,” implying a reversal of differentiation to a more primitive level. Whether cancers in fact arise from “reverse

Figure 7-5 Benign tumor (adenoma) of the thyroid. Note the normal-looking (well-differentiated), colloid-filled thyroid follicles. (Courtesy Dr. Trace Worrell, University of Texas Southwestern Medical School, Dallas, Texas.)

Figure 7-7 Well-differentiated squamous cell carcinoma of the skin. The tumor cells are strikingly similar to normal squamous epithelial cells, with intercellular bridges and nests of keratin pearls (arrow). (Courtesy Dr. Trace Worrell, University of Texas Southwestern Medical School, Dallas, Texas.)

Figure 7-8 Anaplastic tumor showing cellular and nuclear variation in size and shape. The prominent cell in the center field has an abnormal tripolar spindle.

differentiation” of mature normal cells or instead from incomplete differentiation of less mature cells is an important fundamental issue that is discussed later.

Lack of differentiation, or anaplasia, is often associated with many other morphologic changes.

- **Pleomorphism.** Cancer cells often display pleomorphism—variation in size and shape (Fig. 7-9). Thus, cells within the same tumor are not uniform, but range from small cells with an undifferentiated appearance, to *tumor giant cells* many times larger than their neighbors. Some tumor giant cells possess only a single huge polymorphic nucleus, while others may have two or more large, hyperchromatic nuclei (Fig. 7-9). These giant cells are not to be confused with inflammatory Langhans or foreign body giant cells, which are derived from macrophages and contain many small, normal-appearing nuclei.
- **Abnormal nuclear morphology.** Characteristically, the nuclei are disproportionately large for the cell, with

Figure 7-9 Pleomorphic tumor of the skeletal muscle (rhabdomyosarcoma). Note the marked cellular and nuclear pleomorphism, hyperchromatic nuclei, and tumor giant cells. (Courtesy Dr. Trace Worrell, University of Texas Southwestern Medical School, Dallas, Texas.)

a nuclear-to-cytoplasm ratio that may approach 1:1 instead of the normal 1:4 or 1:6. The nuclear shape is variable and often irregular, and the chromatin is often coarsely clumped and distributed along the nuclear membrane, or more darkly stained than normal (*hyperchromatic*). Abnormally large nucleoli are also commonly seen.

- **Mitoses.** Unlike in benign tumors and some well-differentiated malignant neoplasms, in undifferentiated tumors, many cells are in mitosis, reflecting the high proliferative activity of the parenchymal cells. The presence of mitoses, however, does not necessarily indicate that a tumor is malignant or that the tissue is neoplastic. Mitoses are indicative of rapid cell growth. Hence, cells in mitosis are often seen in normal tissues exhibiting rapid turnover, such as the epithelial lining of the gut and nonneoplastic proliferations such as hyperplasias. More important as a morphologic feature of malignancy are *atypical, bizarre mitotic figures*, sometimes with tripolar, quadripolar, or multipolar spindles (Fig. 7-8).
- **Loss of polarity.** In addition to the cytologic abnormalities, the orientation of anaplastic cells is markedly disturbed. Sheets or large masses of tumor cells grow in an anarchic, disorganized fashion.
- **Other changes.** Growing tumor cells obviously require a blood supply, but often the vascular stroma is insufficient, and as a result in many rapidly growing malignant tumors develop large central areas of ischemic necrosis.

As one might surmise, the better the differentiation of the transformed cell, the more completely it retains the functional capabilities of its normal counterpart. Thus, benign neoplasms and well-differentiated carcinomas of endocrine glands frequently secrete hormones characteristic of their origin. Increased levels of these hormones in the blood are used clinically to detect and follow such tumors. Well-differentiated squamous cell carcinomas of the epidermis synthesize keratin, and well-differentiated hepatocellular carcinomas elaborate bile. Highly anaplastic undifferentiated cells, whatever their tissue of origin, lose their resemblance to the normal cells from which they have arisen. In some instances, new and unanticipated functions emerge. Thus, some tumors express fetal proteins that are not produced by comparable cells in the adult, while others express proteins that are normally only found in other types of adult cells. For example, bronchogenic carcinomas may produce corticotropin, parathyroid-like hormone, insulin, glucagon, and other hormones, giving rise to paraneoplastic syndromes (described later). Despite such exceptions, rapidly growing anaplastic tumors are less likely to have specialized functional activity. The cells in benign tumors are almost always well differentiated and resemble their normal cells of origin; the cells in cancer are more or less differentiated, but some derangement of differentiation is always present.

Metaplasia and Dysplasia. *Metaplasia* is defined as the replacement of one type of cell with another type (Chapter 2). Metaplasia is nearly always found in association with tissue damage, repair, and regeneration. Often the replacing cell type is better suited to some alteration in

Figure 7-10 **A**, Carcinoma in situ. A low-power view shows that the epithelium is entirely replaced by atypical dysplastic cells. There is no orderly differentiation of squamous cells. The basement membrane is intact, and there is no tumor in the subepithelial stroma. **B**, A high-power view of another region shows failure of normal differentiation, marked nuclear and cellular pleomorphism, and numerous mitotic figures extending toward the surface.

the local environment. For example, gastroesophageal reflux damages the squamous epithelium of the esophagus, leading to its replacement by glandular (gastric or intestinal) epithelium more suited to an acidic environment.

Dysplasia is a term that literally means “disordered growth.” It is encountered principally in epithelia and is characterized by a constellation of changes that include a loss in the uniformity of the individual cells as well as a loss in their architectural orientation. Dysplastic cells may exhibit considerable pleomorphism and often contain large hyperchromatic nuclei with a high nuclear-to-cytoplasmic ratio. The architecture of the tissue may be disorderly. For example, in dysplastic squamous epithelium the normal progressive maturation of tall cells in the basal layer to flattened squames on the surface may fail in part or entirely, leading to replacement of the epithelium by basal-appearing cells with hyperchromatic nuclei. In addition, mitotic figures are more abundant than in the normal tissue and rather than being confined to the basal layer may instead be seen at all levels, including surface cells.

When dysplastic changes are marked and involve the full thickness of the epithelium, but the lesion does not penetrate the basement membrane, it is considered a **pre-invasive neoplasm** and is referred to as **carcinoma in situ** (Fig. 7-10). Once the tumor cells breach the basement membrane, the tumor is said to be **invasive**. Dysplastic changes are often found adjacent to foci of invasive carcinoma, and in some situations, such as in long-term cigarette smokers and persons with Barrett esophagus, severe epithelial dysplasia frequently antedates the appearance of cancer. Moreover, some mutations associated with full blown cancers (described later) may be present in even “mild” dysplasias. Thus, although **dysplasia may be a precursor to malignant transformation, it does not always progress to cancer**. With removal of the inciting causes, mild to moderate dysplasias that do not involve the entire thickness of epithelium may be completely reversible. Even carcinoma in situ may persist for years before it becomes invasive. Finally, while it should be noted that dysplasia often occurs in metaplastic epithelium, not all metaplastic epithelium is dysplastic.

Local Invasion

The growth of cancers is accompanied by progressive infiltration, invasion, and destruction of the surrounding tissue, whereas nearly all benign tumors grow as cohesive expansile masses that remain localized to their site of origin and lack the capacity to infiltrate, invade, or metastasize to distant sites. Because benign tumors grow and expand slowly, they usually develop a rim of compressed fibrous tissue called a *capsule* that separates them from the host tissue. This capsule consists largely of extracellular matrix deposited by stromal cells such as fibroblasts, which are activated by hypoxic damage resulting from the pressure of the expanding tumor. Such encapsulation does not prevent tumor growth, but it creates a tissue plane that makes the tumor discrete, readily palpable, moveable (non-fixed), and easily excisable by surgical enucleation (Figs. 7-11 and 7-12). There are a few exceptions to this rule, however. For example, hemangiomas (neoplasms composed of tangled blood vessels) are often unencapsulated and permeate the site in which they arise (e.g., the dermis of the skin and the liver); when such lesions are extensive, they may be unresectable.

In contrast, malignant tumors are, in general, poorly demarcated from the surrounding normal tissue, and a well-defined cleavage plane is lacking (Figs. 7-13 and 7-14). Slowly expanding malignant tumors, however, may develop an apparently enclosing fibrous capsule and may push along a broad front into adjacent normal structures. Histologic examination of such “pseudoencapsulated” masses almost always shows rows of cells penetrating the margin and infiltrating the adjacent structures, a crablike pattern of growth that constitutes the popular image of cancer.

Next to the development of metastases, invasiveness is the most reliable feature that differentiates cancers from benign tumors. Most malignant tumors do not recognize normal anatomic boundaries and can be expected to penetrate the wall of the colon or uterus, for example, or fungate through the surface of the skin. Such invasiveness makes their surgical resection difficult or impossible, and even if the tumor appears well circumscribed it is

Figure 7-11 Fibroadenoma of the breast. The tan-colored, encapsulated small tumor is sharply demarcated from the whiter breast tissue.

necessary to remove a considerable margin of apparently normal tissues adjacent to the infiltrative neoplasm in order to ensure complete local excision. As noted earlier, some cancers seem to evolve from a preinvasive stage referred to as *carcinoma in situ*. This commonly occurs in carcinomas of the skin, breast, and certain other sites and is best illustrated by carcinoma of the uterine cervix (Chapter 21). In situ epithelial cancers display the cytologic features of malignancy without invasion of the basement membrane. They may be considered one step removed from invasive cancer; with time, most penetrate the basement membrane and invade the subepithelial stroma.

Metastasis

Metastasis is defined by the spread of a tumor to sites that are physically discontinuous with the primary tumor, and unequivocally marks a tumor as malignant, as by definition benign neoplasms do not metastasize. The invasiveness of cancers permits them to penetrate into blood vessels, lymphatics, and body cavities, providing the opportunity for spread. All malignant tumors can metastasize, but some do so very infrequently. Examples include malignant neoplasms of the glial cells in the central nervous system, called *gliomas*, and basal cell carcinomas of the

Figure 7-12 Microscopic view of fibroadenoma of the breast seen in Figure 7-11. The fibrous capsule (*right*) delimits the tumor from the surrounding tissue. (Courtesy Dr. Trace Worrell, University of Texas Southwestern Medical School, Dallas, Texas.)

Figure 7-13 Cut section of an invasive ductal carcinoma of the breast. The lesion is retracted, infiltrating the surrounding breast substance, and would be stony hard on palpation. (Courtesy Dr. Trace Worrell, University of Texas Southwestern Medical School, Dallas, Texas.)

skin. Both of these cancers invade early in their course, but rarely metastasize. It is evident then that the properties of invasion and metastasis are separable.

In general, the likelihood of a primary tumor metastasizing correlates with lack of differentiation, aggressive local invasion, rapid growth, and large size. There are innumerable exceptions, however. Small, well-differentiated, slowly growing lesions sometimes metastasize widely; conversely, some rapidly growing, large lesions remain localized for years. Many factors relating to both invader and host are involved.

Approximately 30% of newly diagnosed solid tumors (excluding skin cancers other than melanomas) present with metastases. Metastatic spread strongly reduces the possibility of cure; hence, short of prevention of cancer, no achievement would be of greater benefit to patients than an effective means to block metastasis, with the important caveat that many tumors destined to kill the patient have already spread at the time of initial diagnosis. Blood cancers (the leukemias and lymphomas, sometimes called

Figure 7-14 Low power microscopic view of invasive breast cancer. Note the irregular infiltrative borders without a well-defined capsule and intense stromal reaction. (Courtesy Dr. Susan Lester, Brigham and Women's Hospital, Boston, Mass.)

liquid tumors) are derived from blood-forming cells that normally have the capacity to enter the bloodstream and travel to distant sites; as a result, leukemias and lymphomas are often disseminated at diagnosis and are always taken to be malignant.

Pathways of Spread

Dissemination of cancers may occur through one of three pathways: (1) direct seeding of body cavities or surfaces, (2) lymphatic spread, and (3) hematogenous spread. Although iatrogenic spread of tumor cells on surgical instruments may occur—it is the reason, for example, why biopsies of testicular masses are never done—it is generally rare and not discussed further.

Seeding of Body Cavities and Surfaces. Seeding of body cavities and surfaces may occur whenever a malignant neoplasm penetrates into a natural “open field” lacking physical barriers. Most often involved is the peritoneal cavity (Fig. 7-15), but any other cavity—pleural, pericardial, subarachnoid, and joint spaces—may be affected. Such seeding is particularly characteristic of carcinomas arising in the ovaries, which, not infrequently, spread to peritoneal surfaces, which become coated with a heavy cancerous glaze. Remarkably, the tumor cells may remain confined to the surface of the abdominal viscera without penetrating into the substance. Sometimes mucus-secreting appendiceal carcinomas or ovarian carcinomas fill the peritoneal cavity with a gelatinous neoplastic mass referred to as *pseudomyxoma peritonei*.

Lymphatic Spread. Transport through lymphatics is the most common pathway for the initial dissemination of carcinomas (Fig. 7-16). Sarcomas may also use this route. Tumors do not contain functional lymphatics, but lymphatic vessels located at the tumor margins are apparently sufficient for the lymphatic spread of tumor cells. The emphasis on lymphatic spread for carcinomas and hematogenous spread for sarcomas is misleading, because ultimately there are numerous interconnections between the vascular and the lymphatic systems. The pattern of lymph

Figure 7-16 Axillary lymph node with metastatic breast carcinoma. Note the aggregates of tumor cells within the substance of the node and the dilated lymphatic channel. (Courtesy Dr. Susan Lester, Brigham and Women’s Hospital, Boston, Mass.)

node involvement follows the natural routes of lymphatic drainage. Because carcinomas of the breast usually arise in the upper outer quadrants, they generally disseminate first to the axillary lymph nodes. Cancers of the inner quadrants drain to the nodes along the internal mammary arteries. Thereafter, the infraclavicular and supraclavicular nodes may become involved. Carcinomas of the lung arising in the major respiratory passages metastasize first to the perihilar tracheobronchial and mediastinal nodes. Local lymph nodes, however, may be bypassed—so-called skip metastasis—because of venous-lymphatic anastomoses or because inflammation or radiation has obliterated lymphatic channels.

In breast cancer, determining the involvement of axillary lymph nodes is important for assessing the future course of the disease and for selecting suitable therapeutic strategies. To avoid the considerable surgical morbidity associated with a full axillary lymph node dissection, *biopsy of sentinel nodes* is often used to assess the presence or absence of metastatic lesions in the lymph nodes. **A sentinel lymph node is defined as “the first node in a regional lymphatic basin that receives lymph flow from the primary tumor.”** Sentinel node mapping can be done by injection of radiolabeled tracers or colored dyes, and examination of frozen sections of the sentinel lymph node performed during surgery can guide the surgeon to the appropriate therapy. Sentinel node examination has also been used for detecting the spread of melanomas, colon cancers, and other tumors.

In many cases, the regional nodes serve as effective barriers to further dissemination of the tumor, at least for a while. Conceivably, after arrest within the node the cells may be destroyed by a tumor-specific immune response. Drainage of tumor cell debris or tumor antigens, or both, also induces reactive changes within nodes. Thus, enlargement of nodes may be caused by the spread and growth of cancer cells or reactive hyperplasia (Chapter 13). Therefore, nodal enlargement in proximity to a cancer, while it must arouse suspicion, does not necessarily equate with dissemination of the primary lesion.

Figure 7-17 A liver studded with metastatic cancer.

Hematogenous Spread. Hematogenous spread is typical of sarcomas but is also seen with carcinomas. Arteries, with their thicker walls, are less readily penetrated than are veins. Arterial spread may occur, however, when tumor cells pass through the pulmonary capillary beds or pulmonary arteriovenous shunts or when pulmonary metastases themselves give rise to additional tumor emboli. In such vascular spread, several factors influence the patterns of distribution of the metastases. With venous invasion, the bloodborne cells follow the venous flow draining the site of the neoplasm, and the tumor cells often come to rest in the first capillary bed they encounter. Understandably the liver (Fig. 7-17) and the lungs (Fig. 7-18) are most frequently involved in such hematogenous dissemination, because all portal area drainage flows to the liver and all caval blood flows to the lungs. Cancers arising in close proximity to the vertebral column often embolize through the paravertebral plexus, and this pathway is involved in the frequent vertebral metastases of carcinomas of the thyroid and prostate.

Certain cancers have a propensity for invasion of veins. Renal cell carcinoma often invades the branches of the renal vein and then the renal vein itself, from where it may

Table 7-2 Comparisons Between Benign and Malignant Tumors

Characteristics	Benign	Malignant
Differentiation/anaplasia	Well differentiated; structure sometimes typical of tissue of origin	Some lack of differentiation (anaplasia); structure often atypical
Rate of growth	Usually progressive and slow; may come to a standstill or regress; mitotic figures rare and normal	Erratic, may be slow to rapid; mitotic figures may be numerous and abnormal
Local invasion	Usually cohesive, expansile, well-demarcated masses that do not invade or infiltrate surrounding normal tissues	Locally invasive, infiltrating surrounding tissue; sometimes may be misleadingly cohesive and expansile
Metastasis	Absent	Frequent; more likely with large undifferentiated primary tumors

grow in a snakelike fashion up the inferior vena cava, sometimes reaching the right side of the heart. Hepatocellular carcinomas often penetrate portal and hepatic radicles to grow within them into the main venous channels. Remarkably, such intravenous growth may not be accompanied by widespread dissemination. Histologic evidence of penetration of small vessels at the site of the primary neoplasm is obviously an ominous feature.

Many observations suggest that mere anatomic localization of the neoplasm and natural pathways of venous drainage do not wholly explain the systemic distributions of metastases. For example, breast carcinoma preferentially spreads to bone, bronchogenic carcinomas tend to involve the adrenals and the brain, and neuroblastomas spread to the liver and bones. Conversely, skeletal muscles and the spleen, despite receiving a high percentage of the cardiac output and having large vascular beds, are rarely the site of secondary deposits. The probable basis of such tissue-specific homing of tumor cells is discussed later.

The distinguishing features of benign and malignant tumors are summarized in Table 7-2 and Figure 7-19. Having completed our overview of the morphology and behavior of neoplasms, we now discuss the pathogenesis of neoplasia, starting with clues gleaned from studies of the epidemiology of cancer.

KEY CONCEPTS

Characteristics of Benign and Malignant Neoplasms

- Benign and malignant tumors can be distinguished from one another based on the degree of differentiation, rate of growth, local invasiveness, and distant spread.
- Benign tumors resemble the tissue of origin and are well differentiated; malignant tumors are less well differentiated or completely undifferentiated (anaplastic).
- Benign tumors are more likely to retain functions of their cells of origin, whereas malignant tumors sometimes acquire unexpected functions due to derangements in differentiation.

Figure 7-19 Comparison between a benign tumor of the myometrium (leiomyoma) and a malignant tumor of the same origin (leiomyosarcoma).

- Benign tumors are slow growing, while malignant tumors generally grow faster.
- Benign tumors are circumscribed and have a capsule; malignant tumors are poorly circumscribed and invade surrounding normal tissues.
- Benign tumors remain localized at the site of origin, whereas malignant tumors metastasize to distant sites.

Epidemiology of Cancer

Study of cancer patterns in populations has contributed substantially to knowledge about its origins. Epidemiologic studies have established the causative link between smoking and lung cancer, and comparison of diet and cancer rates in the Western world and the developing world has implicated high dietary fat and low fiber in the development of colon cancer. Major insights into the causes of cancer can be obtained by epidemiologic studies that relate particular environmental, racial (possibly hereditary), and cultural influences to the occurrence of specific neoplasms. Certain diseases associated with an increased risk of developing cancer also provide clues to the pathogenesis of cancer. In the following sections, we discuss the overall incidence of cancer and then review factors relating to the patient and the environment that influence the predisposition to cancer.

The Global Impact of Cancer

In 2008, it was estimated that there were about 12.7 million new cancer cases worldwide, leading to 7.6

million deaths (21,000 deaths per day). Due to increasing population size and age, by 2030 it is projected that the number of cancer cases and cancer-related deaths worldwide will increase to 21.4 million and 13.2 million, respectively. Cancer is ubiquitous in human populations; the only certain way to avoid cancer is to not be born, as to live is to incur risk. However, there is remarkable geographic variation in the incidence of specific cancers that is believed to stem mainly from differences in exposure to environmental carcinogens (discussed later), suggesting that many (and perhaps even most) cancers are preventable. The major organ sites affected and the estimated frequency of cancer deaths in the United States are shown in [Figure 7-20](#). The most common tumors in men arise in the prostate, lung, and colon/rectum. In women, cancers of the breast, lung, and colon/rectum are the most frequent. Cancers of the lung, female breast, prostate, and colon/rectum constitute more than 50% of cancer diagnoses and cancer deaths in the United States. In contrast, in the developing world the most common cancers involve the lung, stomach, and liver in men and the breast, cervix, and lung in women.

Most longitudinal data pertaining to cancer incidence comes from developed countries. Age-adjusted death rates (deaths per 100,000 population) for many cancers have changed significantly over the years in the United States. In the last 50 years of the twentieth century, the overall age-adjusted cancer death rate increased significantly in both men and women. However, in men the cancer incidence rate has been stable since 1995 and the cancer death rate has decreased 18.4% since 1990. Similarly, in women the cancer incidence rate also stabilized in 1995 and the cancer death rate has decreased 10.4% since 1991. Among men, nearly 80% of the decrease is accounted for by lower

Figure 7-20 Cancer incidence (A) and mortality (B) by site and sex. Excludes basal cell and squamous cell skin cancers and in situ carcinomas, except urinary bladder. (Adapted from American Cancer Society. Cancer Statistics 2011.)

death rates from lung, prostate, and colorectal cancers; among women, nearly 60% of the decrease is due to reductions in death rates from breast and colorectal cancers. Decreased use of tobacco products is responsible for the reduction in lung cancer deaths, while improved detection and treatment are responsible for the decrease in death rates for colorectal, female breast, and prostate cancer.

The last half-century has also seen a sharp decline in the number of deaths caused by cervical cancer in the United States, which is attributable to the Papanicolaou (Pap) smear test, which enables detection of precursor lesions and early, curable cancers. A downward trend in deaths from stomach cancer in both sexes has been observed that is attributed to a reduction in unknown dietary carcinogens. However, between 1990-1991 and 2004, lung cancer death rates in women, and liver and intrahepatic bile duct cancer death rates in men, increased substantially, offsetting some of the improvement in survival from other cancers. Indeed, although carcinomas of the breast occur about 2.5 times more frequently than those of the lung in women, lung cancer now causes more deaths in women. Deaths due to primary liver cancers, which declined between 1930 and 1970, have approximately doubled over the past 40 years. This number is expected to increase further over the coming decades as a large number of individuals infected with the hepatitis C virus (HCV) begin to develop hepatocellular carcinoma.

Although race is not a clearly defined biological variable, it can define groups at risk for certain cancers. The disparity in cancer mortality rates between white and black Americans persists, but African Americans had the largest decline in cancer mortality during the past decade. Hispanics living in the United States have a lower frequency of the most common tumors seen in the white non-Hispanic population but a higher incidence of tumors of the stomach, liver, uterine cervix, and gallbladder, as well as certain leukemias.

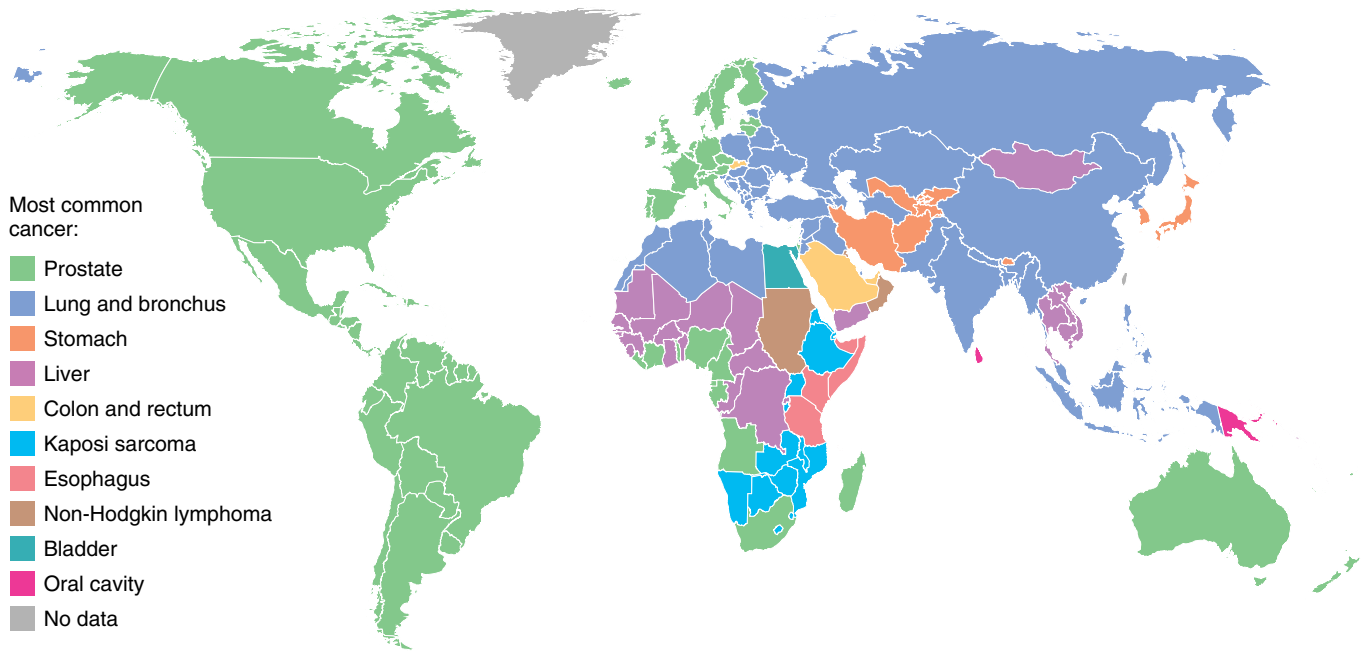

Environmental Factors

Although both genetic and environmental factors contribute to the development of cancer, environmental influences appear to be the dominant risk factors for most cancers. Evidence supporting a central role for environmental factors can be found in the wide geographic variation that exists in the incidence of specific forms of cancer (Fig. 7-21). For example, the most common tumor of men in the United States and most of the developed world is prostate cancer, but in certain countries or regions (most located in the developing world), cancers of the liver, stomach, esophagus, bladder, lung, oropharynx, and the immune system rise to the top of the list. Similarly, the incidence of breast cancer is generally much higher in women in developed countries than in most parts of the developing world. Although racial predispositions cannot be ruled out, it is believed that environmental influences—some known, some not—underlie most of these differences in cancer incidence.

Among the best established environmental factors affecting cancer risk are the following:

- **Infectious agents.** About 15% of all cancers worldwide are believed to be caused directly or indirectly by infectious agents, with the burden of cancers linked to infections being roughly three times higher in the developing world than in the developed world. For example, *human papilloma virus* (HPV), an agent that is spread through sexual contact, is responsible for a large majority of cases of cervical carcinoma and an increasing fraction of head and neck cancers. Specific infectious agents and their associated cancers are discussed later in this chapter.
- **Smoking.** Cigarette smoking has been called the single most important environmental factor contributing to premature death in the United States. Smoking,

A. Worldwide variation of cancer incidence in males

B. Worldwide incidence of breast cancer

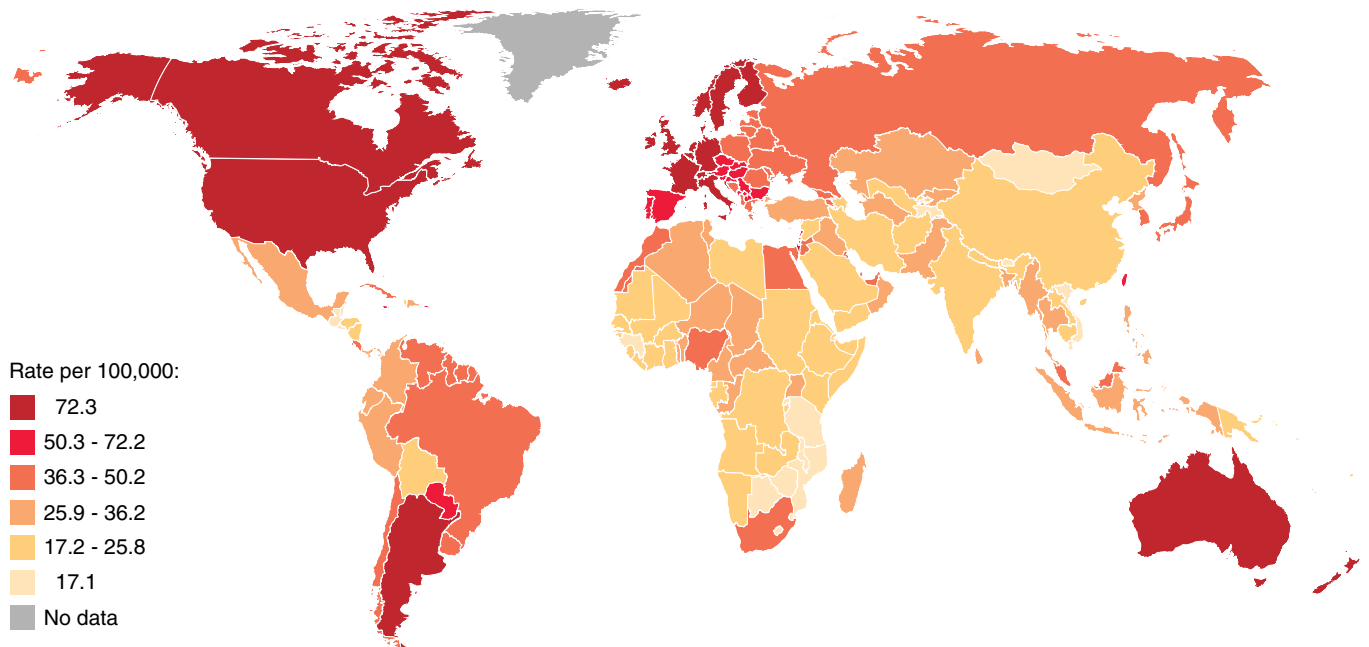

Figure 7-21 Geographic variation in cancer incidence. **A**, Most common cancers in males by country. **B**, Variation in breast cancer incidence in women by country. (Adapted from Global Cancer Facts & Figures, 2nd ed. Atlanta, American Cancer Society, 2011.)

particularly of cigarettes, has been implicated in cancer of the mouth, pharynx, larynx, esophagus, pancreas, bladder, and most significantly, about 90% of lung cancer deaths ([Chapter 9](#)).

- **Alcohol consumption.** Alcohol abuse alone increases the risk of carcinomas of the oropharynx (excluding lip), larynx, and esophagus and, by the development of alcoholic cirrhosis, hepatocellular carcinoma. Alcohol and tobacco together synergistically increase the risk of cancers in the upper airways and digestive tract.
- **Diet.** Although the precise dietary factors that affect cancer risk remain a matter of debate, wide geographic variation in the incidences of colorectal carcinoma, prostate carcinoma, and breast carcinoma has been ascribed to differences in diet.
- **Obesity.** Given that there is an obesity epidemic in the United States that is spreading to other parts of the world ([Chapter 9](#)), it is concerning that weight is strongly associated with cancer risk. Overall, the most overweight individuals in the U.S. population have 52% (men) to 62% (women) higher death rates from cancer

Table 7-3 Occupational Cancers

Agents or Groups of Agents	Human Cancers for Which Reasonable Evidence Is Available	Typical Use or Occurrence
Arsenic and arsenic compounds	Lung carcinoma, skin carcinoma	By-product of metal smelting; component of alloys, electrical and semiconductor devices, medications and herbicides, fungicides, and animal dips
Asbestos	Lung, esophageal, gastric, and colon carcinoma; mesothelioma	Formerly used for many applications because of fire, heat, and friction resistance; still found in existing construction as well as fire-resistant textiles, friction materials (i.e., brake linings), underlayment and roofing papers, and floor tiles
Benzene	Acute myeloid leukemia	Principal component of light oil; despite known risk, many applications exist in printing and lithography, paint, rubber, dry cleaning, adhesives and coatings, and detergents; formerly widely used as solvent and fumigant
Beryllium and beryllium compounds	Lung carcinoma	Missile fuel and space vehicles; hardener for lightweight metal alloys, particularly in aerospace applications and nuclear reactors
Cadmium and cadmium compounds	Prostate carcinoma	Uses include yellow pigments and phosphors; found in solders; used in batteries and as alloy and in metal platings and coatings
Chromium compounds	Lung carcinoma	Component of metal alloys, paints, pigments, and preservatives
Nickel compounds	Lung and oropharyngeal carcinoma	Nickel plating; component of ferrous alloys, ceramics, and batteries; by-product of stainless-steel arc welding
Radon and its decay products	Lung carcinoma	From decay of minerals containing uranium; potentially serious hazard in quarries and underground mines
Vinyl chloride	Hepatic angiosarcoma	Refrigerant; monomer for vinyl polymers; adhesive for plastics; formerly inert aerosol propellant in pressurized containers

Modified from Stellman JM, Stellman SD: Cancer and workplace. *CA Cancer J Clin* 1996;46:70.

than do their slimmer counterparts; it follows that approximately 14% of cancer deaths in men and 20% in women can be attributed to obesity.

- **Reproductive history.** There is strong evidence that life-long cumulative exposure to estrogen stimulation, particularly if unopposed by progesterone, increases the risk of cancers of the breast and endometrium, tissues that are responsive to these hormones. Indeed, some of the differences in breast cancer incidence that are seen across the world are believed to be related to cultural mores that affect the timing and number of pregnancies a woman has during her lifetime.
- **Environmental carcinogens.** There is no paucity of well-characterized environmental carcinogens: they lurk in the ambient environment, in the workplace (Table 7-3), in food, and in personal practices. Individuals may be exposed to carcinogenic factors when they go outside (e.g., ultraviolet [UV] rays, smog), drink well water (e.g., arsenic, particularly in Bangladesh), take certain medications (e.g., methotrexate), go to work (e.g., asbestos), or even while lounging at home (e.g., grilled meat, high-fat diet, alcohol).

It appears that almost everything one does to earn a livelihood or for pleasure is fattening, immoral, illegal, or, even worse, carcinogenic!

Age

Age has an important influence on the likelihood of being afflicted with cancer. Most carcinomas occur in the later years of life (>55 years). Cancer is the main cause of death among women aged 40 to 79 and among men aged 60 to 79; the decline in deaths after age 80 is due to the lower number of individuals who reach this age. The rising incidence of cancer with age is likely explained by the accumulation of somatic mutations associated with

the emergence of malignant neoplasms (discussed later). The decline in immune competence that accompanies aging may also be a factor.

Tragically, children are not spared; cancer accounts for slightly more than 10% of all deaths in children younger than age 15 in the United States, second only to accidents. However, the types of cancers that predominate in children are significantly different from those seen in adults. Carcinomas, the most common general category of tumor in adults, are extraordinarily rare among children. Instead, acute leukemia and distinctive neoplasms of the central nervous system are responsible for approximately 60% of childhood cancer deaths. The common neoplasms of infancy and childhood include the so-called small round blue cell tumors such as neuroblastoma, Wilms tumor, retinoblastoma, acute leukemias, and rhabdomyosarcomas. These are discussed in Chapter 10 and elsewhere in the text.

Acquired Predisposing Conditions

Acquired conditions that predispose to cancer can be divided into chronic inflammations, precursor lesions, and immunodeficiency states. Chronic inflammatory disorders and precursor lesions span a diverse set of conditions that are all associated with increased cellular replication, which appears to create a “fertile” soil for the development of malignant tumors. Indeed, repeated rounds of cell division may be required for neoplastic transformation, in that proliferating cells are the most at risk for accumulating the genetic lesions that lead to carcinogenesis. Tumors arising in the context of chronic inflammation are mostly carcinomas, but also include mesothelioma and several kinds of lymphoma. Immunodeficiency states predispose to virus-induced cancers. Each of these acquired predisposing conditions is described next.

Table 7-4 Chronic Inflammatory States and Cancer

Pathologic Condition	Associated Neoplasm(s)	Etiologic Agent
Asbestosis, silicosis	Mesothelioma, lung carcinoma	Asbestos fibers, silica particles
Inflammatory bowel disease	Colorectal carcinoma	
Lichen sclerosis	Vulvar squamous cell carcinoma	
Pancreatitis	Pancreatic carcinoma	Alcoholism, germline mutations (e.g., in the trypsinogen gene)
Chronic cholecystitis	Gallbladder cancer	Bile acids, bacteria, gallbladder stones
Reflux esophagitis, Barrett esophagus	Esophageal carcinoma	Gastric acid
Sjögren syndrome, Hashimoto thyroiditis	MALT lymphoma	
Opisthorchis, cholangitis	Cholangiocarcinoma, colon carcinoma	Liver flukes (<i>Opisthorchis viverrini</i>)
Gastritis/ulcers	Gastric adenocarcinoma, MALT lymphoma	<i>Helicobacter pylori</i>
Hepatitis	Hepatocellular carcinoma	Hepatitis B and/or C virus
Osteomyelitis	Carcinoma in draining sinuses	Bacterial infection
Chronic cervicitis	Cervical carcinoma	Human papillomavirus
Chronic cystitis	Bladder carcinoma	Schistosomiasis

Adapted from Tlsty TD, Coussens LM: Tumor stroma and regulation of cancer development. *Ann Rev Pathol Mech Dis* 2006;1:119.

Precursor lesions can be defined as localized morphologic changes that are associated with a high risk of cancer. Virtually all precursor lesions arise in epithelial surfaces and are associated with an increased risk of various forms of carcinoma.

- **Chronic inflammation and cancer.** A cause-and-effect relationship between chronic inflammation and cancer was first proposed by Virchow in 1863, and it is now appreciated that cancer risk is increased in individuals affected by a variety of chronic inflammatory diseases, including those with infectious and noninfectious etiologies (Table 7-4). As with any cause of tissue injury, each of these disorders is accompanied by a compensatory proliferation of cells that serves to repair the damage. In some cases, chronic inflammation may increase the pool of tissue stem cells, which may be particularly susceptible to transformation. Additionally the activated immune cells produce reactive oxygen species that are directly genotoxic, as well as inflammatory mediators that may promote bystander cell survival, even in the face of genomic damage. Chronic epithelial injury often leads to metaplasia, the replacement of one cell type with a second that is better able to survive the ongoing insult. In the short term, these changes can be adaptive; the organism must survive, and the damaged cells can be repaired or eliminated

later. However, over longer time periods (years to decades) such alterations may allow cells with potentially oncogenic mutations to survive, eventually leading to cancer. Whatever the precise mechanism, the link between chronic inflammation and cancer has practical implications. For instance, diagnosis and effective treatment of *Helicobacter pylori* gastritis with antibiotics can quell a chronic inflammatory condition that might otherwise lead to the development of a gastric cancer.

- **Precursor lesions and cancer.** As mentioned, the term *precursor lesion* encompasses several entities that are associated with increased cancer risk. Precursor lesions do not inevitably progress to cancer; nevertheless, they are important to recognize because some precursor lesions can be detected by screening procedures and treated, thereby reducing the risk of developing cancer.

Many precursor lesions arise in the setting of chronic inflammation and can be recognized by the presence of metaplasia: examples include *Barrett esophagus* (gastric and colonic metaplasia of the esophageal mucosa in the setting of gastric reflux); *squamous metaplasia* of the bronchial mucosa (in response to smoking) and the bladder mucosa (in response to schistosomiasis infection); and *colonic metaplasia* of the stomach (in the setting of pernicious anemia and chronic atrophic gastritis). Other precursor lesions are noninflammatory hyperplasias. One of the most common precursor lesions of this type is *endometrial hyperplasia*, which is caused by sustained estrogenic stimulation of the endometrium. Another relatively frequent precursor lesion is *leukoplakia*, a thickening of squamous epithelium that may occur in the oral cavity or on the penis or vulva and give rise to squamous carcinoma.

The final group of precursor lesions is benign neoplasms that are at risk for malignant transformation. The classic example of a neoplastic precursor lesion is the colonic *villous adenoma*, which if left untreated progresses to cancer in about 50% of cases. It should be emphasized, however, that most benign tumors transform rarely (e.g., uterine leiomyomas, pleomorphic adenoma) and others not at all (e.g., lipomas). Why many benign tumors have a negligible risk of malignant transformation is an unsettled question; one possibility is that benign tumors at high risk for malignant transformation possess the cancer-enabling property of genomic instability (discussed later), whereas truly benign tumors do not.

- **Immunodeficiency states and cancer.** Patients who are immunodeficient, and particularly those who have deficits in T-cell immunity, are at increased risk for cancers, especially those caused by oncogenic viruses. These virally associated tumors include mainly lymphomas, but also certain carcinomas and even some sarcomas and sarcoma-like proliferations. The complex relationship between infections, immunity, and cancer are discussed later in this chapter.

Genetic Predisposition and Interactions Between Environmental and Inherited Factors

In some families cancer is an inherited trait, usually due to germline mutations in a tumor suppressor gene (described

later). What then can be said about the influence of heredity on sporadic malignant neoplasms, which constitute roughly 95% of cancers in the United States? While the evidence suggests that these cancers are largely attributable to environmental factors or acquired predisposing conditions, lack of family history does not preclude an inherited component. It is generally difficult to sort out the hereditary and nonhereditary contributions because these factors often interact. The interaction between genetic and nongenetic factors is particularly complex when tumor development depends on the action of multiple contributory genes. Even in tumors with a well-defined inherited component, the risk of developing the tumor can be greatly influenced by nongenetic factors. For instance, breast cancer risk in females who inherit mutated copies of the *BRCA1* or *BRCA2* tumor suppressor genes (discussed later) is almost threefold higher for women born after 1940 than for women born before that year, perhaps because of changes in reproductive history. Furthermore, genetic factors can significantly influence the likelihood of developing environmentally induced cancers. Inherited variations (polymorphisms) of enzymes that metabolize procarcinogens to their active carcinogenic forms can influence cancer susceptibility. Of interest in this regard are genes that encode the cytochrome P-450 enzymes. As discussed later, a polymorphism in one of the P-450 loci confers an inherited susceptibility to lung cancers in cigarette smokers. More associations of this type are likely to be found.

KEY CONCEPTS

Epidemiology of Cancer

- The incidence of cancer varies with geography, age, race, and genetic background. Cancers are most common in adults older than 60 years of age, but occurs in adults at all ages and in children and infants. The geographic variation is thought to mainly stem from different environmental exposures.
- Important environmental factors implicated in carcinogenesis include infectious agents, smoking, alcohol, diet, obesity, reproductive history, and exposure to environmental carcinogens.
- The risk of cancer is increased by reparative proliferations caused by chronic inflammation or tissue injury, certain forms of hyperplasia, and immunodeficiency.
- Interactions between environmental factors and genetic factors may be important determinants of cancer risk.

Molecular Basis of Cancer: Role of Genetic and Epigenetic Alterations

Evidence for the genetic origins of cancer have been building up for over several decades. However, a full accounting of the extent of these genetic aberrations is only now coming to light, made possible by technologic advances in DNA sequencing and other methods that permit genome-wide analysis of cancer cells. The complexity of these data is daunting and the messages hidden within them have yet to be fully decoded, but certain “genomic themes” have emerged that are likely relevant to every cancer.

- **Nonlethal genetic damage lies at the heart of carcinogenesis.** The initial damage (or mutation) may be caused by environmental exposures, may be inherited in the germline, or may be spontaneous and random, falling into the category of “bad luck.” The term environmental, used in this context, refers to any acquired mutation caused by exogenous agents, such as viruses or environmental chemicals, or by endogenous products of cellular metabolism.
- **A tumor is formed by the clonal expansion of a single precursor cell that has incurred genetic damage (i.e., tumors are clonal).** Alterations in DNA are heritable, being passed to daughter cells, and thus all cells within an individual tumor share the same set of mutations that were present at the moment of transformation. Such tumor-specific mutations are most often identified by DNA sequencing (e.g., point mutations) or by chromosomal analyses (e.g., chromosomal translocations and copy number changes, discussed later).
- **Four classes of normal regulatory genes—the growth-promoting proto-oncogenes, the growth-inhibiting tumor suppressor genes, genes that regulate programmed cell death (apoptosis), and genes involved in DNA repair—are the principal targets of cancer-causing mutations.** Mutations that activate *proto-oncogenes* generally cause an excessive increase in one of more normal functions of the encoded gene product, or sometimes impart a completely new function on the affected gene product that is oncogenic. Because these mutations cause a “gain-of-function,” they can transform cells despite the presence of a normal copy of the same gene. Thus, in genetic parlance, oncogenes are dominant over their normal counterparts. Mutations that affect *tumor suppressor genes* generally cause a “loss-of-function,” and in most instances both alleles must be damaged before transformation can occur. Thus, mutated tumor suppressor genes usually behave in a recessive fashion. However, there are exceptions: sometimes loss of only a single tumor suppressor gene allele (a state termed *haploinsufficiency*) reduces the activity of the encoded protein enough to release the brakes on cell proliferation and survival. Such a finding indicates that two “doses” of the gene are essential for normal function. *Apoptosis-regulating genes* may acquire abnormalities that result in less death and, therefore, enhanced survival of the cells. These abnormalities include gain-of-function mutations in genes whose products suppress apoptosis and loss-of-function mutations in genes whose products promote cell death. Loss-of-function mutations affecting *DNA repair genes* contribute to carcinogenesis indirectly by impairing the ability of the cell to recognize and repair nonlethal genetic damage in other genes. As a result, affected cells acquire mutations at an accelerated rate, a state referred to as a *mutator phenotype* that is marked by *genomic instability*.
- **Carcinogenesis results from the accumulation of complementary mutations in a stepwise fashion over time (Fig. 7-22).**
 - **Malignant neoplasms have several phenotypic attributes referred to as cancer hallmarks,** such as excessive growth, local invasiveness, and the ability to form distant metastases, which stem from genomic

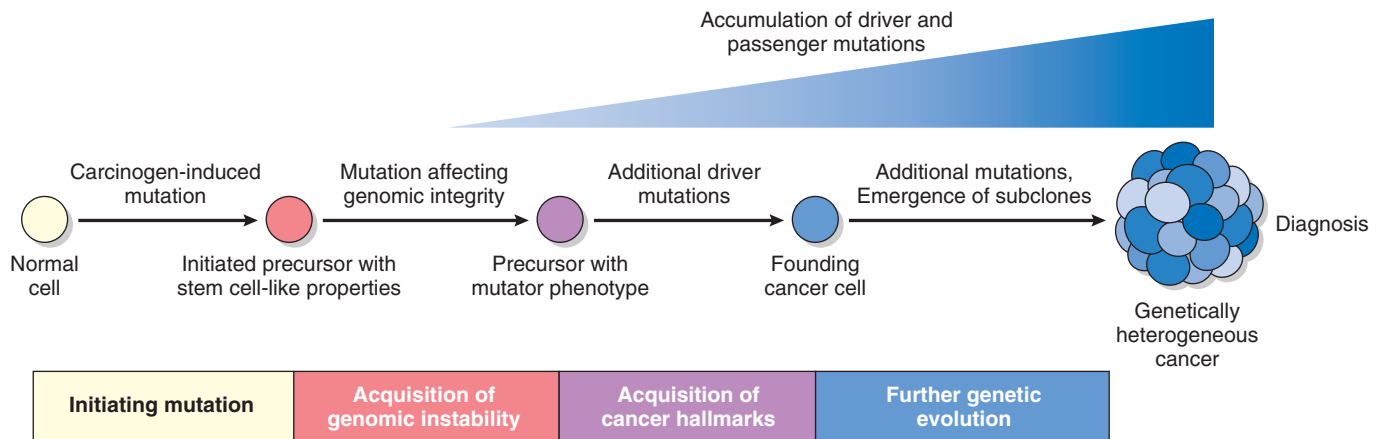

Figure 7-22 Development of a cancer through stepwise acquisition of complementary mutations. The order in which various driver mutations occur in initiated precursor cells is not known and may vary from tumor to tumor. See text for details.

alterations that change the expression and function of key genes and thereby impart a malignant phenotype.

- **Mutations that contribute to the development of the malignant phenotype are referred to as *driver mutations*.** The first driver mutation that starts a cell on the path to malignancy is the *initiating mutation*, which is typically maintained in all of the cells of the subsequent cancer. However, because no single mutation appears to be fully transforming, development of a cancer requires that the “initiated” cell acquire a number of additional driver mutations, each of which also contributes to the development of the cancer. The time over which this occurs is unknown in most cancers, but appears to be lengthy; even in aggressive cancers that clinically seem to appear “out of the blue,” such as childhood acute lymphoblastic leukemia, cells bearing initiating mutations may be found in blood samples taken as long as a decade prior to diagnosis. The persistence of initiated cells during this long preclinical prodrome is consistent with the idea that cancers arise from cells with stem cell-like properties, so-called *cancer stem cells*, that have a capacity for self-renewal and long-term persistence.
- **Loss-of-function mutations in genes that maintain genomic integrity appear to be a common early step on the road to malignancy, particularly in solid tumors.** Mutations that lead to genomic instability not only increase the likelihood of acquiring driver mutations, but also greatly increase the frequency of mutations that have no phenotypic consequence, so-called *passenger mutations*, which are much more common than driver mutations. As a result, by the time a cell acquires all of the driver mutations that are needed for malignant behavior, it may bear hundreds or even thousands of acquired mutations.

Once established, tumors evolve genetically during their outgrowth and progression under the pressure of Darwinian selection (survival of the fittest). Early on, all of the cells in a tumor are genetically identical, being the progeny of a single founding transformed cell. However, by the time a tumor comes to clinical attention (generally

when it attains a mass of about 1 gm, or about 10^9 cells), it has gone through a minimum of 30 cell doublings. This number is likely a substantial underestimation, because some fraction of cells in virtually all tumors die by apoptosis, and sometimes such cells are numerous. During this process, there is competition among tumor cells for access to nutrients and microenvironmental niches, and subclones with the capacity to overgrow their predecessors tend to “win” this Darwinian contest and dominate the tumor mass, only to be replaced by other, still malignant subclones. This pernicious tendency of tumors to become more aggressive over time is referred to as *tumor progression*. As a result, even though malignant tumors are clonal in origin, by the time they become clinically evident their constituent cells are often extremely heterogeneous genetically, particularly tumors with a mutator phenotype (Fig. 7-22).

A skeptical student might well ask, “How do we know that genetically distinct subclones really exist in any particular cancer?” Supportive data are now emerging from studies of solid cancers such as renal cell carcinoma, in which multiple regions of primary tumors and several different metastatic deposits have been subjected to extensive DNA sequencing (Fig. 7-23). As predicted, two types of mutations were identified in these studies: (1) mutations that were present in all tumor sites tested, which were presumably present in the founding cell at the moment of transformation, and (2) mutations that were unique to a subset of tumor sites, which were likely acquired after transformation during the outgrowth and spread of the tumor. This second type of mutation can be used to create tumor “family trees” showing the genetic relationships of various subclones. Remarkably, subclones within tumors appear to diverge genetically in a fashion that is very similar to the manner in which new species are thought to emerge in complex ecosystems; a cardinal example of the latter are the finches on the Galapagos Islands that inspired Darwin, in part, to propose evolution as the origin of the species. In the case of species, this genetic divergence occurs over a period of many millennia, whereas in tumors, subclones may arise and diverge on a timescale of years, months, or even weeks.

Selection of the fittest cells can explain not only the natural history of cancer, but also changes in tumor behavior following therapy. One of the most profound

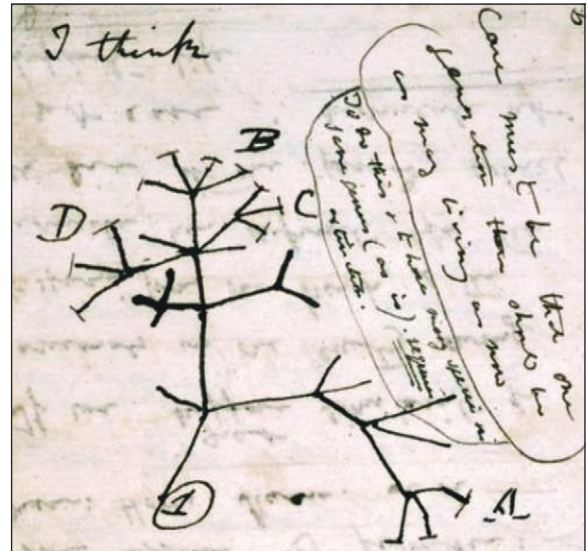

Figure 7-23 Tumor evolution. Evolution of a renal cell carcinoma (*left panel*) and Darwin's finches (*right panel*). The renal cell carcinoma evolutionary tree is based on genetic comparisons drawn from sequencing of DNA obtained from different tumor sites; the finch evolutionary tree was surmised by Darwin based on morphologic comparisons of different species of finches on the Galapagos Islands. (*right panel*, from Notebook B: Transmutation of Species, Charles Darwin, 1837, p.26.)

selective pressures that cancer cells face is effective chemotherapy or radiotherapy given by treating physicians. Tumors that recur after therapy are almost always found to be resistant if the same treatment is given again, presumably because therapy selects for preexistent subclones that, by chance, have a genotype that allows them to survive.

It is increasingly apparent that **in addition to DNA mutations, epigenetic aberrations also contribute to the malignant properties of cancer cells.** Epigenetic modifications include DNA methylation, which tends to silence gene expression, and modifications of histones, the proteins that package DNA into chromatin, which depending on their nature may either enhance or dampen gene expression. Together, *DNA methylation* and *histone modifications* dictate which genes are expressed, which in turn determines the lineage commitment and differentiation state of both normal and neoplastic cells. Epigenetic modifications are usually passed on faithfully to daughter cells, but on occasion (just as with DNA mutations) alterations may occur that result in changes in gene expression. Aberrant DNA methylation in cancer cells is responsible for the silencing of some tumor suppressor genes, while tumor-specific changes in histone modifications may have far-ranging effects on gene expression in cancer cells (see later). The increasing awareness of the role of epigenetic alterations in cancer has revealed a new path forward for cancer treatment; unlike DNA mutations, epigenetic changes are potentially reversible by drugs that inhibit DNA- or histone-modifying factors. Thus, there is considerable interest in treating cancers with drugs that correct epigenetic abnormalities in cancer cells, with some encouraging early results.

We will return to these themes throughout the subsequent discussions, which turns to the cellular and molecular properties that underlie the malignant behavior of cancer cells.

Cellular and Molecular Hallmarks of Cancer

Over the past several decades, hundreds of genes that are mutated in cancer have been discovered. It is traditional to describe the functional consequences of these alterations one gene at a time. However, the blizzard of mutated genes emerging from the sequencing of cancer genomes has blanketed the landscape and revealed the limitations of trying to grasp the fundamental properties of cancer, gene by gene. For example, it is estimated that compilation of a reasonably complete catalog of the major genetic alterations in breast carcinoma will require whole genomic sequencing of thousands of tumors and will lead to the identification of dozens to hundreds of distinct driver mutations—and this is just one of hundreds of different kinds of cancer, some of which are substantially more genetically complex than breast carcinoma.

A much more tractable and conceptually satisfying way to think about the biology of cancer is to consider the common phenotypic properties that are imparted to cancer cells by their diverse genomic and epigenomic alterations. It appears that **all cancers display eight fundamental changes in cell physiology, which are considered the hallmarks of cancer.** These changes are illustrated in [Figure 7-24](#) and consist of the following:

- **Self-sufficiency in growth signals.** Tumors have the capacity to proliferate without external stimuli, usually as a consequence of oncogene activation.
- **Insensitivity to growth-inhibitory signals.** Tumors may not respond to molecules that inhibit the proliferation of normal cells, usually because of inactivation of tumor suppressor genes that encode components of these growth inhibitory pathways.
- **Altered cellular metabolism.** Tumor cells undergo a metabolic switch to aerobic glycolysis (called the

Figure 7-24 Hallmarks of cancer. (Adapted from Hanahan D, Weinberg RA. Hallmarks of cancer: the next generation. *Cell* 2011; 144:646.)

Warburg effect), which enables the synthesis of the macromolecules and organelles that are needed for rapid cell growth.

- **Evasion of apoptosis.** Tumors are resistant to programmed cell death.
- **Limitless replicative potential (immortality).** Tumors have unrestricted proliferative capacity, a stem cell-like property that permits tumor cells to avoid cellular senescence and mitotic catastrophe.
- **Sustained angiogenesis.** Tumor cells, like normal cells, are not able to grow without a vascular supply to bring nutrients and oxygen and remove waste products. Hence, tumors must induce angiogenesis.
- **Ability to invade and metastasize.** Tumor metastases are the cause of the vast majority of cancer deaths and arise from the interplay of processes that are intrinsic to tumor cells and signals that are initiated by the tissue environment.
- **Ability to evade the host immune response.** You will recall that the cells of the innate and adaptive immune system can recognize and eliminate cells displaying abnormal antigens (e.g., a mutated oncoprotein). Cancer cells exhibit a number of alterations that allow them to evade the host immune response.

The acquisition of the genetic and epigenetic alterations that confer these hallmarks may be accelerated by **genomic instability** and by **cancer-promoting inflammation**. These are considered enabling characteristics because they promote cellular transformation and subsequent tumor progression.

In the following sections, each of the hallmarks and enabling characteristics of cancer cells is discussed, focusing on the most important contributing genes and cellular pathways. The discussion of cancer pathophysiology ends with a review of the roles that epigenetic changes and noncoding RNAs play in the disease.

Self-Sufficiency in Growth Signals: Oncogenes

Genes that promote autonomous cell growth in cancer cells are called *oncogenes*, and their unmutated cellular counter-

parts are called *proto-oncogenes*. **Oncogenes are created by mutations in proto-oncogenes and encode proteins called oncoproteins that have the ability to promote cell growth in the absence of normal growth-promoting signals.** *Oncoproteins* resemble the normal products of proto-oncogenes but bear mutations that are often inactivate internal regulatory elements; consequently, their activity in cells does not depend on external signals. Cells expressing oncoproteins are thus freed from the normal checkpoints and controls that limit growth, and as a result proliferate excessively.

To aid in the understanding of the nature and functions of oncoproteins and their role in cancer, it is necessary to briefly describe how normal cells respond to growth factors. Under physiologic conditions growth factor signaling pathways can be resolved into the following steps:

- The binding of a growth factor to its specific receptor
- Transient and limited activation of the growth factor receptor, which, in turn, activates several cytoplasmic signal-transducing proteins
- Transmission of the transduced signal to the nucleus via additional cytoplasmic effector proteins and second messengers or by a cascade of signal transduction molecules
- Induction and activation of nuclear regulatory factors that initiate DNA transcription
- Expression of factors that promote entry and progression of the cell into the cell cycle, ultimately resulting in cell division
- In parallel, changes in the expression of other genes that support cell survival and metabolic alterations that are needed for optimal growth

Aberrations in multiple signaling pathways have been identified in various tumors; many components of these pathways act as oncoproteins when mutated (Table 7-5). Conversely, a number of tumor suppressors act by inhibiting one or more components of these pathways (discussed later). In **Chapter 1**, the major signaling pathways that regulate cellular behavior are laid out, including the receptor tyrosine kinase pathway, the G protein-coupled receptor pathway, the JAK/STAT pathway, the WNT pathway, the Notch pathway, the Hedgehog pathway, the TGF β /SMAD pathway, and the NF- κ B pathway. Abnormalities in all these pathways are implicated in the development and progression of various cancers. This chapter focuses on the receptor tyrosine kinase pathway, because it appears to be the most frequently mutated oncogenic pathway in human neoplasms. Oncogenic mutations involving other signaling pathways are also mentioned, because many exemplify certain key concepts underlying cancer phenotypes and some are the targets of effective therapies.

Traditionally, oncoproteins have been likened to accelerators that speed the replication of cells and their DNA; by contrast, tumor suppressors have been viewed as brakes that slow or arrest this process. This view has merit and we will follow it in our initial description of the activities of oncogenes and tumor suppressors. However, the proliferation of cells not only requires the replication of DNA, but also sufficient biosynthesis of membrane, protein, and various macromolecules and organelles to enable a “mother” cell to divide and produce two complete

Table 7-5 Selected Oncogenes, Their Mode of Activation, and Associated Human Tumors

Category	Proto-Oncogene	Mode of Activation in Tumor	Associated Human Tumor
Growth Factors			
PDGF- β chain	<i>PDGFB</i>	Overexpression	Astrocytoma
Fibroblast growth factors	<i>HST1</i> <i>FGF3</i>	Overexpression Amplification	Osteosarcoma Stomach cancer Bladder cancer Breast cancer Melanoma

HGF	<i>HGF</i>	Overexpression	Hepatocellular carcinomas Thyroid cancer
Growth Factor Receptors			
EGF-receptor family	<i>ERBB1 (EGFR)</i> <i>ERBB2 (HER)</i>	Mutation Amplification	Adenocarcinoma of lung Breast carcinoma
FMS-like tyrosine kinase 3	<i>FLT3</i>	Point mutation	Leukemia
Receptor for neurotrophic factors	<i>RET</i>	Point mutation	Multiple endocrine neoplasia 2A and B, familial medullary thyroid carcinomas
PDGF receptor	<i>PDGFRB</i>	Overexpression, translocation	Gliomas, leukemias
Receptor for KIT ligand	<i>KIT</i>	Point mutation	Gastrointestinal stromal tumors, seminomas, leukemias
ALK receptor	<i>ALK</i>	Translocation, fusion gene formation Point mutation	Adenocarcinoma of lung, certain lymphomas Neuroblastoma
Proteins Involved in Signal Transduction			
GTP-binding (G) proteins	<i>KRAS</i> <i>HRAS</i> <i>NRAS</i> <i>GNAQ</i> <i>GNAS</i>	Point mutation Point mutation Point mutation Point mutation Point mutation	Colon, lung, and pancreatic tumors Bladder and kidney tumors Melanomas, hematologic malignancies Uveal melanoma Pituitary adenoma, other endocrine tumors
Nonreceptor tyrosine kinase	<i>ABL</i>	Translocation Point mutation	Chronic myelogenous leukemia Acute lymphoblastic leukemia
RAS signal transduction	<i>BRAF</i>	Point mutation, Translocation	Melanomas, leukemias, colon carcinoma, others
Notch signal transduction	<i>NOTCH1</i>	Point mutation, Translocation Gene rearrangement	Leukemias, lymphomas, breast carcinoma
JAK/STAT signal transduction	<i>JAK2</i>	Translocation	Myeloproliferative disorders Acute lymphoblastic leukemia
Nuclear Regulatory Proteins			
Transcriptional activators	<i>MYC</i> <i>NMYC</i>	Translocation Amplification	Burkitt lymphoma Neuroblastoma
Cell Cycle Regulators			
Cyclins	<i>CCND1</i> (Cyclin D1)	Translocation Amplification	Mantle cell lymphoma, multiple myeloma Breast and esophageal cancers
Cyclin-dependent kinase	<i>CDK4</i>	Amplification or point mutation	Glioblastoma, melanoma, sarcoma

daughter cells. Cell growth pathways implicated in oncogenesis also initiate signals that promote and coordinate the biosynthesis of all of these cellular components (discussed later). This insight has led to the idea that it may be possible to target many aspects of oncogenic “pro-growth” signaling to therapeutic advantage, including the altered cellular metabolism that is characteristic of cancer cells.

Building on this framework, we next discuss the mechanisms by which cancer cells acquire self-sufficiency in growth signals.

Proto-oncogenes, Oncogenes, and Oncoproteins

Proto-oncogenes have multiple roles, but all participate at some level in signaling pathways that drive proliferation. Thus, pro-growth proto-oncogenes may encode

growth factors, growth factor receptors, signal transducers, transcription factors, or cell cycle components. The corresponding oncogenes generally encode oncoproteins that serve functions similar to their normal counterparts, with the important difference that they are usually constitutively active. **As a result of this constitutive activity, pro-growth oncoproteins endow cells with self-sufficiency in growth.**

Two questions follow: (1) what are the functions of pro-growth oncoproteins and (2) how do the normally “civilized” proto-oncogenes turn into “enemies within?” The ensuing discussion uses receptor tyrosine kinases and downstream signaling components as examples. Receptor tyrosine kinase signaling is complex and has a number of major branchpoints and signaling nodes. Amongst these, Darwinian selection picks out the factors that have the

Figure 7-25 Growth factor signaling pathways in cancer. Growth factor receptors, RAS, PI3K, MYC, and D cyclins are oncoproteins that are activated by mutations in various cancers. GAPs apply brakes to RAS activation, and PTEN serves the same function for PI3K.

greatest impact on the malignant phenotype. Based on this logic, the signal transducer RAS, which operates immediately downstream from receptor tyrosine kinases, and two signaling “arms” that are downstream of RAS, the mitogen-activated protein kinase (MAPK) pathway and the phosphoinositidyl-3-kinase (PI3K)/AKT pathway, appear to be particularly important in promoting cancer cell growth (Fig. 7-25). Most (and possibly all) human cancers have molecular defects that affect one or more components of these pathways; examples are highlighted in Fig. 7-25 and are discussed in some detail below.

Growth Factors. Normal cells require stimulation by growth factors to proliferate. Most soluble growth factors are made by one cell type and act on a neighboring cell to stimulate proliferation (paracrine action). Some cancer cells, however, acquire the ability to synthesize the same growth factors to which they are responsive, creating an autocrine loop. For example, many brain tumors called *glioblastomas* express both platelet-derived growth factor (PDGF) and the PDGF receptor tyrosine kinases, and many sarcomas overexpress both transforming growth factor α (TGF- α) and its cognate receptor, epidermal growth factor receptor (EGFR), another member of the receptor tyrosine

kinase family. In tumors in which an autocrine loop is an important pathogenic element, the growth factor gene itself is usually not altered or mutated. More commonly, signals transduced by other oncoproteins cause overexpression and increased secretion of growth factors, thereby initiating and amplifying the autocrine loop.

Growth Factor Receptors. A large number of oncogenes encode growth factor receptors, of which receptor tyrosine kinases are arguably the most important in cancer. Recall that receptor tyrosine kinases are transmembrane proteins with an extracellular ligand-binding domain and a cytoplasmic tyrosine kinase domain (Chapter 1). Normally, the receptor’s kinase activity is activated transiently by binding of a specific growth factor to the extracellular domain, an event that induces a rapid change in receptor conformation to an active dimeric state. The activated receptor then autophosphorylates tyrosine residues in its own intracellular tail, and these modified residues serve as sites for recruitment of a number of signaling molecules, including RAS and PI3K, which have already been described as key players in receptor tyrosine kinase signaling. The oncogenic versions of these receptors are associated with mutations that lead to constitutive, growth factor-independent tyrosine kinase activity. Hence, the mutant receptors deliver continuous mitogenic signals to the cell, even in the absence of growth factor in the environment.

Receptor tyrosine kinases can be constitutively activated in tumors by multiple mechanisms, including point mutations, gene rearrangements, and gene amplifications. A few of the better characterized oncogenic mutations involving growth factor receptors are listed in Table 7-5; the following are salient examples of clinical importance:

- **ERBB1** encodes the epidermal growth factor receptor (EGFR), which is involved by point mutations in certain cancers. Of greatest clinical importance are several different *ERBB1* point mutations that are found in a subset of lung adenocarcinomas. These mutations result in constitutive activation of the EGFR tyrosine kinase.
- **ERBB2** encodes a different member of the receptor tyrosine kinase family, HER2. Rather than being activated by point mutations, the *ERBB2* gene is amplified in certain breast carcinomas, leading to overexpression of the HER2 receptor and constitutive tyrosine kinase activity.
- **Gene rearrangements** activate other receptor tyrosine kinases, such as the tyrosine kinase ALK. For example, a deletion on chromosome 5 fuses part of the *ALK* gene with part of another gene called *EML4* in a subset of lung adenocarcinomas. The resulting *EML4-ALK* fusion gene encodes a chimeric *EML4-ALK* protein, again with constitutive tyrosine kinase activity.

The role of each of the mutations described earlier in promoting the growth and survival of tumor cells has been proven in no small part by the response of tumors bearing these mutations to therapeutic agents that specifically bind and inhibit these mutated receptor tyrosine kinases. For example, breast cancers with *ERBB2* amplification and overexpression of HER2 generally respond to treatment with antibodies or drugs that block HER2 activity. These inhibitors not only cause the cessation of tumor growth but also induce apoptosis and tumor regression, reflecting the

ability of receptor tyrosine kinase signaling to augment cell survival as well as proliferation. Inhibitors of EGFR and ALK produce similar therapeutic responses in patients with lung adenocarcinomas harboring *ERBB1* mutations or *EML4-ALK* fusion genes, respectively.

Unfortunately, none of these targeted therapies cure advanced lung cancer. In treated patients tumors have often been found to have acquired activating mutations in some other signaling molecule, most often another tyrosine kinase, which sidesteps the effects of the drug, resulting in resistance to the targeted therapy. For example, lung cancers that develop resistance to EGFR inhibitors often have amplifications in a gene called *MET*, which encodes yet another receptor tyrosine kinase. This experience highlights one of the most daunting clinical problems in the treatment of advanced cancers—the presence of subclones within the genetically heterogeneous tumor cell population that are resistant to targeted therapies.

Downstream components of the receptor tyrosine kinase signaling pathway. As mentioned, receptor tyrosine kinase activation stimulates RAS and two major downstream signaling “arms,” the MAPK cascade and the PI3K/AKT pathway. In line with the importance of these pathways in mediating cell growth, RAS, PI3K, and other components of these pathways are frequently involved by gain-of-function mutations in different types of cancer. Of interest, when *RAS* mutations are present in a tumor, activating mutations in receptor tyrosine kinases are almost always absent, at least within the dominant tumor clone, implying that in such tumors activated RAS can completely substitute for tyrosine kinase activity. Thus, lung adenocarcinomas fall into mutually exclusive molecular subtypes that are associated with mutations involving *RAS* or various tyrosine kinase genes, an insight that has important implications for targeted therapies in this type of cancer.

RAS Mutations. Point mutations of RAS family genes constitute the most common type of abnormality involving proto-oncogenes in human tumors. The *RAS* genes, of which there are three in humans (*HRAS*, *KRAS*, *NRAS*), were discovered initially in transforming retroviruses. Approximately 15% to 20% of all human tumors express mutated *RAS* proteins, but in some types of cancers the frequency of *RAS* mutations is much higher. For example, 90% of pancreatic adenocarcinomas and cholangiocarcinomas contain a *RAS* point mutation, as do about 50% of colon, endometrial, and thyroid cancers and about 30% of lung adenocarcinomas and myeloid leukemias. *RAS* mutations are not nearly as prevalent in other kinds of cancers, but are nevertheless detected at low frequencies in most.

Recall that *RAS* proteins are members of a family of membrane-associated small G proteins that bind guanine nucleotides (guanosine triphosphate [GTP] and guanosine diphosphate [GDP]), similar to the larger trimolecular G proteins. They normally flip back and forth between an excited signal-transmitting state in which they are bound to GTP and a quiescent state in which they are bound to GDP. Stimulation of receptor tyrosine kinases by growth factors leads to exchange of GDP for GTP and subsequent conformational changes that generate active *RAS*, which in turn stimulates both the MAPK and PI3K/AKT arms of the receptor tyrosine kinase signaling pathway. These

downstream kinases phosphorylate and activate a number of cytoplasmic effectors as well as several transcription factors that turn on genes that support rapid cell growth. Activation of *RAS* is transient because *RAS* has an intrinsic GTPase activity that is accelerated by *GTPase-activating proteins (GAPs)*, which bind to the active *RAS* and augment its GTPase activity by more than 1000-fold, thereby terminating signal transduction. Thus, *GAPs* prevent uncontrolled *RAS* activity.

Several distinct *RAS* point mutations have been identified in cancer cells that markedly reduce the GTPase activity of the *RAS* protein. As a result, these mutated forms of *RAS* are trapped in the activated GTP-bound form and the cell receives pro-growth signals continuously. It follows from this scenario that the consequences of gain-of-function mutations in *RAS* proteins should be mimicked by loss-of-function mutations in *GAPs* that normally restrain *RAS* activity. Indeed, disabling mutations of neurofibromin 1, a *GAP* encoded by the *NF1* gene, are associated with the inherited cancer syndrome *familial neurofibromatosis type 1* (Chapter 25). *NF1* is therefore an example of a tumor suppressor gene that acts through negative regulation of *RAS* signaling.

Oncogenic BRAF and PI3K Mutations. In addition to *RAS*, other downstream factors in the receptor tyrosine kinase signaling pathway are frequently involved by gain-of-function mutations in various cancers.

- **Mutations in *BRAF*,** a member of the *RAF* family, have been detected in close to 100% of hairy cell leukemias, more than 60% of melanomas, 80% of benign nevi, and a smaller percentage of a wide variety of other neoplasms, including colon carcinomas and dendritic cell tumors. *BRAF* is a serine/threonine protein kinase that sits at the top of a cascade of other serine/threonine kinases of the MAPK family. Like activating *RAS* mutations, activating mutations in *BRAF* stimulate each of these downstream kinases and ultimately activate transcription factors. Mutations in other MAPK family members downstream of *BRAF* are uncommon in cancer, suggesting only mutations affecting factors near the top of the *RAS*/MAPK cascade produce significant pro-growth signals in most cell types.
- **Mutations of the PI3K family of proteins** are also very common in certain cancers. PI3K is heterodimer comprised of a regulatory subunit and a catalytic subunit, of which several tissue-specific isoforms exist. Under normal circumstances, PI3K is recruited by receptor tyrosine kinase activation to plasma membrane-associated signaling protein complexes. Here, like *BRAF*, it activates a cascade of serine/threonine kinases, including *AKT*, which is a key signaling node. *AKT* has many substrates, several of which are particularly important. *mTOR*, a sensor of cellular nutrient status, is activated by *AKT* and in turn stimulates protein and lipid synthesis. *BAD* is a pro-apoptotic protein that inactivated by *AKT*, an effect that enhances cell survival. Similarly, *FOXO* transcription factors, which turn on genes that promote apoptosis, are also negatively regulated by *AKT* phosphorylation. Like *RAS*, PI3K is negatively regulated by an important “braking” factor called *PTEN*. Alterations in virtually all components of the

PI3K/AKT pathway have been found in various cancers, but as with the RAS/MAPK pathway, the factors at the top of the pathway, PI3K and its antagonist, PTEN, are most frequently mutated. PI3K mutations affect the catalytic subunits and generally result in an increase in enzyme activity. For example, about 30% of breast carcinomas have gain-of-function mutations involving the α -isoform of the PI3K catalytic subunit. As would be expected, *PTEN* is a tumor suppressor gene whose function is lost through mutation or epigenetic silencing in many cancers, particularly endometrial carcinomas (Chapter 21).

Because RAS proteins are so frequently mutated in human cancers, much effort has been spent to develop targeted therapy specific for these proteins. Unfortunately, none of the strategies designed to target RAS has so far been successful, in part because the vagaries of RAS protein structure and its mode of signaling make it a particularly difficult protein to inhibit with drugs. In contrast, treatment of patients with advanced melanomas harboring activating BRAF mutations with BRAF inhibitors have produced striking clinical responses. Such responses are strictly restricted to tumors with BRAF mutations, as morphologically identical melanomas without BRAF mutations never respond to BRAF inhibitors. This phenomenon, termed oncogene addiction (described below), highlights the need for molecular analysis to guide appropriate therapy. Multiple drugs that inhibit various PI3K isoforms have also been developed and are now being tested in the clinic.

Alterations in Nonreceptor Tyrosine Kinases. Mutations that confer oncogenic activity occur in several nonreceptor tyrosine kinases that normally localize to the cytoplasm or the nucleus. In many instances the mutations take the form of chromosomal translocations or rearrangements that create fusion genes encoding constitutively active tyrosine kinases. Despite their nonmembranous localization, most of these oncoproteins also activate the same signaling pathways as receptor tyrosine kinases. An important example of this oncogenic mechanism involves the ABL tyrosine kinase. In *chronic myelogenous leukemia* (CML) and some *acute lymphoblastic leukemias*, the *ABL* gene is translocated from its normal abode on chromosome 9 to chromosome 22 (Fig. 7-26), where it fuses with the *BCR* gene (see discussion of **chromosomal translocations** later in this chapter). The resultant chimeric gene encodes a constitutively active, oncogenic *BCR-ABL tyrosine kinase*. The most important contribution of the *BCR* moiety is that it promotes self-association of *BCR-ABL*, which appears to be sufficient to unleash tyrosine kinase activity of *ABL*. This is a recurrent mechanism in cancer, in that many different oncogenic tyrosine kinases consist of fusion proteins in which the non-tyrosine kinase partner drives self-association.

Treatment of CML has been revolutionized by the development of “designer” drugs with low toxicity and high therapeutic efficacy that inhibit the *BCR-ABL* kinase, another example of rational drug design emerging from an understanding of the molecular basis of cancer. The remarkable therapeutic response of CML to *BCR-ABL* inhibitors is one of the first and best examples of *oncogene addiction*, in which tumor cells are highly dependent on the

Figure 7-26 The chromosomal translocation and associated oncogenes in Burkitt lymphoma and chronic myelogenous leukemia.

activity of one or more oncogenes. Despite accumulation of mutations in other cancer-associated genes in CML cells, signaling through the *BCR-ABL* tyrosine kinase is required for most CML tumor cells to proliferate and survive, hence inhibition of its activity is a highly effective therapy. The presence of a *BCR-ABL* fusion gene defines CML and must be the initiating event in this disease; thus, additional mutations acquired by the founding clone are selected for their ability to complement the effects of constant signaling through *BCR-ABL*. *BCR-ABL* signaling can be seen as the central lodgpole around which a complex oncogenic structure is built. If the lodgpole is removed by inhibition of the *BCR-ABL* kinase, the entire structure collapses. Unfortunately, treatment of this “addiction” with *BCR-ABL* inhibitors does not lead to cure. Even though the proliferating component of the tumor is suppressed by *BCR-ABL* inhibitors and the patient seems completely well, rare CML “stem cells” harboring the *BCR-ABL* fusion gene persist, apparently because these cells do not require *BCR-ABL* signals for their survival. As a result, therapy with *BCR-ABL* inhibitors must be continued indefinitely;

otherwise these malignant stem cells will spawn proliferating offspring and the fullblown leukemia will return. This outcome highlights a second important concept that we will return to; the existence of “stem-like” cells in certain cancers that may be particularly resistant to therapeutic targeting.

In other instances, nonreceptor tyrosine kinases are activated by point mutations that abrogate the function of negative regulatory domains that normally hold enzyme activity in check. An example of this type of mutation is found in the nonreceptor tyrosine kinase JAK2. JAK2 participates in the JAK/STAT signaling pathway, which transduces mitogenic signals from growth factor and cytokine receptors that lack tyrosine kinase activity (as describe in [Chapter 1](#)). JAK/STAT activation alters the expression of target genes that bind STAT transcription factors. Several myeloproliferative disorders, particularly polycythemia vera, essential thrombocytosis, and primary myelofibrosis, are highly associated with activating point mutations in JAK2 that relieve the normal dependence of hematopoietic progenitors on growth factors such as erythropoietin ([Chapter 13](#)). Recognition of this molecular lesion has led to the clinical development of JAK2 inhibitors for treatment myeloproliferative disorders, and has stimulated searches for activating mutations in other nonreceptor tyrosine kinases in a wide variety of human cancers.

Transcription Factors. Just as all roads lead to Rome, all signal transduction pathways converge on the nucleus, where the expression of target genes that orchestrate the cell’s orderly advance through the mitotic cycle is activated. Indeed, the ultimate consequence of deregulated mitogenic signaling pathways is inappropriate and continuous stimulation of nuclear transcription factors that drive growth-promoting genes. Thus, not surprisingly, growth autonomy may also occur as a consequence of mutations affecting the transcription factors that regulate the expression of pro-growth genes and cyclins. Transcription factors of this class include the products of the *MYC*, *MYB*, *JUN*, *FOS*, and *REL* proto-oncogenes. Of these, *MYC* is most commonly involved in human tumors, and hence a brief overview of its regulation and function follows.

***MYC* Oncogene.** The *MYC* proto-oncogene is expressed in virtually all eukaryotic cells and belongs to the immediate early response genes, which are rapidly and transiently induced by RAS/MAPK signaling following growth factor stimulation of quiescent cells. Under normal circumstances, *MYC* protein concentrations are tightly controlled at the level of transcription, translation, and protein stability, and virtually all pathways that regulate growth impinge on *MYC* through one or more of these mechanisms. Several single nucleotide polymorphisms (SNPs) that are strongly linked to an elevated risk of cancers, such as prostate and ovarian carcinoma, fall within a large region devoid of recognizable genes that lies next to *MYC* on chromosome 8. Experimental data suggest that these genetic variants alter the function of enhancer elements that regulate *MYC* expression, and that increased cancer risk is associated with variants that bring about higher levels of *MYC* RNA expression in response to certain growth promoting signals.

How *MYC* promotes normal and neoplastic cell growth is incompletely understood, but a multitude of studies

have shown that *MYC* has remarkably broad activities, several of which contribute not only to deregulated cell growth but also to several other hallmarks of cancer.

- ***MYC* activates the expression of many genes that are involved in cell growth.**
 - Some *MYC* target genes, like D cyclins, are directly involved in cell cycle progression.
 - *MYC* also upregulates the expression of rRNA genes and rRNA processing, thereby enhancing the assembly of ribosomes needed for protein synthesis.
 - *MYC* upregulates a program of gene expression that leads to metabolic reprogramming and the Warburg effect, another cancer hallmark (discussed later). Among the genes involved in metabolism that are upregulated by *MYC* are multiple glycolytic enzymes and factors involved in glutamine metabolism, both of which contribute to the generation of metabolic intermediates that are needed for synthesis of macromolecules such as DNA, proteins, and lipids.
 - Based on these protean effects, *MYC* can be considered a master transcriptional regulator of cell growth. Indeed, the fastest growing human tumors, such as Burkitt lymphoma, which virtually always bears a chromosomal translocation involving *MYC* ([Fig. 7-26](#)), are those with the highest levels of *MYC*.
- **In some contexts, *MYC* upregulates expression of telomerase.** As discussed later, telomerase is one of several factors that contribute to the endless replicative capacity (the immortalization) of cancer cells.
- ***MYC* is one of a handful of transcription factors that can act together to reprogram somatic cells into pluripotent stem cells ([Chapter 1](#)).** This capacity has led to suspicions that *MYC* may also contribute to cancer cell “stemness,” another important aspect of the immortality of cancers.

Given the importance of *MYC* in regulation of cell growth, it should come as no surprise that it is deregulated in cancer through a variety of mechanisms. Sometimes deregulation involves genetic alterations of *MYC* itself. In addition to the *MYC* translocations in Burkitt lymphoma and a subset of other B and T cell tumors, *MYC* is amplified in some breast, colon, lung, and many other carcinomas. The functionally identical *NMYC* and *LMYC* genes are also amplified in neuroblastomas ([Fig. 7-27](#)) and small cell cancers of the lung, respectively. In many other instances, oncogenic mutations involving components of upstream signaling pathways elevate *MYC* protein levels by increasing *MYC* transcription, enhancing *MYC* mRNA translation, and/or stabilizing *MYC* protein. Thus, constitutive RAS/MAPK signaling (many cancers), Notch signaling (several hematologic cancers), Wnt signaling (colon carcinoma), and Hedgehog signaling (medulloblastoma) all transform cells in part through upregulation of *MYC*.

Cyclins and Cyclin-Dependent Kinases. As mentioned in [Chapter 1](#), growth factors transduce signals that stimulate the orderly progression of cells through the various phases of the cell cycle, the process by which cells replicate their DNA in preparation for cell division. Progression of cells through the cell cycle is orchestrated by *cyclin-dependent kinases* (CDKs), which are activated by binding

Figure 7-27 Amplification of the *NMYC* gene in human neuroblastomas. The *NMYC* gene, normally present on chromosome 2p, becomes amplified and is seen either as extra chromosomal double minutes or as a chromosomally integrated, homogeneous staining region (HSR). The integration involves other autosomes, such as 4, 9, or 13. (Modified from Brodeur GM: Molecular correlates of cytogenetic abnormalities in human cancer cells: implications for oncogene activation. In Brown EB (ed): Progress in Hematology, Vol 14. Orlando, FL, Grune & Stratton, 1986, p 229-256.)

to *cyclins*, so called because of the cyclic nature of their production and degradation. The CDK-cyclin complexes phosphorylate crucial target proteins that drive cells forward through the cell cycle. While cyclins arouse the CDKs, *CDK inhibitors* (CDKIs), of which there are many, silence the CDKs and exert negative control over the cell cycle (Table 7-6). Expression of these inhibitors is down-regulated by mitogenic signaling pathways, thus promoting the progression of the cell cycle.

There are two main cell cycle checkpoints one at the G_1/S transition and the other at the G_2/M transition, each of which is tightly regulated by a balance of growth promoting and growth suppressing factors, as well as by sensors of DNA damage (Chapter 1). If activated, these DNA-damage sensors transmit signals that arrest cell cycle progression and, if cell damage cannot be repaired, initiate apoptosis. Understandably, defects in the G_1/S checkpoint are more important in cancer, in that these lead to dysregulated growth as well as a mutator phenotype, which (as mentioned) enables cancer development and progression. The major cancer-associated mutations that affect the G_1/S checkpoint can be broadly grouped into two classes:

- **Gain-of-function mutations in D cyclin genes and *CDK4*, oncogenes that promote G_1/S progression.** There are three D cyclin genes, D1, D2, and D3, which are functionally interchangeable and often dysregulated by acquired mutations in cancer, including chromosomal translocations in lymphoid tumors and gene amplification in a variety of solid tumors. Amplification of the *CDK4* gene also occurs in melanomas, sarcomas, and glioblastomas. Mutations affecting cyclin B and

Table 7-6 Cell Cycle Components and Inhibitors That Are Frequently Mutated in Cancer

Cell Cycle Component	Main Function
Cyclins and Cyclin-Dependent Kinases	
CDK4; D cyclins	Form a complex that phosphorylates RB, allowing the cell to progress through the G_1 restriction point
Cell Cycle Inhibitors	
CIP/KIP family: p21, p27 (CDKN1A-D)	Block the cell cycle by binding to cyclin-CDK complexes p21 is induced by the tumor suppressor p53 p27 responds to growth suppressors such as TGF- β
INK4/ARF family (CDKN2A-C)	p16/INK4a binds to cyclin D-CDK4 and promotes the inhibitory effects of RB p14/ARF increases p53 levels by inhibiting MDM2 activity
Cell Cycle Checkpoint Components	
RB	Tumor suppressive "pocket" protein that binds E2F transcription factors in its hypophosphorylated state, preventing G_1/S transition; also interacts with several transcription factors that regulate differentiation
p53	Tumor suppressor altered in the majority of cancers; causes cell cycle arrest and apoptosis. Acts mainly through p21 to cause cell cycle arrest. Causes apoptosis by inducing the transcription of pro-apoptotic genes such as <i>BAX</i> . Levels of p53 are negatively regulated by MDM2 through a feedback loop. p53 is required for the G_1/S checkpoint and is a main component of the G_2/M checkpoint.

cyclin E and other CDKs also occur, but they are much less frequent, presumably because of the preeminent importance of the G_1/S transition in regulating tumor growth rates.

- **Loss-of-function mutations in tumor suppressor genes that inhibit G_1/S progression.** CDKIs that inhibit cyclin D/CDK complexes are frequently mutated or otherwise silenced in many human malignancies. For example, germline mutations of *p16* (*CDKN2A*) are present in 25% of melanoma-prone kindreds, and somatically acquired deletion or inactivation of *p16* is seen in 75% of pancreatic carcinomas, 40% to 70% of glioblastomas, 50% of esophageal cancers, 20% to 70% of acute lymphoblastic leukemias, and 20% of non-small-cell lung carcinomas, soft tissue sarcomas, and bladder cancers. Furthermore, the two most important tumor suppressor genes, *RB* and *TP53*, both encode proteins that inhibit G_1/S progression.

KEY CONCEPTS

Oncogenes, Oncoproteins, and Unregulated Cell Proliferation

Proto-oncogenes: normal cellular genes whose products promote cell proliferation

Oncogenes: mutated or overexpressed versions of proto-oncogenes that function autonomously, having lost dependence on normal growth promoting signals

Oncoprotein: a protein encoded by an oncogene that drives increased cell proliferation through one of several mechanisms

- Constitutive expression of growth factors and their cognate growth factor receptors, setting up an autocrine cell signaling loop
- Mutations in growth factor receptors, non-receptor tyrosine kinases, or downstream signaling molecules that lead to constitutive signaling, such as:
 - Activation of the EGF receptor tyrosine kinase by point mutations (lung cancer); activation of the HER2 receptor tyrosine kinase by gene amplification (breast cancer) ; activation of the JAK2 tyrosine kinase by point mutations (myeloproliferative disorders)
 - Activation of the ABL nonreceptor tyrosine kinase by chromosomal translocation and creation of a BCR-ABL fusion gene (chronic myelogenous leukemia, acute lymphoblastic leukemia)
 - Activation of RAS by point mutations (many cancers)
 - Activation of the PI3K and BRAF serine/threonine kinases by point mutations (many cancers)
- Increased expression of MYC, a master transcription factor that regulates genes needed for rapid cell growth by deregulation through chromosomal translocations (Burkitt lymphoma, other hematologic malignancies); gene amplification (neuroblastoma); increased activity of upstream signaling pathways (many cancers)
- Mutations that increase the activity of cyclin-dependent kinase 4 (CDK4)/D cyclin complexes, which promote cell cycle progression

Insensitivity to Growth Inhibition: Tumor Suppressor Genes

Whereas oncogenes drive the proliferation of cells, the products of most tumor suppressor genes apply brakes to cell proliferation, and abnormalities in these genes lead to failure of growth inhibition, another fundamental hallmark of carcinogenesis. Tumor suppressor proteins form a network of checkpoints that prevent uncontrolled growth. Many tumor suppressors, such as RB and p53, are part of a regulatory network that recognizes genotoxic stress from any source and responds by shutting down proliferation. Indeed, expression of an oncogene in normal cells with intact tumor suppressor genes leads to quiescence, or to permanent cell cycle arrest (oncogene-induced senescence, discussed later), rather than uncontrolled proliferation. Ultimately, the growth-inhibitory pathways may prod the cells into apoptosis. Another set of tumor suppressors seems to be involved in cell differentiation, causing cells to enter a postmitotic, differentiated pool without replicative potential. Similar to mitogenic signals, growth-inhibitory, pro-differentiation signals originate outside the cell and use receptors, signal transducers, and nuclear transcription regulators to accomplish their effects; tumor suppressors form a portion of these networks. Thus, the protein products of tumor suppressor genes may function as transcription factors, cell cycle inhibitors, signal transduction molecules, cell surface receptors, and regulators of cellular responses to DNA damage.

In this section, we describe tumor suppressor genes, their products, and possible mechanisms by which loss of their function contributes to unregulated cell growth

(Table 7-7). Many of our current concepts of tumor suppressors evolved from studies of the retinoblastoma (*RB*) gene, the first tumor suppressor gene discovered, which remains a prototype of genes of this type. Like many discoveries in medicine, *RB* was identified by studying a rare disease, familial retinoblastoma. Approximately 40% of retinoblastomas are familial, with the predisposition to develop the tumor being transmitted as an autosomal dominant trait. Carriers of the retinoblastoma trait have a 10,000-fold increased risk of developing retinoblastoma (often in both eyes) as compared to the general population, and are also at greatly increased risk of developing osteosarcoma and other soft-tissue sarcomas. About 60% of retinoblastomas occur sporadically (virtually always in only one eye), and such patients are not at increased risk for other forms of cancer. To explain these two patterns of occurrence of retinoblastoma, Knudson proposed his now canonic “two-hit” hypothesis of oncogenesis. In molecular terms, Knudson’s hypothesis can be stated as follows (Fig. 7-28):

- Two mutations (hits), involving both alleles of *RB* at chromosome locus 13q14, are required to produce retinoblastoma.
- In familial cases, children inherit one defective copy of the *RB* gene in the germline (the first hit), and the other copy is normal (Fig. 7-28). Retinoblastoma develops when the normal *RB* allele is mutated in retinoblasts as a result of a spontaneous somatic mutation (the second hit). Because such second hits seem to be virtually inevitable in a small fraction of retinoblasts, most individuals inheriting a germline defect in one *RB* allele develop unilateral or bilateral retinoblastoma, and the disease is inherited as an autosomal dominant trait.
- In sporadic cases both normal *RB* alleles must undergo somatic mutation in the same retinoblast (two hits). The probability of this event is low (explaining why retinoblastoma is an uncommon tumor in the general population), but the end result is the same: a retinal cell that has completely lost *RB* function and becomes cancerous.

Note that a child carrying an inherited mutant *RB* allele in all somatic cells is perfectly normal (except for the increased risk of developing cancer); it follows that one defective *RB* gene does not affect cell behavior. Thus, while the genetic trait (increased cancer risk) associated with germline mutations in *RB* is inherited in an autosomal dominant fashion, at the level of the individual cell, loss-of-function mutations in the *RB* gene behave in a recessive fashion.

Subsequent to the identification of *RB*, a large number of other tumor suppressor genes have been discovered, many through study of other types of familial cancers. In general, the major themes that were first appreciated through the study of familial retinoblastoma hold for these other familial cancers: the risk of cancer is inherited as an autosomal dominant trait; tumors acquire a second hit in the sole normal tumor suppressor gene allele; and the same tumor suppressor gene is frequently mutated in sporadic tumors of the same type.

Some of the most important tumor suppressor genes, their associated familial syndromes, and their normal

Table 7-7 Selected Tumor Suppressor Genes and Associated Familial Syndromes and Cancers, Sorted by Cancer Hallmarks*

Gene	Protein	Function	Familial Syndromes	Sporadic Cancers
Inhibitors of Mitogenic Signaling Pathways				
<i>APC</i>	Adenomatous polyposis coli protein	Inhibitor of WNT signaling	Familial colonic polyps and carcinomas	Carcinomas of stomach, colon, pancreas; melanoma
<i>NF1</i>	Neurofibromin-1	Inhibitor of RAS/MAPK signaling	Neurofibromatosis type 1 (neurofibromas and malignant peripheral nerve sheath tumors)	Neuroblastoma, juvenile myeloid leukemia
<i>NF2</i>	Merlin	Cytoskeletal stability, Hippo pathway signaling	Neurofibromatosis type 2 (acoustic schwannoma and meningioma)	Schwannoma, meningioma
<i>PTCH</i>	Patched	Inhibitor of Hedgehog signaling	Gorlin syndrome (basal cell carcinoma, medulloblastoma, several benign tumors)	Basal cell carcinoma, medulloblastoma
<i>PTEN</i>	Phosphatase and tensin homologue	Inhibitor of PI3K/AKT signaling	Cowden syndrome (variety of benign skin, GI, and CNS growths; breast, endometrial, and thyroid carcinoma)	Diverse cancers, particularly carcinomas and lymphoid tumors
<i>SMAD2, SMAD4</i>	SMAD2, SMAD4	Component of the TGF β signaling pathway, repressors of MYC and CDK4 expression, inducers of CDK inhibitor expression	Juvenile polyposis	Frequently mutated (along with other components of the TGF β signaling pathway) in colonic and pancreatic carcinoma
Inhibitors of Cell Cycle Progression				
<i>RB</i>	Retinoblastoma (RB) protein	Inhibitor of G ₁ /S transition during cell cycle progression	Familial retinoblastoma syndrome (retinoblastoma, osteosarcoma, other sarcomas)	Retinoblastoma; osteosarcoma carcinomas of breast, colon, lung
<i>CDKN2A</i>	p16/INK4a and p14/ARF	p16: Negative regulator of cyclin-dependent kinases; p14, indirect activator of p53	Familial melanoma	Pancreatic, breast, and esophageal carcinoma, melanoma, certain leukemias
Inhibitors of “Pro-growth” Programs of Metabolism and Angiogenesis				
<i>VHL</i>	Von Hippel Lindau (VHL) protein	Inhibitor of hypoxia-induced transcription factors (e.g., HIF1 α)	Von Hippel Lindau syndrome (cerebellar hemangioblastoma, retinal angioma, renal cell carcinoma)	Renal cell carcinoma
<i>STK11</i>	Liver kinase B1 (LKB1) or STK11	Activator of AMPK family of kinases; suppresses cell growth when cell nutrient and energy levels are low	Peutz-Jeghers syndrome (GI polyps, GI cancers, pancreatic carcinoma and other carcinomas)	Diverse carcinomas (5%-20% of cases, depending on type)
<i>SDHB, SDHD</i>	Succinate dehydrogenase complex subunits B and D	TCA cycle, oxidative phosphorylation	Familial paraganglioma, familial pheochromocytoma	Paraganglioma
Inhibitors of Invasion and Metastasis				
<i>CDH1</i>	E-cadherin	Cell adhesion, inhibition of cell motility	Familial gastric cancer	Gastric carcinoma, lobular breast carcinoma
Enablers of Genomic Stability				
<i>TP53</i>	p53 protein	Cell cycle arrest and apoptosis in response to DNA damage	Li-Fraumeni syndrome (diverse cancers)	Most human cancers
DNA Repair Factors				
<i>BRCA1, BRCA2</i>	Breast cancer-1 and breast cancer-2 (BRCA1 and BRCA2)	Repair of double-stranded breaks in DNA	Familial breast and ovarian carcinoma; carcinomas of male breast; chronic lymphocytic leukemia (BRCA2)	Rare
<i>MSH2, MLH1, MSH6</i>	MSH1, MLH1, MSH6	DNA mismatch repair	Hereditary nonpolyposis colon carcinoma	Colonic and endometrial carcinoma
Unknown Mechanisms				
<i>WT1</i>	Wilms tumor-1 (WT1)	Transcription factor	Familial Wilms tumor	Wilms tumor, certain leukemias
<i>MEN1</i>	Menin	Transcription factor	Multiple endocrine neoplasia-1 (MEN1; pituitary, parathyroid, and pancreatic endocrine tumors)	Pituitary, parathyroid, and pancreatic endocrine tumors

*Some tumor suppressors impact multiple cancer phenotypes (e.g., p53 affects cell cycle progression, genomic stability, susceptibility to cell death, and cellular metabolism); only a subset of major effects are given for each tumor suppressor gene listed. TCA, tricarboxylic acid.

Figure 7-28 Pathogenesis of retinoblastoma. Two mutations of the *RB* locus on chromosome 13q14 lead to neoplastic proliferation of the retinal cells. In the sporadic form, both *RB* mutations in the tumor-founding retinal cell are acquired. In the familial form, all somatic cells inherit one mutated copy of *RB* gene from a carrier parent, and as a result only one additional *RB* mutation in a retinal cell is required for complete loss of *RB* function.

functions are listed in [Table 7-7](#). Note that while tumor suppressors were initially thought of narrowly as proteins that put the brakes on cell cycle progression and DNA replication, it is now appreciated that some tumor suppressors prevent cellular transformation through other mechanisms, such as by altering cell metabolism (e.g., the serine-threonine kinase *STK11*, discussed later) or by ensuring genomic stability (e.g., the DNA repair factors *BRCA1* and *BRCA2*). Thus, while most tumor suppressors have inhibitory effects on cell growth through one mechanism or another, a more inclusive definition of a tumor suppressor is simply a protein or gene that is associated with suppression of any of the various hallmarks of cancer.

We next consider how the major tumor suppressors function, focusing on those that are most frequently mutated in cancer or that highlight pathogenically important molecular mechanisms.

***RB*: Governor of Proliferation.** *RB*, a key negative regulator of the G_1/S cell cycle transition, is directly or indirectly inactivated in most human cancers. *RB* also controls

cellular differentiation. It exists in an active hypophosphorylated state in quiescent cells and an inactive hyperphosphorylated state in cells passing through the G_1/S cell cycle transition ([Chapter 1](#)). *RB* function may be compromised in two different ways:

- Loss-of-function mutations involving both *RB* alleles
- A shift from the active hypophosphorylated state to the inactive hyperphosphorylated state by gain-of-function mutations that upregulate CDK/cyclin D activity or by loss-of-function mutations that abrogate the activity of CDK inhibitors

As discussed previously, the decision of a cell to progress from G_1 into S is of great importance, since once a cell enters the S phase it is obligated to complete mitosis. High levels of CDK4/cyclin D, CDK6/cyclin D, and CDK2/cyclin E complexes lead to hyperphosphorylation and inhibition of *RB*, releasing E2F transcription factors that drive the expression of genes that are needed for progression to S phase ([Fig. 7-29](#)). Growth factor signaling pathways generally upregulate the activity of CDK/cyclin complexes

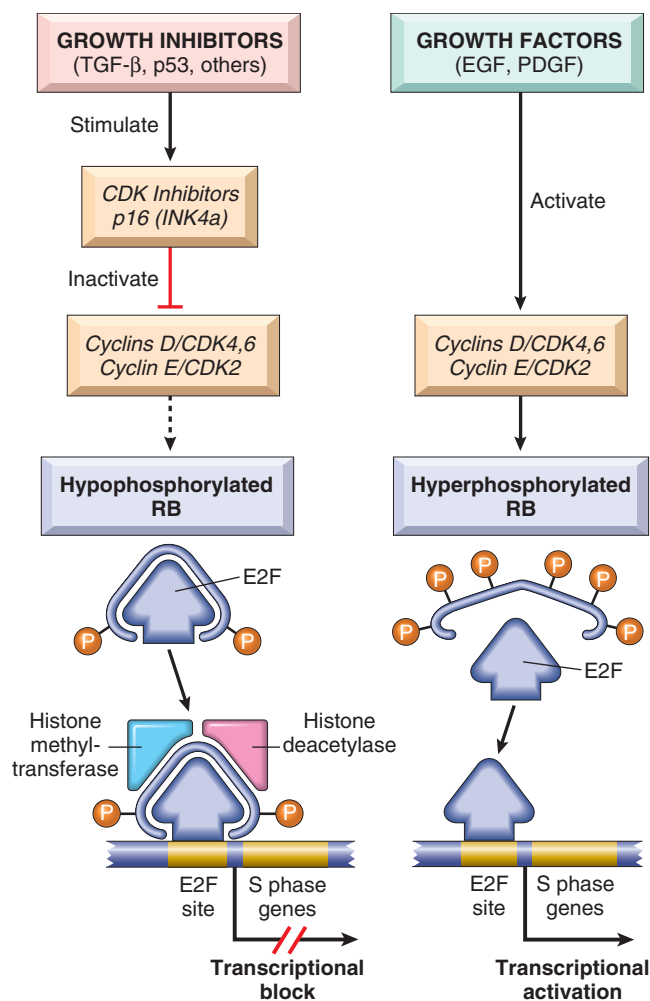

Figure 7-29 The role of RB in regulating the G_1 -S checkpoint of the cell cycle. Hypophosphorylated RB in complex with the E2F transcription factors binds to DNA, recruits chromatin-remodeling factors (histone deacetylases and histone methyltransferases), and inhibits transcription of genes whose products are required for the S phase of the cell cycle. When RB is phosphorylated by the cyclin D-CDK4, cyclin D-CDK6, and cyclin E-CDK2 complexes, it releases E2F. The latter then activates transcription of S-phase genes. The phosphorylation of RB is inhibited by cyclin-dependent kinase inhibitors, because they inactivate cyclin-CDK complexes. Virtually all cancer cells show dysregulation of the G_1 -S checkpoint as a result of mutation in one of four genes that regulate the phosphorylation of RB; these genes are *RB*, *CDK4*, the genes encoding cyclin D proteins, and *CDKN2A* (p16). TGF- β , transforming growth factor- β .

and drive cells through the G_1 /S transition, whereas growth inhibitors tip the balance the other way by upregulating CDK inhibitors. RB is the point of integration of these opposing signals, making it a key player in regulation of cell cycle progression.

It was mentioned previously that germline and somatic loss-of-function mutations of the *RB* gene are associated with retinoblastoma and osteosarcoma, and analyses of cancer cell genomes have identified similar somatic *RB* mutations in a subset of glioblastomas, small-cell carcinomas of lung, breast cancers, and bladder carcinomas. However, given that RB is expressed in all cells, one may ask, why do patients with germline *RB* mutations preferentially develop only a few types of cancer? And,

conversely, why aren't acquired mutations of *RB* found in all kinds of cancer? The reason why persons who inherit one defective allele of *RB* preferentially develop retinoblastoma is not understood, but a possible explanation is that other RB family members exist that may partially complement RB function in cell types other than retinoblasts.

With respect to the second question (i.e., why mutations of *RB* are not more widespread in human tumors), the answer is much simpler: mutations in other genes that control RB phosphorylation can mimic the effect of *RB* loss, and such genes are mutated in many cancers that have normal *RB* genes. Thus, for example, mutational activation of cyclin D or CDK4 and mutational inactivation of CDK inhibitors favors cell proliferation by facilitating the hyperphosphorylation and inactivation of RB. The current paradigm is that **loss of normal cell cycle control is central to malignant transformation and that at least one of four key regulators of the cell cycle (p16/INK4a, cyclin D, CDK4, RB) is dysregulated in the vast majority of human cancers.** In cells that harbor mutations in any one of these other genes, or in upstream factors that regulate their expression and function (e.g., receptor tyrosine kinases, RAS), RB may be functionally inactivated even if the *RB* gene itself is not mutated.

The transforming proteins of several oncogenic animal and human DNA viruses also act, in part, by neutralizing the growth-inhibitory activities of RB. In these cases, the RB protein is functionally inactivated by the binding of a viral protein and no longer acts as a cell cycle inhibitor. Simian virus 40 and polyomavirus large T antigens, adenovirus E1A protein, and HPV E7 protein all bind to the hypophosphorylated form of RB. The binding occurs in the same RB pocket that normally sequesters E2F transcription factors. Of note, in the case of HPV, viral types (such as HPV16) that confer a high risk for the development of cervical carcinoma express E7 protein variants with higher affinity for RB than do lower risk viral types. Thus, the RB protein, unable to bind the E2F transcription factors, is functionally inactivated by these viral oncoproteins, and the E2F factors are free to cause cell cycle progression.

KEY CONCEPTS

RB, Governor of the Cell Cycle

- When hypophosphorylated, RB exerts antiproliferative effects by binding and inhibiting E2F transcription factors that regulate genes required for cells to pass through the G_1 -S phase cell cycle checkpoint. Normal growth factor signaling leads to RB hyperphosphorylation and inactivation, thus promoting cell cycle progression.
- The antiproliferative effect of RB is abrogated in cancers through a variety of mechanisms, including:
 - Loss-of-function mutations affecting *RB*
 - Gene amplifications of CDK4 and cyclin D genes
 - Loss of cyclin-dependent kinase inhibitors (p16/INK4a)
 - Viral oncoproteins that bind and inhibit RB (E7 protein of HPV)

TP53: Guardian of the Genome. TP53, a tumor suppressor gene that regulates cell cycle progression, DNA repair, cellular senescence, and apoptosis, is the most frequently mutated gene in human cancers. Loss-of-function

mutations in *TP53*, located on chromosome 17p13.1, are found in more than 50% of cancers. Moreover, *TP53* mutations occur with some frequency in virtually every type of cancer, including carcinomas of the lung, colon, and breast—the three leading causes of cancer death. In most cases, mutations are present in both *TP53* alleles and are acquired in somatic cells (not inherited in the germline). Less commonly, individuals inherit one mutated *TP53* allele. As in the case of the *RB* tumor suppressor and retinoblastoma, inheritance of a mutated copy of *TP53* predisposes individuals to malignant tumors because only one additional “hit” in the lone normal allele is needed to abrogate *TP53* function. Such individuals, said to have the *Li-Fraumeni syndrome*, have a 25-fold greater chance of developing a malignant tumor by age 50 than the general population. In contrast to individuals who inherit a mutant *RB* allele, the spectrum of tumors that develop in persons with the Li-Fraumeni syndrome is quite varied; the most common types of tumors are sarcomas, breast cancer, leukemias, brain tumors, and carcinomas of the adrenal cortex. People with the Li-Fraumeni syndrome often develop cancer at younger ages and are more likely to suffer from multiple primary tumors of varying types than are normal individuals.

These mutational data, while impressive, only begin to tell the tale of altered *TP53* function in cancer. *TP53* encodes the protein p53, which is tightly regulated at several levels. Analogous to *RB*, many tumors lacking *TP53* mutations have instead other mutations affecting proteins that regulate p53 function. For example, MDM2 and related proteins of the MDM2 family stimulate the degradation of p53; these proteins are frequently overexpressed in malignancies with normal *TP53* alleles. Indeed, the *MDM2* gene is amplified in 33% of human sarcomas, leading to a functional deficiency of p53 in these tumors. Also like *RB*, the transforming proteins of several DNA viruses bind p53 and promote its degradation. Best known of these viral oncoproteins is the E6 protein of high-risk human papilloma viruses, which have causative roles in cervical carcinoma and a subset of squamous cell carcinomas of the head and neck.

The frequent loss of p53 function in human tumors reflects its critical role in prevention of cancer development. p53 carries out this role by serving as the focal point of a large network of signals that sense cellular stress, primarily DNA damage, but also shortened telomeres, hypoxia, and stress caused by excessive pro-growth signaling, as may occur in cells bearing mutations in genes such as *RAS* and *MYC*. In nonstressed, healthy cells, p53 is held at bay through its aforementioned association with MDM2, an enzyme that ubiquitinylates p53, leading to its degradation by the proteasome. As a result, p53 is virtually undetectable in normal cells. In stressed cells, however, p53 is released from the inhibitory effects of MDM2 via two major mechanisms, which vary depending on the nature of the stress (Fig. 7-30).

- **DNA damage and hypoxia.** The key initiators of p53 activation following DNA damage or in cells exposed to hypoxia are two related protein kinases, ataxia-telangiectasia mutated (*ATM*) and ataxia-telangiectasia and Rad3 related (*ATR*). As the name implies, the *ATM* gene was originally identified as the germline mutation

in individuals with ataxia-telangiectasia. Persons with this disease, which is characterized by an inability to repair certain kinds of DNA damage, suffer from an increased incidence of cancer. The types of damage sensed by *ATM* and *ATR* are different, but the downstream effects are similar. Once triggered, both *ATM* and *ATR* stimulate the phosphorylation of a number of proteins, including p53 and MDM2. These posttranslational modifications disrupt the binding and degradation of p53 by MDM2, allowing p53 to accumulate.

- **“Oncogenic” stress.** Activation of oncoproteins such as *RAS* leads to sustained, supraphysiologic signaling through pro-growth pathways such as the *MAPK* and *PI3K/AKT* pathways. Through unknown mechanisms, these aberrant signals create cellular stress and lead to increased expression of p14/*ARF*, which you will recall is encoded by the *CDKN2A* tumor suppressor gene. p14/*ARF* binds MDM2 and displaces p53, again allowing p53 levels to rise in the cell.

Once activated, p53 thwarts neoplastic transformation by inducing either transient cell cycle arrest, senescence (permanent cell cycle arrest), or programmed cell death (apoptosis). Most of these effects are believed to stem from p53’s ability to function as a transcription factor. p53 binds DNA in a sequence-specific fashion and activates the transcription of hundreds of different target genes with p53-binding elements. The key target genes that execute the functions of p53 are not completely defined, but appear to fall into three major categories: (1) those that cause cell cycle arrest; (2) those that cause apoptosis; and (3) those that enhance catabolic metabolism or inhibit anabolic metabolism. The latter group of genes makes intuitive sense; there is no need for a cell that has stopped its cell cycle progression to continue to synthesize the large amounts of macromolecules (e.g., lipids and proteins) that are needed for cell growth and division. Also included in the list of p53 target genes are those encoding two kinds of regulatory RNAs, micro-RNA (miRNAs) and long intervening noncoding (LINC) RNAs, which presumably help to coordinate the p53-dependent cellular response to stress.

Once p53 accumulates in a cell to levels that are sufficient to activate the transcription of target genes, several different outcomes are possible, each more serious than the last with respect to the ultimate fate of the affected cell:

- **Transient p53-induced cell cycle arrest.** Rapid onset, p53-mediated cell cycle arrest may be considered a primordial response to DNA damage. It occurs late in the G_1 phase and is caused in part by p53-dependent transcription of the *CDKN1A* gene, which encodes the CDK inhibitor p21. As discussed, p21 inhibits CDK4/*D* cyclin complexes, thereby maintaining *RB* in an active, hypophosphorylated state and blocking the progression of cells from G_1 phase to S phase. This pause in cell cycling is welcome, as it gives the cells “breathing time” to repair DNA damage. p53 also helps the process by inducing certain proteins, such as *GADD45* (growth arrest and DNA damage), that enhance DNA repair. If DNA damage is repaired successfully, the signals responsible for p53 stabilization cease and p53 levels fall, releasing the cell cycle block. The cells may then revert to a normal state.

Figure 7-30 The role of p53 in maintaining the integrity of the genome. Activation of normal p53 by DNA-damaging agents or by hypoxia leads to cell cycle arrest in G₁ and induction of DNA repair by transcriptional upregulation of the cyclin-dependent kinase inhibitor p21 and the *GADD45* genes. Successful repair of DNA allows cells to proceed with the cell cycle; if DNA repair fails, p53 triggers either apoptosis or senescence. In cells with loss or mutations of the p53 gene, DNA damage does not induce cell cycle arrest or DNA repair, and genetically damaged cells proliferate, giving rise eventually to malignant neoplasms.

- **p53-induced senescence.** Senescence is a state of permanent cell cycle arrest characterized by specific changes in morphology and gene expression that differentiate it from reversible cell cycle arrest. How cells become fixed in the senescence state is unclear. One plausible idea is that senescence is the product of epigenetic changes that result in the formation of heterochromatin at key loci, including genes that are required for progression of cells from the G₁ phase into S phase. Like other p53 responses, senescence may be stimulated in response to a variety of stresses, such as unopposed oncogene signaling, hypoxia, and shortened telomeres. The senescent cells, while not normal, are blocked from developing into tumors.
- **p53-induced apoptosis.** Apoptosis of cells with irreversible DNA damage is the ultimate protective mechanism against neoplastic transformation. p53 directs the

transcription of several pro-apoptotic genes such as *BAX* and *PUMA* (described later), which are believed to tip the balance in favor of cell death via the intrinsic (mitochondrial) pathway.

What determines whether a cell repairs its DNA, becomes senescent, or undergoes apoptosis is uncertain, but both the duration and the level of p53 activation may be deciding factors. It appears that the affinity of p53 for its binding sites in the promoters and enhancers of DNA-repair genes is higher than its affinity for binding sites in pro-apoptotic genes. Thus, the DNA-repair pathway is stimulated first as p53 begins to accumulate. If p53 is sustained at this level due to ineffective DNA repair or other chronic stresses (e.g., that induced by a potentially oncogenic RAS mutation), epigenetic silencing of genes that are needed for cell cycle progression occurs, leading to

senescence. Alternatively, if enough p53 accumulates to stimulate the transcription of the pro-apoptotic genes, the cell dies. While this scheme seems to be generally correct, cell-type-specific variations in response to p53 activation have been observed that are not easily explained, with some cell types succumbing rapidly to apoptosis, and others opting mainly for senescence. Thus, there is still much to be learned about the nuances of p53 function.

With loss of p53 function, DNA damage goes unrepaired, driver mutations accumulate in oncogenes and other cancer genes, and the cell marches blindly along a dangerous path leading to malignant transformation. Moreover, once a cancer is established, its p53 status has several important therapeutic implications. Irradiation and conventional chemotherapy, the two common modalities of cancer treatment, mediate their effects by inducing DNA damage and subsequent apoptosis. Tumors with wild type *TP53* alleles are more likely to be killed by such therapy than tumors with mutated *TP53* alleles. Such is the case with testicular teratocarcinomas and childhood acute lymphoblastic leukemias, which usually have wild type *TP53* alleles. In contrast, tumors such as lung cancers and colorectal cancers, which frequently carry *TP53* mutations, are relatively resistant to chemotherapy and irradiation. A second less obvious but even more nefarious result is that cells with defective p53 acquire a mutator phenotype, a tendency to acquire additional mutations at a high rate. Particularly in patients with advanced stage tumors with mutator phenotypes, it is very likely (and perhaps inevitable) that genetically distinct subclones will arise by chance that are resistant to any single therapy, whether this be radiation, conventional chemotherapy, or molecularly targeted cancer drugs. This theme is discussed later when the enabling properties of genomic instability are discussed more broadly.

The discovery of p53 family members p63 and p73 has revealed that p53 has collaborators. Indeed, p53, p63, and p73 are players in a complex interconnected network with significant crosstalk that is still being unraveled. p53 is ubiquitously expressed, while p63 and p73 show more tissue specificity. For example, p63 is essential for the differentiation of stratified squamous epithelia, while p73 has strong pro-apoptotic effects after DNA damage induced by chemotherapeutic agents.

KEY CONCEPTS

p53, Guardian of the Genome

- The p53 protein is the central monitor of stress in the cell and can be activated by anoxia, inappropriate signaling by mutated oncoproteins, or DNA damage. p53 controls the expression and activity of proteins involved in cell cycle arrest, DNA repair, cellular senescence, and apoptosis.
- DNA damage is sensed by complexes containing kinases of the ATM/ATR family; these kinases phosphorylate p53, liberating it from inhibitors such as MDM2. Active p53 then upregulates the expression of proteins such as the cyclin-dependent kinase inhibitor p21, thereby causing cell-cycle arrest at the G1-S checkpoint. This pause allows cells to repair DNA damage.
- If DNA damage cannot be repaired, p53 induces additional events that lead to cellular senescence or apoptosis.

- The majority of human cancers demonstrate biallelic loss-of-function mutations in *TP53*. Rare patients with Li-Fraumeni syndrome inherit one defective copy of *TP53* and have a very high incidence of a wide variety of cancers.
- Like RB, p53 is inactivated by viral oncoproteins, such as the E6 protein of HPV

Other Tumor Suppressor Genes. There is little doubt that more tumor suppressor genes remain to be discovered. Often, their location is suspected by the detection of recurrent sites of chromosomal deletions, which are now being rapidly identified and characterized by high throughput sequencing of cancer genomes. The known tumor suppressor genes all appear to impact one or more of the hallmarks of cancer. Some that are associated with well-defined clinical syndromes (Table 7-7) or that serve to highlight various mechanisms by which tumor suppressors function are described:

APC: Gatekeeper of Colonic Neoplasia. Adenomatous polyposis coli (APC) is a member of the class of tumor suppressors that function by downregulating growth-promoting signaling pathways. Germline loss-of-function mutations involving the *APC* (5q21) locus are associated with familial adenomatous polyposis, an autosomal dominant disorder in which individuals born with one mutant allele develop thousands of adenomatous polyps in the colon during their teens or 20s (Chapter 17). Almost invariably, one or more of these polyps undergoes malignant transformation, giving rise to colon cancer. As with other tumor suppressor genes, both copies of the *APC* gene must be lost for an adenoma to arise. As discussed later, several additional mutations must then occur for adenomas to progress to cancers. In addition to these hereditary forms of colon cancer, 70% to 80% of nonfamilial colorectal carcinomas and sporadic adenomas also show acquired defects involving both *APC* genes, firmly implicating *APC* loss of function in the pathogenesis of colonic tumors.

APC is a component of the WNT signaling pathway, which has a major role in controlling cell fate, adhesion, and cell polarity during embryonic development (Fig. 7-31). WNT signals through a family of cell surface receptors called frizzled (FRZ), and stimulates several pathways, the central one involving β -catenin and APC. A major function of the APC protein is to hold β -catenin activity in check. In the absence of WNT signaling, APC causes degradation of β -catenin, preventing its accumulation in the cytoplasm. APC does so by forming a macromolecular “destruction” complex that leads to the proteasomal degradation of β -catenin. Signaling by WNT blocks the formation of the destruction complex, stabilizing β -catenin and allowing it to translocate from the cytoplasm to the nucleus. Once in the nucleus β -catenin forms a transcription activation complex with the DNA-binding factor TCF. The β -catenin/TCF complex promotes the growth of colonic epithelial cells by increasing the transcription of *MYC*, *cyclin D1*, and other genes. Because inactivation of the *APC* gene disrupts the destruction complex, β -catenin survives and translocates to the nucleus, where it activates the transcription of pro-growth target genes in cooperation with TCF. Thus, cells that lose APC behave as if they are

Figure 7-31 The role of APC in regulating the stability and function of β -catenin. APC and β -catenin are components of the WNT signaling pathway. **A**, In resting colonic epithelial cells (not exposed to WNT), β -catenin forms a macromolecular complex containing the APC protein. This complex leads to the destruction of β -catenin, and intracellular levels of β -catenin are low. **B**, When normal colonic epithelial cells are stimulated by WNT molecules, the *destruction complex* is deactivated, β -catenin degradation does not occur, and cytoplasmic levels increase. β -catenin translocates to the nucleus, where it binds to TCF, a transcription factor that activates genes involved in cell cycle progression. **C**, When APC is mutated or absent, as frequently occurs in colonic polyps and cancers, the destruction of β -catenin cannot occur. β -catenin translocates to the nucleus and coactivates genes that promote entry into the cell cycle, and cells behave as if they are under constant stimulation by the WNT pathway.

being continuously stimulated by WNT. The importance of the APC/ β -catenin signaling pathway in tumorigenesis is attested to by the fact that many colon tumors with normal APC genes harbor mutations in β -catenin that prevent its APC-dependent destruction, allowing the mutant protein to accumulate in the nucleus and stimulate transcription. Thus, β -catenin, the target of APC, is itself a proto-oncoprotein. Dysregulation of the APC/ β -catenin pathway is not restricted to colon cancers; for example, gain-of-function mutations in β -catenin are present in more than 50% of hepatoblastomas and in approximately 20% of hepatocellular carcinomas.

E-Cadherin. β -catenin binds to the cytoplasmic tail of E-cadherin, a cell surface protein that maintains intercellular adhesiveness. Loss of cell-cell contact, such as in a wound or injury to the epithelium, disrupts the interaction between E-cadherin and β -catenin, and also promotes increased translocation of β -catenin to the nucleus, where it stimulates genes that promote proliferation; this is an appropriate response to injury that can help repair the wound. Reestablishment of these E-cadherin contacts as the wound heals leads to β -catenin again being sequestered at the membrane and reduces in the proliferative signal; these cells are said to be “contact-inhibited.” Loss-of-contact inhibition, by mutation of the E-cadherin/ β -catenin axis, or by other changes, is a key characteristic of carcinomas. Furthermore, loss of E-cadherin can contribute to the

malignant phenotype by allowing easy disaggregation of cells, which can then invade locally or metastasize. Reduced cell surface expression of E-cadherin has been noted in many carcinomas, including those that arise in the esophagus, colon, breast, ovary, and prostate. Germline loss-of-function mutations of the E-cadherin gene, known as *CDH1*, cause familial gastric carcinoma, and a variable proportion of sporadic gastric carcinomas are also associated with loss of E-cadherin expression. The molecular basis of reduced E-cadherin expression in sporadic cancers is varied. In a small proportion of cases, there are mutations in the E-cadherin gene (located on 16q); in other cancers, E-cadherin expression is reduced as a secondary effect of activating mutations in β -catenin genes. Additionally, E-cadherin may be downregulated by transcription repressors, such as SNAIL, that are implicated in epithelial-to-mesenchymal transition and metastasis (discussed later).

CDKN2A. The *CDKN2A* gene locus encodes two protein products: the p16/INK4a cyclin-dependent kinase inhibitor, which blocks CDK4/cyclin D-mediated phosphorylation of RB, thereby reinforcing the RB checkpoint; and p14/ARF, which activates the p53 pathway by inhibiting MDM2 and preventing destruction of p53. Thus, mutation or silencing of *CDKN2A* impacts both the RB and p53 tumor suppressor pathways. p16 also appears to be important in induction of cellular senescence (described later). Germline mutations in *CDKN2A* are associated with familial forms

of melanoma, and sporadic mutations of this locus have been detected in bladder cancer, head and neck tumors, acute lymphoblastic leukemias, and cholangiocarcinomas. In some tumors, such as cervical cancer, p16 is frequently silenced by hypermethylation of the gene rather than mutation (see discussion of [epigenetic changes](#)). Other cyclin-dependent kinase inhibitors also function as tumor suppressors and are frequently mutated or otherwise silenced in many human malignancies.

TGF- β Pathway. In most normal epithelial, endothelial, and hematopoietic cells, TGF- β is a potent inhibitor of proliferation. It regulates cellular processes by binding to TGF- β receptors I and II. Dimerization of the receptor upon ligand binding initiates intracellular signals that involve proteins of the SMAD family. Under normal circumstances, these signals turn on antiproliferative genes (e.g., genes for cyclin-dependent kinase inhibitors) and turn off genes that drive cell growth (e.g., *MYC*, cyclins, and cyclin-dependent kinases). As can be inferred from our earlier discussion, these changes result in decreased phosphorylation of RB and cell cycle arrest.

In many forms of cancer these growth-inhibiting effects are impaired by loss-of-function mutations in the TGF- β signaling pathway. Mutations affecting the type II TGF- β receptor are common in cancers of the colon, stomach, and endometrium, while mutational inactivation of SMAD4 is common in pancreatic cancers. In many other cancers, loss of TGF- β -mediated growth inhibition occurs at the level of key target genes; examples include mutations that lead to loss of p21 function and/or persistent expression of *MYC*. In such cases other preserved elements of the TGF- β -induced program of gene expression may actually facilitate acquisition of cancer hallmarks, such as immune evasion or angiogenesis. Thus TGF- β signaling is a double-edged sword that can prevent or promote tumor growth, depending on the state of other genes in the cell.

PTEN. PTEN (phosphatase and tensin homologue) is a membrane-associated phosphatase encoded by a gene on chromosome 10q23 that is mutated in Cowden syndrome, an autosomal dominant disorder marked by frequent benign growths, such as skin appendage tumors, and an increased incidence of epithelial cancers, particularly of the breast ([Chapter 21](#)), endometrium, and thyroid. As already mentioned, PTEN acts as a tumor suppressor by serving as a brake on the PI3K/AKT arm of the receptor tyrosine kinase pathway. *PTEN* gene function is lost in many cancers through deletion, deleterious point mutations, or epigenetic silencing.

NF1. Individuals who inherit one mutant allele of the *NF1* gene develop numerous benign neurofibromas and optic nerve gliomas as a result of inactivation of the second copy of the gene. This condition is called *neurofibromatosis type 1* ([Chapter 26](#)). Some of the neurofibromas later develop into malignant peripheral nerve sheath tumors. As already discussed, *Neurofibromin*, the protein product of the *NF1* gene, contains a GTPase-activating domain that acts as a brake on RAS signaling. With loss of neurofibromin function, RAS tends to become trapped in an active, signal-emitting state.

NF2. Germline mutations in the *NF2* gene predispose to the development of *neurofibromatosis type 2*. As discussed in [Chapter 26](#), individuals with mutations in *NF2* develop benign bilateral schwannomas of the acoustic nerve. In addition, somatic mutations affecting both alleles of *NF2* have also been found in sporadic meningiomas and ependymomas. The product of the *NF2* gene, called *neurofibromin 2* or *merlin*, is structurally similar to the red cell membrane cytoskeletal protein 4.1 ([Chapter 13](#)), and is related to the ERM (ezrin, radixin, and moesin) family of membrane cytoskeleton-associated proteins. Cells lacking merlin do not establish stable cell-to-cell junctions and are insensitive to normal growth arrest signals generated by cell-to-cell contact.

WT1. Loss-of-function mutations in the *WT1* gene, located on chromosome 11p13, is associated with the development of Wilms tumor, a pediatric kidney cancer. Both inherited and sporadic forms of Wilms tumor occur, and mutational inactivation of the *WT1* locus is seen in both forms. The WT1 protein is a transcriptional activator of genes involved in renal and gonadal differentiation. It regulates the mesenchymal-to-epithelial transition that occurs in kidney development. Though not precisely known, it is likely that the tumorigenic effect of WT1 deficiency is intimately connected with the role of the gene in the differentiation of genitourinary tissues.

Interestingly, although WT1 is a tumor suppressor in Wilms' tumor, a variety of adult cancers, including leukemias and breast carcinomas, overexpress WT1. Since these tissues do not normally express WT1 at all, *WT1* may function as an oncogene in these cancers. Thus, some genes that regulate development may act as a tumor suppressor in one epigenetic context (e.g., *WT1* in a renal progenitor cell) and an oncogene in a second (e.g., *WT1* in a hematopoietic stem cell), an example of "crosstalk" between genes and the epigenome that we discuss later.

PATCHED (PTCH). *PTCH1* is a tumor suppressor gene that encodes a cell membrane protein called PATCHED1. PATCHED proteins are negative regulators of the Hedgehog signaling pathway. Under normal circumstances, binding of soluble factors belonging to the Hedgehog family to PATCH receptors relieves this negative regulation and activates the pathway, which stimulates downstream transcription factors. In the absence of PATCHED proteins, there is unopposed Hedgehog signaling that increases the expression of a number of pro-growth genes, including *NMYC* and D cyclins. Germline loss-of-function mutations in *PTCH1* cause Gorlin syndrome, an inherited condition also known as nevoid basal cell carcinoma syndrome ([Chapter 26](#)) that is associated with greatly increased risks of basal cell carcinoma of the skin and of medulloblastoma, an aggressive cerebellar tumor that arises in children or adolescents. *PTCH1* mutations are also present in 20% to 50% of sporadic cases of basal cell carcinoma and 10% to 25% of sporadic cases of medulloblastoma. About one half of such mutations in basal cell carcinomas are of the type caused by UV exposure. Hedgehog pathway antagonists have been developed and are approved for treatment of advanced basal cell carcinoma, and are also being tested in medulloblastoma.

and other tumors associated with Hedgehog pathway activation.

VHL. Germline loss-of-function mutations of the von Hippel-Lindau (*VHL*) gene on chromosome 3p are associated with hereditary renal cell cancers, pheochromocytomas, hemangioblastomas of the central nervous system, retinal angiomas, and renal cysts. Mutations of the *VHL* gene have also been noted in sporadic renal cell cancers (Chapter 20). The VHL protein is a component of a ubiquitin ligase, a type of protein complex that covalently links ubiquitin chains to specific protein substrates, thereby promoting their degradation by the proteasome. A critical substrate for the VHL ubiquitin ligase is the transcription factor HIF1 α (hypoxia-inducible transcription factor 1 α). In the presence of oxygen, HIF1 α is hydroxylated and binds to VHL, leading to its ubiquitination and degradation. In hypoxic environments the hydroxylation reaction does not occur, and HIF1 α escapes recognition by VHL. As a result HIF1 α accumulates in the nuclei of hypoxic cells and turns on many target genes, including genes encoding the growth/angiogenic factors vascular endothelial growth factor (VEGF) and PDGF, the glucose transporter GLUT1, and several glycolytic enzymes. Loss-of-function mutations in VHL also prevent the ubiquitination and degradation of HIF1 α , even under normoxic conditions, and are accordingly associated with increased levels of angiogenic growth factors and alterations in cellular metabolism that favor growth.

STK11. The *STK11* gene, also known as *LKB1*, encodes a serine/threonine kinase that is an important regulator of cellular metabolism. Loss-of-function mutations of *STK11* give rise to Peutz-Jeghers syndrome, an autosomal dominant disorder associated with benign polyps of the gastrointestinal tract and an increased risk of multiple epithelial cancers, particularly gastrointestinal and pancreatic carcinomas. The function of *STK11* is still being elucidated, but it appears to have pleiotropic effects on multiple facets of cellular metabolism, including glucose uptake, gluconeogenesis, protein synthesis, mitochondrial biogenesis, and lipid metabolism. Sporadic mutations causing *STK11* loss-of-function are found in diverse carcinomas, a finding pointing to the important role of altered cellular metabolism in the establishment and maintenance of the transformed state (discussed later).

KEY CONCEPTS

Mechanism of Action of Major Tumor Suppressor Genes

APC: encodes a factor that negatively regulates the WNT pathway in colonic epithelium by promoting the formation of a complex that degrades β -catenin

- Mutated in familial adenomatous polyposis, autosomal dominant disorder associated with development of thousands of colonic polyps and early onset colon carcinoma; tumor development associated with loss of the single normal *APC* allele
- Mutated in about 70% of sporadic colon carcinomas; tumor development associated with acquired biallelic defects in *APC*

E-cadherin: cell adhesion molecule that plays an important role in contact-mediated growth inhibition of epithelial cells; also binds and sequesters β -catenin, a signaling protein that functions in the WNT pathway

- Germline loss-of-function mutations in the E-cadherin gene (*CDH1*) associated with autosomal dominant familial gastric carcinoma
- Loss of expression seen in many sporadic carcinomas; associated with loss of contact inhibition, loss of cohesiveness, increased invasiveness, and increased WNT signaling

CDKN2A: complex locus that encodes two tumor suppressive proteins, p16/INK4a, a cyclin-dependent kinase inhibitor that augments RB function, and ARF, which stabilizes p53

- Germline loss-of-function mutations are associated with autosomal dominant familial melanoma
- Biallelic loss-of-function seen in diverse cancers, including leukemias, melanomas, and carcinomas

TGF- β pathway: potent inhibitor of cellular proliferation in normal tissues

- Frequent loss-of-function mutations involving TGF- β receptors (colon, stomach, endometrium) or downstream signal transducers (SMADs, pancreas) in diverse carcinomas
- Complex role in carcinogenesis; may also have a pro-oncogenic role by enhancing the immune evasiveness of tumors

PTEN: encodes a lipid phosphatase that is an important negative regulator of PI3K/AKT signaling

- Germline loss-of-function mutations associated with Cowden syndrome, autosomal dominant disorder associated with a high risk of breast and endometrial carcinoma
- Biallelic loss-of-function common in diverse cancers

NF1: encodes neurofibromin 1, a GTPase that acts as a negative regulator of RAS

- Germline loss-of-function mutations cause neurofibromatosis type 1, autosomal dominant disorder associated with a high risk of neurofibromas and malignant peripheral nerve sheath tumors

NF2: encodes neurofibromin 2 (merlin), a cytoskeletal protein involved in contact inhibition

- Germline loss-of-function mutations cause neurofibromatosis type 2, autosomal dominant disorder associated with a high risk of bilateral schwannomas

WT1: encodes a transcription factor that is required for normal development of genitourinary tissues

- Germline loss-of-function mutations associated with Wilms tumor, a pediatric kidney cancer; similar *WT1* mutations also found in sporadic Wilms tumor

PTCH1: encodes membrane receptor that is a negative regulator of the Hedgehog signaling pathway

- Germline loss-of-function mutations cause Gorlin syndrome, autosomal dominant disorder associated with a high risk of basal cell carcinoma and medulloblastoma

- Acquired biallelic loss-of-function mutations of *PTCH1* are seen frequently in sporadic basal cell carcinomas and medulloblastomas

VHL: encodes a component of a ubiquitin ligase that is responsible for degradation of hypoxia-induced factors (HIFs), transcription factors that alter gene expression in response to hypoxia

- Germline loss-of-function mutations cause von Hippel-Lindau syndrome, autosomal dominant disorder associated with a high risk of renal cell carcinoma and pheochromocytoma
- Acquired biallelic loss-of mutations are common in sporadic renal cell carcinoma

Growth-Promoting Metabolic Alterations: The Warburg Effect

Even in the presence of ample oxygen, cancer cells demonstrate a distinctive form of cellular metabolism characterized by high levels of glucose uptake and increased conversion of glucose to lactose (fermentation) via the glycolytic pathway. This phenomenon, called the *Warburg effect* and also known as *aerobic glycolysis*, has been recognized for many years (indeed, Otto Warburg received the Nobel Prize in 1931 for discovery of the effect that bears his name). Clinically, the “glucose-hunger” of tumors is used to visualize tumors via positron emission tomography (PET) scanning, in which patients are injected with ¹⁸F-fluorodeoxyglucose, a nonmetabolizable derivative of glucose that is preferentially taken up into tumor cells (as well as normal, actively dividing tissues such as the bone marrow). Most tumors are PET-positive, and rapidly growing ones are markedly so.

Warburg’s discovery was largely neglected for many years, but over the past decade metabolism has become one of the most active areas of cancer research. Metabolic pathways (like signaling pathways) in normal and cancer cells are still being elucidated and the details are complex, but at the heart of the Warburg effect lies a simple question: why is it advantageous for a cancer cell to rely on seemingly inefficient glycolysis (which generates two molecules of ATP per molecule of glucose) instead of oxidative phosphorylation (which generates up to 36 molecules of ATP per molecule of glucose)? While pondering this question, it is important to recognize that rapidly growing normal cells, such as in embryonic tissues, also rely on aerobic fermentation. Thus, “Warburg metabolism” is not cancer specific, but instead is a general property of growing cells that becomes “fixed” in cancer cells.

The answer to this riddle is simple: **aerobic glycolysis provides rapidly dividing tumor cells with metabolic intermediates that are needed for the synthesis of cellular components, whereas mitochondrial oxidative phosphorylation does not.** The reason growing cells rely on aerobic glycolysis becomes readily apparent when one considers that a growing cell has a strict biosynthetic requirement; it must duplicate all of its cellular components—DNA, RNA, proteins, lipid, and organelles—before it can divide and produce two daughter cells. Recall that the net effect of oxidative phosphorylation is to take a single molecule of

glucose, C₆H₁₂O₆, and combine it with six molecules of O₂ to produce six molecules of H₂O and six molecules of CO₂, which are lost through respiration. Thus, while “pure” oxidative phosphorylation yields abundant ATP, it fails to produce any carbon moieties that can be used to build cellular components that are needed for growth (proteins, lipids, and nucleic acids). Even cells that are not actively growing must shunt some metabolic intermediates away from oxidative phosphorylation in order to synthesize macromolecules that are needed for cellular maintenance.

By contrast, in actively growing cells only a small fraction of the cellular glucose is shunted through the oxidative phosphorylation pathway, such that on average each molecule of glucose that is metabolized produces approximately four molecules of ATP (instead of the two molecules that would be produced by “pure” glycolysis”). Presumably, this balance in glucose utilization (heavily biased toward aerobic fermentation, with a bit of oxidative phosphorylation) hits a metabolic “sweet spot” that is optimal for growth. It follows that growing cells do rely on mitochondrial metabolism. However, the main function of mitochondria in growing cells is not to generate ATP, but rather to carry out reactions that generate metabolic intermediates that can be shunted off and used as precursors in the synthesis of cellular building blocks. For example, lipid biosynthesis requires acetyl-CoA, and acetyl-CoA is largely synthesized in growing cells from intermediates such as citrate that are generated in mitochondria.

So how is this profound reprogramming of metabolism, the Warburg effect, triggered in growing normal and malignant cells? As might be guessed, **metabolic reprogramming is produced by signaling cascades downstream of growth factor receptors, the very same pathways that are deregulated by mutations in oncogenes and tumor suppressor genes in cancers.** Thus, whereas in rapidly growing normal cells aerobic glycolysis ceases when the tissue is no longer growing, in cancer cells this reprogramming persists due to the action of oncogenes and the loss of tumor suppressor gene function. Some of the important points of crosstalk between pro-growth signaling factors and cellular metabolism are shown in [Fig. 7-32](#) and include the following:

- **PI3K/AKT signaling.** PI3K/AKT signaling upregulates the activity of glucose transporters and multiple glycolytic enzymes, thus increasing glycolysis; promotes shunting of mitochondrial intermediates to pathways leading to lipid biosynthesis; and stimulates factors that are required for protein synthesis.
- **Receptor tyrosine kinase activity.** In addition to transmitting growth signals to the nucleus, receptor tyrosine kinase signaling also influences metabolism. Rapidly dividing cells, both normal and malignant, express the M2 isoform of pyruvate kinase, which catalyzes the last step in the glycolytic pathway, the conversion of phosphoenolpyruvate to pyruvate. Receptor tyrosine kinases phosphorylate the M2 isoform of pyruvate kinase, a modification that attenuates its enzymatic activity. This creates a damming effect that leads to the build-up of upstream glycolytic intermediates, which are siphoned off for synthesis of DNA, RNA, and protein. Of note, in contrast to growing tissues and cancer cells, post-mitotic tissues with high demand for ATP such as the brain

Figure 7-32 Metabolism and cell growth. Quiescent cells rely mainly on the Krebs cycle for ATP production; if starved, autophagy (self-eating) is induced to provide a source of fuel. When stimulated by growth factors, normal cells markedly upregulate glucose and glutamine uptake, which provide carbon sources for synthesis of nucleotides, proteins, and lipids. In cancers, oncogenic mutations involving growth factor signaling pathways and other key factors such as MYC deregulate these metabolic pathways, an alteration known as the *Warburg effect*.

express the M1 isoform of pyruvate kinase, which is insensitive to growth factor signaling pathways and efficiently funnels pyruvate, the last intermediate in the glycolytic pathway, into mitochondria where it is metabolized by oxidative phosphorylation to generate ATP, CO_2 , and H_2O .

- **MYC.** As mentioned, pro-growth pathways upregulate expression of the transcription factor MYC, which drives changes in gene expression that support anabolic metabolism and cell growth. Among the most important metabolic factors that are upregulated by MYC are multiple glycolytic enzymes and glutaminase, which is required for mitochondrial utilization of glutamine.

The flipside of the coin is that tumor suppressors often inhibit metabolic pathways that support growth. We have already discussed the “braking” effect on PI3K/AKT signaling of PTEN, which opposes the Warburg effect, and how the STK11 tumor suppressor antagonizes metabolic changes that produce Warburg metabolism. Indeed, it may be that many (and perhaps all) tumor suppressors that induce growth arrest suppress the Warburg effect. For example, p53, arguably the most important tumor suppressor, upregulates target genes that collectively inhibit glucose uptake, glycolysis, lipogenesis, and the generation of NADPH (a key cofactor needed for the biosynthesis of macromolecules). Thus, it is increasingly clear that the functions of many oncoproteins and tumor suppressors are inextricably intertwined with cellular metabolism.

Autophagy. *Autophagy* is a state of severe nutrient deficiency in which cells not only arrest their growth, but also cannibalize their own organelles, proteins, and membranes as carbon sources for energy production (Chapter 2). If this adaptation fails, the cells die. Tumor cells often seem to be able to grow under marginal environmental conditions without triggering autophagy, suggesting that the pathways that induce autophagy are deranged. In keeping with this, several genes that promote autophagy are tumor suppressors. Whether autophagy is always bad from the vantage point of the tumor, however, remains a matter of active investigation and debate. For example, under conditions of severe nutrient deprivation tumor cells may use autophagy to become “dormant,” a state of metabolic hibernation that allows cells to survive hard times for long periods. Such cells are believed to be resistant to therapies that kill actively dividing cells, and could therefore be responsible for therapeutic failures. Thus, autophagy may be a tumor’s friend or foe depending on how the signaling pathways that regulate it are “wired” in a given tumor.

Evasion of Programmed Cell Death (Apoptosis)

Accumulation of neoplastic cells may result not only from activation of growth-promoting oncogenes or inactivation of growth-suppressing tumor suppressor genes, but also from mutations in the genes that regulate apoptosis. In the adult, cell death by apoptosis is a protective response to several pathologic conditions that might

Figure 7-33 Intrinsic and extrinsic pathways of apoptosis and mechanisms used by tumor cells to evade cell death. (1) Loss of p53, leading to reduced function of pro-apoptotic factors such as BAX. (2) Reduced egress of cytochrome *c* from mitochondria as a result of upregulation of anti-apoptotic factors such as BCL2, BCL-XL, and MCL-1. (3) Loss of apoptotic peptidase activating factor 1 (APAF1). (4) Upregulation of inhibitors of apoptosis (IAP). (5) Reduced CD95 level. (6) Inactivation of death-induced signaling complex. FADD, Fas-associated via death domain.

contribute to malignancy if the cells remained viable. A cell with genomic injury can be induced to die, eliminating the chance that such a cell might go on to give rise to a neoplasm. A variety of signals, including DNA damage, deregulation of some of the most potent oncoproteins such as MYC, and loss of adhesion to the basement membrane (termed *anoikis*), can trigger apoptosis. Thus, apoptosis is a barrier that must be surmounted for cancer to develop and progress.

Biochemical Pathways That Lead To Programmed Cell Death. As discussed in Chapter 2, there are two distinct programs that activate apoptosis, the extrinsic and intrinsic pathways. Figure 7-33 shows, in simplified form, the sequence of events that lead to apoptosis by signaling through the death receptor CD95/Fas (extrinsic pathway)

and by DNA damage (intrinsic pathway). Of these two pathways, it is the intrinsic apoptotic pathway (sometimes referred to as the mitochondrial pathway) that is most frequently disabled in cancer.

- Recall that the intrinsic pathway of apoptosis is triggered by a variety of stimuli, including withdrawal of survival factors, stress, and injury. Activation of this pathway leads to permeabilization of the mitochondrial outer membrane, with resultant release of molecules, such as cytochrome *c*, that initiate apoptosis. The integrity of the mitochondrial outer membrane is regulated by pro-apoptotic and anti-apoptotic members of the BCL2 family of proteins. The pro-apoptotic proteins BAX and BAK are required for apoptosis and directly promote mitochondrial permeabilization. Their action is inhibited by the anti-apoptotic members of this family, which are exemplified by BCL2, BCL-XL, and MCL1. A third set of proteins (so-called BH3-only proteins), including BAD, BID, and PUMA, sense death-inducing stimuli and promote apoptosis by neutralizing the actions of anti-apoptotic proteins like BCL2 and MCL1. When the sum total of all BH3 proteins expressed “overwhelms” the anti-apoptotic BCL2/BCL-XL/MCL1 barrier, BAX and BAK are activated and form pores in the mitochondrial membrane. Cytochrome *c* leaks into the cytosol, where it binds to APAF1, activating caspase 9. Caspase 9 then activates downstream caspases such as caspase 3, a typical *executioner caspase* that cleaves DNA and other substrates to cause cell death. Caspases are held in check in healthy cells by members of the *inhibitors of apoptosis protein* (IAP) family.
- The extrinsic pathway is initiated when CD95/Fas binds to its ligand, CD95L/FasL, leading to trimerization of the receptor and its cytoplasmic *death domains*, which attract the intracellular adaptor protein FADD. This protein recruits procaspase 8 to form the death-inducing signaling complex. Procaspase 8 is activated by cleavage into smaller subunits, generating caspase 8. Like caspase 9, caspase 8 then activates downstream executioner caspases. Additionally, caspase 8 can cleave and activate the BH3-only protein BID, activating the intrinsic pathway as well.

Within this framework it is possible to illustrate the multiple ways in which apoptosis is frustrated by cancer cells (Fig. 7-33). Of all these mechanisms, one of the best established is the role of BCL2 in protecting malignant lymphoid cells from apoptosis. As discussed later, approximately 85% of B-cell lymphomas of the follicular type (Chapter 13) carry a characteristic (14;18)(q32;q21) translocation. Recall that 14q32, the site where immunoglobulin heavy chain (IgH) genes are found, is also involved in the pathogenesis of Burkitt lymphoma. Juxtaposition of this transcriptionally active locus with BCL2 (located at 18q21) causes overexpression of the BCL2 protein. This in turn protects lymphocytes from apoptosis and contributes to the survival of transformed B cells. Mice that are engineered to overexpress BCL2 in their B cells develop mainly lymphoid hyperplasia and autoimmune disorders and only infrequently get lymphoma; thus, overexpression of BCL2 must cooperate with other alterations (e.g., constitutive expression of MYC) to augment cancer development.

Nevertheless, most hematopoietic and solid tumors overexpress at least one member of the BCL2 family of anti-apoptotic proteins, suggesting that evasion of apoptosis is generally important in cancer development and progression. Furthermore, chemotherapy and radiation therapy kill cancer cells mainly by inducing apoptosis via the intrinsic pathway, and overexpression of BCL2 family members is believed to have an important role in the resistance of tumors to therapy. This appears to be particularly true for MCL-1, a BCL-2 family member that is normally subject to proteasomal degradation in the setting of DNA damage, but which is often found to be stabilized and overexpressed in drug-resistant cancers.

As mentioned earlier, p53 is an important pro-apoptotic protein that induces apoptosis in cells that are unable to repair DNA damage. The actions of p53 are mediated in part by transcriptional activation of BAX and PUMA, but there are also other connections between p53 and the apoptotic machinery. Thus, the apoptotic machinery in cancer may be thwarted by mutations affecting the component proteins directly, as well as by loss of sensors of genomic integrity such as p53.

The extrinsic pathway in less frequently altered in cancers, but nevertheless also has a role in some types, particularly certain lymphomas. Reduced levels of CD95/Fas may render the tumor cells less susceptible to apoptosis by CD95L/FasL. Other tumors have high levels of FLIP, a protein that can bind the death-induced signaling complex and prevent activation of caspase 8.

KEY CONCEPTS

Evasion of Apoptosis

- Apoptosis can be initiated through intrinsic or extrinsic pathways, both of which result in the activation of a proteolytic cascade of caspases that destroys the cell.
- Abnormalities of both pathways are found in cancer cells, but lesions that incapacitate the intrinsic (mitochondrial) pathway appear to be most common.
- In greater than 85% of follicular B-cell lymphomas, the anti-apoptotic gene *BCL2* is overexpressed due to a (14;18) translocation.
- Overexpression of other BCL2 family members such as MCL-1 is also linked to cancer cell survival and drug resistance.

Limitless Replicative Potential: The Stem Cell-Like Properties of Cancer Cells

All cancers contain cells that are immortal and have limitless replicative potential. Some cell lines established from cancers have now been proliferating ceaselessly in laboratories for more than 60 years, and it is reasonable to expect that they will continue to grow for as long as there are scientists to tend to them. How can it be that cancer cells have seemingly discovered the proverbial fountain of eternal youth? The answers are not completely known, but three interrelated factors appear critical to the immortality of cancer cells: (1) evasion of senescence; (2) evasion of mitotic crisis; (3) the capacity for self-renewal.

- **Evasion of senescence.** As was discussed in the section on cellular aging (Chapter 2), most normal human cells have the capacity to divide 60 to 70 times. After this, the cells become senescent, permanently leaving the cell cycle and never dividing again. The mechanisms that produce senescence are still not well understood, but the senescent state is associated with upregulation of tumor suppressors such as p53 and INK4a/p16 (perhaps in response to the accumulation of DNA damage over time). These tumor suppressors are believed to contribute to senescence in part by maintaining RB in a hypophosphorylated state, which favors cell cycle arrest. As already discussed, the RB-dependent G₁/S cell cycle checkpoint is disrupted in virtually all cancers by a wide variety of acquired genetic and epigenetic aberrations.
- **Evasion of mitotic crisis.** While cells that are resistant to senescence have increased replicative capacity, they are still not immortal; instead, they eventually enter into a phase referred to as *mitotic crisis* and die. This phenomenon has been ascribed to progressive shortening of *telomeres* at the ends of chromosomes. Telomeres are special DNA sequences at the ends of chromosomes that bind several types of protective protein complexes (Chapter 2). Most somatic cells do not express *telomerase*, the enzyme that is responsible for the maintenance of telomeres, and with each cell division their telomeres shorten. When the telomeric DNA is eroded, the exposed chromosome ends are “sensed” as double-stranded DNA breaks. If the affected cells have functional p53, the cell arrests its growth and may undergo apoptosis, but if p53 is dysfunctional, the nonhomologous end-joining pathway is activated and may join the “naked” ends of two chromosomes. This results in dicentric chromosomes that are pulled apart at anaphase, resulting in new double-stranded DNA breaks. The snowballing genomic damage caused by repeated “bridge-fusion-breakage” cycles eventually produces mitotic catastrophe and cell death (Fig. 7-34). Telomerase is expressed at very low levels in most somatic cells, and thus any cells that escape from senescence are very likely to die in mitotic crisis. However, if cells in crisis reactivate telomerase, the cells can restore their telomeres and survive; such cells may have suffered damage to oncogenes and tumor suppressor genes during crisis and are at high risk for malignant transformation. Alternatively, cancers may arise from stem cells (described later), which are normally long-lived in part because they continue to express telomerase. Whatever the mechanism, telomere maintenance is seen in virtually all types of cancers, and in 85% to 95% of cases this is due to upregulation of telomerase. The remaining tumors use another mechanism to maintain their telomeres termed *alternative lengthening of telomeres* that probably depends on DNA recombination.
- **Self-renewal.** Unlike most cells, tissue stem cells and germ cells express telomerase, making them resistant to mitotic crisis, and also somehow avoid the genetic and epigenetic alterations that trigger senescence. In addition, long-lived stem cells also possess another critical property, the capacity for self-renewal. In simple terms, self-renewal means that each time a stem cell divides at least one of the two daughter cells remains a stem cell.

Figure 7-34 Escape of cells from senescence and mitotic catastrophe caused by telomere shortening. Replication of somatic cells, which do not express telomerase, leads to shortened telomeres. In the presence of competent checkpoints, cells undergo arrest and enter nonreplicative senescence. In the absence of checkpoints, DNA repair pathways, such as the nonhomologous end-joining (NHEJ) pathway are inappropriately activated, leading to the formation of dicentric chromosomes. At mitosis the dicentric chromosomes are pulled apart, generating random double-stranded breaks, which then activate DNA-repair pathways, leading to the random association of double-stranded ends and the formation, again, of dicentric chromosomes. Cells undergo numerous rounds of this bridge-fusion-breakage cycle, which generates massive chromosomal instability and numerous mutations. If cells fail to reexpress telomerase, they eventually undergo mitotic catastrophe and death. Reexpression of telomerase allows the cells to escape the bridge-fusion-breakage cycle, thus promoting their survival and tumorigenesis.

In a *symmetric division*, both daughter cells remain stem cells; such divisions may occur during embryogenesis, when stem cell pools are expanding, or during times of stress. In an *asymmetric division*, only one daughter cell remains a stem cell; in such circumstances, the non-stem cell daughter proceeds along some differentiation pathway, losing “stemness” but gaining one or more functions in the process. Such cells in “transit” to a differentiated state are often highly proliferative, but they eventually differentiate, stop dividing, and extinguish themselves.

The continued growth and maintenance of many tissues that contain short-lived cells, such as the formed elements of the bone marrow and blood and the epithelial cells of the gastrointestinal tract and skin, depends on a resident population of tissue stem cells that are capable of self-renewal. Following on this logic, because cancers are immortal and have limitless proliferative capacity, they too must contain cells that self-renew, so-called *cancer stem cells*. While the existence of cancer stem cells is accepted, there is ongoing debate about their identity and their numbers in particular cancers, due in large part to the difficulty in determining whether any particular cell is a cancer stem cell. Thus, the number of “stem cells” that are calculated to be present in a particular tumor can vary widely depending on methodology used to quantify stem cells, leading to

uncertainty about whether cancer stem cells are rare or common in tumors.

Another open question is whether cancer stem cells arise from the transformation of tissue stem cells or from the conversion of conventional somatic cells to transformed cells with the acquired property of “stemness.” The answer seems to be that both scenarios occur in different types of tumors (Fig. 7-35).

- In chronic myelogenous leukemia (CML), the *BCR-ABL* fusion gene that characterizes this tumor is present in a tumor cell subset that has all the properties of a normal hematopoietic stem cell. Thus, CML appears to originate from a transformed hematopoietic stem cell with an ingrained capacity for self-renewal. Similarly, certain epithelial tumors may arise from other adult stem cells, such as those that are present in colonic crypts.
- In contrast, studies of acute myeloid leukemia have shown that the cancer stem cells in this disease arise from more differentiated hematopoietic progenitors that acquire an abnormal capacity for self-renewal. How this occurs is unclear, but it is believed that certain mutated transcription factors, such as a *PML-RARA* fusion protein that is associated with acute promyelocytic leukemia (described later) may have important roles in acquisition of “stemness” (Fig. 7-35). Recall that expression of a small number of transcription factors can result in the epigenetic reprogramming of a

Figure 7-35 Origins of cells with self-renewing capacity in cancer. Cancer stem cells can arise from transformed tissue stem cells (e.g., hematopoietic stem cells in chronic myelogenous leukemia, CML) with intrinsic “stemness” or from proliferating cells that acquire a mutation that confers “stemness” (e.g., granulocyte progenitors in acute promyelocytic leukemia). In both instances, the cancer stem cells undergo asymmetric cell divisions that give rise to committed progenitors that proliferate more rapidly than the cancer stem cells; as a result, most of the malignant cells in both tumors lack self-renewing capacity.

differentiated somatic cell such as a fibroblast into a pluripotent stem cell. Thus, it is easy to imagine how mutations leading to misexpression of certain key transcription factors, such as MYC, might convert a somatic cell into a transformed cell with a capacity for self-renewal. A corollary of this idea is that, unlike normal stem cells and their more differentiated progeny, which have a fixed parent-offspring relationship, cancer cells within a tumor may be able to “de-differentiate” to a stem cell-like state. Indeed, there is evidence that cancers can repopulate their stem cell pools from non-stem cell populations, further complicating efforts to precisely define and selectively target cancer stem cells.

Despite these uncertainties, the concept of cancer stem cells has important implications for cancer therapy. Most notably, if cancer stem cells are essential for tumor persistence, it follows that these cells must be eliminated to eradicate the tumor. It is hypothesized that like normal stem cells, cancer stem cells have a high intrinsic resistance to conventional therapies due to a low rate of cell division and the expression of factors, such as multiple drug resistance-1 (MDR1), that counteract the effects of chemotherapeutic drugs. Thus, the limited success of current therapies may in part be explained by their failure to kill

the malignant stem cells that lie at the root of cancer, an idea that is being actively tested in the laboratory.

KEY CONCEPTS

Limitless Replicative Potential

- A least some cells in all cancers must be stem cell-like; these cells are sometimes referred to as cancer stem cells. These may arise through transformation of a normal stem cell or through acquired genetic lesions that impart a stem-like state on a more mature cell.
- Cancer cells acquire lesions that inactivate senescence signals and reactivate telomerase, which act together to convey limitless replicative potential.

Angiogenesis

Even if a solid tumor possesses all of the genetic aberrations that are required for malignant transformation, it cannot enlarge beyond 1 to 2 mm in diameter unless it has the capacity to induce angiogenesis. Like normal tissues, tumors require delivery of oxygen and nutrients and removal of waste products; presumably the 1- to 2-mm zone represents the maximal distance across which oxygen, nutrients, and waste can diffuse from blood vessels. Growing cancers stimulate neoangiogenesis, during which vessels sprout from previously existing capillaries (Chapter 3). Neovascularization has a dual effect on tumor growth: perfusion supplies needed nutrients and oxygen, and newly formed endothelial cells stimulate the growth of adjacent tumor cells by secreting growth factors, such as insulin-like growth factors (IGFs) and PDGF. While the resulting tumor vasculature is effective at delivering nutrients and removing wastes, it is not entirely normal; the vessels are leaky and dilated, and have a haphazard pattern of connection, features that can be appreciated on angiograms. By permitting tumor cells access to these abnormal vessels, angiogenesis also contributes to metastasis. Angiogenesis is thus an essential facet of malignancy.

How do growing tumors develop a blood supply? The current paradigm is that **angiogenesis is controlled by a balance between angiogenesis promoters and inhibitors; in angiogenic tumors this balance is skewed in favor of promoters.** Early in their development, most human tumors do not induce angiogenesis. Starved of nutrients, these tumors remain small or in situ, possibly for years, until an *angiogenic switch* terminates this stage of vascular quiescence. The molecular basis of the angiogenic switch involves increased production of angiogenic factors and/or loss of angiogenic inhibitors. These factors may be produced by the tumor cells themselves or by inflammatory cells (e.g., macrophages) or other stromal cells associated with the tumors. Proteases, either elaborated by the tumor cells or by stromal cells in response to the tumor, are also involved in regulating the balance between angiogenic and antiangiogenic factors. Many proteases can release proangiogenic basic fibroblast growth factors (bFGF) that are stored in the ECM; conversely, the angiogenesis inhibitors angiostatin and endostatin are produced by proteolytic cleavage of plasminogen and collagen, respectively.

The local balance of angiogenic and antiangiogenic factors is influenced by several factors:

- Relative lack of oxygen due to hypoxia stabilizes HIF1 α , an oxygen-sensitive transcription factor mentioned earlier, which then activates the transcription of the proangiogenic cytokines VEGF and bFGF. These factors create an angiogenic gradient that stimulates the proliferation of endothelial cells and guides the growth of new vessels toward the tumor. VEGF also increases the expression of ligands that activate the Notch signaling pathway, which regulates the branching and density of the new vessels (Chapter 3).
- Mutations involving tumor suppressors and oncogenes in cancers also tilt the balance in favor of angiogenesis. For example, p53 can stimulate expression of antiangiogenic molecules, such as thrombospondin-1, and repress expression of proangiogenic molecules such as VEGF. Thus, loss of p53 in tumor cells not only removes cell cycle checkpoints and alters tumor cell metabolism but also provides a more permissive environment for angiogenesis.
- The transcription of VEGF is also influenced by signals from the RAS-MAP kinase pathway, and gain-of-function mutations in RAS or MYC upregulate the production of VEGF. bFGF and VEGF are commonly expressed in a wide variety of tumor cells, and elevated levels can be detected in the serum and urine of a significant fraction of cancer patients.

The idea that angiogenesis is essential if solid tumors are to grow to clinically significant sizes has provided a powerful impetus for the development of therapeutic agents that block angiogenesis. These agents are now a part of the armamentarium that oncologists use against cancers; a cardinal example is bevacizumab, a monoclonal antibody that neutralizes VEGF activity and is approved for use in the treatment of multiple cancers. However, angiogenesis inhibitors have not been nearly as effective as was hoped based on preclinical studies conducted using mouse models of cancer; they can prolong life, but usually for only a few months and at very high financial cost. The mechanisms that underlie the persistence and ultimate progression of cancers in the face of therapy with angiogenesis inhibitors are not yet clear. Perhaps there is emergence of tumor subclones that by virtue of greater invasive and metastatic potential gain ready access to existing host vessels. The modest benefit of anti-angiogenic therapy highlights the pernicious nature of advanced cancers, which can even elude therapies directed at stromal support cells such as endothelium that are genomically stable and thus presumably “immune” to the Darwinian pressures that lead cancer cells to acquire more malignant phenotypes over time. Improvements are only possible with greater understanding of the “escape routes” through which tumor cells sidestep the effects of the angiogenesis inhibitors that are now in use.

KEY CONCEPTS

Angiogenesis

- Vascularization of tumors is essential for their growth and is controlled by the balance between angiogenic and anti-angiogenic factors that are produced by tumor and stromal cells.

- Hypoxia triggers angiogenesis through the actions of HIF-1 α on the transcription of the proangiogenic factor VEGF.
- Many other factors regulate angiogenesis; for example, p53 induces synthesis of the angiogenesis inhibitor thrombospondin-1, while RAS, MYC, and MAPK signaling all upregulate VEGF expression and stimulate angiogenesis.
- VEGF inhibitors are used to treat a number of advanced cancers and prolong the clinical course, but are not curative.

Invasion and Metastasis

Invasion and metastasis are the results of complex interactions between cancer cells and normal stroma and are the major causes of cancer-related morbidity and mortality. Hence, they are the subjects of intense scrutiny. Studies in mice and humans reveal that although millions of cells are released into the circulation each day from a primary tumor, only a few metastases are produced. Indeed, tumor cells can be frequently detected in the blood and marrow of patients with breast cancer who have not, and do not ever, develop overt metastatic disease. Why is the metastatic process so inefficient? For tumor cells to emerge from a primary mass, enter blood vessels or lymphatics, and produce a secondary growth at a distant site, they must go through a series of steps (summarized in Fig. 7-36), each of which is inefficient and subject to a multitude of controls; hence, at any point in the sequence, the breakaway cells may not survive. In this discussion, the metastatic cascade is divided into two phases: (1) invasion of the extracellular matrix (ECM) and (2) vascular dissemination, homing of tumor cells, and colonization. Subsequently, the molecular genetics of the metastatic cascade, as currently understood, are presented.

Invasion of Extracellular Matrix

The structural organization and function of normal tissues is to a great extent determined by interactions between cells and the ECM. As discussed in Chapter 1, tissues are organized into compartments separated from each other by two types of ECM: basement membrane and interstitial connective tissue. Although organized differently, each of these components of ECM is made up of collagens, glycoproteins, and proteoglycans. As shown in Figure 7-36, tumor cells must interact with the ECM at several stages in the metastatic cascade. A carcinoma must first breach the underlying basement membrane, then traverse the interstitial connective tissue, and ultimately gain access to the circulation by penetrating the vascular basement membrane. This process is repeated in reverse when tumor cell emboli extravasate at a distant site. Invasion of the ECM initiates the metastatic cascade and is an active process that can be resolved into several steps (Fig. 7-37):

- “Loosening up” of tumor cell–tumor cell interactions
- Degradation of ECM
- Attachment to novel ECM components
- Migration and invasion of tumor cells

Dissociation of cancer cells from one another is often the result of alterations in intercellular adhesion molecules and is the first step in the process of invasion.

Figure 7-36 The metastatic cascade. Sequential steps involved in the hematogenous spread of a tumor.

Normal epithelial cells are tightly glued to each other and the ECM by a variety of adhesion molecules. Cell-cell interactions are mediated by the cadherin family of transmembrane glycoproteins. *E-cadherins* mediate the homotypic adhesion of epithelial cells, serving to both hold the cells together and to relay signals between the cells. In several epithelial tumors, including adenocarcinomas of the colon, stomach, and breast, *E-cadherin* function is lost. Presumably, this reduces the ability of cells to adhere to each other and facilitates their detachment from the primary tumor and their advance into the surrounding tissues.

Degradation of the basement membrane and interstitial connective tissue is the second step in invasion. Tumor cells may accomplish this by either secreting proteolytic enzymes themselves or by inducing stromal cells

(e.g., fibroblasts and inflammatory cells) to elaborate proteases. Many different families of proteases, such as matrix metalloproteinases (MMPs), cathepsin D, and urokinase plasminogen activator, have been implicated in tumor cell invasion. MMPs regulate tumor invasion not only by remodeling insoluble components of the basement membrane and interstitial matrix but also by releasing

Figure 7-37 Sequence of events in the invasion of epithelial basement membranes by tumor cells. Tumor cells detach from each other because of reduced adhesiveness and attract inflammatory cells. Proteases secreted from tumor cells and inflammatory cells degrade the basement membrane. Binding of tumor cells to proteolytically generated binding sites and tumor cell migration follow.

ECM-sequestered growth factors. Indeed, cleavage products of collagen and proteoglycans also have chemotactic, angiogenic, and growth-promoting effects. For example, MMP9 is a gelatinase that cleaves type IV collagen of the epithelial and vascular basement membrane and also stimulates release of VEGF from ECM-sequestered pools. Benign tumors of the breast, colon, and stomach show little type IV collagenase activity, whereas their malignant counterparts overexpress this enzyme. Concurrently, the concentrations of metalloproteinase inhibitors are reduced so that the balance is tilted greatly toward tissue degradation. Indeed, overexpression of MMPs and other proteases has been reported for many tumors.

The third step in invasion involves changes in attachment of tumor cells to ECM proteins. Normal epithelial cells have receptors, such as integrins, for basement membrane laminin and collagens that are polarized at their basal surface; these receptors help to maintain the cells in a resting, differentiated state. Loss of adhesion in normal cells leads to induction of apoptosis, while, not surprisingly, tumor cells are resistant to this form of cell death. Additionally, the matrix itself is modified in ways that promote invasion and metastasis. For example, cleavage of the basement membrane proteins collagen IV and laminin by MMP2 or MMP9 generates novel sites that bind to receptors on tumor cells and stimulate migration.

Locomotion is the final step of invasion, propelling tumor cells through the degraded basement membranes and zones of matrix proteolysis. Migration is a multistep process that involves many families of receptors and signaling proteins that eventually impinge on the actin cytoskeleton. Cells must attach to the matrix at the leading edge, detach from the matrix at the trailing edge, and contract the actin cytoskeleton to ratchet forward. Such movement seems to be stimulated and directed by tumor cell-derived cytokines, such as autocrine motility factors. In addition, cleavage products of matrix components (e.g., collagen, laminin) and some growth factors (e.g., IGFs I and II) have chemotactic activity for tumor cells. Furthermore, proteolytic cleavage liberates growth factors bound to matrix molecules. Stromal cells also produce paracrine effectors of cell motility, such as hepatocyte growth factor/scatter factor, which binds to the receptor tyrosine kinase MET on tumor cells. The concentration of hepatocyte growth factor/scatter factor is elevated at the advancing edge of the highly invasive brain tumor glioblastoma, supporting its role in motility.

It has become clear in recent years that the ECM and stromal cells surrounding tumor cells are not a mere static barrier for tumor cells to traverse but instead constitute a varied environment in which reciprocal signaling between tumor cells and stromal cells may either promote or prevent tumorigenesis and/or tumor progression. Stromal cells that interact with tumors include innate and adaptive immune cells (discussed later), as well as fibroblasts. A variety of studies have demonstrated that tumor-associated fibroblasts exhibit altered expression of genes that encode ECM molecules, proteases, protease inhibitors, and various growth factors. Thus, tumor cells reside in a complex and ever-changing milieu composed of ECM, growth factors, fibroblasts, and immune cells, with significant cross-talk among all the components. It is easy to imagine that tumors come to be dominated by subclones

that are most successful at co-opting this environment to their own malignant purposes.

Vascular Dissemination and Homing of Tumor Cells

Once in the circulation, tumor cells are vulnerable to destruction by a variety of mechanisms, including mechanical shear stress, apoptosis stimulated by loss of adhesion (termed *anoikis*), and innate and adaptive immune defenses. The details of tumor immunity are considered later.

Within the circulation, tumor cells tend to aggregate in clumps. This is favored by homotypic adhesions among tumor cells as well as heterotypic adhesion between tumor cells and blood cells, particularly platelets (Fig. 7-36). Formation of platelet-tumor aggregates may enhance tumor cell survival and implantability. Tumor cells may also bind and activate coagulation factors, resulting in the formation of emboli. Arrest and extravasation of tumor emboli at distant sites involves adhesion to the endothelium, followed by egress through the basement membrane. Involved in these processes are adhesion molecules (integrins, laminin receptors) and proteolytic enzymes, discussed earlier. Of particular interest is the CD44 adhesion molecule, which is expressed on normal T lymphocytes and is used by these cells to migrate to selective sites in lymphoid tissues. Such migration is accomplished by the binding of CD44 to hyaluronate on high endothelial venules. Solid tumors also often express CD44, which appears to enhance their spread to lymph nodes and other metastatic sites.

The site at which circulating tumor cells leave the capillaries to form secondary deposits is related to the anatomic location and vascular drainage of the primary tumor and the tropism of particular tumors for specific tissues. Most metastases occur in the first capillary bed available to the tumor. Many observations, however, suggest that natural pathways of drainage do not wholly explain the distribution of metastases. For example, prostatic carcinoma preferentially spreads to bone, bronchogenic carcinomas tend to involve the adrenals and the brain, and neuroblastomas spread to the liver and bones. Such organ tropism may be related to the following mechanisms:

- Tumor cells may have adhesion molecules whose ligands are expressed preferentially on the endothelial cells of the target organ.
- Chemokines have an important role in determining the target tissues for metastasis. For instance, some breast cancer cells express the chemokine receptors CXCR4 and CCR7.
- In some cases, the target tissue may be a nonpermissive environment—“unfavorable soil,” so to speak, for the growth of tumor seedlings. For example, although well-vascularized, skeletal muscle and spleen are rarely sites of metastasis.

Alas, tumor cells do not read textbooks of pathology, and there is still much to be learned about the factors that govern their spread. Despite their “cleverness” in escaping their tissue of origin, circulating tumor cells are quite inefficient in colonizing distant organs. Moreover, even when metastases are established, they may grow to only small, clinically insignificant sizes. Indeed, the concept of *dormancy*, referring to the prolonged survival

of micrometastases without progression, is well described in melanoma and in breast and prostate cancer. Although the molecular mechanisms of colonization are still being unraveled in mouse models, a consistent theme seems to be that tumor cells secrete cytokines, growth factors, and ECM molecules that act on the resident stromal cells, which in turn make the metastatic site habitable for the cancer cell. For example, breast cancer metastases to bone are osteolytic because of the activation of osteoclasts in the metastatic site. Breast cancer cells secrete parathyroid hormone-related protein (PTHrP), which stimulates osteoblasts to make RANK ligand (RANKL). RANKL then activates osteoclasts, which degrade the bone matrix and release growth factors embedded within it, like IGF and TGF- β . With a better molecular understanding of the mechanisms of metastasis our ability to target them therapeutically will be greatly enhanced.

Molecular Genetics of Metastasis Development

Why do only some tumors metastasize? What are the genetic and epigenetic changes that allow metastases? Why is the metastatic process so inefficient? Several competing theories have been proposed to explain how the metastatic phenotype arises.

- The *clonal evolution model* suggests that as mutations accumulate in genetically unstable cancer cells and the tumor become heterogeneous (Fig. 7-38A), a rare subset

Figure 7-38 Mechanisms of metastasis development within a primary tumor. A nonmetastatic primary tumor is shown (light blue) on the left side of all diagrams. Four models are presented: **A**, Metastasis is caused by rare variant clones that develop in the primary tumor. **B**, Metastasis is caused by the gene expression pattern of most cells of the primary tumor, referred to as a metastatic signature. **C**, A combination of **A** and **B**, in which metastatic variants appear in a tumor with a metastatic gene signature. **D**, Metastasis development is greatly influenced by the tumor stroma, which may regulate angiogenesis, local invasiveness, and resistance to immune elimination, allowing cells of the primary tumor, as in **C**, to become metastatic.

of tumor cell subclones acquires a pattern of gene expression that is permissive for all steps involved in metastasis.

- A subset of breast cancers has a metastatic gene expression signature similar to that found in metastases, although no clinical evidence for metastasis is apparent. It is hypothesized that in these tumors with a “*metastasis signature*” most if not all cells develop a predilection for metastatic spread during early stages of carcinogenesis (Fig. 7-38B).
- A third idea that combines the two above supposes that the metastatic signature is necessary but not sufficient for metastasis, and that additional mutations are needed for metastasis to occur (Fig. 7-38C).
- Finally, there is evidence the capacity for metastasis involves not only properties intrinsic to the cancer cells but also the characteristics of their microenvironment, such as the components of the stroma, the presence of infiltrating immune cells, and angiogenesis (Fig. 7-38D).

One open question in the field is whether there are genes whose principal or sole contribution to tumorigenesis is to control metastasis. This question is of more than academic interest, because if altered forms of certain genes promote or suppress the metastatic phenotype, their detection in a primary tumor would have both prognostic and therapeutic implications. Because metastasis is a complex phenomenon involving a variety of steps and pathways, it is thought that “*metastasis oncogenes*” or “*metastasis suppressor genes*” are few in number. A metastasis suppressor gene is defined as a gene whose loss promotes the development of metastasis without an effect on the primary tumor. At least a dozen genes lost in metastatic lesions have been confirmed to function as “*metastasis suppressors*.” Their molecular functions are varied and not completely clear; however, most appear to affect various signaling pathways.

Among candidates for metastasis oncogenes are *SNAIL* and *TWIST*, which encode transcription factors whose primary function is to promote epithelial-to-mesenchymal transition (EMT). In EMT, carcinoma cells downregulate certain epithelial markers (e.g., E-cadherin) and upregulate certain mesenchymal markers (e.g., vimentin and smooth muscle actin). These changes are believed to favor the development of a promigratory phenotype that is essential for metastasis. Loss of E-cadherin expression seems to be a key event in EMT, and *SNAIL* and *TWIST* are transcriptional repressors that downregulate E-cadherin expression. EMT has been documented mainly in breast cancers; whether it is a general phenomenon in other solid tumors remains to be established.

Role of Stromal Elements in Metastasis

In the preceding sections we have seen several examples of interaction between tumor cells and stromal elements. For example, macrophages in the stroma secrete matrix-degrading proteases, and cleavage of ECM proteins can release latent angiogenic factors and growth factors, such as TGF β . Successful tumor cells must co-opt these and other interactions and use them to promote their growth and invasion, and it follows that these interactions, and the stromal cells themselves, are potential targets in cancer treatment. We have already discussed the use of

angiogenesis inhibitors in cancer patients; of even greater potential benefit are therapies that overcome another hallmark of cancer cells—the ability to evade the host immune response (discussed next).

KEY CONCEPTS

Invasion and Metastasis

- Ability to invade tissues, a hallmark of malignancy, occurs in four steps: loosening of cell-cell contacts, degradation of ECM, attachment to novel ECM components, and migration of tumor cells.
- Cell-cell contacts are lost by the inactivation of E-cadherin through a variety of pathways.
- Basement membranes and interstitial matrix degradation is mediated by proteolytic enzymes secreted by tumor cells and stromal cells, such as matrix metalloproteases and cathepsins.
- Proteolytic enzymes also release growth factors sequestered in the ECM and generate chemotactic and angiogenic fragments from cleavage of ECM glycoproteins.
- The metastatic site of many tumors can be predicted by the location of the primary tumor. Many tumors arrest in the first capillary bed they encounter (lung and liver, most commonly).
- Some tumors show organ tropism, probably due to expression of adhesion or chemokine receptors whose ligands are expressed by endothelial cells the metastatic site.
- Genes that promote epithelial-mesenchymal transitions, like *TWIST* and *SNAIL*, may be important metastasis genes in epithelial tumors

Evasion of Host Defense

Long one of the “holy grails” of oncology, the promise of therapies that enable the host immune system to recognize and destroy cancer cells is finally coming to fruition, largely due to a clearer understanding of the ways by which cancer cells evade the host response. Paul Ehrlich first conceived the idea that tumor cells can be recognized as “foreign” and eliminated by the immune system. Subsequently, Lewis Thomas and Macfarlane Burnet formalized this concept by coining the term *immune surveillance*, which implies that a normal function of the immune system is to constantly “scan” the body for emerging malignant cells and destroy them. This idea has been supported by many observations—the presence of lymphocytic infiltrates around tumors and reactive changes in lymph nodes draining sites of cancer; experimental results, mostly with transplanted tumors; the increased incidence of some cancers in immunodeficient people and mice; the direct demonstration of tumor-specific T cells and antibodies in patients; and most recently and most directly, the response of advanced cancers to therapeutic agents that act by stimulating latent host T-cell responses (described later).

The fact that cancers occur in immunocompetent individuals indicates that immune surveillance is imperfect; however, that some tumors escape such policing does not preclude the possibility that many others were aborted. Assuming that the immune system is capable of recognizing and eliminating nascent cancers, it follows that the

tumors that do grow out must be composed of cells that are either invisible to the host immune system or that release factors that actively suppress host immunity. The term *cancer immunoediting* has been used to describe the ability of the immune system to shape and mold the immunogenic properties of tumor cells in a fashion that ultimately leads to the darwinian selection of subclones that are best able to avoid immune elimination. In support of this idea, in the past several years it has become evident that tumors produce a number of factors that promote immune tolerance and immune suppression, and that therapeutic agents that neutralize these factors can lead to tumor regression, even in patients with advanced cancers. These encouraging clinical responses constitute strong evidence that evasion of host immunity is indeed a hallmark of many, if not all, human cancers.

The following section explores some of the important questions about tumor immunity: What is the nature of tumor antigens? What host effector systems recognize tumor cells? How do tumors evade these host mechanisms? And, how can immune reactions against tumors be exploited therapeutically?

Tumor Antigens

Antigens found in tumors that elicit an immune response have been demonstrated in many experimentally induced tumors and in some human cancers. Tumor antigens can be classified according to their molecular structure and source.

The main classes of tumor antigen are as follows (Fig. 7-39):

- **Products of mutated genes.** Neoplastic transformation, as discussed, results from genetic alterations in proto-oncogenes and tumor suppressor genes; these mutated genes encode variant proteins that have never been seen by the immune system and are thus recognized as non-self. Additionally, because of genetic instability, cancers often harbor a high burden of mutations throughout their genomes. Most of these acquired mutations are likely to be “passengers,” mutations that are neutral in terms of cancer cell fitness and thus unrelated to the transformed phenotype. However, by chance, some of these passenger mutations may fall in the coding sequences of genes and give rise to protein variants that serve as tumor antigens. The products of altered proto-oncogenes, tumor suppressor genes, and “passenger” genes are translated in the cytoplasm of tumor cells, and like any cytoplasmic protein, they may enter the class I MHC antigen-processing pathway and be recognized by CD8+ T cells. In addition, these proteins may enter the class II antigen-processing pathway in antigen-presenting cells that have phagocytosed dead tumor cells, and thus be recognized by CD4+ T cells also. Some cancer patients have circulating CD4+ and CD8+ T cells that can respond to peptides derived from mutated oncoproteins such as RAS, p53, and BCR-ABL. In animals, immunization with mutated RAS or p53 proteins induces CTLs and rejection responses against tumors expressing these mutated proteins. However, the tumor-specific neoantigens that are recognized by CTLs in patients with cancer are for the most part currently unknown.

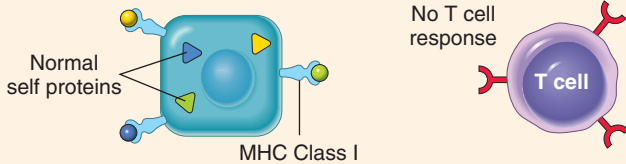

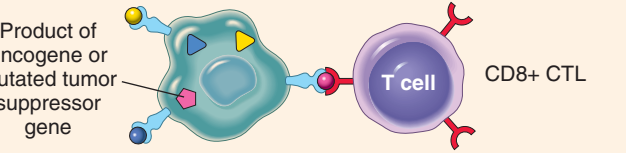

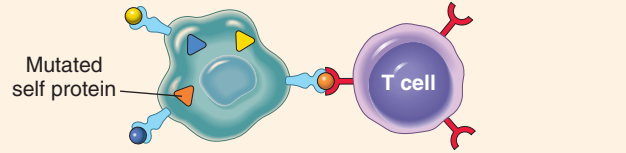

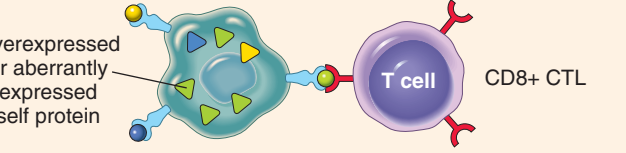

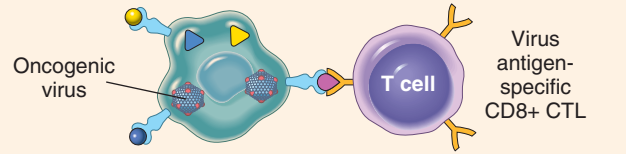

Normal host cell displaying multiple MHC-associated self antigens		EXAMPLES
Tumor cells expressing different types of tumor antigens		Oncogene products: mutated RAS, BCR/ABL fusion proteins Tumor suppressor gene products: mutated p53 protein
		Various mutant proteins in carcinogen, or radiation, induced animal tumors; various mutated proteins in melanomas
		Overexpressed: tyrosinase, gp100, MART in melanomas Aberrantly expressed: cancer-testis antigens (MAGE, BAGE)
		Human papilloma virus E6, E7 proteins in cervical carcinoma; EBNA proteins in EBV-induced lymphoma

Figure 7-39 Tumor antigens recognized by CD8+ T cells. (Modified from Abbas AK, Lichtman AH: Cellular and Molecular Immunology, 5th ed. Philadelphia, WB Saunders, 2003.)

- Overexpressed or aberrantly expressed cellular proteins.** Tumor antigens may also be normal cellular proteins that are abnormally expressed in tumor cells. One such antigen is tyrosinase, an enzyme involved in melanin biosynthesis that is expressed only in normal melanocytes and melanomas. It may be surprising that the immune system is able to respond to this normal self-antigen. The probable explanation is that tyrosinase is normally produced in such small amounts and in so few normal cells that it is not recognized by the immune system and fails to induce tolerance. Another group of tumor antigens, the *cancer-testis antigens*, are encoded by genes that are silent in all adult tissues except germ cells in the testis—hence their name. Although the protein is present in the testis it is not expressed on the cell surface in an antigenic form, because sperm do not express MHC class I antigens. Thus, for all practical purposes these antigens are tumor specific. Prototypic of this group is the melanoma antigen gene (MAGE) family. Although originally described in melanomas, MAGE antigens are expressed by a variety of tumor types. For example, MAGE-1 is expressed on 37% of melanomas and a variable number of lung, liver, stomach, and esophageal carcinomas. There are several other members of the MAGE family, variously called RAGE, GAGE, and other fanciful acronyms.
- Tumor antigens produced by oncogenic viruses.** Several viruses are associated with cancers. Not surprisingly, these viruses produce proteins that are recognized as foreign by the immune system. The most potent of these antigens are proteins produced by latent DNA viruses; examples in humans include human papilloma virus (HPV) and Epstein-Barr virus (EBV). There is abundant evidence that CTLs recognize antigens of these viruses and that a competent immune system plays a role in surveillance against virus-induced tumors because of its ability to recognize and kill virus-infected cells. In fact, the concept of immune surveillance against tumors is best established for DNA virus-induced tumors.
- Oncofetal antigens.** Oncofetal antigens are proteins that are expressed at high levels on cancer cells and in normal developing (fetal) tissues. Although originally believed to be completely specific for tumors and fetal tissues, as techniques for detecting these antigens have improved, it became clear that their expression in adults is not limited to tumors. Amounts of these proteins are increased in tissues and in the circulation in various inflammatory conditions, and they are even found in small quantities in normal tissues. There is no evidence that oncofetal antigens are important inducers or targets of antitumor immunity. However, oncofetal proteins

are sufficiently specific that they can serve as markers that aid in tumor diagnosis and clinical management. The two most thoroughly characterized oncofetal antigens are carcinoembryonic antigen (CEA) and α -fetoprotein (AFP). These are discussed in the section on “[Tumor Markers](#).”

- **Altered cell surface glycolipids and glycoproteins.** Most human and experimental tumors express higher than normal levels and/or abnormal forms of surface glycoproteins and glycolipids, which may be diagnostic markers and targets for therapy. These altered molecules include gangliosides, blood group antigens, and mucins. Mucins are high-molecular-weight glycoproteins containing numerous O-linked carbohydrate side chains on a core polypeptide. Tumors often have dysregulated expression of the enzymes that synthesize these carbohydrate side chains, which leads to the appearance of tumor-specific epitopes on the carbohydrate side chains or on the abnormally exposed polypeptide core. Several mucins have been the focus of diagnostic and therapeutic studies, including CA-125 and CA-19-9, expressed on ovarian carcinomas, and MUC-1, expressed on both ovarian and breast carcinomas. Unlike many mucins, MUC-1 is an integral membrane protein that is normally expressed only on the apical surface of breast ductal epithelium, a site that is relatively sequestered from the immune system. In ductal carcinomas of the breast, however, the molecule is expressed in an unpolarized fashion and contains new, tumor-specific carbohydrate and peptide epitopes detectable by mouse monoclonal antibodies. The peptide epitopes induce both antibody and T-cell responses in cancer patients and are therefore considered candidates for tumor vaccines in patients with breast cancer and possibly ovarian cancer as well.
- **Cell type-specific differentiation antigens.** Tumors express molecules that are normally present on the cells of origin. These antigens are called *differentiation antigens* because they are specific for particular lineages or differentiation stages of various cell types. Such differentiation antigens are typically normal self-antigens, and therefore they do not induce immune responses in tumor-bearing hosts. Their importance is as potential targets for immunotherapy and for identifying the tissue of origin of tumors. There are now several examples of monoclonal antibodies that recognize cell type specific antigens that are highly effective anti-tumor agents. Antibodies against CD20, a transmembrane protein that is expressed on the surface of all normal mature B cells, have broad cytotoxic activity against mature B-cell lymphomas and leukemias and are widely used in the treatment of these tumors. These antibodies are believed to induce cell killing through several mechanisms, including opsonization and phagocytosis of tumor cells, antibody-dependent cell-mediated cytotoxicity and complement fixation. Anti-CD20 antibodies also kill normal B cells, but because hematopoietic stem cells are spared, normal B cells reemerge following treatment.

Monoclonal antibodies may also be covalently coupled to drugs, toxins, or radiochemicals; in this instance, the antibody serves as guided missile that delivers a therapeutic warhead to cancers expressing

particular surface antigens. This strategy has now produced effective treatments for several cancers. For example, CD30 is a member of the TNF receptor family of transmembrane proteins that is expressed by particular T cell lymphomas and most Hodgkin lymphomas. Antibodies against CD30 linked to a cytotoxic drug have recently produced remarkable responses in patients with CD30-positive lymphomas that have failed conventional therapies. Other antibodies of this type, such as toxin-conjugated antibodies specific for HER2, are now being evaluated. Finally, bispecific antibodies engineered to have two different antigen recognition surfaces, one that binds tumor antigens and a second that binds to the CD3 signaling molecule on T cells, have produced some promising results in clinical trials.

Antitumor Effector Mechanisms

Cell-mediated immunity is the dominant antitumor mechanism in vivo. Although sera from cancer patients may contain antibodies that recognize tumors, there is limited evidence that they play a protective role under physiologic conditions. The cellular effectors that mediate immunity are described in [Chapter 6](#).

- **Cytotoxic T lymphocytes.** The antitumor effect of cytotoxic T cells reacting against tumor antigens is well established in experimentally induced tumors. In humans, CD8+ CTLs have a clear protective role against virus-associated neoplasms (e.g., EBV- and HPV-induced tumors), and several studies have shown that the number of tumor-infiltrating CD8+ T cells and the presence of a “gene signature” associated with CD8+ CTLs correlates with a better prognosis in a variety of cancers, not only those caused by oncogenic viruses.
- **Natural killer cells.** NK cells are lymphocytes that are capable of destroying tumor cells without prior sensitization and thus may provide the first line of defense against tumor cells. After activation with IL-2 and IL-15, NK cells can lyse a wide range of human tumors, including many that seem to be nonimmunogenic for T cells. While the importance of NK cells in host response against spontaneous tumors is still not well established, cytokines that activate NK cells are being used for immunotherapy.
- **Macrophages.** Activated macrophages exhibit cytotoxicity against tumor cells in vitro. T cells, NK cells, and macrophages may collaborate in antitumor reactivity, because interferon- γ , a cytokine secreted by T cells and NK cells, is a potent activator of macrophages. Activated macrophages may kill tumors by mechanisms similar to those used to kill microbes (e.g., production of reactive oxygen species; [Chapter 2](#)).

Immune Surveillance and Escape

Given the many potential antitumor mechanisms, is there any evidence that they operate in vivo to prevent emergence of neoplasms? One strong argument for the existence of immune surveillance is the increased frequency of cancers in the setting of immunodeficiency. Persons with congenital immunodeficiencies develop cancers at about 200 times the rate in immunocompetent individuals. Immunosuppressed transplant recipients and persons with AIDS also have an increased incidence of malignancies.

Most (but not all) of these neoplasms are aggressive lymphomas composed of mature B cells. Particularly illustrative is the rare X-linked recessive immunodeficiency disorder termed *XLP* (*X-linked lymphoproliferative syndrome*), caused by mutations in the gene encoding an adapter protein, SAP, which participates in NK and T-cell signaling pathways. In affected boys, EBV infection does not take the usual self-limited form of infectious mononucleosis but instead evolves into a chronic or sometimes fatal form of infectious mononucleosis or, even worse, a lymphoma comprised of EBV-infected B cells.

Most cancers occur in persons who do not suffer from any overt immunodeficiency. It is evident, then, that tumor cells must develop mechanisms to escape or evade the immune system in immunocompetent hosts. Several such mechanisms may be operative (Fig. 7-40).

- **Selective outgrowth of antigen-negative variants.** During tumor progression, strongly immunogenic subclones may be eliminated, an example of immunoeediting that has already been discussed.
- **Loss or reduced expression of MHC molecules.** Tumor cells may fail to express normal levels of HLA class I

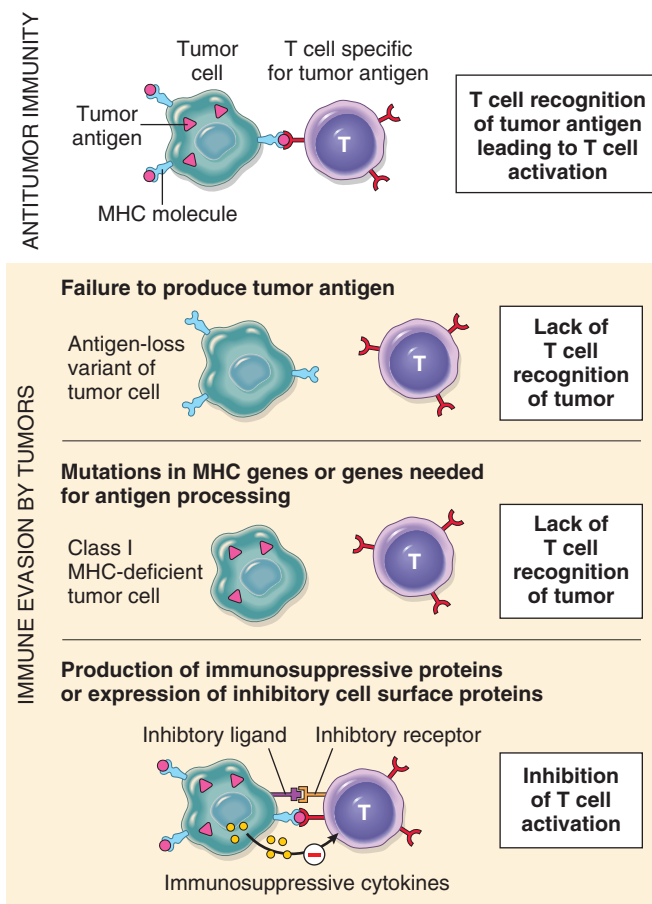

Figure 7-40 Mechanisms by which tumors evade the immune system. Tumors may evade immune responses by losing expression of antigens or major histocompatibility complex (MHC) molecules or by producing immunosuppressive cytokines or ligands such as PD-L1 for inhibitory receptors on T cells. (Reprinted from Abbas AK, Lichtman AH, Pillai S: Cellular and Molecular Immunology, 7th ed. Philadelphia, WB Saunders, 2012.)

molecules, thereby escaping attack by cytotoxic T cells. Such cells, however, may trigger NK cells if the tumor cells express ligands for NK cell activating receptors.

- **Activation of immunoregulatory pathways.** An important emerging concept is that tumor cells actively inhibit tumor immunity by engaging normal pathways of immune regulation that serve as “checkpoints” in immune responses. Through a variety of mechanisms, tumor cells may downregulate the expression of costimulatory factors on antigen-presenting cells, such as dendritic cells; as a result, the antigen presenting cells fail to engage the stimulatory receptor CD28 and instead activate the inhibitory receptor CTLA-4 on effector T cells. This not only prevents sensitization but also may induce long-lived unresponsiveness in tumor-specific T cells. Tumor cells also may upregulate the expression of PD-L1 and PD-L2, cell surface proteins that activate the programmed death-1 (PD-1) receptor on effector T cells. PD-1, like CTLA-4, may inhibit T cell activation. Antibodies that block the inhibitory CTLA-4 or PD-1 receptors have produced promising results in clinical trials conducted in patients with advanced-stage solid tumors. Additional clinical trials are being planned using both PD-1 and CTLA-4 blocking antibodies in combination with each other and with conventional or targeted chemotherapy. The success of these agents has led to a new paradigm in cancer immunotherapy, sometimes called “checkpoint blockade”. This is centered on the idea that treatments that remove the “brakes” imposed by tumors on host anti-tumor immune responses can be highly effective in treating cancer.
- **Secretion of immunosuppressive factors by cancer cells.** Tumors may secrete several products that inhibit the host immune response. TGF- β is secreted in large quantities by many tumors and is a potent immunosuppressant. Other tumors secrete galectins, sugar-rich lectin-like factors that skew T-cell responses so as to favor immunosuppression. Many other soluble factors produced by tumors are also suspected of inhibiting the host immune response, including interleukin-10, prostaglandin E2, certain metabolites derived from tryptophan, and VEGF, which can inhibit the diapedesis of T cells from the vasculature into the tumor bed.
- **Induction of regulatory T cells (Tregs).** Some studies suggest that tumors produce factors that favor the development of immunosuppressive regulatory T cells, which could also contribute to “immuno-evasion.”

Thus, it seems that there is no dearth of mechanisms by which tumor cells can outwit the host immune system. Nevertheless, the aforementioned response of tumors to immunomodulatory agents, such as antibodies that block CTLA-4 and PD-1, has generated tremendous excitement around the potential of modern cancer immunotherapy. The major challenges now are to determine which immune evasion mechanisms are most important in human cancers (preferably using sensitive and specific biomarker tests that can be performed on each individual patient’s cancer) and to develop a broader set of therapies that overcome these mechanisms and induce effective host immunity.

KEY CONCEPTS

Evasion of Immune Surveillance

- Tumor cells can be recognized by the immune system as non-self and destroyed.
- Antitumor activity is mediated by predominantly cell-mediated mechanisms. Tumor antigens are presented on the cell surface by MHC class I molecules and are recognized by CD8⁺ CTLs.
- The different classes of tumor antigens include products of mutated proto-oncogenes, tumor suppressor genes, overexpressed or aberrantly expressed proteins, tumor antigens produced by oncogenic viruses, oncofetal antigens, altered glycolipids and glycoproteins, and cell type-specific differentiation antigens.
- Immunosuppressed patients have an increased risk for development of cancer, particularly types caused by oncogenic DNA viruses.
- In immunocompetent patients, tumors may avoid the immune system by several mechanisms, including selective outgrowth of antigen-negative variants, loss or reduced expression of histocompatibility antigens, and immunosuppression mediated by expression of certain factors (e.g., TGF- β , PD-1 ligand, galectins) by the tumor cells.
- Antibodies that overcome these mechanisms of immune evasion are showing promise in clinical trials conducted in patients with advanced cancer.

Genomic Instability

Genetic aberrations that increase mutation rates are very common in cancers and expedite the acquisition of driver mutations that are required for transformation and subsequent tumor progression. Although humans literally swim in environmental agents that are mutagenic (e.g., chemicals, radiation, sunlight), cancers are relatively rare outcomes of these encounters. This state of affairs results from the ability of normal cells to repair DNA damage, the death of cells with irreparable damage (see “**Evasion of Apoptosis**” earlier), and other mechanisms, such as oncogene-induced senescence and immune surveillance.

We have previously discussed the role of the *TP53* tumor suppressor gene in protecting the genome from potentially oncogenic damage, both by arresting cell division to provide time for repair of DNA damage caused by environmental mutagens and by initiating apoptosis in irreparably damaged cells. The importance of DNA repair in maintaining the integrity of the genome is further highlighted by several inherited disorders in which genes that encode proteins involved in DNA repair are defective. Individuals born with such inherited defects in DNA-repair proteins are at a greatly increased risk of developing cancer. Moreover, defects in repair mechanisms are present in certain kinds of sporadic human cancers. Mutations in DNA-repair genes themselves are not oncogenic, but their abnormalities greatly enhance the occurrence of mutations in other genes during the process of normal cell division. Typically, genomic instability occurs when both copies of the DNA repair gene are lost; however, some work has suggested that haploinsufficiency of at least a subset of these genes may also promote cancer. As explained below, defects in three types of DNA-repair systems—mismatch

repair, nucleotide excision repair, and recombination repair—contribute to different types of cancers.

Hereditary Nonpolyposis Colon Cancer Syndrome. Hereditary nonpolyposis colon cancer (HNPCC) syndrome is an autosomal dominant disorder characterized by familial carcinomas of the colon affecting predominantly the cecum and proximal colon (Chapter 17). It results from defects in a family of genes encoding a group of proteins that work together to carry out *DNA mismatch repair*. When a strand of DNA is being replicated, these proteins act as “spell checkers.” For example, if there is an erroneous pairing of G with T rather than the normal A with T, the mismatch-repair factors correct the defect. Individuals with HNPCC syndrome inherit one abnormal copy of a mismatch repair gene. Trouble arises when cells acquire loss-of-function mutations, presumably at random, in their normal alleles. With “proofreading” function lost, errors gradually accumulate throughout the genome, and some of these errors may by chance activate proto-oncogenes or inactivate tumor suppressor genes. With time, a cancer may result. Thus, DNA-repair genes behave like tumor suppressor genes in their mode of inheritance, but in contrast to tumor suppressor genes (and oncogenes), they affect cell growth only indirectly—by allowing mutations in other genes during the process of normal cell division.

One of the hallmarks of patients with mismatch-repair defects is *microsatellite instability*. Microsatellites are tandem repeats of one to six nucleotides found throughout the genome. In normal people the length of these microsatellites remains constant. However, in people with HNPCC, these satellites are unstable and increase or decrease in length in tumor cells, creating alleles not found in normal cells of the same patient.

Of the various DNA mismatch-repair genes, at least four are involved in the pathogenesis of HNPCC. Germline mutations in the *MSH2* and *MLH1* genes each account for approximately 30% of cases. The remaining cases have mutations in other mismatch repair genes. Although HNPCC accounts only for 2% to 4% of all colonic cancers, microsatellite instability can be detected in about 15% of sporadic colon cancers. The cancer genes that are mutated in HNPCC tumors have not yet been fully characterized but include the genes encoding TGF- β receptor II, the TCF component of the β -catenin pathway, *BAX*, and other oncogenes and tumor suppressor genes.

Xeroderma Pigmentosum. Individuals with another inherited disorder of DNA repair, xeroderma pigmentosum, are at increased risk for the development of cancers of the skin particularly following exposure to the UV light contained in sun rays. UV radiation causes cross-linking of pyrimidine residues, preventing normal DNA replication. Such DNA damage is repaired by the nucleotide excision repair system. Several proteins are involved in *nucleotide excision repair*, and an inherited loss of any one can give rise to xeroderma pigmentosum.

Diseases with Defects in DNA Repair by Homologous Recombination. Several rare autosomal recessive cancer syndromes have been described that are characterized by hypersensitivity to certain kinds of DNA-damaging agents, such as ionizing radiation (*Bloom syndrome* and

ataxia-telangiectasia), or DNA cross-linking agents, such as many chemotherapeutic drugs (*Fanconi anemia*). The phenotype of these diseases is complex and includes, in addition to predisposition to cancer, features such as neural symptoms (*ataxia-telangiectasia*), bone marrow aplasia (*Fanconi anemia*), and developmental defects (*Bloom syndrome*).

- As mentioned earlier, the gene mutated in *ataxia-telangiectasia*, *ATM*, is important in recognizing and responding to DNA damage caused by ionizing radiation. Persons with *Bloom syndrome* have a predisposition to a very broad spectrum of tumors. The defective gene encodes a helicase that participates in DNA repair by homologous recombination.
- There are 13 genes that make up the *Fanconi anemia* complex; mutation of any one of these genes can result in the phenotype. Interestingly, *BRCA2*, which is mutated in some individuals with familial breast cancer, is also mutated in a subset of persons with *Fanconi anemia*.
- Mutations in two genes, *BRCA1* and *BRCA2*, account for 25% of cases of familial breast cancer. In addition to breast cancer, women with *BRCA1* mutations have a substantially higher risk of epithelial ovarian cancers, and men have a slightly higher risk of prostate cancer. Likewise, mutations in the *BRCA2* gene increase the risk of breast cancer in both men and women as well as cancer of the ovary, prostate, pancreas, bile ducts, stomach, melanocytes, and B lymphocytes. Although their functions have not been elucidated fully, cells that lack these genes develop chromosomal breaks and severe aneuploidy. It appears that the *Fanconi anemia* proteins and the *BRCA* proteins form a DNA-damage response network whose purpose is to repair certain types of DNA damage using the homologous recombination repair pathway. Defects in this pathway leads to the activation of the salvage nonhomologous end joining pathway, formation of dicentric chromosomes, bridge-fusion-breakage cycles, and massive aneuploidy. Although linkage of *BRCA1* and *BRCA2* to familial breast cancers is established, these genes are rarely inactivated in sporadic cases of breast cancer. In this regard, *BRCA1* and *BRCA2* are different from other tumor suppressor genes, such as *APC* and *p53*, which are inactivated in both familial and sporadic cancers.

Cancers Resulting from Mutations Induced by Regulated Genomic Instability: Lymphoid Neoplasms. A special type of DNA damage plays a central role in the pathogenesis of tumors of B and T lymphocytes. As described in [Chapter 6](#), adaptive immunity relies on the ability of B and T cells to diversify their antigen receptor genes. Early B and T cells both express a pair of gene products, *RAG1* and *RAG2*, that carry out V(D)J segment recombination, permitting the assembly of functional antigen receptor genes. In addition, after encountering antigen mature B cells express a specialized enzyme called antigen-induced cytosine deaminase (*AID*), which catalyzes both immunoglobulin gene class switch recombination and somatic hypermutation. Errors during antigen receptor gene assembly and diversification are responsible for many of the mutations that cause lymphoid neoplasms ([Chapter 13](#)).

KEY CONCEPTS

Genomic Instability as Enabler of Malignancy

- Persons with inherited mutations of genes involved in DNA repair systems are at greatly increased risk for the development of cancer.
- Patients with *HNPCC syndrome* have defects in the mismatch repair system, leading to development of carcinomas of the colon. These patients' genomes show microsatellite instability, characterized by changes in length of short repeats throughout the genome.
- Patients with *xeroderma pigmentosum* have a defect in the nucleotide excision repair pathway and are at increased risk for the development of cancers of the skin exposed to UV light, because of an inability to repair pyrimidine dimers.
- Syndromes involving defects in the homologous recombination DNA repair system constitute a group of disorders—*Bloom syndrome*, *ataxia-telangiectasia*, and *Fanconi anemia*—that are characterized by hypersensitivity to DNA-damaging agents, such as ionizing radiation. *BRCA1* and *BRCA2*, which are mutated in familial breast cancers, are involved in DNA repair.
- Mutations incurred in lymphoid cells due to expression of gene products that induce genomic instability (*RAG1*, *RAG2*, *AID*) are important causes of lymphoid neoplasms.

Cancer-Enabling Inflammation

Infiltrating cancers provoke a chronic inflammatory reaction, leading some to liken them to “wounds that do not heal.” In patients with advanced cancers, this inflammatory reaction can be so extensive as to cause systemic signs and symptoms, such as anemia (due to inflammation-induced sequestration of iron and downregulation of erythropoietin production, [Chapter 14](#)), fatigue, and cachexia (described later). However, studies carried out on cancers in animal models suggest that inflammatory cells also modify the local tumor microenvironment to enable many of the hallmarks of cancer. These effects may stem from direct interactions between inflammatory cells and tumor cells, or through indirect effects of inflammatory cells on other resident stromal cells, particularly cancer-associated fibroblasts and endothelial cells. Proposed cancer-enabling effects of inflammatory cells and resident stromal cells include the following:

- **Release of factors that promote proliferation.** Infiltrating leukocytes and activated stromal cells have been shown to secrete a wide variety of growth factors, such as EGF, and proteases that can liberate growth factors from the extracellular matrix (ECM).
- **Removal of growth suppressors.** As mentioned, the growth of epithelial cells is suppressed by cell-cell and cell-ECM interactions. Proteases released by inflammatory cells can degrade the adhesion molecules that mediate these interactions, removing a barrier to growth.
- **Enhanced resistance to cell death.** Recall that detachment of epithelial cells from basement membranes and from cell-cell interactions can lead to a particular form of cell death called *anoikis*. It is suspected that tumor-associated macrophages may prevent *anoikis* by

expressing adhesion molecules such as integrins that promote direct physical interactions with tumor cells. There is also substantial evidence that stromal cell-cancer cell interactions increase the resistance of cancer cells to chemotherapy, presumably by activating signaling pathways that promote cell survival in the face of stresses such as DNA damage.

- **Inducing angiogenesis.** Inflammatory cells release numerous factors, including VEGF, which can stimulate angiogenesis.
- **Activating invasion and metastasis.** Proteases released from macrophages foster tissue invasion by remodeling the ECM, while factors such as TNF and EGF may directly stimulate tumor cell motility. As mentioned, other factors released from stromal cells, such as TGF- β , may promote epithelial-mesenchymal transitions, which is considered to be a key event in the process of invasion and metastasis.
- **Evading immune destruction.** A variety of soluble factors released by macrophages and other stromal cells are believed to contribute to the immunosuppressive microenvironment of tumors, including TGF- β and a number of other factors that either favor the recruitment of immunosuppressive T regulatory cells or suppress the function of CD8+ cytotoxic T cells. Furthermore, there is abundant evidence in murine cancer models and emerging evidence in human disease that advanced cancers contain mainly alternatively activated (M2) macrophages (Chapter 3), cells induced by cytokines such as IL-4 and IL-13. These macrophages produce cytokines that promote angiogenesis, fibroblast proliferation, and collagen deposition, all of which are commonly observed in invasive cancers. In addition, they appear to suppress effective host immune responses to cancer cells through mechanisms that remain to be elucidated.

A thorough understanding of how cancers “manipulate” inflammatory cells to support their growth and survival remains elusive. However, the results from animal studies are intriguing and raise the possibility of therapies directed at tumor-induced inflammation and its downstream consequences. Of note in this regard, COX2 inhibitors have been shown to decrease the incidence of colonic adenomas and are now approved for treatment of patients with familial adenomatous polyposis.

Dysregulation of Cancer-Associated Genes

The genetic damage that activates oncogenes or inactivates tumor suppressor genes may be subtle (e.g., point mutations) or may involve segments of chromosomes large enough to be detected in a routine karyotype. Activation of oncogenes and loss of function of tumor suppressor genes by mutations were discussed earlier in this chapter. Here we first discuss chromosomal abnormalities and then end this section by discussing the epigenetic changes that contribute to carcinogenesis and the role of noncoding RNAs.

Chromosomal Changes

Certain chromosomal abnormalities are highly associated with particular neoplasms and inevitably lead to the

dysregulation of genes with an integral role in the pathogenesis of that tumor type. Specific recurrent chromosomal abnormalities have been identified in most leukemias and lymphomas, many sarcomas, and an increasing number of carcinomas. In addition, whole chromosomes may be gained or lost. Although changes in chromosome number (aneuploidy) and structure are generally considered to be late phenomena in cancer progression, in some cases (e.g., in cells that have lost their telomeres, Figure 7-34), it can be an early event that initiates the transformation process.

Historically, chromosomal changes in cancer were identified through karyotyping, the morphologic identification of metaphase chromosomes prepared from clinical specimens. Today, however, cancer cell karyotypes are being reconstructed in research labs from deep sequencing of cancer cell genomes, and it is possible that conventional karyotyping will be supplanted by other methods even in clinical laboratories in the years to come. Whatever technology is used, the study of chromosomal changes in tumor cells is important. First, genes in the vicinity of recurrent chromosomal breakpoints or deletions are very likely to be either oncogenes (e.g., *MYC*, *BCL2*, *ABL*) or tumor suppressor genes (e.g., *APC*, *RB*). Second, certain karyotypic abnormalities have diagnostic value or important prognostic or therapeutic implications. For example, tests that detect and quantify *BCR-ABL* fusion genes or their mRNA products are essential for the diagnosis of CML and are used to monitor the response to BCR-ABL kinase inhibitors. Many additional chromosomal aberrations that are characteristic of specific tumor types are presented in later chapters.

Chromosomal Translocations. Any type of chromosomal rearrangement—translocations, inversions, amplifications, and even small deletions—can activate proto-oncogenes, but chromosomal translocation is the most common mechanism described to date. Notable examples of oncogenes activated by chromosomal translocations are listed in Table 7-8. Translocations can activate proto-oncogenes in two ways:

- By promoter or enhancer substitution, in which the translocation results in overexpression of a proto-oncogene by swapping its regulatory elements with those of another gene, typically one that is highly expressed.
- By formation of a fusion gene in which the coding sequences of two genes are fused in part or in whole, leading to the expression of a novel chimeric protein with oncogenic properties.

Overexpression of a proto-oncogene caused by translocation is exemplified by Burkitt lymphoma. Virtually all Burkitt lymphomas have a translocation involving chromosome 8q24, where the *MYC* gene resides, and one of the three chromosomes that carry an immunoglobulin gene. At its normal locus, *MYC* is tightly controlled, and is most highly expressed in actively dividing cells. In Burkitt lymphoma the most common translocation moves the *MYC*-containing segment of chromosome 8 to chromosome 14q32 (See Fig. 7-26), placing it close to the immunoglobulin heavy chain (*IGH*) gene. The genetic notation for the translocation is t(8;14)(q24;q32). The molecular

*Genes in bold type are involved in multiple rearrangements.

mechanisms of the translocation-mediated overexpression of *MYC* are variable, as are the precise breakpoints within the *MYC* gene. In most cases the translocation removes regulatory sequences of the *MYC* gene and replaces them with the control regions of the *IGH* gene, which is highly expressed in B-cells. The *MYC* coding sequences remain intact and the *MYC* protein is constitutively expressed at high levels. The almost invariable presence of *MYC* translocations in Burkitt lymphomas attests to the importance of *MYC* overactivity in the pathogenesis of this tumor.

There are many other examples of translocations involving oncogenes and antigen receptor loci in lymphoid tumors. For these (or any other) translocations to occur, double-stranded DNA breaks must occur simultaneously in at least two places in the genome and the free DNA ends must then be joined to create two new derivative chromosomes. In lymphoid cells most of these molecular misadventures are believed to occur during attempts at normal antigen receptor gene recombination (which occurs in both B- and T-cell progenitors) or class-switch recombination (which is confined to antigen-stimulated mature B cells). Not unexpectedly, tumors with translocations involving immunoglobulin genes are always of B-cell origin, and tumors with translocations involving T cell receptor genes are always of T-cell origin. The affected genes are diverse, but as with translocations involving *MYC*, the net effect is overexpression of some protein with oncogenic activity.

The *Philadelphia chromosome*, characteristic of CML and a subset of B-cell acute lymphoblastic leukemias (Chapter 13), provides the prototypic example of a chromosomal rearrangement that creates a fusion gene encoding a chimeric oncoprotein. In this instance, the two chromosome breaks lie within the *ABL* gene on chromosome 9 and within the *BCR* (breakpoint cluster region) gene on chromosome 22 (Fig. 7-26). Non-homologous end-joining then leads to a reciprocal translocation that creates an oncogenic *BCR-ABL* fusion gene on the derivative chromosome 22 (the so-called Philadelphia chromosome).

The *BCR-ABL* fusion gene encodes a chimeric BCR-ABL protein with constitutive tyrosine kinase activity. Although the translocations are cytogenetically identical in CML and

B-cell acute lymphoblastic leukemias (B-ALL), the structure of the resulting *BCR-ABL* fusion genes and proteins they encode usually differ slightly in these two tumors. Since the discovery of *BCR-ABL* in CML, many other fusion oncogenes encoding constitutively active tyrosine kinases have been described in a broad array of human cancers. Like BCR-ABL, these fusion proteins drive oncogenic signaling pathways and have sometimes proven to be targets of effective therapies.

Other oncogenic fusion genes encode nuclear factors that regulate transcription or chromatin structure. In contrast to overactive tyrosine kinases, less is generally known about how nuclear oncoproteins function. An exception with important clinical consequences is found in a form of leukemia called *acute promyelocytic leukemia* (APML). APML is virtually always associated with a reciprocal translocation between chromosomes 15 and 17 that produces a *PML-RARA* fusion gene (Fig. 7-41). How this fusion gene functions is now reasonably well understood.

- The fusion gene encodes a chimeric protein consisting of part of a protein called PML and part of the retinoic acid receptor- α (*RAR α*). Normal *RAR α* binds to DNA and activates transcription in the presence of retinoids. Among the *RAR α* responsive genes are a number that are needed for the differentiation of myeloid progenitors into neutrophils.
- The *PML-RAR α* oncoprotein has diminished affinity for retinoids, such that at physiologic levels retinoids do not bind to *PML-RAR α* to any significant degree. In this “unliganded” state, it retains the capacity to bind DNA, but instead of activating transcription, it inhibits transcription through recruitment of transcriptional repressors. This interferes with the expression of genes that are needed for differentiation, leading to a “pile-up” of proliferating myeloid progenitors that replace normal bone marrow elements.
- When given in pharmacologic doses, all-trans retinoic acid binds to *PML-RAR α* and causes a conformational change that results in the displacement of repressor complexes and the recruitment of different complexes that activate transcription. This exchange overcomes the block in gene expression, causing the neoplastic myeloid progenitors to differentiate into neutrophils and die, clearing the marrow over several days and allowing for recovery of normal hematopoiesis.

This highly effective therapy is the first example of *differentiation therapy*, in which immortal tumor cells are induced to differentiate into their mature progeny, which have limited life spans. It has also spurred efforts to develop drugs that target other nuclear oncoproteins, despite the inherent difficulty of the problem.

Deletions. Chromosomal deletions are another very prevalent structural abnormality in tumor cells. Deletion of specific regions of chromosomes is associated with the loss of particular tumor suppressor genes.

As we discussed earlier, deletions involving chromosome 13q14, the site of the *RB* gene, are associated with retinoblastoma, and deletion of the *VHL* tumor suppressor gene on chromosome 3p is a very common event in renal cell carcinomas. Ongoing sequencing of cancer cell genomes will undoubtedly reveal many more examples of deletions

Figure 7-41 Molecular pathogenesis of acute promyelocytic leukemia and basis for response to all-trans retinoic acid. ATRA, all-trans retinoic acid; RA, retinoic acid; RXR, binding partner for normal RAR α and PML-RAR α fusion protein encoded by a chimeric gene created by the (15;17) translocation in acute promyelocytic leukemia.

involving tumor suppressor genes, as well as small insertions of DNA from one site into another. It should be noted that not all deletions lead to loss of gene function; a few activate oncogenes through the same mechanisms as chromosomal translocations. For example, about 25% of T-cell acute lymphoblastic leukemias have small deletions of chromosome 1 that juxtapose the *TAL1* proto-oncogene with a nearby active promoter, leading to overexpression of the *TAL1* transcription factor. Similarly, deletions involving chromosome 5 in a subset of lung cancers produce an oncogenic *EML4-ALK* fusion gene encoding a constitutively active tyrosine kinase. It is likely that more “cryptic” deletions that activate oncogenes will be discovered through deep sequencing of cancer genomes.

Gene Amplification. Overexpression of oncogenes may also result from reduplication and amplification of their DNA sequences. Such amplification may produce up to several hundred copies of the oncogene in the tumor cell. In some cases the amplified genes produce chromosomal changes that can be identified microscopically. Two mutually exclusive patterns are seen: (1) multiple small extra-chromosomal structures called *double minutes* and (2) *homogeneous staining regions*. The latter derive from the insertion of the amplified genes into new chromosomal locations, which may be distant from the normal location of the involved oncogene. The affected chromosomal regions lack a normal pattern of light and dark-staining

bands, appearing homogeneous in karyotypes (Fig. 7-27). From a clinical perspective the most important amplifications are *NMYC* in neuroblastoma and *ERBB2* in breast cancers. *NMYC* is amplified in 25% to 30% of neuroblastomas, and its amplification is associated with poor prognosis. *ERBB2* amplification occurs in about 20% of breast cancers. As already mentioned, antibody therapy directed against the HER2 receptor encoded by *ERBB2* is an effective therapy for this molecular subset of breast cancers.

Chromothripsis. The true extent of chromosome rearrangements in cancer is only now coming into view thanks to sequencing of entire cancer cell genomes, which allows for comprehensive “reconstruction” of chromosomes from DNA sequences. Genomic sequencing has revealed not only many simple rearrangements (e.g., small deletions, duplications, or inversions) that were not appreciated by prior methods, but also much more dramatic chromosome “catastrophes” termed *chromothripsis* (literally, chromosome shattering). Chromothripsis is observed in 1% to 2% of cancers as a whole, but is found in up to 25% of osteosarcomas and other bone cancers and at relatively high frequency in gliomas as well. It appears to result from a single event in which dozens to hundreds of chromosome breaks occur within part or across the entirety of a single chromosome or several chromosomes. The genesis of these breaks is unknown, but DNA repair mechanisms are activated in affected cells that stitch the pieces together in a

haphazard way, creating many chromosome rearrangements and also resulting in the loss of some chromosome segments. It is hypothesized that such catastrophic events by chance simultaneously activate oncogenes and inactivate tumor suppressors, thereby expediting the process of carcinogenesis.

KEY CONCEPTS

Genetic Lesions in Cancer

- Tumor cells may acquire several types of oncogenic mutations, including point mutations and other nonrandom chromosomal abnormalities, such as translocations, deletions, and gene amplifications.
- Balanced translocations contribute to carcinogenesis by overexpression of oncogenes or generation of novel fusion proteins with altered signaling capacity. Deletions frequently cause loss of tumor suppressor gene function, and occasionally activate proto-oncogenes. Gene amplification generally increases the expression and function of oncogenes.
- Genomic sequencing has revealed numerous “cryptic” (subcytogenetic) rearrangements, mainly small deletions and insertions (“indels”), as well as chromothripsis, in which a chromosome is “shattered” and then reassembled in a haphazard way.

Epigenetic Changes

Epigenetic changes have important roles in many aspects of the malignant phenotype, including the expression of cancer genes, the control of differentiation and self-renewal, and even drug sensitivity and drug resistance. As discussed in Chapter 1, “epigenetics” refers to factors other than the sequence of DNA that regulate gene expression (and, thereby, cellular phenotype). Recall that these factors include histones modifications catalyzed by enzymes associated with chromatin regulatory complexes; DNA methylation, a modification created by DNA methyltransferases; and other less well characterized proteins that regulate the higher order organization of DNA (e.g., looping of enhancer elements onto gene promoters).

It has been recognized for more than a hundred years that the nuclei of cancer cells display abnormal morphologies, which (as discussed earlier) may take the form of hyperchromasia, chromatin clumping, or chromatin clearing (so-called vesicular nuclear chromatin). These altered appearances stem from disturbances of chromatin organization, the basis of which has been obscure. One of the most notable findings emerging from the sequencing of cancer genomes has been the identification of numerous mutations involving genes that encode epigenetic regulatory proteins (Table 7-9). As a result, it is now suspected that the altered morphologic appearance of cancer cells reflects acquired genetic defects in factors that maintain the epigenome. Indeed, methods that allow genome-wide assessment of the cell’s epigenome are now available and have begun to reveal widespread epigenetic alterations in cancers, which can be broadly divided into the following categories:

- **Silencing of tumor suppressor genes by local hypermethylation of DNA.** Some cancer cells exhibit selective

Table 7-9 Examples of Epigenomic Regulatory Genes that are Mutated in Cancer

Gene(s)	Function	Tumor (Approximate Frequency of Mutation)
<i>DNMT3A</i>	DNA methylation	Acute myeloid leukemia (20%)
<i>MLL1</i>	Histone methylation	Acute leukemia in infants (90%)
<i>MLL2</i>	Histone methylation	Follicular lymphoma (90%)
<i>CREBBP/EP300</i>	Histone acetylation	Diffuse large B cell lymphoma (40%)
<i>ARID1A</i>	Nucleosome positioning/chromatin remodeling	Ovarian clear cell carcinoma (60%), endometrial carcinoma (30%-40%)
<i>SNF5</i>	Nucleosome positioning/chromatin remodeling	Malignant rhabdoid tumor (100%)
<i>PBRM1</i>	Nucleosome positioning/chromatin remodeling	Renal carcinoma (30%)

hypermethylation of the promoters of tumor suppressor genes that results in their transcriptional silencing. Typically, hypermethylation occurs on only one allele and the function of the other copy of the affected tumor suppressor gene is lost through another mechanism, such as a disabling point mutation or a deletion. One of several examples of a tumor suppressor gene that is hypermethylated in several cancers is *CDKN2A*, which you will recall is a complex locus that encodes two tumor suppressors, p14/ARF and p16/INK4a, that enhance p53 and RB activity, respectively.

- **Global changes in DNA methylation.** In addition to local hypermethylation of tumor suppressor genes, many tumors exhibit abnormal patterns of DNA methylation throughout their genomes, sometimes in the form of hypermethylation and other times as hypomethylation. Tumors commonly exhibiting abnormal DNA methylation, such as acute myeloid leukemia, sometimes have mutations in genes encoding DNA methyltransferases or other factors that influence DNA methylation (Table 7-9), suggesting that the observed alterations have a genetic basis. The most obvious potential consequence of global changes in methylation is altered expression of multiple genes, which may be overexpressed or underexpressed compared to normal depending on the nature of local changes. In addition, however, mice engineered to have hypomethylated genomes also exhibit chromosomal instability; thus, altered DNA methylation may contribute to tumorigenesis in several ways.
- **Changes in histones.** Cancer cells often demonstrate changes in histones near genes that influence cellular behavior. As with changes in DNA methylation, in an increasing number of instances it appears that these alterations have a genetic basis, being attributable to mutations that affect the activities of protein complexes that “write”, “read” and “erase” histone marks, or that position nucleosomes on DNA (Table 7-9). Details have yet to emerge, but it is virtually certain that these lesions somehow alter the expression of sets of genes that contribute to the malignant phenotype.

Much remains to be deciphered about the state of the “epigenome” in various cancers and its contribution to the malignant state, but several aspects of the relationship merit emphasis.

- The lineage-specificity of certain oncogenes and tumor suppressor genes has an epigenetic basis. You may have noticed that tumor suppressors and oncoproteins can be broadly divided into two classes, those that are mutated or otherwise dysregulated in many cancers (e.g., RAS, MYC, p53), and those that are mutated in a restricted subset of tumors (e.g., VHL in renal cell carcinomas, APC in colon carcinoma) and are thus lineage restricted. A cancer cell’s lineage or differentiation state, like that of normal cells, is generated by epigenetic modifications that produce a pattern of gene expression that characterizes that particular cell type. It follows that lineage-restricted cancer genes only act within epigenetic contexts in which key oncogenic targets are controlled by these genes.
- The epigenome is an attractive therapeutic target. Because the epigenetic state of a cell depends on reversible modifications that are carried out by enzymes (which are generally good drug targets), there is intense interest in developing drugs that target epigenomic modifiers in cancer and other diseases. Inhibitors of histone deacetylases, chromatin erasers that remove acetyl groups from histones, are approved for use in certain lymphoid tumors, and DNA methylation inhibitors are now being used to treat myeloid tumors, based in part on the idea that these drugs may reactivate tumor suppressor genes. Other drugs that target specific chromatin writers and chromatin readers are also now being tested in clinical trials.
- Cancers may exhibit considerable epigenetic heterogeneity. Just as genomic instability gives rise to genetic heterogeneity in cancers, it is feared that cancers will also prove to have extensive epigenetic heterogeneity from cell to cell within individual tumors. One consequence of such heterogeneity may be drug resistance. For example, epigenetic alterations can lead to the resistance of lung cancer cells to inhibitors of EGF receptor signaling. When the inhibitors are removed, the lung cancer cells revert to their prior inhibitor-sensitive state. If widespread, such epigenetic plasticity may join genetic heterogeneity as yet another barrier to the development of curative cancer therapies.

Noncoding RNAs and Cancer

As discussed in [Chapter 1](#), microRNAs (miRs) are small noncoding, single-stranded RNAs, approximately 22 nucleotides in length, that mediate sequence-specific inhibition of messenger RNA (mRNA) translation through the action of the RNA-induced silencing complex (RISC). Given that miRs control normal cell growth, differentiation, and cell survival, it is not surprising that they play a role in carcinogenesis. Altered miR expression, sometimes stemming from amplifications and deletions of miR loci, has been identified in many cancers. Decreased expression of certain miRs increases the translation of oncogenic mRNAs; such miRs have tumor suppressive activity. Conversely, overexpression of other miRs represses the

expression of tumor suppressor genes; such miRs promote tumor development and are often referred to as *onco-miRs*. Specific examples of contributions of miRs to cancer are numerous; the following are among the best established:

- **OncomiRs.** miR-200 has been shown to promote epithelial-mesenchymal transitions believed to be important in invasiveness and metastasis; and miR-155, originally identified at the site of retroviral insertions in avian lymphomas, is overexpressed in many human B cell lymphomas and indirectly upregulates a large number of genes that promote proliferation, including *MYC*.
- **Tumor suppressive miRs.** Deletions affecting certain tumor suppressive miRs, such as miR-15 and miR-16, are among the most frequent genetic lesions in chronic lymphocytic leukemia, a common tumor of older adults. In this context, it appears that their loss leads to upregulation of the anti-apoptotic protein BCL-2.
- **Tumor suppressive properties of miR processing factors.** Study of families that are prone to the development of an unusual collection of neoplasms, including certain rare ovarian and testicular tumors, unexpectedly identified heterozygous germline defects in *DICER*, a gene that encodes an endonuclease that is required for the processing and production of functional miRs. Thus, *DICER* is tumor suppressive in certain cellular contexts. Whether the tumor suppressive function of *DICER* stems from its involvement in processing of miRs remains to be established.

The involvement of miRs is likely the proverbial tip-of-the-iceberg with respect to the role of noncoding RNAs in cancer. Systematic genomic analyses have revealed that more than 60% of the genome is transcribed into RNAs, most of which are noncoding and believed to have regulatory functions ([Chapter 1](#)). These noncoding RNAs fall into several classes: piwi-interacting RNAs (piRNAs), the most common type of small noncoding RNA, which (like miRs) are believed to have a role in post-transcriptional gene silencing; snoRNAs, which are important in maturation of rRNA and the assembly of ribosomes; and long intervening noncoding RNAs (lincRNAs), some of which regulate the activity of chromatin “writers,” the factors that modify histones and thereby control gene expression. Abnormalities in the expression of these regulatory RNAs have also been implicated in several human diseases, including cancer, and many more examples of cancer-associations are likely to be forthcoming.

Molecular Basis of Multistep Carcinogenesis

Given that malignant tumors must acquire multiple “hallmarks” of cancer, it follows that cancers result from the stepwise accumulation of multiple mutations that act in complementary ways to produce a fully malignant tumor. The notion that malignant tumors arise from a protracted sequence of events is supported by epidemiologic, experimental, and molecular studies, and the study of oncogenes and tumor suppressor genes has provided a firm molecular footing for the concept of multistep carcinogenesis. Genome-wide sequencing of cancers has revealed as few as ten or so mutations in certain leukemias

Figure 7-42 Molecular model for the evolution of colorectal cancers through the adenoma-carcinoma sequence. Although *APC* mutation is an early event and loss of *TP53* occurs late in the process of tumorigenesis, the timing for the other changes may be variable. Note also that individual tumors may not have all of the changes listed. *Top right*, cells that gain oncogene signaling without loss of *TP53* eventually enter oncogene-induced senescence. LOH, loss-of-heterozygosity.

to many thousands of mutations in tumors that arise following chronic exposure to carcinogens, such as lung cancers associated with cigarette smoking. Although the presence of multiple mutations is consistent with the idea that no single mutation will suffice to produce a cancer, as already mentioned it is often difficult to determine which mutations in a tumor drive oncogenesis and which are "passengers," mutations that provide no advantage to the tumor cell and are merely along for the ride.

A more direct answer to the question "how many mutations does it take to establish a fully malignant tumor?" comes from experimental attempts to transform normal human cells with combinations of oncogenes, some derived from transforming viruses (described later). For example, normal human epithelial cells can be transformed by the following combination of events: (1) activation of RAS; (2) inactivation of RB; (3) inactivation of p53; (4) inactivation of PP2A, a tumor suppressive phosphatase that is a negative regulator of many signaling pathways; and (5) constitutive expression of telomerase. Cells bearing all of these alterations are immortal and produce invasive, fully malignant growths when injected into immunodeficient mice.

Unlike in the laboratory, these events presumably never occur simultaneously during the natural development of a human cancer, but instead occur in a stepwise fashion. What is the evidence that this is so? A classic example of incremental acquisition of the malignant phenotype is found in colon carcinoma. Many of these cancers evolve through a series of morphologically identifiable stages: colon epithelial hyperplasia followed by formation of

adenomas that progressively enlarge and ultimately undergo malignant transformation (Chapter 17). Molecular analyses of proliferations at each of these stages have indeed shown that precancerous lesions have fewer mutations than adenocarcinomas and suggest a tendency to acquire particular mutations in the sequence illustrated in Figure 7-42. According to this scheme, inactivation of the *APC* tumor suppressor gene occurs first, followed by activation of RAS and, ultimately, loss of a tumor suppressor gene on 18q and loss of *TP53*. While multiple mutations, including gain of oncogenes and loss of tumor suppressors, are required for carcinogenesis, the precise temporal sequence of mutations does not appear to be fixed and may be different in each organ and tumor type.

Similar evidence for stepwise progression also exists for other recognizable precursor lesions to epithelial cancers, such as dysplasias of the cervix, hyperplasias of the endometrium, and the evolution of oral cancers. These are described in subsequent chapters.

Carcinogenic Agents and Their Cellular Interactions

More than 200 years ago the London surgeon Sir Percival Pott correctly attributed scrotal skin cancer in chimney sweeps to chronic exposure to soot. Based on this observation, the Danish Chimney Sweeps Guild ruled that its members must bathe daily. No public health measure since that time has achieved so much in controlling a form of

cancer! Subsequently, hundreds of chemicals have been shown to be carcinogenic in animals. Some of the major agents are presented in Table 7-10.

Steps Involved in Chemical Carcinogenesis

As discussed earlier, carcinogenesis is a multistep process. This is readily demonstrated in experimental models of chemical carcinogenesis, in which the stages of initiation and progression during cancer development were first described. The classic experiments that allowed the distinction between initiation and promotion were performed on mouse skin (Fig. 7-43), and revealed the following concepts relating to the initiation-promotion sequence:

- **Initiation** results from exposure of cells to a sufficient dose of a carcinogenic agent; an initiated cell is altered, making it potentially capable of giving rise to a tumor. Initiation alone, however, is not sufficient for tumor formation (Fig. 7-43, treatment group 1).
- **Initiation causes permanent DNA damage (mutations); it is therefore rapid and irreversible and has “memory.”** Thus, tumors are produced even if the application of the promoting agent is delayed for several months after a single application of the initiator (Fig. 7-43, treatment group 3).
- **Promoters can induce tumors to arise from initiated cells, but they are nontumorigenic by themselves.** Furthermore, tumors do not result when the promoting agent is applied before, rather than after, the initiating agent (Fig. 7-43, treatment group 4). This indicates that, in contrast to the effects of initiators, the cellular changes resulting from the application of promoters do not affect DNA directly and are reversible. As discussed later, promoters enhance the proliferation of initiated cells, an effect that may contribute to the acquisition of additional mutations.

Although the concepts of initiation and promotion have been derived largely from experiments involving induction of skin cancer in mice, they are also useful concepts when considering the roles of certain factors that

Figure 7-43 Experiments demonstrating the initiation and promotion phases of carcinogenesis in mice. Group 2: application of promoter repeated at twice-weekly intervals for several months. Group 3: application of promoter delayed for several months and then applied twice weekly.

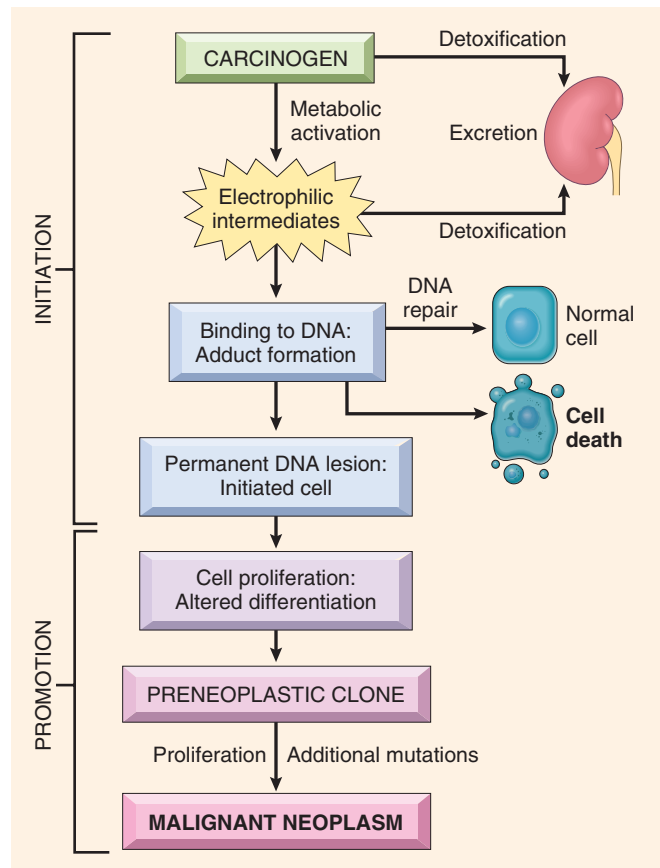

Figure 7-44 General schema of events in chemical carcinogenesis. Note that promoters cause clonal expansion of the initiated cell, thus producing a preneoplastic clone. Further proliferation induced by the promoter or other factors causes accumulation of additional mutations and emergence of a malignant tumor.

contribute to human cancers. With this brief overview, initiation and promotion can be examined in more detail (Fig. 7-44). All initiating chemical carcinogens are highly reactive electrophiles (have electron-deficient atoms) that can react with nucleophilic (electron-rich) sites in the cell. Their targets are DNA, RNA, and proteins, and in some cases these interactions cause cell death. Initiation, obviously, inflicts nonlethal damage to the DNA that cannot be repaired. The mutated cell then passes on the DNA lesions to its daughter cells. Chemicals that can cause initiation of carcinogenesis can be classified into two categories: direct acting and indirect acting.

Direct-Acting Carcinogens

Direct-acting carcinogens require no metabolic conversion to become carcinogenic. Most are weak carcinogens but some are important because they are cancer chemotherapeutic drugs (e.g., alkylating agents). Tragically, in some instances these agents have successfully cured, controlled, or delayed recurrence of certain types of cancer (e.g., leukemia, lymphoma, and ovarian carcinoma), only to evoke later a second form of cancer, usually acute myeloid leukemia. The risk of induced cancer is low, but its existence dictates judicious use of such agents.

Indirect-Acting Carcinogens

The designation indirect-acting carcinogen refers to chemicals that require metabolic conversion to become active carcinogens; the carcinogenic product of metabolism is called an *ultimate carcinogen*. Some of the most potent indirect chemical carcinogens—the polycyclic hydrocarbons—are present in fossil fuels. Others, for example, benzo[*a*]pyrene (the active component of soot, which Potts showed to be carcinogenic), are formed during the high-temperature combustion of tobacco in cigarettes and are implicated in the causation of lung cancer. Polycyclic hydrocarbons may also be produced from animal fats during the process of broiling or grilling meats and are present in smoked meats and fish. The principal active products in many hydrocarbons are epoxides, which form covalent adducts (addition products) with molecules in the cell, principally DNA, but also with RNA and proteins.

The aromatic amines and azo dyes are another class of indirect-acting carcinogens that were widely used in the past in the aniline dye and rubber industries. Many other occupational carcinogens are listed in Table 7-10.

Most chemical carcinogens require metabolic activation for conversion into ultimate carcinogens (Fig. 7-44). Certain metabolic pathways may inactivate (detoxify) the procarcinogen or its derivatives. Most of the known carcinogens are metabolized by *cytochrome P-450-dependent*

mono-oxygenases. The genes that encode these enzymes are polymorphic, and the activity and inducibility of these enzymes vary significantly among individuals (described further in Chapter 9). Because these enzymes are essential for the activation of procarcinogens, the susceptibility to carcinogenesis is related in part to the particular polymorphic variants that an individual inherits. Thus, it may be possible to assess cancer risk in a given individual by genetic analysis of such enzyme polymorphisms.

The metabolism of polycyclic aromatic hydrocarbons, such as benzo[*a*]pyrene by the product of the P-450 gene, *CYP1A1*, provides an instructive example. Approximately 10% of the white population has a highly inducible form of this enzyme that is associated with an increased risk of lung cancer in smokers. Light smokers with the susceptible *CYP1A1* genotype have a sevenfold higher risk of developing lung cancer compared with smokers without the permissive genotype. It should be appreciated, however, that not all variation in the activation or detoxification of carcinogens is genetically determined. Age, sex, and nutritional status also influence the internal dose of toxicants produced and hence the risk of cancer development in a particular individual.

Molecular Targets of Chemical Carcinogens. Because malignant transformation results from mutations, it comes as no surprise that most chemical initiating agents target DNA and are mutagenic. There is no single or unique alteration associated with cancer initiation. Nor is there any apparent predisposition for initiators to cause mutations in particular genes; presumably, mutations occur throughout the genome and cells that by chance suffer damage to the “usual suspects”, oncogenes and tumor suppressors such as *RAS* and *TP53*, gain a potential selective advantage and are at risk for subsequent transformation.

This is not to say that mutations induced by carcinogens occur in an entirely random fashion. Because of their chemical structures, some carcinogens interact preferentially with particular DNA sequences or bases, and thus produce mutations that are clustered at “hotspots” or that are enriched for particular base substitutions. One illustrative example of a chemical carcinogen associated with a mutational “hotspot” is *aflatoxin B₁*, a naturally occurring agent produced by some strains of a mold called *Aspergillus*. *Aspergillus* grows on improperly stored grains and nuts, and there is a strong correlation between the dietary level of this food contaminant and the incidence of hepatocellular carcinoma in parts of Africa and the Far East. Interestingly, aflatoxin B₁-associated hepatocellular carcinomas tend to have a particular mutation in *TP53*, a G:C→T:A transversion in codon 249 that produces an arginine to serine substitution in the p53 protein. In contrast, *TP53* mutations are infrequent in liver tumors from areas where aflatoxin contamination of food does not occur, and few of these mutations involve codon 249. Similarly, lung cancers associated with smoking have a 10-fold higher mutational burden on average than lung cancers in nonsmokers, and these excess mutations are strongly skewed toward particular base substitutions known to be caused by carcinogens in cigarette smoke (the proverbial “smoking gun”). With sequencing of cancer genomes becoming routine, it is likely that other “carcinogen signatures” will be discovered; these associations

Table 7-10 Major Chemical Carcinogens

Direct-Acting Carcinogens
Alkylating Agents
β-Propiolactone
Dimethyl sulfate
Diepoxybutane
Anticancer drugs (cyclophosphamide, chlorambucil, nitrosoureas, and others)
Acyating Agents
1-Acetyl-imidazole
Dimethylcarbonyl chloride
Procarcinogens That Require Metabolic Activation
Polycyclic and Heterocyclic Aromatic Hydrocarbons
Benz[<i>a</i>]anthracene
Benzo[<i>a</i>]pyrene
Dibenz[<i>a,h</i>]anthracene
3-Methylcholanthrene
7,12-Dimethylbenz[<i>a</i>]anthracene
Aromatic Amines, Amides, Azo Dyes
2-Naphthylamine (β-naphthylamine)
Benidine
2-Acetylaminofluorene
Dimethylaminoazobenzene (butter yellow)
Natural Plant and Microbial Products
Aflatoxin B ₁
Griseofulvin
Cycasin
Safrole
Betel nuts
Others
Nitrosamine and amides
Vinyl chloride, nickel, chromium
Insecticides, fungicides
Polychlorinated biphenyls

may prove useful in epidemiologic studies of chemical carcinogenesis.

Additional potential carcinogens in the workplace and at home include vinyl chloride, arsenic, nickel, chromium, insecticides, fungicides, and polychlorinated biphenyls. Finally, nitrites used as food preservatives have caused concern, in that they cause nitrosylation of amines contained in the food. The nitrosoamines so formed are suspected to be carcinogenic.

Promotion of Chemical Carcinogenesis

Promoters are chemical agents that are not mutagenic, but which instead stimulate cellular proliferation. It is self-evident that in the absence of proliferation, tumors cannot arise. In tissues that are normally quiescent, such as the liver, the mitogenic stimulus may be provided by the initiating agent. This occurs if the carcinogenic initiator is toxic and kills a large number of cells, thereby stimulating regeneration of the surviving cells. In classic experimental systems, however, the carcinogenic potential of initiators is only revealed upon the subsequent administration of promoters (e.g., phorbol esters, hormones, phenols, and drugs), which by definition are nontumorigenic. Application of promoters leads to proliferation and clonal expansion of initiated (mutated) cells. Driven to proliferate, subclones of the initiated cells suffer various additional mutations, and eventually a cancerous clone with all the necessary hallmark characteristics may emerge. It is likely that many factors contributing to oncogenesis in humans also act by stimulating proliferation and thus can be thought of conceptually as tumor promoters; examples include unopposed estrogenic stimulation of the endometrium and breast, and chronic inflammatory processes associated with tissue repair (e.g., inflammatory bowel disease, chronic hepatitis, and Barrett esophagus).

KEY CONCEPTS

Chemical Carcinogenesis

- Chemical carcinogens have highly reactive electrophile groups that directly damage DNA, leading to mutations and eventually cancer.
- Direct-acting agents do not require metabolic conversion to become carcinogenic, while indirect-acting agents are not active until converted to an ultimate carcinogen by endogenous metabolic pathways. Hence, polymorphisms of endogenous enzymes such as cytochrome P-450 may influence carcinogenesis.
- After exposure of a cell to a mutagen or an initiator, tumorigenesis can be enhanced by exposure to promoters, which stimulate proliferation of the mutated cells.
- Examples of human carcinogens are direct-acting agents (e.g., alkylating agents used for chemotherapy), indirect acting agents (e.g., benzo[a]pyrene, azo dyes, aflatoxin), and promoters or agents that cause pathologic hyperplasias of the endometrium or regenerative activity in the liver.

Radiation Carcinogenesis

Radiant energy, in the form of the UV rays of sunlight or as ionizing electromagnetic and particulate radiation, is

carcinogenic. UV light is clearly implicated in the causation of skin cancers, and ionizing radiation exposure from medical or occupational exposure, nuclear plant accidents, and atomic bomb detonations has produced a variety of cancers. Although the contribution of radiation to the total human burden of cancer is probably small, the well-known latency of damage caused by radiant energy and its cumulative effect require extremely long periods of observation and make it difficult to ascertain its full significance. An increased incidence of breast cancer has become apparent decades later among women exposed during childhood to atomic bomb tests. The incidence peaked during 1988-1992 and then declined. Moreover, possible additive or synergistic effects of radiation with other potentially carcinogenic factors add another dimension to the picture.

Ultraviolet Rays

Exposure to UV rays derived from the sun, particularly in fair-skinned individuals, is associated with an increased incidence of squamous cell carcinoma, basal cell carcinoma, and melanoma of the skin. The degree of risk depends on the type of UV rays, the intensity of exposure, and the quantity of the light-absorbing "protective mantle" of melanin in the skin. Persons of European origin who have fair skin that repeatedly becomes sunburned but sturdily refuses to tan and who live in locales receiving a great deal of sunlight (e.g., Queensland, Australia, close to the equator) have among the highest incidence of skin cancers (melanomas, squamous cell carcinomas, and basal cell carcinomas) in the world. Nonmelanoma skin cancers are associated with total cumulative exposure to UV radiation, whereas melanomas are associated with intense intermittent exposure – as occurs with sunbathing. The UV portion of the solar spectrum can be divided into three wavelength ranges: UVA (320-400 nm), UVB (280-320 nm), and UVC (200-280 nm). Of these, UVB is believed to be responsible for the induction of cutaneous cancers. UVC, although a potent mutagen, is not considered significant because it is filtered out by the ozone layer surrounding the earth (hence the concern about ozone depletion).

The carcinogenicity of UVB light is due to formation of pyrimidine dimers in DNA. If the energy in a photon of UV light is absorbed by DNA, the result is a chemical reaction that leads to covalent crosslinking of pyrimidine bases, particularly adjacent thymidine residues in the same strand of DNA. This distorts the DNA helix and prevents proper pairing of the dimer with bases in the opposite DNA strand. Pyrimidine dimers are repaired by the nucleotide excision repair pathway. There are five steps in nucleotide excision repair, and in mammalian cells the process may involve 30 or more proteins. It is postulated that with excessive sun exposure, the capacity of the nucleotide excision repair pathway is overwhelmed, and error-prone non-templated DNA-repair mechanisms become operative that provide for the survival of the cell at the cost of genomic mutations that, in some instances, lead to cancer. The importance of the nucleotide excision repair pathway of DNA repair is most graphically illustrated by the high frequency of cancers in individuals with the hereditary disorder *xeroderma pigmentosum* (discussed previously). The role of UV exposure in the etiology of melanoma has been somewhat controversial. However, recent sequencing of melanoma genomes has revealed a very large number

of mutations that appear to stem from nontemplated error-prone repair of pyrimidine dimers, reinforcing the belief that sun exposure has an important causative role in this potentially lethal cancer.

Ionizing Radiation

Electromagnetic (x-rays, γ rays) and particulate (α particles, β particles, protons, neutrons) radiations are all carcinogenic. The evidence is so voluminous that a few examples suffice. Many individuals pioneering the use of x-rays developed skin cancers. Miners of radioactive elements in central Europe and the Rocky Mountain region of the United States have a tenfold increased incidence of lung cancers compared to the rest of the population. Most telling is the follow-up of survivors of the atomic bombs dropped on Hiroshima and Nagasaki. Initially there was a marked increase in the incidence of certain forms of leukemia after an average latent period of about 7 years. Subsequently the incidence of many solid tumors with longer latent periods (e.g., carcinomas of the breast, colon, thyroid, and lung) increased. Of great concern in the current era of widespread use of computerized tomography (CT scans) are studies that have shown that children who get two or three CT scans have a threefold higher risk of leukemia, and those that received five to 10 such scans have a threefold higher risk of brain tumors. The overall risk in children is very low (roughly one excess leukemia and one excess brain tumor over 10 years per 10,000 CT scans), but nevertheless emphasizes the need to minimize radiation exposure whenever possible.

In humans there is a hierarchy of vulnerability of different tissues to radiation-induced cancers. Most frequent are myeloid leukemias (tumors of granulocytes and their precursors; [Chapter 13](#)). Cancer of the thyroid follows closely but only in the young. In the intermediate category are cancers of the breast, lungs, and salivary glands. In contrast, skin, bone, and the gastrointestinal tract are relatively resistant to radiation-induced neoplasia, even though the gastrointestinal epithelial cells are vulnerable to the acute cell-killing effects of radiation, and the skin is “first in line” for all external radiation. Nonetheless, the physician must not forget: practically *any* cell can be transformed into a cancer cell by sufficient exposure to radiant energy.

KEY CONCEPTS

Radiation Carcinogenesis

- Ionizing radiation causes chromosome breakage, translocations, and, less frequently, point mutations, leading to genetic damage and carcinogenesis.
- UV rays induce the formation of pyrimidine dimers within DNA, leading to mutations. Therefore, UV rays can give rise to squamous cell carcinomas and melanomas of the skin. Individuals with defects in the repair of pyrimidine dimers suffer from Xeroderma pigmentosa and are at particularly high risk.
- Exposure to radiation during imaging procedures such as CT scans is linked to a very small, but measurable, increase in cancer risk in children.

Microbial Carcinogenesis

Many RNA and DNA viruses have proved to be oncogenic in animals as disparate as frogs and primates. Despite intense scrutiny, however, only a few viruses have been linked with human cancer. Our discussion focuses on human oncogenic viruses as well as the role of the bacterium *Helicobacter pylori* in gastric cancer.

Oncogenic RNA Viruses

Human T-Cell Leukemia Virus Type 1. Although the study of animal retroviruses has provided spectacular insights into the molecular basis of cancer, only one human retrovirus, human T-cell leukemia virus type 1 (HTLV-1), is firmly implicated in the pathogenesis of cancer in humans.

HTLV-1 causes adult T-cell leukemia/lymphoma (ATLL), a tumor that is endemic in certain parts of Japan, the Caribbean basin, South America, and Africa, and found sporadically elsewhere, including the United States. Worldwide, it is estimated that 15 to 20 million people are infected with HTLV-1. Similar to the human immunodeficiency virus, which causes AIDS, HTLV-1 has tropism for CD4+ T cells, and hence this subset of T cells is the major target for neoplastic transformation. Human infection requires transmission of infected T cells via sexual intercourse, blood products, or breastfeeding. Leukemia develops in only 3% to 5% of the infected individuals, typically after a long latent period of 40 to 60 years. A high fraction of the leukemias express the transcription factor FoxP3, a marker of regulatory T cells (Tregs) that act to suppress immune responses. It is hypothesized that the neoplastic expansion of Tregs in ATLL may underlie the susceptibility of affected patients to opportunistic infections, which are a frequent cause of death.

There is little doubt that HTLV-1 infection of T lymphocytes is necessary for leukemogenesis, but the molecular mechanisms of transformation are not certain. In contrast to several murine retroviruses, HTLV-1 does not contain an oncogene, and no consistent integration next to a proto-oncogene has been discovered. In leukemic cells, however, viral integration shows a clonal pattern. In other words, although the site of viral integration in host chromosomes is random (the viral DNA is found at different locations in different cancers), the site of integration is identical within all cells of a given cancer. This would not occur if HTLV-1 were merely a passenger that infects cells after transformation; rather, it means that HTLV-1 must have been present at the moment of transformation, placing it at the “scene of the crime.”

The HTLV-1 genome contains the *gag*, *pol*, *env*, and long-terminal-repeat regions typical of all retroviruses, but, in contrast to other leukemia viruses, it contains another gene referred to as *tax*. **Several aspects of HTLV-1’s transforming activity are attributable to Tax**, the protein product of this gene. Tax is essential for viral replication, because it stimulates transcription of viral RNA from the 5’ long terminal repeat. However, Tax also alters the transcription of several host cell genes and interacts with certain host cell signaling proteins. By doing so, Tax contributes to the acquisition of several cancer hallmarks, including the following:

- **Increased pro-growth signaling and cell survival.** Tax interacts with PI3K and thereby stimulates AKT; as

discussed earlier, these kinases participate in the cascade that promotes both cell survival and metabolic alterations that enhance cell growth. Tax also directly upregulates the expression of cyclin D2 and represses the expression of multiple CDK inhibitors, changes that promote cell cycle progression. Finally, Tax can activate the transcription factor NF- κ B, which promotes the survival of many cell types, including lymphocytes.

- **Increased genomic instability.** Tax may also cause genomic instability by interfering with DNA-repair functions and inhibiting cell cycle checkpoints activated by DNA damage. In line with these defects, HTLV-1-associated leukemias tend to be highly aneuploid.

The precise steps that lead to the development of adult T-cell leukemia/lymphoma are still not known, but a plausible scenario is as follows. Infection by HTLV-1 causes the expansion of a nonmalignant polyclonal cell population through stimulatory effects of Tax on cell proliferation. The proliferating T cells are at increased risk of mutations and genomic instability due to the effects of Tax, and possibly other viral factors as well. This instability allows the accumulation of mutations and chromosomal abnormalities, and eventually a monoclonal neoplastic T-cell population emerges.

Oncogenic DNA Viruses

As with RNA viruses, several oncogenic DNA viruses that cause tumors in animals have been identified. Of the various human DNA viruses, five—HPV, Epstein-Barr virus (EBV), hepatitis B virus (HBV), Merkel cell polyoma virus, and Kaposi sarcoma herpesvirus, also called human herpesvirus 8—have been implicated in the causation of human cancer. Merkel cell polyomavirus has been identified in Merkel cell carcinomas and is described in [Chapter 25](#). Kaposi sarcoma herpesvirus is discussed in [Chapters 6 and 11](#). Although not a DNA virus, hepatitis C virus (HCV) is also associated with cancer and is discussed here briefly.

Human Papillomavirus. At least 70 genetically distinct types of HPV have been identified. Some types (e.g., 1, 2, 4, and 7) cause benign squamous papillomas (warts) in humans. In contrast, high-risk HPVs (e.g., types 16 and 18) have been implicated in the genesis of squamous cell carcinomas of the cervix, anogenital region, and head and neck (particularly tumors arising in the tonsillar mucosa). These cancers are sexually transmitted diseases, caused by transmission of HPV. In contrast to cervical cancers, genital warts have low malignant potential and are associated with low-risk HPVs, predominantly HPV-6 and HPV-11. Interestingly, in benign warts, the HPV genome is maintained in a nonintegrated episomal form, while in cancers the HPV genome is integrated into the host genome, suggesting that integration of viral DNA is important for malignant transformation. As with HTLV-1, the site of viral integration in host chromosomes is random, but the pattern of integration is clonal. Cells in which the viral genome has integrated show significantly more genomic instability. Because the integration site is random, there is no consistent association with a host proto-oncogene. Rather, integration interrupts the viral DNA within the E1/E2 open reading frame, leading to loss of the E2 viral repressor and overexpression of the oncoproteins E6 and

Figure 7-45 Transforming effects of HPV E6 and E7 proteins. The net effect of HPV E6 and E7 proteins is to immortalize cells and remove the restraints on cell proliferation (see [Fig. 7-29](#)). TERC, telomerase catalytic subunit. (Modified from Münger K, Howley PM: Human papillomavirus immortalization and transformation functions. *Virus Res* 2002;89:213-228.)

E7. Indeed, **the oncogenic potential of HPV can largely be explained by the activities of the two viral genes encoding E6 and E7** ([Fig. 7-45](#)).

- **Oncogenic activities of E6.** The E6 protein binds to and mediates the degradation of p53, and also stimulates the expression of TERT, the catalytic subunit of telomerase, which you will recall contributes to the immortalization of cells. E6 from high-risk HPV types has a higher affinity for p53 than E6 from low-risk HPV types. Interestingly the E6-p53 interaction may offer some clues regarding polymorphisms and risk factors for development of cervical cancer. Human *TP53* is polymorphic at codon 72, encoding either a proline or arginine residue at that position. The p53 Arg72 variant is much more susceptible to degradation by E6. Not surprisingly, infected individuals with the Arg72 polymorphism are more likely to develop cervical carcinomas.
- **Oncogenic activities of E7.** The E7 protein has effects that complement those of E6, all of which are centered on speeding cells through the G₁-S cell cycle checkpoint. It binds to the RB protein and displaces the E2F transcription factors that are normally sequestered by RB, promoting progression through the cell cycle. As with E6 proteins and p53, E7 proteins from high-risk HPV types have a higher affinity for RB than do E7 proteins from low-risk HPV types. E7 also inactivates the CDK inhibitors p21 and p27. Finally, E7 proteins from high-risk HPVs (types 16, 18, and 31) also bind and presumably activate cyclins E and A.

To summarize, **high-risk HPV types express oncogenic proteins that inactivate tumor suppressors, activate cyclins, inhibit apoptosis, and combat cellular senescence.** Thus, it is evident that HPV proteins promote many of the hallmarks of cancer. The primacy of HPV infection in the causation of cervical cancer is confirmed by the effectiveness of HPV vaccines in preventing cervical cancer. However, infection with HPV itself is not sufficient for

carcinogenesis. For example, when human keratinocytes are transfected with DNA from HPV types 16, 18, or 31 in vitro, they are immortalized but do not form tumors in experimental animals. Co-transfection with a mutated RAS gene results in full malignant transformation. In addition to such genetic co-factors, HPV in all likelihood also acts in concert with environmental factors. These include cigarette smoking, coexisting microbial infections, dietary deficiencies, and hormonal changes, all of which have been implicated in the pathogenesis of cervical cancers. A high proportion of women infected with HPV clear the infection by immunologic mechanisms, but others do not, some for unknown reasons, some because of acquired immune abnormalities, such as those that result from HIV infection. As might be expected, women who are coinfecting with high-risk HPV types and HIV have an elevated risk of cervical cancer.

Epstein-Barr Virus. EBV, a member of the herpesvirus family, has been implicated in the pathogenesis of several human tumors: the African form of Burkitt lymphoma; B-cell lymphomas in immunosuppressed individuals (particularly in those with HIV infection or undergoing immunosuppressive therapy after organ or bone marrow transplantation); a subset of Hodgkin lymphoma; nasopharyngeal and some gastric carcinomas; and rare forms of T-cell lymphoma and natural killer (NK) cell lymphoma. The most common EBV-associated tumors are those derived from B cells and nasopharyngeal carcinoma; other EBV-associated neoplasms are discussed elsewhere in this book.

EBV infects B lymphocytes and possibly epithelial cells of the oropharynx. The virus uses the complement receptor CD21 to attach to and infect B cells. The infection of B cells is latent; that is, there is no viral replication and the cells are not killed. However, B cells latently infected with EBV express viral proteins that result in the ability to propagate indefinitely in vitro (immortalization). The molecular basis of B-cell proliferation induced by EBV is complex, but as with other viruses it involves the “hijacking” of several normal signaling pathways. One EBV gene, latent membrane protein-1 (*LMP-1*), acts as an oncogene, in that its expression in transgenic mice induces B-cell lymphomas. *LMP-1* behaves like a constitutively active CD40 receptor, a key recipient of helper T-cell signals that stimulate B-cell growth (Chapter 6). *LMP-1* activates the NF- κ B and JAK/STAT signaling pathways and promotes B-cell survival and proliferation, all of which occur autonomously (i.e., without T cells or other outside signals) in EBV-infected B cells. Concurrently, *LMP-1* prevents apoptosis by activating *BCL2*. Thus, the virus “borrows” normal B-cell activation pathways to expand the pool of latently infected cells. Another EBV gene, *EBNA-2*, encodes a nuclear protein that mimics a constitutively active Notch receptor. *EBNA-2* transactivates several host genes, including cyclin D and the *SRC* family of proto-oncogenes. In addition, the EBV genome contains a gene encoding a viral cytokine, vIL-10, that was “borrowed” from the host genome. This viral cytokine can prevent macrophages and monocytes from activating T cells and is required for EBV-dependent transformation of B cells. In immunologically normal individuals, EBV-driven polyclonal B-cell proliferation in vivo is readily controlled, and the individual either

Figure 7-46 Possible evolution of EBV-induced Burkitt lymphoma.

remains asymptomatic or develops a self-limited episode of infectious mononucleosis (Chapter 8). Evasion of the immune system seems to be a key step in EBV-related oncogenesis.

Burkitt lymphoma is a neoplasm of B lymphocytes that is endemic in central Africa and New Guinea, areas where it is the most common childhood tumor. A morphologically identical lymphoma occurs sporadically throughout the world. The association between endemic Burkitt lymphoma and EBV is quite strong (Fig. 7-46):

- More than 90% of African tumors carry the EBV genome
- One hundred percent of the patients have elevated antibody titers against viral capsid antigens
- Serum antibody titers against viral capsid antigens are correlated with the risk of developing the tumor

Although EBV is intimately involved in the causation of Burkitt lymphoma, several observations suggest that additional factors are also involved. (1) EBV infection is not limited to the geographic locales where Burkitt lymphoma is found; in fact, it is a ubiquitous virus that infects almost all humans worldwide. (2) The EBV genome is found in only 15% to 20% of sufferers of Burkitt lymphoma outside Africa. (3) There are significant differences in the patterns of viral gene expression in EBV-transformed (but not tumorigenic) B-cell lines and Burkitt lymphoma cells. Most notably, Burkitt lymphoma cells do not express *LMP-1*,

EBNA2, and other EBV proteins that drive B-cell growth and immortalization.

Given these observations, how then does EBV contribute to the genesis of endemic Burkitt lymphoma? One possibility is shown in [Figure 7-46](#). In regions of the world where Burkitt lymphoma is endemic, concomitant infections such as malaria impair immune competence, allowing sustained B-cell proliferation. Eventually, T-cell immunity directed against EBV antigens such as EBNA2 and LMP-1 eliminates most of the EBV-infected B cells, but a small number of cells downregulate expression of these immunogenic antigens. These cells persist indefinitely, even in the face of normal immunity. Lymphoma cells may emerge from this population only with the acquisition of specific mutations, most notably translocations that activate the *MYC* oncogene. It should be noted that in nonendemic areas 80% of tumors are unrelated to EBV, but virtually all endemic and sporadic tumors possess the t(8;14) or other translocations that dysregulate *MYC*. Thus, although sporadic Burkitt lymphomas are triggered by mechanisms other than EBV, they appear to develop through similar oncogenic pathways.

In summary, **in the case of Burkitt lymphoma, it seems that EBV is not directly oncogenic, but by acting as a polyclonal B-cell mitogen, it sets the stage for the acquisition of the (8;14) translocation and other mutations that ultimately produce a full-blown cancer.** In most individuals, EBV infection is readily controlled by effective immune responses, and virtually all infected individuals remain asymptomatic or develop self-limited infectious mononucleosis. In regions of Africa where Burkitt lymphoma is endemic, poorly understood cofactors (e.g., chronic malaria) may favor the acquisition of additional genetic events (e.g., the t(8;14)) that lead to transformation.

The role played by EBV is more direct in EBV-positive B-cell lymphomas in immunosuppressed patients. Some persons with AIDS or who receive immunosuppressive therapy for preventing allograft rejection develop EBV-positive B-cell tumors, often at multiple sites and within extranodal tissues such as the gut or the central nervous system. These proliferations are polyclonal at the outset but can evolve into monoclonal neoplasms. In contrast to Burkitt lymphoma, the tumors in immunosuppressed patients uniformly express LMP-1 and EBNA2, which are antigenic and can be recognized by cytotoxic T cells. Also, in contrast to Burkitt lymphoma, they usually lack *MYC* translocations. These potentially lethal proliferations can be subdued if the immunological status of the host improves, as may occur with withdrawal of immunosuppressive drugs in transplant recipients.

Nasopharyngeal carcinoma is also associated with EBV infection. This tumor is endemic in southern China, in some parts of Africa, and in the Inuit population of the Arctic. In contrast to Burkitt lymphoma, 100% of nasopharyngeal carcinomas obtained from all parts of the world contain EBV. The structure of the viral genome is identical (clonal) in all of the tumor cells within individual tumors, excluding the possibility that EBV infection occurred after tumor development. Antibody titers to viral capsid antigens are greatly elevated, and in endemic areas patients develop IgA antibodies before the appearance of the tumor. The uniform association of EBV with nasopharyngeal carcinoma suggests that EBV has a central role in the genesis

of the tumor, but (as with Burkitt lymphoma) the restricted geographic distribution indicates that genetic or environmental cofactors, or both, also contribute to tumor development. Unlike Burkitt lymphoma, LMP-1 is expressed in nasopharyngeal carcinoma cells and, as in B cells, activates the NF- κ B pathway. NF- κ B in turn upregulates the expression of factors such as VEGF, FGF-2, MMP9, and COX2 that may contribute to oncogenesis.

The relationship of EBV to the pathogenesis of Hodgkin lymphoma, yet another EBV-associated tumor, is discussed in [Chapter 13](#).

Hepatitis B and C Viruses. Epidemiologic studies strongly suggest a close association between hepatitis B and C virus infection and the occurrence of liver cancer ([Chapter 18](#)). It is estimated that 70% to 85% of hepatocellular carcinomas worldwide are caused by infection with hepatitis B virus (HBV) or hepatitis C virus (HCV). HBV is endemic in countries of the Far East and Africa; correspondingly, these areas have the highest incidence of hepatocellular carcinoma. Despite compelling epidemiologic and experimental evidence incriminating HBV and HCV, the mode of action of these viruses in liver tumorigenesis is not fully elucidated. The HBV and HCV genomes do not encode any viral oncoproteins, and although the HBV DNA is integrated within the human genome, there is no consistent pattern of integration in liver cells. Indeed, **while the oncogenic effects of HBV and HCV are multifactorial, the dominant effect seems to be immunologically mediated chronic inflammation and hepatocyte death leading to regeneration and, over time, genomic damage.** It is also suspected that in the setting of unresolved chronic inflammation, as occurs in viral hepatitis or chronic gastritis caused by *H. pylori* (see later), the immune response may become maladaptive, promoting rather than preventing tumorigenesis.

As with any cause of hepatocellular injury, chronic viral infection leads to the compensatory proliferation of hepatocytes. This regenerative process is aided and abetted by a plethora of growth factors, cytokines, chemokines, and other bioactive substances. These are produced by activated immune cells and promote cell survival, tissue remodeling, and angiogenesis ([Chapter 3](#)). The activated immune cells also produce other mediators, such as reactive oxygen species, that are genotoxic and mutagenic. One key molecular step seems to be activation of the NF- κ B pathway in hepatocytes in response to mediators derived from the activated immune cells. Activation of the NF- κ B pathway within hepatocytes blocks apoptosis, allowing the dividing hepatocytes to incur genotoxic stress and to accumulate mutations. Although this seems to be the dominant mechanism in the pathogenesis of virus-induced hepatocellular carcinoma, the HBV genome also contains genes that may directly promote the development of cancer. For example, an HBV gene known as *HBx* can activate a variety of transcription factors and several signal transduction pathways. In addition, viral integration can cause structural changes in chromosomes that dysregulate oncogenes and tumor suppressor genes.

Although not a DNA virus, HCV is also strongly linked to the pathogenesis of liver cancer. The molecular mechanisms used by HCV are less well defined than are those of HBV. In addition to chronic liver cell injury and

compensatory regeneration, components of the HCV genome, such as the HCV core protein, may have a direct effect on tumorigenesis, possibly by activating a variety of growth-promoting signal transduction pathways.

Helicobacter pylori

First incriminated as a cause of peptic ulcers, *H. pylori* now has acquired the dubious distinction of being the first bacterium classified as a carcinogen. Indeed, *H. pylori* infection is implicated in the genesis of both gastric adenocarcinomas and gastric lymphomas.

The scenario for the development of gastric adenocarcinoma is similar to that of HBV- and HCV-induced liver cancer, as it involves increased epithelial cell proliferation in a background of chronic inflammation. As in viral hepatitis, the inflammatory milieu contains numerous genotoxic agents, such as reactive oxygen species. There is an initial development of chronic gastritis, followed by gastric atrophy, intestinal metaplasia of the lining cells, dysplasia, and cancer. This sequence takes decades to complete and occurs in only 3% of infected patients. Like HBV and HCV, the *H. pylori* genome also contains genes directly implicated in oncogenesis. Strains associated with gastric adenocarcinoma have been shown to contain a “pathogenicity island” that contains cytotoxin-associated A (*CagA*) gene. Although *H. pylori* is noninvasive, *CagA* penetrates into gastric epithelial cells, where it has a variety of effects, including the initiation of a signaling cascade that mimics unregulated growth factor stimulation.

As mentioned earlier, *H. pylori* is associated with an increased risk for the development of gastric lymphomas as well. The gastric lymphomas are of B-cell origin, and because the tumors recapitulate some of the features of normal Peyer’s patches, they are often called lymphomas of mucosa-associated lymphoid tissue, or MALTomas (also discussed in Chapters 13 and 17). Their molecular pathogenesis is incompletely understood but seems to involve strain-specific *H. pylori* factors, as well as host genetic factors, such as polymorphisms in the promoters of inflammatory cytokines such as IL-1 β and tumor necrosis factor (TNF). It is thought that *H. pylori* infection leads to the appearance of *H. pylori*-reactive T cells, which in turn stimulate a polyclonal B-cell proliferation. In chronic infections, currently unknown mutations may be acquired that give individual cells a growth advantage. These cells grow out into a monoclonal “MALToma” that nevertheless remains dependent on T-cell stimulation of B-cell pathways that activate the transcription factor NF- κ B. At this stage, eradication of *H. pylori* by antibiotic therapy “cures” the lymphoma by removing the antigenic stimulus for T cells. At later stages, however, additional mutations may be acquired that cause constitutive NF- κ B activation. At this point, the MALToma no longer requires the antigenic stimulus of the bacterium for growth and survival and develops the capacity to spread beyond the stomach to other tissues.

KEY CONCEPTS

Viral and Bacterial Oncogenesis

HTLV-1: a retrovirus that is endemic in Japan, the Caribbean, and parts of South America and Africa that causes adult T-cell leukemia/lymphoma

- HTLV-1 encodes the viral protein Tax, which turns on pro-growth and pro-survival signaling pathways (PI3K/AKT, NF- κ B), leading to a polyclonal expansion of T cells.
- After a long latent period (decades), a small fraction of HTLV-1-infected individuals develop adult T-cell leukemia/lymphoma, a CD4+ tumor that arises from an HTLV-1 infected cell, presumably due to acquisition of additional mutations in the host cell genome.

HPV: an important cause of benign warts, cervical cancer, and oropharyngeal cancer

- Oncogenic types of HPV encode two viral oncoproteins, E6 and E7, that bind to Rb and p53, respectively, with high affinity and neutralize their function.
- Development of cancer is associated with integration of HPV into the host genome and additional mutations needed for acquisition of cancer hallmarks.
- HPV cancers can be prevented by vaccination against high-risk HPV types.

EBV: ubiquitous herpesvirus implicated in the pathogenesis of Burkitt lymphomas, B-cell lymphomas in patients with T-cell immunosuppression (HIV infection, transplant recipients), and several other cancers

- The EBV genome harbors several genes encoding proteins that trigger B cell signaling pathways; in concert, these signals are potent inducers of B cell growth and transformation.
- In the absence of T-cell immunity, EBV-infected B cells can rapidly “grow out” as aggressive B-cell tumors.
- In the presence of normal T-cell immunity, a small fraction of infected patients develop EBV-positive B-cell tumors (Burkitt lymphoma, Hodgkin lymphoma) or carcinomas (nasopharyngeal, gastric carcinoma)

Hepatitis B virus and hepatitis C virus: cause of between 70% and 85% of hepatocellular carcinomas worldwide

- Oncogenic effects are multifactorial; dominant effect seems to be immunologically mediated chronic inflammation, hepatocellular injury, and reparative hepatocyte proliferation.
- HBx protein of HBV and the HCV core protein can activate signal transduction pathways that also may contribute to carcinogenesis.

***H. pylori*:** implicated in gastric adenocarcinoma and MALT lymphoma

- Pathogenesis of *H. pylori*-induced gastric cancers is multifactorial, including chronic inflammation and reparative gastric cell proliferation.
- *H. pylori* pathogenicity genes, such as *CagA*, also may contribute by stimulating growth factor pathways.
- Chronic *H. pylori* infection leads to polyclonal B-cell proliferations that may give rise to a monoclonal B-cell tumor (MALT lymphoma) of the stomach as a result of accumulation of mutations.

Clinical Aspects of Neoplasia

Ultimately the importance of neoplasms lies in their effects on patients. Although malignant tumors are of course

more threatening than benign tumors, any tumor, even a benign one, may cause morbidity and mortality.

Local and Hormonal Effects

Location is a critical determinant of the clinical effects of both benign and malignant tumors. Tumors may impinge upon vital tissues and impair their functions, cause death of involved tissues, and provide a nidus for infection. A small (1 cm) pituitary adenoma, although benign and possibly nonfunctional, can compress and destroy the surrounding normal gland and thus lead to serious hypopituitarism. Cancers arising within or metastatic to an endocrine gland may cause an endocrine insufficiency by destroying the gland. Neoplasms in the gut, both benign and malignant, may cause obstruction as they enlarge. Infrequently, peristaltic movement telescopes the neoplasm and its affected segment into the downstream segment, producing an obstructing intussusception (Chapter 17). Symptoms produced by a cancer due to its position can (ironically) be lifesaving; for example, the few survivors of pancreatic cancer are those whose tumors “fortuitously” obstruct bile ducts early in their course, leading to the appearance of jaundice and other symptoms at a stage of the disease when surgical cure is still possible.

Benign and malignant neoplasms arising in endocrine glands can cause clinical problems by producing hormones. Such functional activity is more typical of benign than of malignant tumors, which may be so undifferentiated to have lost such capability. A benign beta-cell adenoma of the pancreatic islets less than 1 cm in diameter may produce sufficient insulin to cause fatal hypoglycemia. In addition, nonendocrine tumors may elaborate hormones or hormone-like products and give rise to paraneoplastic syndromes (discussed later). The erosive and destructive growth of cancers or the expansile pressure of a benign tumor on any natural surface, such as the skin or mucosa of the gut, may cause ulcerations, secondary infections, and bleeding. Melena (blood in the stool) and hematuria, for example, are characteristic of neoplasms of the gut and urinary tract. Neoplasms, benign as well as malignant, may cause problems in varied ways, but all are far less common than our next topic, the cachexia of malignancy.

Cancer Cachexia

Individuals with cancer commonly suffer progressive loss of body fat and lean body mass accompanied by profound weakness, anorexia, and anemia, referred to as *cachexia*. Cancer cachexia is associated with:

- Equal loss of both fat and lean muscle
- Elevated basal metabolic rate
- Evidence of systemic inflammation (e.g., an increase in acute phase reactants, Chapter 6)

The mechanisms that underlie cancer cachexia are not understood. Inflammation related to the interplay between cancer and the immune system is likely to have a role. TNF α (originally known as cachectin) is a leading suspect among several mediators released from immune cells that may contribute to cachexia. Humoral factors released from tumor cells such as proteolysis inducing factor have been implicated in the loss of muscle mass, which is discussed further in Chapter 9.

Paraneoplastic Syndromes

Some cancer-bearing individuals develop signs and symptoms that cannot readily be explained by the anatomic distribution of the tumor or by the elaboration of hormones indigenous to the tissue from which the tumor arose; these are known as paraneoplastic syndromes. These occur in about 10% of persons with cancer. Despite their relative infrequency, paraneoplastic syndromes are important to recognize, for several reasons:

- They may be the earliest manifestation of an occult neoplasm.
- In affected patients they can cause significant clinical problems and may even be lethal.
- They may mimic metastatic disease and therefore confound treatment.

A classification of paraneoplastic syndromes and their presumed origins is presented in Table 7-11. A few comments on some of the more common and interesting syndromes follow.

Endocrinopathies are frequently encountered paraneoplastic syndromes. The responsible cancers are not of endocrine origin and the secretory activity of such tumors is referred to as ectopic hormone production. *Cushing syndrome* is the most common endocrinopathy. Approximately 50% of individuals with this endocrinopathy have carcinoma of the lung, chiefly the small-cell type. It is caused by excessive production of corticotropin or corticotropin-like peptides. The precursor of corticotropin is a large molecule known as pro-opiomelanocortin. Lung cancer patients with Cushing syndrome have elevated serum levels of both pro-opiomelanocortin and corticotropin. The former is not found in serum of patients with excess corticotropin produced by the pituitary.

Hypercalcemia is probably the most common paraneoplastic syndrome; in fact, symptomatic hypercalcemia is more often related to some form of cancer than to hyperparathyroidism. Two general processes are involved in cancer-associated hypercalcemia: (1) *osteolysis* induced by cancer, whether primary in bone, such as multiple myeloma, or metastatic to bone from any primary lesion, and (2) the production of *calcemic humoral substances* by extraosseous neoplasms. Only the second mechanism is considered to be paraneoplastic; hypercalcemia due to primary or secondary involvement of the skeleton by tumor is not a paraneoplastic syndrome.

Several humoral factors have been associated with paraneoplastic hypercalcemia of malignancy. The most important, *parathyroid hormone-related protein* (PTHrP), is a molecule related to, but distinct from, parathyroid hormone (PTH). PTHrP resembles the native hormone only in its N terminus. It has some biologic actions similar to those of PTH, and both hormones share a G protein-coupled receptor, known as PTH/PTHrP receptor (often referred to as PTH-R or PTHrP-R). In contrast to PTH, PTHrP is produced in small amounts by many normal tissues, including keratinocytes, muscles, bone, and ovary. It regulates calcium transport in the lactating breast and across the placenta, and seems to modulate pulmonary development and remodeling. Tumors most often associated with paraneoplastic hypercalcemia are carcinomas of the breast, lung, kidney, and ovary. In breast cancers, hypercalcemia

Table 7-11 Paraneoplastic Syndromes

Clinical Syndromes	Major Forms of Underlying Cancer	Causal Mechanism
Endocrinopathies		
Cushing syndrome	Small-cell carcinoma of lung Pancreatic carcinoma Neural tumors	ACTH or ACTH-like substance
Syndrome of inappropriate antidiuretic hormone secretion	Small-cell carcinoma of lung Intracranial neoplasms	Antidiuretic hormone or atrial natriuretic hormones
Hypercalcemia	Squamous cell carcinoma of lung Breast carcinoma Renal carcinoma Adult T-cell leukemia/lymphoma	Parathyroid hormone-related protein (PTHrP), TGF- α , TNF, IL-1
Hypoglycemia	Ovarian carcinoma Fibrosarcoma Other mesenchymal sarcomas	Insulin or insulin-like substance
Polycythemia	Renal carcinoma Cerebellar hemangioma Hepatocellular carcinoma	Erythropoietin
Nerve and Muscle syndromes		
Myasthenia	Bronchogenic carcinoma Thymic neoplasms	Immunologic
Disorders of the central and peripheral nervous system	Breast carcinoma	
Dermatologic Disorders		
Acanthosis nigricans	Gastric carcinoma Lung carcinoma Uterine carcinoma	Immunologic; secretion of epidermal growth factor
Dermatomyositis	Bronchogenic carcinoma Breast carcinoma	Immunologic
Osseous, Articular, and Soft Tissue Changes		
Hypertrophic osteoarthropathy and clubbing of the fingers	Bronchogenic carcinoma Thymic neoplasms	Unknown
Vascular and Hematologic Changes		
Venous thrombosis (Trousseau phenomenon)	Pancreatic carcinoma Bronchogenic carcinoma Other cancers	Tumor products (mucins that activate clotting)
Disseminated intravascular coagulation	Acute promyelocytic leukemia Prostatic carcinoma	Tumor products that activate clotting
Nonbacterial thrombotic endocarditis	Advanced cancers	Hypercoagulability
Red cell aplasia	Thymic neoplasms	Unknown
Others		
Nephrotic syndrome	Various cancers	Tumor antigens, immune complexes

ACTH, Adrenocorticotropic hormone; IL, interleukin; TGF, transforming growth factor; TNF, tumor necrosis factor.

due to PTHrP production is often exacerbated by osteolytic bone metastases. The most common lung neoplasm associated with hypercalcemia is squamous cell carcinoma. In addition to PTHrP, several other factors, such as IL-1, TGF- α , TNF, and dihydroxyvitamin D, have also been causally implicated in the hypercalcemia of malignancy.

The *neuromyopathic paraneoplastic syndromes* take diverse forms, such as peripheral neuropathies, cortical cerebellar degeneration, a polymyopathy resembling polymyositis, and a myasthenic syndrome similar to *myasthenia gravis* (Chapter 27). The cause of these syndromes is poorly understood. In some cases, antibodies, presumably induced against tumor cell antigens (Chapter 28) that cross-react with neuronal cell antigens, have been detected. It is postulated that some visceral cancers ectopically express certain neural antigens. For some unknown reason, the

immune system recognizes these antigens as foreign and mounts an immune response.

Acanthosis nigricans is a disorder characterized by gray-black patches of thickened, hyperkeratotic skin with a velvety appearance. It occurs rarely as a genetically determined disease in juveniles or adults (Chapter 25). In addition, in about 50% of the cases, particularly in those over age 40, the appearance of such lesions is associated with some form of cancer. Sometimes the skin changes appear before the cancer is discovered.

Hypertrophic osteoarthropathy is encountered in 1% to 10% of patients with lung carcinoma. Rarely, other forms of cancer are involved. This disorder is characterized by (1) periosteal new bone formation, primarily at the distal ends of long bones, metatarsals, metacarpals, and proximal phalanges; (2) arthritis of the adjacent joints; and (3)

clubbing of the digits. Although the osteoarthropathy is seldom seen in noncancer patients, clubbing of the fingertips may be encountered in liver diseases, diffuse lung disease, congenital cyanotic heart disease, ulcerative colitis, and other disorders. The cause of hypertrophic osteoarthropathy is unknown.

Several vascular and hematologic manifestations may appear in association with a variety of forms of cancer. As mentioned in the discussion of thrombosis (Chapter 4), *migratory thrombophlebitis* (Trousseau syndrome) may be encountered in association with deep-seated cancers, most often carcinomas of the pancreas or lung. *Disseminated intravascular coagulation* may complicate a diversity of clinical disorders (Chapter 14); among cancers, it is most commonly associated with acute promyelocytic leukemia and prostatic adenocarcinoma. Bland, small, nonbacterial fibrinous vegetations sometimes form on the cardiac valve leaflets (more often on left-sided valves), particularly in individuals with advanced mucin-secreting adenocarcinomas. These lesions, called *nonbacterial thrombotic endocarditis*, are described further in Chapter 12. The vegetations are potential sources of emboli that can further complicate the course of the cancer.

Grading and Staging of Tumors

Methods to quantify the probable clinical aggressiveness of a given neoplasm and its apparent extent and spread in the individual patient are necessary for making an accurate prognosis and for comparing end results of various treatment protocols. For instance, the results of treating well-differentiated thyroid adenocarcinoma that is localized to the thyroid gland will be different from those obtained from treating highly anaplastic thyroid cancers that have invaded the neck organs. Systems have been developed to express, at least in semiquantitative terms, the level of differentiation, or grade, and extent of spread of a cancer within the patient, or stage, as parameters of the clinical gravity of the disease.

- **Grading.** Grading of a cancer is based on the degree of differentiation of the tumor cells and, in some cancers, the number of mitoses or architectural features. Grading schemes have evolved for each type of malignancy, and generally range from two categories (low grade and high grade) to four categories. Criteria for the individual grades vary in different types of tumors and so are not detailed here, but all attempt, in essence, to judge the extent to which the tumor cells resemble or fail to resemble their normal counterparts. Although histologic grading is useful, the correlation between histologic appearance and biologic behavior is less than perfect. In recognition of this problem and to avoid spurious quantification, it is common practice to characterize a particular neoplasm in descriptive terms, for example, well-differentiated, mucin-secreting adenocarcinoma of the stomach, or poorly differentiated pancreatic adenocarcinoma.
- **Staging.** The staging of solid cancers is based on the size of the primary lesion, its extent of spread to regional lymph nodes, and the presence or absence of blood-borne metastases. The major staging system currently in use is the American Joint Committee on Cancer Staging.

This system uses a classification called the *TNM system*—*T* for primary tumor, *N* for regional lymph node involvement, and *M* for metastases. TNM staging varies for specific forms of cancer, but there are general principles. The primary lesion is characterized as T1 to T4 based on increasing size. T0 is used to indicate an in situ lesion. N0 would mean no nodal involvement, whereas N1 to N3 would denote involvement of an increasing number and range of nodes. M0 signifies no distant metastases, whereas M1 or sometimes M2 indicates the presence of metastases and some judgment as to their number.

KEY CONCEPTS

Clinical Aspects of Tumors

Cachexia: progressive loss of body fat and lean body mass, accompanied by profound weakness, anorexia, and anemia, that is caused by release of factors by the tumor or host immune cells

Paraneoplastic syndromes: symptom complexes in individuals with cancer that cannot be explained by tumor spread or release of hormones that are indigenous to the tumor “cell of origin.” For example:

- Endocrinopathies (Cushing syndrome, hypercalcemia)
- Neuropathic syndromes (polymyopathy, peripheral neuropathies, neural degeneration, myasthenic syndromes)
- Skin disorders (acanthosis nigricans)
- Skeletal and joint abnormalities (hypertrophic osteoarthritis)
- Hypercoagulability (migratory thrombophlebitis, disseminated intravascular coagulation, nonbacterial thrombotic endocarditis)

Grading: determined by cytologic appearance; based on the idea that behavior and differentiation are related, with poorly differentiated tumors having more aggressive behavior

Staging: determined by surgical exploration or imaging, is based on size, local and regional lymph node spread, and distant metastases; of greater clinical value than grading

Laboratory Diagnosis of Cancer

Every year the approach to laboratory diagnosis of cancer becomes more complex, more sophisticated, and more specialized. For virtually every neoplasm mentioned in this text, the experts have characterized several subcategories; we must walk, however, before we can run. Each of the following sections attempts to present the state of the art, avoiding details of technologies.

Histologic and Cytologic Methods. The laboratory diagnosis of cancer is, in most instances, not difficult. The two ends of the benign-malignant spectrum pose no problem; however, in the middle lies a gray zone that novices dread and where experts tread cautiously. The focus here is on the roles of the clinician (often a surgeon) and the pathologist in facilitating the correct diagnosis.

Clinical data are invaluable for accurate pathologic diagnosis, but often clinicians underestimate its value. Radiation changes in the skin or mucosa can be similar to

those associated with cancer. Sections taken from a healing fracture can mimic an osteosarcoma. Moreover, the laboratory evaluation of a lesion can be only as good as the specimen made available for examination. It must be adequate, representative, and properly preserved. Several sampling approaches are available: (1) excision or biopsy, (2) needle aspiration, and (3) cytologic smears. When excision of a small lesion is not possible, selection of an appropriate site for biopsy of a large mass requires awareness that the periphery may not be representative and the center largely necrotic. Appropriate preservation involves such actions as prompt immersion of at least a portion of the specimen in a fixative (usually a formalin solution) and (depending on the differential diagnosis) rapid allocation of tissue for other studies such as cytogenetics, flow cytometry, and molecular diagnostics (described later). Requesting “quick-frozen section” diagnosis is sometimes desirable, for example, in determining the nature of a mass lesion, in evaluating the margins of an excised cancer to ascertain that the entire neoplasm has been removed, or in making decisions about what additional studies beyond histology are needed. This method permits histologic evaluation within minutes. In experienced, competent hands, frozen-section diagnosis is highly accurate, but there are particular instances in which the better histologic detail provided by the more time-consuming routine methods is needed—for example, when extremely radical surgery, such as the amputation of an extremity, may be indicated. Better to wait a day or two, despite the delay, than to perform inadequate or unnecessary surgery.

Fine-needle aspiration of tumors is another approach that is widely used. The procedure involves aspirating cells and attendant fluid with a small-bore needle, followed by cytologic examination of the stained smear. This method is used most commonly for the assessment of readily palpable lesions in sites such as the breast, thyroid, and lymph nodes. Modern imaging techniques permit extension of the method to lesions in deep-seated structures, such as pelvic lymph nodes and pancreas. Fine-needle aspiration is less invasive and more rapidly performed than are needle biopsies. It obviates surgery and its attendant risks. Although it entails some difficulties, such as small sample size and sampling errors, in experienced hands it is reliable, rapid, and useful.

Cytologic smears provide yet another method for the detection of cancer (Chapter 22). This approach is widely used to screen for carcinoma of the cervix, often at an in situ stage, but it is also used to evaluate many other forms of suspected malignancy in which tumor cells are easily accessible or shed, such as endometrial carcinoma, lung carcinoma, bladder and prostatic tumors, and gastric carcinomas; for the identification of tumor cells in abdominal, pleural, joint, and cerebrospinal fluids; and, less commonly, with other forms of neoplasia.

As pointed out earlier, cancer cells have lowered cohesiveness and exhibit a range of morphologic changes encompassed by the term anaplasia. Thus, shed cells can be evaluated for the features of anaplasia indicative of their origin from a tumor (Figs. 7-47 and 7-48). In these cases, judgment must be rendered based on the features of individual cells or, at most, a clump of cells, without the supporting evidence of loss of orientation of one cell to another, and (most importantly) evidence of invasion. This

method permits differentiation among normal, dysplastic, and malignant cells and, in addition, permits the recognition of cellular changes characteristic of carcinoma in situ. The gratifying control of cervical cancer through screening with Pap smears is the best testament to the value of cytology.

Although histology and exfoliative cytology remain the foundation of cancer diagnosis, they have inherent limits; for example, it can be difficult to determine the nature of a poorly differentiated tumor of any type, and some specific tumor types are notoriously difficult to distinguish based on their morphologic appearance alone (e.g., various types of acute leukemias and lymphomas). These limitations have spurred the widespread application of immunohistochemistry and flow cytometry, which can be used to make these diagnostic distinctions. Another rapidly expanding modality is molecular diagnostics, which is being used increasingly to identify cancers that are amenable to treatment with so-called targeted therapies, drugs that are directed at mutated oncoproteins. Only some highlights of these diagnostic modalities are presented.

Figure 7-48 An abnormal cervicovaginal smear shows numerous malignant cells that have pleomorphic, hyperchromatic nuclei; interspersed are normal polymorphonuclear leukocytes. (Courtesy Dr. P. K. Gupta, University of Pennsylvania, Philadelphia, Pa.)

Immunohistochemistry. The availability of specific antibodies has greatly facilitated the identification of cell products or surface markers. Examples of the utility of immunohistochemistry in the diagnosis or management of malignant neoplasms follow.

- **Categorization of undifferentiated malignant tumors.** In many cases malignant tumors of diverse origin resemble each other because of limited differentiation. These tumors are often quite difficult to distinguish on the basis of routine hematoxylin and eosin (H&E)-stained tissue sections. For example, certain anaplastic carcinomas, lymphomas, melanomas, and sarcomas may look quite similar, but they must be accurately identified because their treatment and prognosis are different. Antibodies specific to intermediate filaments have proved to be of particular value in such cases, because solid tumor cells often contain intermediate filaments characteristic of their cell of origin. For example, the presence of cytokeratins, detected by immunohistochemistry, points to an epithelial origin (carcinoma) (Fig. 7-49), whereas desmin is specific for neoplasms of muscle cell origin. Other useful immunohistochemical markers include lineage-specific membrane proteins (e.g., CD20, a marker of B-cell tumors) and transcription factors.
- **Determination of site of origin of metastatic tumors.** Many cancer patients present with metastases. In some the primary site is obvious or readily detected on the basis of clinical or radiologic features. In cases in which the origin of the tumor is obscure, immunohistochemical detection of tissue-specific or organ-specific antigens in a biopsy specimen of the metastatic deposit can lead to the identification of the tumor source. For example, prostate-specific antigen (PSA) and thyroglobulin are markers of carcinomas of the prostate and thyroid, respectively.
- **Detection of molecules that have prognostic or therapeutic significance.** Immunohistochemical detection of hormone (estrogen/progesterone) receptors in breast cancer cells is of prognostic and therapeutic value because these cancers are susceptible to antiestrogen therapy (Chapter 23). In general, receptor-positive breast cancers have a better prognosis than receptor

Figure 7-49 Anticytokeratin immunoperoxidase stain of a tumor of epithelial origin (carcinoma). (Courtesy Dr. Melissa Upton, University of Washington, Seattle, Wash.)

negative tumors. Protein products of oncogenes such as *ERBB2* in breast cancers can also be detected by immunostaining. Breast cancers with strong immunohistochemical staining for the protein product of the *ERBB2* gene product, HER2, generally have a poor prognosis, but are amenable to treatment with antibodies that block the activity of the HER2 receptor. Because high-level expression of HER2 is caused by amplification of *ERBB2*, fluorescent in situ hybridization (FISH) to confirm *ERBB2* gene amplification is sometimes used as an adjunct to immunohistochemical studies. Similarly, immunohistochemical stains for ALK protein can be used to identify lung cancers and lymphomas expressing constitutively active ALK fusion proteins.

Flow Cytometry. Flow cytometry can rapidly and quantitatively measure several individual cell characteristics, but is mainly used to identify cellular antigens expressed by “liquid” tumors, those that arise from blood-forming tissues. These include B- and T-cell lymphomas and leukemias, as well as myeloid neoplasms. An advantage of flow cytometry over immunohistochemistry is that multiple antigens can be assessed simultaneously on individual cells using combinations of specific antibodies linked to different fluorescent dyes. Monoclonal antibodies directed against various lymphohematopoietic cells are listed in Chapter 13.

Circulating Tumor Cells. Instrumentation that permits detection, quantification, and characterization of rare solid tumor cells (e.g., carcinoma, melanoma) circulating in the blood is being explored as a diagnostic modality. Some of the latest devices rely on three-dimensional flow cells coated with antibodies specific for tumor cells of interest (e.g., carcinoma cells) that efficiently capture rare tumor cells present in the blood. Such methods currently fall in the realm of clinical research, but have the potential to permit earlier diagnosis, to gauge the risk of metastasis, and to provide a minimally invasive means of assessing the response of tumor cells to therapy.

Molecular and Cytogenetic Diagnostics. Several molecular or cytogenetic techniques—some established, others emerging—have been used for diagnosis and, in some cases, for predicting behavior of tumors.

- **Diagnosis of malignant neoplasms.** Although molecular methods are not the primary modality of cancer diagnosis, they are of considerable value in selected cases. T and B cell tumors are derived from single cells with unique antigen receptor gene rearrangements, whereas reactive lymphoid proliferations contain many different lymphocyte clones, each with a different set of rearrangements antigen receptor genes. For this reason, PCR-based evaluation of rearranged T-cell receptor or immunoglobulin genes allows distinction between monoclonal (neoplastic) and polyclonal (reactive) proliferations. Many hematopoietic neoplasms (leukemias and lymphomas) are associated with specific translocations that activate oncogenes. Detection of such translocations, usually by routine cytogenetic analysis or by FISH (Chapter 5), is often extremely helpful in diagnosis. Diagnosis of sarcomas (Chapter 26) with

characteristic translocations is also aided by molecular techniques, in part because chromosome preparations are often difficult to obtain from solid tumors. For example, many sarcomas of childhood, so-called round blue cell tumors (Chapter 10), can be difficult to distinguish from each other on the basis of morphology. However, the presence of the characteristic (11;22) (q24;q12) translocation, established by PCR, in one of these tumors confirms the diagnosis of Ewing sarcoma. Another diagnostic platform that is finding increasing use is **DNA microarrays**, either tiling arrays, which cover the entire human genome, or single-nucleotide polymorphism arrays (SNP chips), which allow high-resolution mapping of copy number changes (either deletions or amplifications) genome-wide.

- **Prognosis of malignant neoplasms.** Certain genetic alterations are associated with poor prognosis, and hence their detection allows stratification of patients for therapy. For example, amplification of the *NMYC* gene and deletions of 1p bode poorly for patients with neuroblastoma, and oligodendrogliomas in which the only genomic abnormality is the loss of chromosomes 1p and 19q respond well to therapy and are associated with long-term survival when compared to tumors with intact 1p and 19q but with EGF receptor amplification.
- **Detection of minimal residual disease.** After treatment of patients with leukemia or lymphoma, the presence of minimal disease or the onset of relapse can be monitored by PCR-based amplification of nucleic acid sequences unique to the malignant clone. For example, detection of *BCR-ABL* transcripts by PCR gives a measure of the residual leukemia cells in treated patients with CML. The prognostic importance of minimal residual disease has been established in acute leukemia and is being evaluated in other neoplasms.
- **Diagnosis of hereditary predisposition to cancer.** As discussed earlier, germline mutations in several tumor suppressor genes, including *BRCA1*, *BRCA2*, and the *RET* proto-oncogene, are associated with a high risk of developing specific cancers. Thus, detection of these mutated alleles may allow the patient and physician to devise an aggressive screening program, consider the option of prophylactic surgery, and counsel relatives, who may also be at risk. Such analysis usually requires detection of a specific mutation (e.g., *RET* gene) or sequencing of the entire gene. The latter is necessitated when several different cancer-associated mutations are known to exist. Although the detection of mutations in such cases is relatively straightforward, the ethical issues surrounding presymptomatic diagnosis are complex.
- **Guiding therapy with oncoprotein-directed drugs.** An increasing number of chemotherapeutic agents target oncoproteins that are only present in a subset of cancers of a particular type. Thus, the molecular identification of genetic lesions that produce these oncoproteins is essential for optimal treatment of patients. Current examples of genetic lesions that guide therapy and are frequently tested for in molecular diagnostic laboratories include the *PML-RARA* fusion gene in acute promyelocytic leukemia; the *BCR-ABL* fusion gene in chronic myelogenous leukemia and acute

lymphoblastic leukemia; *ERBB1* (EGFR) mutations and *ALK* gene rearrangements in lung cancer; and *BRAF* mutations in melanoma.

Molecular Profiles of Tumors: The Future of Cancer Diagnostics

Until recently, molecular studies of tumors involved the analysis of individual genes. However, the past few years have seen the introduction of revolutionary technologies that can rapidly sequence an entire genome; assess epigenetic modifications genome-wide (the epigenome); quantify all of the RNAs expressed in a cell population (the transcriptome); measure many proteins simultaneously (the proteome); and take a snapshot of all of the cell's metabolites (the metabolome). Thus, we have entered the age of "omics!"

The most common method for large-scale analysis of RNA expression in use today in research laboratories is based on DNA microarrays, but newer methods that involve RNA sequencing have appeared that offer a more comprehensive and quantitative assessment of RNA expression. However, RNA is prone to degradation and is a more difficult analyte to work with than DNA in clinical practice. Furthermore, DNA sequencing is technically simpler than RNA sequencing, permitting the development of methods that rely on massively parallel sequencing (so-called next generation [NextGen] sequencing). The increases in DNA sequencing capacity and speed that such methods have enabled over the past decade have been breath taking, and are matched by equally remarkable decreases in cost. The first reasonably complete draft of the sequence of the human genome, released in 2003, took 12 years of work and cost about \$2,700,000,000. At present, using NextGen sequencing, certain cancer centers are completing the process of whole genome sequencing for individual tumors in 28 days, which includes the time required for the extraordinarily complex task of assembling and analyzing the sequencing data. The cost of whole genome sequencing has now fallen under \$3,000, and is continuing to drop; there is no doubt that the long promised \$1,000 genome is now in sight.

These advances have enabled the systematic sequencing and cataloging of genomic alterations in various human cancers, much of it within a large consortium sponsored by the National Cancer Institute called The Cancer Genome Atlas (TCGA). The complexity of the genetic aberrations identified in these genome-wide studies has inspired informaticians to create new ways of displaying the data, such as circos plots (Fig. 7-50), which provide a snapshot of all of the genetic alterations that exist in a particular tumor.

The main impact of cancer genome sequencing to date has been in the area of research: identification of new mutations that underlie various cancers; description of the full panoply of genetic lesions that are found in individual cancers; and a greater appreciation of the genetic heterogeneity that exists in individual cancers from area to area. As noted, a few centers are piloting the use of whole genome sequencing to manage patients, but most efforts in the clinical realm are focused on developing sequencing methods that permit identification of therapeutically "actionable" genetic lesions in a timely fashion at a reasonable cost. Such approaches seem particularly applicable to

Figure 7-50 A circos plot showing genetic alterations in a single lung cancer in a male patient. Each of the 24 chromosomes in the cancer is displayed in a circle. The positions of various tumor-specific aberrations are mapped onto these chromosomes as follows: **a**, Structural rearrangements in chromosomes. The blue lines denote intrachromosomal rearrangements, while the red lines denote interchromosomal rearrangements. **b**, Regions of loss of heterozygosity and allelic imbalance (overrepresentation of one allele versus the second) are in green. **c**, Copy number profiles, showing copy number losses (in red), and copy gains (in blue). **d**, Point mutations, represented as red dots.

tumors such as lung carcinomas, which are genetically diverse and require a “personalized” approach if targeted therapy is to succeed. Thus, the current trend in molecular diagnostic laboratories is to develop methods that permit several hundred exons of key genes to be sequenced simultaneously at sufficient “depth” (fold coverage of the sequence in question) to reliably detect any mutations that might be present in as few as 5% of tumor cells. A second method that is moving rapidly into clinical practice involves the use of DNA arrays to identify changes in DNA copy number, such as amplifications and deletions. Arrays containing probes that span the entire genome at some standard spacing can detect all but the smallest copy number aberrations, providing information that is complementary to that obtained from DNA sequencing. Other “omics”, such as proteomics and epigenomics, are currently being used mainly in the realm of clinical research, but with many drugs that target the cancer epigenome moving into the clinic, it can be anticipated that tests directed at assessing the state of the epigenome that predict response to such agents are soon to follow.

The excitement created by the development of new techniques for the global molecular analysis of tumors has led some scientists to predict that the end of histopathology is in sight. Indeed, with the advent of targeted therapies, it can be argued that we are in the midst of a paradigm shift in which the most important part of the work-up of a cancer sample is the identification of molecular targets, rather than histopathologic diagnosis (Fig. 7-51). For example, it is now appreciated that histopathologically

distinct cancers all often harbor the same gain-of-function mutation in the serine/threonine kinase BRAF, a component of the RAS signaling pathway (Fig. 7-52). In principle, all of these diverse “BRAfomas” are candidates for treatment with BRAF inhibitors. However, early studies have shown that the effectiveness of BRAF inhibitors vary widely depending on histologic subtype: hairy cell leukemias with BRAF mutations appear to have sustained responses, melanomas respond transiently, and colon carcinomas respond little, if at all, for reasons that remain to be determined. In this specific case, one could argue that the lineage distinctions that seem to predict response to BRAF inhibitors could be made by expression profiling. However, histopathologic inspection of tumors also provides information about other important characteristics of cancers, such as anaplasia, invasiveness, and tumor heterogeneity. Histopathology coupled with in situ biomarker tests performed on tissue sections also remains the best way to assess tumor:stromal cell interactions, such as angiogenesis and host immune responses; the latter may have an increasingly important role in guiding therapeutic interventions that are designed to counteract immune evasion by tumors. Thus, what lies ahead is not the replacement of one set of techniques by another. On the contrary, for the foreseeable future the most accurate diagnosis and assessment of prognosis in cancer patients will be arrived at by a combination of morphologic and molecular techniques.

Tumor Markers

Biochemical assays for tumor-associated enzymes, hormones, and other tumor markers in the blood cannot be used for definitive diagnosis of cancer; however, they contribute to the detection of cancer and in some instances are useful in determining the effectiveness of therapy or the appearance of a recurrence.

A host of tumor markers have been described, and new candidates are identified every year. Only a few have stood the test of time and proved to have clinical usefulness.

The application of several markers, listed in [Table 7-12](#), is considered in the discussion of specific forms of neoplasia in other chapters, so only a few widely used examples suffice here. Blood tests for *prostate specific antigen* (PSA), a marker for prostatic adenocarcinoma, are frequently used

Table 7-12 Selected Tumor Markers

Tumor Markers	Tumor Types
Hormones	
Human chorionic gonadotropin	Trophoblastic tumors, nonseminomatous testicular tumors
Calcitonin	Medullary carcinoma of thyroid
Catecholamine and metabolites	Pheochromocytoma and related tumors
Ectopic hormones	See Table 7-11
Oncofetal Antigens	
α -Fetoprotein	Liver cell cancer, nonseminomatous germ cell tumors of testis
Carcinoembryonic antigen	Carcinomas of the colon, pancreas, lung, stomach, and heart
Isoenzymes	
Prostatic acid phosphatase	Prostate cancer
Neuron-specific enolase	Small-cell cancer of lung, neuroblastoma
Specific Proteins	
Immunoglobulins	Multiple myeloma and other gammopathies
Prostate-specific antigen and prostate-specific membrane antigen	Prostate cancer
Mucins and Other Glycoproteins	
CA-125	Ovarian cancer
CA-19-9	Colon cancer, pancreatic cancer
CA-15-3	Breast cancer
Cell-Free DNA Markers	
<i>TP53</i> , <i>APC</i> , <i>RAS</i> mutants in stool and serum	Colon cancer
<i>TP53</i> , <i>RAS</i> mutants in stool and serum	Pancreatic cancer
<i>TP53</i> , <i>RAS</i> mutants in sputum and serum	Lung cancer
<i>TP53</i> mutants in urine	Bladder cancer

in clinical practice. Prostatic carcinoma can be suspected when elevated levels of PSA are found in the blood. However, PSA screening highlights problems encountered with virtually every tumor marker. Although PSA levels are often elevated in cancer, PSA levels also may be elevated in benign prostatic hyperplasia (Chapter 18). Furthermore, there is no PSA level that ensures that a person does not have prostate cancer. Thus, the PSA test suffers from both low sensitivity and low specificity, limitations discussed in detail in Chapter 18.

Other tumor markers occasionally used in clinical practice include *carcinoembryonic antigen* (CEA), which is elaborated by carcinomas of the colon, pancreas, stomach, and breast, and *alpha-fetoprotein* (AFP), which is produced by hepatocellular carcinomas, yolk sac remnants in the gonads, and occasionally teratocarcinomas and embryonal cell carcinomas. Unfortunately, like PSA, the serum levels of both of these markers can be elevated by a variety of nonneoplastic conditions as well. Thus, as with PSA, CEA and AFP assays lack both specificity and sensitivity required for the early detection of cancers, but they are useful for detection of recurrences after excision. With successful resection of the tumor, these markers disappear from the serum; their persistence or reappearance almost always signifies tumor lurking within.

Other widely used markers include *human chorionic gonadotropin* (HCG) for testicular tumors, CA-125 for ovarian tumors, and *immunoglobulin* in multiple myeloma and other secretory plasma cell tumors. The development of tests to detect cancer markers in blood and body fluids is an active area of research, and are focused in particular on the analysis of DNA that is shed from dying tumor cells. Some of the cell-free DNAs being evaluated as tumor markers include mutated *APC*, *TP53*, and *RAS* sequences in the stool of individuals with colorectal carcinomas; mutated *TP53* and hypermethylated genes in the sputum of persons with lung cancer and in the saliva of persons with head and neck cancers; and mutated *TP53* in the urine of patients with bladder cancer.

With all of the advances in genomic analyses and targeted therapies, one can safely predict that we are on the cusp of the golden age of tumor diagnosis and treatment. Those of you who are in medical school now can safely assume that the expectations for rapid advances in cancer diagnosis and therapy will be realized while you are still in practice. Get ready!

KEY CONCEPTS

Laboratory Diagnosis of Cancer

- Several sampling approaches exist for the diagnosis of tumors, including excision, biopsy, fine-needle aspiration, and cytologic smears.
- Immunohistochemistry and flow cytometry studies help in the diagnosis and classification of tumors, because distinct protein expression patterns define different entities.
- Molecular analyses are used to determine diagnosis, prognosis, the detection of minimal residual disease, and the diagnosis of hereditary predisposition to cancer.
- Molecular profiling of tumors by RNA expression profiling, DNA sequencing, and DNA copy number arrays are useful in molecular stratification of otherwise identical tumors or

those of distinct histogenesis that share a mutation for the purpose of targeted treatment and prognostication.

- Proteins released by tumors into the serum, such as PSA, can be used to screen populations for cancer and to monitor for recurrence after treatment.
- Assays of circulating tumor cells and of DNA shed into blood, stool, sputum, and urine are under development.

Emerging Infectious Diseases 400

General Principles of Microbial Pathogenesis

Despite the availability of effective vaccines and antibiotics, infectious diseases remain an important health problem throughout the world. In the United States and other high-income countries, infectious diseases are particularly

important causes of death among older adults and in people who are immunosuppressed or who suffer from debilitating chronic diseases. In the developing world, inadequate access to medical care and malnutrition contribute to a heavy burden of infectious diseases. In these areas, six of the ten leading causes of death are infectious diseases. Tragically, most of these deaths occur in children, with respiratory and diarrheal infections taking the greatest toll.

How Microorganisms Cause Disease

Over the past few years, it has become evident that humans and other animals harbor a complex ecosystem of microbial flora (the *microbiome*) that has important roles in health and disease. It is estimated that the normal human body harbors 10 times more microbial cells than human cells! Most of these commensal organisms coexist happily with their human hosts, occupying microenvironmental niches that might otherwise be filled by potential pathogens, and in doing so help to prevent infectious disease. However, under conditions where normal host defenses are breached or attenuated (described below), even “healthy” microbial flora may cause symptomatic infections and can even be fatal.

Most infectious diseases are caused by pathogenic, non-commensal organisms, which exhibit a wide range of virulence. Highly infectious microbes produce disease in a high fraction of healthy individuals, sometimes at “doses” of only a few organisms. Other microbes are minimally pathogenic, requiring large exposures and concomitant breaches of host defenses to cause disease. We will start our review of infectious disease at the beginning of the process, the establishment of a “beachhead” in the host, and then discuss dissemination and transmission of infection, before turning to specific infectious diseases.

Routes of Entry of Microbes

Microbes can enter the host by breaching epithelial surfaces, inhalation, ingestion, or sexual transmission (Table 8-1). In general, respiratory, gastrointestinal, and genitourinary tract infections in otherwise healthy persons are caused by virulent microorganisms with the ability to damage or penetrate the epidermis or mucosal epithelium. By contrast, skin infections in healthy persons are mainly caused by less virulent organisms that enter the skin through superficial injuries.

Skin

The intact keratinized epidermis protects against infection by serving as a strong mechanical barrier and by producing antimicrobial *fatty acids* and *defensins*, small peptides that are toxic to bacteria. These and other substances secreted by the skin create an environmental niche that is occupied by potential opportunistic organisms. Certain fungi (*dermatophytes*) can cause superficial infections of the intact stratum corneum, hair, and nails, but **most skin infections are initiated by mechanical injury of the epidermis**. The injury may range from minor trauma (superficial pricks and abrasions), to large wounds, burns, and pressure-related ulcers, particularly in diabetics. In the hospital setting, infections may stem from intravenous catheters in patients or needle sticks in healthcare workers. Some pathogens penetrate the skin via an insect or animal bite; vectors for such infections include a wide range of unpleasant characters, such as fleas, ticks, mosquitoes, mites, lice, and rabid animals. In general, microorganisms can not traverse the unbroken skin; exceptions include the larvae of *Schistosoma*, which release enzymes that dissolve the adhesive proteins that hold keratinocytes together.

Gastrointestinal Tract

Most gastrointestinal pathogens are transmitted by food or drink contaminated with fecal material. When hygiene fails, diarrheal disease becomes rampant. The gastrointestinal tract has several local defenses. Of these, *acidic gastric secretions* are particularly important since they are highly effective at killing certain organisms. Healthy volunteers do not become infected with *Vibrio cholerae* unless they are fed 10^{11} organisms, but neutralizing stomach acid reduces the necessary infectious dose by 10,000-fold. A *viscous layer of mucus* covers the gut throughout its length, protecting the surface epithelium. *Pancreatic enzymes* and

Table 8-1 Routes of Microbial Infection

Site	Major Local Defense(s)	Basis for Failure of Local Defense	Pathogens (examples)
Skin	Epidermal barrier	Mechanical defects (punctures, burns, ulcers) Needle sticks Arthropod and animal bites Direct penetration	<i>S. aureus</i> , <i>Candida albicans</i> , <i>Pseudomonas aeruginosa</i> HIV, hepatitis viruses Yellow fever, plague, Lyme disease, malaria, rabies <i>Schistosoma</i>
GI Tract	Epithelial barrier Acidic secretions Bile and pancreatic enzymes Normal protective flora	Attachment and local proliferation of microbes Attachment and local invasion of microbes Uptake through M cells Acid-resistant cysts and eggs Resistant microbial external coats Broad spectrum antibiotic use	<i>Vibrio cholerae</i> , <i>Giardia</i> <i>Shigella</i> , <i>Salmonella</i> , <i>Campylobacter</i> Poliovirus, certain pathogenic bacteria Many protozoa and helminths Hepatitis A, rotavirus, Norovirus <i>Clostridium difficile</i>
Respiratory Tract	Mucociliary clearance Resident alveolar macrophages	Attachment and local proliferation of microbes Ciliary paralysis by toxins Resistance to killing by phagocytes	Influenza viruses <i>Haemophilus influenzae</i> , <i>M. pneumoniae</i> , <i>Bordetella pertussis</i> <i>M. tuberculosis</i>
Urogenital Tract	Urination Normal vaginal flora Intact epidermal/epithelial barrier	Obstruction, microbial attachment and local proliferation Antibiotic use Microbial attachment and local proliferation Direct infection/local invasion Local trauma	<i>E. coli</i> <i>Candida albicans</i> <i>N. gonococcus</i> Herpes viruses, syphilis Various sexually transmitted diseases, e.g., human papilloma virus

bile detergents can destroy organisms with envelopes, such as certain viruses. As in the skin, antimicrobial *defensins* are produced by gut epithelial cells. *IgA antibodies*, produced in mucosal lymphoid tissues such as Peyer patches and secreted into the gut lumen (Chapter 18), can neutralize potential pathogens. *Peristalsis* can clear organisms, preventing their local overgrowth. Finally, as already mentioned, the *normal gut flora* creates a microenvironment that discourages colonization by potential pathogens, such as *Clostridium difficile*.

Gastrointestinal tract infections may occur when local defenses are circumvented by a pathogen, or when they are so weakened that even normal flora produce disease. Many notorious gastrointestinal pathogens are intrinsically resistant to local defenses, particularly those that enter the host by ingestion. *Norovirus* (the scourge of the cruise ship industry) is a non-enveloped virus that is resistant to inactivation by acid, bile, and pancreatic enzymes and hence easily spread in places where people are crowded together. Similarly, intestinal protozoa and some intestinal helminths transmitted as cysts or eggs, respectively, have acid-resistant outer coats, and some bacteria, such as *Shigella*, are also resistant to acid; hence, as few as 100 organisms of each can cause illness.

Enteropathogenic pathogens may establish symptomatic gastrointestinal disease through several distinct mechanisms:

- *Adhesion and local proliferation.* Examples include *V. cholerae* and enterotoxigenic *Escherichia coli*, which bind to the intestinal epithelium and multiply in the overlying mucous layer. Here, these organisms elaborate potent exotoxins that are responsible for symptomatic disease.
- *Adhesion and mucosal invasion.* Pathogens such as *Shigella*, *Salmonella enterica*, *Campylobacter jejuni*, and *Entamoeba histolytica* invade the intestinal mucosa and lamina propria and cause ulceration, inflammation, and hemorrhage that manifest clinically as dysentery.
- *“Hijacking” of host pathways of antigen uptake.* You will recall that mucosal lymphoid tissues such as Peyer patches are covered by specialized epithelial cells called M cells, which are responsible for uptake and delivery of antigens to underlying lymphoid tissues. Ironically, multiple infectious agents, including poliovirus, are taken up into the host through this same pathway.

There are several caveats to the themes laid out above. Some organisms contaminating food can produce gastrointestinal disease without ever establishing an infection in the host. A cardinal example is *S. aureus*, which elaborates a powerful exotoxin during its growth in contaminated food that is responsible for acute food poisoning. Diminished local defenses due to loss of gastric acidity, broad-spectrum antibiotic treatment, ileus, or mechanical obstruction may exacerbate infections caused by virulent pathogens and allow organisms of low pathogenicity to establish disease. Other opportunistic organisms such as *Candida* only produce gastrointestinal disease when the immune system is weakened. In this setting, *Candida* has a particular predilection for establishing infections in squamous mucosae (e.g., oral thrush, esophagitis), but may also involve other sites.

Respiratory Tract

A plethora of microorganisms, including viruses, bacteria, and fungi, are inhaled daily, mainly in dust or aerosol particles. The distance these particles travel into the respiratory system is inversely proportional to their size. Large particles are trapped in the mucociliary blanket that lines the nose and the upper respiratory tract. Microorganisms trapped in the mucus layer are transported by ciliary action to the back of the throat, where they are swallowed and cleared. By contrast, particles smaller than 5 microns are carried into the alveoli, where they are phagocytosed by resident alveolar macrophages or by neutrophils recruited to the lung by cytokines.

The microorganisms that infect the healthy respiratory tract evade local defenses through several different mechanisms. Some pathogenic respiratory viruses attach to and enter epithelial cells in the lower respiratory tract and pharynx. For example, influenza viruses have envelope proteins called hemagglutinins that bind to sialic acid on the surface of epithelial cells. Attachment induces the host cell to endocytose the virus, leading to viral entry and replication. The resulting damage to the respiratory epithelium sets the stage for superinfection by *S. pneumoniae* and *S. aureus*, often leading to serious pneumonias. Certain bacterial respiratory pathogens, including *Haemophilus influenzae*, *M. pneumoniae*, and *Bordetella pertussis*, release toxins that enhance their ability to establish an infection by impairing ciliary activity. Another important mechanism of establishing respiratory infection is primary resistance to killing following phagocytosis. A classic example is *Mycobacterium tuberculosis*, which gains a foothold in alveoli by surviving within the phagolysosomes of macrophages.

Other organisms establish disease when local or systemic defenses are impaired. Chronic impairment of mucociliary defense mechanisms occurs in smokers and in people with cystic fibrosis, while acute injury occurs in patients undergoing mechanical ventilation and in those who aspirate gastric acid. Many other infectious agents cause respiratory infections primarily in the setting of systemic immunodeficiency. Examples include fungal infections by *P. jiroveci* in AIDS patients and by *Aspergillus* species in patients with neutropenia.

Urogenital Tract

Urine is sterile, and the urinary tract is protected from infection by regular emptying during micturition. Urinary tract pathogens (e.g., *E. coli*) almost always gain access via the urethra and must be able to adhere to urothelium to avoid being washed away. Anatomy plays an important role in dictating risk. Women have more than 10 times as many urinary tract infections as men because the distance between the urinary bladder and skin (i.e., the length of the urethra) is 5 cm in women versus 20 cm in men. Understandably, **obstruction of urinary flow or reflux of urine compromises normal defenses and increases susceptibility to urinary tract infections.**

From puberty until menopause the vagina is protected from pathogens by lactobacilli, which ferment glucose to lactic acid, producing a low pH environment that suppresses the growth of pathogens. Antibiotics can kill the lactobacilli and allow overgrowth of yeast, causing vaginal

candidiasis. The uterine cervix is covered by squamous mucosa that is also resistant to infection. However, minor trauma may expose immature proliferating epithelial cells that are susceptible to infection by human papilloma viruses, an important sexually transmitted pathogen that is the cause of most cases of cervical carcinoma (Chapters 7 and 22).

Vertical Transmission

Vertical transmission of infectious agents from mother to fetus or newborn child is a common mode of transmission of certain pathogens, and may occur through several different routes.

- **Placental-fetal transmission.** This is most likely to occur when the mother is infected with a pathogen during pregnancy. Some of the resulting infections interfere with fetal development, and understandably the degree and type of damage depend on the age of the fetus at the time of infection. For example, rubella infection during the first trimester can lead to heart malformations, mental retardation, cataracts, or deafness, while rubella infection during the third trimester has little effect.
- **Transmission during birth.** This mode of transmission is caused by contact with infectious agents during passage through the birth canal. Examples include gonococcal and chlamydial conjunctivitis.
- **Postnatal transmission in maternal milk.** Agents transmitted in this fashion include cytomegalovirus (CMV), human immunodeficiency virus (HIV), and hepatitis B virus (HBV).

Spread and Dissemination of Microbes Within the Body

While some disease-causing microorganisms remain localized to the initial site of infection, others have the capacity to invade tissues and spread to distant sites via the lymphatics, the blood, or the nerves (Fig. 8-1). Pathogens can spread within the body in several ways. Some extracellular pathogens secrete enzymes that break down tissues, allowing the organisms to advance virtually unimpeded. For example, *S. aureus* secretes hyaluronidase, which degrades the extracellular matrix between host cells, allowing the microbes to follow tissue planes of least resistance. Eventually the organisms may travel through the lymphatics to regional lymph nodes and the blood, potentially leading to bacteremia and spread to distant organs, such as heart and bone. Certain viruses, such as rabies, poliovirus, and *Varicella*, spread to the central nervous system by infecting peripheral nerves and then traveling intracellularly along axons. However, the most common and efficient mode of microbial dissemination is through the bloodstream. Some blood-borne pathogens, such as certain viruses (e.g., poliovirus, hepatitis B virus), most bacteria and fungi, some protozoa (e.g., African trypanosomes), and helminths are transported free in plasma, while others are carried within leukocytes (e.g., herpesviruses, HIV, mycobacteria, and certain fungi and protozoa) or red cells (e.g., malarial parasites).

The consequences of blood-borne spread of pathogens vary widely depending on the virulence of the organism, the magnitude of the infection, the pattern of seeding, and host factors such as immune status. Sporadic

Figure 8-1 Routes of entry and dissemination of microbes. To enter the body, microbes penetrate the epithelial or mucosal barriers. Infection may remain localized at the site of entry or spread to other sites in the body. Most common microbes (selected examples are shown) spread through the lymphatics or bloodstream (either freely or within inflammatory cells). However, certain viruses and bacterial toxins may also travel through nerves. (Adapted from Mims CA: *The Pathogenesis of Infectious Disease*, 4th ed. San Diego, Academic Press, 1996.)

bloodstream invasion by low-virulence or nonvirulent microbes (e.g., during brushing of teeth) is common but is quickly controlled by normal host defenses. By contrast, disseminated viremia, bacteremia, fungemia, or parasitemia by virulent pathogens often produces severe illness and is a serious threat to life. As discussed in Chapter 4, such infections may produce a systemic inflammatory response syndrome that manifests as fever, low blood pressure, and coagulopathies that may progress to organ failure and death if unchecked, even in previously healthy individuals. In other instances, the major signs of spread of the infection are related to tissue seeding. These may take the form of a single large infectious nidus (an abscess or tuberculoma), multiple small sites of infection (e.g., miliary tuberculosis or *Candida* microabscesses), or infection of the heart and vessels (infectious endocarditis and mycotic aneurysm).

Other microbes cause characteristic patterns of disease because of tropism for specific tissues. These include already mentioned neurotropic viruses (rabies, poliovirus, varicella) and certain parasites. For example, after penetrating the skin, *Schistosoma mansoni* parasites localize to blood vessels of the portal system and mesentery, leading

to damage in the liver and intestine. Similarly, *Schistosoma hematobium* travels to vessels in the urinary bladder and causes cystitis.

Release from the Body and Transmission of Microbes

Infectious microbes use a variety of “exit strategies” to ensure their transmission from one host to the next. Depending on the location of infection, release may be accomplished by skin shedding, coughing, sneezing, voiding of urine or feces, during sexual contact, or through insect vectors. Some pathogens are released for only brief periods of time or periodically during disease flares, but others, such as the enteric pathogen *S. typhi*, may be shed for long periods by asymptomatic carrier hosts. Once released, pathogens also show wide variation in hardiness. Some survive for extended periods of time in dust, food, or water. Bacterial spores, protozoan cysts, and helminth eggs can remain viable in a cool and dry environment for months to years. By contrast, some fragile pathogens persist outside of the body for only short periods of time and must be passed quickly from person to person, often by direct contact.

Most pathogens are transmitted from person to person by respiratory, fecal-oral, or sexual routes. Viruses and bacteria spread by the respiratory route are infectious only when lesions are open to the airways. With coughing, the pathogens are aerosolized in droplets and released into the air. Some respiratory pathogens, including influenza viruses, are spread in large droplets that travel no more than 3 feet from the source, but others, including *M. tuberculosis* and varicella-zoster virus, spread in small droplets or within dust particles that can travel much longer distances.

Understandably, most enteric pathogens are spread by the fecal-oral route, that is, by ingestion of stool-contaminated water or food. Water-borne viruses involved in epidemic outbreaks that are spread in this fashion include hepatitis A and E viruses, poliovirus, and rotavirus. Other important pathogens spread by the fecal-oral route include *V. cholerae*, *Shigella*, *Campylobacter jejuni*, and *Salmonella*. Some parasitic helminthes (e.g., hookworms, schistosomes) shed eggs in stool that hatch as larvae that are capable of penetrating the skin of the next host. Sexual transmission often entails prolonged intimate or mucosal contact and is responsible for spread of a wide variety of pathogens, including viruses (e.g., *Herpes simplex*, HIV, human papilloma virus), bacteria (*T. pallidum*, *Gonococcus*), protozoa (*Candida*) and even arthropods (*Phthirus pubis*, or crab lice).

Besides these major routes of transmission, pathogens exist that exploit virtually every imaginable means for spreading to a new host. Saliva is responsible for transmitting viruses that replicate in the salivary gland or oropharynx, including Epstein-Barr virus and rabies virus, which may be spread by an amorous kiss or a frenzied bite, respectively. Protozoa and helminths have evolved particularly complex life cycles that often involve intermediate hosts bearing successive developmental stages of the pathogen. Some of the most important human pathogens are protozoa that are spread through blood meals taken by arthropod vectors (mosquitoes, ticks, mites). Finally, a few pathogens can be transmitted from animals to humans (termed *zoonotic infections*), either by direct contact,

consumption of animal products, or via an invertebrate vector.

KEY CONCEPTS

Transmission and Dissemination of Microbes

- Transmission of infections can occur by contact (direct and indirect), respiratory route, fecal-oral route, sexual transmission, vertical transmission or insect/arthropod vectors.
- A pathogen can establish infection if it possesses virulence factors that overcome normal host defenses or if the host defenses are compromised.
- Host defenses against infection include:
 - Skin: tough keratinized barrier, low pH, fatty acids
 - Respiratory system: alveolar macrophages, mucociliary clearance by bronchial epithelium, IgA
 - GI system: acidic gastric pH, viscous mucus, pancreatic enzymes and bile, defensins, IgA, and normal flora
 - Urogenital tract: repeated flushing and acidic environment created by commensal flora
- Pathogens can proliferate locally, at the site of initial infection, or spread to other sites by direct extension (invasion) or by transport in the lymphatics, the blood, or nerves.

Host-Pathogen Interactions

Host Defenses against Infection

The outcome of infection is determined by the virulence of the microbe and the nature of the host immune response, which may either eliminate the infection or, in some cases, exacerbate or even be the principal cause of tissue damage. The host has a large and complex armamentarium of defenses against pathogens, including physical barriers and components of the innate and adaptive immune systems, which were discussed extensively in [Chapter 6](#). The complexity of the immune system is a testimony to the remarkable selective pressures that infectious diseases place on humans and other animals; there is little doubt that the ability to survive in a world full of pathogenic microbes was (and remains) one of the most important forces shaping human evolution. Unfortunately, Darwinian forces also drive the continuing evolution of a remarkable array of highly diverse microbes, which are constantly threatening to get a step ahead of host defenses.

We will return to the issue of newly emerging infections later in this Chapter. In the next section, we discuss the various mechanisms by which pathogens evade the host and cause disease.

Immune Evasion by Microbes

Most pathogenic microbes have developed one or more strategies that allow them to evade host defenses (Fig. 8-2). The mechanisms of evasion are probably even more numerous than the mechanisms of effective host response, as any microbe that by chance acquires resistance to an effective host response is likely, over time, to rise in prevalence in the microbial population. Some salient examples of immune evasion by microbes are as follows:

Figure 8-2 An overview of mechanisms used by viral and bacterial pathogens to evade innate and adaptive immunity. (Modified with permission from Finlay B, McFadden G: Anti-immunology: evasion of the host immune system by bacterial and viral pathogens. Cell 2006;124:767-782.)

- **Antigenic variation.** This is an important mechanism for escape from antibody-mediated host defenses. Antibodies against microbial antigens can block microbial adhesion and uptake into cells, act as opsonins to facilitate phagocytosis, and fix complement, and cytotoxic T cells recognize microbial antigens expressed in the context of MHC molecules on the surface of infected host cells. To escape recognition, microbes have many strategies that allow them to “change their coats” by expressing different surface antigens. Spirochetes belonging to *Borrelia* species and trypanosomes have sophisticated genetic mechanisms that allow them to periodically switch their major surface proteins. Influenza viruses have a complex RNA genome that allows for frequent recombination events, permitting antigenic “drift” and “shifts”. In a less elegant but nevertheless effective fashion, other microbes simply generate numerous genetic variants through mutation. For example, there are over 90 different serotypes of *S. pneumoniae*, each with different capsular polysaccharides. Similarly, the low fidelity of viral RNA polymerases of HIV and many respiratory viruses (including influenza virus) create viral antigenic variation (Table 8-2).
- **Resistance to antimicrobial peptides.** You will recall from Chapter 6 that epithelial cells and some leukocytes produce cationic antimicrobial peptides such as defensins and cathelicidins that are toxic to microbes, in part by forming pores in microbial membranes. These peptides can also augment anti-microbial immunity by inducing the production of pro-inflammatory

chemokines and cytokines. Resistance to these peptides is a factor in the virulence of a number of pathogens, including *Shigella* ssp, *S. aureus*, and *Candida*. Microbial strategies to avoid killing by peptides include changes in net surface charge and membrane hydrophobicity that prevent antimicrobial peptide insertion and pore formation, secretion of proteins that inactivate or degrade the peptides, and pumps that export the peptides.

- **Resistance to killing by phagocytes.** Phagocytosis and killing of bacteria by neutrophils and macrophages are a critical host defense against extracellular bacteria; accordingly, pathogens have evolved a wealth of resistance mechanisms at virtually every level of the process. The carbohydrate capsule on the surface of many bacteria that cause pneumonia or meningitis (*S. pneumoniae*, *N. meningitidis*, *H. influenzae*) prevents phagocytosis of the organisms by neutrophils. *E. coli* that cause meningitis in newborns synthesize a special capsule containing sialic acid that will not bind C3b, which is critical for activation of the alternative complement pathway and opsonization-directed phagocytosis. *S. aureus* expresses protein A, which binds the Fc portion of antibodies and so inhibits phagocytosis. Other bacteria make proteins that variously kill phagocytes, prevent their migration, or diminish their oxidative burst. Finally, some pathogens are resistance to intracellular killing in phagocytes, including mycobacteria, *Listeria*, *Cryptococcus neoformans*, and certain protozoa (e.g., leishmania, trypanosomes, toxoplasmas).
- **Evasion of apoptosis and manipulation of host cell metabolism.** Some viruses produce proteins that interfere with apoptosis of the host cell, which may buy them the time necessary to replicate, enter latency, or even transform host cells. Microbes that replicate intracellularly (viruses, some bacteria, fungi and protozoa) also express factors that modulate autophagy, which appears to enhance their ability to evade degradation and to replicate.
- **Resistance to cytokine-, chemokine- and complement-mediated host defense.** Many viruses express factors that interfere with the actions of cytokines, chemokines, or complement. For example, some viruses produce soluble homologues of IFN- α/β or IFN- γ receptors that function as “decoys” and sop up and inhibit the actions of secreted IFNs. Viruses also produce proteins that inhibit the JAK/STAT pathway, a key signaling cascade that

Table 8-2 Mechanisms of Antigenic Variation

Type	Example	Disease
High mutation rate	HIV	AIDS
	Influenza virus	Influenza
Genetic reassortment	Influenza virus	Influenza
	Rotavirus	Diarrhea
Genetic rearrangement (e.g., gene recombination, gene conversion, site-specific inversion)	<i>Borrelia burgdorferi</i>	Lyme disease
	<i>Neisseria gonorrhoeae</i>	Gonorrhea
	<i>Trypanosoma</i> sp.	African sleeping sickness
	<i>Plasmodium</i> sp.	Malaria
Large diversity of serotypes	Rhinoviruses	Colds
	<i>Streptococcus pneumoniae</i>	Pneumonia
	<i>Streptococcus pneumoniae</i>	Meningitis

lies downstream of IFN receptors. Other viruses produce proteins that inactivate or inhibit double-stranded RNA-dependent protein kinase (PKR), an important mediator of the antiviral effects of IFN, or produce proteins that block complement activation.

- *Evasion of recognition by CD4+ helper T cells and CD8+ cytotoxic T cells.* This is also an important mode of immune evasion by viruses, which involves several different mechanisms. Several DNA viruses (e.g., HSV, CMV, and EBV) bind to or alter localization of major histocompatibility complex (MHC) class I proteins, impairing peptide presentation to CD8+ T cells. Downregulation of MHC class I molecules could lead to targeting by NK cells, but herpesviruses also express MHC class I homologues that inhibit NK cells by engaging NK cell inhibitory receptors (Chapter 6). Herpesviruses also can target MHC class II molecules for degradation, impairing antigen presentation to CD4+ T helper cells.
- Another strategy exploits *immunoregulatory mechanisms to downregulate anti-microbial T cell responses.* During chronic viral infections, antigen-specific T cells initially acquire effector functions but gradually lose their potency as infection progresses. This loss of function, termed T cell exhaustion, is a feature of chronic infections by HIV, hepatitis C virus, and hepatitis B virus. A major mechanism regulating T cell exhaustion is upregulation of immunoinhibitory T cell pathways. The PD-1 pathway, which normally functions to maintain T cell tolerance to self-antigens, is an important mediator of T cell exhaustion during chronic viral infection.
- The ultimate means of avoiding the immune system is to “lie low” by establishing a state of *latent infection* in which few if any viral genes are expressed. Examples include latent infections of neurons by *herpes simplex* and *Varicella* and of B lymphocytes by Epstein-Barr virus. These latent infections persist in an asymptomatic state throughout life, but may produce disease if the viruses are “awakened” from their latent state and enter a phase of viral replication. Other pathogens infect leukocytes, and in doing so interfere with their function, leading to persistent infection. A classic example is HIV, which infects CD4+ T cells and by doing so sets the stage for T cell dysfunction and persistent, progressive disease.

KEY CONCEPTS

Immune evasion by microbes

After bypassing host tissue barriers, infectious microorganisms must also evade host innate and adaptive immunity to successfully proliferate and be transmitted to the next host. Strategies include:

- Antigenic variation
- Inactivating antibodies or complement
- Resisting phagocytosis, e.g. by producing a capsule
- Suppressing the host adaptive immune response, e.g. by interfering with cytokines or inhibiting MHC expression and antigen presentation.
- Establishing latency, during which viruses survive in a silent state in infected cells.

Injurious Effects of Host Immunity

As mentioned earlier, while generally beneficial, the host immune response to microbes can sometimes be the major cause of tissue injury. The granulomatous inflammatory reaction to *M. tuberculosis* sequesters the bacilli and prevents their spread, but it also can produce tissue damage and fibrosis. Similarly, damage to hepatocytes following hepatitis B virus and hepatitis C virus infection is mainly due to the effects of the immune response on infected liver cells rather than cytopathic effects of the virus. Humoral immune responses to microbes also can have pathologic consequences. Following infection with *S. pyogenes*, antibodies produced against the streptococcal M protein can cross-react with cardiac proteins and damage the heart, leading to rheumatic heart disease. Similarly, poststreptococcal glomerulonephritis is caused by immune complexes formed between antistreptococcal antibodies and circulating streptococcal antigens; these complexes deposit in the renal glomeruli, producing inflammation in the kidney.

Inflammation elicited by microbes also underlies a wide variety of chronic inflammatory disorders as well as some forms of cancer. A cycle of inflammation and epithelial injury is involved in the pathogenesis of inflammatory bowel disease, with microbes playing at least a peripheral role (Chapter 17). Viruses (hepatitis B virus, hepatitis C virus) and bacteria (*H. pylori*) that are not known to carry or activate oncogenes are associated with cancers, presumably because these microbes trigger chronic inflammation, which provides fertile ground for the development of cancer (Chapter 7).

Infections in People with Immunodeficiencies

Inherited or acquired defects in innate and adaptive immunity (Chapter 6) often impair only part of the immune system, rendering the affected individual susceptible to specific types of infections. These rare disorders have served to illuminate important aspects of specific components of host defense, as well as the unique vulnerabilities of certain pathogens. The following are some specific examples:

- *Antibody deficiencies*, as seen in patients with X-linked agammaglobulinemia, lead to increased susceptibility to infections by extracellular bacteria, including *S. pneumoniae*, *H. influenzae*, and *S. aureus*, as well as a few viruses (rotavirus and enteroviruses).
- *Complement defects* in early components of the complement cascade lead to susceptibility to infections by encapsulated bacteria, such as *S. pneumoniae*, whereas deficiencies of the late membrane attack complex components (C5-C9) are associated with *Neisseria* infections.
- *Defects in neutrophil function* lead to increased susceptibility to infections with *S. aureus*, some gram-negative bacteria, and fungi.
- *Defects in Toll-like receptor (TLR) signaling pathways* have varied effects. Mutations in MyD88 or IRAK4, which are downstream of several TLRs, predispose to pyogenic bacterial infections, particularly invasive infections with *S. pneumoniae*, while impaired TLR3 responses are associated with childhood herpes simplex virus encephalitis.

- *T-cell defects* lead to susceptibility to intracellular pathogens, particularly viruses and some parasites. Inherited mutations that impair the generation of T_H1 cells (such as mutations in IL-12 or IFN- γ receptors, or the transcription factor STAT1) are associated with atypical mycobacterial infections. By contrast, defects that impair the generation of T_H17 cells (such as mutations in STAT3) are associated with chronic mucocutaneous candidiasis.

Even more common are acquired immunodeficiencies. Worldwide, the most common cause of immunodeficiency is infection with HIV, the cause of AIDS. While most organisms that infect people with AIDS were common pathogens before the era of HIV, others were uncommon (cryptococcus, pneumocystis), and one, Kaposi sarcoma herpesvirus (KSHV), also called human herpesvirus-8 (HHV-8), was discovered as a result of research in AIDS patients.

Other causes of acquired immunodeficiencies include infiltrative processes that suppress bone marrow function (such as leukemia), immunosuppressive drugs used to treat patients with autoimmune diseases and organ transplant recipients, as well as drugs used to treat cancer, and hematopoietic stem cell transplantation. Therapy to prevent rejection of organ transplants leads to severe immunosuppression, making transplant recipients very susceptible to infectious diseases. Patients receiving hematopoietic stem cell transplants have profound defects in innate and adaptive immunity during the time that it takes for the donated stem cells to engraft, and become susceptible to infection with almost any organism, including opportunistic organisms that seldom cause disease in healthy people (e.g., *Aspergillus* species and *Pseudomonas* species).

Decline of immune responses can result in reactivation of latent infection and severe pathologic manifestations. Such reactivation is seen in latent viral infections (e.g., herpesviruses) and some bacterial infections (e.g., tuberculosis). At least some of the increased incidence of certain infections in the elderly may be due to age-related declines in immune function.

Diseases of organ systems other than the immune system also can make patients susceptible to diseases due to specific microorganisms. People with cystic fibrosis commonly get respiratory infections with *P. aeruginosa*, *S. aureus*, and *Burkholderia cepacia*. Lack of splenic function in people with sickle cell disease makes them susceptible to infection with encapsulated bacteria such as *S. pneumoniae*, which are normally opsonized and phagocytosed by splenic macrophages. Burns destroy skin, removing this barrier to microbes and allowing infection with pathogens such as *P. aeruginosa*. Finally, malnutrition can impair immune defenses.

Host Damage

Infectious agents establish infection and damage tissues by three mechanisms:

- They can contact or enter host cells and cause cell death directly, or cause changes in cellular metabolism and proliferation that can eventually lead to transformation.

- They may release toxins that kill cells at a distance, release enzymes that degrade tissue components, or damage blood vessels and cause ischemic necrosis.
- They can induce host immune responses that, though directed against the invader, cause additional tissue damage. As already mentioned, the defensive responses of the host constitute a double-edged sword: They are necessary to overcome the infection but at the same time may directly contribute to tissue damage.

Here we describe some of the mechanisms whereby viruses and bacteria damage host tissues.

Mechanisms of Viral Injury

Viruses can directly damage host cells by entering them and replicating at the host's expense. The predilection for viruses to infect certain cells and not others is called *tropism* and may be determined by physical factors, surface proteins that are required for viral entry, and other factors that are required for viral replication. Each is discussed below briefly.

A major determinant of tissue tropism is the presence of viral receptors on host cells. Viruses have surface proteins that bind to particular proteins found on the surface of host cells. Many of these host cell proteins normally function as receptors for host factors. For example, HIV glycoprotein gp120 binds to CD4 on T cells and to the chemokine receptors CXCR4 (mainly on T cells) and CCR5 (mainly on macrophages) (Chapter 6), while Epstein-Barr virus binds to complement receptor 2 (also known as CR2 or CD21) on B cells. Other tropisms are explained by different kinds of cell-lineage specific factors. For example, JC virus infection, which causes leukoencephalopathy (Chapter 28), is restricted to oligodendroglial cells in the CNS; this is because the expression of JC viral genes needed for a productive infection requires host transcription factors that are only expressed in glial cells, and not in neurons or endothelial cells.

Physical barriers also can contribute to tissue tropism. For example, enteroviruses replicate in the intestine in part because they can resist inactivation by acids, bile, and digestive enzymes. Rhinoviruses infect host cells only within the upper respiratory tract because they replicate optimally at the lower temperatures found in sites exposed to the ambient atmosphere.

Once viruses are inside host cells, they can damage or kill the cells by a number of mechanisms (Fig. 8-3):

- *Direct cytopathic effects.* Some viruses kill cells by preventing synthesis of critical host macromolecules (e.g., host cell DNA, RNA, or proteins), or by producing degradative enzymes and toxic proteins. For example, poliovirus inactivates cap-binding protein, which is essential for translation of host cell mRNAs but leaves translation of poliovirus mRNAs unaffected. Herpes simplex virus produces proteins that inhibit the synthesis of cellular DNA and mRNA, as well as other proteins that degrade host DNA. Viruses can induce cell death by a variety of means, including by activating so-called death receptors (members of the TNF receptor family) on the plasma membrane and by triggering the intracellular apoptotic machinery. During the course of productive viral infection, large amounts of viral proteins are synthesized in infected cells, including unfolded or

Figure 8-3 Mechanisms by which viruses cause injury to cells.

misfolded proteins that activate the ER stress response; this, too, activates pro-apoptotic pathways. Finally, some viruses encode proteins that are pro-apoptotic; the HIV vpr protein is one such example.

- **Anti-viral immune responses.** Host lymphocytes can recognize and destroy virus-infected cells. Cytotoxic T lymphocytes (CTLs) are important for defense against viral infections, but CTLs also can be responsible for tissue injury, as discussed previously.
- **Transformation of infected cells.** Oncogenic viruses can stimulate cell growth and survival by a variety of mechanisms, including expression of virus-encoded oncogenes, expression of viral proteins that inactivate key tumor suppressors, and insertional mutagenesis, in which expression of host genes is altered by the insertion of the viral genome into the genes or the flanking host genome. The mechanisms of viral transformation are numerous and are discussed in Chapter 7.

Mechanisms of Bacterial Injury

Bacterial Virulence. Bacterial damage to host tissues depends on the ability of the bacteria to adhere to host cells, to invade cells and tissues, or to deliver toxins. Pathogenic bacteria have *virulence genes* that encode proteins that confer these properties. An example of the importance of such genes can be found in the various strains of *Salmonella*. All *Salmonella* strains that infect humans are closely related enough to form a single species,

meaning that they share many “housekeeping” genes. Differences in a relatively small number of pathogenicity genes determine whether an isolate of *Salmonella* causes life-threatening typhoid fever or self-limited enteritis. Virulence genes are frequently found grouped together in clusters called *pathogenicity islands*.

Mobile genetic elements such as plasmids and bacteriophages can transmit functionally important genes to bacteria, including genes that influence pathogenicity and drug resistance. Genes for toxins are sometimes found in plasmids but are more often found in the genomes of bacteriophages, including the genes that encode the toxins responsible for the pathogenesis of cholera, diphtheria and botulism. Genes for acquired antibiotic resistance traits are more frequently found on plasmids, which can spread not only within bacterial species but also between more distantly related organisms. For example, a plasmid with genes for vancomycin resistance can spread not only between species of *Enterococcus*, but also to more distantly related (and virulent) *S. aureus*.

Many bacteria coordinately regulate gene expression within a large population by a process called *quorum sensing*. For example, bacteria can induce expression of virulence factors as they grow to high concentration in tissue. This may allow bacteria growing in discrete host sites, such as an abscess or consolidated pneumonia, to overcome host defenses. *S. aureus* coordinately regulates virulence factors by secreting *autoinducer peptides*. As the bacteria increase in numbers, the level of the autoinducer peptide increases, stimulating toxin production. Within the population, some bacteria produce the autoinducer peptide and others respond to it by secreting toxins. Thus, because of quorum sensing, unicellular bacteria acquire some of the more complex properties of multicellular organisms, in which different cells perform different functions.

Communities of bacteria can also form *biofilms* in which the organisms live within a viscous layer of extracellular polysaccharides that adhere to host tissues or devices such as intravascular catheters and artificial joints. In addition to enhancing adherence to host tissues, biofilms increase the virulence of bacteria by protecting the microbes from immune effector mechanisms and increasing their resistance to antimicrobial drugs. Biofilm formation seems to be particularly important in the persistence and relapse of bacterial endocarditis, artificial joint infections, and respiratory infections in people with cystic fibrosis.

Bacterial Adherence to Host Cells. *Adhesins* are bacterial surface proteins that bind bacteria to host cells or extracellular matrix. Adhesins are limited in structural type but have a broad range of host cell specificity. *Streptococcus pyogenes* adheres to host tissues using the adhesins protein F and teichoic acid, which project from the bacterial cell wall and bind to fibronectin on the surface of host cells and in the extracellular matrix.

Pili are filamentous proteins on the surface of bacteria that act as adhesins. The stalks of pili are composed of conserved repeating subunits, while the variable subunits on the tips of the pili determine the tissue-binding specificity of the bacteria. For example, strains of *E. coli* that cause urinary tract infections specifically express a pilus which binds to a gal(α 1-4)gal moiety expressed on uroepithelial cells. Pili can be targets of the host antibody response and,

in turn, some bacteria such as *N. gonorrhoeae*, vary their pili to escape from the host immune system.

Virulence of Intracellular Bacteria. Bacteria have evolved a variety of mechanisms for entering host cells. Some bacteria use the host immune response to gain entry into macrophages. Opsonization of bacteria with antibodies or the complement protein C3b promotes phagocytosis of bacteria by macrophages. Like many bacteria, *M. tuberculosis* activates the alternative complement pathway, resulting in opsonization with C3b. Once coated with C3b, *M. tuberculosis* binds to the CR3 complement receptor on macrophages, enters the macrophages, and replicates within phagosomes. Gram-negative bacteria use a complex secretion system to enter epithelial cells. This type III secretion system consists of needle-like structures projecting from the bacterial surface that bind to host cells. These proteins then form pores in the host cell membrane and inject bacterial proteins that mediate the rearrangement of the host cell cytoskeleton in a fashion that facilitates bacterial entry. Once inside the host cell, other bacteria such as *Listeria monocytogenes* modify the actin cytoskeleton to promote the direct spreading of the organism to neighboring cells, allowing the bacteria to evade immune effector mechanisms.

After bacteria enter the host cell, their fate (and that of the infected cell) varies greatly depending on the organism. *Shigella* and *E. coli* inhibit host protein synthesis, replicate rapidly, and lyse the host cell within hours. Most bacteria are killed within macrophages when the phagosome fuses with an acidic lysosome to form a phagolysosome, but certain bacteria elude this host defense. For example, *M. tuberculosis* blocks fusion of the lysosome with the phagosome, allowing it to proliferate unchecked within the macrophage. Other bacteria avoid destruction in macrophages by leaving the phagosome and entering the cytoplasm. *L. monocytogenes* produces a pore-forming protein called listeriolysin O and two phospholipases that degrade the phagosome membrane, allowing the bacterium to escape into the cytoplasm.

Facultative intracellular bacteria infect epithelial cells (*Shigella* and enteroinvasive *E. coli*), macrophages (*M. tuberculosis*, *M. leprae*), or both (*S. typhi*). The growth of bacteria in cells can allow them to escape from certain effector mechanisms of the immune response (e.g., antibodies and complement), and can also facilitate the spread of the bacteria. An example of the latter is the migration of infected macrophages carrying *M. tuberculosis* from the lung to draining lymph nodes and other more distant sites.

Bacterial Toxins. Any bacterial substance that contributes to illness can be considered a toxin. Toxins are classified as *endotoxins*, which are components of the bacterial cell, and *exotoxins*, which are proteins that are secreted by the bacterium.

Bacterial endotoxin is a lipopolysaccharide (LPS) in the outer membrane of Gram-negative bacteria that both stimulates host immune responses and injures the host. Lipid A, which anchors LPS in the host cell membrane through long-chain fatty acids, has the endotoxin activity of LPS. Lipid A is connected to a conserved core carbohydrate chain, which is attached to a variable carbohydrate chain called the O antigen. The response to lipid A is

beneficial in that it activates protective immunity in several ways. It induces the production of important cytokines and chemoattractants (chemokines) by immune cells and increases the expression of costimulatory molecules, which enhance T-lymphocyte activation. However, high levels of endotoxin play a pathogenic role in septic shock, disseminated intravascular coagulation (DIC), and adult respiratory distress syndrome, mainly through induction of excessive levels of cytokines such as TNF, IL-1, and IL-12. LPS binds to the cell-surface receptor CD14, and the complex then binds to Toll-like receptor 4 (TLR4), a pattern recognition receptor that activates cells of the innate immune system.

Exotoxins are secreted bacterial proteins that cause cellular injury and disease. They can be classified into broad categories by their site or mechanism of action. These are briefly described next and discussed in more detail in the specific sections about each type of bacteria.

- **Enzymes.** Bacteria secrete a variety of enzymes (proteases, hyaluronidases, coagulases, fibrinolysins) that act on their respective substrates in vitro, but the role of only a few of these in disease is understood. For example, exfoliative toxins produced by *S. aureus* cause staphylococcal scalded skin syndrome by degrading proteins that hold keratinocytes together, causing the epidermis to detach from the deeper skin.
- **Toxins that alter intracellular signaling or regulatory pathways.** Most of these toxins have an active (A) subunit with enzymatic activity and a binding (B) subunit that binds to receptors on the cell surface and delivers the A subunit into the cell cytoplasm. The effects of these toxins are diverse and depend on the binding specificity of the B domain and the cellular pathways affected by the A domain. A-B toxins are made by many bacteria including *Bacillus anthracis*, *V. cholerae*, and some strains of *E. coli*.
- **Neurotoxins** produced by *Clostridium botulinum* and *Clostridium tetani* inhibit release of neurotransmitters, resulting in paralysis. These toxins do not kill neurons; instead, the A domains interact specifically with proteins involved in secretion of neurotransmitters at the synaptic junction. Both tetanus and botulism can result in death from respiratory failure due to paralysis of the chest and diaphragm muscles.
- **Superantigens** are bacterial toxins that stimulate very large number of T lymphocytes by binding to conserved portions of the T-cell receptor, leading to massive T-lymphocyte proliferation and cytokine release. The high levels of cytokines can lead to capillary leak and shock. Superantigens made by *S. aureus* and *S. pyogenes* cause toxic shock syndrome (TSS).

KEY CONCEPTS

How Microorganisms Cause Disease

- Diseases caused by microbes involve interplay between microbial virulence factors and host responses.
- Infectious agents cause death or dysfunction by directly interacting with the cell.

- Injury may be due to local or systemic release of microbial products including endotoxin (LPS), exotoxins or superantigens.
- Pathogens can induce immune responses that cause tissue damage. Absence of an immune response may reduce damage induced by some infections; conversely, immune compromise can allow uncontrolled expansion of opportunistic agents or of microorganisms that can directly cause injury.

Sexually Transmitted Infections

A variety of organisms can be transmitted through sexual contact (Table 8-3). Groups at greater risk for sexually transmitted infections (STIs) include adolescents, men who have sex with men, and people who use illegal drugs parenterally. While the increased risk among these groups is partially due to unsafe sexual practices, limited access to health care is often a contributing factor. The presence of an STI in children, unless acquired during birth, strongly suggests sexual abuse.

Some pathogens, such as *C. trachomatis* and *N. gonorrhoeae*, are almost always spread by sexual intercourse, whereas others, such as *Shigella* species and *E. histolytica*, are typically spread by other means, but are also occasionally spread by oral-anal sex. To reduce the spread of STIs, it is expected that these infections be reported to public health authorities so that people who have had intimate contact with the person may be tested and treated.

Although the various pathogens that cause STIs differ in many ways, some general features should be noted.

- STIs may become established and spread from the urethra, vagina, cervix, rectum, or oral pharynx. Organisms that

cause STIs depend on direct contact for person-to-person spread because these pathogens do not survive in the environment. Transmission of STIs often occurs from asymptomatic people who do not realize that they have an infection.

- Infection with one STI-associated organism increases the risk for additional STIs. This is mainly because the risk factors are the same for all STIs. In addition, the epithelial injury caused by *N. gonorrhoeae* or *C. trachomatis* can increase the chance of co-infection with the other, as well as the risk of HIV infection if there is concomitant exposure.
- The microbes that cause STIs can be spread from a pregnant woman to the fetus and cause severe damage to the fetus or child. Perinatally acquired *C. trachomatis* causes conjunctivitis, and neonatal HSV infection is much more likely to cause visceral and CNS disease than is infection acquired later in life. Syphilis frequently causes miscarriage. HIV infection may be fatal to children infected with the virus prenatally or perinatally. Diagnosis of STIs in pregnant women is critical, because intrauterine or neonatal transmission of STIs can often be prevented by treatment of the mother or newborn. Antiretroviral treatment of pregnant women with HIV infection and their newborn infants can reduce the transmission of HIV to offspring from 25% to less than 2%.

Syphilis is discussed later in this chapter, and other STIs are described in Chapters 21 and 22.

Spectrum of Inflammatory Responses to Infection

In contrast to the vast molecular diversity of microbes, the morphologic patterns of tissue responses to microbes are limited, as are the mechanisms directing these responses.

Table 8-3 Classification of Important Sexually Transmitted Diseases

Pathogens	Disease or Syndrome and Population Principally Affected		
	Males	Females	Both
Viruses			
Herpes simplex virus			Primary and recurrent herpes, neonatal herpes
Hepatitis B virus			Hepatitis
Human papillomavirus	Cancer of penis (some cases)	Cervical dysplasia and cancer, vulvar cancer	Condyloma acuminatum
Human immunodeficiency virus			Acquired immunodeficiency syndrome
Chlamydiae			
<i>Chlamydia trachomatis</i>	Urethritis, epididymitis, proctitis	Urethral syndrome, cervicitis, Bartholinitis, salpingitis and sequelae	Lymphogranuloma venereum
Mycoplasmas			
<i>Ureaplasma urealyticum</i>	Urethritis		
Bacteria			
<i>Neisseria gonorrhoeae</i>	Epididymitis, prostatitis, urethral stricture	Cervicitis, endometritis, Bartholinitis, salpingitis, and sequelae (infertility, ectopic pregnancy, recurrent salpingitis)	Urethritis, proctitis, pharyngitis, disseminated gonococcal infection
<i>Treponema pallidum</i>			Syphilis
<i>Haemophilus ducreyi</i>			Chancroid
<i>Klebsiella granulomatis</i>			Granuloma inguinale (donovanosis)
Protozoa			
<i>Trichomonas vaginalis</i>	Urethritis, balanitis	Vaginitis	

Table 8-4 Spectrum of Inflammatory Responses to Infection

Type of Response	Pathogenesis	Examples
Suppurative (Purulent) Infection	Increased vascular permeability Leukocyte infiltration (neutrophils) Chemoattractants from bacteria Formation of “pus”	Staphylococcal pneumonia Tissue abscesses
Mononuclear and granulomatous inflammation	Mononuclear cell infiltrates (monocytes, macrophages, plasma cells, lymphocytes) Cell-mediated immune response to pathogens (“persistent antigen”) Formation of granulomata	Syphilis Tuberculosis
Cytopathic-cytoproliferative reactions	Viral transformation of cells Necrosis or proliferation (including multinucleation) Linked to neoplasia	Human Papilloma Virus Herpesvirus
Tissue necrosis	Toxin or lysis mediated destruction Lack of inflammatory cells Rapidly progressive processes	<i>Clostridium perfringens</i> Hepatitis B
Chronic inflammation/scarring	Repetitive injury leads to fibrosis Loss of normal parenchyma	Chronic hepatitis (cirrhosis)
No reaction	Severe immune compromise	<i>Mycobacterium avium</i> in untreated AIDS (T-cell deficiency) Mucormycosis in bone marrow transplant patients (neutropenia)

Therefore, many pathogens produce similar reaction patterns, and few features are unique or pathognomonic for a particular microorganism. Moreover, sometimes the nature of the interaction between the microorganism and the host determines the histologic features of the inflammatory response. Thus, pyogenic bacteria, which normally evoke vigorous leukocyte responses, may cause rapid tissue necrosis with little leukocyte exudation in a profoundly neutropenic host. Similarly, in a normal patient, *M. tuberculosis* causes well-formed granulomas with few mycobacteria present, whereas in an AIDS patient the same mycobacteria multiply profusely in macrophages, which fail to coalesce into granulomas, which are summarized in [Table 8-4](#) and described below.

There are five major histologic patterns of tissue reaction in infections.

Suppurative (Purulent) Inflammation

This pattern is characterized by increased vascular permeability and leukocytic infiltration, predominantly of neutrophils ([Fig. 8-4](#)). The neutrophils are attracted to the site of infection by release of chemoattractants from the “pyogenic” (pus-forming) bacteria that evoke this response, mostly extracellular gram-positive cocci and gram-negative rods. Masses of dying and dead neutrophils and liquefactive necrosis of the tissue form pus. The sizes of purulent lesions range from tiny microabscesses formed in multiple organs during bacterial sepsis secondary to a colonized heart valve, to diffuse involvement of entire lobes of the lung in pneumonia. How destructive the lesions are depends on their location and the organism involved. For example, pneumococci usually spare alveolar walls and cause lobar pneumonia that resolves completely, whereas staphylococci and *Klebsiella* species destroy alveolar walls and form abscesses that heal with scar formation. Bacterial pharyngitis resolves without sequelae, whereas untreated acute bacterial inflammation of a joint can destroy the joint in a few days.

Mononuclear and Granulomatous Inflammation

Diffuse, predominantly mononuclear, interstitial infiltrates are a common feature of all chronic inflammatory processes, but when they develop acutely, they often are a response to viruses, intracellular bacteria, or intracellular parasites. In addition, spirochetes and helminths provoke chronic inflammatory responses. Which mononuclear cell predominates within the inflammatory lesion depends on the host immune response to the organism. For example, plasma cells are abundant in the primary and secondary lesions of syphilis ([Fig. 8-5](#)), whereas lymphocytes predominate in HBV infection or viral infections of the brain. The presence of these lymphocytes reflects cell-mediated immune responses against the pathogen or pathogen-infected cells. At the other extreme, macrophages may become filled with organisms, as occurs in *M. avium-intracellulare* infections in AIDS patients, who cannot mount an effective immune response to the organisms. *Granulomatous inflammation* is a distinctive form of

Figure 8-4 Suppurative (purulent) infection. Pneumococcal pneumonia with extensive neutrophilic infiltrate.

Figure 8-5 Secondary syphilis in the dermis with perivascular lymphoplasmacytic infiltrate and endothelial proliferation.

mononuclear inflammation usually evoked by infectious agents that resist eradication and are capable of stimulating strong T cell-mediated immunity (e.g., *M. tuberculosis*, *Histoplasma capsulatum*, schistosome eggs). Granulomatous inflammation is characterized by accumulation and aggregation of activated macrophages called “epithelioid” cells, some of which may fuse to form giant cells. Granulomas may contain a central area of caseous necrosis (see [Chapter 3](#) and “Tuberculosis” in this chapter).

Cytopathic-Cytoproliferative Reaction

These reactions are usually produced by viruses. The lesions are characterized by cell necrosis or cellular proliferation, usually with sparse inflammatory cells. Some viruses replicate within cells and make viral aggregates that are visible as inclusion bodies (e.g., herpesviruses or adenovirus) or induce cells to fuse and form multinucleated cells called polykaryons (e.g., measles virus or herpesviruses). Focal cell damage in the skin may cause epithelial cells to become detached, forming blisters ([Fig. 8-6](#)). Some viruses can cause epithelial cells to proliferate (e.g., venereal warts caused by HPV or the umbilicated papules of molluscum contagiosum caused by poxviruses). Finally, viruses can contribute to the development of malignant neoplasms ([Chapter 7](#)).

Figure 8-6 Herpesvirus blister in mucosa. See [Figure 8-9](#) for viral inclusions.

Figure 8-7 *Schistosoma haematobium* infection of the bladder with numerous calcified eggs and extensive scarring.

Tissue Necrosis

Clostridium perfringens and other organisms such as *C. diphtheriae* that secrete powerful toxins cause such rapid and severe necrosis (gangrenous necrosis) that tissue damage is the dominant feature. The parasite *E. histolytica* causes colonic ulcers and liver abscesses characterized by extensive tissue destruction with liquefactive necrosis and little inflammatory infiltrate. Some viruses can cause widespread and severe necrosis of host cells associated with inflammation, as exemplified by total destruction of the temporal lobes of the brain by herpesvirus or the liver by HBV.

Chronic Inflammation and Scarring

Many infections elicit chronic inflammation, which can lead either to complete healing or to extensive scarring. For example, chronic HBV infection may cause cirrhosis of the liver, in which dense fibrous septae surround nodules of regenerating hepatocytes with complete loss of normal liver architecture and consequent changes in blood flow. Sometimes the exuberant scarring response is the major cause of dysfunction (e.g., the “pipestem” fibrosis of the liver or fibrosis of the bladder wall caused by schistosomal eggs [[Fig. 8-7](#)] or the constrictive fibrous pericarditis in tuberculosis).

These patterns of tissue reaction are useful guidelines for analyzing microscopic features of infectious processes, but they rarely appear in pure form because different types of host reactions often occur at the same time. For example, the lung of an AIDS patient may be infected with CMV, which causes cytolytic changes, and at the same time by *Pneumocystis*, which causes interstitial inflammation. Similar patterns of inflammation also can be seen in tissue responses to physical or chemical agents and in inflammatory diseases of unknown cause ([Chapter 3](#)).

Special Techniques for Diagnosing Infectious Agents

The gold standards for diagnosis of infections are culture, biochemical or serologic identification, and, in some cases, molecular diagnosis, depending on the organism in question. Some infectious agents or their products can be directly observed in hematoxylin and eosin-stained

Table 8-5 Special Techniques for Diagnosing Infectious Agents

Techniques	Infectious Agents
Gram stain	Most bacteria
Acid-fast stain	Mycobacteria, nocardiae (modified)
Silver stains	Fungi, legionellae, <i>Pneumocystis</i>
Periodic acid-Schiff	Fungi, amoebae
Mucicarmine	Cryptococci
Giemsa	<i>Campylobacter</i> , leishmaniae, malaria parasites
Antibody stains	All classes
Culture	All classes
DNA probes	All classes

sections (e.g., the inclusion bodies formed by CMV and herpes simplex virus [HSV]; bacterial clumps, which usually stain blue; *Candida* and *Mucor* among the fungi; most protozoans; and all helminths). Many infectious agents, however, are best visualized by special stains that identify organisms on the basis of particular characteristics of their cell wall or coat—Gram, acid-fast, silver, mucicarmine, and Giemsa stains—or by staining with specific antibodies (Table 8-5). Regardless of the staining technique, organisms are typically easiest to identify at the advancing edge of a lesion rather than at its center, particularly if there is necrosis. Acute infections can be diagnosed serologically by detecting pathogen-specific antibodies in the serum. The presence of specific IgM antibody shortly after the onset of symptoms is often diagnostic. Alternatively, specific antibody titers can be measured during the early, acute infection and again 4-6 weeks later during the convalescent period; a four-fold rise in titer is usually considered diagnostic.

Nucleic acid amplification tests, such as polymerase chain reaction (PCR) and transcription-mediated amplification, are increasingly being used for rapid identification of microbes. These molecular diagnostic assays have become routine for diagnosis of gonorrhea, chlamydial infection, tuberculosis, and herpes encephalitis. In some cases, molecular assays are much more sensitive than conventional testing. PCR testing of cerebrospinal fluid (CSF) for HSV encephalitis has a sensitivity of about 80%, while viral culture of CSF has a sensitivity of less than 10%. Similarly, nucleic acid testing for genital *Chlamydia* detects 10% to 30% more infections than does conventional *Chlamydia* culture. In other cases, such as gonorrhea, the sensitivity of nucleic acid testing is similar to that of culture. In people infected with HIV, quantification of HIV RNA is an important guide to management of antiretroviral therapy. The management of HBV and HCV infections is similarly guided by nucleic acid–based viral quantification or typing to predict resistance to antiviral drugs. Mass spectroscopy is another technique that identifies specific components of an infectious agent by size and charge distribution and can allow for the rapid identification of cultured bacteria.

This concludes our discussion of the general principles of the pathogenesis and pathology of infectious disease. We now turn to specific infections caused by viruses, bacteria, fungi, and parasites, and focuses on their *pathogenic mechanisms* and *pathologic changes* rather than details of

clinical features, which are available in clinical textbooks. Infections that typically involve a specific organ are discussed in other chapters.

Viral Infections

Viruses are the cause of many clinically important acute and chronic infections, which may affect virtually every organ system (Table 8-6).

Acute (Transient) Infections

The viruses that cause transient infections are structurally heterogeneous, but all elicit effective immune responses that eliminate the pathogens, limiting the durations of the infections. However, specific viruses exhibit widely differing degrees of genetic diversity, a variable that has an important impact on the susceptibility of the host to re-infection by viruses of the same type. The mumps virus, for example, has only one genetic subtype and infects people only once, whereas other viruses, such as influenza viruses, can repeatedly infect the same individual because

Table 8-6 Selected Human Viruses and Viral Diseases

Organ System	Species	Disease
Respiratory	Adenovirus	Upper and lower respiratory tract infections, conjunctivitis, diarrhea
	Rhinovirus	Upper respiratory tract infection
	Influenza viruses A, B Respiratory syncytial virus	Influenza Bronchiolitis, pneumonia
Digestive	Mumps virus	Mumps, pancreatitis, orchitis
	Rotavirus	Childhood gastroenteritis
	Norovirus	Gastroenteritis
	Hepatitis A virus	Acute viral hepatitis
	Hepatitis B virus	Acute or chronic hepatitis
	Hepatitis D virus	With HBV, acute or chronic hepatitis
Systemic with skin eruptions	Hepatitis C virus	Acute or chronic hepatitis
	Hepatitis E virus	Enterically transmitted hepatitis
	Measles virus	Measles (rubeola)
	Rubella virus	German measles (rubella)
	Varicella-zoster virus	Chickenpox, shingles
Systemic with hematopoietic disorders	Herpes simplex virus 1	Oral herpes (“cold sore”)
	Herpes simplex virus 2	Genital herpes
	Cytomegalovirus	Cytomegalic inclusion disease
Arboviral and hemorrhagic fevers	Epstein-Barr virus	Infectious mononucleosis
	HIV-1 and HIV-2	AIDS
Skin/genital warts	Dengue virus 1-4	Dengue hemorrhagic fever
	Yellow fever virus	Yellow fever
Central nervous system	Papillomavirus	Condyloma; cervical carcinoma
	Poliovirus	Poliomyelitis
	JC virus	Progressive multifocal leukoencephalopathy (opportunistic)

new genetic variants arise periodically in nature. Immunity to some viruses wanes with time, and this too may allow the same virus to infect the host repeatedly (e.g., respiratory syncytial virus).

Measles

Measles is an acute viral infection that affects multiple organs and causes a wide range of disease, from mild, self-limited infections to severe systemic manifestations.

Measles (rubeola) virus is a leading cause of vaccine-preventable death and illness worldwide. More than 20 million people acquire measles each year. In 2010, measles accounted for an estimated 139,000 deaths globally, the majority in children in developing countries. Because of poor nutrition and lack of access to medical care, children in developing countries are 10 to 1000 times more likely to die of measles than are children in developed countries. Measles can produce severe disease in people with defects in cellular immunity (e.g., people infected with HIV or people with a hematologic malignancy). Epidemics of measles occur among unvaccinated individuals. In the United States, the incidence of measles has decreased dramatically since 1963, when a measles vaccine was licensed, and endemic transmission was eliminated in 2000. The diagnosis may be made clinically, by serology, or by detection of viral antigen in nasal exudates or urinary sediments.

Pathogenesis. Measles virus is a single-stranded RNA virus of the paramyxovirus family, which includes mumps, respiratory syncytial virus, parainfluenza virus (a cause of croup), and human metapneumovirus. There is only one serotype of measles virus. Measles virus is transmitted by respiratory droplets. Three cell-surface receptors have been identified for the virus: CD46 (a complement-regulatory protein that inactivates C3 convertases), signaling lymphocytic activation molecule (SLAM, a molecule involved in T-cell activation), and nectin 4 (adherens junction protein). CD46 is expressed on all nucleated cells, while SLAM is expressed on cells of the immune system, and nectin 4 is expressed on epithelial cells. All of these receptors bind the viral hemagglutinin protein.

Measles can replicate in a variety of cell types, including epithelial cells and leukocytes. The virus initially multiplies within the respiratory tract and then spreads to local lymphoid tissues. Replication of the virus in lymphatic tissue is followed by viremia and systemic dissemination to many tissues, including the conjunctiva, skin, respiratory tract, urinary tract, small blood vessels, lymphatic system, and CNS. Most children develop T-cell-mediated immunity to measles virus that helps control the viral infection and produces the measles rash. Hence, the rash is less frequent in people with deficiencies in cell-mediated immunity. In addition, in malnourished children with poor medical care, measles virus may cause croup, pneumonia, diarrhea and protein-losing enteropathy, keratitis leading to scarring and blindness, encephalitis, and hemorrhagic rashes (“black measles”).

Antibody-mediated immunity to measles virus protects against reinfection. Measles also can cause transient but profound immunosuppression, resulting in secondary bacterial and viral infections, which are responsible for much of measles-related morbidity and mortality. Alterations of

both innate and adaptive immune responses occur following measles infection, including defects in dendritic cell and lymphocyte function. Subacute sclerosing panencephalitis ([Chapter 28](#)) and measles inclusion body encephalitis (in immunocompromised individuals) are rare late complications of measles. The pathogenesis of subacute sclerosing panencephalitis is not well understood, but a replication-defective variant of measles may be involved in this persistent viral infection.

MORPHOLOGY

The blotchy, reddish brown rash of measles virus infection on the face, trunk, and proximal extremities is produced by dilated skin vessels, edema, and a mononuclear perivascular infiltrate. Ulcerated mucosal lesions in the oral cavity near the opening of the Stensen ducts (the pathognomonic **Koplik spots**) are marked by necrosis, neutrophilic exudate, and neovascularization. The lymphoid organs typically have marked follicular hyperplasia, large germinal centers, and randomly distributed multinucleate giant cells, called **Warthin-Finkeldey cells**, which have eosinophilic nuclear and cytoplasmic inclusion bodies. These are pathognomonic of measles and are also found in the lung and sputum ([Fig. 8-8](#)). The milder forms of measles pneumonia show the same peribronchial and interstitial mononuclear cell infiltration that is seen in other nonlethal viral infections.

Mumps

Mumps is an acute systemic viral infection usually associated with pain and swelling of the salivary glands. Like measles virus, mumps virus is a member of the paramyxovirus family. Mumps virus has two types of surface glycoproteins, one with hemagglutinin and neuraminidase activities and the other with cell fusion and cytolytic activities. Mumps viruses enter the upper respiratory tract through inhalation of respiratory droplets, spread to draining lymph nodes where they replicate in lymphocytes (preferentially in activated T cells), and then spread through the blood to the salivary and other glands. Mumps virus infects salivary gland ductal epithelial cells, resulting in desquamation of involved cells, edema, and inflammation that leads to the classic salivary gland pain and swelling.

Figure 8-8 Measles giant cells in the lung. Note the glassy eosinophilic intranuclear inclusions.

Mumps virus also can spread to other sites, including the CNS, testis, ovary, and pancreas. Aseptic meningitis is the most common extrasalivary gland complication of mumps infection, occurring in up to 15% of cases. The mumps vaccine has reduced the incidence of mumps by 99% in the United States. The diagnosis is usually made clinically, but serology, viral culture, or PCR assays can be used for definitive diagnosis.

MORPHOLOGY

Mumps parotitis is bilateral in 70% of cases. The affected glands are enlarged, have a doughy consistency, and are moist, glistening, and reddish-brown on cross-section. On microscopic examination the gland interstitium is edematous and diffusely infiltrated by macrophages, lymphocytes, and plasma cells, which compress acini and ducts. Neutrophils and necrotic debris may fill the duct lumen and cause focal damage to the lining epithelium.

In **mumps orchitis** testicular swelling may be marked, caused by edema, mononuclear cell infiltration, and focal hemorrhages. Because the testis is tightly contained within the tunica albuginea, parenchymal swelling may compromise the blood supply and cause areas of infarction. The testicular damage can lead to scarring, atrophy, and, if severe, sterility.

Infection and damage of acinar cells in the **pancreas** may release digestive enzymes, causing parenchymal and fat necrosis and neutrophil-rich inflammation. **Mumps encephalitis** causes perivenous demyelination and perivascular mononuclear cuffing.

Poliovirus Infection

Poliovirus causes an acute systemic viral infection, leading to a wide range of manifestations, from mild, self-limited infections to paralysis of limb muscles and respiratory muscles. Poliovirus is a spherical, unencapsulated RNA virus of the enterovirus genus. Other enteroviruses cause childhood diarrhea as well as rashes (coxsackievirus A), conjunctivitis (enterovirus 70), viral meningitis (coxsackieviruses and echovirus), and myopericarditis (coxsackievirus B). There are three serotypes of poliovirus, each of which is included in the Salk formalin-fixed (killed) vaccine and the Sabin oral, attenuated (live) vaccine. These vaccines have nearly eradicated polio, because the poliovirus infects only humans, shows limited genetic variation, and is effectively neutralized by antibodies generated by immunization. Nevertheless, this scourge persists in parts of the developing world, particularly in areas of political unrest and war. According to global polio surveillance data, in 2013, a total of 328 polio cases were reported from Afghanistan, Cameroon, Ethiopia, Kenya, Nigeria, Pakistan, Somalia, and Syria.

Poliovirus, like other enteroviruses, is transmitted by the fecal-oral route. The virus infects human cells by binding to CD155, an epithelial adhesion molecule. The virus is ingested and replicates in the mucosa of the pharynx and gut, including tonsils and Peyer patches in the ileum. Poliovirus then spreads through lymphatics to lymph nodes and eventually the blood, producing transient viremia and fever. Although most poliovirus infections are asymptomatic, in about 1 of 100 infected persons poliovirus invades the CNS and replicates in motor neurons

of the spinal cord (spinal poliomyelitis) or brain stem (bulbar poliomyelitis). Antiviral antibodies control the disease in most cases; it is not known why they fail to contain the virus in some individuals. Viral spread to the nervous system may be through the blood or by retrograde transport of the virus along axons of motor neurons. Rare cases of poliomyelitis that occur after vaccination are caused by mutations of the attenuated viruses to wild-type forms. The diagnosis can be made by viral culture or PCR of throat secretions or stool, or by serology. The neurologic features and neuropathology of poliovirus infection are described in [Chapter 28](#).

West Nile Virus

West Nile Virus is an acute systemic viral infection that causes a mild, self-limited infection or neuroinvasive disease associated with long-term neurologic sequelae.

West Nile virus is an arthropod-borne virus (arbovirus) of the flavivirus group, which also includes viruses that cause dengue fever and yellow fever. West Nile virus has a broad geographic distribution in the Old World, including Africa, the Middle East, Europe, Southeast Asia, and Australia. It was first detected in the United States in 1999 during an outbreak in New York City, and has since spread across the United States; in the year 2013, a least one case was reported in 44 states. West Nile virus is transmitted by mosquitoes to birds and to mammals. Infected birds develop prolonged viremia and are the major reservoir for the virus. Humans are incidental hosts. Most affected patients acquire the infection from a mosquito bite; less commonly, human-to-human transmission occurs by blood transfusion, organ transplantation, breast-feeding, or transplacental spread.

After inoculation by a mosquito, West Nile virus replicates in skin dendritic cells, which then migrate to lymph nodes. Here, the virus replicates further, enters the bloodstream, and, in some individuals, crosses the blood-brain barrier. In the CNS, the virus infects neurons. Chemokines have critical roles in recruiting leukocytes to the CNS, where they assist in viral clearance. The chemokine receptor CCR5 contributes to resistance to neuroinvasive infection, hence mutations in both copies of the CCR5 gene that lead to loss of function are associated with an increased rate of symptomatic infection. Recall that in HIV infection the role of this receptor is the opposite—CCR5 loss-of-function is protective because HIV uses the receptor to infect host T cells ([Chapter 6](#)).

West Nile virus infection is usually asymptomatic, but in 20% of infected individuals it gives rise to a fever, headache, myalgia, fatigue, anorexia, and nausea. A maculopapular rash is seen in approximately half the cases. CNS complications (meningitis, encephalitis, meningoencephalitis) occur in about 1 in 150 clinically apparent infections. Meningoencephalitis has a mortality of about 10% and results in long-term cognitive and neurologic impairment in many survivors. Perivascular and leptomeningeal chronic inflammation, microglial nodules ([Chapter 28](#)), and neuronophagia predominantly involving the temporal lobes and brain stem have been observed in patients who died of West Nile virus infection. Immunosuppressed persons and older adults appear to be at the greatest risk for severe disease. Rare complications include hepatitis, myocarditis, and pancreatitis. The diagnosis is usually

made by serology, but viral culture and PCR-based tests are also used.

Viral Hemorrhagic Fever

Viral hemorrhagic fever (VHF) is a severe life-threatening multisystem syndrome in which there is vascular dysregulation and damage, leading to shock. VHF is caused by enveloped RNA viruses belonging to four different genera: Arenaviridae, Filoviridae, Bunyaviridae, and Flaviviridae. These viruses can produce a spectrum of illnesses, ranging from a mild acute disease characterized by fever, headache, myalgia, rash, neutropenia, and thrombocytopenia to severe, life-threatening disease in which there is sudden hemodynamic deterioration and shock. All these viruses pass through an animal or insect host during their life cycles and therefore their ranges are restricted to areas in which their hosts reside. Humans are incidental hosts who are infected when they come into contact with infected hosts (typically rodents) or insect vectors (mosquitoes and ticks). Some viruses that cause hemorrhagic fever (Ebola, Marburg, Lassa) also can spread from person to person.

The pathogenesis of the infection and its complications vary among the different viruses but there are some common features. Damage to blood vessels is often prominent. It may be caused by direct infection of and damage to endothelial cells, or infection of macrophages and dendritic cells leading to production of inflammatory cytokines. There may be hemorrhagic manifestations, including petechiae, caused by a combination of thrombocytopenia or platelet dysfunction, endothelial injury, cytokine-induced disseminated intravascular coagulation, and deficiency of clotting factors because of hepatic injury. Hemorrhages may be prominent in some infections (e.g. Congo-Crimean fever) but are rarely life-threatening. Necrosis of tissues secondary to the vascular lesions and hemorrhages may be seen and varies from mild and focal to massive, but the attendant inflammatory response is usually minimal.

Latent Infections (Herpesvirus Infections)

Latency is defined as the persistence of viral genomes in cells that do not produce infectious virus. Dissemination of the infection and tissue injury stem from reactivation of the latent virus. The viruses that most frequently establish latent infections in humans are *herpesviruses*. These are large encapsulated viruses with double-stranded DNA genomes that encode approximately 70 proteins. Herpesviruses cause acute infection followed by latent infection in which the viruses persist in a noninfectious form with periodic reactivation and shedding of infectious virus.

There are eight types of human herpesviruses, belonging to three subgroups that are defined by the type of cell most frequently infected and the site of latency: α -group viruses, including HSV-1, HSV-2, and VZV, which infect epithelial cells and produce latent infection in neurons; lymphotropic β -group viruses, including CMV, human herpesvirus-6 (which causes exanthem subitum, also known as roseola infantum and sixth disease, a benign rash of infants), and human herpesvirus-7 (a virus without a known disease association), which infect and produce latent infection in a variety of cell types; and the γ -group

viruses EBV and KSHV/HHV-8, the cause of Kaposi sarcoma, which produce latent infection mainly in lymphoid cells. In addition, herpesvirus simiae (monkey B virus) is an Old World monkey virus that resembles HSV-1 and can cause fatal neurologic disease in animal handlers, usually resulting from an animal bite.

Herpes Simplex Viruses

HSV-1 and HSV-2 differ serologically but are closely related genetically and cause a similar set of primary and recurrent infections. Both viruses replicate in the skin and the mucous membranes at the site of entry of the virus (usually oropharynx or genitals), where they produce infectious virions and cause vesicular lesions of the epidermis. The viruses spread to sensory neurons that innervate these primary sites of replication. Viral nucleocapsids are transported along axons to the neuronal cell bodies, where the viruses establish latent infection. In immunocompetent hosts, primary HSV infection resolves in a few weeks, although the virus remains latent in nerve cells. During latency the viral DNA remains within the nucleus of the neuron, and only latency-associated viral RNA transcripts (LATs) are synthesized. No viral proteins appear to be produced during latency. LATs may contribute to latency by conferring resistance to apoptosis, silencing lytic gene expression through heterochromatin formation, and serving as precursors for microRNAs that downregulate expression of critical HSV lytic genes. Reactivation of HSV-1 and HSV-2 may occur repeatedly with or without symptoms, and results in the spread of virus from the neurons to the skin or to mucous membranes. Reactivation can occur in the presence of host immunity, because HSVs have developed ways to avoid immune recognition. For example, HSVs can evade antiviral CTLs by inhibiting the MHC class I recognition pathway, and elude humoral immune defenses by producing receptors for the Fc domain of immunoglobulin and inhibitors of complement.

In addition to causing cutaneous lesions, HSV-1 is the major infectious cause of corneal blindness in the United States. Corneal epithelial disease is thought to be due to direct viral damage, while corneal stromal disease appears to be immune-mediated. HSV-1 is also the major cause of fatal sporadic encephalitis in the United States. When the infection spreads to the brain, it usually involves the temporal lobes and orbital gyri of the frontal lobes. Inherited mutations in TLR3 or components of its signaling pathway increase the risk of HSV encephalitis. In addition, neonates and individuals with compromised cellular immunity (e.g., secondary to HIV infection or chemotherapy) may suffer disseminated herpesvirus infections. HSV-2 infection increases the risk of HIV transmission by four-fold and increases the risk of HIV acquisition by two- to three-fold.

MORPHOLOGY

HSV-infected cells contain large, pink to purple **intranuclear inclusions** (Cowdry type A) that consist of viral replication proteins and virions at various stage of assembly that push the host cell chromatin out to the edges of the nucleus (Fig. 8-9). Due to cell fusion, HSVs also produces inclusion-bearing multinucleated syncytia.

Figure 8-9 A herpesvirus blister showing glassy intranuclear viral inclusion bodies.

HSV-1 and HSV-2 cause lesions ranging from self-limited cold sores and gingivostomatitis to life-threatening disseminated visceral infections and encephalitis. **Fever blisters or cold sores** favor the facial skin around mucosal orifices (lips, nose), where their distribution is frequently bilateral and independent of skin dermatomes. Intraepithelial vesicles (blisters), which are formed by intracellular edema and ballooning degeneration of epidermal cells, frequently burst and crust over, but some may result in superficial ulcerations.

Gingivostomatitis, which is usually encountered in children, is caused by HSV-1. It is a vesicular eruption extending from the tongue to the retropharynx and causing cervical lymphadenopathy. Swollen, erythematous HSV lesions of the fingers or palm (herpetic whitlow) occur in infants and, occasionally, in health care workers.

Genital herpes is more often caused by HSV-2 than by HSV-1. It is characterized by vesicles on the genital mucous membranes as well as on the external genitalia that are rapidly converted into superficial ulcerations, rimmed by an inflammatory infiltrate (Chapter 22). Herpesvirus (usually HSV-2) can be transmitted to neonates during passage through the birth canal of infected mothers. Although HSV-2 infection in the neonate may be mild, more commonly it is fulminating with generalized lymphadenopathy, splenomegaly, and necrotic foci throughout the lungs, liver, adrenals, and CNS.

Two forms of **corneal lesions** are caused by HSV (Chapter 29). **Herpes epithelial keratitis** shows typical virus-induced cytolysis of the superficial epithelium. In contrast, **herpes stromal keratitis** is characterized by infiltrates of mononuclear cells around keratinocytes and endothelial cells, leading to neovascularization, scarring, opacification of the cornea, and eventual blindness. Here, the damage is caused by an immunologic reaction to the HSV infection, rather than the cytopathic effects of the virus itself.

Herpes simplex encephalitis is described in Chapter 28.

Disseminated skin and visceral herpes infections are usually encountered in hospitalized patients with some form of underlying cancer or immunosuppression. **Herpes esophagitis** is frequently complicated by superinfection with bacteria or fungi. **Herpes bronchopneumonia**, sometimes stemming from intubation of a patient with active oral lesions, is often necrotizing, and **herpes hepatitis** may cause liver failure.

Varicella-Zoster Virus (VZV)

Acute infection with VZV causes chickenpox and reactivation of latent VZV causes shingles (also called herpes zoster). Chickenpox is mild in children but more severe in adults and in immunocompromised people. Shingles is a source of morbidity in older and immunosuppressed persons. Like HSV, VZV infects mucous membranes, skin, and neurons and causes a self-limited primary infection in immunocompetent individuals. Also like HSV, VZV evades immune responses and establishes a latent infection in sensory ganglia. In contrast to HSV, VZV is transmitted in epidemic fashion by respiratory aerosols, disseminates hematogenously, and causes widespread vesicular skin lesions. Latent VZV infection is seen in neurons and/or satellite cells around neurons in the dorsal root ganglia. Reactivation and clinical recurrences causing shingles are uncommon but may occur many years after the primary infection. Localized recurrence of VZV is most frequent and painful in dermatomes innervated by the trigeminal ganglia, where the virus is most likely to be latent. VZV rarely recurs in immunocompetent individuals (in only 1-4% of infected individuals), but immunosuppressed or older persons can have multiple recurrences of VZV. For this reason, vaccination to prevent shingles is now recommended in all patients over age 60 years, and in younger adults with chronic disorders that may impair immunity. VZV infection is diagnosed by viral culture or detection of viral antigens in cells scraped from superficial lesions.

MORPHOLOGY

The **chickenpox** rash occurs approximately 2 weeks after respiratory infection. Lesions appear in multiple waves centrifugally from the torso to the head and extremities. Each lesion progresses rapidly from a macule to a vesicle, which resembles a dewdrop on a rose petal. On histologic examination, chickenpox lesions show intraepithelial vesicles (Fig. 8-10) with intranuclear inclusions in epithelial cells at the base of the vesicles. After a few days most chickenpox vesicles rupture, crust over, and heal by regeneration, leaving no scars. However, bacterial superinfection of vesicles that are ruptured by trauma may lead to destruction of the basal epidermal layer and residual scarring.

Shingles occurs when VZV that has long remained latent in the dorsal root ganglia after a previous chickenpox infection is reactivated and infects sensory nerves that carry it to one or

Figure 8-10 Skin lesion of chickenpox (varicella-zoster virus) with intraepithelial vesicle.

Figure 8-11 Dorsal root ganglion with varicella-zoster virus infection. Note the ganglion cell necrosis and associated inflammation. (Courtesy Dr. James Morris, Radcliffe Infirmary, Oxford, England.)

more dermatomes. There, the virus infects keratinocytes and causes vesicular lesions, which, unlike chickenpox, are often associated with intense itching, burning, or sharp pain because of concomitant radiculoneuritis. This pain is especially severe when the trigeminal nerves are involved; rarely, the geniculate nucleus is involved, causing facial paralysis (Ramsay Hunt syndrome). The sensory ganglia contain a dense, predominantly mononuclear infiltrate, with herpetic intranuclear inclusions within neurons and their supporting cells (Fig. 8-11). VZV can also cause interstitial pneumonia, encephalitis, transverse myelitis, and necrotizing visceral lesions, particularly in immunosuppressed people.

Cytomegalovirus

Cytomegalovirus (CMV), a β -group herpesvirus, can produce a variety of disease manifestations, depending on the age of the host, and, more importantly, on the host's immune status. CMV latently infects monocytes and their bone marrow progenitors and can be reactivated when cellular immunity is depressed. CMV causes an asymptomatic or mononucleosis-like infection in healthy individuals but devastating systemic infections in neonates and in immunocompromised people, in whom the virus may infect many different cell types and tissues. As its name implies, CMV-infected cells exhibit gigantism of both the entire cell and its nucleus, which typically contains a large inclusion surrounded by a clear halo ("owl's eye").

Transmission of CMV can occur by several mechanisms, depending on the age group affected. These include the following:

- *Transplacental transmission*, from a newly acquired or primary infection in a mother who does not have protective antibodies (congenital CMV).
- *Neonatal transmission*, through cervical or vaginal secretions at birth, or later through breast milk from a mother who has active infection (perinatal CMV).
- *Transmission through saliva* during preschool years, especially in day care centers. Toddlers so infected readily transmit the virus to their parents.
- *Transmission by the genital route* is the dominant mode after about 15 years of age. Spread may also occur via respiratory secretions and the fecal-oral route.

- *Iatrogenic transmission*, at any age through organ transplants or blood transfusions.

Acute CMV infection induces transient but severe immunosuppression. CMV can infect dendritic cells and impair antigen processing and the ability of dendritic cells to stimulate T lymphocytes. Similar to other herpesviruses, CMV can evade immune defenses by downmodulating MHC class I and II molecules and by producing homologues of TNF receptor, IL-10, and MHC class I molecules. Interestingly, CMV can evade NK cells by producing ligands that block activating receptors and class I-like proteins that engage inhibitory receptors. Thus, CMV both hides from and actively suppresses immune responses.

MORPHOLOGY

Infected cells are strikingly enlarged, often to a diameter of 40 μm , and show cellular and nuclear pleomorphism. Prominent **intranuclear basophilic inclusions** spanning half the nuclear diameter are usually set off from the nuclear membrane by a clear halo (Fig. 8-12). Within the cytoplasm of infected cells, smaller basophilic inclusions can also be seen. In the glandular organs, the parenchymal epithelial cells are infected; in the brain, the neurons; in the lungs, the alveolar macrophages and epithelial and endothelial cells; and in the kidneys, the tubular epithelial and glomerular endothelial cells. Disseminated CMV causes focal necrosis with minimal inflammation in virtually any organ.

Congenital Infections. Infection acquired in utero may take many forms. In approximately 95% of cases it is asymptomatic. However, sometimes when the virus is acquired from a mother with primary infection (who does not have protective antibodies), classic *cytomegalic inclusion disease* develops. Cytomegalic inclusion disease resembles erythroblastosis fetalis. Affected infants may suffer intra-uterine growth retardation, and present with jaundice, hepatosplenomegaly, anemia, bleeding due to thrombocytopenia, and encephalitis. In fatal cases the brain is often smaller than normal (microcephaly) and may show foci of calcification. Diagnosis of neonatal CMV is made by viral culture or PCR amplification of viral DNA in urine or saliva.

Figure 8-12 Cytomegalovirus: distinct nuclear and ill-defined cytoplasmic inclusions in the lung.

The infants who survive usually have permanent deficits, including intellectual disability, hearing loss, and other neurologic impairments. The congenital infection is not always devastating, however, and may take the form of interstitial pneumonitis, hepatitis, or a hematologic disorder. Most infants with this milder form of cytomegalic inclusion disease recover, although a few develop intellectual disability later. Uncommonly, a totally asymptomatic infection may be followed months to years later by neurologic sequelae, including delayed-onset intellectual disability and deafness.

Perinatal Infections. Infection acquired during passage through the birth canal or from breast milk is usually asymptomatic due to protective maternal anti-CMV antibodies, which are transmitted to the fetus across the placenta. Despite the lack of symptoms, many of these infants continue to excrete CMV in their urine or saliva for months to years. Subtle effects on hearing and intelligence later in life have been reported in some studies. Much less commonly, infected infants develop interstitial pneumonitis, failure to thrive, rash, or hepatitis.

Cytomegalovirus Mononucleosis. In healthy young children and adults the disease is nearly always asymptomatic. In surveys around the world, 50% to 100% of adults have antibodies to CMV, indicating previous exposure. **The most common clinical manifestation of CMV infection in immunocompetent hosts beyond the neonatal period is an infectious mononucleosis-like illness, with fever, atypical lymphocytosis, lymphadenopathy, and hepatitis, marked by hepatomegaly and abnormal liver function tests.** The diagnosis is made by serology. Most people recover without any sequelae, but the virus may continue to be excreted in body fluids for months to years. Irrespective of the presence or absence of symptoms, infected individuals remain seropositive for life and the virus is never cleared, persisting in latently infected leukocytes.

CMV in Immunosuppressed Individuals. **Immunocompromised individuals (e.g., transplant recipients, HIV-infected individuals) are susceptible to severe CMV infection;** these may be either primary infections or reactivation of latent CMV. In the past, CMV was the most common opportunistic viral pathogen in AIDS, but the frequency of serious CMV infection in HIV-positive people has been greatly reduced by antiretroviral treatment. Recipients of solid-organ transplants (heart, liver, kidney) also may contract CMV from the donor organ.

In all these settings, serious, even life-threatening, disseminated CMV infections in immunosuppressed people primarily affect the lungs (pneumonitis) and gastrointestinal tract (colitis). In the pulmonary infection an interstitial mononuclear infiltrate with foci of necrosis develops, accompanied by the typical enlarged cells with inclusions. The pneumonitis can progress to full-blown acute respiratory distress syndrome. Intestinal necrosis and ulceration can develop and be extensive, leading to the formation of pseudomembranes and debilitating diarrhea. Diagnosis of CMV infections is made by demonstration of characteristic morphologic alterations in tissue sections, viral culture, rising antiviral antibody titer, detection of CMV antigens,

and PCR-based detection of CMV DNA. The antigen-detection and PCR-based assays have revolutionized the approach to monitoring CMV infection in people after transplantation.

Chronic Productive Infections

In some infections the immune system is unable to eliminate the virus, and continued viral replication leads to persistent viremia. The high mutation rate of viruses such as HIV and HBV may contribute to their escape from control by the immune system. HIV and HBV infection are described in [Chapters 6 and 18](#), respectively.

Transforming Viral Infections

Some viruses can transform infected cells into benign or malignant tumor cells. Oncogenic viruses can stimulate cell growth and survival by a variety of mechanisms, as discussed in [Chapter 7](#). Several viruses have been implicated in the causation of human cancer, including EBV, HPV, HBV, and HTLV-1. EBV is discussed here; others are discussed in later chapters.

Epstein-Barr Virus (EBV)

EBV causes infectious mononucleosis, a benign, self-limited lymphoproliferative disorder, and is associated with the pathogenesis of several human tumors, most commonly certain lymphomas and nasopharyngeal carcinoma. Infectious mononucleosis is discussed here and EBV-associated neoplasms are discussed in [Chapter 7](#).

Infectious mononucleosis is characterized by fever, sore throat, generalized lymphadenopathy, splenomegaly, and the appearance in the blood of atypical activated T lymphocytes (mononucleosis cells). Some people develop hepatitis, meningoencephalitis, and pneumonitis. Infectious mononucleosis occurs principally in late adolescents or young adults among upper socioeconomic classes in developed nations. In the rest of the world, primary infection with EBV occurs in childhood and is usually asymptomatic.

Pathogenesis. EBV is transmitted by close human contact, frequently through the saliva during kissing. EBV infects B cells and possibly epithelial cells of the oropharynx. It has been hypothesized that EBV initially infects oropharyngeal epithelial cells and then spreads to underlying lymphoid tissue (tonsils and adenoids), where mature B cells are infected ([Fig. 8-13](#)). Of note, people with X-linked agammaglobulinemia, who lack B cells, do not become latently infected with EBV or shed virus, suggesting that B cells are the main reservoir of infection. An EBV envelope glycoprotein binds CD21 (CR2), the receptor for the C3d component of complement ([Chapter 3](#)), which is present on B cells. Infection of B cells may take one of two forms. In a minority of B cells, infection is lytic, leading to viral replication and eventual cell lysis accompanied by release of virions, which may infect other B cells. In most B cells, however, EBV establishes latent infection, during which the virus persists as an extrachromosomal episome.

A small number of EBV-encoded proteins are believed to be particularly important in the establishment of latency, as follows:

Figure 8-13 Outcomes of Epstein-Barr virus (EBV) infection. In an individual with normal immune function, infection is usually either asymptomatic or leads to mononucleosis. In the setting of cellular immunodeficiency, the proliferation of infected B cells may be uncontrolled, leading to the development of B-cell neoplasms. In other instances, persons without overt evidence of immunodeficiency develop EBV-positive tumors, which are usually (but not always) also derived from B cells. One secondary genetic event that collaborates with EBV to cause B-cell transformation is a balanced 8;14 chromosomal translocation, which is seen in Burkitt lymphoma. EBV is also implicated in the pathogenesis of nasopharyngeal carcinoma, Hodgkin lymphoma, and certain other rare non-Hodgkin lymphomas.

- *Epstein-Barr nuclear antigen 1 (EBNA1)* binds the EBV genome to host cell chromosomes during mitosis, thereby ensuring that viral episomes are partitioned evenly to daughter cells when infected cells divide.
- *Latent membrane protein 1 (LMP1)* drives B-cell activation and proliferation. LMP1 does so by mimicking a constitutively active form of CD40, a B cell surface receptor. Like activated CD40, LMP1 binds to TNF receptor-associated factors (TRAFs), adaptor molecules that trigger downstream events that activate NF- κ B and the JAK/STAT signaling pathway. In addition, LMP1 prevents apoptosis by activating Bcl-2.
- *EBNA2* also promotes B-cell activation and replication. It turns on the transcription of several host cell genes, including genes that encode proteins that drive cell cycle entry, such as cyclin D.

- EBV produces a *homologue of IL-10 (vIL-10)*, which inhibits macrophages and dendritic cells and suppresses anti-viral T cell responses.

As a result of the actions of these EBV proteins, B cells that are latently infected with EBV are activated and begin to proliferate and to disseminate. This uncontrolled, expanding polyclonal population of EBV-infected B cells secretes antibodies with many specificities, including antibodies that recognize sheep or horse red cells. These so-called heterophile antibodies are detected in diagnostic tests for mononucleosis. EBV-infected B cells may also produce autoantibodies, for example against platelets, leading to transient immune mediated thrombocytopenia in a small subset of patients with mononucleosis.

EBV is shed in the saliva. It is not known whether the source of the virus is B cells, oropharyngeal epithelial cells, or both.

The symptoms of infectious mononucleosis appear upon initiation of the host immune response. Cellular immunity mediated by CD8+ cytotoxic T cells and NK cells is the most important component of this response. The *atypical lymphocytes* seen in the blood, characteristic of this disease, are mainly EBV-specific CD8+ cytotoxic T cells, but also include CD16+ NK cells. The reactive proliferation of T cells is largely centered in lymphoid tissues, which accounts for the lymphadenopathy and splenomegaly. Early in the course of the infection, IgM antibodies are formed against viral capsid antigens; later, IgG antibodies are formed that persist for life. In otherwise healthy persons, the fully developed humoral and cellular responses to EBV act as brakes on viral shedding, resulting in the elimination of B cells expressing the full complement of EBV latency-associated genes. In hosts with acquired defects in cellular immunity (e.g., AIDS, organ transplantation), reactivation of EBV can lead to B-cell proliferation, which can progress through a multistep process to EBV-associated B-cell lymphomas. EBV also contributes to the development of some cases of Burkitt lymphoma ([Chapter 13](#)), in which a chromosomal translocation (most commonly an 8:14 translocation) involving the *MYC* oncogene is the critical oncogenic event ([Fig. 8-13](#)).

MORPHOLOGY

The major alterations involve the blood, lymph nodes, spleen, liver, CNS, and, occasionally, other organs. The **peripheral blood** shows absolute lymphocytosis; more than 60% of white blood cells are lymphocytes. Between 5% and 80% of these are large, **atypical lymphocytes**, 12 to 16 μ m in diameter, characterized by an abundant cytoplasm containing multiple clear vacuolations, an oval, indented, or folded nucleus, and scattered cytoplasmic azurophilic granules ([Fig. 8-14](#)). These atypical lymphocytes, most of which express CD8, are sufficiently distinctive to strongly suggest the diagnosis.

The **lymph nodes** are typically discrete and enlarged throughout the body, particularly in the posterior cervical, axillary, and inguinal regions. On histologic examination the most striking feature is the expansion of paracortical areas due to activation of T cells (immunoblasts). A minor population of EBV-infected B cells expressing *EBNA2*, *LMP1*, and other

Figure 8-14 Atypical lymphocytes in infectious mononucleosis.

latency-specific genes can also be detected in the paracortex using specific antibodies. EBV-infected B cells resembling Reed-Sternberg cells (the malignant cells of Hodgkin lymphoma, [Chapter 13](#)) may be found. B-cell areas (follicles) may also show mild hyperplasia. The T-cell proliferation is sometimes so exuberant that it is difficult to distinguish the nodal morphology from that seen in malignant lymphomas. Similar changes commonly occur in the tonsils and lymphoid tissue of the oropharynx.

The **spleen** is enlarged in most cases, weighing between 300 and 500 gm. It is usually soft and fleshy, with a hyperemic cut surface. The histologic changes are analogous to those of the lymph nodes, showing an expansion of white pulp follicles and red pulp sinusoids due to the presence of numerous activated T cells. These spleens are especially vulnerable to rupture, possibly in part because the rapid increase in size produces a tense, fragile splenic capsule.

The **liver** is usually involved to some degree, although hepatomegaly is at most moderate. On histologic examination, atypical lymphocytes are seen in the portal areas and sinusoids, and scattered, isolated cells or foci of parenchymal necrosis may be present. This histologic picture is similar to that of other forms of viral hepatitis.

Clinical Features. EBV in young children classically presents with fever, sore throat, lymphadenitis, and the other features mentioned earlier. However, malaise, fatigue, and lymphadenopathy are the common presentation in young adults with infectious mononucleosis and can raise the specter of leukemia or lymphoma; EBV also can present as a fever of unknown origin without significant lymphadenopathy or other localized findings, hepatitis resembling one of the hepatotropic viral syndromes, or a febrile rash resembling rubella. **The diagnosis depends on the following findings (in increasing order of specificity): (1) lymphocytosis with the characteristic atypical lymphocytes in the peripheral blood, (2) a positive heterophile antibody reaction (Monospot test), and (3) a rising titer of specific antibodies for EBV antigens (viral capsid antigens, early antigens, or Epstein-Barr nuclear antigen).** In most patients, infectious mononucleosis resolves within 4 to 6 weeks, but sometimes the fatigue lasts longer. One or more complications occasionally supervene. Perhaps most common is marked hepatic dysfunction with jaundice,

elevated hepatic enzyme levels, disturbed appetite, and rarely, even liver failure. Other complications involve the nervous system, kidneys, bone marrow, lungs, eyes, heart, and spleen. Splenic rupture can occur even with minor trauma, leading to hemorrhage that may be fatal.

A more serious complication in those lacking T-cell immunity, such as HIV-infected individuals, or individuals receiving immunosuppressive therapy (e.g., bone marrow or solid-organ transplant recipients), is unimpeded B-cell proliferation. This process can be initiated by an acute infection or reactivation of latent B cell infection and usually begins as polyclonal B-cell proliferation that transforms to monoclonal B-cell lymphoma. As detailed in [Chapter 13](#), EBV also causes another distinctive form of lymphoma, called *Burkitt lymphoma*, particularly in certain geographic locales.

Serious consequences of EBV infection occur in individuals suffering from the X-linked lymphoproliferation syndrome (also known as *Duncan disease*), a disorder caused by mutations in the *SH2D1A* gene, which encodes a signaling protein that participates in T-cell and NK-cell activation and antibody production. This rare inherited immunodeficiency is characterized by an ineffective immune response to EBV. Patients are usually normal until they are acutely infected with EBV, often during adolescence. In more than half of the cases, EBV causes an acute overwhelming infection that may be fatal. Others succumb to EBV-positive B-cell lymphoma or infections related to hypogammaglobulinemia.

Bacterial Infections

Different classes of bacteria are responsible for diverse infections ([Table 8-7](#)).

Gram-Positive Bacterial Infections

Common gram-positive pathogens include *Staphylococcus*, *Streptococcus*, and *Enterococcus*, each of which causes many types of infections. Diphtheria, listeriosis, anthrax, and nocardiosis are less common infections also caused by gram-positive rods and discussed here. *Clostridia* are discussed with the anaerobes.

Staphylococcal Infections

***S. aureus* causes a myriad of skin lesions (boils, carbuncles, impetigo, and scalded-skin syndrome) as well as abscesses, sepsis, osteomyelitis, pneumonia, endocarditis, food poisoning, and toxic shock syndrome (Fig. 8-15).** *S. aureus* are pyogenic gram-positive cocci that form clusters resembling bunches of grapes. The general characteristics of *S. aureus* infection are reviewed here. Specific organ infections are described in other chapters. Coagulase-negative staphylococci, such as *S. epidermidis*, cause opportunistic infections in catheterized patients, patients with prosthetic cardiac valves, and drug addicts. *S. saprophyticus* is a common cause of urinary tract infections in young women.

Pathogenesis. *S. aureus* produces a multitude of virulence factors, which include surface proteins involved in adherence and evasion of the host immune response, secreted

Table 8-7 Selected Human Bacterial Pathogens and Associated Diseases

Organ System	Species	Frequent Disease Presentations
Respiratory	<i>Streptococcus pyogenes</i> <i>Corynebacterium diphtheria</i> <i>Bordetella pertussis</i> <i>Streptococcus pneumonia</i> <i>Mycobacterium tuberculosis</i> <i>Legionella pneumophila</i>	Pharyngitis Diphtheria Pertussis Lobar pneumonia Tuberculosis Legionnaire disease

enzymes that degrade host structures, secreted toxins that damage host cells, and proteins that cause antibiotic resistance. *S. aureus* expresses surface receptors for fibrinogen (called *clumping factor*), fibronectin, and vitronectin, and uses these molecules to bind to host endothelial cells. Staphylococci infecting prosthetic valves and catheters have a polysaccharide capsule that allows them to attach to artificial materials and resist host cell phagocytosis. Staphylococci also have on their surface protein A, which binds the Fc portion of immunoglobulins, allowing the organism to escape antibody-mediated killing.

Bacterial Toxins. *S. aureus* produces multiple *membrane-damaging (hemolytic) toxins*. These include α -toxin, a protein that intercalates into the plasma membrane of host cells, forming pores that allow toxic levels of calcium to leak into cells; β -toxin, a sphingomyelinase; and δ -toxin, which is a

detergent-like peptide. Staphylococcal γ -toxin and leukocidin lyse red cells and phagocytes, respectively.

The *exfoliative A and B toxins* produced by *S. aureus* are serine proteases that cleave the desmosomal protein desmoglein 1, which holds epidermal cells tightly together. This causes keratinocytes to detach from one another and from the underlying basement membrane, resulting in a loss of barrier function that often leads to secondary skin infections. Exfoliation may occur locally at the site of infection (bullous impetigo) or may result in widespread loss of the superficial epidermis (staphylococcal scalded-skin syndrome).

Superantigens produced by *S. aureus* cause food poisoning and toxic shock syndrome. Toxic shock syndrome came to public attention because of its association with the use of hyperabsorbent tampons, which became colonized with *S. aureus* during use. It is now clear that toxic shock syndrome can be caused by growth of *S. aureus* at many sites, most commonly the vagina and infected surgical sites. This syndrome is characterized by hypotension (shock), renal failure, coagulopathy, liver disease, respiratory distress, a generalized erythematous rash, and soft tissue necrosis at the site of infection. If not promptly treated, it can be fatal. Toxic shock syndrome can also be caused by *Streptococcus pyogenes*. Bacterial superantigens cause polyclonal T cell proliferation by binding to conserved portions of MHC molecules and to relatively conserved portions of T-cell receptor β chains. In this manner superantigens may stimulate up to 20% of T lymphocytes, leading to release of cytokines such as TNF and IL-1, in such large amounts that they may trigger the systemic inflammatory response syndrome (Chapter 4). Superantigens produced by *S. aureus* also cause vomiting, presumably by affecting the CNS or the enteric nervous system.

**Figure 8-15** The many consequences of staphylococcal infection.

Antibiotic resistance is a growing problem in treatment of *S. aureus* infections. Methicillin-resistant *S. aureus* (MRSA) are resistant to nearly all penicillin and cephalosporin antibiotics. Until recently, MRSA was mainly found in healthcare facilities, but community-acquired MRSA infections are now common in many areas. As a result, empirical treatment of staphylococcal infections with penicillin and cephalosporin antibiotics is less likely to be effective.

MORPHOLOGY

Whether the lesion is located in the skin, lungs, bones, or heart valves, *S. aureus* causes pyogenic inflammation that is distinctive for its local destruction of host tissue.

Excluding impetigo, which is restricted to the superficial epidermis, staphylococcal skin infections are centered around the hair follicles where they begin. A **furuncle**, or **boil**, is a focal suppurative inflammation of the skin and subcutaneous tissue. They may be solitary or multiple or recur in successive crops. Furuncles are most frequent in moist, hairy areas, such as the face, axillae, groin, legs, and submammary folds. Beginning in a single hair follicle, a boil develops into a growing and deepening abscess that eventually “comes to a head” by thinning and rupturing the overlying skin. A **carbuncle** is a deeper suppurative infection that spreads laterally beneath the deep subcutaneous fascia and then burrows superficially to erupt in multiple adjacent skin sinuses. Carbuncles typically appear beneath the skin of the upper back and posterior neck, where fascial planes favor their spread. **Hidradenitis** is chronic suppurative infection of apocrine glands, most often in the axilla. Infections of the nail bed (**paronychia**) or on the palmar side of the fingertips (**felons**) are exquisitely painful. They may follow trauma or embedded splinters and, if deep enough, destroy the bone of the terminal phalanx or detach the fingernail.

S. aureus lung infections (Fig. 8-16) have a polymorphonuclear infiltrate similar to that of *S. pneumoniae* infections (Fig. 8-4), but cause much more tissue destruction. Lung infections usually arise from a hematogenous source, such as an infected thrombus, or in the setting of a predisposing condition such as influenza.

Figure 8-16 Staphylococcal abscess of the lung with extensive neutrophilic infiltrate and destruction of the alveoli (contrast with Fig. 8-4). The inset shows the same area on Gram stain highlighting clusters of bacteria.

Staphylococcal scalded-skin syndrome, also called Ritter disease, most frequently occurs in children with *S. aureus* infection of the nasopharynx or skin. There is a sunburn-like rash that spreads over the entire body and evolves into fragile bullae that lead to partial or total skin loss. The desquamation of the epidermis in staphylococcal scalded-skin syndrome occurs at the level of the granulosa layer, distinguishing it from toxic epidermal necrolysis, or Lyell disease, which is secondary to drug hypersensitivity and causes desquamation at the level of the epidermal-dermal junction (Chapter 25).

Streptococcal and Enterococcal Infections

Streptococci cause suppurative infections of the skin, oropharynx, lungs, and heart valves. They are also responsible for a number of postinfectious syndromes, including rheumatic fever (Chapter 12), immune complex glomerulonephritis (Chapter 20), and erythema nodosum (Chapter 25). These bacteria are gram-positive cocci that grow in pairs or chains. β -hemolytic streptococci are typed according to their surface carbohydrate (Lancefield) antigens. *S. pyogenes* (group A) causes pharyngitis, scarlet fever, erysipelas, impetigo, rheumatic fever, toxic shock syndrome, and glomerulonephritis. *S. agalactiae* (group B) colonizes the female genital tract and causes sepsis and meningitis in neonates and chorioamnionitis in pregnancy. *S. pneumoniae*, the most important α -hemolytic streptococcus, is a common cause of community-acquired pneumonia in older adults and meningitis in children and adults. The viridans-group streptococci include α -hemolytic and nonhemolytic streptococci found in normal oral flora that are a common cause of endocarditis. *S. mutans* is the major cause of dental caries. Streptococcal infections are diagnosed by culture, and, in those with pharyngitis, by the rapid streptococcal antigen test.

Enterococci are gram-positive cocci that grow in chains. They are often resistant to commonly used antibiotics and are a significant cause of endocarditis and urinary tract infections.

Pathogenesis. The different species of streptococci produce many virulence factors and toxins. *S. pyogenes*, *S. agalactiae*, and *S. pneumoniae* have capsules that resist phagocytosis. *S. pyogenes* also expresses M protein, a surface protein that prevents bacteria from being phagocytosed, and a complement C5a peptidase that degrades this chemotactic peptide. *S. pyogenes* secretes a phage-encoded pyrogenic exotoxin that causes fever and rash in scarlet fever. Poststreptococcal acute rheumatic fever is probably caused by antistreptococcal M protein antibodies and T cells that cross-react with cardiac proteins. Virulent *S. pyogenes* have been referred to as flesh-eating bacteria because they cause a rapidly progressive necrotizing fasciitis. Although the antiphagocytic capsule is the most important virulence factor of *S. pneumoniae*, it also produces pneumolysin, a toxin that inserts into host cell membranes and lyses cells, greatly increasing tissue damage. *S. mutans* produces caries by metabolizing sucrose to lactic acid (which causes demineralization of tooth enamel) and by secreting high-molecular-weight glucans that promote aggregation of bacteria and plaque formation.

Enterococci are low-virulence bacteria, although they do have an antiphagocytic capsule and produce enzymes that

Figure 8-17 Streptococcal erysipelas.

injure host tissues. The emergence of enterococci as pathogens is primarily due to their resistance to antibiotics.

MORPHOLOGY

Streptococcal infections are characterized by diffuse interstitial neutrophilic infiltrates with minimal destruction of host tissues. The skin lesions caused by streptococci (furuncles, carbuncles, and impetigo) resemble those of staphylococci.

Erysipelas is caused by exotoxins from superficial infection with *S. pyogenes*. It is characterized by rapidly spreading erythematous cutaneous swelling that may begin on the face or, less frequently, on the body or an extremity. The rash has a sharp, well-demarcated, serpiginous border and may form a “butterfly” distribution on the face (Fig. 8-17). On histologic examination there is a diffuse, edematous, neutrophilic inflammatory reaction in the dermis and epidermis extending into the subcutaneous tissues. Microabscesses may be formed, but tissue necrosis is usually minor.

Streptococcal pharyngitis, which is the major antecedent of poststreptococcal glomerulonephritis (Chapter 20), is marked by edema, epiglottic swelling, and punctate abscesses of the tonsillar crypts, sometimes accompanied by cervical lymphadenopathy. Swelling associated with severe pharyngeal infection may encroach on the airways, especially if there is peritonsillar or retropharyngeal abscess formation.

Scarlet fever, associated with pharyngitis caused by *S. pyogenes*, is most common between the ages of 3 and 15 years. It is manifested by a punctate erythematous rash that is most prominent over the trunk and inner aspects of the arms and legs. The face is also involved, but usually a small area about the mouth remains relatively unaffected, producing circumoral pallor. The skin usually becomes hyperkeratotic and scaly during defervescence.

S. pneumoniae is an important cause of lobar pneumonia (described in Chapter 15 and pictured in Fig. 8-4).

Diphtheria

Diphtheria is caused by *Corynebacterium diphtheriae*, a slender gram-positive rod with clubbed ends that spreads from person to person in respiratory droplets or skin exudate. Respiratory diphtheria causes pharyngeal

or, less often, nasal or laryngeal infection. There is toxin-mediated formation of a gray pharyngeal membrane, and damage to the heart, nerves, and other organs. Cutaneous diphtheria causes chronic ulcers with a dirty gray membrane, but does not cause systemic damage. *C. diphtheriae* produces a phage-encoded A-B toxin that blocks host cell protein synthesis. The A fragment does this by catalyzing the covalent transfer of adenosine diphosphate (ADP)-ribose to elongation factor-2 (EF-2). This inhibits EF-2 function, which is required for the translation of mRNA into protein. A single molecule of diphtheria toxin can kill a cell by ADP-ribosylating, and thereby inactivating, more than a million EF-2 molecules. Immunization with diphtheria toxoid (formalin-fixed toxin) stimulates production of toxin-neutralizing antibodies that protect people from the lethal effects of the toxin.

MORPHOLOGY

Inhaled *C. diphtheriae* carried in respiratory droplets proliferate at the site of attachment on the mucosa of the nasopharynx, oropharynx, larynx, or trachea. The bacteria also form satellite lesions in the esophagus or lower airways. Release of exotoxin causes necrosis of the epithelium, accompanied by an outpouring of a dense fibrinosuppurative exudate. The coagulation of this exudate on the ulcerated necrotic surface creates a tough, dirty gray to black, superficial membrane, sometimes called **pseudo-membrane** because it is not formed by viable tissue (Fig. 8-18). There is an intense neutrophilic infiltration in the underlying tissues with marked vascular congestion, interstitial edema, and fibrin exudation. When the membrane sloughs off its inflamed and vascularized bed, bleeding and asphyxiation may occur. With control of the infection, the membrane is coughed up or removed by enzymatic digestion, and the inflammatory reaction subsides.

Although the bacterial invasion remains localized, with entry of exotoxin into the blood and its systemic distribution, there may be fatty change in the myocardium with isolated myofiber necrosis, polyneuritis with degeneration of the myelin sheaths and axis cylinders, and (less commonly) fatty change and focal necroses of parenchymal cells in the liver, kidneys, and adrenals.

Listeriosis

Listeria monocytogenes is a gram-positive bacillus that causes severe food-borne infections in vulnerable hosts. Outbreaks of *L. monocytogenes* infection have been linked to contaminated dairy products, chicken, and hot dogs. Pregnant women, neonates, older adults, and immunosuppressed persons are particularly susceptible to severe *L. monocytogenes* infection. In pregnant women, *L. monocytogenes* causes an amnionitis that may result in abortion, stillbirth, or neonatal sepsis. In neonates and immunosuppressed adults, it can cause disseminated disease (granulomatosis infantiseptica of the newborn) and an exudative meningitis.

L. monocytogenes is a facultative intracellular pathogen, and therefore, T cells play a particularly important role in the host immune response. The bacteria bind to receptors on host epithelial cells and macrophages and are phagocytosed. The bacteria escape from the phagolysosome using a pore-forming protein, listeriolysin O, and two phospholipases. In the host cell cytoplasm, Act A, a bacterial surface protein, binds to host cell cytoskeletal proteins and induces actin polymerization. This in turn generates sufficient force to propel the bacteria into adjacent, uninfected host cells. Resting macrophages fail to kill the intracellular bacteria, whereas macrophages that are activated by IFN- γ can. Accordingly, an effective host response to *L. monocytogenes* depends on IFN- γ produced by NK cells early in the course of the infection and T cells in chronic infection. Patients with defects in cell-mediated immunity, such as those with reduced levels of CD4+ lymphocytes, are at increased risk for listeriosis.

MORPHOLOGY

In acute infections, *L. monocytogenes* evokes an exudative pattern of inflammation with numerous neutrophils. The meningitis it causes is macroscopically and microscopically indistinguishable from that resulting from infection with other pyogenic bacteria (Chapter 28). **The finding of gram-positive, mostly intracellular bacilli in the CSF is virtually diagnostic.** More varied lesions may be encountered in neonates and immunosuppressed adults. Focal abscesses alternating with grayish or yellow nodules representing necrotic amorphous tissue debris can occur in any organ, including the lung, liver, spleen, and lymph nodes. In infections of longer duration, macrophages appear in large numbers, but granulomas are rare. Infants born with *L. monocytogenes* sepsis often have a papular red rash over the extremities, and listerial abscesses can be seen in the placenta. A smear of the meconium will disclose the gram-positive bacilli.

Anthrax

Anthrax is characterized by necrotizing inflammatory lesions in the skin or gastrointestinal tract or systemically. It is caused by *Bacillus anthracis*, a large, spore-forming gram-positive rod-shaped bacterium found in environmental sources. Livestock become infected by spores in their environment or feed. Humans usually become infected by eating or handling meat or products (e.g., wool or hides) from infected animals. There are a small number of cases of anthrax each year, most of which occur in the developing world. Anthrax spores can be made into a fine powder, creating a potent biologic weapon that is a potential bioterrorism threat. In 1979, accidental

release of *B. anthracis* spores at a military research institute in Russia killed 66 people. In 2001, 22 people in the United States were infected with *B. anthracis*, mostly through spores delivered in the mail.

There are three major forms of anthrax.

- **Cutaneous anthrax**, which makes up 95% of naturally occurring infections, begins as a painless, pruritic papule that develops into a vesicle within 2 days. As the vesicle enlarges, striking edema may occur around it, with development of regional lymphadenopathy. After the vesicle ruptures, the remaining ulcer becomes covered with a characteristic black eschar, which dries and falls off as the person recovers. Bacteremia is rare.
- **Inhalational anthrax** occurs when airborne spores are inhaled. The spores are carried by phagocytes to lymph nodes where they germinate, producing bacilli that release toxins that cause hemorrhagic mediastinitis. After a prodromal illness of 1 to 6 days characterized by fever, cough, and chest or abdominal pain, there is abrupt onset of increased fever, hypoxia, and sweating. Frequently, meningitis develops from bacteremia. Inhalational anthrax rapidly leads to shock and frequently death within 1 to 2 days.
- **Gastrointestinal anthrax** is usually contracted by eating undercooked meat contaminated with *B. anthracis*. Initially, the person has nausea, abdominal pain, and vomiting, followed by severe, bloody diarrhea and, sometimes, bacteremia. Mortality is approximately 40%.

Pathogenesis. *B. anthracis* produces potent toxins and an antiphagocytic polyglutamyl capsule. The mechanisms of action of anthrax toxins are well understood (Fig. 8-19). They have A and B subunits. The B subunit is also called the *protective antigen*, because antibodies against it protect against the toxins. Following infection the B subunit is released into the circulation and binds to a cell surface

Figure 8-19 Mechanism of action of anthrax toxins. Note that each B subunit binds either EF or LF but not both (as shown for simplicity). (Adapted from Mouton M, Lacy DB, Cunningham K, et al: 2001: A year of major advances in anthrax toxin research. Trends Microbiol 2002;10:287.)

receptor that is highly expressed on endothelial cells. Then a host protease removes a fragment of the B subunit, and the remaining fragment self-associates to form a heptamer. The B unit is not toxic, but serves to deliver the toxic A units into cells. Anthrax toxin has two alternate A subunits: *edema factor* (EF) and *lethal factor* (LF), each named for the effect of the toxin in experimental animals. One to three molecules of the EF or LF bind to a B subunit heptamer, and this complex is endocytosed into the host cell. Each B heptamer binds either EF or LF. The low pH of the endosome causes a conformational change in the B heptamer, which then forms a channel in the endosome membrane through which the EF or LF moves into the cytoplasm. In the cytoplasm, EF binds to calcium and calmodulin to form an adenylate cyclase. The active enzyme converts ATP to intracellular cyclic adenosine monophosphate (cAMP), altering cell function. LF has a different mechanism of action. LF is a protease that destroys mitogen-activated protein kinase kinases (MAPKKs). These kinases regulate the activity of MAPKs, which are important regulators of cell growth and differentiation (Chapter 1). The mechanism of cell death caused by dysregulation of MAPKs is not understood.

MORPHOLOGY

Anthrax lesions at any site are typified by necrosis and exudative inflammation rich in neutrophils and macrophages. The presence of large, boxcar-shaped gram-positive extracellular bacteria in chains, seen histopathologically or grown in culture, suggests the diagnosis.

Inhalational anthrax causes numerous foci of hemorrhage in the mediastinum and hemorrhagic lymphadenitis of hilar and peribronchial lymph nodes. The lungs typically show a perihilar interstitial pneumonia with infiltration of macrophages and neutrophils and pulmonary vasculitis. Hemorrhagic lung lesions associated with vasculitis are also present in about half of cases. Mediastinal lymph nodes are expanded by edema and by macrophages containing phagocytosed apoptotic lymphocytes. *B. anthracis* is most likely to be seen in the alveolar capillaries and venules and, to a lesser degree, within the alveolar space and draining hilar lymph nodes (Fig. 8-20). In fatal cases, however, the organism may be found in multiple organs (spleen, liver, intestines, kidneys, adrenal glands, and meninges).

Figure 8-20 *Bacillus anthracis* in the subcapsular sinus of a hilar lymph node of a patient who died of inhalational anthrax. Figure 8-21 *Nocardia asteroides* in a Gram-stained sputum sample. Note the beaded, branched gram-positive organisms and leukocytes. (Courtesy Dr. Ellen Jo Baron, Stanford University Medical Center, Stanford, Calif.)

Nocardia

***Nocardia* are aerobic gram-positive bacteria found in soil that cause opportunistic infections.** The organism grows in distinctive branched chains. In culture, *Nocardia* form thin aerial filaments resembling hyphae. Despite this morphologic similarity to molds, *Nocardia* are true bacteria.

Nocardia asteroides causes respiratory infections, most often in patients with defects in immunity due to prolonged steroid use, HIV infection, or diabetes mellitus. Respiratory infection with *N. asteroides* causes an indolent illness with fever, weight loss, and cough, which may be mistaken for tuberculosis or malignancy. In some cases *N. asteroides* infections disseminate from the lungs to the CNS. Infections of the CNS are also indolent and cause varying neurologic deficits depending on the site of the lesions. *Nocardia brasiliensis* causes skin infections following injuries contaminated with soil. Manifestations include cellulitis, lymphocutaneous disease, and actinomycetoma with formation of nodules that progress to form chronic draining fistulae.

MORPHOLOGY

Nocardia appear in tissue as slender gram-positive organisms arranged in branching filaments (Fig. 8-21). Irregular staining gives the filaments a beaded appearance. *Nocardia* stain with modified acid-fast stains (Fite-Faraco stain), unlike *Actinomyces*, which may appear similar on Gram stain of tissue. *Nocardia* elicit a suppurative response with central liquefaction and surrounding granulation and fibrosis. Granulomas do not form.

Gram-Negative Bacterial Infections

Only a few gram-negative bacteria are discussed in this section. A number of important gram-negative pathogens are discussed in the appropriate chapters of organ systems, including bacterial causes of gastrointestinal infections and urinary tract infections. Anaerobic gram-negative organisms are considered later in this chapter. Gram-negative bacterial infections are usually diagnosed by culture.

Neisserial Infections

Neisseria are gram-negative diplococci that are flattened on the adjoining sides, giving the pair the shape of a coffee bean. These aerobic bacteria have stringent nutritional requirements and grow best on enriched media such as lysed sheep's blood agar. The two clinically significant *Neisseria* are *N. meningitidis* and *N. gonorrhoeae*.

***N. meningitidis* is a significant cause of bacterial meningitis, particularly among adolescents and young adults.** The organism is a common colonizer of the oropharynx and is spread by the respiratory route. An immune response leads to elimination of the colonizing organism in most people, and this response is protective against subsequent infection with the same serotype of bacteria. There are several capsular serotypes of *N. meningitidis*, however five of them cause most cases of disease. Invasive disease mainly occurs when people encounter new strains to which they are not immune, as may happen to young children or to young adults living in crowded quarters such as military barracks or college dormitories. *N. meningitidis* is endemic in the United States, but epidemics occur periodically in sub-Saharan Africa and cause thousands of deaths. Conjugate vaccines for *N. meningitidis* composed of capsular polysaccharides conjugated to antigenic proteins are available and are highly effective at preventing disease.

Even in the absence of preexisting immunity, only a small fraction of people infected with *N. meningitidis* develop meningitis. The bacteria must invade respiratory epithelial cells and travel to their basolateral side to enter the blood. In the blood, the bacterial capsule inhibits opsonization and destruction of the bacteria by complement proteins. The importance of complement as a first-line defense against *N. meningitidis* is shown by the increased rates of serious infection among people who have inherited defects in the complement proteins (C5 to C9) that form the membrane attack complex, or patients with paroxysmal nocturnal hemoglobinuria (Chapter 14) who are being treated with an antibody inhibitor of the membrane attack complex. If *N. meningitidis* escapes the host response, the consequences can be severe. Although antibiotic treatment greatly reduces the mortality of *N. meningitidis* infection, about 10% of infected patients still die. The pathology of pyogenic meningitis is discussed in Chapter 28.

***N. gonorrhoeae* is an important cause of sexually transmitted disease (STD),** with more than 300,000 cases reported each year in the United States. It is second only to *C. trachomatis* among bacterial STDs. Infection in men causes urethritis. In women, *N. gonorrhoeae* infection is often asymptomatic and so may go unnoticed. Untreated gonorrhea may lead to pelvic inflammatory disease, which can cause infertility or ectopic pregnancy (Chapter 22). Infection is diagnosed by culture and PCR tests.

Although *N. gonorrhoeae* infection usually manifests locally in the genital or cervical mucosa, pharynx, or anorectum, disseminated infections may occur. Like *N. meningitidis*, *N. gonorrhoeae* is much more likely to become disseminated in people who lack the complement proteins that form the membrane attack complex. Disseminated infection of adults and adolescents usually causes septic arthritis accompanied by a rash of hemorrhagic papules and pustules. Neonatal *N. gonorrhoeae* infection causes

conjunctivitis that may lead to blindness and, rarely, sepsis. The eye infection, which is preventable by instillation of silver nitrate or antibiotics in the newborn's eyes, remains an important cause of blindness in some developing nations.

Pathogenesis. *Neisseria* organisms adhere to and invade nonciliated epithelial cells at the site of entry (nasopharynx, urethra, or cervix). Adherence of *N. gonorrhoeae* to epithelial cells is initially mediated by long pili, which bind to CD46, a protein expressed on all human nucleated cells. OPA proteins (so named because they make bacterial colonies opaque), located in the outer membrane of the bacteria, increase binding of *Neisseria* organisms to epithelial cells and promote entry of bacteria into cells.

Neisseria use antigenic variation as a strategy to escape the immune response. The existence of multiple capsular serotypes of *N. meningitidis* results in meningitis in some people on exposure to a new strain, as discussed above. In addition, *Neisseria* species also can generate new antigens by special genetic mechanisms, which permit a single bacterial clone to change its expressed antigens and escape immune defenses. Such mechanisms involve both pili and OPA proteins:

- Recombination of genes encoding pili proteins. The pili are composed of polypeptides encoded by the pilin gene, which consists of a promoter and coding sequences for 10 to 15 pili protein variants. At any point in time, only one of these coding sequences is adjacent to the promoter, allowing it to be expressed. Periodically, homologous recombination shuttles one of the other pilin coding sequences next to the promoter, resulting in expression of a different pili variant.
- Expression of different OPA proteins. Each OPA gene has several repeats of a five-nucleotide sequence, which are frequently deleted or duplicated. These changes shift the reading frame of the gene so that it encodes new sequences. Stop codons are also introduced by the additions and deletions, which determine whether each OPA gene is expressed or silent. Thus, *Neisseria* can express one, none, or multiple OPA proteins at any time.

Pertussis

Pertussis, or whooping cough, caused by the gram-negative coccobacillus *Bordetella pertussis*, is an acute, highly communicable illness characterized by paroxysms of violent coughing followed by a loud inspiratory "whoop." In the United States, the incidence of pertussis has risen dramatically, with large epidemics occurring in 2005, 2010, and 2012. Although the reasons for this increase are not clear, the acellular pertussis vaccine currently in use is less effective than the vaccine used before 1997, and this may be a factor in the changing epidemiology of this disease. In areas of the developing world where vaccination is not widely practiced, pertussis kills hundreds of thousands of children each year. The diagnosis is best made by PCR, because culture is less sensitive.

Pathogenesis. *B. pertussis* colonizes the brush border of the bronchial epithelium and also invades macrophages. It contains a filamentous hemagglutinin that binds to carbohydrates on the surface of respiratory epithelial cells, as well as to CR3 (Mac-1) integrins on macrophages. Pertussis

Figure 8-22 Whooping cough showing a haze of bacilli (arrows) entangled with the cilia of bronchial epithelial cells. The inset highlights the haze of bacilli by immunohistochemistry using a monoclonal antibody reactive to the lipooligosaccharide A of *Bordetella pertussis*. (Images courtesy Dr. Christopher Paddock of the Centers for Disease Control, Atlanta, Ga.)

toxin is a typical A-B toxin that is composed of five subunits. The A unit, like cholera toxin, ADP-ribosylates and inactivates guanine nucleotide-binding proteins, so these G proteins can no longer transduce signals. The B component contains four subunits that bind to extracellular molecules and allow the A subunit to enter cells. The B subunit can also bind to cell surface molecules such as TLR-4 and through these it can initiate signaling events in cells. Collectively, pertussis toxin subunits impair host defenses by inhibiting neutrophils and macrophages and paralyzing cilia, among other effects.

B. pertussis also produces a toxic adenylate cyclase that enters host cells and converts ATP to cAMP. The rise in cAMP inhibits phagocytosis and the oxidative burst in neutrophils, and can cause apoptosis of macrophages. In addition, pertussis toxin inhibits neutrophil recruitment into the airways and has inhibitory effects on macrophages; the mechanisms underlying these effects are not understood.

MORPHOLOGY

Bordetella bacteria cause a laryngotracheobronchitis that in severe cases features bronchial mucosal erosion, hyperemia, and copious mucopurulent exudate (Fig. 8-22). Unless superinfected, the lung alveoli remain open and intact. In parallel with a striking peripheral lymphocytosis (up to 90%), there is hypercellularity and enlargement of the mucosal lymph follicles and peribronchial lymph nodes.

Pseudomonas Infection

Pseudomonas aeruginosa is an opportunistic aerobic gram-negative bacillus that is a frequent, deadly pathogen of people with cystic fibrosis, severe burns, or neutropenia. Many people with cystic fibrosis die of pulmonary failure secondary to chronic infection with *P. aeruginosa*. *P. aeruginosa* can be very resistant to antibiotics, making these infections difficult to treat. It often infects extensive

skin burns, which can lead to sepsis. *P. aeruginosa* is a common cause of hospital-acquired infections; it has been cultured from washbasins, respirator tubing, nursery cribs, and even antiseptic-containing bottles. It also causes corneal keratitis in wearers of contact lenses, endocarditis and osteomyelitis in intravenous drug abusers, external otitis (swimmer's ear) in healthy individuals, and severe external otitis in people with diabetes.

Pathogenesis. *P. aeruginosa* produces several toxins that contribute to local tissue damage. The organism secretes an A-B exotoxin called *exotoxin A* that, like diphtheria toxin, inhibits protein synthesis by ADP-ribosylating the ribosomal protein EF-2, leading to the death of host cells. *P. aeruginosa* also secretes damaging enzymes that destroy extracellular matrix (elastase), kill leukocytes (leukocidin), and destroy cell membranes (hemolysins). In the lungs of people with cystic fibrosis, *P. aeruginosa* secretes a mucoid exopolysaccharide called *alginate*, which forms a biofilm that protects bacteria from antibodies, complement, phagocytes, and antibiotics. The organism rapidly develops antibiotic resistance through other mechanisms as well, making treatment difficult.

MORPHOLOGY

Pseudomonas causes a **necrotizing pneumonia** that is distributed through the terminal airways in a fleur-de-lis pattern, with striking pale necrotic centers and red, hemorrhagic peripheral areas. On microscopic examination, masses of organisms are seen that tend to be most concentrated in the walls of blood vessels, where host cells undergo coagulative necrosis (Fig. 8-23). This picture of gram-negative **bacterial vasculitis** accompanied by thrombosis and hemorrhage, although not pathognomonic, is highly suggestive of *P. aeruginosa* infection.

Bronchial obstruction caused by mucus plugging and subsequent *P. aeruginosa* infection are frequent complications of cystic fibrosis. Despite antibiotic treatment and the host immune response, chronic *P. aeruginosa* infection may result in bronchiectasis and pulmonary fibrosis (Chapter 15).

In skin burns, *P. aeruginosa* proliferates widely, penetrating deeply into the veins and spreading hematogenously.

Figure 8-23 *Pseudomonas* vasculitis in which masses of organisms form a perivascular blue haze.

Well-demarcated necrotic and hemorrhagic oval skin lesions, called **ecthyma gangrenosum**, often appear. Disseminated intravascular coagulation is a frequent complication of *P. aeruginosa* bacteremia.

Plague

Yersinia pestis is a gram-negative facultative intracellular bacterium that causes an invasive, frequently fatal, infection called **plague**. It is transmitted from rodents to humans by fleabites or, less often, from one human to another by aerosols. Plague, also named *Black Death*, caused three great pandemics that killed an estimated 100 million people in Egypt and Byzantium in the sixth century; one quarter of Europe's population in the fourteenth and fifteenth centuries; and tens of millions in India, Myanmar, and China at the beginning of the twentieth century. Most cases now occur in Africa, but the organism is endemic in many parts of the world, including nations in the former Soviet Union, the Americas, and Asia. Wild rodents in the rural western United States are infected with *Y. pestis*, and are the source of 10 to 15 human cases every year. *Y. enterocolitica* and *Y. pseudotuberculosis* are genetically similar to *Y. pestis*; these bacteria cause fecal-orally transmitted ileitis and mesenteric lymphadenitis.

Y. pestis ensures its own spread by forming a biofilm that obstructs the gut of the infected flea. The starving flea bites and regurgitates before it feeds, and thus infects the rodent or human that it is biting. The bacteria spread from the site of inoculation to lymphoid tissues, where they proliferate and inhibit the host from mounting an effective response. *Y. pestis* has a plasmid-borne complex of genes, the Yop virulon, which encodes a type III secretion system, a hollow syringe-like structure that projects from the bacterial surface, binds to host cells, and injects bacterial proteins, called *Yops* (*Yersinia* outercoat proteins), into the cell. YopE, YopH, and YopT block phagocytosis by inactivating molecules that regulate actin polymerization. YopJ inhibits the signaling pathways that are activated by LPS, blocking the production of inflammatory cytokines.

MORPHOLOGY

Yersinia pestis causes lymph node enlargement (buboes), pneumonia, or sepsis with a striking neutrophilia. The distinctive histologic features include (1) massive proliferation of the organisms, (2) early appearance of protein-rich and polysaccharide-rich effusions with few inflammatory cells, (3) necrosis of tissues and blood vessels with hemorrhage, thrombosis, and marked tissue swelling, and (4) neutrophilic infiltrates that accumulate adjacent to necrotic areas as healing begins.

In **bubonic plague** the infected fleabite is usually on the legs, where it forms a small pustule or ulcer. The draining lymph nodes enlarge dramatically within a few days and become soft, pulpy, and plum colored, and may infarct or rupture through the skin. In **pneumonic plague** there is a severe, confluent, hemorrhagic and necrotizing bronchopneumonia, often with fibrinous pleuritis. In **septicemic plague** lymph nodes throughout the body as well as organs rich in mononuclear phagocytes develop foci of necrosis. Fulminant bacteremia also induces disseminated intravascular coagulation with widespread hemorrhages and thrombi.

Chancroid (Soft Chancre)

Chancroid is an acute, sexually transmitted, ulcerative infection caused by *Haemophilus ducreyi*. The disease is most common in tropical and subtropical areas among lower socioeconomic groups and men who have frequent sex with prostitutes. Chancroid is one of the most common causes of genital ulcers in Africa and Southeast Asia, where it probably serves as an important cofactor in the transmission of HIV infection. Chancroid is uncommon in the United States, with 20 to 50 cases per year reported to the Centers for Disease Control and Prevention (CDC) in the past several years. The organism is difficult to grow in culture and PCR-based tests are not widely available, so chancroid is likely to be underdiagnosed.

MORPHOLOGY

Four to 7 days after inoculation, a tender erythematous papule involving the external genitalia develops. In males, the primary lesion is usually on the penis; in females, most lesions occur in the vagina or the periurethral area. Over several days, the surface of the primary lesion erodes to produce an irregular, painful ulcer. In contrast to the primary chancre of syphilis, the ulcer of chancroid is not indurated, and multiple lesions may be present. The base of the ulcer is covered by shaggy, yellow-gray exudate. The regional lymph nodes become enlarged and tender in about 50% of cases within 1 to 2 weeks after primary infection. If the infection is not treated, the enlarged nodes (buboes) may erode the overlying skin to produce chronic, draining ulcers.

Microscopically, the ulcer of chancroid contains a superficial zone of neutrophilic debris and fibrin, and an underlying zone of granulation tissue containing areas of necrosis and thrombosed vessels. A dense, lymphoplasmacytic inflammatory infiltrate is present beneath the layer of granulation tissue. Coccobacilli are sometimes demonstrable in Gram or silver stains, but they are often obscured by other bacteria that colonize the ulcer base.

Granuloma Inguinale

Granuloma inguinale, or donovanosis, is a sexually transmitted chronic inflammatory disease caused by *Klebsiella granulomatis* (formerly called *Calymmatobacterium donovani*), a minute, encapsulated, coccobacillus. Granuloma inguinale is uncommon in the United States and Western Europe but is endemic in rural areas in some developing countries. Untreated cases are characterized by the development of extensive scarring, often associated with lymphatic obstruction and lymphedema (elephantiasis) of the external genitalia. Culture of the organism is difficult, and PCR assays are not widely available, so the diagnosis is made by microscopic examination of smears or biopsy samples of the ulcer.

MORPHOLOGY

Granuloma inguinale begins as a raised papular lesion on the moist stratified squamous epithelium of the genitalia or, rarely, the oral mucosa or pharynx. The lesion eventually ulcerates and develops abundant granulation tissue, which manifests grossly

as a protuberant, soft, painless mass. As the lesion enlarges, its borders become raised and indurated. Disfiguring scars may develop in untreated cases and are sometimes associated with urethral, vulvar, or anal **strictures**. Regional lymph nodes typically are spared or show only nonspecific reactive changes, in contrast to chancroid.

Microscopic examination of active lesions reveals marked epithelial hyperplasia at the borders of the ulcer, sometimes mimicking carcinoma (pseudoeitheliomatous hyperplasia). A mixture of neutrophils and mononuclear inflammatory cells is present at the base of the ulcer and beneath the surrounding epithelium. The organisms are demonstrable in Giemsa-stained smears of the exudate as minute, encapsulated coccobacilli (Donovan bodies) in macrophages. Silver stains (e.g., the Warthin-Starry stain) may also demonstrate the organism.

Mycobacteria

Bacteria in the genus *Mycobacterium* are slender, aerobic rods that grow in straight or branching chains. Mycobacteria have a unique waxy cell wall composed of unusual glycolipids and lipids including mycolic acid, which makes them acid-fast, meaning they will retain stains even on treatment with a mixture of acid and alcohol. They are weakly gram positive.

Tuberculosis

Tuberculosis is a serious chronic pulmonary and systemic disease caused most often by *M. tuberculosis*. The source of transmission is humans with active tuberculosis who release mycobacteria present in sputum. Oropharyngeal and intestinal tuberculosis contracted by drinking milk contaminated with *M. bovis* is rare in countries where milk is routinely pasteurized, but it is still seen in countries that have tuberculous dairy cows and unpasteurized milk.

Epidemiology. According to the World Health Organization (WHO), tuberculosis is estimated to affect more than a billion individuals worldwide, with 8.7 million new cases and 1.4 million deaths each year. But there is significant progress toward WHO targets for reduction in cases of tuberculosis. Globally, between 2010 and 2011, new cases of tuberculosis fell at a rate of 2.2%, and mortality has decreased by 41% since 1990. Infection with HIV makes people susceptible to rapidly progressive tuberculosis; 13% of the people who developed tuberculosis in 2011 were HIV-positive. In 2011 there were 10,528 new cases of tuberculosis in the United States, 62% of which occurred in foreign-born people.

Tuberculosis flourishes wherever there is poverty, crowding, and chronic debilitating illness. In the United States, tuberculosis is mainly a disease of older adults, immigrants from high-burden countries, racial and ethnic minorities, and people with AIDS. Certain disease states also increase the risk: diabetes mellitus, Hodgkin lymphoma, chronic lung disease (particularly silicosis), chronic renal failure, malnutrition, alcoholism, and immunosuppression.

It is important that infection with *M. tuberculosis* be differentiated from active disease. Most infections are acquired by person-to-person transmission of airborne

organisms from an active case to a susceptible host. In most healthy people primary tuberculosis is asymptomatic, although it may cause fever and pleural effusion. Generally, the only evidence of infection, if any remains, is a tiny, fibrocalcific pulmonary nodule at the site of the infection. Viable organisms may remain dormant in such lesions for decades. If immune defenses are lowered, the infection may be reactivated, producing communicable and potentially life-threatening disease.

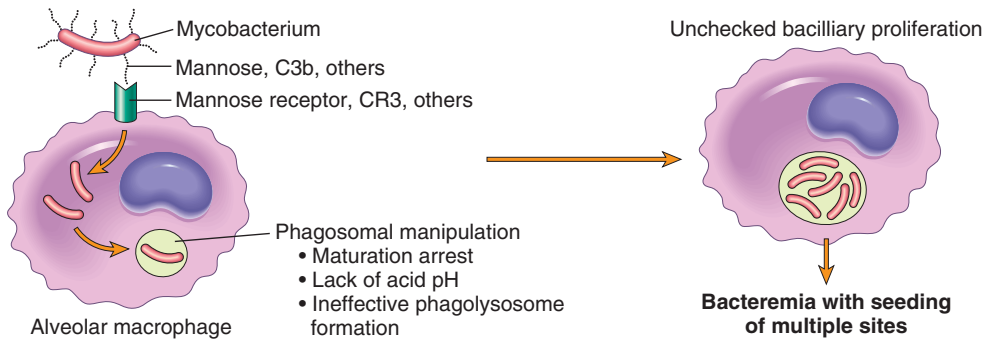

Infection typically leads to the development of delayed hypersensitivity to *M. tuberculosis* antigens, which can be detected by the tuberculin (PPD, or Mantoux) skin test. About 2 to 4 weeks after infection, intracutaneous injection of purified protein derivative of *M. tuberculosis* induces a visible and palpable induration that peaks in 48 to 72 hours. *A positive tuberculin test signifies T-cell-mediated immunity to mycobacterial antigens* but does not differentiate between infection and active disease. False-negative reactions may occur in the setting of certain viral infections, sarcoidosis, malnutrition, Hodgkin lymphoma, immunosuppression, and (notably) overwhelming active tuberculous disease. False-positive reactions may result from infection by atypical mycobacteria or prior vaccination with BCG (*Bacillus Calmette-Guerin*), an attenuated strain of *M. bovis* that is used as a vaccine in some countries.

Pathogenesis. The outcome of infection in a previously unexposed, immunocompetent person depends on the development of anti-mycobacterial T-cell-mediated immunity. These T cells control the host response to the bacteria and also result in development of pathologic lesions, such as caseating granulomas and cavitation.

Infection by *M. tuberculosis* proceeds in steps, from initial infection of macrophages to a subsequent T_H1 response that both contains the bacteria and causes tissue damage (Fig. 8-24). Early in infection, *M. tuberculosis* replicates essentially unchecked within macrophages, while later in infection, the cell response stimulates macrophages to contain the proliferation of the bacteria. The steps in infection are the following.

- **Entry into macrophages.** *M. tuberculosis* enters macrophages by phagocytosis mediated by several receptors expressed on the phagocyte, including mannose binding lectin and CR3.
- **Replication in macrophages.** *M. tuberculosis* inhibits maturation of the phagosome and blocks formation of the phagolysosome, allowing the bacterium to replicate unchecked within the vesicle, protected from the microbicidal mechanisms of lysosomes. The bacterium blocks phagolysosome formation by inhibiting Ca²⁺ signals and the recruitment and assembly of the proteins that mediate phagosome-lysosome fusion. Thus, during the earliest stage of primary tuberculosis (<3 weeks) in the nonsensitized individual, bacteria proliferate in the pulmonary alveolar macrophages and air spaces, resulting in bacteremia and seeding of multiple sites. Despite the bacteremia, most people at this stage are asymptomatic or have a mild flu-like illness.
- Multiple pathogen associated molecular patterns (Chapter 6) of *M. tuberculosis*, including lipoproteins and glycolipids, are recognized by innate immune receptors, including Toll-like receptors such as TLR2.

A. INFECTION BEFORE ACTIVATION OF CELL MEDIATED IMMUNITY

B. INITIATION AND CONSEQUENCES OF CELL MEDIATED IMMUNITY

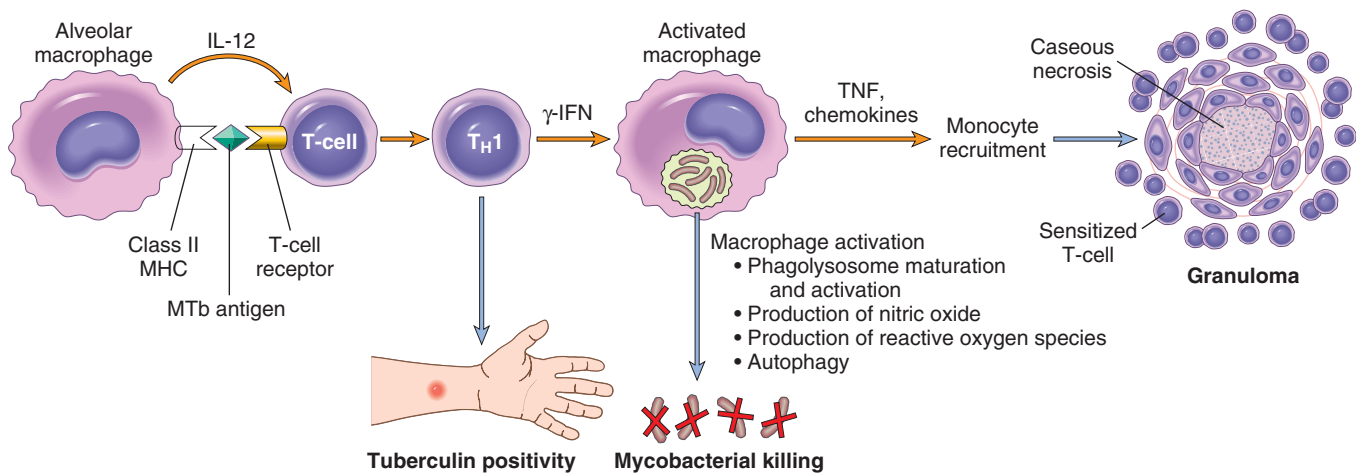

Figure 8-24 The sequence of events in primary pulmonary tuberculosis, commencing with inhalation of virulent *Mycobacterium tuberculosis* organisms and culminating with the development of cell-mediated immunity to the organism. **A**, Events occurring during early infection, before activation of T-cell-mediated immunity. **B**, The initiation and consequences of T-cell-mediated immunity. The development of resistance to the organism is accompanied by the appearance of a positive tuberculin test. γ -IFN, interferon- γ ; MHC, major histocompatibility complex; MTB, *M. tuberculosis*; TNF, tumor necrosis factor.

This initiates and enhances the innate and adaptive immune responses to *M. tuberculosis*, as described below.

- **The T_H1 response.** About 3 weeks after infection, a T-helper 1 (T_H1) response is mounted that activates macrophages, enabling them to become bactericidal. The response is initiated by mycobacterial antigens that enter draining lymph nodes and are displayed to T cells. Differentiation of T_H1 cells depends on IL-12, which is produced by antigen-presenting cells that have encountered the mycobacteria. Stimulation of TLR2 by mycobacterial ligands promotes production of IL-12 by dendritic cells.
- **T_H1 -mediated macrophage activation and killing of bacteria.** T_H1 cells, both in lymph nodes and in the lung, produce IFN- γ . IFN- γ is the critical mediator that enables macrophages to contain the *M. tuberculosis* infection. First, IFN- γ stimulates maturation of the phagolysosome in infected macrophages, exposing the bacteria to a lethal acidic, oxidizing environment. Second, IFN- γ stimulates expression of inducible nitric oxide synthase, which produces nitric oxide (NO). NO combines with other oxidants to create reactive nitrogen intermediates,

which appear to be particularly important for killing of mycobacterium. Third, IFN- γ mobilizes antimicrobial peptides (defensins) against the bacteria. Finally, IFN- γ stimulates autophagy, a process that sequesters and then destroys damaged organelles and intracellular bacteria such as *M. tuberculosis*.

- **Granulomatous inflammation and tissue damage.** In addition to stimulating macrophages to kill mycobacteria, the T_H1 response orchestrates the formation of granulomas and caseous necrosis. Macrophages activated by IFN- γ differentiate into the “epithelioid histiocytes” that aggregate to form granulomas; some epithelioid cells may fuse to form giant cells. In many people this response halts the infection before significant tissue destruction or illness occur. In other people the infection progresses due to advanced age or immunosuppression, and the ongoing immune response results in caseation necrosis. Activated macrophages also secrete TNF and chemokines, which promote recruitment of more monocytes. The importance of TNF is underscored by the fact that patients with rheumatoid arthritis who are treated with a TNF antagonist have an increased risk of tuberculosis reactivation.

- *Role of other immune cells.* In addition to the T_H1 response, NKT cells that recognize mycobacterial lipid antigens bound to CD1 on antigen-presenting cells, or T cells that express a $\gamma\delta$ T-cell receptor, also make IFN- γ . However, it is clear that T_H1 cells have a central role in this process, since defects in any of the steps in generating a T_H1 response result in absence of resistance and disease progression.
- *Host susceptibility to disease.* People with genetic deficiencies in the IL-12 pathway and the IFN- γ pathway, including STAT1 a signal transducer for IFN- γ , are vulnerable to severe mycobacterial infections. Polymorphisms in a large number of genes, including HLA, IFN- γ , IFN- γ receptor, and TLR2 have been found to be associated with susceptibility to tuberculosis, but the contribution of these associations to disease development is still under investigation.
- *Immunological state in active tuberculosis.* It is not entirely clear why some people progress from latent to active tuberculosis. Recent studies demonstrate that neutrophils in the blood of people with active tuberculosis express a group of genes that are upregulated by type I and type II interferons. The expression levels of these interferon-responsive genes correspond to the extent of lung disease as assessed by radiographic analysis. Furthermore, the expression levels of these genes fall in response to treatment for tuberculosis. This type of analysis suggests that an early interferon response is a harbinger of development of active disease, and has potential utility for diagnosis of active tuberculosis or for monitoring the extent of or response to treatment of active disease. A caveat is that while most patients with latent tuberculosis do not have this pattern of gene expression, 10 to 20% of them do.

In summary, immunity to *M. tuberculosis* is primarily mediated by T_H1 cells, which stimulate macrophages to kill the bacteria. This immune response, while largely effective, comes at the cost of accompanying tissue destruction. Reactivation of the infection or re-exposure to the bacilli in a previously sensitized host results in rapid mobilization of a defensive reaction but also increased tissue necrosis. Just as T-cell immunity and resistance are correlated, so, too, the loss of T-cell immunity (indicated by tuberculin negativity in a previously tuberculin-positive individual) may be an ominous sign that resistance to the organism has faded.

Clinical Features. Clinical tuberculosis is separated into two important pathophysiologic types: “primary” tuberculosis, which occurs in the nonimmune host, and “secondary” tuberculosis, which occurs in the host who is immune to *M. tuberculosis*. The many clinical-pathologic patterns of tuberculosis are shown in [Figure 8-25](#).

Primary tuberculosis is the form of disease that develops in a previously unexposed and therefore unsensitized, person. Clinically significant disease develops in about 5% of newly infected people. With primary tuberculosis the source of the organism is exogenous. In most people, the primary infection is contained, but in others, primary tuberculosis is progressive. The diagnosis of progressive primary tuberculosis in adults can be difficult. In contrast to secondary tuberculosis (apical disease with

cavitation; see later), progressive primary tuberculosis more often resembles an acute bacterial pneumonia with consolidation of the lobe, hilar adenopathy, and pleural effusion. Lymphohematogenous dissemination following primary infection may result in the development of tuberculous meningitis and miliary tuberculosis (discussed later).

Secondary tuberculosis is the pattern of disease that arises in a previously sensitized host. It may follow shortly after primary tuberculosis, but more commonly it appears many years after the initial infection, usually when host resistance is weakened. It most commonly stems from reactivation of a latent infection, but may also result from exogenous reinfection in the face of waning host immunity or when a large inoculum of virulent bacilli overwhelms the host immune system. Reactivation is more common in low-prevalence areas, while reinfection plays an important role in regions of high contagion.

Secondary pulmonary tuberculosis classically involves the apex of the upper lobes of one or both lungs. Because of the preexistence of hypersensitivity, the bacilli elicit a prompt and marked tissue response that tends to wall off the focus of infection. As a result, the regional lymph nodes are less prominently involved early in secondary disease than they are in primary tuberculosis. On the other hand, cavitation occurs readily in the secondary form. Indeed, cavitation is almost inevitable in neglected secondary tuberculosis, and erosion of the cavities into an airway is an important source of infection because the person now coughs sputum that contains bacteria.

Localized secondary tuberculosis may be asymptomatic. When manifestations appear, they are usually insidious in onset. Systemic symptoms, probably related to cytokines released by activated macrophages (e.g., TNF and IL-1), often appear early in the course and include malaise, anorexia, weight loss, and fever. Commonly, the fever is low grade and remittent (appearing late each afternoon and then subsiding), and night sweats occur. With progressive pulmonary involvement, increasing amounts of sputum, at first mucoid and later purulent, appear. Some degree of hemoptysis is present in about half of all cases of pulmonary tuberculosis. Pleuritic pain may result from extension of the infection to the pleural surfaces. Extrapulmonary manifestations of tuberculosis are legion and depend on the organ system involved.

The diagnosis of pulmonary disease is based in part on the history and on physical and radiographic findings of consolidation or cavitation in the apices of the lungs. Ultimately, however, tubercle bacilli must be identified. Acid-fast smears and cultures of the sputum of patients suspected of having tuberculosis should be performed. Culture on solid agar media show growth at 3 to 6 weeks, but culture in liquid media can provide an answer within 2 weeks. PCR amplification of *M. tuberculosis* DNA allows for even more rapid diagnosis. A PCR test has recently come into use that both identifies the presence of *M. tuberculosis* and, if the organism is detected, whether it is resistant to rifampin. This PCR assay is as sensitive as culture in acid-fast smear-positive samples, but it is slightly less sensitive in smear-negative tuberculosis, and substantially less sensitive in children. Thus, culture remains the gold standard because it also allows testing of drug susceptibility. Multidrug resistance is now seen more commonly than

Figure 8-25 The natural history and spectrum of tuberculosis. (Adapted from a sketch provided by Professor R.K. Kumar, The University of New South Wales, School of Pathology, Sydney, Australia.)

it was in past years; hence, all newly diagnosed cases in the United States are treated with at least four drugs, unless the susceptibility of the bacterium from the source case is known. The prognosis is generally good if infections are localized to the lungs, except when they are caused by drug-resistant strains or occur in aged, debilitated, or immunosuppressed individuals, who are at high risk for developing extrapulmonary tuberculosis as well as progression of pulmonary disease.

All stages of HIV infection are associated with an increased risk of tuberculosis. The use of HAART reduces the risk of tuberculosis in people with HIV infection, but even with HAART, people infected with HIV are more likely to develop symptomatic tuberculosis. A low CD4 count before starting HAART is an important risk factor for development of tuberculosis, which underscores the role of the immune response in keeping reactivation of *M. tuberculosis* in check. Pulmonary manifestations of tuberculosis in HIV-infected individuals are extremely variable, ranging from focal lesions to multifocal infiltrates to localized apical disease with cavitation. The extent of immunodeficiency also determines the frequency of extrapulmonary involvement, rising from 10% to 15% in mildly immunosuppressed people to greater than 50% in those with severe immune deficiency. Other atypical features of tuberculosis

in HIV-positive people include an increased frequency of false-negative sputum smears and tuberculin tests (the latter sometimes referred to as “anergy”), and the absence of characteristic granulomas in tissues, particularly in the late stages of HIV. The increased frequency of sputum smear-negativity is paradoxical because these immunosuppressed patients typically have higher bacterial loads. The likely explanation is that cavitation and bronchial damage are more severe in immunocompetent individuals, resulting in more bacilli in expelled sputum. In contrast, the absence of bronchial wall destruction due to reduced T-cell-mediated hypersensitivity results in the excretion of fewer bacilli in the sputum.

MORPHOLOGY

Primary Tuberculosis. In countries where consumption of infected milk has been eliminated, primary tuberculosis almost always begins in the lungs. Typically, the inhaled bacilli implant in the distal airspaces of the lower part of the upper lobe or the upper part of the lower lobe, usually close to the pleura. As sensitization develops, a 1- to 1.5-cm area of gray-white inflammation with consolidation emerges, known as the Ghon focus. In most cases, the center of this focus undergoes caseous

necrosis. Tubercle bacilli, either free or within phagocytes, drain to the regional nodes, which also often caseate. **This combination of parenchymal lung lesion and nodal involvement is referred to as the Ghon complex** (Fig. 8-26). During the first few weeks there is also lymphatic and hematogenous dissemination to other parts of the body. In approximately 95% of cases, development of cell-mediated immunity controls the infection. Hence, the Ghon complex undergoes progressive fibrosis, often followed by radiologically detectable calcification (Ranke complex), and despite seeding of other organs, no lesions develop.

Histologically, sites of active involvement are marked by a characteristic granulomatous inflammatory reaction that forms both caseating and noncaseating tubercles (Fig. 8-27A to C). Individual tubercles are microscopic; it is only when multiple granulomas coalesce that they become macroscopically visible. The granulomas are usually enclosed within a fibroblastic rim punctuated by lymphocytes. Multinucleated giant cells are present in the granulomas. Immunocompromised people do not form the characteristic granulomas and their macrophages contain many bacilli (Fig. 8-27D).

Secondary Tuberculosis. The initial lesion is usually a small focus of consolidation, less than 2 cm in diameter, within 1 to 2 cm of the apical pleura. Such foci are sharply circumscribed,

Figure 8-26 Primary pulmonary tuberculosis, Ghon complex. The gray-white parenchymal focus is under the pleura in the lower part of the upper lobe (red arrow). Hilar lymph nodes with caseation are seen on the left (blue arrow).

Figure 8-27 The morphologic spectrum of tuberculosis. Characteristic tubercle at low magnification (A) and high magnification (B) shows central granular caseation surrounded by epithelioid and multinucleated giant cells. This is the usual response in people who have developed cell-mediated immunity to the organism. Inset: Acid-fast stain shows rare positive (red) organisms. C, Occasionally, even in immunocompetent patients, tubercular granulomas may not show central caseation; hence regardless of the presence or absence of caseous necrosis, use of special stain for acid-fast organisms is indicated when granulomas are present. D, In this specimen from an immunocompromised patient, sheets of foamy macrophages packed with mycobacteria are seen (acid-fast stain).

Figure 8-28 Secondary pulmonary tuberculosis. The upper parts of both lungs are riddled with gray-white areas of caseation and multiple areas of softening and cavitation.

firm and gray-white to yellow in color and have variable degrees of central caseation and peripheral fibrosis (Fig. 8-28). In immunocompetent individuals, the initial parenchymal focus undergoes progressive fibrous encapsulation, leaving only fibrocalcific scars. Histologically, the active lesions show characteristic coalescent tubercles with central caseation. Tubercle bacilli can often be identified with acid-fast stains in early exudative and caseous phases of granuloma formation but are usually too few to be found in the late, fibrocalcific stages. Localized, apical, secondary pulmonary tuberculosis may heal with fibrosis either spontaneously or after therapy, or the disease may progress and extend along several different pathways.

Progressive pulmonary tuberculosis may ensue in older adults and immunosuppressed people. The apical lesion expands into adjacent lung and eventually erodes into bronchi and vessels. This evacuates the caseous center, creating a ragged, irregular cavity that is poorly walled off by fibrous tissue. Erosion of blood vessels results in hemoptysis. With adequate treatment the process may be arrested, although healing by fibrosis often distorts the pulmonary architecture. The cavities, now free of inflammation, may persist or become fibrotic. If the treatment is inadequate or if host defenses are impaired, the infection may spread via airways, lymphatic channels, or the vascular system. **Miliary pulmonary disease** occurs when organisms draining through lymphatics enter the venous blood and circulate back to the lung. Individual lesions are either microscopic or small, visible (2-mm) foci of yellow-white consolidation scattered through the lung parenchyma (the adjective “miliary” is derived from the resemblance of these foci to millet seeds). Miliary lesions may expand and coalesce, resulting in consolidation of large regions or even whole lobes of the lung. With progressive pulmonary tuberculosis, the pleural cavity is invariably involved, and serous **pleural effusions**, **tuberculous empyema**, or **obliterative fibrous pleuritis** may develop. Progressive primary tuberculosis that occurs in immunosuppressed individuals spreads in a similar manner.

Endobronchial, endotracheal, and laryngeal tuberculosis may develop by spread through lymphatic channels or from expectorated infectious material. The mucosal lining may be studded with minute granulomatous lesions that may only be apparent microscopically.

Systemic miliary tuberculosis occurs when bacteria disseminate through the systemic arterial system. Miliary

tuberculosis is most prominent in the liver, bone marrow, spleen, adrenals, meninges, kidneys, fallopian tubes, and epididymis, but could involve any organ (Fig. 8-29).

Isolated tuberculosis may appear in any of the organs or tissues seeded hematogenously and may be the presenting manifestation. Organs that are commonly involved include the meninges (tuberculous meningitis), kidneys (renal tuberculosis), adrenals (formerly an important cause of Addison disease), bones (osteomyelitis), and fallopian tubes (salpingitis). When the vertebrae are affected, the disease is referred to as **Pott disease**. Paraspinal “cold” abscesses in these patients may track along tissue planes and present as an abdominal or pelvic mass.

Lymphadenitis is the most frequent presentation of extrapulmonary tuberculosis, usually occurring in the cervical region (“scrofula”). In HIV-negative individuals, lymphadenitis tends to be unifocal and localized. HIV-positive people, on the other hand, almost always have multifocal disease, systemic symptoms, and either pulmonary or other organ involvement by active tuberculosis.

As previously mentioned, **intestinal tuberculosis** contracted by the drinking of contaminated milk is common in countries where bovine tuberculosis is present and milk is not pasteurized. In countries where milk is pasteurized, intestinal tuberculosis is more often caused by the swallowing of coughed-up infective material in patients with advanced pulmonary disease. Typically the organisms are seeded to mucosal lymphoid aggregates of the small and large bowel, which then undergo granulomatous inflammation that can lead to ulceration of the overlying mucosa, particularly in the ileum. Healing creates strictures.

Mycobacterium avium Complex

Mycobacterium avium and *M. intracellulare* are separate species, but the infections they cause are so similar that they are simply referred to as *M. avium* complex, or MAC. MAC is common in soil, water, dust, and domestic animals. **Clinically significant infection with MAC is uncommon except among people with T-cell immunodeficiency due to AIDS, and immunosuppression resulting from treatment for transplant rejection or autoimmune diseases.** In patients with marked T-cell immunodeficiency, MAC

Figure 8-29 Miliary tuberculosis of the spleen. The cut surface shows numerous gray-white tubercles.

Figure 8-30 *Mycobacterium avium* infection in a patient with AIDS, showing massive infection with acid-fast organisms. This pattern is more common in patients with acquired immunodeficiencies.

causes widely disseminated infections, and organisms proliferate abundantly in many organs, including the lungs and gastrointestinal system. Patients are feverish, with drenching night sweats and weight loss. In the rare case of MAC in a person without HIV, the organisms primarily infect the lung, causing a productive cough and sometimes fever and weight loss.

MORPHOLOGY

The hallmark of MAC infections in patients with HIV is abundant acid-fast bacilli within macrophages (Fig. 8-30).

Depending on the severity of immune deficiency, MAC infections can be widely disseminated throughout the mononuclear phagocyte system, causing enlargement of involved lymph nodes, liver, and spleen, or localized to the lungs. There may be a yellowish pigmentation to these organs secondary to the large number of organisms present in swollen macrophages. Granulomas, lymphocytes, and tissue destruction are rare.

Leprosy

Leprosy, or Hansen disease, is a slowly progressive infection caused by *M. leprae* that mainly affects the skin and peripheral nerves. Despite its low communicability, leprosy remains endemic among people living in several developing tropical nations.

Pathogenesis. The source of infection and route of transmission are not known, however human respiratory secretions or soil are likely origins. *M. leprae* is taken up by macrophages and disseminates in the blood, but it replicates primarily in relatively cool tissues of the skin and extremities. It proliferates best at 32° to 34°C, the temperature of the human skin. Like *M. tuberculosis*, *M. leprae* secretes no toxins, and its virulence is based on properties of its cell wall, which is similar enough to that of *M. tuberculosis* that immunization with BCG confers some protection against *M. leprae* infection. Cell-mediated immunity is manifested by delayed-type hypersensitivity reactions to dermal injections of a bacterial extract called *lepromin*.

M. leprae causes two strikingly different patterns of disease, called **tuberculoid** and **lepromatous**. The helper T-lymphocyte response to *M. leprae* determines whether an individual has **tuberculoid** or **lepromatous** leprosy. People with the less severe *tuberculoid leprosy* have dry, scaly skin lesions that lack sensation. They often have asymmetric involvement of large peripheral nerves. The more severe form, *lepromatous leprosy*, includes symmetric skin thickening and nodules. In lepromatous leprosy, widespread invasion of the mycobacteria into Schwann cells and into endoneural and perineural macrophages damages the peripheral nervous system. In advanced cases of lepromatous leprosy, *M. leprae* is present in sputum and blood. People can also have intermediate forms of disease, called *borderline leprosy*.

As mentioned earlier, tuberculoid and lepromatous leprosy are associated with different T cell responses. People with tuberculoid leprosy have a T_H1 response associated with production of IL-2 and IFN- γ . As with *M. tuberculosis*, IFN- γ functions to mobilize an effective host macrophage response and hence the microbial burden is low. Lepromatous leprosy is associated with a weak T_H1 response and, in some cases, a relative increase in the T_H2 response. The net result is weak cell-mediated immunity and an inability to control the bacteria, which can be readily visualized in tissue sections. Occasionally, most often in the lepromatous form, antibodies are produced against *M. leprae* antigens. Paradoxically, these antibodies are usually not protective, but they may form immune complexes with free antigens that can lead to erythema nodosum, vasculitis, and glomerulonephritis.

MORPHOLOGY

Tuberculoid leprosy begins with localized flat, red skin lesions that enlarge and develop irregular shapes with indurated, elevated, hyperpigmented margins and depressed pale centers (central healing). Neuronal involvement predominates tuberculoid leprosy. Nerves become enclosed within granulomatous inflammatory reactions and, if small (e.g., the peripheral twigs), are destroyed (Fig. 8-31). Nerve degeneration causes skin anesthesia and skin and muscle atrophy that render the person liable to trauma of the affected parts, leading to the development of chronic skin ulcers. Contractures, paralyzes, and autoamputation of fingers or toes may ensue. Facial nerve involvement can lead to paralysis of the eyelids, with keratitis and corneal ulcerations. On microscopic examination, all sites of involvement have granulomatous lesions closely resembling those found in tuberculosis. Because of the strong host defense, bacilli are almost never found, hence the name **paucibacillary** leprosy. The presence of granulomas and absence of bacteria reflect strong T-cell immunity. Because leprosy pursues an extremely slow course, spanning decades, most patients die with leprosy rather than of it.

Lepromatous leprosy involves the skin, peripheral nerves, anterior eye chamber, upper airways (down to the larynx), testes, hands, and feet. The vital organs and CNS are rarely affected, presumably because the core temperature is too high for growth of *M. leprae*. Lepromatous lesions contain large aggregates of lipid-laden macrophages (lepra cells), often filled with masses ("globi") of acid-fast bacilli (Fig. 8-32). Because of the abundant bacteria, lepromatous leprosy is referred to as

Figure 8-31 Two types of inflammatory infiltrates common in leprosy are: **A**, dense dermal macrophage infiltration surrounding adnexa, vessels, and nerves (resulting in subcutaneous nodules) and **B**, dense chronic lymphocytic and histiocytic infiltration into large nerve bundles (resulting in mononeuropathy).

multibacillary. Macular, papular, or nodular lesions form on the face, ears, wrists, elbows, and knees. With progression, the nodular lesions coalesce to yield a distinctive leonine facies. Most skin lesions are hypoesthetic or anesthetic. Lesions in the nose may cause persistent inflammation and bacilli-laden discharge. The peripheral nerves, particularly the ulnar and peroneal nerves where they approach the skin surface, are symmetrically invaded with mycobacteria, with minimal inflammation. Loss of sensation and trophic changes in the hands and feet follow the nerve lesions. Lymph nodes contain aggregates of bacteria-filled foamy macrophages in the paracortical (T cell) areas and reactive germinal centers. In advanced disease, aggregates of macrophages are also present in the splenic red pulp and the liver. The testes are usually extensively involved, leading to destruction of the seminiferous tubules and consequent sterility.

Spirochetes

Spirochetes are gram-negative, slender corkscrew-shaped bacteria with axial periplasmic flagella wound around a

Figure 8-32 Lepromatous leprosy. Acid-fast bacilli (“red snappers”) within macrophages.

helical protoplasm. The bacteria are covered in a membrane called an outer sheath, which may mask bacterial antigens from the host immune response. *Treponema pallidum* subsp. *pallidum* is the microaerophilic spirochete that causes syphilis, a chronic venereal disease with multiple clinical presentations. Other closely related treponemes cause yaws (*Treponema pallidum* subsp. *pertenue*) and pinta (*Treponema pallidum* subsp. *carateum*).

Syphilis

Syphilis is a chronic sexually transmitted disease with varied clinical and pathologic manifestations. The causative spirochete, *T. pallidum* subsp. *pallidum*, hereafter referred to simply as *T. pallidum*, is too slender to be seen in Gram stain, but it can be visualized by silver stains and immunofluorescence techniques (Fig. 8-33). Transplacental transmission of *T. pallidum* occurs readily, and active disease during pregnancy results in congenital syphilis. *T. pallidum* cannot be grown in culture. Public health programs and penicillin treatment reduced the number of cases of syphilis in the United States from the late 1940s until the 1970s. The number of cases has been relatively

Figure 8-33 *Treponema pallidum* (Steiner silver stain) showing several spirochetes in histologic sections of placental syphilis.

stable in recent years, with approximately 14,000 being reported in 2010.

Pathogenesis. Proliferative endarteritis affecting small vessels with a surrounding plasma cell-rich infiltrate is characteristic of all stages of syphilis. Much of the pathology of syphilis can be ascribed to the ischemia produced by the vascular lesions. The pathogenesis of endarteritis is unknown.

The immune response to *T. pallidum* reduces the burden of bacteria and can lead to resolution of local lesions but does not reliably eliminate the systemic infection. Superficial sites of infection (chancres and rashes) have an intense inflammatory infiltrate that includes T cells, plasma cells and macrophages that surround the bacteria. The infiltrating CD4+ T cells are T_H1 cells that may activate macrophages to kill the bacteria. Treponeme-specific antibodies are detectable and these activate complement in the lesion and opsonize the bacteria for phagocytosis by macrophages. In many patients, the organism persists despite these host responses. A protein in the outer membrane of *T. pallidum*, TprK, accumulates structural diversity during the course of infection through gene conversion (recombination) between silent donor sites and the *tprK* gene and this might contribute to antigenic diversity that allows the organism to persist.

Syphilis is divided into three stages, with distinct clinical and pathologic manifestations (Fig. 8-34).

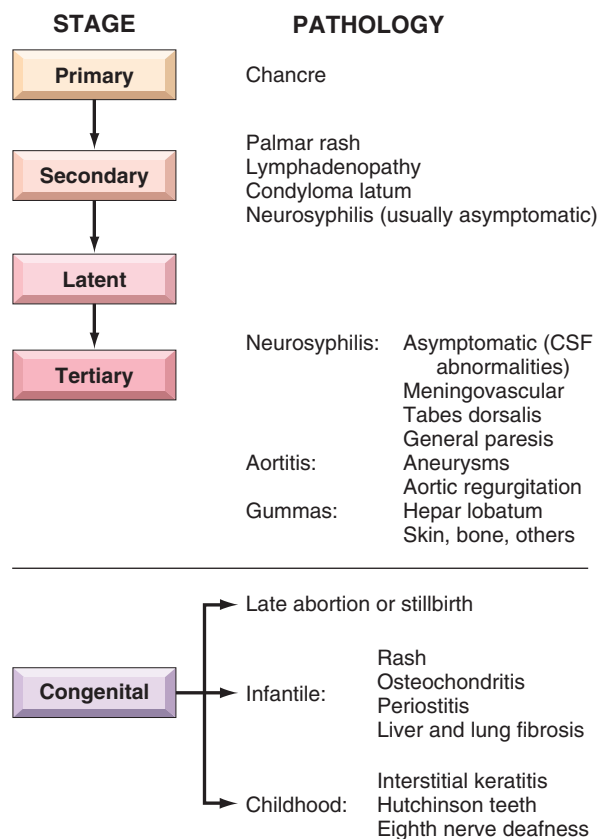

Figure 8-34 Protean manifestations of syphilis.

Primary Syphilis. This stage, occurring approximately 3 weeks after infection, features a single firm, nontender, raised, red lesion (chancre) located at the site of treponemal invasion on the penis, cervix, vaginal wall, or anus. The chancre heals with or without therapy. Spirochetes are plentiful within the chancre and spread from there throughout the body by hematologic and lymphatic dissemination.

Secondary Syphilis. This stage is marked by painless, superficial lesions of the skin and mucosal surfaces. It occurs 2 to 10 weeks after the primary chancre in approximately 75% of untreated people. Skin lesions frequently occur on the palms or soles of the feet, may be maculopapular, scaly, or pustular. Moist areas of the skin, such as the anogenital region, inner thighs, and axillae, may have *condylomata lata*, which are broad-based, elevated plaques. Silvery-gray superficial erosions may form on the oral, pharyngeal and genital mucous membranes. Lymphadenopathy, mild fever, malaise, and weight loss are also common in secondary syphilis. Asymptomatic neurosyphilis (discussed below) occurs in 8-40% of patients and symptomatic neurosyphilis, with meningitis, visual changes or hearing changes, occurs in 1-2%. Secondary syphilis lasts several weeks and then the person enters the latent stage of the disease.

Tertiary Syphilis. Tertiary syphilis has three main manifestations: cardiovascular syphilis, neurosyphilis, and so-called *benign tertiary syphilis*. These may occur alone or in combination. Tertiary syphilis occurs in one third of untreated patients, usually after a latent period of 5 years or more.

- *Cardiovascular syphilis*, in the form of syphilitic aortitis, accounts for more than 80% of cases of tertiary disease. The pathogenesis of this vascular lesion is not known, but the scarcity of treponemes and the intense inflammatory infiltrate suggest that the immune response plays a role. The aortitis leads to slowly progressive dilation of the aortic root and arch, which causes aortic valve insufficiency and aneurysms of the proximal aorta (Chapter 11).
- *Neurosyphilis* may be symptomatic or asymptomatic. Symptomatic neurosyphilis is discussed in Chapter 28. Asymptomatic neurosyphilis, which accounts for about one third of neurosyphilis cases, is initially suspected on detection of CSF abnormalities such as pleocytosis (increased numbers of inflammatory cells), elevated protein levels, or decreased glucose, and is confirmed by detection of antibodies stimulated by the spirochetes (discussed later) in the CSF. Antibiotics are given for a longer time if the spirochetes have spread to the CNS, so patients with tertiary syphilis should be tested for neurosyphilis even if they do not have neurologic symptoms.
- *Benign tertiary syphilis* is characterized by the formation of *gummas* in bone, skin, and the mucous membranes of the upper airway and mouth. Gummas are nodular lesions probably related to the development of delayed hypersensitivity to the bacteria. Skeletal involvement characteristically causes pain, tenderness, swelling, and pathologic fractures. Gummas in the skin and mucous membranes may produce nodular lesions or, rarely,

destructive, ulcerative lesions. Gummas are rare because of the use of effective antibiotics.

Congenital Syphilis. Congenital syphilis occurs most frequently during maternal primary or secondary syphilis, when the spirochetes are most numerous. Intrauterine death and perinatal death each occurs in approximately 25% of cases of untreated congenital syphilis.

Manifestations of congenital syphilis are divided into those that occur in the first 2 years of life (infantile syphilis) and those that occur later (tardive syphilis). Infantile syphilis is often manifested by nasal discharge and congestion (snuffles) in the first few months of life. A desquamating or bullous rash can lead to sloughing of the skin, particularly of the hands and feet and around the mouth and anus. Hepatomegaly and skeletal abnormalities are common. Late manifestations develop in nearly half of untreated children with neonatal syphilis.

Serologic Tests for Syphilis. Serology remains the mainstay of diagnosis of syphilis. Serologic tests include nontreponemal antibody tests and antitreponemal antibody tests. Nontreponemal tests measure antibody to cardiolipin, a phospholipid present in both host tissues and *T. pallidum*. These antibodies are detected in the rapid plasma reagin (RPR) and Venereal Disease Research Laboratory (VDRL) tests. Treponemal antibody tests measure antibodies that specifically react with *T. pallidum*. These include the fluorescent treponemal antibody absorption test and the *T. pallidum* enzyme immunoassay test.

The use of these tests is complex because of differences in the antibody responses they measure and imperfections in the tests.

- Both treponemal and nontreponemal tests are only moderately sensitive (~70%-85%) for primary syphilis.
- Both types of tests are very sensitive (>95%) for secondary syphilis.
- Treponemal tests are very sensitive for tertiary and latent syphilis. In contrast, nontreponemal antibody titers fall with time and so nontreponemal tests are somewhat less sensitive for tertiary or latent syphilis.
- Nontreponemal antibody levels fall with successful treatment of syphilis, and so changes in the titers detected in these tests can be used to monitor therapy.
- Treponemal tests, which are nonquantitative, remain positive even after successful therapy.
- Both nontreponemal and treponemal tests can be used to screen for syphilis, but positive results should be confirmed using a test of the other type (e.g., confirm nontreponemal positive test results with a treponemal test). Confirmatory testing is needed because false-positive results can occur in both nontreponemal and treponemal tests. Causes of false-positive results in these tests include pregnancy, autoimmune diseases, and infections other than syphilis.

MORPHOLOGY

In primary syphilis a chancre occurs on the penis or scrotum of 70% of men and on the vulva or cervix of 50% of women. The chancre is a slightly elevated, firm, reddened

Figure 8-35 Syphilitic chancre in the scrotum (see Fig. 8-35 for the histopathology of syphilis). (Courtesy Dr. Richard Johnson, Beth Israel-Deaconess Hospital, Boston, Mass.)

papule, up to several centimeters in diameter, that erodes to create a clean-based shallow ulcer. The contiguous induration creates a button-like mass directly adjacent to the eroded skin, providing the basis for the designation hard chancre (Fig. 8-35). On histologic examination, the chancre contains an intense infiltrate of plasma cells, with scattered macrophages and lymphocytes and a proliferative endarteritis. The endarteritis starts with endothelial cell activation and proliferation and progresses to intimal fibrosis (Fig. 8-5). The regional nodes are usually enlarged due to nonspecific acute or chronic lymphadenitis, plasma cell-rich infiltrates, or granulomas.

In secondary syphilis widespread mucocutaneous lesions involve the oral cavity, palms of the hands, and soles of the feet. The rash frequently consists of discrete red-brown macules less than 5 mm in diameter, but it may be follicular, pustular, annular, or scaling. Red lesions in the mouth or vagina contain the most organisms and are the most infectious. Histologically, the mucocutaneous lesions of secondary syphilis show the same plasma cell infiltrate and obliterative endarteritis as the primary chancre, although the inflammation is often less intense.

Tertiary syphilis most frequently involves the aorta; the CNS; and the liver, bones, and testes. The aortitis is caused by endarteritis of the vasa vasorum of the proximal aorta. Occlusion of the vasa vasorum results in scarring of the media of the proximal aortic wall, causing a loss of elasticity. There may be narrowing of the coronary artery ostia caused by subintimal scarring with resulting myocardial ischemia. The morphologic and clinical features of syphilitic aortitis are discussed in greater detail with diseases of the blood vessels (Chapter 11).

Neurosyphilis takes one of several forms, designated meningovascular syphilis, tabes dorsalis, and general paresis (Chapter 28).

Figure 8-36 Trichrome stain of liver shows a gumma (scar), stained blue, caused by tertiary syphilis (the hepatic lesion is also known as hepar lobatum).

Syphilitic gummas are white-gray and rubbery, occur singly or multiply, and vary in size from microscopic lesions resembling tubercles to large tumor-like masses. They occur in most organs but particularly in skin, subcutaneous tissue, bone, and joints. In the liver, scarring as a result of gummas may cause a distinctive hepatic lesion known as hepar lobatum (Fig. 8-36). On histologic examination, the gummas have centers of coagulated, necrotic material and margins composed of plump, palisading macrophages and fibroblasts surrounded by large numbers of mononuclear leukocytes, chiefly plasma cells. Treponemes are scant in gummas and are difficult to demonstrate.

The rash of **congenital syphilis** is more severe than that of adult secondary syphilis. It is a bullous eruption of the palms and soles of the feet associated with epidermal sloughing.

Syphilitic osteochondritis and periostitis affect all bones, but lesions of the nose and lower legs are most distinctive. Destruction of the vomer causes collapse of the bridge of the nose and, later on, the characteristic saddle nose deformity. Periostitis of the tibia leads to excessive new bone growth on the anterior surfaces and anterior bowing, or saber shin. There is also widespread disturbance in endochondral bone formation. The epiphyses become widened as the cartilage overgrows, and cartilage is found in displaced islands within the metaphysis.

The **liver** is often severely affected in congenital syphilis. Diffuse fibrosis permeates lobules to isolate hepatic cells into small nests, accompanied by the characteristic lymphoplasmacytic infiltrate and vascular changes. Gummas are occasionally found in the liver, even in early cases. The **lungs** may be affected by a diffuse interstitial fibrosis. In the syphilitic stillborn, the lungs appear pale and airless (pneumonia alba). The generalized spirochetemia may lead to diffuse interstitial inflammatory reactions in virtually any other organ (e.g., the pancreas, kidneys, heart, spleen, thymus, endocrine organs, and CNS).

The late manifestations of congenital syphilis include a distinctive **triad of interstitial keratitis, Hutchinson teeth, and eighth-nerve deafness**. In addition to interstitial keratitis, the ocular changes include choroiditis and abnormal retinal pigmentation. Hutchinson teeth are small incisors shaped like a screwdriver or a peg, often with notches in the enamel. Eighth-nerve deafness and optic nerve atrophy develop secondary to meningovascular syphilis.

Lyme Disease

Lyme disease is a common arthropod-borne illness caused by the spirochete, *Borrelia burgdorferi*, which can be localized or disseminated with a tendency to cause persistent chronic arthritis. It is named for the Connecticut town where there was an epidemic of arthritis associated with skin erythema in the mid-1970s. It is caused by several subspecies of the spirochete *Borrelia burgdorferi*, which is transmitted from rodents to people by *Ixodes* deer ticks. Lyme disease is endemic in the United States, Europe, and Japan. In the United States there were approximately 33,000 confirmed and probable cases reported in 2011. Most cases occur in the northeastern states and the upper Midwest. In endemic areas, *B. burgdorferi* infects up to 50% of ticks, which may also be infected with *Ehrlichia* and *Babesia*. Serology is the main method of diagnosis, but PCR can be done on infected tissue.

Lyme disease involves multiple organ systems and is divided into three stages (Fig. 8-37).

- In *stage 1 (localized infection)* spirochetes multiply and spread in the dermis at the site of a tick bite, causing an expanding area of redness, often with a pale center. This lesion, called *erythema migrans*, may be accompanied by fever and lymphadenopathy. The rash spontaneously disappears in 4 to 12 weeks.
- In *stage 2 (disseminated infection)* spirochetes spread hematogenously throughout the body and cause secondary skin lesions, lymphadenopathy, migratory joint and muscle pain, cardiac arrhythmias, and meningitis often associated with cranial nerve involvement.
- *Stage 3 (persistent infection)* manifests many months after the tick bite. *B. burgdorferi* usually causes a chronic arthritis sometimes with severe damage to large joints. Less often, patients will have polyneuropathy and encephalitis that vary from mild to debilitating.

Pathogenesis. *B. burgdorferi* does not produce LPS or exotoxins that damage the host. **Much of the pathology associated with *B. burgdorferi* is thought to be secondary to the immune response against the bacteria and the inflammation that accompanies it.** The initial immune response is stimulated by binding of bacterial lipoproteins to TLR2

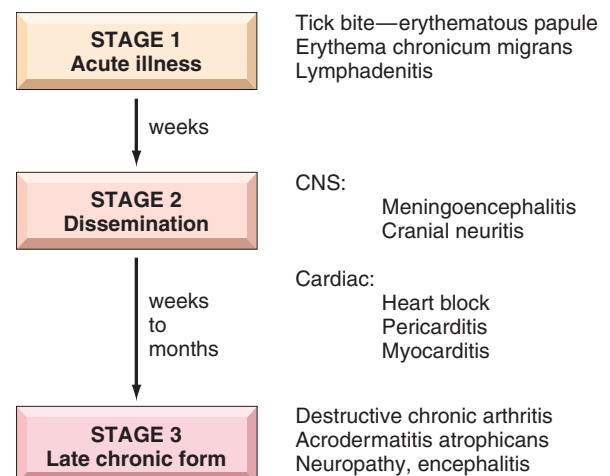

Figure 8-37 Clinical stages of Lyme disease.

on macrophages. In response, these cells release proinflammatory cytokines (IL-6 and TNF) and generate bactericidal reactive nitrogen intermediates, reducing but usually not eliminating the infection.

The inflammatory lesions are likely triggered by T cells and cytokines. *Borrelia*-specific antibodies, made 2 to 4 weeks after infection, direct complement-mediated phagocytosis and killing of the bacteria; however, *B. burgdorferi* escapes the antibody response through antigenic variation. Similar to *Borrelia hermsii*, a cause of endemic relapsing fever, *B. burgdorferi* has a plasmid with a single promoter sequence and multiple coding sequences for an antigenic surface protein, VlsE, each of which can shuttle into position next to the promoter and be expressed. Thus, as the antibody response to one VlsE protein is mounted, bacteria expressing an alternate VlsE protein can escape immune recognition. Chronic manifestations of Lyme disease, such as the late arthritis, are probably caused by the immune response against persistent bacteria.

MORPHOLOGY

Skin lesions caused by *B. burgdorferi* are characterized by edema and a lymphocytic-plasma cell infiltrate. In early Lyme arthritis, the synovium resembles early rheumatoid arthritis, with villous hypertrophy, lining-cell hyperplasia, and abundant lymphocytes and plasma cells in the subsynovium. A distinctive feature of Lyme arthritis is an arteritis, which produces onionskin-like lesions resembling those seen in lupus (Chapter 6). In late Lyme disease there may be extensive erosion of the cartilage in large joints. In Lyme meningitis the CSF is hypercellular, due to a marked lymphoplasmacytic infiltrate, and contains antispinochete IgGs.

Anaerobic Bacteria

Many anaerobic bacteria are normal flora in sites of the body that have low oxygen levels. The anaerobic flora cause disease (abscesses or peritonitis) when they are introduced into normally sterile sites or when the balance of organisms is upset and pathogenic anaerobes overgrow (e.g., *Clostridium difficile* colitis with antibiotic treatment). Environmental anaerobes also cause disease (tetanus, botulism, and gas gangrene).

Abscesses Caused by Anaerobes

Commensal bacteria from adjacent sites (oropharynx, intestine, and female genital tract) are the usual cause of abscesses, so the species found in an abscess often reflect the normal flora in that site. Abscesses are usually caused by mixed anaerobic and facultative aerobic bacterial infections. Because most anaerobes that cause abscesses are part of the normal flora, it is not surprising that these organisms do not produce significant toxins.

The bacteria found in head and neck abscesses reflect oral and pharyngeal flora. Common anaerobes at this site include the gram-negative bacilli *Prevotella* and *Porphyromonas* species, often mixed with the facultative *S. aureus* and *S. pyogenes*. *Fusobacterium necrophorum*, an oral commensal, causes Lemierre syndrome, characterized by infection of the lateral pharyngeal space and septic jugular vein thrombosis. Abdominal abscesses are caused by the anaerobes of the gastrointestinal tract, including gram-positive

Peptostreptococcus and *Clostridium* species, as well as gram-negative *Bacteroides fragilis* and *E. coli*. Genital tract infections in women (e.g., Bartholin cyst abscesses and tubo-ovarian abscesses) are caused by anaerobic gram-negative bacilli, such as *Prevotella* species, often mixed with *E. coli* or *Streptococcus agalactiae*.

MORPHOLOGY

Abscesses caused by anaerobes contain discolored and foul-smelling pus that is often poorly walled off. Otherwise, these lesions pathologically resemble those of the common pyogenic infections. Gram stain reveals mixed infection with gram-positive and gram-negative rods and gram-positive cocci mixed with neutrophils.

Clostridial Infections

Clostridium species are gram-positive bacilli that grow under anaerobic conditions and produce spores that are present in the soil. Four types of disease are caused by *Clostridium*:

- *C. perfringens*, *C. septicum*, and other species cause cellulitis and myonecrosis of traumatic and surgical wounds (*gas gangrene*), uterine myonecrosis often associated with illegal abortions, mild food poisoning, and infection of the small bowel associated with ischemia or neutropenia that often leads to severe sepsis.
- *C. tetani*, the cause of *tetanus*, proliferates in puncture wounds and in the umbilical stump of newborn infants and releases a potent neurotoxin that causes increased muscle tone and generalized spasms of skeletal muscles (lockjaw). Tetanus toxoid (formalin-fixed tetanus toxin) is part of the DPT (diphtheria, pertussis, and tetanus) immunization, and this has greatly decreased the incidence of tetanus worldwide.
- *C. botulinum*, the cause of *botulism*, grows in inadequately cooked foods and releases a potent neurotoxin that blocks synaptic release of acetylcholine and causes flaccid paralysis of respiratory and skeletal muscles.
- *C. difficile* overgrows other intestinal flora in antibiotic-treated people, releases toxins, and causes *pseudomembranous colitis* (Chapter 17).

Clostridial infections can be diagnosed by culture (cellulitis, myonecrosis), toxin assays (pseudomembranous colitis), or both (botulism).

Pathogenesis. *Clostridium perfringens* does not grow in the presence of oxygen, so tissue death is essential for growth of the bacteria in the host. **These bacteria release collagenase and hyaluronidase that degrade extracellular matrix proteins and contribute to bacterial invasiveness, but their most powerful virulence factors are the many toxins they produce.** *C. perfringens* secretes 14 toxins, the most important of which is α -toxin. This toxin has multiple actions. It is a phospholipase C that degrades lecithin, a major component of cell membranes, and so destroys red cells, platelets, and muscle cells, causing myonecrosis. It also has a sphingomyelinase activity that contributes to nerve sheath damage.

Ingestion of food contaminated with *C. perfringens* causes a brief diarrhea. Spores, usually in contaminated meat, survive cooking, and the organism proliferates in

cooling food. *C. perfringens* enterotoxin forms pores in the epithelial cell membranes, lysing the cells and disrupting tight junctions between epithelial cells.

The neurotoxins produced by *C. botulinum* and *C. tetani* both inhibit release of neurotransmitters, resulting in paralysis. Botulism toxin, eaten in contaminated foods or absorbed from wounds infected with *C. botulinum*, binds gangliosides on motor neurons and is transported into the cell. In the cytoplasm, the A fragment of botulism toxin cleaves a protein, called synaptobrevin, that mediates fusion of neurotransmitter-containing vesicles with the neuron membrane. By blocking vesicle fusion, botulism toxin prevents the release of acetylcholine at the neuromuscular junction, resulting in flaccid paralysis. If the respiratory muscles are affected, botulism can lead to death. The widespread use of botulism toxin (Botox) in cosmetic surgery is based on its ability to cause paralysis of strategically chosen muscles on the face. Tetanus toxin causes a violent spastic paralysis by blocking release of γ -aminobutyric acid, a neurotransmitter that inhibits motor neurons.

C. difficile produces toxin A, an enterotoxin that stimulates chemokine production and thus attracts leukocytes, and toxin B, a cytotoxin, which causes distinctive cytopathic effects in cultured cells. Both toxins are glucosyl transferases and are part of a pathogenicity island that is absent from the chromosomes of nonpathogenic strains of *C. difficile*.

MORPHOLOGY

The most significant lesions are caused by *C. perfringens*; these are described next. **Clostridial cellulitis**, which originates in wounds, can be differentiated from infection caused by pyogenic cocci by its foul odor, its thin, discolored exudate, and the relatively quick and wide tissue destruction. On microscopic examination, the amount of tissue necrosis is disproportionate to the number of neutrophils and gram-positive bacteria present (Fig. 8-38). Clostridial cellulitis, which often has granulation tissue at its borders, is treatable by debridement and antibiotics.

In contrast, **clostridial gas gangrene** is life-threatening and is characterized by marked edema and enzymatic necrosis of involved muscle cells 1 to 3 days after injury. An extensive fluid exudate, which is lacking in inflammatory cells, causes swelling of the affected region and the overlying skin, which develops large bullous vesicles that rupture. Gas bubbles caused by bacterial fermentation appear within the gangrenous tissues. As the infection progresses, the inflamed muscles become soft, blue-black, friable, and semifluid as a result of the massive proteolytic action of the released bacterial enzymes. On microscopic examination there is severe **myonecrosis**, extensive hemolysis, and marked vascular injury, with thrombosis. *C. perfringens* is also associated with dusk-colored, wedge-shaped infarcts in the small bowel, particularly in neutropenic people. Regardless of the site of entry, when *C. perfringens* disseminates hematogenously there is widespread formation of gas bubbles.

Despite the severe neurologic damage caused by botulinum and tetanus toxins, the neuropathologic changes are subtle and nonspecific.

Figure 8-38 Boxcar-shaped gram-positive *Clostridium perfringens* intermingled with necrotic debris in gangrenous tissue.

Obligate Intracellular Bacteria

Obligate intracellular bacteria proliferate only within host cells, although some may survive outside of cells. These organisms are well adapted to the intracellular environment, with membrane pumps to capture amino acids and ATP for energy. Some are unable to synthesize ATP at all (e.g., *Chlamydia*), while others synthesize at least some of their own ATP (e.g., the rickettsiae).

Chlamydial Infections

C. trachomatis is a small gram-negative bacterium that is an obligate intracellular parasite. *C. trachomatis* exists in two forms during its unique life cycle. The infectious form, called the *elementary body*, is a metabolically inactive, spore-like structure. Host cells take up the elementary body by receptor-mediated endocytosis. The bacteria prevent fusion of the endosome and lysosome by an unknown mechanism. Inside the endosome the elementary body differentiates into a metabolically active form, called the *reticulate body*. The reticulate body uses ATP and amino acids from the host cell to replicate and forms new infectious elementary bodies.

The various diseases caused by *C. trachomatis* infection are associated with different serotypes of the bacteria: urogenital infections and inclusion conjunctivitis (serotypes D through K), lymphogranuloma venereum (serotypes L1, L2, and L3), and an ocular infection of children, trachoma (serotypes A, B, and C). The venereal infections caused by *C. trachomatis* are discussed here.

Genital infection by *C. trachomatis* is the most common sexually transmitted bacterial disease in the world. In 2010, approximately 1.3 million cases of genital chlamydia were reported to the CDC. Before the identification of *C. trachomatis*, people infected with this organism were diagnosed with nongonococcal urethritis.

Genital *C. trachomatis* infections (other than lymphogranuloma venereum, discussed later) are associated with clinical features that are similar to those caused by *N. gonorrhoeae*. Patients may develop epididymitis, prostatitis, pelvic inflammatory disease, pharyngitis, conjunctivitis, perihepatic inflammation, and proctitis. Unlike *N. gonorrhoeae* urethritis, *C. trachomatis* urethritis in men may be

asymptomatic and so may go untreated. Both *N. gonorrhoeae* and *C. trachomatis* frequently cause asymptomatic infections in women. *C. trachomatis* urethritis can be diagnosed by culture of the bacteria in human cell lines, but amplified nucleic acid tests performed on genital swabs or urine specimens are more sensitive and have supplanted cultures.

Genital infection with the L serotypes of *C. trachomatis* causes *lymphogranuloma venereum*, a chronic, ulcerative disease. Lymphogranuloma venereum is a sporadic disease in the United States and Western Europe, but it is endemic in parts of Asia, Africa, the Caribbean region, and South America. The infection initially manifests as a small, often unnoticed, papule on the genital mucosa or nearby skin. Two to 6 weeks later, growth of the organism and the host response in draining lymph nodes produce swollen, tender lymph nodes, which may coalesce and rupture. If not treated, the infection can subsequently cause fibrosis and strictures in the anogenital tract. Rectal strictures are particularly common in women.

MORPHOLOGY

The features of *C. trachomatis* **urethritis** are virtually identical to those of gonorrhea. The primary infection is characterized by a mucopurulent discharge containing a predominance of neutrophils. Organisms are not visible in Gram-stained smears or sections.

The lesions of **lymphogranuloma venereum** contain a mixed granulomatous and neutrophilic inflammatory response. Variable numbers of chlamydial inclusions are seen in the cytoplasm of epithelial cells or inflammatory cells. Regional lymphadenopathy is common, usually occurring within 30 days of infection. Lymph node involvement is characterized by a granulomatous inflammatory reaction associated with irregularly shaped foci of necrosis containing neutrophils (stellate abscesses). With time, the inflammatory reaction is dominated by nonspecific chronic inflammatory infiltrates and extensive fibrosis. The latter, in turn, may cause local lymphatic obstruction, lymphedema, and strictures. In active lesions, the diagnosis of lymphogranuloma venereum may be made by demonstration of the organism in biopsy sections or smears of exudate. In more chronic cases, the diagnosis rests with the demonstration of antibodies to the appropriate chlamydial serotypes in the patient's serum.

Rickettsial Infections

Members of the *Rickettsiales* are vector-borne obligate intracellular bacteria that cause epidemic and scrub typhus, spotted fevers (*Rickettsia rickettsii* and others), ehrlichiosis, and anaplasmosis. These organisms have the structure of gram-negative, rod-shaped bacteria, although they stain poorly with Gram stain.

- **Epidemic typhus** (caused by *Rickettsia prowazekii*) is transmitted from person to person by body lice. It is associated with wars and poverty, when individuals live in close contact with poor hygiene. Manifestations include a rash that is initially macular, progressing to a petechial, maculopapular rash on the entire body except the face, palms, and soles.

Figure 8-39 Peripheral blood granulocytes (band neutrophils) containing *Anaplasma* inclusions (arrows). (Courtesy Dr. Tad Weiczorek, Faulkner Hospital, Boston, Mass.)

- **Scrub typhus** (caused by *Orientia tsutsugamushi*) is transmitted by chiggers. It is endemic in areas of Asia, Australia, and some islands in the western Pacific and Indian oceans. Fever, headache, myalgia and cough are usual symptoms, sometimes accompanied by a characteristic eschar and associated lymphadenopathy from the chigger bite.
- **Rocky Mountain spotted fever** (caused by *Rickettsia rickettsii*) is transmitted to humans by dog ticks. It is most common in the southeastern and south-central United States. It begins as a nonspecific severe illness with fever, myalgias, and gastrointestinal distress, and progresses to a widespread macular then petechial rash that can involve the palms and soles.
- **Ehrlichiosis** (caused by *Ehrlichia chaffeensis*) and **anaplasmosis** (*Anaplasma phagocytophilum*) are tick-transmitted diseases. The bacteria predominantly infect monocytes (*Ehrlichia chaffeensis*) or neutrophils (*Anaplasma phagocytophilum*). Characteristic cytoplasmic inclusions (morulae), composed of masses of bacteria that occasionally take the shape of a mulberry, are present in leukocytes (Fig. 8-39). Ehrlichiosis and anaplasmosis are characterized by abrupt onset of fever, headache, and malaise, and may progress to respiratory insufficiency, renal failure, and shock. Rash occurs in approximately 40% of people with *E. chaffeensis* infections.

Rickettsial diseases are usually diagnosed clinically and confirmed by serology or immunostaining of the organisms.

Pathogenesis. The severe manifestations of rickettsial infections are primarily due to infection of endothelial cells and the consequent endothelial dysfunction and injury. The rickettsiae that cause typhus and spotted fevers predominantly infect vascular endothelial cells, especially those in the lungs and brain. The bacteria enter the endothelial cells by endocytosis, but they escape from the endosome into the cytoplasm. The organisms proliferate in the endothelial cell cytoplasm and then either lyse the cell

(typhus group) or spread from cell to cell (spotted fever group). The widespread endothelial dysfunction can cause shock, peripheral and pulmonary edema, and disseminated intravascular coagulation, as well as renal failure and a variety of CNS manifestations that can include coma.

The innate immune response to rickettsial infection is mounted by NK cells, which produce IFN- γ , reducing bacterial proliferation. Subsequent cytotoxic T lymphocyte responses are critical for elimination of rickettsial infections. IFN- γ and TNF produced by activated NK cells and T cells stimulate the production of bactericidal nitric oxide derivatives. Cytotoxic T cells lyse infected cells, reducing bacterial proliferation.

MORPHOLOGY

Typhus Fever. In mild cases the gross changes are limited to a rash and small hemorrhages due to the vascular lesions. In more severe cases, there may be areas of necrosis of the skin and gangrene of the tips of the fingers, nose, earlobes, scrotum, penis, and vulva. In such cases, irregular ecchymotic hemorrhages may be found internally, principally in the brain, heart muscle, testes, serosal membrane, lungs, and kidneys.

The most prominent microscopic changes are small vessel lesions and focal areas of hemorrhage and inflammation in various organs and tissues. Endothelial swelling in the capillaries, arterioles, and venules may narrow the lumens of these vessels. A cuff of mononuclear inflammatory cells usually surrounds the affected vessel. The vascular lumens are sometimes thrombosed. Necrosis of the vessel wall is unusual in typhus (compared with Rocky Mountain spotted fever). Vascular thromboses lead to gangrenous necrosis of the skin and other structures in a minority of cases. In the brain, characteristic typhus nodules are composed of focal microglial proliferations with an infiltrate of mixed T lymphocytes and macrophages (Fig. 8-40).

Scrub typhus, or mite-borne infection, is usually a milder version of typhus fever. The rash is usually transitory or might not appear. Vascular necrosis or thrombosis is rare, but there may be a prominent inflammatory lymphadenopathy.

Rocky Mountain Spotted Fever. A hemorrhagic rash that extends over the entire body, including the palms of the hands and soles of the feet, is the hallmark of Rocky Mountain spotted

Figure 8-40 Typhus nodule in the brain.

Figure 8-41 Rocky Mountain spotted fever with a thrombosed vessel and vasculitis.

fever. An eschar at the site of the tick bite is uncommon with Rocky Mountain spotted fever but is often seen with *R. akari*, *R. africae*, and *R. conorii* infection. The vascular lesions that underlie the rash often lead to acute necrosis, fibrin extravasation, and occasionally thrombosis of the small blood vessels, including arterioles (Fig. 8-41). In severe Rocky Mountain spotted fever, foci of necrotic skin appear, particularly on the fingers, toes, elbows, ears, and scrotum. The perivascular inflammatory response, similar to that of typhus, is seen in the brain, skeletal muscle, lungs, kidneys, testes, and heart muscle. The vascular lesions in the brain may involve larger vessels and produce microinfarcts. A noncardiogenic pulmonary edema causing adult respiratory distress syndrome is the major cause of death in patients with Rocky Mountain spotted fever.

Fungal Infections

Fungi are eukaryotes with cell walls that grow as multicellular filaments (mold) or individual cells alone or in chains (yeast). Cell walls give fungi their shape. Yeasts are round to oval and mainly reproduce by budding. Some yeasts, such as *Candida albicans*, can produce buds that fail to detach and become elongated, producing a chain of elongated yeast cells called *pseudohyphae*. Molds consist of threadlike filaments (hyphae) that grow and divide at their tips. They can produce round cells, called *conidia*, that easily become airborne, disseminating the fungus. Many medically important fungi are dimorphic, existing as yeast or molds, depending on environmental conditions (yeast form at human body temperature and a mold form at room temperature). Fungal infections can be diagnosed by histologic examination, although definitive identification of some species requires culture.

Fungal infections, also called *mycoses*, are of four major types:

- *Superficial and cutaneous mycoses* are common and limited to the very superficial or keratinized layers of skin, hair, and nails.
- *Subcutaneous mycoses* involve the skin, subcutaneous tissues, and lymphatics and rarely disseminate systemically.

- *Endemic mycoses* are caused by dimorphic fungi that can produce serious systemic illness in healthy individuals.
- *Opportunistic mycoses* can cause life-threatening systemic diseases in individuals who are immunosuppressed or who carry implanted prosthetic devices or vascular catheters. Some of the fungi that cause opportunistic mycoses are discussed below; those involving specific organs are discussed in other chapters.

Yeast

Candidiasis

Most *Candida* infections originate when the normal commensal flora breach the skin or mucosal barriers. Residing normally in the skin, mouth, gastrointestinal tract, and vagina, *Candida* species usually live as benign commensals and seldom produce disease in healthy people. *Candida* species, usually *C. albicans*, are the most frequent cause of human fungal infections. These infections may be confined to the skin or mucous membranes or may disseminate widely. In otherwise healthy people *Candida* cause vaginitis and diaper rash. Individuals with diabetes and burn patients are particularly susceptible to superficial candidiasis. In individuals with indwelling intravenous lines or catheters, or undergoing peritoneal dialysis, *Candida* can spread into the bloodstream. Severe disseminated candidiasis most commonly occurs in patients who are neutropenic due to leukemia, chemotherapy, or hematopoietic stem cell transplantation, and may cause shock and disseminated intravascular coagulation.

Pathogenesis. A single strain of *Candida* can be successful as a commensal or a pathogen. *Candida* can shift between different phenotypes. Phenotypic switching involves coordinated regulation of phase-specific genes and provides a way for *Candida* to adapt to changes in the host environment (produced by antibiotic therapy, the immune response, or altered host physiology). These variants can exhibit altered colony morphology, cell shape, antigenicity, and virulence.

Candida produce a large number of functionally distinct adhesins that mediate adherence to host cells and contribute to virulence. These adhesins include (1) an integrin-like protein, which binds to fibrinogen, fibronectin, and laminin; (2) a protein that binds to epithelial cells; and (3) several agglutinins that bind to endothelial cells or fibronectin. Adhesion is an important determinant of virulence, since strains with reduced adherence to cells *in vitro* are avirulent in experimental models *in vivo*. Differential expression of adhesins by yeast and filamentous forms leads to recognition of distinct receptors on host cells.

Candida produce a number of enzymes that contribute to invasiveness, including at least nine secreted aspartyl proteinases, which may promote tissue invasion by degrading extracellular matrix proteins, and catalases, which may enable the organism to resist oxidative killing by phagocytic cells.

The ability of *C. albicans* to grow as biofilms also contributes to its capacity to cause disease. *Candida* biofilms are microbial communities consisting of mixtures of yeast, filamentous forms, and fungal-derived extracellular matrix.

C. albicans can form biofilms on implanted medical devices that reduce the organism's susceptibility to immune responses and antifungal drug therapy.

Neutrophils, macrophages and T_H17 cells are important for protection against *Candida* infection.

- Neutrophils and macrophages phagocytose *Candida*, and oxidative killing by these phagocytes is a first line of host defense. The important role of neutrophils and macrophages is illustrated by the increased risk of *Candida* infections in individuals with neutropenia or defects in NADPH oxidase or myeloperoxidase. Filamentous forms, but not yeast, can escape from phagosomes and enter the cytoplasm and proliferate.
- *Candida* yeast activate dendritic cells through multiple pathways, more so than do the filamentous forms of the fungi. For example, β -1,3-glucan expressed by the yeast engages dectin on dendritic cells and induces IL-6 and IL-23 production, which promotes T_H17 responses. The T_H17 responses elicited by *Candida* are responsible for recruiting neutrophils and monocytes (Chapter 6). These responses are critical for protection against *Candida* infection, as shown by recurrent mucocutaneous candidiasis in individuals with either low T-cell counts due to HIV infection or inherent defects in T_H17 cell development.

MORPHOLOGY

In tissue sections, *C. albicans* can appear as yeast, pseudohyphae, and, less commonly, true hyphae, defined by the presence of septae (Fig. 8-42). Pseudohyphae, an important diagnostic clue, are a chain of budding yeast cells joined end to end at constrictions. All forms may be present together in the same tissue. The organisms may be seen in routine hematoxylin and eosin stains, but a variety of special fungal stains (Gomori methenamine-silver, periodic acid-Schiff) are commonly used to better visualize them.

Most commonly candidiasis takes the form of a superficial infection on mucosal surfaces of the oral cavity (**thrush**). Florid proliferation of the fungi creates gray-white, dirty-looking pseudomembranes composed of matted organisms and inflammatory debris. Deep to the surface, there is mucosal hyperemia and inflammation. This form of candidiasis is seen in newborns, debilitated people, children receiving oral steroids for asthma, and following a course of broad-spectrum antibiotics that destroy competing normal bacterial flora. The other major risk group includes HIV-positive patients; people with oral thrush for no obvious reason should be evaluated for HIV infection.

***Candida* esophagitis** is commonly seen in AIDS patients and in those with hematolymphoid malignancies. These patients present with dysphagia (painful swallowing) and retrosternal pain; endoscopy demonstrates white plaques and pseudomembranes resembling oral thrush on the esophageal mucosa (Fig. 8-42).

***Candida* vaginitis** is common, especially in women who are diabetic, pregnant, or on oral contraceptive pills. It is usually associated with intense itching and a thick, curdlike discharge.

Cutaneous candidiasis can present in many different forms, including infection of the nail proper (onychomycosis), nail folds (paronychia), hair follicles (folliculitis), moist, intertriginous skin, such as armpits or webs of the fingers and toes (intertrigo), and penile skin (balanitis). Diaper rash is a cutaneous

Figure 8-42 The morphology of *Candida* infections. **A**, Severe candidiasis of the distal esophagus. **B**, Hematoxylin and eosin stain of esophageal candidiasis reveals the dense mat of *Candida*. **C**, Characteristic pseudohyphae and budding yeast of *Candida*. candidal infection seen in the perineum of infants, the region in contact with wet diapers.

Invasive candidiasis is caused by bloodborne dissemination of organisms to various tissues or organs. Common patterns include (1) renal abscesses, (2) myocardial abscesses and endocarditis, (3) brain microabscesses and meningitis, (4) endophthalmitis (virtually any eye structure can be involved), and (5) hepatic abscesses. In any of these locations, depending on the immune status of the infected person, the fungus may evoke little inflammation cause the usual suppurative response, or occasionally produce granulomas. People with acute leukemias who are profoundly neutropenic after chemotherapy are particularly prone to developing systemic disease. *Candida* endocarditis is the most common fungal endocarditis, usually occurring in the setting of prosthetic heart valves or in intravenous drug abusers. In the latter group the tricuspid valve is involved.

Cryptococcosis

Two species of cryptococcus are known to cause disease in humans, *C. neoformans* and *C. gattii*, both of which grow as encapsulated yeasts. It has long been recognized that while *C. neoformans* may cause meningoencephalitis in otherwise healthy individuals, it more frequently presents as an opportunistic infection in people with AIDS, leukemia, lymphoma, systemic lupus erythematosus, or sarcoidosis, as well as in immunosuppressed transplant recipients. Many of these patients receive high-dose corticosteroids, a

major risk factor for *C. neoformans* infection. *Cryptococcus neoformans* is present in the soil and in bird (particularly pigeon) droppings and infects people when it is inhaled.

C. gattii was an obscure infectious agent until 1999, when it was identified as the cause of an outbreak of cryptococcal disease in the American Pacific Northwest and contiguous areas of British Columbia. It has subsequently been linked to cryptococcal infections worldwide. Because most current tests used to diagnose cryptococcal infections (discussed later) do not distinguish between *C. gattii* and *C. neoformans*, the true incidence of infections caused by these two agents is currently uncertain. Based on findings from areas where *C. gattii* is now specifically tested for, it appears that *C. gattii* is more likely than *C. neoformans* to cause disease in immunologically normal individuals and to present with large lesions that produce mass effects or that mimic the radiologic appearance of a neoplasm. *C. gattii* is associated with certain species of trees, is found in soil, and like *C. neoformans* is acquired by inhalation.

Pathogenesis. *Cryptococcus* has several virulence factors that enable it to evade host defenses, as follows:

- **Polysaccharide capsule.** Glucuronoxylomannan inhibits phagocytosis by alveolar macrophages, leukocyte migration, and recruitment of inflammatory cells. *C. neoformans* can undergo phenotypic switching, which leads to changes in the structure and size of the capsular polysaccharide, providing a means to evade immune responses.

Figure 8-43 Mucicarmine stain of cryptococci (staining red) in a Virchow-Robin perivascular space of the brain (soap-bubble lesion).

- **Melanin production.** Laccase in the yeast catalyzes the formation of melanin which (1) has antioxidant properties, (2) decreases antibody-mediated phagocytosis, (3) counteracts the effects of antifungal agents, (4) binds iron, (5) and provides cell wall integrity.
- **Enzymes.** Serine proteinase cleaves fibronectin and other basement membrane proteins, which may aid tissue invasion. Mannitol dehydrogenase produces mannitol, which leads to osmotic edema and inhibits killing of the yeast by neutrophils and reactive oxygen species.

MORPHOLOGY

Cryptococcus has yeast but not pseudohyphal or hyphal forms. **The 5- to 10- μm cryptococcal yeast has a highly characteristic thick gelatinous capsule containing a polysaccharide that stains intense red with periodic acid-Schiff and mucicarmine in tissues (Fig. 8-43)** and can be detected with antibody-coated beads in an agglutination assay. India ink preparations create a negative image, visualizing the thick capsule as a clear halo within a dark background. Although the lung is the primary site of infection, pulmonary involvement is usually mild and asymptomatic, even while the fungus is spreading to the CNS. *C. gattii* appears to be particularly likely to form a solitary pulmonary granuloma similar to the circumscribed (coin) lesions caused by *Histoplasma*.

The major lesions caused by cryptococcus are in the CNS, involving the meninges, cortical gray matter, and basal nuclei. The host response to cryptococci is extremely variable. In immunosuppressed people, organisms may evoke virtually no inflammatory reaction, so gelatinous masses of fungi grow in the meninges or expand the perivascular Virchow-Robin spaces within the gray matter, producing the so-called soap-bubble lesions (Fig. 8-43). In severely immunosuppressed persons, *C. neoformans* may disseminate widely to the skin, liver, spleen, adrenals, and bones. In nonimmunosuppressed people or in those with protracted disease, the fungi induce a chronic granulomatous reaction composed of macrophages, lymphocytes, and foreign body-type giant cells. Suppuration also may occur, as well as a rare granulomatous arteritis of the circle of Willis.

Molds

Aspergillosis

Aspergillus is a ubiquitous mold that causes allergies (allergic bronchopulmonary aspergillosis) in otherwise healthy people and serious sinusitis, pneumonia, and invasive disease in immunocompromised individuals. The major conditions that predispose to *Aspergillus* infection are neutropenia and use of corticosteroids. *Aspergillus fumigatus* is the most common pathogenic species of the fungus.

Pathogenesis. *Aspergillus* species are transmitted as airborne conidia, and the lung is the major portal of entry. The small size of *A. fumigatus* spores, approximately 2 to 3 μm , enables them to reach alveoli. Alveolar macrophages recognize *Aspergillus* through TLR2 and the lectin dectin-1, which recognizes β -1,3-glucan when it is exposed on the swollen conidia. Both receptors activate phagocytes to ingest and kill the conidia. In immunosuppressed states, conidia can germinate into hyphae, which then invade tissues. TLRs can recognize products of the fungal hyphae and trigger the release of pro-inflammatory mediators, including TNF- α , IL- β , and chemokines. Neutrophils produce reactive oxygen intermediates that kill hyphae. Invasive aspergillosis is highly associated with neutropenia and impaired neutrophil defenses.

Aspergillus produces several virulence factors, including adhesins, antioxidants, enzymes, and toxins. Conidia, whose cell walls are built of β -1, 3-glucan and galactomannan (both molecules can be measured in serum as markers of invasiveness), can bind to fibrinogen, laminin, complement, fibronectin, collagen, albumin, and surfactant proteins, but receptor-ligand interactions are not well defined. *Aspergillus* produces several antioxidant defenses, including melanin pigment, mannitol, catalases, and superoxide dismutases. This fungus also produces phospholipases, proteases, and toxins, but their roles in pathogenicity are not clear. The carcinogen aflatoxin is made by *Aspergillus* species growing on the surface of peanuts and may contribute to liver cancer in Africa. Sensitization to *Aspergillus* spores produces an allergic alveolitis (Chapter 15). Allergic bronchopulmonary aspergillosis, associated with hypersensitivity arising from superficial colonization of the bronchial mucosa, often occurs in asthmatic people.

MORPHOLOGY

Colonizing aspergillosis (aspergilloma) refers to growth of the fungus in pulmonary cavities and minimal or no invasion of the tissues (the nose also is often colonized). The cavities are usually the result of prior tuberculosis, bronchiectasis, old infarcts, or abscesses. Proliferating masses of hyphae form brownish "fungus balls" lying free within the cavities. The surrounding inflammatory reaction may be sparse, or there may be chronic inflammation and fibrosis. People with aspergillomas usually have recurrent hemoptysis.

Invasive aspergillosis is an opportunistic infection that is confined to immunosuppressed hosts. The primary lesions are usually in the lung, but widespread hematogenous dissemination with involvement of the heart valves and brain is common.

Figure 8-44 *Aspergillus* infection. **A**, Invasive aspergillosis of the lung in a bone marrow transplant patient. **B**, Gomori methenamine-silver (GMS) stain shows septate hyphae with acute-angle branching, consistent with *Aspergillus*.

The pulmonary lesions take the form of necrotizing pneumonia with sharply delineated, rounded, gray foci and hemorrhagic borders; they are often referred to as target lesions (Fig. 8-44A).

***Aspergillus* forms fruiting bodies (usually in lung cavities) and septate filaments, 5 to 10 μm thick, branching at acute angles (40 degrees) (Fig. 8-44B).** *Aspergillus* hyphae cannot be distinguished from *Pseudallescheria boydii* and *Fusarium* species by morphology alone. *Aspergillus* has a tendency to invade blood vessels, therefore areas of hemorrhage and infarction are usually superimposed on the necrotizing, inflammatory tissue reactions. Rhinocerebral *Aspergillus* infection in immunosuppressed individuals resembles that caused by Mucormycoses (e.g., *Mucor*, *Rhizopus*).

Zygomycosis (Mucormycosis)

Mucormycotina are widely distributed in nature and cause no harm to immunocompetent individuals, but they infect immunosuppressed people, causing mucormycosis. Mucormycosis (formerly zygomycosis) is an opportunistic infection caused by bread mold fungi, including *Mucor*, *Rhizopus*, *Lichtheimia* (formerly *Absidia*), and *Cunninghamella*, which belong to the family Mucormycetes. Major predisposing factors are neutropenia, corticosteroid use, diabetes mellitus, iron overload, and breakdown of the cutaneous barrier (e.g., as a result of burns, surgical wounds, or trauma).

Pathogenesis. Immune responses to Mucormycotina differ from other fungi and the organisms have variable natural resistance. As with *Aspergillus*, Mucormycotina are transmitted by airborne asexual spores. Inhaled spores commonly produce infection in the sinuses and the lungs, but percutaneous exposure or ingestion can also lead to infection. Macrophages provide the initial defense by phagocytosis and non-oxidative killing of germinating sporangiospores. Mucormycotina hyphal components are recognized by TLR2, which results in a pro-inflammatory cascade of cytokines including IL-6 and TNF- α . Neutrophils have a key role in killing hyphae after germination by directly damaging hyphae walls. If the macrophages or neutrophils are compromised in numbers or function, the probability of an established and then invasive infection is greatly increased. There is natural variation in resistance

to both phagocytosis of spores and neutrophil damage to hyphae depending on the species of Mucormycotina causing infection; thus, some infections can appear more aggressive than others despite a similar milieu. Lastly, the availability of free iron (a promoter of Mucormycotina growth) increases probability of infection, as seen in people with diabetes (increased free iron due to ketoacidosis and/or glycosylation-induced poor iron affinity) and patients on chronic iron chelation treatment (where deferoxamine acts as a siderophore within the fungi).

MORPHOLOGY

Mucormycetes form nonseptate hyphae of variable width (6-50 μm) with frequent right angle branching, distinct from *Aspergillus* hyphae, that are readily demonstrated by hematoxylin and eosin or special fungal stains (Fig. 8-45). The three primary sites of invasion are the nasal sinuses, lungs, and gastrointestinal tract, depending on whether the spores (which are widespread in dust and air) are inhaled or ingested. Most commonly in individuals with diabetes, the fungus may spread from nasal sinuses to the orbit and brain, giving rise to **rhinocerebral mucormycosis**. The Mucormycotina cause local tissue necrosis, invade arterial walls, and penetrate the periorbital tissues and cranial vault. Meningoencephalitis follows,

Figure 8-45 Meningeal blood vessels with angioinvasive *Mucor* species. Note the irregular width and near right-angle branching of the hyphae. Compare with *Aspergillus*, Fig. 8-44.

sometimes complicated by cerebral infarctions when fungi invade arteries and induce thrombosis.

Lung involvement with Mucormycotina may be secondary to rhinocerebral disease, or it may be primary in people with severe immunodeficiency. The lung lesions combine areas of hemorrhagic pneumonia with vascular thrombi and distal infarctions.

Dimorphic Fungi

The medically important dimorphic fungi are discussed in [Chapter 15](#) and include blastomyces, histoplasma, and coccidioidomyces. Suffice it to say that **they grow as yeast in human tissue but as a hyaline mold under some laboratory culture conditions, typically at room temperature.** On histological examination, the organisms have characteristic yeast appearances but can be somewhat difficult to speciate if organisms are rare. The immune response can range from suppurative to granulomatous depending on the organism and stage of disease. If concurrent cultures from a sample begin to demonstrate hyaline mold, this indicates that the organism is dimorphic and specific treatment can be started.

Parasitic Infections

Protozoa

Protozoa are unicellular eukaryotic organisms. The parasitic protozoa are transmitted by insects or by the fecal-oral route and, in humans, mainly reside in the blood or intestine ([Table 8-8](#)). Most protozoal infections are diagnosed by microscopic examination of blood smears or lesions.

Malaria

Malaria, caused by the intracellular parasite *Plasmodium*, affects more than 160 million people worldwide and kills more than 500,000 people each year. According to the WHO, 90% of deaths from malaria occur in sub-Saharan

Africa, where malaria is a leading cause of death in children younger than 5 years old. *Plasmodium falciparum* (the cause of severe cerebral malaria) and the four other malaria parasites that infect humans (*P. vivax*, *P. ovale*, *P. knowlesi*, and *P. malariae*) are all transmitted by female Anopheles mosquitoes, which are widely distributed throughout Africa, Asia, and Latin America. Nearly all of the approximately 1500 new cases of malaria each year in the United States occur in travelers or immigrants. Mass spraying to eliminate the mosquito vectors was successful initially but ultimately failed when DDT was removed from the market due to environmental concerns. Worldwide public health efforts to control malaria today face the challenges of insecticide-resistant mosquitoes and drug-resistant *Plasmodium* species. Currently, a combination of mosquito control and anti-malarial drugs is viewed as the means to decrease the incidence.

Life Cycle and Pathogenesis. The life cycles of the *Plasmodium* species are similar, although *P. falciparum* differs in ways that contribute to its greater virulence. *P. vivax*, *P. ovale*, *P. knowlesi*, and *P. malariae* cause low levels of parasitemia, mild anemia, and, in very rare instances, splenic rupture and nephrotic syndrome. ***P. falciparum* infection is associated with high levels of parasitemia, that may lead to severe anemia, cerebral symptoms, renal failure, pulmonary edema, and death, depending on the susceptibility of the host.**

The life cycle of *Plasmodium* species is simple, as it involves only humans and mosquitoes, but the development of the parasite is complex, as it passes through several morphologically distinct forms. The infectious stage of *Plasmodium*, the *sporozoite*, is found in the salivary glands of female mosquitoes. When the mosquito takes a blood meal, sporozoites are released into the human's blood and, within minutes, attach to and invade liver cells by binding to the hepatocyte receptor for the serum proteins thrombospondin and properdin ([Fig. 8-46](#)). Within liver cells, malaria parasites multiply, releasing as many as 30,000 *merozoites* (asexual, haploid forms) when each infected hepatocyte ruptures. During *P. falciparum* infection, rupture usually occurs within 8 to 12 weeks. In contrast, *P. vivax* and *P. ovale* form latent *hypnozoites* in hepatocytes, which cause relapses of malaria weeks to months after initial infection. The infection of the liver and development of merozoites is called the *exoerythrocytic* stage. This stage is asymptomatic. Once released from the liver, *Plasmodium* merozoites use a lectin-like molecule to bind to sialic acid residues on glycoprotein molecules on the surface of red cells and invade by active membrane penetration. Within the red cells (*erythrocytic* stage) the parasites grow in a membrane-bound digestive vacuole, hydrolyzing hemoglobin through secreted enzymes. The *trophozoite* is the first stage of the parasite in the red cell and is defined by the presence of a single chromatin mass. The next stage, the *schizont*, has multiple chromatin masses, each of which develops into a merozoite. Upon lysis of the red cell, the new merozoites infect additional red cells. Paroxysmal fever, chills, and rigors characteristic of malaria occur when the merozoites are released into the blood. As discussed later, release of merozoites induces the host cells to produce cytokines such as TNF that cause fever. The periodicity of such paroxysms (every 48-72 hours) varies with

Table 8-8 Selected Human Protozoal Diseases

Location	Species	Disease
Luminal or epithelial	<i>Entamoeba histolytica</i>	Amebic dysentery; liver abscess
	<i>Balantidium coli</i>	Colitis
	<i>Giardia lamblia</i>	Diarrheal disease, malabsorption
	<i>Isospora belli</i> , <i>Cryptosporidium</i> sp.	Chronic enterocolitis or malabsorption or both
	<i>Trichomonas vaginalis</i>	Urethritis, vaginitis
Central nervous system	<i>Naegleria fowleri</i>	Meningoencephalitis
	<i>Acanthamoeba</i> sp.	Meningoencephalitis or ophthalmitis
Bloodstream	<i>Plasmodium</i> sp.	Malaria
	<i>Babesia microti</i> , <i>B. bovis</i>	Babesiosis
	<i>Trypanosoma</i> sp.	African sleeping sickness
Intracellular	<i>Trypanosoma cruzi</i>	Chagas disease

the species of the malarial parasite. Although most malaria parasites within the red cells develop into merozoites, some parasites develop, under specific conditions, into sexual forms called *gametocytes* that infect the mosquito when it takes its blood meal.

Plasmodium falciparum causes more severe disease than the other *Plasmodium* species do. Several features of *P. falciparum* account for its greater pathogenicity:

- *P. falciparum* is able to infect red blood cells of any age, whereas other species infect only young or old red cells, which are a smaller fraction of the red cell pool.
- *P. falciparum* causes infected red cells to clump together (rosette) and to stick to endothelial cells lining small blood vessels (sequestration), which blocks blood flow. Several proteins, including *P. falciparum* erythrocyte membrane protein 1 (PfEMP1), associate and form knobs on the surface of red cells (Fig. 8-46). PfEMP1 binds to ligands on endothelial cells, including CD36, thrombospondin, VCAM-1, ICAM-1, and E-selectin. Red cell sequestration decreases tissue perfusion and leads to ischemia, which is responsible for the manifestations of cerebral malaria, the major cause of death in children with malaria.
- In *P. falciparum* infection, GPI-linked proteins, including merozoite surface antigens, are released from infected

red cells and induce cytokine production by host cells. These cytokines, including TNF, IFN- γ , and IL-1, suppress production of red blood cells, increase fever, stimulate the production of reactive nitrogen species (leading to tissue damage), and induce expression of endothelial receptors for PfEMP1 (increasing sequestration).

Host resistance to *Plasmodium* can be intrinsic or acquired. Intrinsic resistance stems from inherited alterations that reduce the susceptibility of red cells to productive *Plasmodium* infections. Resistance may also be acquired following repeated or prolonged exposure to *Plasmodium* species, which stimulates a partially protective immune response.

Several types of mutations affecting red cells are highly prevalent in parts of the world where malaria is endemic and are absent in other parts of the world. Most of these mutations are deleterious in homozygous form, suggesting that they are maintained in populations due to a selective advantage for heterozygous carriers against malaria. The mutations fall into four broad classes.

- Point mutations in globin genes—sickle cell disease (HbS), HbC disease (hemoglobinopathies)
- Mutations leading to globin deficiencies— α - and β -thalassemia
- Mutations affecting red cell enzymes—glucose-6-phosphate dehydrogenase (G6PD) deficiency
- Mutations causing red cell membrane defects—absence of DARC (Duffy surface blood group), band 3, spectrin

P. vivax enters red cells by binding to the Duffy blood group antigen, and most of the population of West Africa is not susceptible to infection by *P. vivax* because they do not have the Duffy antigen. The mechanisms of the protective effects of the other three types of mutations are less well understood, but likely involve a favorable shift in the balance between the growth of intraerythrocytic parasites and their clearance by host phagocytes.

Individuals living where *Plasmodium* is endemic often gain partial immune-mediated resistance to malaria, evidenced by reduced illness despite infection. Antibodies and T lymphocytes specific for *Plasmodium* reduce disease manifestations, although the parasite has developed strategies to evade the host immune response. *P. falciparum* uses antigenic variation to escape from antibody responses to PfEMP1. Each haploid *P. falciparum* genome has about 50 *var* genes, each encoding a variant of PfEMP1. The mechanism of *var* regulation is not known, but at least 2% of the parasites switch PfEMP1 genes each generation. Cytotoxic T cells may also be important in resistance to *P. falciparum*. Current vaccine trials have demonstrated decreases in severe disease but only modest efficacy against clinical infection.

MORPHOLOGY

The diagnostic test for malaria infection is examination of a Giemsa-stained peripheral blood smear, which permits the asexual stages of the parasite to be identified within infected red cells. Insertion of parasite proteins into the red cell membrane leads to recognition by macrophages,

Figure 8-47 Field's stain of *Plasmodium falciparum*-infected red cells marginating within a capillary in cerebral malaria.

particularly in the spleen. *Plasmodium falciparum* infection leads to **splenomegaly**, due to both congestion and hyperplasia of the red pulp, and the spleen may eventually exceed 1000 gm in weight. In chronic infections, the spleen becomes increasingly fibrotic and brittle, with a thick capsule and fibrous trabeculae. The parenchyma is gray or black because the phagocytes contain granular, brown-black, faintly birefringent hemozoin pigment. Macrophages with engulfed parasitized red cells are also numerous.

With progression of malaria, the liver becomes enlarged and pigmented. Kupffer cells are heavily laden with malarial pigment, parasites, and cellular debris, while some pigment is also present in the parenchymal cells. Pigmented phagocytic cells may be found dispersed throughout the bone marrow, lymph nodes, subcutaneous tissues, and lungs. The kidneys are often enlarged and congested with a dusting of pigment in the glomeruli and hemoglobin casts in the tubules.

In **cerebral malaria** caused by *P. falciparum*, brain vessels are plugged with parasitized red cells (Fig. 8-47). Around the vessels there are ring hemorrhages that are probably related to local hypoxia incident to the vascular stasis and small focal inflammatory reactions (called **malarial** or **Dürck granulomata**). With more severe hypoxia, there is degeneration of neurons, focal ischemic softening, and occasionally scant inflammatory infiltrates in the meninges.

Nonspecific focal hypoxic lesions in the heart may be induced by the progressive anemia and circulatory stasis in chronically infected people. In some, the myocardium shows focal interstitial infiltrates. Finally, in the nonimmune patient, pulmonary edema or shock with disseminated intravascular coagulation may cause death, sometimes in the absence of other characteristic lesions.

Babesiosis

Babesia microti and *Babesia divergens* are malaria-like protozoans transmitted by the same deer ticks that carry Lyme disease and granulocytic ehrlichiosis. The white-footed mouse is the reservoir for *B. microti*, and in some areas, nearly all mice have a persistent low-level parasitemia. *B. microti* survives well in refrigerated blood, and several cases of transfusion-acquired babesiosis have been reported. *Babesia* parasitize red cells and cause fever and

hemolytic anemia. The symptoms are mild except in debilitated or splenectomized individuals, who develop severe, potentially fatal parasitemias.

MORPHOLOGY

In blood smears, *Babesia* organisms superficially resemble *P. falciparum* ring stages, but lack hemozoin pigment, exhibit greater pleomorphism, and form characteristic tetrads (Maltese cross), which are diagnostic, if found (Fig. 8-48). The level of *B. microti* parasitemia is a good indication of the severity of infection (about 1% in mild cases and up to 30% in splenectomized persons). In fatal cases the anatomic findings are related to shock and hypoxia, and include jaundice, hepatic necrosis, acute renal tubular necrosis, adult respiratory distress syndrome, erythrophagocytosis, and visceral hemorrhages.

Leishmaniasis

Leishmaniasis is a chronic inflammatory disease of the skin, mucous membranes, or viscera caused by obligate intracellular, kinetoplast-containing (kinetoplastid) protozoan parasites transmitted through the bite of infected sandflies. Leishmaniasis is endemic throughout the Middle East, South Asia, Africa, and Latin America. It may also be epidemic, as is tragically the case in Sudan, India, Bangladesh, and Brazil, where tens of thousands of people have died of visceral leishmaniasis. Leishmanial infection, like infections by other intracellular organisms (mycobacteria, *Histoplasma*, *Toxoplasma*, and trypanosomes), is exacerbated by conditions that interfere with T-cell function, such as AIDS. Culture or histologic examination is used to diagnose the infection.

Pathogenesis. The life cycle of *Leishmania* involves two forms: the promastigote, which develops and lives extracellularly in the sandfly vector, and the amastigote, which multiplies intracellularly in host macrophages. Mammals, including rodents, dogs, and foxes, are reservoirs of *Leishmania*. When sandflies bite infected humans or animals, macrophages harboring amastigotes are ingested. The amastigotes differentiate into promastigotes, multiply within the digestive tract of the sandfly and migrate to the salivary gland, where they are poised for transmission by the fly bite. When the infected fly bites a person, the slender, flagellated infectious promastigotes

Figure 8-48 Erythrocytes with *Babesia*, including the distinctive Maltese cross form. (Courtesy Lynne Garcia, LSG and Associates, Santa Monica, Calif.)

are released into the host dermis along with the sandfly saliva, which potentiates parasite infectivity. The promastigotes are phagocytosed by macrophages, and the acidity within the phagolysosome induces them to transform into round amastigotes that lack flagella but contain a single mitochondrion with its DNA massed into a unique suborganelle, the kinetoplast. Amastigotes proliferate within macrophages, and dying macrophages release progeny amastigotes that can infect additional macrophages.

How far the amastigotes spread throughout the body depends on the *Leishmania* species and host, and determines the extent of disease. There are several forms of disease and that are caused by different species of *Leishmania*.

- Cutaneous disease
 - Old World—*Leishmania major* and *Leishmania tropica*
 - New World—*Leishmania mexicana* and *Leishmania braziliensis*
- Mucocutaneous disease (also called *espundia*)
 - New World—*L. braziliensis*
- Visceral disease involving the liver, spleen, and bone marrow
 - Old World—*Leishmania donovani* and *Leishmania infantum*
 - New World—*Leishmania chagasi*

Tropism of *Leishmania* species seems to be linked in part to the optimal temperature for their growth. Parasites that cause visceral disease grow best at 37°C, whereas parasites that cause mucocutaneous disease grow better at lower temperatures. However, cutaneous *Leishmania* species often are viscerotropic in HIV patients.

Leishmania manipulate innate host defenses to facilitate their entry and survival in macrophages. Promastigotes produce two abundant surface glycoconjugates that contribute to their virulence.

- Lipophosphoglycan forms a dense glycocalyx that both activates complement (leading to C3b deposition on the parasite surface) and inhibits complement action (by preventing membrane attack complex insertion into the parasite membrane). Thus, the parasite becomes coated with C3b but avoids destruction by the membrane attack complex. Instead, the C3b on the surface of the parasite binds to Mac-1 and CR1 on macrophages, targeting the promastigote for phagocytosis.
- Gp63 is a zinc-dependent proteinase that cleaves complement and some lysosomal antimicrobial enzymes. Gp63 also binds to fibronectin receptors on macrophages and promotes promastigote adhesion to macrophages.

Leishmania amastigotes also produce molecules that facilitate their survival and replication within macrophages. Amastigotes reproduce in macrophage phagolysosomes, which normally have a pH of 4.5. However, the amastigotes protect themselves from this hostile environment by expressing a proton-transporting ATPase, which maintains the phagolysosome pH at 6.5.

The primary mechanisms of resistance and susceptibility to *Leishmania* are mediated through T_H1 and T_H2 responses. Parasite-specific CD4⁺ T_H1 cells are needed to control *Leishmania* in mice and humans. *Leishmania* evade host immunity by impairing the development of the T_H1

Figure 8-49 Giemsa stain of a tissue macrophage with *Leishmania donovani* parasites.

response. In animal models, mice that are resistant to *Leishmania* infection produce high levels of T_H1-derived IFN- γ , which activates macrophages to kill the parasites through reactive oxygen species. By contrast, mouse strains that are susceptible to leishmaniasis mount a dominant T_H2 response. T_H2 cytokines such as IL-4, IL-13, and IL-10 prevent effective killing of *Leishmania* by inhibiting the microbicidal activity of macrophages.

MORPHOLOGY

Leishmania species produce four different types of lesions in humans: visceral, cutaneous, mucocutaneous, and diffuse cutaneous. In **visceral leishmaniasis**, parasites invade macrophages throughout the mononuclear phagocyte system (Fig. 8-49), and cause severe systemic disease marked by hepatosplenomegaly, lymphadenopathy, pancytopenia, fever, and weight loss. The spleen may weigh as much as 3 kg. Phagocytic cells are enlarged and filled with *Leishmania*, many plasma cells are present, and the normal architecture of the spleen is obscured. In the late stages, the liver becomes increasingly fibrotic. Phagocytic cells crowd the bone marrow and also may be found in the lungs, gastrointestinal tract, kidneys, pancreas, and testes. Often there is hyperpigmentation of the skin in individuals of South Asian ancestry, which is why the disease is called *kala-azar* (*black fever* in Hindi). In the kidneys there may be an immune complex-mediated mesangioproliferative glomerulonephritis, and in advanced cases there may be amyloid deposition. People with advanced leishmaniasis can develop life-threatening secondary bacterial infections, such as pneumonia, sepsis or tuberculosis. Hemorrhages related to thrombocytopenia may also be fatal.

Cutaneous leishmaniasis is a relatively mild, localized disease consisting of ulcers on exposed skin. The lesion begins as a papule surrounded by induration, changes into a shallow and slowly expanding ulcer, often with heaped-up borders, and usually heals by involution within 6 to 18 months without treatment. On microscopic examination, the lesion shows granulomatous inflammation, usually with many giant cells and few parasites.

Mucocutaneous leishmaniasis is found only in the New World. Moist, ulcerating, or nonulcerating lesions develop in the

nasopharyngeal areas and, with progression, may be highly destructive and disfiguring. Microscopic examination reveals a mixed inflammatory infiltrate composed of parasite-containing macrophages with lymphocytes and plasma cells. Later, the tissue inflammatory response becomes granulomatous, and the number of parasites declines. Eventually, the lesions remit and scar, although reactivation may occur after long intervals by mechanisms that are not currently understood.

Diffuse cutaneous leishmaniasis is a rare form of dermal infection found in Ethiopia and adjacent East Africa and in Central and South America. Diffuse cutaneous leishmaniasis begins as a single skin nodule, which continues spreading until the entire body is covered by nodular lesions. Microscopically, they contain aggregates of foamy macrophages stuffed with leishmania.

African Trypanosomiasis

African trypanosomes are kinetoplastid parasites that proliferate as extracellular forms in the blood and cause sustained or intermittent fevers, lymphadenopathy, splenomegaly, progressive brain dysfunction (sleeping sickness), cachexia, and death. *Trypanosoma brucei rhodesiense* infection, which occurs in East Africa and is often acute and virulent, is a zoonotic infection that is best combated by reducing infected fly populations. *Trypanosoma brucei gambiense* infection occurring in West Africa tends to spread from human to human via fly bites and requires active case detection and treatment. Tsetse flies (genus *Glossina*) transmit African *Trypanosoma* to humans either from the reservoir of parasites found in wild and domestic animals (*T. brucei rhodesiense*) or from other humans (*T. brucei gambiense*). Within the fly, the parasites multiply in the stomach and then in the salivary glands before developing into nondividing trypomastigotes, which are transmitted to humans and animals with the next blood meal.

Pathogenesis. African trypanosomes are covered by a single, abundant, glycolipid-anchored protein called the *variant surface glycoprotein (VSG)*. As parasites proliferate in the bloodstream, the host produces antibodies to the VSG, which, in association with phagocytes, kill most of the organisms, causing a spike of fever. A small number of parasites, however, undergo a genetic rearrangement and produce a different VSG on their surface and so escape the host immune response. These successor trypanosomes multiply until the host mounts a new anti-VSG response and kills most of them, but then another clone with a distinct VSG takes over. In this way, African trypanosomes cause waves of fever before they finally invade the CNS. Trypanosomes have many VSG genes, only one of which is expressed at a time. The parasite uses an elegant mechanism to turn VSG genes on and off. Although VSG genes are scattered throughout the trypanosome genome, only VSG genes found within *bloodstream expression sites* near the ends of chromosomes (the telomeres) are transcribed. New VSG genes are periodically moved into the bloodstream expression sites, mainly by homologous recombination. A specialized RNA polymerase that transcribes VSG genes associates with only a single bloodstream expression site, limiting expression to one VSG gene at a time.

Figure 8-50 Slender bloodstream parasites of African trypanosomiasis.

MORPHOLOGY

A large, red, rubbery chancre forms at the site of the insect bite and contains numerous parasites surrounded by a dense, predominantly mononuclear, inflammatory infiltrate. With chronicity, the lymph nodes and spleen enlarge due to infiltration by lymphocytes, plasma cells, and macrophages, which are filled with dead parasites. Trypanosomes, which are small and difficult to visualize (Fig. 8-50), concentrate in capillary loops, such as the choroid plexus and glomeruli. When parasites breach the blood-brain barrier and invade the CNS, a leptomeningitis develops that extends into the perivascular Virchow-Robin spaces, and eventually a demyelinating panencephalitis occurs. Plasma cells containing cytoplasmic globules filled with immunoglobulins are frequent and are referred to as **Mott cells**. Chronic disease leads to progressive cachexia; patients, devoid of energy and normal mentation, literally waste away.

Chagas Disease

***Trypanosoma cruzi* is a kinetoplastid, intracellular protozoan parasite that causes American trypanosomiasis (Chagas disease).** Chagas disease occurs rarely in the United States and Mexico but is more common in South America, particularly Brazil. *T. cruzi* parasites infect many animals, including cats, dogs, and rodents. The parasites are transmitted between animals and to humans by triatomine bugs (also known as kissing bugs or reduviids), which hide in the cracks of loosely constructed houses, feed on the sleeping inhabitants, and pass the parasites in the feces; the infectious parasites enter the host through damaged skin or through mucous membranes. At the site of skin entry there may be a transient, erythematous nodule. Another important route of infection is oral ingestion of the parasites due to contamination of food products with triatomine bugs and/or their feces. Once in the host, *T. cruzi* invades human cells through interaction with a variety of molecules including TLRs, kinins, and receptors for TGF, EGF, tyrosine kinases, and LDL.

Pathogenesis. While most intracellular pathogens avoid the toxic contents of lysosomes, *T. cruzi* actually requires brief exposure to the acidic phagolysosome for development of amastigotes, the intracellular stage of the parasite.

To ensure exposure to lysosomes, *T. cruzi* trypomastigotes elevate the concentration of cytoplasmic calcium in host cells, which promotes fusion of the phagosome and lysosome. In addition to enhancing amastigote development, the low pH of the lysosome activates pore-forming proteins that disrupt the lysosomal membrane, releasing the parasite into the cell cytoplasm. Parasites reproduce as rounded amastigotes in the cytoplasm of host cells and then develop flagella, lyse host cells, enter the bloodstream, and penetrate smooth, skeletal, and heart muscles.

Chagas disease primarily affects the heart and in endemic areas, it is a major cause of sudden death due to cardiac arrhythmia. In acute Chagas disease, which is mild in most individuals, cardiac damage results from direct invasion of myocardial cells by the organisms and the subsequent inflammation. Rarely, acute Chagas disease presents with high parasitemia, fever, or progressive cardiac dilation and failure, often with generalized lymphadenopathy or splenomegaly. In chronic Chagas disease, which occurs in 20% of people 5 to 15 years after initial infection, the mechanism of cardiac damage has two components.

- The presence of persistent *T. cruzi* parasites leads to a continued immune response with a striking inflammatory infiltration of the myocardium, even though only scant organisms may be present.
- The parasite also may induce autoimmune responses, such that antibodies and T cells that recognize parasite proteins cross-react with host myocardial cells, nerve cells, and extracellular proteins such as laminin. For example, cross-reactive antibodies may induce electrophysiologic dysfunction of the heart.

Damage to myocardial cells and to conductance pathways causes a dilated cardiomyopathy and cardiac arrhythmias. In addition, damage to the myenteric plexus causes dilation of the colon (megacolon) and esophagus. This is particularly common in Brazilian endemic areas where as many as 50% of the patients with lethal carditis have colonic and esophageal disease.

MORPHOLOGY

In lethal **acute myocarditis**, the changes are diffusely distributed throughout the heart. Clusters of amastigotes cause swelling of individual myocardial fibers and create intracellular pseudocysts. There is focal myocardial cell necrosis accompanied by extensive, dense, acute interstitial inflammatory infiltration throughout the myocardium, often associated with four-chamber cardiac dilation (Chapter 12).

In **chronic Chagas disease** the heart is typically dilated, rounded, and increased in size and weight. Often, there are mural thrombi that, in about half of autopsy cases, have given rise to pulmonary or systemic emboli or infarctions. On histologic examination, there are interstitial and perivascular inflammatory infiltrates composed of lymphocytes, plasma cells, and monocytes. There are scattered foci of myocardial cell necrosis and interstitial fibrosis, especially toward the apex of the left ventricle, which may undergo aneurysmal dilation and thinning. Even with dilation of the esophagus and colon, parasites cannot be found within ganglia of myenteric plexus. Chronic Chagas cardiomyopathy is often treated by cardiac transplantation.

Metazoa

Metazoa are multicellular, eukaryotic organisms. The parasitic metazoa are contracted by consuming the parasite, often in undercooked meat, or by direct invasion of the host through the skin or via insect bites. Metazoa dwell in many sites of the body, including the intestine, skin, lung, liver, muscle, blood vessels, and lymphatics. The infections are diagnosed by microscopic identification of larvae or ova in excretions or tissues, and by serology.

Strongyloidiasis

Strongyloides stercoralis infects tens of million people worldwide and is endemic in the southeastern United States, South America, sub-Saharan Africa, and Southeast Asia. **The worms live in the soil and infect humans when larvae penetrate the skin, travel in the circulation to the lungs, and then travel up the trachea to be swallowed.** Female worms reside in the mucosa of the small intestine, where they produce eggs by asexual reproduction (parthenogenesis). Most of the larvae are passed in the stool and then may contaminate soil to continue the cycle of infection.

In immunocompetent hosts, *S. stercoralis* may cause diarrhea, bloating, and occasionally malabsorption. Unlike other parasitic worms, *S. stercoralis* larvae hatched in the gut can invade the colon mucosa and reinstate infection (autoinfection). Immunocompromised hosts, particularly people on prolonged corticosteroid therapy, can have very high worm burdens (hyperinfection) due to uncontrolled autoinfection, leading to fatal disease. Corticosteroids inhibit the functions of eosinophils that accumulate in tissues in response to infection, induce apoptosis in immune cells, and stimulate female *Strongyloides* directly to increase infective larvae production. In addition, other disease states which perturb immune control mechanisms (e.g., organ transplantation, lymphoma, HIV/AIDS, HTLV-1) have increased risks. Hyperinfection can be complicated by sepsis caused by intestinal bacteria, which enter the blood following damage to the intestinal wall by the invading larvae.

MORPHOLOGY

In mild strongyloidiasis, worms, mainly larvae, are present in the duodenal crypts but are not seen in the underlying tissue. There is an eosinophil-rich infiltrate in the lamina propria with mucosal edema. Hyperinfection with *S. stercoralis* results in invasion of larvae into the colonic submucosa, lymphatics, and blood vessels, with an associated mononuclear infiltrate. There are many adult worms, larvae, and eggs in the crypts of the duodenum and ileum (Fig. 8-51). Worms of all stages may be found in other organs, including skin and lungs, and may even be found in large numbers in sputum.

Tapeworms (Cestodes): Cysticercosis and Hydatid Disease

Taenia solium and *Echinococcus granulosus* are cestode parasites (tapeworms) that cause cysticercosis and hydatid infections, respectively. Both diseases are caused by larvae that develop after ingestion of tapeworm eggs. These tapeworms have a complex life cycle requiring two mammalian hosts: a definitive host, in which the worm reaches sexual

Figure 8-51 *Strongyloides* hyperinfection in a patient treated with high-dose cortisone. A female, her eggs, and rhabditoid larvae are in the duodenal crypts; filariform larvae are entering the blood vessels and muscularis mucosa. (Courtesy Dr. Franz C. Von Lichtenberg, Brigham and Women's Hospital, Boston, Mass.)

maturity, and an intermediate host, in which the worm does not reach sexual maturity.

Taenia solium tapeworms consist of a head (scolex) that has suckers and hooklets that attach to the intestinal wall, a neck, and many flat segments called *proglottids* that contain both male and female reproductive organs. New proglottids develop behind the scolex. The most distal proglottids are mature and contain many eggs, and they can detach and be shed in the feces. *T. solium* can be transmitted to humans in two ways, ingestion of larval cysts or eggs, with distinct outcomes.

- Larval cysts, called cysticerci, are ingested in undercooked pork and attach to the intestinal wall, where they develop into mature adult tapeworms. These can grow to many meters in length and produce mild abdominal symptoms. The parasite life cycle is completed with this mode of infection and cysticercosis does not develop.
- When intermediate hosts (pigs or humans) ingest eggs in food or water contaminated with human feces, the larvae hatch, penetrate the gut wall, disseminate hematogenously, and encyst in many organs, giving rise to clinical symptoms of cysticercosis. The most serious manifestations result from encystment in the brain (neurocysticercosis). Convulsions, increased intracranial pressure, and other neurologic disturbances may occur. Adult tapeworms are not produced with this mode of infection since larval cysts lodged in various tissues cannot develop into mature worms. Viable *T. solium* cysts often do not produce symptoms and can evade host immune defenses by producing taeniaestatin and paramyosin, which seem to inhibit complement activation. When the cysticerci die and degenerate, an inflammatory response develops.

Taenia saginata, the beef tapeworm, and *Diphyllobothrium latum*, the fish tapeworm, are acquired by eating undercooked meat or fish. In humans these parasites live only in the gut, and do not form cysticerci.

Hydatid disease is caused by ingestion of eggs of echinococcal species. For *Echinococcus granulosus* the definitive host is the dog and the usual intermediate hosts

are sheep. For *Echinococcus multilocularis* the fox is the most important definitive host, and rodents are intermediate hosts. Humans are accidental intermediate hosts, infected by ingestion of food contaminated with eggs shed by dogs or foxes. Eggs hatch in the duodenum and invade the liver, lungs, or bones.

MORPHOLOGY

Cysticerci may be found in any organ, but the more common locations include the brain, muscles, skin, and heart. Cerebral symptoms depend on the precise location of the cysts, which may be intraparenchymal, attached to the arachnoid, or freely floating in the ventricular system. The cysts are ovoid and white to opalescent, often grape-sized, and contain an invaginated scolex with hooklets that are bathed in clear cyst fluid (Fig. 8-52). The cyst wall is more than 100 μm thick, is rich in glycoproteins, and evokes little host inflammatory response when it is intact. When cysts degenerate, however, there is inflammation, followed by focal scarring, and calcifications, which may be visible by radiography.

About two thirds of human *E. granulosus* cysts are found in the liver, 5% to 15% in the lung, and the rest in bones and brain or other organs. In the various organs the larvae lodge within the capillaries and first incite an inflammatory reaction composed principally of mononuclear leukocytes and eosinophils. Many such larvae are destroyed, but others encyst. The cysts begin at microscopic levels and progressively increase in size, so that in 5 years or more they may have achieved dimensions of more than 10 cm in diameter. Enclosing an opalescent fluid is an inner, nucleated, germinative layer and an outer, opaque, non-nucleated layer. The outer non-nucleated layer is distinctive and has innumerable delicate laminations. Outside this opaque layer, there is a host inflammatory reaction that produces a zone of fibroblasts, giant cells, and mononuclear and eosinophilic cells. In time a dense fibrous capsule forms. Daughter cysts often develop within the large mother cyst. These appear first as minute projections of the germinative layer that develop central vesicles and thus form tiny brood capsules. Degenerating scolices of the worm produce a fine, sandlike sediment within the hydatid fluid (hydatid sand).

Trichinosis

Trichinella is a species of nematode parasite that is acquired by ingestion of larvae in undercooked meat from infected

Figure 8-52 Portion of a cysticercus cyst in the skin.

animals (usually pigs, boars, or horses) that have themselves been infected by eating rats or meat products containing *T. spiralis*, *T. nativa*, or *T. britovi*. In the United States the number of *T. spiralis*-infected pigs has been greatly reduced by laws requiring proper cooking of food fed to hogs; the number of reported human infections in the United States is now less than 20 cases each year. Still, trichinosis remains widespread in other parts of the world, where undercooked meat, including noncommercial livestock and game (e.g., bear), is commonly eaten.

The life cycle of *T. spiralis* begins in the human intestine but ends within muscle as humans are dead-end hosts. In the human gut, *T. spiralis* larvae develop into adults that mate and release new larvae, which penetrate into the tissues. Larvae disseminate hematogenously and penetrate muscle cells, causing fever, myalgias, marked eosinophilia, and periorbital edema. Less commonly, the larvae lodge in the heart, lungs, and brain, and patients can develop dyspnea, encephalitis, and cardiac failure. In striated skeletal muscle, *T. spiralis* larvae become intracellular parasites, increase dramatically in size, and modify the host muscle cell (referred to as the *nurse cell*) so that it loses its striations, gains a collagenous capsule, and develops a plexus of new blood vessels around itself. The nurse cell-parasite complex is largely asymptomatic, and the worm may persist for years before it dies and calcifies. Antibodies to larval antigens, which include an immunodominant carbohydrate epitope called *tyvelose*, may reduce reinfection and are useful for serodiagnosis of the disease.

***Trichinella spiralis* and other invasive nematodes stimulate a T_H2 response**, with production of IL-4, IL-5, IL-10, and IL-13. The cytokines produced by T_H2 cells activate eosinophils and mast cells, both of which are associated with the inflammatory response to these parasites. In animal models of *T. spiralis* infection, the T_H2 response is associated with increased contractility of the intestine, which expels adult worms from the gut and subsequently reduces the number of larvae in the muscles. While the T_H2 response indirectly reduces the number of larvae in muscle by eliminating adults from the intestine, it is not clear whether the intramuscular inflammatory response, which is composed of mononuclear cells and eosinophils, is effective against the larvae.

MORPHOLOGY

During the invasive phase of trichinosis, cell destruction can be widespread with heavy infections and may be lethal. In the heart there is a patchy interstitial myocarditis characterized by many eosinophils and scattered giant cells. The myocarditis can lead to scarring. Larvae in the heart do not encyst and are difficult to identify, because they die and disappear. In the lungs, trapped larvae cause focal edema and hemorrhages, sometimes with an allergic eosinophilic infiltrate. In the CNS, larvae cause a diffuse lymphocytic and eosinophilic infiltrate, with focal gliosis in and about small capillaries of the brain.

Trichinella spiralis preferentially encysts in striated skeletal muscles with the richest blood supply, including the diaphragm and the extraocular, laryngeal, deltoid, gastrocnemius, and intercostal muscles (Fig. 8-53). Coiled larvae are approximately 1 mm long and are surrounded by membrane-bound vacuoles within nurse cells, which in turn are surrounded by new blood

Figure 8-53 Multiple coiled *Trichinella spiralis* larvae within skeletal muscle cells.

vessels and an eosinophil-rich mononuclear cell infiltrate. This infiltrate is greatest around dying parasites, which eventually calcify and leave behind scars that are sufficiently characteristic to suggest the diagnosis of trichinosis.

Schistosomiasis

Schistosomiasis infects approximately 230 million persons and kills more than 200,000 individuals annually. The affected organs and hence the site of major disease vary with the species. *Shistosoma mansoni* and *S. japonicum* affect the liver and the gut predominantly. Most deaths are due to hepatic cirrhosis, which is caused by *S. mansoni* in Latin America, Africa, and the Middle East and by *S. japonicum* and *S. mekongi* in East Asia. By contrast, *S. haematobium*, found in Africa, causes chronic granulomatous bladder inflammation that may lead to hematuria, obstructive uropathy, and carcinoma. *Schistosoma* flukes, like all trematodes, require passage through freshwater snails that live in the slow-moving water of tropical rivers, lakes, and irrigation ditches, ironically linking agricultural development with spread of the disease. Acute schistosomiasis in humans can be a severe febrile illness that peaks about 2 months after infection. Severe hepatic fibrosis is a serious manifestation of chronic schistosomiasis (see later).

Pathogenesis. Much of the pathology of schistosomiasis is caused by host inflammatory reactions to different stages of the parasite. The life cycle of *Schistosoma* involves stepwise infection of several human tissues, each associated with host inflammatory responses. After release from snails, ciliated miracidium larvae mature into infectious schistosome larvae (cercariae) that swim through fresh water and penetrate human skin with the aid of powerful proteolytic enzymes that degrade the keratinized layer. There is minimal skin reaction. Schistosomes migrate through the skin into the peripheral vasculature and lymphatics, travel to the lungs and heart, from where they are disseminated widely, including the mesenteric, splanchnic and portal circulation, ultimately reaching the hepatic vessels where they mature (*S. mansoni* and *S. japonicum*).

Mature male-female worm pairs then migrate once again and settle in the venous system (commonly the portal or pelvic veins). Females produce hundreds to thousands of eggs per day which secrete proteases and elicit localized inflammatory reactions. This inflammatory response to egg migration is necessary for passive transfer across the intestine and, in the case of *S. haematobium*, bladder walls, allowing the eggs to be shed in stool or urine, respectively. Infection of freshwater snails completes the life cycle.

Eggs that are carried by the portal circulation into the hepatic parenchyma can cause severe chronic inflammation in the liver. This immune response to *S. mansoni* and *S. japonicum* eggs is responsible for the most serious complication of schistosomiasis, liver fibrosis. The helper T-cell response in the early stage is dominated by T_H1 cells that produce IFN- γ , which stimulates macrophages to secrete high levels of the cytokines TNF, IL-1, and IL-6 that cause fever. Chronic schistosomiasis is associated with a dominant T_H2 response, associated with the presence of alternatively activated macrophages. Both types of helper T cells contribute to the formation of granulomas surrounding eggs in the liver. Hepatic fibrosis is a serious manifestation of chronic schistosomiasis in which T_H2 cells and alternatively activated macrophages may play the major role.

MORPHOLOGY

In early *S. mansoni* or *S. japonicum* infections, white, pinhead-sized granulomas are scattered throughout the gut and liver. At the center of the granuloma is the schistosome egg, which contains a miracidium; this degenerates over time and calcifies. The granulomas are composed of macrophages, lymphocytes, neutrophils, and eosinophils, which are distinctive for helminth infections (Fig. 8-54). The liver is darkened by regurgitated heme-derived pigments from the schistosome gut, which, like malaria pigments, are iron-free and accumulate in Kupffer cells and splenic macrophages.

Figure 8-54 *Schistosoma haematobium* infection of the bladder (left) showing dense fibrosis, scattered granulomas, and a cross section of adult worms in a vessel (arrow). High magnification (right) demonstrates miracidium-containing eggs (arrow), prominent eosinophils, histiocytes, and giant cells.

Figure 8-55 Pipe-stem fibrosis of the liver due to chronic *Schistosoma japonicum* infection.

In late *S. mansoni* or *S. japonicum* infections, inflammatory patches or pseudopolyps may form in the colon. The surface of the liver is bumpy, and cut surfaces reveal granulomas and widespread fibrosis and portal enlargement without intervening regenerative nodules. Because these fibrous triads resemble the stem of a clay pipe, the lesion is named **pipe-stem fibrosis** (Fig. 8-55). The fibrosis often obliterates the portal veins, leading to portal hypertension, severe congestive splenomegaly, esophageal varices, and ascites. Schistosome eggs, diverted to the lung through portal collaterals, may produce granulomatous pulmonary arteritis with intimal hyperplasia, progressive arterial obstruction, and ultimately heart failure (cor pulmonale). On histologic examination, arteries in the lungs show disruption of the elastic layer by granulomas and scars, luminal organizing thrombi, and angiomatoid lesions similar to those of idiopathic pulmonary hypertension (Chapter 15). Patients with hepatosplenic schistosomiasis also have an increased frequency of mesangioproliferative or membranous glomerulopathy (Chapter 20), in which glomeruli contain deposits of immunoglobulin and complement but rarely schistosome antigen.

In *S. haematobium* infection, inflammatory cystitis due to massive egg deposition and granulomas appears early, leading to mucosal erosions and hematuria. Later, the granulomas calcify and develop a sandy appearance, which, if severe, may line the wall of the bladder and cause a dense concentric rim (calcified bladder) on radiographic films. The most frequent complication of *S. haematobium* infection is inflammation and fibrosis of the ureteral walls, leading to obstruction, hydronephrosis, and chronic pyelonephritis. There is also an association between urinary schistosomiasis and squamous cell carcinoma of the bladder (Chapter 21).

Lymphatic Filariasis

Lymphatic filariasis is transmitted by mosquitoes and is caused by closely related nematodes, *Wuchereria bancrofti* and *Brugia* species (*B. malayi* or *B. timori*), which are responsible for 90% and 10%, respectively, of the 90 million infections worldwide. In endemic areas, which include parts of Latin America, sub-Saharan Africa, and Southeast Asia, filariasis causes a spectrum of diseases.

- Asymptomatic microfilaremia
- Recurrent lymphadenitis
- Chronic lymphadenitis with swelling of the dependent limb or scrotum (elephantiasis)
- Tropical pulmonary eosinophilia.
