As is the case with leprosy and leishmanial infections, some of the different disease manifestations caused by lymphatic filariae are likely related to variations in host T-cell responses to the parasites.

Pathogenesis. Infective larvae released by mosquitoes into the tissues during a blood meal develop within lymphatic channels into adult males and females, which mate and release microfilariae that enter into the bloodstream. When they bite infected individuals the mosquitoes can take up the microfilariae and transmit the disease. The filarial genome project has led to the identification of a number of filarial molecules that enable the organism to evade or inhibit immune defenses. *Brugia malayi* produces:

- Several surface glycoproteins with antioxidant function, which may protect from superoxide and free oxygen radicals
- Homologs of cystatins, cysteine protease inhibitors, which can impair the MHC class II antigen-processing pathway
- Serpins, serine protease inhibitors, which can inhibit neutrophil proteases, critical inflammatory mediators
- Homologs of TGF- β , which can bind to mammalian TGF- β receptors and downregulate inflammatory responses.

In addition, symbiotic *Wolbachia* bacteria infect filarial nematodes and contribute to pathogenesis of disease. *Wolbachia* are required for nematode development and reproduction, and antibiotics that eradicate *Wolbachia* impair nematode survival and fertility. It has been hypothesized that LPS from *Wolbachia* also stimulates inflammatory responses.

Immunologic responses to the filarial worms produce damage to the human host. In chronic lymphatic filariasis, damage to the lymphatics is caused directly by the adult parasites and by a T_H1-mediated immune response, which stimulates the formation of granulomas around the adult parasites. There may be an *IgE-mediated hypersensitivity* response to microfilariae in *tropical pulmonary eosinophilia*. IgE and eosinophils may be stimulated by IL-4 and IL-5, respectively, secreted by filaria-specific T_H2 helper T cells. Tropical pulmonary eosinophilia is seen most commonly in either individuals of Southern Asian or northern Latin American descent, suggesting that host factors contribute to this disorder (Chapter 15).

MORPHOLOGY

Chronic filariasis is characterized by **persistent lymphedema** of the extremities, scrotum, penis, or vulva (Fig. 8-56). Frequently there is hydrocele and lymph node enlargement. In severe and long-lasting infections, chylous weeping of the enlarged scrotum may ensue, or a chronically swollen leg may develop tough subcutaneous fibrosis and epithelial hyperkeratosis, termed

Figure 8-56 Massive edema and elephantiasis caused by filariasis of the leg. (Courtesy Dr. Willy Piessens, Harvard School of Public Health, Boston, Mass.)

elephantiasis. Elephantoid skin shows dilation of the dermal lymphatics, widespread lymphocytic infiltrates and focal cholesterol deposits; the epidermis is thickened and hyperkeratotic. Adult filarial worms—live, dead, or calcified—are present in the draining lymphatics or nodes, surrounded by (1) mild or no inflammation, (2) an intense eosinophilia with hemorrhage and fibrin (recurrent filarial funiculoepididymitis), or (3) granulomas. Over time, the dilated lymphatics develop polypoid infoldings. In the testis, hydrocele fluid, which often contains cholesterol crystals, red cells, and hemosiderin, induces thickening and calcification of the tunica vaginalis.

Lung involvement by microfilariae is marked by eosinophilia caused by T_H2 responses and cytokine production (tropical eosinophilia) or by dead microfilariae surrounded by stellate, hyaline, eosinophilic precipitates embedded in small epithelioid granulomas (Meyers-Kouwenaar bodies). Typically, these patients lack other manifestations of filarial disease.

Onchocerciasis

Onchocerca volvulus is a filarial nematode **that is the leading cause of preventable blindness in sub-Saharan Africa**. It is transmitted by black flies and affects 18 million people in Africa, South America, and Yemen. An aggressive campaign of ivermectin treatment has dramatically reduced the incidence of *Onchocerca* infection in West Africa. Since vector's preferred habitat is near fast moving water there is higher incidence of human disease near rivers, accounting for the name *river blindness* given to this disease. It is estimated that there are 270,000 people who are blind due to onchocerciasis.

The disease attributable to onchocerciasis is primarily due to inflammation induced by microfilaria. Adult *O. volvulus* parasites mate in the dermis, where they are surrounded by a mixed infiltrate of host cells that produces a characteristic subcutaneous nodule (onchocercoma). Inseminated females produce microfilariae, which accumulate in the skin and disseminate to the eye chambers.

Figure 8-57 Microfilaria-laden gravid female of *Onchocerca volvulus* in a subcutaneous fibrous nodule.

Ivermectin kills only immature worms, not adult worms, so parasites repopulate the host a few months after treatment. Doxycycline treatment blocks reproduction of *O. volvulus* for up to 24 months by killing *Wolbachia*, already mentioned as symbiotic bacteria that are required for the fertility of the filarial species.

MORPHOLOGY

Onchocerca volvulus causes chronic, itchy dermatitis with focal darkening or loss of pigment and scaling, referred to as *leopard, lizard, or elephant skin*. Foci of epidermal atrophy and elastic fiber breakdown may alternate with areas of hyperkeratosis, hyperpigmentation with pigment incontinence, dermal atrophy, and fibrosis. The subcutaneous onchocercoma is composed of a fibrous capsule surrounding adult worms and a mixed chronic inflammatory infiltrate that includes fibrin, neutrophils, eosinophils, lymphocytes, and giant cells (Fig. 8-57). The progressive eye lesions begin with punctate keratitis along with small, fluffy opacities of the cornea caused by degenerating microfilariae, which evoke an eosinophilic infiltrate. This is followed by a sclerosing keratitis that opacifies the cornea, beginning at the scleral limbus. Keratitis is sometimes accentuated by treatment with antifilarial drugs (Mazzotti reaction). Microfilariae in the anterior chamber cause iridocyclitis and glaucoma, whereas involvement of the choroid and retina results in atrophy and loss of vision.

Emerging Infectious Diseases

The rapidly expanding human population juxtaposed with environmental infractions allow the emergence of new pathogens and the re-emergence of old infectious agents. Although infectious diseases such as leprosy have been known since biblical times, and parasitic schistosomes and mycobacteria have been demonstrated in Egyptian mummies, a surprising number of new infectious agents continue to be discovered (Table 8-9). The infectious causes of some diseases with significant morbidity and mortality were previously unrecognized, because some of the infectious agents are difficult to culture; examples include *Helicobacter pylori* gastritis, HBV and HCV, and *Legionella*

pneumophila. Some infectious agents are genuinely new to humans, e.g., HIV, which causes AIDS, and *B. burgdorferi*, which causes Lyme disease. Other infections have become much more common because of immunosuppression caused by AIDS or therapy for transplant rejection and some cancers (e.g., CMV, Kaposi sarcoma herpesvirus, *Mycobacterium avium-intracellulare*, *Pneumocystis jiroveci*, and *Cryptosporidium parvum*). Finally, infectious diseases that are common in one area may be introduced into a new area. For example, West Nile virus has been common in Europe, Asia, and Africa for years but was first described in the United States in 1999.

Human demographics and behavior are important contributors to the emergence of infectious diseases. AIDS was first recognized in the United States as predominantly a disease of homosexuals and injection drug users, but heterosexual transmission is now common. In sub-Saharan Africa, the area of the world with the highest number of AIDS cases, it is predominantly a heterosexual disease. Changes in the environment occasionally drive rates of infectious diseases. Reforestation of the eastern United States has led to massive increases in the populations of deer and mice, which carry the ticks that transmit Lyme disease, babesiosis, and ehrlichiosis. Failure of DDT to control the mosquitoes that transmit malaria and the development of drug-resistant parasites have dramatically increased the morbidity and mortality of *Plasmodium falciparum* infection in Asia, Africa, and Latin America. Microbial adaptation to widespread antibiotic use contributed to the emergence of drug resistance in many species of bacteria, including *M. tuberculosis*, *N. gonorrhoeae*, *S. aureus*, and *E. faecium*. Infections with antibiotic-resistant

Table 8-9 Some Recently Recognized Infectious Agents and Manifestations

Date Recognized	Infectious Agent	Manifestations
1977	Ebola virus	Epidemic Ebola hemorrhagic fever
	Hantaan virus	Hemorrhagic fever with renal syndrome
	<i>Legionella pneumophila</i> <i>Campylobacter jejuni</i>	Legionnaire disease Enteritis
1980	HTLV-I	T-cell lymphoma or leukemia, HTLV-associated myelopathy
1981	<i>Staphylococcus aureus</i>	Toxic shock syndrome
1982	<i>Escherichia coli</i> 0157:H7	Hemorrhagic colitis, hemolytic- uremic syndrome
	<i>Borrelia burgdorferi</i>	Lyme disease
1983	HIV	AIDS
	<i>Helicobacter pylori</i>	Gastric ulcers
1988	Hepatitis E	Enterically transmitted hepatitis
1989	Hepatitis C	Hepatitis C
1992	<i>Vibrio cholerae</i> 0139	New epidemic cholera strain
	<i>Bartonella henselae</i>	Cat-scratch disease
1995	KSHV (HHV-8)	Kaposi sarcoma in AIDS
1999	West Nile virus	West Nile fever, neuroinvasive disease
2003	SARS coronavirus	Severe acute respiratory syndrome

bacteria are a continuing problem due to widespread use of antibiotics (e.g., MRSA and vancomycin-resistant *Enterococcus*). Human commercial use of dense populations of domestic animals (e.g., pigs, chickens) juxtaposed to habitat destruction of other disease reservoirs (e.g., bats and wild birds) can lead to acquisition of either unique traits in common pathogens such as influenza or emergence of unique viruses such as severe acute respiratory syndrome (SARS) virus and West Nile Virus. Because these pathogens are novel, humans lack immunity and so these infections can quickly spread through the population as pandemics, as was seen with influenza A H1N1 in 2009.

Agents of Bioterrorism. Sadly, the anthrax attacks in the United States in 2001 transformed the theoretical threat of bioterrorism into reality. The CDC has evaluated the microorganisms that pose the greatest danger as weapons on the basis of the efficiency with which disease can be transmitted, how difficult the microorganisms are to produce and distribute, what can be done to defend against them, and the extent to which they are likely to alarm the public and produce widespread fear.

- Category A agents pose the highest risk and can be readily disseminated or transmitted from person to person, can cause high mortality with potential for major public health impact, might cause public panic and social disruption, and might require special action for public health preparedness. For example, smallpox is a category A agent because of its high transmissibility in any climate or season, case mortality rate of 30% or greater, and lack of effective antiviral therapy. This agent can be easily disseminated because of the stability of the virus in aerosol form and the very small dose needed for infection. Smallpox naturally spreads from person to person mainly by direct contact with virus in skin lesions or contaminated clothing or bedding. Symptoms appear after 7 to 17 days. Initially there is high fever, headache, and backache, followed by the appearance of the rash, which first appears on the mucosa of the mouth and pharynx, face, and forearms and later spreads to the trunk and legs and becomes vesicular and later pustular. Because people can be contagious during the incubation period, this virus has the potential to continue to spread throughout an unprotected population. Since vaccination ended in the United States in 1972 and vaccination immunity has waned, the population is highly susceptible to smallpox. Recent concern that smallpox could be used for bioterrorism has led to a return of vaccination for selected groups in the United States and Israel.
- Category B agents are relatively easy to disseminate, produce moderate morbidity but low mortality, and require specific diagnostic and disease surveillance. Many of these agents are foodborne or waterborne. Examples include *Brucella* sp., *Vibrio cholerae*, and ricin toxin from castor beans.
- Category C agents include emerging pathogens that could be engineered for mass dissemination because of availability, ease of production and dissemination, potential for high morbidity and mortality, and great impact on health. Examples include Hantavirus and Nipahvirus.

Many diseases are caused or influenced by environmental factors. Broadly defined, the term *environment* encompasses the various indoor, outdoor, and occupational settings in which human beings live and work. In each of these settings, the air people breathe, the food and water they consume, and the toxic agents they are exposed to are major determinants of health. The environmental factors that influence our health pertain to individual behavior (“personal environment”) and include tobacco use, alcohol ingestion, recreational drug consumption, diet, and the like, or the external (ambient and workplace) environment. In general, in developed countries personal behavior has a larger effect on health than the ambient environment, but new threats related to global warming (described later) may change this equation.

The term *environmental disease* refers to conditions caused by exposure to chemical or physical agents in the ambient, workplace, and personal environment, including

diseases of nutritional origin. Disease related to environmental exposures mostly comes to the public’s attention after dramatic events, such as the methyl mercury contamination of Minamata Bay in Japan in the 1960s, the exposure to dioxin in Seveso, Italy, in 1976, the leakage of methyl isocyanate gas in Bhopal, India, in 1984, the intentional contamination of Tokyo subways by the organophosphate pesticide sarin in 1995, and the Fukushima nuclear meltdown following the tsunami in 2011. Fortunately, these types of disasters are rare, but more subtle forms of environmental disease caused by chronic exposure to relatively low levels of contaminants, occupational injuries, and nutritional deficiencies are extremely common. The International Labor Organization has estimated that work-related injuries and illnesses kill approximately 2 million people per year globally (more deaths than are caused by road accidents and wars combined). In the United States in 2012, there were nearly 3 million occupational injuries

and illnesses. Disease related to malnutrition is even more pervasive. In 2010, it was estimated that 925 million people were malnourished—one in every seven persons worldwide. Children are disproportionately affected by undernutrition, which accounts for more than 50% of childhood mortality worldwide. Estimating the burden of disease in the general population caused by nonoccupational exposures to toxic agents is complicated by the diversity of agents and difficulties in determining the extent and duration of exposures. But whatever the precise numbers, it is clear that environmental diseases are major causes of disability and suffering, and constitute a heavy financial burden, particularly in developing countries.

In this chapter, we first consider two key issues in global health: the global burden of disease, and the emerging problem of the health effects of climate change. We then discuss the mechanisms of toxicity of chemical and physical agents, and address specific environmental disorders, including those of nutritional origin.

Environmental Effects on Global Disease Burden

Since 1990 a World Health Organization project entitled “The Global Burden of Disease” (GBD) has set the standard for reporting global health information. The GBD estimates the burden imposed by environmental disease, including those caused by communicable and nutritional diseases. It

does so in part by applying a metric called *DALY* (disability-adjusted life year), which is defined as the sum of years of life lost due to premature mortality and years of life lost to disability in a population. DALY reporting provides a high degree of uniformity for health information gathered about acute and chronic diseases in different parts of the world and at multiple locations in a single country. A comparison of causes of morbidity and mortality from 1990 to 2010 generated by the GBD project has revealed the following trends:

- **On a worldwide basis, there were dramatic increases in mortality due to HIV/AIDS and associated infections**, which peaked in 2006. Other changes included an 11.2% decrease in aggregate deaths from infectious disease, maternal, neonatal, and nutritional disorders; a 39.2% increase in deaths from noncommunicable diseases (e.g., cancer, cardiovascular diseases, and diabetes); and a 9.2% increase in deaths from injuries (Fig. 9-1). All are attributable in part to aging of the world’s population from a mean age of 26.1 years to a mean age of 29.5 years. As a consequence of these shifts, the global healthy life expectancy at birth, an estimate of expected years of life free of disability, rose for men from 54.4 years to 58.3 years and for women from 57.8 years to 61.8 years.
- **Undernutrition is the single leading global cause of health loss (defined as morbidity and premature death).** It is estimated that about one third of the disease burden in developing countries is, directly or indirectly,

Figure 9-1 The changing global burden of disease, 1990-2010. Estimated percentage of years of life lost to diseases, accidents, war, and disaster is shown for this 20-year period.

due to poor general nutrition or deficiencies in specific nutrients that increase the risk of infections.

- **Ischemic heart disease and cerebrovascular disease remain the leading causes of death in developed countries.** In these countries the main risk factors associated with loss of healthy life are smoking, high blood pressure, obesity, high cholesterol, and alcohol abuse.
- **In developing countries, five of the 10 leading causes of death are infectious diseases:** respiratory infections, human immunodeficiency virus/acquired immunodeficiency syndrome (HIV/AIDS), diarrheal diseases, tuberculosis, and malaria. In 2010, HIV/AIDS and related infections such as tuberculosis were responsible for about 45% of years of life lost in Southern sub-Saharan Africa and about 10% in Southeast Asia.
- **In the postnatal period, about 50% of all deaths in children younger than 5 years of age are attributed to only three conditions, all preventable: pneumonia, diarrheal diseases, and malaria.** Nevertheless, thanks largely to public health measures, some progress has been made on this front; worldwide, deaths in children younger than 5 years of age declined from approximately 11.5 million in 1990 to approximately 7 million in 2010, even though the number of live births increased steadily during this time.

Emerging infectious diseases also constitute an important component of the global burden of disease. Emerging infections are defined as infectious disorders whose incidence has recently increased or could reasonably be expected to increase in the near future. Their emergence may occur by chance, but often finds its basis in some change in environmental and socioeconomic conditions. Categories of emerging infectious diseases include: (1) *diseases caused by newly evolved strains or organisms*, such as multidrug-resistant tuberculosis, chloroquine-resistant malaria, and methicillin-resistant *Staphylococcus aureus*; (2) *diseases caused by pathogens endemic in other species that recently “jumped” to human populations*, such as HIV; and (3) *diseases caused by pathogens that have been present in human populations but show a recent increase in incidence*. An example of the latter is dengue fever, which due to warming climate appears poised to spread into the southern United States.

Health Effects of Climate Change

Without immediate action, climate change stands to become the preeminent global cause of environmental disease in the twenty-first century and beyond. Temperature measurements show that the earth has warmed at an accelerating rate over the past 50 years, perhaps at a rate greater than in any period during the preceding 1000 years. Since 1960 the global average temperature has increased by approximately 0.6°C, with the greatest increases seen over land areas between 40 degrees north and 70 degrees north. Notably, nine of the 10 hottest years in the meteorologic record have occurred in the twenty-first century. These increases in global temperature have been accompanied by the rapid loss of glacial and sea ice, leading to predictions that the iconic glaciers of Glacier National Park in Montana and Mt. Kilimanjaro in Tanzania may disappear by the year 2025, and that the Arctic Ocean will be completely ice-free in summer by no later than the year 2040.

Although politicians quibble, among scientists there is a general acceptance that climate change is, at least in part, man-made. The principal culprit is the rising atmospheric level of greenhouse gases, particularly carbon dioxide (CO₂) released through the burning of fossil fuels (Fig. 9-2A), as well as ozone (an important air pollutant, discussed later) and methane. These gases, along with water vapor, produce the so-called greenhouse effect by absorbing and re-emitting infrared energy radiated from the Earth's surface that otherwise would be lost into space. The annual average level of atmospheric CO₂ in late 2012 (about 391 ppm) was higher than at any point in approximately 650,000 years and, without changes in human behavior, is expected to increase to between 500 to 1200 ppm by the end of this century — levels not experienced for tens of millions of years. This increase stems not only from increased CO₂ production but also from deforestation and the attendant decrease in carbon fixation by plants.

Depending on which computer model is used, increased levels of greenhouse gases are projected to cause the global temperature to rise by 2°C to 5°C by the year 2100 (Fig. 9-2B). Part of the uncertainty about the extent of the

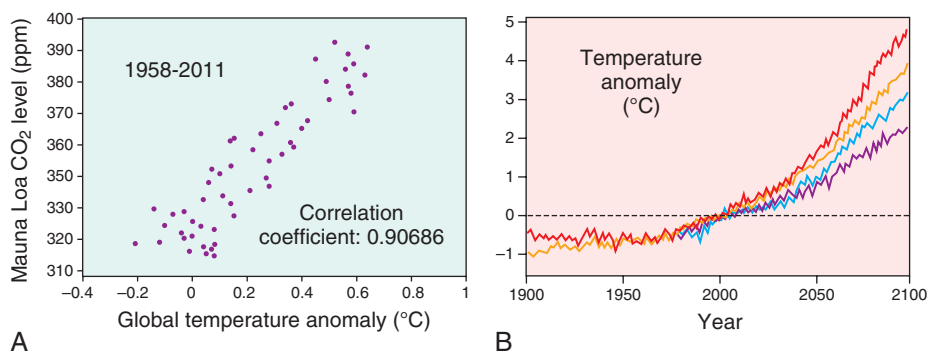

Figure 9-2 Climate change, past and future. **A**, Correlation of CO₂ levels measured at the Mauna Loa Observatory in Hawaii with average global temperature trends over the past 50 years. “Global temperature” in any given year was deduced at the Hadley Center (United Kingdom) from measurements taken at more than 3000 weather stations located around the globe. **B**, Predicted temperature increases during the twenty-first century. Different computer models plot anticipated rises in global temperatures of 2°C to 5°C by the year 2100. (**A**, Courtesy Dr. Richard Aster, Department of Geophysics, Colorado State University, Fort Collins, Colo.)

temperature increase stems from questions about the degree to which positive-feedback loops will exacerbate factors driving the process. Examples of such self-reinforcing loops are increases in surface heat absorption due to loss of reflective ice and snow; increases in water vapor due to greater evaporation from warming rivers, lakes, and oceans; large releases of CO₂ and methane from organic matter in thawing Arctic “permafrost” and submarine methane hydrates; and decreased sequestration of CO₂ in oceans due to reduced growth of organisms, such as diatoms, that serve as carbon sinks. Increased heat energy in the oceans and atmosphere is also projected to increase the variability and severity of weather events, such as floods, droughts, and storms. An additional worrisome effect of increased atmospheric CO₂ concentrations is increasing acidity of the oceans, which may disrupt marine ecosystems and fisheries.

The health impacts of climate change will depend on its extent and rapidity, the nature and severity of the ensuing consequences, and humankind’s ability to mitigate the damage. Even in the best case scenario, however, climate change is expected to have a serious negative impact on human health by increasing the incidence of a number of diseases, including the following:

- *Cardiovascular, cerebrovascular, and respiratory diseases*, all of which will be worsened by heat waves and air pollution
- *Gastroenteritis, cholera, and other foodborne and waterborne infectious diseases*, caused by contamination as a consequence of floods and disruption of clean water supplies and sewage treatment, after heavy rains and other environmental disasters
- *Vector-borne infectious diseases, such as malaria and dengue fever*, due to changes in vector number and geographic distribution related to increased temperatures, crop failures, and more extreme weather variation (e.g., more frequent and severe El Niño events)
- *Malnutrition*, caused by changes in local climate that disrupt crop production. Such changes are anticipated to be most severe in tropical locations, in which average temperatures may already be near or above crop tolerance levels; it is estimated that by 2080, agricultural productivity may decline by 10% to 25% in some developing countries as a consequence of climate change.

Beyond these disease-specific effects, it is estimated that melting of glacial ice, particularly in Greenland, combined with the thermal expansion of warming oceans, will raise sea levels by at least 1 to 2 feet by 2100. Of greater worry, temperatures in the vicinity of the western Antarctic ice sheet rose 2.4°C between 1958 and 2010, one of the greatest increases in temperature seen at any location on earth during this period. Complete melting of the western Antarctic ice shelf, which is certain to occur in coming centuries if current trends continue, will raise oceans levels by an additional 5 meters—approximately 16.5 feet. Approximately 10% of the world’s population—roughly 600 million people—live in low-lying areas that are at risk for flooding even if the rise in ocean levels is at the low end of these estimates. The resulting displacement of people will disrupt lives and commerce, creating conditions ripe for political unrest, war, and poverty, the “vectors” of malnutrition, sickness, and death.

Both developed and developing countries will suffer the consequences of climate change, but the burden will be greatest in developing countries, which to date have been least culpable for increases in greenhouse gases to date. This equation is changing rapidly, however, owing to the growth of the economies of India and China, which has recently surpassed the United States to become the largest producer of CO₂ in the world. The urgent challenge is to develop new renewable energy resources that stem the production of greenhouse gases.

Toxicity of Chemical and Physical Agents

Toxicology is defined as the science of poisons. It studies the distribution, effects, and mechanisms of action of toxic agents. More broadly, it also includes the study of the effects of physical agents such as radiation and heat. Approximately 4 billion pounds of toxic chemicals, including 72 million pounds of recognized carcinogens, are released per year in the United States. Of about 100,000 chemicals in commercial use in the United States, only a very small proportion has been tested experimentally for health effects. Several agencies in the United States set permissible levels of exposure to known environmental hazards (e.g., the maximum level of carbon monoxide in air that is noninjurious or the tolerable levels of radiation that are harmless or “safe”). Factors such as the complex interaction between various pollutants, and the age, genetic predisposition, and the different tissue sensitivities of exposed persons, create wide variations in individual sensitivity to toxic agents, limiting the value of establishing rigid “safe levels” for entire populations. Nevertheless, such cut-offs are useful for comparative studies of the effects of harmful agents between specific populations, and for estimating risk of disease in heavily exposed individuals.

We now consider some basic principles relevant to the effects of toxic chemicals and drugs.

- The *definition of a poison* is not straightforward. It is basically a quantitative concept strictly dependent on *dosage*. The quote from Paracelsus in the sixteenth century that “all substances are poisons; the right dosage differentiates a poison from a remedy” is even more valid today, given the proliferation of pharmaceutical drugs with potentially harmful effects.
- *Xenobiotics* are exogenous chemicals in the environment in air, water, food, and soil that may be absorbed into the body through inhalation, ingestion, and skin contact (Fig. 9-3).
- Chemicals may be excreted in urine or feces; eliminated in expired air; or may accumulate in bone, fat, brain, or other tissues.
- Chemicals may act at the site of entry or at other sites following transport through the blood.
- *Most solvents and drugs are lipophilic*, which facilitates their transport in the blood by lipoproteins and their penetration through the plasma membrane into cells.
- Most solvents, drugs, and xenobiotics are metabolized to form inactive water-soluble products (*detoxification*), or are *activated to form toxic metabolites*. The reactions that metabolize xenobiotics into nontoxic products, or

Figure 9-3 Human exposure to pollutants. Pollutants in the air, water, and soil are absorbed through the lungs, gastrointestinal tract, and skin. In the body they may act at the site of absorption but are generally transported through the bloodstream to various organs where they may be stored or metabolized. Xenobiotics may be metabolized to water-soluble compounds that are excreted, or to toxic metabolites, a process referred to as activation.

that activate xenobiotics to generate toxic compounds (Figs. 9-3 and 9-4), occur in two phases. In *phase I* reactions, chemicals undergo hydrolysis, oxidation, or reduction. Products of phase I reactions are often metabolized into water-soluble compounds through *phase II* reactions, which include glucuronidation, sulfation, methylation, and conjugation with glutathione. Water-soluble compounds are readily excreted. Enzymes that catalyze the biotransformation of xenobiotics and drugs are known as *drug-metabolizing enzymes*.

- The most important catalyst of phase I reactions is the *cytochrome P-450 enzyme system* (abbreviated as *CYP*) located primarily in the endoplasmic reticulum of the liver but also present in skin, lungs, and gastrointestinal mucosa, and other organs. CYPs are a large family of

heme-containing enzymes, each with preferred substrate specificities. **The P-450 system catalyzes reactions that either detoxify xenobiotics or, less commonly, convert xenobiotics into active compounds that cause cellular injury.** Both types of reactions may produce, as a byproduct, *reactive oxygen species (ROS)*, which can cause cellular damage (Chapter 2). Examples of metabolic activation of chemicals through CYPs are the production of the toxic trichloromethyl free radical from carbon tetrachloride in the liver, and the generation of a DNA-binding metabolite from benzo[*a*]pyrene, a carcinogen present in cigarette smoke. CYPs participate in the metabolism of a large number of common therapeutic drugs such as acetaminophen, barbiturates, warfarin, and anticonvulsants, and also in alcohol metabolism (discussed later).

There is great variation in the activity of CYPs among individuals. The variation may be a consequence of genetic polymorphisms in specific CYPs, but more commonly it is due to exposure to drugs or chemicals that induce or diminish CYP activity. Known CYP inducers include environmental chemicals, drugs, smoking, alcohol, and hormones. In contrast, fasting or starvation can decrease CYP activity.

Inducers of CYP do so by binding to nuclear receptors, which then heterodimerize with the retinoic X receptor (RXR) to form a transcriptional activation complex that associates with promoter elements located in the 5'-flanking region of CYP genes. Nuclear receptors participating in CYP induction responses include the aryl hydrocarbon receptor, the peroxisome proliferator-activated receptors (*PPAR*), and two orphan nuclear receptors, constitutive androstane receptor (*CAR*), and pregnane X receptor (*PXR*).

This brief overview of the general mechanisms of toxicity provides the background for the discussion of environmental diseases presented in this chapter.

Environmental Pollution

Air Pollution

Air pollution is a significant cause of morbidity and mortality worldwide, particularly among at-risk individuals with preexisting pulmonary or cardiac disease. Air is precious to life, but can also carry many potential causes of disease. Airborne microorganisms have long been major causes of morbidity and mortality, especially in developing countries. More widespread are airborne chemical and particulate pollutants, especially in industrialized nations. Here, we consider these hazards in outdoor and indoor air.

Outdoor Air Pollution

The ambient air in industrialized nations is contaminated with an unsavory mixture of gaseous and particulate pollutants, more heavily in cities and in proximity to heavy industry. In the United States, the Environmental Protection Agency monitors and sets allowable upper limits for six pollutants: sulfur dioxide, carbon monoxide, ozone, nitrogen dioxide, lead, and particulate matter. Collectively, these agents produce the well-known *smog* (smoke and fog) that sometimes stifles large cities such as Beijing, Los

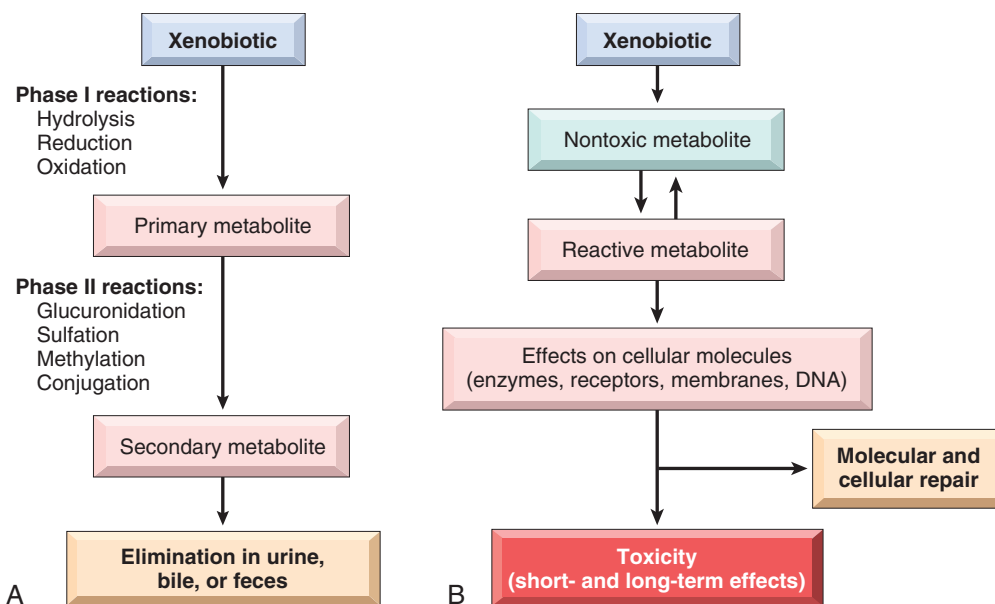

Figure 9-4 Xenobiotic metabolism. **A**, Xenobiotics can be metabolized to nontoxic metabolites and eliminated from the body (detoxification). **B**, Xenobiotic metabolism may also result in the formation of a reactive metabolite that is toxic to cellular components. If repair is not effective, short- and long-term effects develop. (Based on Hodgson E: *A Textbook of Modern Toxicology*, 3rd ed. Hoboken, NJ, Wiley, 2004.)

Angeles, Houston, Cairo, New Delhi, Mexico City, and São Paulo. It may seem that air pollution is a modern phenomenon, but this is hardly the case. John Evelyn wrote in 1661 that inhabitants of London suffered from “Catharrs, Phthisicks and Consumptions” (bronchitis, pneumonia, and tuberculosis) and breathed “nothing but an impure and thick mist, accompanied by a fuliginous and filthy vapour, which renders them obnoxious to a thousand inconveniences, corrupting the lungs, and disordering the entire habit of their bodies.” The first environmental control law, proclaimed by Edward I in 1306, was straightforward in its simplicity: “whoever should be found guilty of burning coal shall suffer the loss of his head.” What has changed in modern times is the nature and sources of air pollutants, and the types of regulations that control their emission.

Although the lungs bear the brunt of the adverse consequences, air pollutants can affect many organ systems. Except for some comments on smoking, pollutant-caused lung diseases are discussed in [Chapter 15](#). Major health effects of outdoor pollutants are summarized in [Table 9-1](#). Ozone, sulfur dioxide, particulates, and carbon monoxide are discussed here.

Ozone (O_3) is produced by interaction of ultraviolet (UV) radiation and oxygen (O_2) in the stratosphere and naturally accumulates in the so-called ozone layer 10 to 30 miles above the earth’s surface. This layer protects life on earth by absorbing the most dangerous UV radiation emitted by the sun. During the past 35 years, the stratospheric ozone layer decreased in both thickness and extent due to the widespread use of chlorofluorocarbon gases in air conditioners and refrigerators and as aerosol propellants. When released into the atmosphere, these gases drift up into the stratosphere and participate in chemical reactions that destroy ozone. Due to prevailing stratospheric air currents, the resulting depletion has been most profound in polar regions, particularly over Antarctica during the winter

months. Recognition of the problem led in 1987 to the Montreal Protocol, a series of international agreements that currently calls for a complete phase-out of chlorofluorocarbon use by 2020. Decreased use of chlorofluorocarbons over the past 25 years has reduced the size of the yearly ozone “hole” over Antarctica, suggesting that this global environmental challenge is being met successfully.

In contrast to the “good” ozone in the stratosphere, ozone that accumulates in the lower atmosphere (*ground-level ozone*) is one of the most pernicious air pollutants.

Table 9-1 Health Effects of Outdoor Air Pollutants

Pollutant	Populations at Risk	Effects
Ozone	Healthy adults and children	Decreased lung function Increased airway reactivity Lung inflammation
	Athletes, outdoor workers Asthmatics	Decreased exercise capacity Increased hospitalizations
Nitrogen dioxide	Healthy adults Asthmatics Children	Increased airway reactivity Decreased lung function Increased respiratory infections
	Sulfur dioxide	Healthy adults Individuals with chronic lung disease Asthmatics
Acid aerosols	Healthy adults Children Asthmatics	Altered mucociliary clearance Increased respiratory infections Decreased lung function Increased hospitalizations
Particulates	Children Individuals with chronic lung or heart disease Asthmatics	Increased respiratory infections Decreased lung function Excess mortality Increased attacks

Data from Bascom R, et al: Health effects of outdoor air pollution. *Am J Respir Crit Care Med* 153:477, 1996.

Ground-level ozone is a gas formed by the reaction of nitrogen oxides and volatile organic compounds in the presence of sunlight. These chemicals are released by industrial emissions and motor vehicle exhaust. Ozone toxicity is in large part mediated by the production of free radicals, which injure epithelial cells along the respiratory tract and type I alveolar cells, and cause the release of inflammatory mediators. Healthy individuals exposed to ozone experience upper respiratory tract inflammation and mild symptoms (decreased lung function and chest discomfort), but exposure is much more dangerous for people with asthma or emphysema.

Even low levels of ozone may be detrimental to the lung function of normal individuals when mixed with other air pollutants. Unfortunately, air pollutants often combine to create a veritable “witches’ brew” of ozone and other agents such as *sulfur dioxide* and particulates. Sulfur dioxide is produced by power plants burning coal and oil, from copper smelting, and as a byproduct of paper mills. Released into the air, it may be converted into sulfuric acid and sulfuric trioxide, which cause a burning sensation in the nose and throat, difficulty in breathing, and asthma attacks in susceptible individuals.

Particulate matter (known as “soot”) is a particularly important cause of morbidity and mortality related to pulmonary inflammation and secondary cardiovascular effects. Based on studies of large cities in the United States, it is estimated that there is a 0.5% increase in overall daily mortality for every 10 mg/m³ increase in 10 μm particles in outdoor air, mainly due to exacerbations of pulmonary and cardiac disease. Particulates are emitted by coal- and oil-fired power plants, by industrial processes burning these fuels, and by diesel exhaust. Although the particles have not been well characterized chemically or physically, *fine or ultrafine particles less than 10 μm in diameter* are the most harmful. They are readily inhaled into the alveoli, where they are phagocytosed by macrophages and neutrophils, which respond by releasing a number of inflammatory mediators. In contrast, particles that are greater than 10 μm in diameter are of lesser consequence, because they are generally removed in the nose, or trapped by the mucociliary epithelium of the airways.

Carbon monoxide is a systemic asphyxiant that is an important cause of accidental and suicidal death. Carbon monoxide (CO) is a nonirritating, colorless, tasteless, odorless gas that is produced during any process that results in the incomplete oxidation of hydrocarbons. From the standpoint of human health, the most important environmental source of CO is the burning of carbonaceous materials, as occurs in automotive engines, furnaces, and cigarettes. CO is short-lived in the atmosphere, being rapidly oxidized to carbon dioxide (CO₂); thus, elevated levels in ambient air are transient and occur only in close proximity to sources of CO. Chronic poisoning may occur in individuals working in environments such as tunnels, underground garages, and in highway toll booths with high exposures to automobile fumes. Of greater concern is acute toxicity. In a small, closed garage, the average running car can produce sufficient CO to induce coma or death within 5 minutes, and CO concentrations can also rapidly rise to toxic levels with improper use of gasoline-powered generators (e.g., during power outages) or following mine fires. CO kills in part by inducing central nervous system (CNS) depression,

which appears so insidiously that victims are often unaware of their plight. Hemoglobin has 200-fold greater affinity for CO than for oxygen, and the resultant carboxyhemoglobin cannot carry O₂. Systemic hypoxia develops when the hemoglobin is 20% to 30% saturated with CO; unconsciousness and death are likely with 60% to 70% saturation.

MORPHOLOGY

Chronic poisoning by CO develops because carboxyhemoglobin, once formed, is remarkably stable. Even with low-level, but persistent, exposure to CO, carboxyhemoglobin may rise to life-threatening levels in the blood. The slowly developing hypoxia can insidiously evoke widespread ischemic changes in the central nervous system; these are particularly marked in the basal ganglia and lenticular nuclei. With cessation of exposure to CO, the patient usually recovers, but there may be permanent neurologic sequelae, such as impairment of memory, vision, hearing, and speech. The diagnosis is made by measuring carboxyhemoglobin levels in the blood.

Acute poisoning by CO is generally a consequence of accidental exposure or suicide attempt. In light-skinned individuals, **acute poisoning is marked by a characteristic generalized cherry-red color of the skin and mucous membranes**, which result from high levels of carboxyhemoglobin. This effect of CO on coloration may result in a failure to recognize the oxygen-starved state of the victim (and parenthetically is used by the meat industry in the United States to keep meat appearing fresh—caveat emptor!). If death occurs rapidly, morphologic changes may not be present; with longer survival the brain may be slightly edematous, with punctate hemorrhages and hypoxia-induced neuronal changes. The morphologic changes are not specific and stem from systemic hypoxia.

Indoor Air Pollution

As we increasingly “button up” our homes to exclude the environment, the potential for pollution of the indoor air increases. The most common pollutant is *tobacco smoke* (discussed later), but additional offenders are CO, nitrogen dioxide (both already mentioned as outdoor pollutants), and asbestos (Chapter 15). Volatile substances containing polycyclic aromatic hydrocarbons generated by cooking oils and coal burning are important indoor pollutants in some regions of China. Only a few comments about other agents are made here.

- *Wood smoke*, containing various oxides of nitrogen and carbon particulates, is an irritant that may predispose to lung infections and may contain polycyclic hydrocarbons, important carcinogens.
- *Bioaerosols* range from microbiologic agents capable of causing infectious diseases such as Legionnaires disease, viral pneumonia, and the common cold, to less threatening but nonetheless distressing allergens derived from pet dander, dust mites, and fungi and molds responsible for rhinitis, eye irritation, and asthma.
- *Radon*, a radioactive gas derived from uranium widely present in soil and in homes, can cause lung cancer in uranium miners. However, it does not seem that low-level chronic exposures in the home increase lung cancer risk, at least for nonsmokers.

- Exposure to *formaldehyde*, used in the manufacture of building materials (e.g., cabinetry, furniture, adhesives) may be a health problem in refugees from environmental disasters living in poorly ventilated trailers. At concentrations of 0.1 ppm or higher, it causes breathing difficulties and a burning sensation in the eyes and throat, and can trigger asthma attacks. Formaldehyde is classified as a carcinogen for humans and animals.
- The so-called *sick building syndrome* remains an elusive problem; it may be a consequence of exposure to one or more indoor pollutants, possibly due to poor ventilation.

KEY CONCEPTS

Environmental Diseases and Environmental Pollution

- Environmental diseases are conditions caused by exposure to chemical or physical agents in the ambient, workplace, and personal environments.
- Exogenous chemicals known as *xenobiotics* enter the body through inhalation, ingestion, and skin contact, and can either be eliminated or accumulate in fat, bone, brain, and other tissues.
- Xenobiotics can be converted into nontoxic products, or activated to generate toxic compounds, through a two-phase reaction process that involves the cytochrome P-450 system.
- The most common and important air pollutants are ozone (which in combination with oxides and particulate matter forms smog), sulfur dioxide, acid aerosols, and particles less than 10 μm in diameter.
- Carbon monoxide poisoning an important cause of death from accidents and suicide; it binds hemoglobin with high affinity, leading to systemic asphyxiation associated with CNS depression.
- A variety of pollutants, including smokes, bioaerosols, radon, and formaldehyde, may accumulate in indoor air and cause disease.

Metals as Environmental Pollutants

Lead, mercury, arsenic, and cadmium are the heavy metals most commonly associated with harmful effects in humans.

Lead

Lead is a readily absorbed metal that binds to sulfhydryl groups in proteins and interferes with calcium metabolism, effects that lead to hematologic, skeletal, neurologic, gastrointestinal, and renal toxicities. Lead exposure may occur through contaminated air, food and water. For most of the twentieth century the major sources of lead in the environment were lead-containing house paints and gasoline. Although limits have been set for the amounts of lead contained in residential paints and use of leaded gasoline in road vehicles was banned in the United States in 1996, lead contamination remains an important health hazard, particularly for children. The large-scale recall of toys containing lead in 2007 alerted the general public to the dangers of lead exposures. There are many sources of lead in the environment, such as from mining, foundries,

batteries, and spray painting, which constitute occupational hazards. However, *flaking lead paint* in older houses and soil contamination pose major hazards to youngsters. During the past 30 years, the median blood level of lead in preschool children in the United States decreased from 15 $\mu\text{g}/\text{dL}$ to the present level of less than 2 $\mu\text{g}/\text{dL}$ due to public health measures. Nevertheless, blood levels of lead in children living in older homes containing lead-based paint or lead-contaminated dust often exceed 5 $\mu\text{g}/\text{dL}$, the level at which the Centers for Disease Control and Prevention (CDC) recommends that measures be taken to limit further exposure. While treatment for lead poisoning in children is currently mandated only when blood lead levels are $\geq 45 \mu\text{g}/\text{dL}$, it is believed that *subclinical lead poisoning* may occur in children with blood lead levels considerably below this mark. The results of low-level lead poisoning include subtle deficits in intellectual capacity, behavioral problems such as hyperactivity, and poor organizational skills. Lead poisoning, although less common in adults, occurs mainly as an occupational hazard in those involved in the manufacturing of batteries, pigments, car radiators, and tin cans. The main clinical features of lead poisoning in children and adults are shown in [Figures 9-5 and 9-6](#).

Most of the absorbed lead (80% to 85%) is incorporated into bone and developing teeth, where it competes with calcium; its half-life in bone is 20 to 30 years. High levels of lead cause *CNS disturbances* in adults and children, but *peripheral neuropathies* predominate in adults. Children absorb more than 50% of ingested lead (compared with

Figure 9-5 Effects of lead poisoning in children related to blood levels. (Modified from Bellinger DC, Bellinger AM: Childhood lead poisoning: the tortuous path from science to policy. *J Clin Invest* 116:853; 2006.)

Figure 9-6 Pathologic features of lead poisoning in adults.

≤15% in adults); the higher intestinal absorption and the more permeable blood-brain barrier of children create a high susceptibility to brain damage. The neurotoxic effects of lead are attributed to the inhibition of neurotransmitters caused by the disruption of calcium homeostasis. Other effects of lead exposure include the following:

- Lead interferes with the normal remodeling of cartilage and primary bone trabeculae in the epiphyses in children. This causes increased bone density detected as radiodense “lead lines” (Fig. 9-7; another type of lead line appears in the gums as a result of hyperpigmentation).
- Lead inhibits the healing of fractures by increasing chondrogenesis and delaying cartilage mineralization.
- Lead inhibits the activity of two enzymes involved in heme synthesis, δ -aminolevulinic acid dehydratase and

ferrochelatase. Ferrochelatase catalyzes the incorporation of iron into protoporphyrin, and its inhibition causes a rise in protoporphyrin levels. The resulting heme deficiency causes various abnormalities, but the most obvious is a *microcytic hypochromic anemia* stemming from the suppression of hemoglobin synthesis.

The diagnosis of lead poisoning requires constant awareness of its prevalence. In children it may be suspected on the basis of neurologic and behavioral changes, or by unexplained microcytic anemia. Definitive diagnosis requires the detection of elevated blood levels of lead and free (or zinc-bound) red cell protoporphyrin.

MORPHOLOGY

The major anatomic targets of lead toxicity are the bone marrow and blood, nervous system, gastrointestinal tract, and kidneys (Fig. 9-6).

Blood and marrow changes occur fairly rapidly and are characteristic. The inhibition of ferrochelatase by lead may result in the appearance of a few **ring sideroblasts**, red cell precursors with iron-laden mitochondria that are detected with a Prussian blue stain. In the peripheral blood the defect in hemoglobin synthesis appears as a **microcytic, hypochromic anemia** that is often accompanied by mild **hemolysis**. Even more distinctive is a **punctate basophilic stippling of the red cells**.

Brain damage is prone to occur in children. It can be very subtle, producing mild dysfunction, or it can be massive and lethal. In young children, sensory, motor, intellectual, and psychologic impairments have been described, including reduced IQ, learning disabilities, retarded psychomotor development, blindness, and, in more severe cases, psychoses,

Figure 9-7 Lead poisoning. Impaired remodeling of calcified cartilage in the epiphyses (arrows) of the wrist has caused a marked increase in their radiodensity, so that they are as radiopaque as the cortical bone. (Courtesy Dr. G. W. Dietz, Department of Radiology, University of Texas Southwestern Medical School, Dallas, Texas.)

seizures, and coma (Fig. 9-5). Lead toxicity in the mother may impair brain development in the prenatal infant. The anatomic changes underlying the more subtle functional deficits are ill-defined, but there is concern that some of the defects may be permanent. At the more severe end of the spectrum lies marked brain edema, demyelination of the cerebral and cerebellar white matter, and necrosis of cortical neurons accompanied by diffuse astrocytic proliferation. In adults the CNS is less often affected, but frequently a **peripheral demyelinating neuropathy** appears, typically involving the motor nerves of the most commonly used muscles. Thus, the extensor muscles of the wrist and fingers are often the first to be affected (causing wrist-drop), followed by paralysis of the peroneal muscles (causing foot-drop).

The **gastrointestinal tract** is also a major source of clinical manifestations. Lead “colic” is characterized by extremely severe, poorly localized abdominal pain.

Kidneys may develop proximal tubular damage associated with intranuclear inclusions consisting of protein aggregates. Chronic renal damage leads eventually to interstitial fibrosis and possibly renal failure. Decreases in uric acid excretion can lead to gout (“saturnine gout”).

Mercury

Like lead, mercury binds to sulfhydryl groups in certain proteins with high affinity, leading to damage in the CNS and the kidney. Mercury has had many uses throughout history, for example, as a pigment in cave paintings, a cosmetic, a remedy for syphilis, and a component of diuretics. Alchemists tried (without much success) to produce gold from mercury. Poisoning from inhalation of mercury vapors has long been recognized and is associated with tremor, gingivitis, and bizarre behavior, such as that displayed by the Mad Hatter in *Alice in Wonderland*. There are three forms of mercury: metallic mercury (also referred to as elemental mercury), inorganic mercury compounds (mostly mercuric chloride), and organic mercury (mostly methyl mercury). Today, the main sources of exposure to mercury are contaminated fish (methyl mercury) and mercury vapors released from metallic mercury in dental amalgams, a possible occupational hazard for dental workers. In some areas of the world, mercury used in gold mining has contaminated rivers and streams.

Inorganic mercury from the natural degassing of the earth’s crust or from industrial contamination is converted to organic compounds such as methyl mercury by bacteria. Methyl mercury enters the food chain, and in carnivorous fish such as swordfish, shark, and bluefish, may be concentrated to levels a million-fold higher than in the surrounding water. Disasters caused by the consumption of fish contaminated by the release of methyl mercury from industrial sources in Minamata Bay and the Agano River in Japan caused widespread mortality and morbidity. Acute exposure through consumption of bread made from grain treated with a methyl mercury-based fungicide in Iraq in 1971 resulted in hundreds of deaths and thousands of hospitalizations. The medical disorders associated with the Minamata episode became known as *Minamata disease* and include cerebral palsy, deafness, blindness, mental retardation, and major CNS defects in children exposed in utero. For unclear reasons, *the developing brain is extremely sensitive to methyl mercury*. The lipid solubility

of methyl mercury and metallic mercury facilitate their accumulation in the brain, disturbing neuromotor, cognitive, and behavioral functions. Intracellular glutathione, by acting as sulfhydryl donor, is the main protective mechanism against mercury-induced CNS and kidney damage.

Mercury continues to be released into the environment by power plants and other industrial sources, and there are serious concerns about the effects of chronic low-level exposure to methyl mercury in the food supply. To protect against potential fetal brain damage, the CDC has recommended that pregnant women avoid consumption of fish known to contain high levels of mercury.

Arsenic

Arsenic salts interfere with several aspects of cellular metabolism, leading to toxicities that are most prominent in the gastrointestinal tract, nervous system, skin, and heart. Arsenic was the poison of choice in Renaissance Italy, with members of the Borgia and Medici families being highly skilled practitioners of the art of its use. Because of its favored use as a murder weapon among royal families, arsenic has been called “the poison of kings and the king of poisons.” Deliberate poisoning by arsenic is exceedingly rare today, but exposure to arsenic is an important health problem in many areas of the world. Arsenic is found naturally in soils and water, and is used in products such as wood preservers and herbicides and other agricultural products. It may be released into the environment from mines and smelting industries. Arsenic is present in Chinese and Indian herbal medicine, and arsenic trioxide is a frontline treatment for acute promyelocytic leukemia (Chapter 7). Large concentrations of inorganic arsenic are present in ground water in countries such as Bangladesh, Chile, and China. Between 35 and 77 million people in Bangladesh drink water contaminated with arsenic, constituting one of the greatest environmental cancer risks yet uncovered.

The most toxic forms of arsenic are the trivalent compounds arsenic trioxide, sodium arsenite, and arsenic trichloride. If ingested in large quantities, arsenic causes *acute gastrointestinal, cardiovascular, and CNS toxicities* that are often fatal. These effects may be attributed in part to interference with mitochondrial oxidative phosphorylation, since trivalent arsenic can replace the phosphates in adenosine triphosphate. However, arsenic also has pleiotropic effects on the activity of a number of other enzymes and ion channels, and these too may contribute to certain toxicities.

- *Neurologic effects* usually occur 2 to 8 weeks after exposure and consist of a sensorimotor neuropathy that causes paresthesias, numbness, and pain.
- Chronic exposure to arsenic causes *skin changes* consisting of hyperpigmentation and hyperkeratosis
- The most serious consequence of chronic exposure is the *increased risk for the development of cancers*, particularly of the lungs, bladder and skin. Arsenic-induced skin tumors differ from those induced by sunlight; they are often multiple and usually appear on the palms and soles. The mechanisms of arsenic carcinogenesis in skin and lung have not been elucidated but may involve defects in nucleotide excision repair mechanisms that protect against DNA damage.

- Finally, there is also evidence that chronic exposure to arsenic in drinking water can cause non-malignant respiratory disease.

Cadmium

Cadmium is preferentially toxic to the kidneys and the lungs through uncertain mechanisms that may involve increased production of reactive oxygen species. In contrast to the other metals discussed in this section, cadmium toxicity is a relatively modern problem. It is an occupational and environmental pollutant generated by mining, electroplating, and production of nickel-cadmium batteries, which are usually disposed of as household waste. Cadmium can contaminate the soil and plants directly or through fertilizers and irrigation water. Food is the most important source of cadmium exposure for the general population. Its toxic effects require its uptake into cells via transporters such as ZIP8, which normally serves as a transporter for zinc.

The principal toxic effects of excess cadmium take the form of *obstructive lung disease* caused by necrosis of alveolar epithelial cells, and *renal tubular damage* that may progress to *end-stage renal disease*. A survey completed in 2008 showed that 5% of the U.S. population age 20 years and older have urinary cadmium levels that may produce subtle kidney injury and calcium loss. Cadmium exposure can also cause skeletal abnormalities associated with calcium loss. Cadmium-containing water used to irrigate rice fields in Japan caused a disease in postmenopausal women known as “Itai-Itai” (ouch-ouch), a combination of osteoporosis and osteomalacia associated with renal disease. Finally, cadmium exposure is also associated with an elevated risk of lung cancer, which has been demonstrated in workers exposed occupationally and in populations living near zinc smelters. Cadmium is not directly genotoxic and most likely produces DNA damage through the generation of reactive oxygen species (Chapter 2).

phosphorylation and the function of a variety of proteins. It causes toxic effects in the gastrointestinal tract, CNS, and cardiovascular system; long-term exposure causes skin lesions and carcinomas.

- Cadmium from nickel-cadmium batteries and chemical fertilizers can contaminate soil. Excess cadmium causes obstructive lung disease and kidney damage.

Occupational Health Risks: Industrial and Agricultural Exposures

More than 10 million occupational injuries occur annually in the United States and approximately 65,000 people die as a consequence of work-related accidents and illnesses. Work-related accidents are the biggest occupational health problem in developing countries, while work-related diseases are more frequent in industrialized countries. Industrial exposures to toxic agents are as varied as the industries themselves. They range from mere irritation of the respiratory mucosa by formaldehyde or ammonia fumes; to lung cancer induced by exposure to asbestos, arsenic, or uranium mining; to leukemia caused by chronic exposure to benzene. Human diseases associated with occupational exposures are listed in Table 9-2. Following are examples of important agents that contribute to occupational diseases. Toxicity caused by metals is discussed earlier in this chapter.

- *Organic solvents* are widely used in huge quantities worldwide. Some, such as *chloroform* and *carbon tetrachloride*, are found in degreasing and dry cleaning agents and paint removers. Acute exposure to high levels of vapors from these agents can cause dizziness and confusion, leading to CNS depression and even coma. Lower levels are toxic for the liver and kidneys. Occupational exposure of rubber workers to *benzene* and *1,3-butadiene* increases the risk of leukemia. Benzene is oxidized by hepatic CYP2E1 to toxic metabolites that disrupt the differentiation of hematopoietic cells in the bone marrow, leading to dose-dependent marrow aplasia and an increased risk of acute myeloid leukemia.
- *Polycyclic hydrocarbons* may be released during the combustion of fossil fuels, particularly when coal and gas are burned at high temperatures (e.g., in steel foundries), and are present in tar and soot (Pott identified soot as the cause of scrotal cancers in chimney sweeps in 1775; Chapter 7). Polycyclic hydrocarbons are among the most potent carcinogens, and industrial exposures have been implicated in the development of lung and bladder cancer.
- *Organochlorines* (and halogenated organic compounds in general) are synthetic lipophilic products that resist degradation. Important organochlorines used as pesticides include DDT (*dichlorodiphenyltrichloroethane*), lindane, aldrin, and dieldrin. Nonpesticide organochlorines include *polychlorinated biphenyls (PCBs)* and *dioxin (TCDD; 2,3,7,8-tetrachlorodibenzo-p-dioxin)*. DDT was banned in the United States in 1973, but *p, p'-DDE*, a long-lasting DDT metabolite, is still detectable in the blood of a sizable minority of U.S. inhabitants. DDT is

KEY CONCEPTS

Toxic Effects of Heavy Metals

- Lead, mercury, arsenic, and cadmium are the heavy metals most commonly associated with toxic effects in humans.
- Children absorb more ingested lead than adults; the main source of exposure for children is lead-containing paint in older housing.
- Excess lead causes CNS defects in children and peripheral neuropathy in adults. It also interferes with the remodeling of cartilage and causes anemia by interfering with hemoglobin synthesis.
- The major source of exposure to mercury is contaminated fish. The developing brain is highly sensitive to methyl mercury, which accumulates in the CNS.
- Exposure of the fetus to high levels of mercury in utero may lead to Minamata disease, characterized by cerebral palsy, deafness, and blindness.
- Arsenic is naturally found in soil and water and is a component of some wood preservatives and herbicides. Excess arsenic interferes with mitochondrial oxidative

Table 9-2 Human Diseases Associated with Occupational Exposures

Organ/System	Effect	Toxicant
Cardiovascular system	Heart disease	Carbon monoxide, lead, solvents, cobalt, cadmium
Respiratory system	Nasal cancer Lung cancer Chronic obstructive lung disease Hypersensitivity Irritation Fibrosis	Isopropyl alcohol, wood dust Radon, asbestos, silica, bis(chloromethyl)ether, nickel, arsenic, chromium, mustard gas, uranium Grain dust, coal dust, cadmium Beryllium, isocyanates Ammonia, sulfur oxides, formaldehyde Silica, asbestos, cobalt
Nervous system	Peripheral neuropathies Ataxic gait Central nervous system depression Cataracts	Solvents, acrylamide, methyl chloride, mercury, lead, arsenic, DDT Chlordane, toluene, acrylamide, mercury Alcohols, ketones, aldehydes, solvents Ultraviolet radiation
Urinary system	Renal toxicity Bladder cancer	Mercury, lead, glycol ethers, solvents Naphthylamines, 4-aminobiphenyl, benzidine, rubber products
Reproductive system	Male infertility Female infertility/stillbirths Teratogenesis	Lead, phthalate plasticizers, cadmium Lead, mercury Mercury, polychlorinated biphenyls
Hematopoietic system	Leukemia	Benzene
Skin	Folliculitis and acneiform dermatosis Cancer	Polychlorinated biphenyls, dioxins, herbicides Ultraviolet radiation
Gastrointestinal tract	Liver angiosarcoma	Vinyl chloride

Data from Leigh JP, et al: Occupational injury and illness in the United States. Estimates of costs, morbidity, and mortality, Arch Intern Med 157:1557, 1997; Mitchell FL: Hazardous waste. In Rom WN (ed): Environmental and Occupational Medicine, 2nd ed. Boston, Little, Brown, 1992, p 1275; and Levi PE: Classes of toxic chemicals. In Hodgson E, Levi PE (eds): A Textbook of Modern Toxicology. Stamford, CT, Appleton & Lange, 1997, p 229.

- on the list of recommended insecticides for indoor uses in areas in which malaria is endemic. PCB (another banned substance), dioxin, and PBDEs (polybrominated diphenyl ethers used as flame retardants) are also detectable in a large proportion of the U.S. population. Most organochlorines disrupt hormonal balance because of antiestrogenic or antiandrogenic activity.
- **Dioxins** and **PCBs** can cause skin disorders such as folliculitis and a dermatosis known as *chloracne* that is characterized by acne, cyst formation, hyperpigmentation, and hyperkeratosis, generally around the face and behind the ears. These toxins can also cause abnormalities in the liver and CNS. Because PCBs induce CYPs, workers exposed to these substances may show abnormal drug metabolism. Environmental disasters in Japan and China in the late 1960s caused by the consumption of rice oil contaminated by PCBs during its production poisoned about 2000 people in each episode. The primary manifestation of the disease (Yusho in Japan; Yu-Cheng in China) was chloracne and hyperpigmentation of the skin and nails. Aficionados of political intrigues may recall that Viktor Yushenko, a former President of Ukraine, was poisoned by dioxins and suffered severe disfigurement as a result.
 - Inhalation of mineral dusts causes chronic, nonneoplastic lung diseases known as *pneumoconioses*. This term also includes diseases induced by organic and inorganic particulates, and chemical fume- and vapor-induced nonneoplastic lung diseases. The most common pneumoconioses are caused by exposures to *coal dust* (e.g., mining of hard coal), *silica* (e.g., sandblasting, stone cutting), *asbestos* (e.g., mining, fabrication, insulation work), and *beryllium* (e.g., mining, fabrication). Exposure to these agents nearly always occurs in the workplace. However, the increased risk of cancer as a result of

asbestos exposure extends to the family members of asbestos workers and to other individuals exposed outside the workplace. Pneumoconioses and their pathogenesis are discussed in [Chapter 15](#).

- Exposure to *vinyl chloride* used in the synthesis of polyvinyl resins leads to the development of angiosarcoma of the liver, an uncommon type of hepatic tumor.
- **Bisphenol A (BPA)** is used in the synthesis of polycarbonate food and water containers and of epoxy resins that line almost all food bottles and cans; as a result, exposure to BPA is virtually ubiquitous in humans. BPA has long been known as a potential endocrine disruptor. Several large retrospective studies have linked elevated urinary BPA levels to heart disease in adult populations. In addition, infants who drink from BPA-containing containers may be particularly susceptible to its endocrine effects. In 2010, Canada was the first country to list BPA as a toxic substance, and the largest makers of baby bottles and “sippy” cups have stopped using BPA in the manufacturing process. The extent of the human health risks associated with BPA remains uncertain, however, and requires further study.

Effects of Tobacco

Smoking is the most readily preventable cause of death in humans. The main culprit is cigarette smoking, but smokeless tobacco (e.g., snuff, chewing tobacco) is also harmful to health and an important cause of oral cancer. The use of tobacco products not only creates personal risks, but passive tobacco inhalation from the environment (“*second-hand smoke*”) can cause lung cancer in non-smokers. Two thirds of smokers live in 10 countries, led by China, which accounts for nearly 30%, and India with about 10%, followed by Indonesia, Russia, the United States, Japan, Brazil, Bangladesh, Germany, and Turkey. In

the United States alone, tobacco is responsible for more than 400,000 deaths annually, one third of these attributable to lung cancer. Indeed, tobacco is the leading exogenous cause of human cancers, including 90% of lung cancers.

From 1998 to 2007 in the United States, the incidence of smoking declined modestly, but this trend failed to continue, and approximately 20% of adults remain smokers. More disturbing, the world's most populous country, China, has become the world's largest producer and consumer of cigarettes. China has approximately 350 million smokers who in aggregate consume about 33% of all cigarettes smoked worldwide. It is estimated that more than 1 million people in China die each year of smoking-related diseases; this rate is projected to rise to 8 million deaths each year by 2050. Worldwide, cigarette smoking causes more than 4 million deaths annually, mostly from cardiovascular disease, various types of cancers, and chronic respiratory problems. These figures are expected to rise to 8 million tobacco-related deaths by 2020, the major increase occurring in developing countries. Of people alive today, an estimated 500 million will die of tobacco-related illnesses.

Tobacco reduces overall survival through dose-dependent effects that are often expressed as pack-years, the average number of cigarette packs smoked each day multiplied by the number of years of smoking. The cumulative effects of smoking over time are striking. For instance, while about 75% of nonsmokers are alive at age 70, only about 50% of smokers survive to that age (Fig. 9-8). The only good news is that cessation of smoking greatly reduces, within 5 years, overall mortality and the risk of

Figure 9-8 The effects of smoking on survival. The study compared age-specific death rates for current cigarette smokers with that of individuals who never smoked regularly (British Doctors Study). Measured at age 75, the difference in survival between smokers and nonsmokers is 7.5 years. (Modified from Stewart BW, Kleihues P (eds): World Cancer Report. Lyon, IARC Press, 2003.)

Table 9-3 Effects of Selected Tobacco Smoke Constituents

Substance	Effect
Tar	Carcinogenesis
Polycyclic aromatic hydrocarbons	Carcinogenesis
Nicotine	Ganglionic stimulation and depression; tumor promotion
Phenol	Tumor promotion; mucosal irritation
Benzo[a]pyrene	Carcinogenesis
Carbon monoxide	Impaired oxygen transport and utilization
Formaldehyde	Toxicity to cilia; mucosal irritation
Nitrogen oxides	Toxicity to cilia; mucosal irritation
Nitrosamine	Carcinogenesis

death from cardiovascular diseases. Lung cancer mortality decreases by 21% within 5 years, but the excess risk persists for 30 years.

The number of potentially noxious chemicals in tobacco smoke is extraordinary. Tobacco contains between 2000 and 4000 substances, more than 60 of which have been identified as carcinogens. Table 9-3 provides only a partial list and includes various types of injuries produced by these agents. *Nicotine*, an alkaloid present in tobacco leaves, is not a direct cause of tobacco-related diseases, but is strongly addictive. Without it, it would be easy for smokers to stop the habit. Nicotine binds to nicotinic acetylcholine receptors in the brain, and stimulates the release of catecholamines from sympathetic neurons. This activity is responsible for the acute effects of smoking, such as the increase in heart rate and blood pressure, and the elevation in cardiac contractility and output.

Smoking and Lung Cancer. Agents in smoke have a direct irritant effect on the tracheobronchial mucosa, producing inflammation and increased mucus production (bronchitis). Cigarette smoke also causes the recruitment of leukocytes to the lung, with increased local elastase production and subsequent injury to lung tissue, leading to *emphysema*. Components of cigarette smoke, particularly *polycyclic hydrocarbons* and *nitrosamines* (Table 9-4), are potent carcinogens in animals and are directly involved in the development of lung cancer in humans (Chapter 15). CYPs (cytochrome P-450 phase I enzymes) and phase II enzymes increase the water solubility of the carcinogens, facilitating their excretion. However, some intermediates produced by CYPs are electrophilic and form DNA adducts. If such

Table 9-4 Suspected Organ-Specific Carcinogens in Tobacco Smoke

Organ	Carcinogen
Lung, larynx	Polycyclic aromatic hydrocarbons 4-(Methylnitrosoamino)-1-(3-pyridyl)-1-butane (NNK) Polonium 210
Esophagus	<i>N'</i> -Nitrosornicotine (NNN)
Pancreas	NNK
Bladder	4-Aminobiphenyl, 2-naphthylamine
Oral cavity (smoking)	Polycyclic aromatic hydrocarbons, NNK, NNN
Oral cavity (snuff)	NNK, NNN, polonium 210

Data from Szczeny LB, Holbrook JH: Cigarette smoking. In Rom WH (ed): Environmental and Occupational Medicine, 2nd ed. Boston, Little, Brown, 1992, p 1211.

Figure 9-9 The risk of lung cancer is determined by the number of cigarettes smoked. (Modified from Stewart BW, Kleihues P (eds): World Cancer Report. Lyon, IARC Press, 2003.)

adducts persist, they can cause mutations in oncogenes and tumor suppressors (Chapter 7). Most tellingly, deep sequencing of the genomes of lung cancers that occur in smokers has revealed the presence of thousands of mutations of a type that is produced by carcinogens in tobacco smoke in experimental settings. The risk of developing lung cancer is related to the number of pack years or cigarettes smoked per day (Fig. 9-9). Moreover, smoking increases the risk of other carcinogenic influences. Witness the ten-fold higher incidence of lung carcinomas in asbestos workers and uranium miners who smoke over those who do not smoke, and the interaction between tobacco consumption and alcohol in the development of oral cancers (Fig. 9-10).

Smoking and Other Diseases. In addition to lung cancer, smoking is linked to many other malignant and nonmalignant disorders that affect numerous organ systems (Fig. 9-11).

- Cigarette smoking is associated with *cancers of the esophagus, pancreas, bladder, kidney, cervix, and bone marrow*.
- The toll taken by nonmalignant conditions associated with smoking is even more terrible. The most common diseases caused by cigarette smoking involve the lung and include *emphysema, chronic bronchitis, and chronic obstructive pulmonary disease*, conditions that are discussed in Chapter 15.
- Cigarette smoking is also strongly linked to the development of *atherosclerosis* and its major complication, *myocardial infarction*. The causal mechanisms probably relate to several factors, including increased platelet aggregation, decreased myocardial oxygen supply (because of significant lung disease coupled with the hypoxia related to the CO content of cigarette smoke) accompanied by an increased oxygen demand, and a decreased threshold for ventricular fibrillation. Smoking has a multiplicative effect on the incidence of myocardial infarction when combined with hypertension and hypercholesterolemia.
- In addition to having deleterious effects on the smoker, smoking also harms the developing fetus. Maternal

smoking increases the risk of *spontaneous abortions* and *preterm births* and results in *intrauterine growth retardation* (Chapter 10). Birth weights of infants born to mothers who stopped smoking before pregnancy are, however, normal.

- Exposure to *environmental tobacco smoke (passive smoke inhalation)* is associated with some of the same detrimental effects that result from active smoking. It is estimated that the relative risk of lung cancer in nonsmokers exposed to environmental smoke is about 1.3 times higher than that of nonsmokers who are not exposed to smoke. In the United States, approximately 3000 lung cancer deaths in nonsmokers older than 35 years can be attributed each year to environmental tobacco smoke. Even more striking is the increased risk of coronary atherosclerosis and fatal myocardial infarction. Studies report that every year 30,000 to 60,000 cardiac deaths in the United States are associated with exposure to passive smoke. Passive smoke inhalation in nonsmokers can be estimated by measuring the blood levels of *cotinine*, a metabolite of nicotine. During the period of 1999 to 2008, the prevalence of elevated cotinine levels in nonsmokers in the United States fell from 52% to 40% thanks to bans on smoking in public places, but exposure to environmental tobacco smoke in the home remains a major public health concern, particularly for children who may develop respiratory illnesses and asthma.

It is clear that the transient pleasure of smoking comes with a heavy long-term price. A new part of the picture is electronic cigarettes, devices that simulate cigarette

Figure 9-10 Multiplicative increase in the risk of laryngeal cancer from the interaction between cigarette smoking and alcohol consumption. (Modified from Stewart BW, Kleihues P (eds): World Cancer Report. Lyon, IARC Press, 2003.)

Figure 9-11 Summary of the adverse effects of smoking: those that are more common are in boldface.

smoking by delivering vaporized nicotine and flavorings, which are rising in popularity. As of 2013, however, the WHO has not indicated if these devices are effective in helping smokers to quit or if they have adverse health effects of their own.

KEY CONCEPTS

Health Effects of Tobacco

- Smoking is the most prevalent preventable cause of human death.
- Tobacco smoke contains more than 2000 compounds. Among these are nicotine, which is responsible for tobacco addiction, and potent carcinogens—mainly, polycyclic aromatic hydrocarbons, nitrosamines, and aromatic amines.
- Approximately 90% of lung cancers occur in smokers. Smoking is also associated with an increased risk of cancers of the oral cavity, larynx, esophagus, stomach, bladder, and kidney, as well as some forms of leukemia. Cessation of smoking reduces the risk of lung cancer.
- Smokeless tobacco use is an important cause of oral cancers. Tobacco consumption interacts with alcohol in multiplying the risk of oral, laryngeal, and esophageal cancer and increases the risk of lung cancers from

occupational exposures to asbestos, uranium, and other agents.

- Tobacco use is an important risk factor for development of atherosclerosis and myocardial infarction, peripheral vascular disease, and cerebrovascular disease. In the lungs, in addition to cancer, it predisposes to emphysema, chronic bronchitis, and chronic obstructive disease.
- Maternal smoking increases the risk of abortion, premature birth, and intrauterine growth retardation.

Effects of Alcohol

Ethanol consumption in moderate amounts is generally not injurious (and may even protect against some disorders), but in excessive amounts alcohol causes serious physical and psychological damage. In this section we describe the steps of alcohol metabolism and the major health consequences associated with alcohol abuse.

Despite all the attention given to illicit drugs such as cocaine and heroin, alcohol abuse is a far more widespread hazard and claims many more lives. Fifty percent of adults in the Western world drink alcohol, and about 5% to 10% have chronic alcoholism. It is estimated that there are more than 10 million chronic alcoholics in the United States and that alcohol consumption is responsible for more than 100,000 deaths annually. More than 50% of these deaths result from accidents caused by drunken driving and alcohol-related homicides and suicides, and about 15,000 annual deaths are a consequence of cirrhosis of the liver. Worldwide, alcohol accounts for approximately 1.8 million deaths per year (3.2% of all deaths).

After consumption, ethanol is absorbed unaltered in the stomach and small intestine. It is then distributed to all the tissues and fluids of the body in direct proportion to the blood level. Less than 10% is excreted unchanged in the urine, sweat, and breath. The amount exhaled is proportional to the blood level and forms the basis of the breath test used by law enforcement agencies. A concentration of 80 mg/dL in the blood constitutes the legal definition of drunk driving in the United States. For an average individual, this alcohol concentration may be reached after consumption of three standard drinks, about three (12 ounce) bottles of beer, 15 ounces of wine, or 4 to 5 ounces of 80 proof distilled spirits. Drowsiness occurs at 200 mg/dL, stupor at 300 mg/dL, and coma, with possible respiratory arrest, at higher levels. The rate of metabolism affects the blood alcohol level. Chronic alcoholics can tolerate levels of up to 700 mg/dL, a situation that is partially explained by accelerated ethanol metabolism caused by a fivefold to 10-fold induction of liver CYPs (discussed later). The effects of alcohol also vary by age, sex, and body fat.

Most of the alcohol in the blood is oxidized to *acetaldehyde* in the liver by three enzyme systems consisting of alcohol dehydrogenase, the microsomal ethanol-oxidizing system, and catalase (Fig. 9-12). The main enzyme system involved in alcohol metabolism is alcohol dehydrogenase, located in the cytosol of hepatocytes. At high blood alcohol levels, the microsomal ethanol-oxidizing system participates in its metabolism. Catalase, which uses hydrogen peroxide as its substrate, is of minor importance, metabolizing no more than 5% of ethanol in the liver. Acetaldehyde

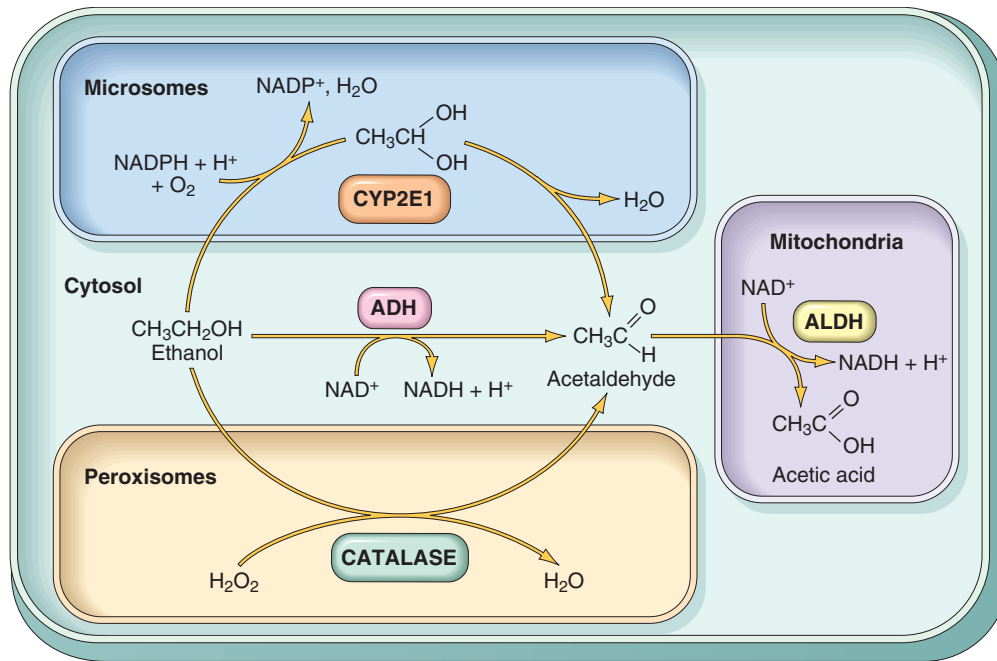

Figure 9-12 Metabolism of ethanol: oxidation of ethanol to acetaldehyde by three different routes and the generation of acetic acid. Note that oxidation by ADH (alcohol dehydrogenase) takes place in the cytosol; the cytochrome P-450 system and its CYP2E1 isoform are located in the endoplasmic reticulum (microsomes), and catalase is located in peroxisomes. Oxidation of acetaldehyde by ALDH (aldehyde dehydrogenase) occurs in mitochondria. ADH oxidation is the most important route; catalase is involved in only 5% of ethanol metabolism. Oxidation through CYPs may also generate reactive oxygen species (not shown). (From Parkinson A: Biotransformation of xenobiotics. In Klassen CD [ed]: Casarett and Doull's Toxicology: The Basic Science of Poisons, 6th ed. New York, McGraw-Hill, 2001, p 133.)

produced by alcohol metabolism is converted to *acetate* by acetaldehyde dehydrogenase, which is then utilized in the mitochondrial respiratory chain.

The microsomal oxidation system involves CYPs, particularly CYP2E1 located in the smooth endoplasmic reticulum. Induction of CYPs by alcohol explains the increased susceptibility of alcoholics to other compounds metabolized by the same enzyme system, which include drugs, anesthetics, carcinogens, and industrial solvents. Note, however, that when alcohol is present in the blood at high concentrations, it competes with other CYP2E1 substrates and delays drug catabolism, potentiating the depressant effects of narcotic, sedative, and psychoactive drugs in the CNS.

The oxidation of ethanol produces toxic metabolites and disrupts certain metabolic pathways, the most important of which include the following:

- *Acetaldehyde*, the direct product of alcohol oxidation, has many toxic effects and is responsible for some of the acute effects of alcohol and for the development of oral cancers. The efficiency of alcohol metabolism varies between populations, depending on the expression levels of alcohol dehydrogenase and acetaldehyde dehydrogenase isozymes, and the presence of genetic variants that alter enzyme activity. About 50% of Asians have very low alcohol dehydrogenase activity, due to the substitution of lysine for glutamine at residue 487 (the normal allele is termed ALDH2*1 and the inactive variant is designated as ALDH2*2). The ALDH2*2 protein has dominant-negative activity, such that even one copy of the ALDH2*2 allele reduces acetaldehyde

dehydrogenase activity significantly. Individuals homozygous for the ALDH2*2 allele are completely unable to oxidize acetaldehyde and cannot tolerate alcohol, experiencing nausea, flushing, tachycardia, and hyperventilation after its ingestion.

- Alcohol oxidation by alcohol dehydrogenase causes the reduction of nicotinamide adenine dinucleotide (NAD) to NADH, with a consequent decrease in NAD and increase in NADH. NAD is required for fatty acid oxidation in the liver and for the conversion of lactate into pyruvate. Its deficiency is a main cause of the accumulation of fat in the liver of alcoholics. The increase in the NADH/NAD ratio in alcoholics also causes lactic acidosis.
- Metabolism of ethanol in the liver by CYP2E1 produces reactive oxygen species, which cause lipid peroxidation of hepatocyte cell membranes. Alcohol also causes the release of endotoxin (lipopolysaccharide) from gram-negative bacteria in the intestinal flora, which stimulates the production of TNF (tumor necrosis factor) and other cytokines from macrophages and Kupffer cells, leading to hepatic injury. However, it must be said that the mechanisms by which alcohol causes liver injury remain to be completely defined.

The adverse effects of ethanol can be classified as acute or chronic.

Acute alcoholism exerts its effects mainly on the CNS, but it may induce hepatic and gastric changes that are reversible if alcohol consumption is discontinued. Even with moderate intake of alcohol, multiple fat droplets accumulate in the cytoplasm of hepatocytes (*fatty change* or *hepatic*

steatosis). The gastric changes are *acute gastritis* and *ulceration*. In the CNS, alcohol is a depressant, first affecting subcortical structures (probably the high brain stem reticular formation) that modulate cerebral cortical activity. Consequently, there is stimulation and disordered cortical, motor, and intellectual behavior. At progressively higher blood levels, cortical neurons and then lower medullary centers are depressed, including those that regulate respiration. Respiratory arrest may follow.

Chronic alcoholism affects not only the liver and stomach, but virtually all other organs and tissues as well. Chronic alcoholics suffer significant morbidity and have a shortened life span, related principally to damage to the liver, gastrointestinal tract, CNS, cardiovascular system, and pancreas.

- The *liver* is the main site of chronic injury. In addition to fatty change mentioned above, chronic alcoholism causes alcoholic hepatitis and cirrhosis, as described in [Chapter 18](#). Cirrhosis is associated with portal hypertension and an increased risk for the development of hepatocellular carcinoma.
- In the *gastrointestinal tract*, chronic alcoholism can cause massive bleeding from gastritis, gastric ulcer, or esophageal varices (associated with cirrhosis), which may be fatal.
- *Thiamine (vitamin B₁) deficiency* is common in chronic alcoholics. The principal lesions resulting from this deficiency are *peripheral neuropathies* and the *Wernicke-Korsakoff syndrome* (see [Table 9-9](#) in this chapter and [Chapter 28](#)); cerebral atrophy, cerebellar degeneration, and optic neuropathy may also occur.
- Alcohol has diverse effects on the cardiovascular system. Injury to the myocardium may produce dilated congestive cardiomyopathy (*alcoholic cardiomyopathy*, discussed in [Chapter 12](#)). Chronic alcoholism is also associated with an increased incidence of hypertension, and heavy alcohol consumption, with attendant liver injury, results in decreased levels of HDL, increasing the likelihood of coronary heart disease.
- Excessive alcohol intake increases the risk of *acute and chronic pancreatitis* ([Chapter 19](#)).
- The use of ethanol during pregnancy can cause *fetal alcohol syndrome*, which is marked by microcephaly, growth retardation, and facial abnormalities in the newborn, and reduction in mental functions as the child grows older. It is difficult to establish the minimal amount of alcohol consumption that can cause fetal alcohol syndrome, but consumption during the first trimester of pregnancy is particularly harmful. It has been estimated that the prevalence of frequent and binge drinking among pregnant women is approximately 6% and that fetal alcohol syndrome affects 1 to 4.8 per 1000 children born in the United States.
- Chronic alcohol consumption is associated with an *increased incidence of cancer* of the oral cavity, esophagus, liver, and, in women, possibly the breast. Acetaldehyde is considered to be the main agent associated with alcohol-induced laryngeal and esophageal cancer, in that acetaldehyde-DNA adducts have been detected in some tumors from these tissues. Individuals with one copy of the ALDH2*2 allele who drink are at a higher risk for developing cancer of the esophagus. As

mentioned earlier, alcohol and cigarette smoke synergize in the causation of various cancers.

- Ethanol is a substantial source of energy (empty calories). Chronic alcoholism leads to malnutrition and nutritional deficiencies, particularly of the B vitamins.

Not all is gloom and doom, however. Moderate amounts of alcohol (about 20-30 gm/day, corresponding to approximately 250 mL of wine) have been reported to increase high-density lipoprotein (HDL) levels, inhibit platelet aggregation, and lower fibrinogen levels, providing a possible basis for protective effects against coronary heart disease. More broadly, epidemiologic studies have linked light to moderate alcohol consumption with increased overall survival as compared to teetotalers and heavy drinkers. Although it remains uncertain whether these survival benefits are due to alcohol consumption per se or to other covariates (e.g., having a lifestyle that permits one to enjoy a good glass of wine on a daily basis), it seems that the old saying is true, at least with respect to alcohol—all things in moderation!

KEY CONCEPTS

Alcohol—Metabolism and Health Effects

- Acute alcohol abuse causes drowsiness at blood levels of approximately 200 mg/dL. Stupor and coma develop at higher levels.
- Alcohol is oxidized to acetaldehyde in the liver by alcohol dehydrogenase, by the cytochrome P-450 system, and by catalase, which is of minor importance. Acetaldehyde is converted to acetate in mitochondria and utilized in the respiratory chain.
- Alcohol oxidation by alcohol dehydrogenase depletes NAD, leading to accumulation of fat in the liver and metabolic acidosis.
- The main effects of chronic alcoholism are fatty liver, alcoholic hepatitis, and cirrhosis, which leads to portal hypertension and increases the risk for development of hepatocellular carcinoma.
- Chronic alcoholism can cause bleeding from gastritis and gastric ulcers, peripheral neuropathy associated with thiamine deficiency, alcoholic cardiomyopathy, and acute and chronic pancreatitis.
- Chronic alcoholism is a major risk factor for cancers of the oral cavity, larynx, and esophagus. The risk is greatly increased by concurrent smoking or use of smokeless tobacco.

Injury by Therapeutic Drugs and Drugs of Abuse

Injury by Therapeutic Drugs (Adverse Drug Reactions)

Adverse drug reactions refer to untoward effects of drugs that are given in conventional therapeutic settings. These reactions are extremely common in the practice of medicine; an exotic, but easily seen example is discoloration of the skin caused by the antibiotic minocycline ([Fig. 9-13](#)).

Figure 9-13 Adverse drug reaction. Skin pigmentation caused by minocycline, a long-acting tetracycline derivative. **A**, Diffuse blue-gray pigmentation of the forearm; **B**, Deposition of drug metabolite/iron/melanin pigment particles in the dermis. (Courtesy Dr. Zsolt Argenyi, Department of Pathology, University of Washington, Seattle, Wash.)

Much more common are drug reactions that are due to direct actions of the drug or to immunologically based hypersensitivity reactions. Drug-induced hypersensitivity reactions most commonly present as skin rashes, but they may also mimic autoimmune disorders such as systemic lupus erythematosus (Chapter 6), hemolytic anemia, and immune thrombocytopenia (Chapter 13). Adverse drug reactions affect almost 10% of patients admitted to a hospital.

The number of fatal adverse drug reactions is debated, but by some accounts may be as high as 140,000 deaths per year. Table 9-5 lists common pathologic findings in adverse drug reactions and the drugs most frequently involved. Many of the drugs that produce adverse reactions, such as antineoplastic agents, are highly potent, and the adverse reactions are accepted risks of the treatment. In this section, adverse reactions to commonly used drugs are examined, first discussing the unwelcome effects of anticoagulants, menopausal hormone therapy (MHT), oral contraceptives (OCs), and anabolic steroids and then discussing the effects of acetaminophen and aspirin, because all are commonly used.

Anticoagulants

In 2011, the two drugs that most frequently caused adverse reactions reported to the Food and Drug Administration were the oral anticoagulants warfarin and dabigatran.

Warfarin is an antagonist of vitamin K, and dabigatran is a direct inhibitor of thrombin. The principal complications associated with both of these medications are bleeding, which can be fatal, and thrombotic complications such as embolic stroke stemming from undertreatment. Warfarin is inexpensive and its effects are easy to monitor, but many drugs and foods rich in vitamin K either interfere with its metabolism or abrogate its function. As a result, maintaining anticoagulation in a relatively safe therapeutic range can be problematic. Pharmacologic interactions of drugs with dabigatran metabolism have not been described, but many bleeding complications nevertheless occur. It is primarily used to prevent thromboembolism in patients

Table 9-5 Common Adverse Drug Reactions and Their Agents

Reaction	Major Offenders
Bone Marrow And Blood Cells*	
Granulocytopenia, aplastic anemia, pancytopenia	Antineoplastic agents, immunosuppressives, chloramphenicol
Hemolytic anemia, thrombocytopenia	Penicillin, methyl dopa, quinidine, heparin
Cutaneous	
Urticaria, macules, papules, vesicles, petechiae, exfoliative dermatitis, fixed drug eruptions, abnormal pigmentation	Antineoplastic agents, sulfonamides, hydantoins, some antibiotics, and many other agents
Cardiac	
Arrhythmias	Theophylline, hydantoins, digoxin
Cardiomyopathy	Doxorubicin, daunorubicin
Renal	
Glomerulonephritis	Penicillamine
Acute tubular necrosis	Aminoglycoside antibiotics, cyclosporin, amphotericin B
Tubulointerstitial disease with papillary necrosis	Phenacetin, salicylates
Pulmonary	
Asthma	Salicylates
Acute pneumonitis	Nitrofurantoin
Interstitial fibrosis	Busulfan, nitrofurantoin, bleomycin
Hepatic	
Fatty change	Tetracycline
Diffuse hepatocellular damage	Halothane, isoniazid, acetaminophen
Cholestasis	Chlorpromazine, estrogens, contraceptive agents
Systemic	
Anaphylaxis	Penicillin
Lupus erythematosus syndrome (drug-induced lupus)	Hydralazine, procainamide
Bleeding	Warfarin, dabigatran
Central Nervous System	
Tinnitus and dizziness	Salicylates
Acute dystonic reactions and parkinsonian syndrome	Phenothiazine antipsychotics
Respiratory depression	Sedatives

*Affected in almost half of all drug-related deaths.

with atrial fibrillation who are at high risk for thrombotic stroke.

Menopausal Hormone Therapy (MHT)

The most common type of MHT (previously referred to as hormone replacement therapy, or HRT) consists of the administration of estrogens together with a progestogen. Because of the risk of uterine cancer, estrogen therapy alone is used only in hysterectomized women. Initially used to counteract “hot flashes” and other symptoms of menopause, early clinical studies suggested that MHT use in postmenopausal women could prevent or slow the progression of osteoporosis (Chapter 26) and reduce the likelihood of myocardial infarction. However, subsequent randomized clinical trials have produced decidedly mixed results. In 2002, the Women’s Health Initiative stunned the medical community by reporting that a large prospective placebo controlled trial failed to find support for some of the presumed beneficial effects of the therapy. This study involved approximately 17,000 women who were taking a combination of estrogen (conjugated equine estrogens) and a synthetic progestin (medroxyprogesterone acetate). Although MHT did reduce the number of fractures in women on treatment, researchers also reported that after 5 years of treatment, combination MHT increased the risk of breast cancer (Chapter 23), stroke, and venous thromboembolism and had no effect on the incidence of coronary heart disease. The shockwaves produced by these findings led to a drastic decrease in the use of MHT, from 16 million prescriptions in 2001 to 6 million in 2006, which was accompanied by an apparent drop in the incidence of newly diagnosed breast cancers. But during the past few years there has been a reappraisal of the risks and benefits of MHT. These newer analyses showed that MHT effects depend on the type of hormone therapy regimen used (combination estrogen-progestin versus estrogen alone), the age and risk factor status of the woman at the start of treatment, the duration of the treatment, and possibly the hormone dose, formulation, and route of administration. The current risk:benefit consensus can be summarized as follows:

- Combination estrogen-progestin increases the risk of breast cancer after a median time of 5 to 6 years. In contrast, estrogen alone in women with hysterectomy is associated with a borderline reduction in risk of breast cancer.
- MHT may have a protective effect on the development of atherosclerosis and coronary disease in women younger than age 60 years, but there is no protection in women who started MHT at an older age. These data support the notion that there may be a critical therapeutic window for MHT effects on the cardiovascular system. Protective effects in younger women depend in part on the response of estrogen receptors and healthy vascular endothelium. However, MHT should not be used for prevention of cardiovascular disease or other chronic diseases.
- MHT increases the risk of stroke and venous thromboembolism (VTE), including deep vein thrombosis and pulmonary embolism. The increase in VTE is more pronounced during the first 2 years of treatment and in women who have other risk factors such as

immobilization and hypercoagulable states caused by prothrombin or factor V Leiden mutations (Chapter 4). Whether risks of VTE and stroke are lower with transdermal than oral routes of estrogen administration warrants further study.

As can be appreciated from these associations, assessment of risks and benefits when considering the use of MHT in women is complex. The current feeling is that these agents have a role in the management of menopausal symptoms in early menopause but should not be used long term for chronic disease prevention.

Oral Contraceptives (OCs)

Worldwide, more than 100 million women use hormonal contraception. OCs nearly always contain a synthetic estradiol and a variable amount of a progestin, but some preparations contain only progestins. They act by inhibiting ovulation or preventing implantation. Currently prescribed OCs contain a much smaller amount of estrogens (as little as 20 µg of ethinyl estradiol) than the earliest formulations, and are associated with fewer side effects. Transdermal and implantable formulations have also become available. Hence, the results of epidemiologic studies should be interpreted in the context of the dosage and the delivery system. Nevertheless, there is good evidence to support the following conclusions:

- *Breast carcinoma*: The prevailing opinion is that OCs *do not* increase breast cancer risk.
- *Endometrial cancer and ovarian cancers*: OCs have a protective effect against these tumors.
- *Cervical cancer*: OCs may increase risk of cervical carcinomas in women infected with human papillomavirus, although it is unclear whether the increased risk merely reflects greater sexual activity in women on OCs.
- *Thromboembolism*: Most studies indicate that OCs, including the newer low-dose (less than 50 µg of estrogen) preparations, are associated with a threefold to sixfold increased risk of venous thrombosis and pulmonary thromboembolism due to a hypercoagulable state induced by elevated hepatic synthesis of coagulation factors. This risk may be even higher with newer “third-generation” OCs that contain synthetic progestins, particularly in women who are carriers of the factor V Leiden mutation. To put this complication into context, however, the risk of thromboembolism associated with OC use is two to six times lower than the risk of thromboembolism associated with pregnancy.
- *Cardiovascular disease*: There is considerable uncertainty about the risk of atherosclerosis and myocardial infarction in users of OCs. It seems that OCs do not increase the risk of coronary artery disease in women younger than 30 years or in older women who are nonsmokers, but the risk does approximately double in women older than 35 years who smoke.
- *Hepatic adenoma*: There is a well-defined association between the use of OCs and this rare benign hepatic tumor, especially in older women who have used OCs for prolonged periods. The tumor appears as a large, solitary, and well-encapsulated mass.

Ultimately, the pros and cons of OCs must be viewed in the context of their wide applicability and acceptance as a

form of contraception that protects against unwanted pregnancies.

Anabolic Steroids

The use of steroids to increase performance by baseball players, track-and-field athletes, and wrestlers has received wide publicity during the past decade. Anabolic steroids are synthetic versions of testosterone, and for performance enhancement they are used at doses that are about 10 to 100 times higher than therapeutic indications. The high concentration of testosterone and its derivatives inhibits production and release of luteinizing hormone and follicle-stimulating hormone by a feedback mechanism, and increases the amount of estrogens, which are produced from anabolic steroids. Anabolic steroids have multiple adverse effects including stunted growth in adolescents, acne, gynecomastia, and testicular atrophy in males, and growth of facial hair and menstrual changes in women. Other effects include psychiatric disturbances and an increased risk of myocardial infarction. Hepatic cholestasis may develop in individuals receiving orally administered anabolic steroids.

Acetaminophen

Acetaminophen is the most commonly used analgesic in the United States. It is present in more than 300 products, alone or in combination with other agents. Hence, acetaminophen toxicity is common, being responsible for more than 50,000 emergency room visits per year. In the United States, it is the cause of about 50% of cases of acute liver failure, with 30% mortality. Intentional overdose (attempted suicide) is the most common cause of acetaminophen toxicity in Great Britain, but unintentional overdose is the most frequent cause in the United States, representing almost 50% of the total intoxication cases.

At therapeutic doses, about 95% of acetaminophen undergoes detoxification in the liver by phase II enzymes and is excreted in the urine as glucuronate or sulfate conjugates (Fig. 9-14). About 5% or less is metabolized through the activity of CYPs (primarily CYP2E) to NAPQI (*N*-acetyl-*p*-benzoquinoneimine), a highly reactive metabolite. NAPQI is normally conjugated with glutathione (GSH), but when acetaminophen is taken in large doses unconjugated NAPQI accumulates and causes hepatocellular injury, leading to *centrilobular necrosis* that may progress to *liver failure*. The injury produced by NAPQI involves two mechanisms: (1) covalent binding to hepatic proteins, which causes damage to cellular membranes and mitochondrial dysfunction, and (2) depletion of GSH, making hepatocytes more susceptible to reactive oxygen species-induced injury. Because alcohol induces CYP2E in the liver, toxicity can occur at lower doses in chronic alcoholics.

The window between the usual dose (0.5 gm) and the toxic dose (15 to 25 gm) is large, and the drug is ordinarily very safe. Toxicity begins with nausea, vomiting, diarrhea, and sometimes shock, followed in a few days by evidence of jaundice. Overdoses of acetaminophen can be treated at its early stages (within 12 hours) by administration of *N*-acetylcysteine, which restores GSH levels. In serious overdose liver failure ensues, starting with centrilobular necrosis that may extend to entire lobules; in such circumstances liver transplantation is the only hope for survival. Some patients also show evidence of concurrent renal damage.

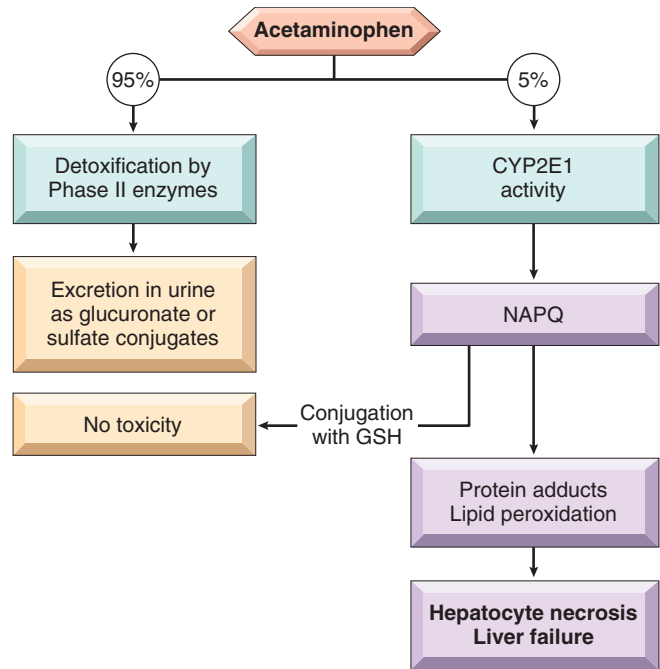

Figure 9-14 Acetaminophen metabolism and toxicity. (See text for details.) (Courtesy Dr. Xavier Vaquero, Department of Pathology, University of Washington, Seattle, Wash.)

Aspirin (Acetylsalicylic Acid)

Aspirin overdose may result from accidental ingestion of a large number of tablets by young children; in adults overdose is frequently suicidal. Much less commonly, salicylate poisoning is caused by the excessive use of ointments containing oil of wintergreen (methyl salicylate). Acute salicylate overdose causes alkalosis as a consequence of the stimulation of the respiratory center in the medulla. This is followed by metabolic acidosis and accumulation of pyruvate and lactate, caused by uncoupling of oxidative phosphorylation and inhibition of the Krebs cycle. Metabolic acidosis enhances the formation of non-ionized forms of salicylates, which diffuse into the brain and produce effects from nausea to coma. Ingestion of 2 to 4 gm by children or 10 to 30 gm by adults may be fatal, but survival has been reported after ingestion of doses five times larger.

Chronic aspirin toxicity (salicylism) may develop in persons who take 3 gm or more daily for long periods of time for treatment of chronic pain or inflammatory conditions. Chronic salicylism is manifested by headaches, dizziness, ringing in the ears (tinnitus), hearing impairment, mental confusion, drowsiness, nausea, vomiting, and diarrhea. The CNS changes may progress to convulsions and coma. The morphologic consequences of chronic salicylism are varied. Most often there is an acute erosive gastritis (Chapter 17), which may produce overt or covert gastrointestinal bleeding and lead to gastric ulceration. A bleeding tendency may appear concurrently with chronic toxicity, because aspirin acetylates platelet cyclooxygenase and irreversibly blocks the production of thromboxane A_2 , an activator of platelet aggregation. Petechial hemorrhages may appear in the skin and internal viscera, and bleeding from gastric ulcerations may be exaggerated. With the recognition of gastric ulceration and bleeding as an important complication of ingestion of large doses of aspirin, chronic toxicity is now quite uncommon.

Proprietary analgesic mixtures of aspirin and phenacetin or its active metabolite, acetaminophen, when taken over several years, can cause tubulointerstitial nephritis with renal papillary necrosis, referred to as *analgesic nephropathy* (Chapter 20).

Injury by Nontherapeutic Agents (Drug Abuse)

According to the United Nations Office on Drugs and Crime, it is estimated in the year 2010 approximately 153 million to 300 million people between 15 and 64 years of age used an illicit substance at least once. In most instances, occasional users of illicit “recreational” drugs suffer no apparent long-term health effects, but (depending on the drug) acute effects may take a significant toll in the form of accidents, violence, or even fatal drug-related complications. Drug abuse generally involves the repeated or chronic use of mind-altering substances, beyond therapeutic or social norms, and may lead to drug addiction and overdose, both serious public health problems. Common drugs of abuse are listed in Table 9-6. Considered here are cocaine, heroin, amphetamines, and marijuana, among others.

Cocaine

Globally, cocaine use is greatest in North America, Western and Central Europe, Australia, and New Zealand; in each of these countries, it is estimated from 1% to 2% of adults younger than age 65 years used cocaine in 2010. According to national surveys, the numbers of users in the United States has decline substantially in recent years, from approximately 2.4 million in 2006 to approximately 1.5 million in 2010.

Cocaine is extracted from the leaves of the coca plant, and is usually prepared as a water-soluble powder, cocaine

Figure 9-15 The effect of cocaine on neurotransmission. The drug inhibits reuptake of the neurotransmitters dopamine and norepinephrine in the central and peripheral nervous systems.

hydrochloride. Sold on the street, it is liberally diluted with talcum powder, lactose, or other look-alikes. Cocaine can be snorted or dissolved in water and injected subcutaneously or intravenously. Crystallization of the pure alkaloid yields nuggets of *crack*, so called because of the cracking or popping sound it makes when heated to produce vapors that are inhaled. The pharmacologic actions of cocaine and crack are identical, but crack is far more potent.

Cocaine produces an intense euphoria and stimulation, making it one of the most addictive drugs. Experimental animals will press a lever more than 1000 times and forgo food and drink to obtain it. In the cocaine user, although physical dependence generally does not occur, the psychological withdrawal is profound and can be extremely difficult to treat. Intense cravings are particularly severe in the first several months after abstinence and can recur for years.

The acute and chronic effects of cocaine on various organ systems are as follows:

- **Cardiovascular effects.** The most serious physical effects of cocaine relate to its acute action on the cardiovascular system, where it behaves as a sympathomimetic (Fig. 9-15). It facilitates neurotransmission both in the CNS, where it blocks the reuptake of dopamine, and at adrenergic nerve endings, where it blocks the reuptake of

Table 9-6 Common Drugs of Abuse

Class	Molecular Target	Example
Opioid narcotics	Mu opioid receptor (agonist)	Heroin, Hydromorphone (Dilaudid) Oxycodone (OxyContin) Methadone (Dolophine) Meperidine (Demerol)
Sedative-hypnotics	GABA _A receptor (agonist)	Barbiturates Ethanol Methaqualone (Quaalude) Glutethimide (Doriden) Ethchlorvynol (Placidyl)
Psychomotor stimulants	Dopamine transporter (antagonist) Serotonin receptors (toxicity)	Cocaine Amphetamines 3,4-methylenedioxymethamphetamine (MDMA, ecstasy)
Phencyclidine-like drugs	NMDA glutamate receptor channel (antagonist)	Phencyclidine (PCP, angel dust) Ketamine
Cannabinoids	CBI cannabinoid receptors (agonist)	Marijuana Hashish
Hallucinogens	Serotonin 5-HT ₂ receptors (agonist)	Lysergic acid diethylamide (LSD) Mescaline Psilocybin

GABA, γ -aminobutyric acid; 5-HT₂, 5-hydroxytryptamine; NMDA, *N*-methyl *D*-aspartate. From Hyman SE: A 28-year-old man addicted to cocaine. JAMA 286:2586, 2001.

both epinephrine and norepinephrine while stimulating the presynaptic release of norepinephrine. The net effect is the accumulation of these two neurotransmitters in synapses, resulting in excess stimulation, manifested by *tachycardia*, *hypertension*, and *peripheral vasoconstriction*. Cocaine may also induce *myocardial ischemia* by causing *coronary artery vasoconstriction* and by enhancing platelet aggregation and thrombus formation. Cigarette smoking potentiates cocaine-induced coronary vasospasm. Thus, the dual effect of cocaine, causing increased myocardial oxygen demand by its sympathomimetic action, and, at the same time, decreasing coronary blood flow, sets the stage for myocardial ischemia that may lead to myocardial infarction. Cocaine can also precipitate *lethal arrhythmias* by enhanced sympathetic activity as well as by disrupting normal ion (K^+ , Ca^{2+} , Na^+) transport in the myocardium. These toxic effects are not necessarily dose related, and a fatal event may occur in a first time user with what is a typical mood-altering dose.

- **CNS.** The most common acute effects on the CNS are hyperpyrexia (thought to be caused by aberrations of the dopaminergic pathways that control body temperature) and seizures.
- **Effects on pregnancy.** In pregnant women, cocaine may cause acute decreases in blood flow to the placenta, resulting in fetal hypoxia and spontaneous abortion. Neurologic development may be impaired in the fetus of pregnant women who are chronic drug users.
- **Other effects.** Chronic cocaine use may cause (1) perforation of the nasal septum in snorters, (2) decreased lung diffusing capacity in those who inhale the smoke, and (3) development of dilated cardiomyopathy.

Opiates

In 2010, there were an estimated 13 to 21 million users of opiates worldwide, with the highest levels of use being in North America (an estimated 4% of people between 15 and 64 years of age). Opiate drugs of abuse include synthetic prescription opiates such as oxycodone (OxyContin) and “street drugs,” most notably heroin. Heroin is an addictive opioid derived from the poppy plant that is closely related to morphine. Its use is even more harmful than that of cocaine. As sold on the street, it is cut (diluted) with an agent (often talc or quinine); thus, the size of the dose is not only variable but also usually unknown to the buyer. Heroin, along with any contaminating substances, is usually self-administered intravenously or subcutaneously. The effects on the CNS are varied and include euphoria, hallucinations, somnolence, and sedation. Heroin has a wide range of other adverse physical effects related to (1) the pharmacologic action of the agent, (2) reactions to the cutting agents or contaminants, (3) hypersensitivity reactions to the drug or its adulterants (quinine itself has neurologic, renal, and auditory toxicity), and (4) diseases contracted incident to the use of contaminated needles. Some of the most important adverse effects of heroin follow:

- **Sudden death.** Sudden death, usually related to overdose, is an ever-present risk, because drug purity is generally unknown (ranging from 2% to 90%). The yearly mortality among heroin users in the United States is estimated

to be between 1% and 3%. Sudden death can also occur if heroin is taken after tolerance for the drug, built up over time, is lost (as during a period of incarceration). The mechanisms of death include profound respiratory depression, arrhythmia and cardiac arrest, and severe pulmonary edema.

- **Pulmonary injury.** Pulmonary complications include moderate to severe edema, septic embolism from endocarditis, lung abscess, opportunistic infections, and foreign-body granulomas from talc and other adulterants. Although granulomas occur principally in the lung, they are sometimes found in the mononuclear phagocyte system, particularly in the spleen, liver, and lymph nodes that drain the upper extremities. Examination under polarized light often highlights trapped talc crystals, sometimes enclosed within foreign-body giant cells.
- **Infections.** Infectious complications are common. The four sites most commonly affected are the skin and subcutaneous tissue, heart valves, liver, and lungs. In a series of addicted patients admitted to the hospital, more than 10% had endocarditis, which often takes a distinctive form involving right-sided heart valves, particularly the tricuspid. Most cases are caused by *S. aureus*, but fungi and a multitude of other organisms have also been implicated. Viral hepatitis is the most common infection among addicted persons and is acquired by the sharing of dirty needles. In the United States, this practice has also led to a very high incidence of HIV infection in intravenous drug abusers.
- **Skin.** Cutaneous lesions are probably the most frequent telltale sign of heroin addiction. Acute changes include abscesses, cellulitis, and ulcerations due to subcutaneous injections. Scarring at injection sites, hyperpigmentation over commonly used veins, and thrombosed veins are the usual sequelae of repeated intravenous inoculations.
- **Kidneys.** Kidney disease is a relatively common hazard. The two forms most frequently encountered are amyloidosis (generally secondary to skin infections) and focal and segmental glomerulosclerosis; both induce proteinuria and the nephrotic syndrome.

Abuse of oxycodone, an oral opiate available by prescription for treatment of pain, has increased sharply in recent years in the United States. According to the National Institute of Drug Abuse, approximately 5% of high school seniors took oxycodone in the year 2010, sometimes with tragic results due to the potent respiratory suppressant effect of the drug. The overall number of yearly fatalities attributed to abuse of prescription opiates in the United States rose from approximately 3000 in 1999 to approximately 12,000 deaths in 2008. Most of this increase is attributable to abuse of oxycodone, which has surpassed heroin as the leading cause of opiate-related death in the United States.

Amphetamines and Related Drugs

Methamphetamine. This addictive drug, known as “speed” or “meth,” is closely related to amphetamine but has stronger effects in the CNS. Methamphetamine use rose rapidly in the United States in the early 2000s, peaking in the year 2005, but has fallen steadily since that time. According

to national surveys, use of methamphetamine fell to approximately 350,000 users in 2010, a decrease of more than 50% since 2006. Methamphetamine acts by releasing dopamine in the brain, which inhibits presynaptic neurotransmission at corticostriatal synapses, slowing glutamate release. Methamphetamine produces a feeling of euphoria, which is followed by a “crash.” Long-term use leads to violent behaviors, confusion, and psychotic features that include paranoia and hallucinations.

MDMA. MDMA (3,4 methylenedioxymethamphetamine) is popularly known as *ecstasy*. MDMA is used mainly by young people between the ages of 14 and 34 years in North America, Europe, and Australia. It is generally taken orally. Its effects, which include euphoria and hallucinogen-like feelings that last 4 to 6 hours, are partly attributable to an increase in serotonin release in the CNS. As the drug wears off, this increased release coupled with its ability to interfere with serotonin synthesis causes a subsequent a post-use drop in serotonin that is only slowly replenished. MDMA use also reduces the number of serotonergic axon terminals in the striatum and the cortex, and it may increase the peripheral effects of dopamine and adrenergic agents. MDMA tablets may be spiked with other drugs, including methamphetamine and cocaine, which greatly enhance the effects on the CNS.

Marijuana

It is estimated that between 2.6% to 5% of adults worldwide (119 million to 224 million people) used marijuana (or “pot”) in 2010, making it far and away the most widely used illicit drug globally. Several states in the United States have legalized the “recreational” use of marijuana in 2013, and more appear poised to follow; thus, its status as an illicit drug is undergoing reevaluation.

Marijuana is made from the leaves of the *Cannabis sativa* plant, which contain the psychoactive substance Δ^9 -tetrahydrocannabinol (THC). About 5% to 10% of THC is absorbed when it is smoked in a hand-rolled cigarette (“joint”). Despite numerous studies, the central question of whether the drug has persistent adverse physical and functional effects remains unresolved. Some of the untoward anecdotal effects may be allergic or idiosyncratic reactions or possibly related to contaminants in the preparations rather than to the pharmacologic effects of marijuana. Among the beneficial effects of marijuana is its potential use to treat nausea secondary to cancer chemotherapy and as an agent capable of decreasing pain in some chronic conditions that are otherwise difficult to treat. The functional and organic CNS consequences of marijuana smoking have received most scrutiny. Its use distorts sensory perception and impairs motor coordination, but these acute effects generally clear in 4 to 5 hours. With continued use these changes may progress to cognitive and psychomotor impairments, such as inability to judge time, speed, and distance, a potential cause of automobile accidents. Marijuana increases the heart rate and sometimes blood pressure, and it may cause angina in a person with coronary artery disease.

The respiratory system is also affected by chronic marijuana smoking; laryngitis, pharyngitis, bronchitis, cough and hoarseness, and asthma-like symptoms have all been described, along with mild but significant airway

obstruction. Marijuana cigarettes contain a large number of carcinogens that are also present in tobacco. Smoking a marijuana cigarette, compared with a tobacco cigarette, is associated with a threefold increase in the amount of tar inhaled and retained in the lungs, presumably because of the larger puff volume, deeper inhalation, and longer breath holding.

In addition to the use of THC as a recreational drug, a large number of studies have characterized the *endogenous cannabinoid system*, which consists of the *cannabinoid receptors CB1 and CB2*, and the endogenous lipid ligands known as *endocannabinoids*. This system participates in the regulation of the hypothalamic-pituitary-adrenal axis, and modulates the control of appetite, food intake, and energy balance, as well as fertility and sexual behavior.

Other Drugs

The variety of drugs that have been tried by those seeking “new experiences” (e.g., “highs,” “lows,” “out-of-body experiences”) defies belief. These drugs include various stimulants, depressants, analgesics, and hallucinogens (Table 9-6). Among these are PCP (phencyclidine, an anesthetic agent), analgesics such as Vicodin, and ketamine, an anesthetic agent used in animal surgery. Most drugs of abuse are used by males more often than by females. The exception is prescription tranquilizers, which are abused by women about twice as often as by men and which often lead to chronic dependencies.

Chronic inhalation of vapors of spray paints, paint thinners, and some glues that contain toluene (“glue sniffing” or “huffing”) can cause cognitive abnormalities and magnetic resonance imaging–detectable brain damage that ranges from mild to severe dementia. Because inhalants are used haphazardly and in various combinations, not much is known about the long-time deleterious effects of most of these agents. However, their acute effects are clear: they cause bizarre and often aggressive behavior that leads to violence or depressed mood and suicidal ideation.

New drugs of abuse emerge yearly. An example is so-called *bath salts*, intentionally misnamed substances that appeared in 2010 and have nothing to do with bathing. Bath salts usually contain 4-methyl-meth-cathinone and methylenedioxypropylvalerone, chemicals that have amphetamine-like effects when snorted or eaten. Bath salts have been associated with agitation, psychosis, myocardial infarction, and suicide. They will no doubt be declared illegal, only to be replaced by the next generation of illicit “designer” drugs.

KEY CONCEPTS

Drug Injury

- Drug injury may be caused by therapeutic drugs (adverse drug reactions) or nontherapeutic agents (drug abuse).
- Antineoplastic agents, anticoagulants, MHT preparations and oral contraceptives, acetaminophen, and aspirin are among the therapeutic drugs involved most frequently.
- MHT increases the risk of endometrial and breast cancers and thromboembolism and does not appear to protect against ischemic heart disease. Oral contraceptives have a protective effect against endometrial and ovarian cancers

but increase the risk of thromboembolism and hepatic adenomas.

- Overdose of acetaminophen may cause centrilobular liver necrosis, leading to liver failure. Early treatment with agents that restore GSH levels may limit toxicity. Aspirin blocks the production of thromboxane A₂, which may produce gastric ulceration and bleeding.
- The common drugs of abuse include sedative-hypnotics (barbiturates, ethanol), psychomotor stimulants (cocaine, methamphetamine, ecstasy), opioid narcotics (heroin, oxycodone), hallucinogens, and cannabinoids (marijuana)

Injury by Physical Agents

Injury induced by physical agents is divided into the following categories: mechanical trauma, thermal injury, electrical injury, and injury produced by ionizing radiation. Each type is considered separately.

Mechanical Trauma

Mechanical forces may inflict a variety of forms of damage. The type of injury depends on the shape of the colliding object, the amount of energy discharged at impact, and the tissues or organs that bear the impact. Bone and head injuries result in unique damage and are discussed elsewhere (Chapters 26 and 28). All soft tissues react similarly to mechanical forces, and the patterns of injury can be divided into abrasions, contusions, lacerations, incised wounds, and puncture wounds. This is just a small sampling of the various forms of trauma encountered by forensic pathologists, who deal with wounds produced by shooting, stabbing, blunt force, traffic accidents, and other causes. In addition to morphologic analyses, forensic pathology now includes molecular methods for identity testing and sophisticated methods to detect the presence of foreign substances. Details about the practice of forensic pathology can be found in specialized textbooks.

Thermal Injury

Both excessive heat and excessive cold are important causes of injury. Burns are the most common cause of thermal injury and are discussed first; a brief discussion of hyperthermia and hypothermia follows.

Thermal Burns

In the United States, approximately 450,000 persons per year receive medical treatment for burn injuries. Eighty percent of burns are caused by fire or by scalding, the latter being a major cause of injury in children. It is estimated that approximately 3500 persons die each year as a consequence of injuries caused by fire and smoke inhalation, mostly originating in homes. Since the 1970s, marked decreases have been seen in both mortality rates and the length of hospitalizations of burn patients. In recent years there were approximately 45,000 hospitalizations per year for burns; among those treated in specialized burn centers (about 55% of those hospitalized), the survival rate was more than 95%, a remarkable testimony to improvements in the care of patients with severe burns. These

improvements have been achieved by a better understanding of the systemic effects of massive burns, the prevention of wound infection, and the use of treatments that promote the healing of skin surfaces.

The clinical significance of a burn injury depends on the following factors:

- Depth of the burns
- Percentage of body surface involved
- Internal injuries caused by the inhalation of hot and toxic fumes
- Promptness and efficacy of therapy, especially fluid and electrolyte management and prevention or control of wound infections

Burns used to be classified as first degree to fourth degree, according to the depth of the injury (first-degree burns being the most superficial), but are now classified as superficial, partial thickness, and full-thickness burns.

- *Superficial burns* (formerly known as *first-degree burns*) are confined to the epidermis.
- *Partial thickness burns* (formerly known as *second-degree burns*) involve injury to the dermis.
- *Full-thickness burns* (formerly known as *third-degree burns*) extend to the subcutaneous tissue. Full-thickness burns may also involve damage to muscle tissue underneath the subcutaneous tissue (these were known formerly as fourth-degree burns).

Shock, sepsis, and respiratory insufficiency are the greatest threats to life in burn patients. Particularly in burns of more than 20% of the body surface, there is a rapid (within hours) shift of body fluids into the interstitial compartments, both at the burn site and systemically, due to the *systemic inflammatory response syndrome*, leading to shock (Chapter 4). Because of widespread vascular leakiness, generalized edema, including pulmonary edema, can be severe. An important pathophysiologic effect of burns is the development of a *hypermetabolic state* associated with excess heat loss and an increased need for nutritional support. It is estimated that when more than 40% of the body surface is burned, the resting metabolic rate may double.

The burn site is ideal for the growth of microorganisms; the serum and debris provide nutrients, and the burn injury compromises blood flow, blocking effective inflammatory responses. As a result, virtually all burns become colonized with bacteria. Infections are defined by the presence of greater than 10⁵ bacteria per gram of tissue, and invasive local infection is defined by the presence of greater than 10⁵ bacteria per gram in unburned tissue adjacent to the burn. The most common offender is the opportunist *Pseudomonas aeruginosa*, but antibiotic-resistant strains of other common hospital-acquired bacteria, such as methicillin-resistant *S. aureus*, and fungi, particularly *Candida* species, may also be involved. Furthermore, cellular and humoral defenses against infections are compromised, and both lymphocyte and phagocyte functions are impaired. Direct bacteremic spread and release of toxic substances such as endotoxin from the local site have dire consequences. Pneumonia or septic shock with renal failure and/or the acute respiratory distress syndrome (Chapter 15) are the most common serious sequelae.

Organ system failure resulting from burn sepsis has greatly diminished during the past 30 years, because of the introduction of techniques for early excision and grafting of the burn wound. Removal of the burn wound decreases infection and reduces the need for reconstructive surgery. Grafting is done with split-thickness skin grafts; dermal substitutes, which serve as a bed for cell repopulation, may be used in large full-thickness burns.

Injury to the airways and lungs may develop within 24 to 48 hours after the burn and may result from the direct effect of heat on the mouth, nose, and upper airways or from the inhalation of heated air and noxious gases in the smoke. Water-soluble gases, such as chlorine, sulfur oxides, and ammonia, may react with water to form acids or alkalis, particularly in the upper airways, producing inflammation and swelling, which may lead to partial or complete airway obstruction. Lipid-soluble gases, such as nitrous oxide and products of burning plastics, are more likely to reach deeper airways, producing pneumonitis.

In burn survivors the development of hypertrophic scars, both at the site of the original burn and at donor graft sites, and itching may become long-term, difficult-to-treat problems. Hypertrophic scarring is a common complication of burn injury marked by excessive deposition of collagen in the healing wound bed; its etiology is not well understood.

MORPHOLOGY

Grossly, full-thickness burns are white or charred, dry, and painless (because of destruction of nerve endings), whereas, depending on the depth, partial-thickness burns are pink or mottled with blisters and painful. Histologically, devitalized tissue reveals coagulative necrosis, adjacent to vital tissue that quickly accumulates inflammatory cells and marked exudation.

Hyperthermia

Prolonged exposure to elevated ambient temperatures can result in heat cramps, heat exhaustion, and heat stroke.

- *Heat cramps* result from loss of electrolytes via sweating. Cramping of voluntary muscles, usually in association with vigorous exercise, is the hallmark. Heat-dissipating mechanisms are able to maintain normal core body temperature.
- *Heat exhaustion* is probably the most common hyperthermic syndrome. Its onset is sudden, with prostration and collapse, and it results from a failure of the cardiovascular system to compensate for hypovolemia caused by dehydration. After a period of collapse, which is usually brief, equilibrium is spontaneously re-established if the victim is able to rehydrate.
- *Heat stroke* is associated with high ambient temperatures, high humidity, and exertion. Older adults, individuals undergoing intense physical stress (including young athletes and military recruits), and persons with cardiovascular disease are at particularly high risk for heat stroke. Thermoregulatory mechanisms fail, sweating ceases, and the core body temperature rises to more than 40°C, leading to multiorgan dysfunction that can be rapidly fatal. The hyperthermia is accompanied

by marked generalized vasodilation, with peripheral pooling of blood and a decreased effective circulating blood volume. Hyperkalemia, tachycardia, arrhythmias, and other systemic effects are common. Particularly important, however, are sustained contractions of skeletal muscle that can exacerbate the hyperthermia and lead to muscle necrosis (rhabdomyolysis). These phenomena appear to stem from nitrosylation of ryanodine receptor 1 (RYR1), which is located in the sarcoplasmic reticulum of skeletal muscle. RYR1 regulates the release of calcium from the sarcoplasm. Heat stroke deranges RYR1 function and allows calcium to leak into the cytoplasm, where it stimulates muscle contraction and heat production. Inherited mutations in *RYR1* occur in the condition called *malignant hyperthermia*, characterized by a “heat-stroke-like” rise in core body temperature and muscle contractures following exposure to common anesthetics. *RYR1* mutations may also increase the susceptibility to heat stroke in humans and produce heat intolerance in mice. Of interest, mice with *RYR1* mutations are protected from heat stroke by drugs that inhibit calcium leakage from the sarcoplasm, suggesting that it may be possible to develop specific therapies for those who develop or are at high risk for heat stroke and malignant hyperthermia.

Hypothermia

Prolonged exposure to low ambient temperature leads to hypothermia, a condition seen all too frequently in homeless persons. High humidity, wet clothing, and dilation of superficial blood vessels resulting from the ingestion of alcohol hasten the lowering of body temperature. At a body temperature of about 90°F, loss of consciousness occurs, followed by bradycardia and atrial fibrillation at lower core temperatures.

Hypothermia causes injury by two mechanisms:

- *Direct effects* are probably mediated by physical disruptions within cells by high salt concentrations caused by the crystallization of intra- and extracellular water.
- *Indirect effects* result from circulatory changes, which vary depending on the rate and duration of the temperature drop. Slow chilling may induce vasoconstriction and increase vascular permeability, leading to edema and hypoxia. Such changes are typical of “trench foot.” This condition developed in soldiers who spent long periods of time in waterlogged trenches during the First World War (1914-1918), frequently causing gangrene that necessitated amputation. With sudden, persistent chilling, the vasoconstriction and increased viscosity of the blood in the local area may cause ischemic injury and degenerative changes in peripheral nerves. In this situation, vascular injury and edema become evident only after the temperature begins to return to normal. However, during the period of ischemia, hypoxic changes and infarction of the affected tissues (e.g., gangrene of toes or feet) may develop.

Electrical Injury

Electrical injuries, which are often fatal, can arise from contact with low-voltage currents (i.e., in the home and

workplace) or high-voltage currents carried by high-power lines or produced by lightning. Injuries are of two types: (1) burns and (2) ventricular fibrillation or cardiac and respiratory center failure, resulting from disruption of normal electrical impulses. The type of injury and the severity and extent of burns depend on the strength (amperage), duration, and path of the electric current within the body.

Voltage in the household and workplace (120 or 220 V) is high enough that with low resistance at the site of contact (as when the skin is wet), sufficient current can pass through the body to cause serious injury, including *ventricular fibrillation*. If the current flow is sustained, it may generate enough heat to produce burns at the site of entry and exit as well as in internal organs. An important characteristic of alternating current, the type supplied to most homes, is that it induces tetanic muscle spasm, so that when a live wire or switch is grasped, irreversible clutching is likely to occur, prolonging the period of current flow. This results in a greater likelihood of developing extensive electrical burns and, in some cases, spasm of the chest wall muscles, producing death from asphyxia. Currents generated from high-voltage sources cause similar damage; however, because of the large current flows generated, these are more likely to produce paralysis of medullary centers and extensive burns. Lightning is a classic cause of high-voltage electrical injury. Magnetic fields and microwave radiation, when sufficiently intense, may also produce burns, usually of the skin and subjacent connective tissue, and may also interfere with cardiac pacemakers.

Injury Produced by Ionizing Radiation

Radiation is energy that travels in the form of waves or high-speed particles. Radiation has a wide range of energies that span the electromagnetic spectrum; it can be divided into nonionizing and ionizing radiation. The energy of nonionizing radiation such as UV and infrared light, microwave, and sound waves, can move atoms in a molecule or cause them to vibrate, but is not sufficient to displace bound electrons from atoms. By contrast, *ionizing radiation* has sufficient energy to remove tightly bound electrons. Collision of electrons with other molecules releases electrons in a reaction cascade, referred to as ionization. The main sources of ionizing radiation are *x-rays* and *gamma rays* (electromagnetic waves of very high frequencies), *high-energy neutrons*, *alpha particles* (composed of two protons and two neutrons), and *beta particles*, which are essentially electrons. At equivalent amounts of energy, alpha particles induce heavy damage in a restricted area, whereas x-rays and gamma rays dissipate energy over a longer, deeper course, and produce considerably less damage per unit of tissue. About 50% of the total dose of ionizing radiation received by the U.S. population is human-made, mostly originating from medical devices and radioisotopes. In fact, the exposure of patients to ionizing radiation during radiologic imaging tests roughly doubled between the early 1980s and 2006, mainly because of much more widespread use of CT scans.

Ionizing radiation is a double-edged sword. It is indispensable in medical practice, being used in the treatment of cancer, in diagnostic imaging, and in therapeutic or

diagnostic radioisotopes, but it also produces adverse short- and long-term effects such as *fibrosis*, *mutagenesis*, *carcinogenesis*, and *teratogenesis*.

Radiation Units. Several somewhat confusing terms are used to describe radiation dose, which can be quantified according to the amount of radiation emitted by a source, the amount of radiation that is absorbed by a person, and the biologic effect of the radiation. Commonly used terms are as follows:

- *Curie (Ci)* represents the disintegrations per second of a radionuclide (radioisotope). One Ci is equal to 3.7×10^{10} disintegrations per second. This is an expression of the amount of radiation emitted by a source.
- *Gray (Gy)* is a unit that expresses the energy absorbed by the target tissue per unit mass. One Gray corresponds to absorption of 10^4 erg/gm of tissue. A Centigray (cGy), which is the absorption of 100 erg/gm of tissue, is equivalent to 100 Rad (radiation absorbed dose), abbreviated as R. The cGy terminology has now replaced the Rad in medical practice.
- *Sievert (Sv)* is a unit of equivalent dose that depends on the biologic rather than the physical effects of radiation (it replaced a unit called “Rem”). For the same absorbed dose, various types of radiation produce different amounts of damage. The equivalent dose controls for this variation and thereby provides a uniform measure of biologic dose. The equivalent dose (expressed in *Sieverts*) corresponds to the absorbed dose (expressed in Grays) multiplied by the relative biologic effectiveness of the radiation. The relative biologic effectiveness depends on the type of radiation, the type and volume of the exposed tissue, the duration of the exposure, and some other biologic factors (discussed below). The effective dose of x-rays in radiographs and computed tomography is commonly expressed in milliSieverts (mSv). For x-radiation, 1 mSv = 1 mGy.

Main Determinants of the Biologic Effects of Ionizing Radiation. In addition to the physical properties of the radiation, its biologic effects depend heavily on the following factors.

- *Rate of delivery* significantly modifies the biologic effect. Although the effect of radiant energy is cumulative, divided doses may allow cells to repair some of the damage between exposures. Thus, fractionated doses of radiant energy have a cumulative effect only to the extent that repair during the “recovery” intervals is incomplete. Radiation therapy of tumors exploits the general capability of normal cells to repair themselves and recover more rapidly than tumor cells, and thus not sustain as much cumulative radiation damage.
- *Field size* has a great influence on the consequences of irradiation. The body can sustain relatively high doses of radiation when delivered to small, carefully shielded fields, whereas smaller doses delivered to larger fields may be lethal.
- *Cell proliferation.* Because ionizing radiation damages DNA, rapidly dividing cells are more vulnerable to injury than are quiescent cells (Fig. 9-16). Except at extremely high doses that impair DNA transcription,

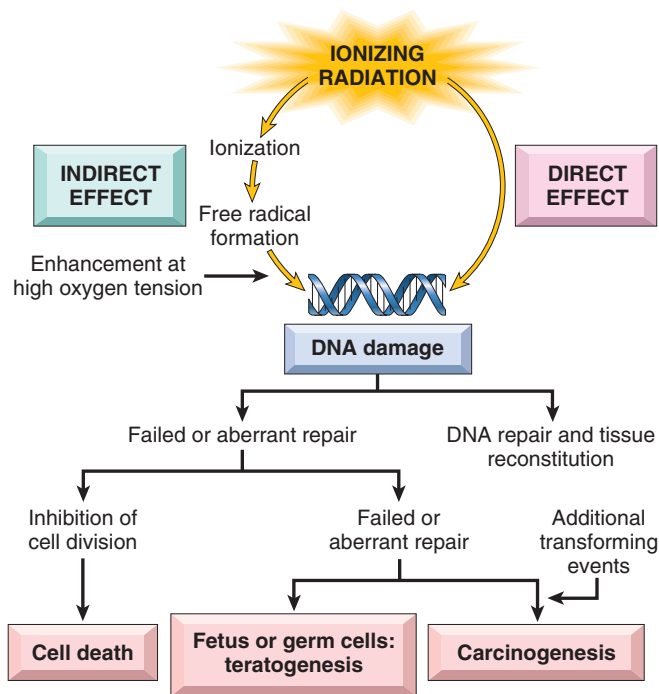

Figure 9-16 Effects of ionizing radiation on DNA and its consequences. The effects on DNA can be direct, or most importantly, indirect, through free radical formation.

irradiation does not kill nondividing cells, such as neurons and muscle cells. However, as discussed in [Chapter 7](#), in dividing cells DNA damage is detected by sensors that produce signals leading to the upregulation of p53, the “guardian of the genome”. p53 in turn upregulates the expression of genes that initially lead to cell cycle arrest and, if the DNA damage is too great to be repaired, genes that cause cell death through apoptosis. Understandably, therefore, tissues with a high rate of cell division, such as *gonads, bone marrow, lymphoid tissue,* and the *mucosa of the gastrointestinal tract*, are extremely vulnerable to radiation, and the injury is manifested early after exposure.

- **Oxygen effects and hypoxia.** The production of reactive oxygen species from reactions with free radicals generated by radiolysis of water is the major mechanism by which DNA is damaged by ionizing radiation. Poorly vascularized tissues with low oxygenation, such as the center of rapidly growing tumors, are generally less sensitive to radiation therapy than nonhypoxic tissues.
- **Vascular damage.** Damage to endothelial cells, which are moderately sensitive to radiation, may cause narrowing or occlusion of blood vessels leading to impaired healing, fibrosis, and chronic ischemic atrophy. These changes may appear months or years after exposure ([Fig. 9-17](#)). Late effects in tissues with a low rate of cell proliferation, such as the brain, kidney, liver, muscle, and subcutaneous tissue, may include cell death, atrophy, and fibrosis. These effects are associated with vascular damage and the release of proinflammatory mediators in irradiated areas.

[Figure 9-18](#) shows the overall consequences of radiation exposure. These consequences vary according to the

dose of radiation and the type of exposure. [Table 9-7](#) lists the estimated threshold doses for acute effects of radiation aimed at specific organs; [Table 9-8](#) lists the syndromes caused by exposure to various doses of total-body radiation.

MORPHOLOGY

Cells surviving radiant energy damage show a wide range of structural **changes in chromosomes** that are related to double-stranded DNA breaks, including deletions, translocations, and fragmentation. The mitotic spindle often becomes disorderly, and polyploidy and aneuploidy may be encountered. **Nuclear swelling** and condensation and clumping of chromatin may appear; disruption of the nuclear membrane may also be noted. Apoptosis may occur. Several **abnormal nuclear morphologies** may be seen. Giant cells with pleomorphic nuclei or more than one nucleus may appear and persist for years after exposure. At extremely high doses of radiant energy, markers of cell death, such as nuclear pyknosis and lysis, appear quickly.

In addition to affecting DNA and nuclei, radiant energy may induce a variety of **cytoplasmic changes**, including cytoplasmic swelling, mitochondrial distortion, and degeneration of the endoplasmic reticulum. Plasma membrane breaks and focal defects may be seen. The histologic constellation of cellular pleomorphism, giant-cell formation, conformational changes in nuclei, and abnormal mitotic figures creates a more than passing similarity between radiation-injured cells and cancer cells, a problem that plagues the pathologist when evaluating irradiated tissues for the possible persistence of tumor cells.

Vascular changes and interstitial fibrosis are also prominent in irradiated tissues ([Fig. 9-19](#)). During the immediate postirradiation period, vessels may show only dilation. With time, or with higher doses, a variety of degenerative changes appear, including endothelial cell swelling and vacuolation, or even necrosis and dissolution of the walls of small vessels such as capillaries and venules. Affected vessels may rupture or thrombose. Still later, endothelial cell proliferation and collagenous hyalinization and thickening of the intima are seen in irradiated vessels, resulting in marked narrowing or even obliteration of the vascular lumens. At this time, an increase in interstitial collagen in the irradiated field usually becomes evident, leading to scarring and contractions.

Figure 9-18 Overview of the major morphologic consequences of radiation injury. Early changes occur in hours to weeks; late changes occur in months to years. ARDS, Acute respiratory distress syndrome.

Total-Body Irradiation. Exposure of large areas of the body to even very small doses of radiation may have devastating effects. Doses below 1 Sv produce minimal symptoms, if any. However, higher levels of exposure cause health effects known as *acute radiation syndromes*, which at progressively higher doses involve the hematopoietic, gastrointestinal, and central nervous systems. The syndromes associated with total-body exposure to ionizing radiation are presented in [Table 9-8](#).

Acute Effects on Hematopoietic and Lymphoid Systems. The hematopoietic and lymphoid systems are extremely

susceptible to radiation injury and deserve special mention. With high dose levels and large exposure fields, *severe lymphopenia* may appear within hours of irradiation, along with shrinkage of the lymph nodes and spleen. Radiation kills lymphocytes directly, both in the circulation and in tissues (nodes, spleen, thymus, gut). With sublethal doses of radiation, regeneration from viable precursors is prompt, leading to restoration of a normal blood lymphocyte count within weeks to months. Hematopoietic precursors in the bone marrow are also quite sensitive to radiant energy, which produces a dose-dependent *marrow aplasia*. The acute effects of marrow irradiation on peripheral blood counts reflects the kinetics of turnover of the formed elements—the granulocytes, platelets, and red cells, which have half-lives of less than a day, 10 days, and 120 days, respectively. After a brief rise in the circulating neutrophil count, *neutropenia* appears within several days. Neutrophil counts reach their nadir, often at counts near zero, during the second week. If the patient survives, recovery of the normal granulocyte count may require 2 to 3 months. *Thrombocytopenia* appears by the end of the first week, with the platelet count nadir occurring somewhat later than that of granulocytes; recovery is similarly delayed. *Anemia* appears after 2 to 3 weeks and may persist for months. Understandably, higher doses of radiation produce more severe cytopenias and more prolonged periods of recovery. Very high doses kill marrow stem cells and induce permanent aplasia (*aplastic anemia*) marked by a failure of blood count recovery, whereas with lower doses the aplasia is transient.

Fibrosis. A common consequence of radiation therapy for cancer is the development of fibrosis in the tissues included in the irradiated field ([Fig. 9-19](#)). Fibrosis may occur weeks or months after irradiation as a consequence of the replacement of dead parenchymal cells by connective tissue, leading to the formation of scars and adhesions. Vascular damage, the death of tissue stem cells, and the release of cytokines and chemokines that promote inflammation and fibroblast activation are the main contributors to the development of radiation-induced fibrosis ([Figs. 9-20](#) and [9-21](#)). Common sites of fibrosis after radiation treatment are the lungs, the salivary glands after radiation therapy for head and neck cancers, and colorectal and pelvic areas after treatment for cancer of the prostate, rectum, or cervix.

DNA Damage and Carcinogenesis. Ionizing radiation can cause multiple types of DNA damage, including single-base damage, single- and double-stranded breaks, and

Table 9-7 Estimated Threshold Doses for Acute Radiation Effects on Specific Organs

Health Effect	Organ	Dose (Sv)
Temporary sterility	Testes	0.15
Depression of hematopoiesis	Bone marrow	0.50
Reversible skin effects (e.g., erythema)	Skin	1-2
Permanent sterility	Ovaries	2.5-6
Temporary hair loss	Skin	3-5
Permanent sterility	Testis	3.5
Cataract	Lens of eye	5

Lethality	None	None	Variable (0% to 80%)	100%	100%

DNA-protein cross-links. In surviving cells, simple defects may be repaired by various enzyme systems present in most mammalian cells. The most serious damage to DNA consists of *double-stranded breaks (DSBs)*. Two types of mechanisms can repair DSBs in mammalian cells: *homologous recombination* and *nonhomologous end joining (NHEJ)*, with NHEJ being the most common repair pathway. DNA repair through NHEJ often produces mutations, including short deletions or duplications, or gross chromosomal aberrations such as translocations and inversions. If the replication of cells containing DSBs is not stopped by cell cycle checkpoint controls ([Chapter 1](#)), cells with chromosomal damage persist and may initiate carcinogenesis many years later. More recently it has been recognized that these abnormal cells also produce a “bystander effect,” that is, they alter the behavior of nonirradiated surrounding cells through the production of growth factors and cytokines. Bystander effects are referred to as non-target effects of radiation.

Cancer Risks from Exposures to Radiation. Any cell capable of division that has sustained a mutation has the potential to become cancerous. Thus, an increased incidence of neoplasms may occur in any organ after exposure to ionizing radiation. The level of radiation required to increase the risk of cancer development is difficult to determine, but there is little doubt that acute or prolonged

exposures that result in doses of greater than 100 mSv cause serious consequences, including cancer. Proof of this risk is found in the increased incidence of leukemias and solid tumors in several organs (e.g., thyroid, breast, and lungs) in survivors of the atomic bombings of Hiroshima and Nagasaki; the high number of thyroid cancers in survivors of the Chernobyl accident; the high incidence of thyroid tumors, and the elevated frequency of leukemias and birth defects, in inhabitants of the Marshall Islands exposed to nuclear fallout; and the development of “second cancers,” such as acute myeloid leukemia, myelodysplastic syndrome, and solid tumors, in individuals who received radiation therapy for cancers such as Hodgkin lymphoma. The long-term cancer risks caused by radiation exposures in the range of 5 to 100 mSv are much more difficult to establish, because accurate measurements of risks require large population groups ranging from 50,000 to 5 million people. Nevertheless, for x-rays and gamma rays there is good evidence for a statistically significant increase in the risk of cancer at acute doses of greater than 50 mSv and “reasonable” evidence for acute doses of greater than 5 mSv; as a point of reference, a single posteroanterior chest radiograph, a lateral chest film chest radiograph, and a computed tomography of the chest deliver effective doses to the lungs of 0.01, 0.15, and 10 mSv, respectively. It is believed that the risk of secondary cancers following irradiation is greatest in children. This is based in part on

Figure 9-19 Fibrosis and vascular changes in salivary glands produced by radiation therapy of the neck region. **A**, Normal salivary gland; **B**, fibrosis caused by radiation; **C**, fibrosis and vascular changes consisting of fibrointimal thickening and arteriolar sclerosis. a recent large-scale epidemiologic study showing that children who receive at least two CT scans have very small but measurable increased risks for leukemia and malignant brain tumors, and on older studies showing that radiation therapy to the chest is particularly likely to produce breast cancers when administered to adolescent females.

Increased risk of cancer development may also be associated with occupational exposures. *Radon* gas is a ubiquitous product of the spontaneous decay of uranium. Its carcinogenic effects are largely attributable to two decay products, *polonium 214* and *polonium 218* (or “radon daughters”), which emit alpha particles. Polonium 214 and 218 produced from inhaled radon tend to deposit in the lung, and chronic exposure in uranium miners may give rise to lung carcinomas. Risks are also present in homes in which the levels of radon are very high, comparable to those found in mines. However, there is little evidence to suggest that radon contributes to the risk of lung cancer in the average household. For historical reasons, we also mention here the development of osteogenic sarcomas after radium exposure in radium dial painters, chemists, radiologists, and patients exposed to radium as a treatment for various ailments during the first part of the twentieth century.

KEY CONCEPTS

Radiation Injury

- Ionizing radiation may injure cells directly or indirectly by generating free radicals from water or molecular oxygen
- Ionizing radiation damages DNA; therefore, rapidly dividing cells such as germ cells, and those in the bone marrow and gastrointestinal tract are very sensitive to radiation injury
- DNA damage that is not adequately repaired may result in mutations that predispose affected cells to neoplastic transformation
- Ionizing radiation may cause vascular damage and sclerosis, resulting in ischemic necrosis of parenchymal cells and their replacement by fibrous tissue

Nutritional Diseases

Malnutrition, also referred to as *protein energy malnutrition* or *PEM*, is a consequence of inadequate intake of proteins and calories, or deficiencies in the digestion or absorption of proteins, resulting in the loss of fat and muscle tissue, weight loss, lethargy, and generalized weakness. Millions of people in developing nations are malnourished and starving, or living on the cruel edge of starvation. In the industrial world and, more recently, also in developing countries, *obesity* has become a major public health problem due to its association with the development of diseases such as diabetes, atherosclerosis, and cancer.

The sections that follow barely skim the surface of nutritional disorders. Particular attention is devoted to PEM, anorexia nervosa and bulimia, deficiencies of vitamins and trace minerals, obesity, and a brief overview of the relationships of diet to atherosclerosis and cancer. Other nutrients and nutritional issues are discussed in the context of specific diseases.

Dietary Insufficiency

An appropriate diet should provide (1) sufficient energy, in the form of carbohydrates, fats, and proteins, for the body’s daily metabolic needs; (2) amino acids and fatty acids to be used as building blocks for synthesis of proteins and lipids; and (3) vitamins and minerals, which function as coenzymes or hormones in vital metabolic pathways or, as in the case of calcium and phosphate, as important structural components. In *primary malnutrition*, one or all of these components are missing from the diet. By contrast, in *secondary malnutrition*, malnutrition results from malabsorption, impaired utilization or storage, excess loss, or increased need for nutrients.

There are several conditions that may lead to primary or secondary malnutrition.

- *Poverty*. Homeless persons, aged individuals, and children of the poor often suffer from PEM as well as trace nutrient deficiencies. In poor countries, poverty, crop failures, livestock deaths, and drought, often in times of war and political upheaval, create the setting for the malnourishment of children and adults.

- *Infections.* PEM increases susceptibility to many common infectious diseases. Conversely, infections have a negative effect on nutrition, thus establishing a vicious cycle.
- *Acute and chronic illnesses.* The basal metabolic rate becomes accelerated in many illnesses resulting in increased daily requirements for all nutrients. Failure to recognize these nutritional needs may delay recovery. PEM is often present in patients with wasting diseases, such as *advanced cancers* and *AIDS* (discussed later).
- *Chronic alcoholism.* Alcoholic persons may sometimes suffer PEM but more frequently have deficiencies of vitamins, especially thiamine, pyridoxine, folate, and vitamin A, as a result of poor diet, defective gastrointestinal absorption, abnormal nutrient utilization and storage, increased metabolic needs, and an increased rate of loss. A failure to recognize the likelihood of thiamine deficiency in persons with chronic alcoholism may result in irreversible brain damage (e.g., *Wernicke encephalopathy* and *Korsakoff psychosis*, discussed in [Chapter 28](#)).
- *Ignorance and failure of diet supplementation.* Even the affluent may fail to recognize that infants, adolescents, and pregnant women have increased nutritional needs. Ignorance about the nutritional content of various foods is also a contributing factor. Some examples are: iron deficiency in infants fed exclusively artificial milk diets; polished rice used as the mainstay of a diet may lack adequate amounts of thiamine; lack of iodine from food and water in regions removed from the oceans, unless supplementation is provided.
- *Self-imposed dietary restriction.* *Anorexia nervosa*, *bulimia*, and less overt eating disorders affect many individuals who are concerned about body image and are obsessed with body weight (anorexia and bulimia are discussed later).
- *Other causes.* Additional causes of malnutrition include gastrointestinal diseases and malabsorption syndromes, genetic diseases, specific drug therapies (which block uptake or utilization of particular nutrients), and inadequate total parenteral nutrition.

Protein-Energy Malnutrition

Severe PEM is a serious, often lethal disease that preferentially affects children. It is common in low-income countries, where it affects up to 30% of children and is a major factor in high death rates among children younger than 5 years of age. It is estimated that malnutrition is responsible for approximately 50% of deaths in infancy and childhood each year in developing countries. In developed countries, PEM often occurs in older and debilitated patients in nursing homes and hospitals, but also occurs with disturbing frequency in children living in poverty, even in the United States.

Malnutrition is determined according to the *body mass index* (BMI, weight in kilograms divided by height in meters squared). A BMI less than 16 kg/m² is considered malnutrition (normal range 18.5 to 25 kg/m²). In more practical ways, a child whose weight falls to less than 80% of normal (provided in standard tables) is considered malnourished. However, loss of weight may be masked by generalized edema, as discussed later. Other helpful

parameters are the evaluation of fat stores (thickness of skin folds), muscle mass (reduced circumference of mid-arm), and serum proteins (albumin and transferrin levels provide a measure of the adequacy of the visceral protein compartment).

Marasmus and Kwashiorkor. In malnourished children, PEM presents as a range of clinical syndromes, all characterized by a dietary intake of protein and calories inadequate to meet the body's needs. The two ends of the spectrum of PEM syndromes are known as *marasmus* and *kwashiorkor*. From a functional standpoint, there are two differentially regulated protein compartments in the body: the somatic compartment, represented by proteins in skeletal muscles, and the visceral compartment, represented by protein stores in the visceral organs, primarily the liver. As we shall see, the somatic compartment is affected more severely in marasmus, and the visceral compartment is depleted more severely in kwashiorkor.

A child is considered to have *marasmus* when weight falls to 60% of normal for sex, height, and age. A marasmic child suffers growth retardation and loss of muscle, the latter resulting from catabolism and depletion of the somatic protein compartment. This seems to be an adaptive response that provides the body with amino acids as a source of energy. The visceral protein compartment, which is presumably more precious and critical for survival, is only marginally depleted, and hence serum albumin levels are either normal or only slightly reduced. In addition to muscle proteins, subcutaneous fat is also mobilized and used as fuel. The production of leptin (discussed later) is low, which may stimulate the hypothalamic-pituitary-adrenal axis to produce high levels of cortisol that contribute to lipolysis. With such losses of muscle and subcutaneous fat, the *extremities are emaciated*; by comparison, the head appears too large for the body ([Fig. 9-22A](#)). Anemia and manifestations of multiple vitamin deficiencies are present, and there is evidence of *immune deficiency*, particularly T-cell-mediated immunity. Hence, concurrent infections are usually present, which impose additional nutritional demands. Unfortunately, images of children dead or near death with marasmus, have become commonplace in television and newspaper reports of famine and disasters in various areas of the world.

Kwashiorkor occurs when protein deprivation is relatively more severe than the deficit in total calories ([Fig. 9-22B](#)). This is the most common form of PEM seen in African children who have been weaned too early and subsequently fed, almost exclusively, a carbohydrate diet (*kwashiorkor*, from the Ga language in Ghana, describes a disease in a young child that occurs following the arrival or another baby). The prevalence of kwashiorkor is also high in impoverished countries of Southeast Asia. Less severe forms may occur worldwide in persons with chronic diarrheal states in which protein is not absorbed or in those with chronic protein loss due to conditions such as protein-losing enteropathies, the nephrotic syndrome, or after extensive burns. Cases of kwashiorkor resulting from fad diets or replacement of milk by rice-based beverages have been reported in the United States.

In kwashiorkor, marked protein deprivation is associated with severe depletion of the visceral protein compartment, and the resultant hypoalbuminemia gives rise to

Figure 9-22 Childhood malnutrition. **A**, Marasmus. Note the loss of muscle mass and subcutaneous fat; the head appears to be too large for the emaciated body. **B**, Kwashiorkor. The infant shows generalized edema, seen as ascites and puffiness of the face, hands, and legs. (**A**, From Clinic Barak, Reisebericht Kenya.)

generalized or dependent edema (Fig. 9-22B). The loss of weight in these patients is masked by the increased fluid retention. In further contrast to marasmus, there is relative sparing of subcutaneous fat and muscle mass. Children with kwashiorkor have characteristic *skin lesions*, with alternating zones of hyperpigmentation, areas of desquamation, and hypopigmentation, giving a “flaky paint” appearance. *Hair changes* include overall loss of color or alternating bands of pale and darker hair. Other features that differentiate kwashiorkor from marasmus include an enlarged, *fatty liver* (resulting from reduced synthesis of the carrier protein component of lipoproteins), and the development of apathy, listlessness, and loss of appetite. Vitamin deficiencies are likely to be present, as are *defects in immunity* and *secondary infections*. As already stated, marasmus and kwashiorkor are two ends of a spectrum, and considerable overlap exists between these conditions.

PEM in the developed world. In the United States, secondary PEM often develops in chronically ill, older, and bedridden patients. An 18-item questionnaire known as the *Mininutritional Assessment* (MNA) is often used to measure the nutritional status of older persons. It is estimated that more than 50% of older residents in nursing homes in the United States are malnourished. Weight loss of more than 5% associated with PEM increases the risk of mortality in nursing home patients by almost five-fold. The most obvious signs of secondary PEM include: (1) depletion of subcutaneous fat in the arms, chest wall, shoulders, or metacarpal regions; (2) wasting of the quadriceps and deltoid muscles; and (3) ankle or sacral edema. Bedridden or hospitalized malnourished patients have an increased risk of infection, sepsis, impaired wound healing, and death after surgery.

MORPHOLOGY

The main anatomic changes in PEM are (1) growth failure, (2) peripheral edema in kwashiorkor, and (3) loss of body fat and atrophy of muscle, more marked in marasmus.

The **liver** in kwashiorkor, but not in marasmus, is enlarged and fatty; superimposed cirrhosis is rare. In kwashiorkor (rarely in marasmus) the **small bowel** shows a decrease in the mitotic index in the crypts of the glands, associated with mucosal atrophy and loss of villi and microvilli. In such cases concurrent loss of small intestinal enzymes occurs, most often manifested as disaccharidase deficiency. Hence, infants with kwashiorkor initially may not respond well to full-strength, milk-based diets. With treatment, the mucosal changes are reversible.

The **bone marrow** in both kwashiorkor and marasmus may be hypoplastic, mainly as a result of decreased numbers of red cell precursors. The peripheral blood commonly reveals mild to moderate anemia, which is often multifactorial in origin; nutritional deficiencies of iron, folate, and protein, as well as the suppressive effects of infection (anemia of chronic disease) may all contribute. Depending on the predominant factor, the red cells may be microcytic, normocytic, or macrocytic.

The **brain** in infants who are born to malnourished mothers and who suffer PEM during the first 1 or 2 years of life has been reported by some to show cerebral atrophy, a reduced number of neurons, and impaired myelination of white matter.

Many other changes may be present, including (1) thymic and lymphoid atrophy (more marked in kwashiorkor than in marasmus), (2) anatomic alterations induced by intercurrent infections, particularly with all manner of endemic worms and other parasites, and (3) deficiencies of other required nutrients such as iodine and vitamins.

Cachexia. PEM is a common complication in patients with AIDS or advanced cancers, and in these settings it is known as *cachexia*. Cachexia occurs in about 50% of cancer patients, most commonly in individuals with gastrointestinal, pancreatic, and lung cancers, and is responsible for about 30% of cancer deaths. It is a highly debilitating condition characterized by extreme weight loss, fatigue, muscle atrophy, anemia, anorexia, and edema. Mortality is generally the consequence of atrophy of the diaphragm and other respiratory muscles.

The precise causes of cachexia are not known, but it is clear that mediators secreted by tumors and during chronic inflammatory reactions contribute to its development:

- *Proteolysis-inducing factor*, which is a glycosylated polypeptide excreted in the urine of weight-losing patients with pancreatic, breast, colon, and other cancers
- *Lipid-mobilizing factor*, which increases fatty acid oxidation, and proinflammatory cytokines, such as TNF (originally known as *cachectin*), and IL-6.

Proteolysis-inducing factor and proinflammatory cytokines cause skeletal muscle breakdown through the NF- κ B-induced activation of the ubiquitin proteasome pathway, which promotes the degradation of skeletal muscle structural proteins such as myosin heavy chain by upregulating the expression of several muscle-specific ubiquitin ligases. Other data implicate acquired abnormalities of the myofibril dystrophin-glycoprotein complex (Fig. 9-23), the same

Figure 9-23 Mechanisms of cancer cachexia. Proteolysis-inducing factor (PIF) produced by tumors and TNF and other cytokines produced by host immune cells activate NF- κ B and initiate the transcription of the muscle-specific ubiquitin ligases. These ligases in turn ubiquitinate structural components of myofibrils such as myosin heavy chain, leading to their degradation by the proteasome.

membrane complex that is defective in several forms of muscular dystrophy (Chapter 27).

Anorexia Nervosa and Bulimia

Anorexia nervosa is self-induced starvation, resulting in marked weight loss; *bulimia* is a condition in which the patient binges on food and then induces vomiting. Anorexia nervosa has the highest death rate of any psychiatric disorder. Bulimia is more common than anorexia nervosa, and generally has a better prognosis; it is estimated to occur in 1% to 2% of women and 0.1% of men, with an average onset at 20 years of age. These eating disorders occur primarily in previously healthy young women who have developed an obsession with body image and thinness. The neurobiologic underpinnings of these diseases are unknown, but it has been suggested that altered serotonin metabolism may be an important component.

The clinical findings in anorexia nervosa are generally similar to those in severe PEM. In addition, effects on the endocrine system are prominent. *Amenorrhea*, resulting from decreased secretion of gonadotropin-releasing hormone, and subsequent decreased secretion of luteinizing hormone and follicle-stimulating hormone, is so common that its presence is considered a diagnostic feature. Other common findings related to *decreased thyroid hormone release* include cold intolerance, bradycardia, constipation, and changes in the skin and hair. In addition, dehydration and electrolyte abnormalities are frequently present. The skin becomes dry and scaly. *Bone density is decreased*, most likely because of low estrogen levels, mimicking the postmenopausal acceleration of osteoporosis. Anemia, lymphopenia, and hypoalbuminemia may be present. A major complication of anorexia nervosa (and also bulimia) is an increased susceptibility to *cardiac arrhythmia* and *sudden death*, resulting from hypokalemia.

In bulimia, *binge eating* is the norm. Large amounts of food, principally carbohydrates, are ingested, only to be followed by induced vomiting. Although menstrual irregularities are common, amenorrhea occurs in less than 50% of bulimic patients because weight and gonadotropin levels remain near normal. The major medical complications relate to frequent vomiting and the chronic use of laxatives and diuretics. They include (1) *electrolyte imbalances* (hypokalemia), which predispose the patient to cardiac arrhythmias; (2) *pulmonary aspiration* of gastric contents; and (3) *esophageal and gastric rupture*. Nevertheless, there are no specific signs or symptoms; thus, the diagnosis of bulimia relies on a comprehensive psychological assessment of the person.

Vitamin Deficiencies

Thirteen vitamins are necessary for health; vitamins A, D, E, and K are *fat-soluble*, and all others are *water-soluble*. The distinction between fat- and water-soluble vitamins is important. Fat-soluble vitamins are more readily stored in the body, but they may be poorly absorbed in fat malabsorption disorders, caused by disturbances of digestive functions (Chapter 17). Certain vitamins can be synthesized endogenously – vitamin D from precursor steroids, vitamin K and biotin by the intestinal microflora, and niacin from tryptophan, an essential amino acid.

Notwithstanding this endogenous synthesis, a dietary supply of all vitamins is essential for health.

A deficiency of vitamins may be primary (dietary in origin) or secondary to disturbances in intestinal absorption, transport in the blood, tissue storage, or metabolic conversion. In the following sections, vitamins A, D, and C are presented in some detail because of their wide-ranging activities and the morphologic changes of deficient states. This is followed by presentation in tabular form of the main consequences of deficiencies of the remaining vitamins (E, K, and the B complex) and some essential minerals. However, it should be emphasized that deficiency of a single vitamin is uncommon, and that single or multiple vitamin deficiencies may be associated with PEM.

Vitamin A

The major functions of vitamin A are maintenance of normal vision, regulation of cell growth and differentiation, and regulation of lipid metabolism. Vitamin A is the name given to a group of related compounds that include *retinol* (vitamin A alcohol), *retinal* (vitamin A aldehyde), and *retinoic acid* (vitamin A acid), which have similar biologic activities.

Retinol is the chemical name given to vitamin A. It is the transport form and, as retinol ester, also the storage form. The generic term *retinoids* encompasses vitamin A in its various forms and both natural and synthetic chemicals that are structurally related to vitamin A, but may not necessarily have vitamin A-like biologic activity. Animal-derived foods such as liver, fish, eggs, milk, and butter are important dietary sources of preformed vitamin A. Yellow and leafy green vegetables such as carrots, squash, and spinach supply large amounts of carotenoids, provitamins that can be metabolized to active vitamin A in the body. Carotenoids contribute approximately 30% of the vitamin A in human diets; the most important of these is β -carotene, which is efficiently converted to vitamin A. The Recommended Dietary Allowance for vitamin A is expressed in retinol equivalents, to take into account both preformed vitamin A and β -carotene.

Vitamin A is a fat-soluble vitamin, and its absorption requires bile, pancreatic enzymes, and some level of antioxidant activity in the food. Retinol (generally ingested as retinol ester) and β -carotene are absorbed in the intestine, where β -carotene is also converted to retinol (Fig. 9-24). Retinol is then transported in chylomicrons to the liver for esterification and storage. Uptake in liver cells takes place through the apolipoprotein E receptor. More than 90% of the body's vitamin A reserves are stored in the liver, predominantly in the perisinusoidal stellate (Ito) cells. In healthy persons who consume an adequate diet, these reserves are sufficient to meet the body's demands for at least 6 months. Retinol esters stored in the liver can be mobilized; before release, retinol binds to a specific retinol-binding protein (RBP), synthesized in the liver. The uptake of retinol/RBP in peripheral tissues is dependent on cell surface receptors specific for RBP. After uptake, retinol binds to a cellular RBP, and the RBP is released back into the blood. Retinol may also be stored in peripheral tissues as retinol ester or may be oxidized to form retinoic acid, which has important effects on epithelial differentiation and growth.

Figure 9-24 Vitamin A metabolism.

Function. In humans, the main functions of vitamin A are the following:

- **Maintenance of normal vision.** The visual process involves four forms of vitamin A-containing pigments: rhodopsin in the rods, the most light-sensitive pigment and therefore important in reduced light, and three iodopsins in cone cells, each responsive to specific colors in bright light. The synthesis of rhodopsin from retinol involves (1) oxidation to all-*trans*-retinal, (2) isomerization to 11-*cis*-retinal, and (3) covalent association with the 7-transmembrane rod protein opsin to form rhodopsin. A photon of light causes the isomerization of 11-*cis*-retinal to all-*trans*-retinal, which dissociates from rhodopsin. This induces a conformational change in opsin, triggering a series of downstream events that generate a nerve impulse, which is transmitted via neurons from the retina to the brain. During dark adaptation, some of the all-*trans*-retinal is reconverted to

11-*cis*-retinal, but most is reduced to retinol and lost to the retina, dictating the need for continuous supply.

- **Cell growth and differentiation.** Vitamin A and retinoids play an important role in the orderly differentiation of mucus-secreting epithelium; when a deficiency state exists, the epithelium undergoes *squamous metaplasia*, differentiating into a keratinizing epithelium. Activation of retinoic acid receptors (RARs) by their ligands causes the release of corepressors and the obligatory formation of heterodimers with another retinoid receptor, known as the *retinoic X receptor* (RXR). Both RAR and RXR have three isoforms, α , β , and γ . The RAR/RXR heterodimers bind to retinoic acid response elements located in the regulatory regions of genes that encode receptors for growth factors, tumor suppressor genes, and secreted proteins. Through these effects, retinoids regulate cell growth and differentiation, cell cycle control, and other biologic responses. *All-trans-retinoic acid*, a potent acid derivative of vitamin A, has the highest affinity for RARs compared with other retinoids.
- **Metabolic effects of retinoids.** The retinoic X receptor (RXR), believed to be activated by 9-*cis* retinoic acid, can form heterodimers with other nuclear receptors, such as (as we have seen) nuclear receptors involved in drug metabolism, the peroxisome proliferator-activated receptors (PPARs), and vitamin D receptors. PPARs are key regulators of fatty acid metabolism, including fatty acid oxidation in fat tissue and muscle, adipogenesis, and lipoprotein metabolism. The association between RXR and PPAR γ provides an explanation for the metabolic effects of retinoids on adipogenesis.
- **Host resistance to infections.** Vitamin A supplementation can reduce morbidity and mortality from some forms of diarrhea, and in preschool children with measles, supplementation can improve the clinical outcome. The beneficial effect of vitamin A in diarrheal diseases may be related to the maintenance and restoration of

the integrity of the epithelium of the gut. The effects of vitamin A on infections also derive in part from its ability to stimulate the immune system, although the mechanisms are not entirely clear. Infections may reduce the bioavailability of vitamin A by inhibiting retinol binding protein synthesis in the liver through the acute-phase response associated with many infections. The drop in hepatic retinol binding protein causes a decrease in circulating retinol, which reduces the tissue availability of vitamin A.

In addition, retinoids, β -carotene, and some related carotenoids function as photoprotective and antioxidant agents.

Retinoids are used clinically for the treatment of skin disorders such as severe acne and certain forms of psoriasis, and also in the treatment of acute promyelocytic leukemia. As discussed in [Chapter 7](#), *all-trans*-retinoic acid induces the differentiation and subsequent apoptosis of acute promyelocytic leukemia cells through its ability to bind to a PML-RAR α fusion protein that characterizes this form of cancer. A different isomer, 13-*cis* retinoic acid, has been used with some success in the treatment of childhood neuroblastoma.

Vitamin A Deficiency. Vitamin A deficiency occurs worldwide either as a consequence of general undernutrition or as a secondary deficiency in individuals with conditions that cause malabsorption of fats. In children, stores of vitamin A are depleted by infections, and the absorption of the vitamin is poor in newborn infants. Adult patients with malabsorption syndromes, such as celiac disease, Crohn disease, and colitis, may develop vitamin A deficiency, in conjunction with depletion of other fat-soluble vitamins. Bariatric surgery and, in older persons, continuous use of mineral oil as a laxative may lead to deficiency. The pathologic effects of vitamin A deficiency are summarized in [Figure 9-25](#).

Figure 9-25 Vitamin A deficiency, its major consequences in the eye and in the production of keratinizing metaplasia of specialized epithelial surfaces, and its possible role in epithelial metaplasia. Not depicted are night blindness and immune deficiency.

As already discussed, vitamin A is a component of rhodopsin and other visual pigments. Not surprisingly, one of the earliest manifestations of vitamin A deficiency is impaired vision, particularly in reduced light (*night blindness*). Other effects of deficiency are related to the role of vitamin A in maintaining the differentiation of epithelial cells. Persistent deficiency gives rise to *epithelial metaplasia* and *keratinization*. The most devastating changes occur in the eyes and are referred to as *xerophthalmia* (dry eye). First, there is dryness of the conjunctiva (*xerosis conjunctivae*) as the normal lacrimal and mucus-secreting epithelium is replaced by keratinized epithelium. This is followed by a buildup of keratin debris in small opaque plaques (*Bitot spots*) that progresses to erosion of the roughened corneal surface, softening and destruction of the cornea (*keratomalacia*), and blindness.

In addition to the ocular epithelium, the epithelium lining the upper respiratory passage and urinary tract also undergoes *squamous metaplasia*. Loss of the mucociliary epithelium of the airways predisposes to secondary pulmonary infections, and desquamation of keratin debris in the urinary tract predisposes to renal and urinary bladder stones. Hyperplasia and *hyperkeratinization of the epidermis* with plugging of the ducts of the adnexal glands may produce follicular or papular dermatosis. Another very serious consequence is immune deficiency, which is responsible for higher mortality rates from common infections such as measles, pneumonia, and infectious diarrhea. In parts of the world where deficiency of vitamin A is prevalent, dietary supplements reduce mortality by 20% to 30%.

Vitamin A Toxicity. Both short- and long-term excesses of vitamin A may produce toxic manifestations, a point of concern because of the megadoses touted by certain sellers of supplements. The consequences of acute hypervitaminosis A were first described by Gerrit de Veer in 1597, a ship's carpenter stranded in the Arctic, who recounted in his diary the serious symptoms that he and other members of the crew developed after eating polar bear liver. With this cautionary tale in mind, the adventurous eater should be aware that acute vitamin A toxicity has also been described in individuals who ingested the livers of whales, sharks, and even tuna.

The symptoms of acute vitamin A toxicity include headache, dizziness, vomiting, stupor, and blurred vision, symptoms that may be confused with those of a brain tumor (*pseudotumor cerebri*). Chronic toxicity is associated with weight loss, anorexia, nausea, vomiting, and bone and joint pain. Retinoic acid stimulates osteoclast production and activity, leading to increased bone resorption and high risk of fractures. Although synthetic retinoids used for the treatment of acne are not associated with these types of conditions, their use in pregnancy should be avoided because of the well-established teratogenic effects of retinoids.

Vitamin D

The major function of the fat-soluble vitamin D is the maintenance of adequate plasma levels of calcium and phosphorus to support metabolic functions, bone mineralization, and neuromuscular transmission. Vitamin D is required for the prevention of bone diseases known as

rickets (in children whose epiphyses have not already closed), *osteomalacia* (in adults), and *hypocalcemic tetany*. This latter condition is a convulsive state caused by an insufficient extracellular concentration of ionized calcium, which is required for normal neural excitation and the relaxation of muscles. Rickets was nearly endemic in large European cities and poor areas of New York and Boston at the end of the nineteenth century. Although cod liver oil was recognized for its anti-rachitic properties in the early part of that century, it took almost 100 years for it to be accepted by the medical profession as an effective preventive agent (it did not help that cod liver oil consumed in fishing villages in Northern Europe, Scandinavia, and Iceland was a dark, foul-smelling liquid). In addition to its effects on calcium and phosphorus homeostasis, vitamin D has effects in nonskeletal tissues.

Metabolism of Vitamin D. The major source of vitamin D for humans is its endogenous synthesis from a precursor, 7-dehydrocholesterol, in a photochemical reaction that requires solar or artificial UV light in the range of 290 to 315 nm (UVB radiation). This reaction results in the synthesis of *cholecalciferol*, known as *vitamin D₃*. Herein, the term *vitamin D* is used to refer to this compound. Under usual conditions of sun exposure, about 90% of the required vitamin D is endogenously synthesized the skin. However, individuals with dark skin generally have a lower level of vitamin D production because of melanin pigmentation. Dietary sources, such as deep-sea fish, plants, and grains, contribute the remaining required vitamin D and depend on adequate intestinal fat absorption. In plants, vitamin D is present in a precursor form (*ergosterol*), which is converted to vitamin D in the body.

The main steps of vitamin D metabolism are summarized as follows:

1. Photochemical synthesis of vitamin D from 7-dehydrocholesterol in the skin and absorption of vitamin D from foods and supplements in the gut
2. Binding of vitamin D from both of these sources to plasma α_1 -globulin (*D-binding protein* or *DBP*) and transport into the liver
3. Conversion of vitamin D into 25-hydroxycholecalciferol (25-OH-D) in the liver, through the action of 25-hydroxylases, including CYP27A1 and other CYPs
4. Conversion of 25-OH-D into 1,25-dihydroxyvitamin D, [1 α ,25(OH)₂D₃], the most active form of vitamin D, by the enzyme 1 α -hydroxylase in the kidney

The production of 1,25-dihydroxyvitamin D in the kidney is regulated by three main mechanisms (Fig. 9-26):

- *Hypocalcemia stimulates secretion of parathyroid hormone (PTH)*, which in turn augments the conversion of 25-OH-D into 1,25-dihydroxyvitamin D by activating 1 α -hydroxylase
- *Hypophosphatemia directly activates 1 α -hydroxylase*, increasing the production of 1,25-dihydroxyvitamin D
- *Through a feedback mechanism*, increased levels of 1,25-dihydroxyvitamin D down-regulate its own synthesis through inhibition of 1 α -hydroxylase activity

Functions. Like retinoids and steroid hormones, 1,25-dihydroxyvitamin D acts by binding to a high-affinity nuclear receptor (*vitamin D receptor*), which associates with

Figure 9-26 Vitamin D metabolism. Vitamin D is produced from 7-dehydrocholesterol in the skin or is ingested in the diet. It is converted in the liver into 25(OH)D, and in kidney into 1,25(OH)₂D (1,25-dihydroxyvitamin D), the active form of the vitamin. 1,25(OH)₂D stimulates the expression of RANKL, an important regulator of osteoclast maturation and function, on osteoblasts, and enhances the intestinal absorption of calcium and phosphorus in the intestine. DBP, Vitamin D-binding protein (α_1 -globulin); FGF23, fibroblast growth factor 23.

the already mentioned RXR. This heterodimeric complex binds to vitamin D response elements located in the regulatory sequences of vitamin D target genes. The receptors for 1,25-dihydroxyvitamin D are present in most cells of the body. In the small intestine, bones, and kidneys, signals transduced via these receptors regulate plasma levels of calcium and phosphorus. Beyond its role on skeletal homeostasis, vitamin D has immunomodulatory and anti-proliferative effects. 1,25-dihydroxyvitamin D also appears to act through mechanisms that do not require the transcription of target genes. These alternative mechanisms involve the binding of 1,25-dihydroxyvitamin D to a

membrane-associated vitamin D receptor (mVDR), leading to the activation of protein kinase C and opening of calcium channels.

Effects of Vitamin D on Calcium and Phosphorus Homeostasis. The main functions of 1,25-dihydroxyvitamin D on calcium and phosphorus homeostasis are the following:

- **Stimulation of intestinal calcium absorption.** 1,25-dihydroxyvitamin D stimulates intestinal absorption of calcium in the duodenum through the interaction of 1,25-dihydroxyvitamin D with nuclear vitamin D

Figure 9-27 Rickets. **A**, Normal costochondral junction of a young child illustrating formation of cartilage palisades and orderly transition from cartilage to new bone. **B**, Detail of a rachitic costochondral junction in which the palisades of cartilage is lost. Darker trabeculae are well-formed bone; paler trabeculae consist of uncalcified osteoid. **C**, Rickets: note bowing of legs due to formation of poorly mineralized bones. (**B**, Courtesy Dr. Andrew E. Rosenberg, Massachusetts General Hospital, Boston, Mass.)

receptor and the formation of a complex with RXR. The complex binds to vitamin D response elements and activates the transcription of TRPV6 (a member of the transient receptor potential vanilloid family), which encodes a critical calcium transport channel.

- *Stimulation of calcium reabsorption in the kidney.* 1,25-dihydroxyvitamin D increases calcium influx in distal tubules of the kidney through the increased expression of TRPV5, another member of the transient receptor potential vanilloid family. TRPV5 expression is also regulated by PTH in response to hypocalcemia.
- *Interaction with PTH in the regulation of blood calcium.* Vitamin D maintains calcium and phosphorus at supersaturated levels in the plasma. The parathyroid glands have a key role in the regulation of extracellular calcium concentrations. These glands have a calcium receptor that senses even small changes in blood calcium concentrations. In addition to their effects on calcium absorption in the intestine and kidneys already described, both 1,25-dihydroxyvitamin D and PTH enhance the expression of RANKL (receptor activator of NF- κ B ligand) on osteoblasts. RANKL binds to its receptor (RANK) located in preosteoclasts, thereby inducing the differentiation of these cells into mature osteoclasts (Chapter 26). Through the secretion of hydrochloric acid and activation of proteases such as cathepsin K, osteoclasts dissolve bone and release calcium and phosphorus into the circulation.
- *Mineralization of bone.* Vitamin D contributes to the mineralization of osteoid matrix and epiphyseal cartilage in both flat and long bones. It stimulates osteoblasts to synthesize the calcium-binding protein osteocalcin, involved in the deposition of calcium during bone development. Flat bones develop by intramembranous bone formation, in which mesenchymal cells

differentiate directly into osteoblasts, which synthesize the collagenous osteoid matrix on which calcium is deposited. Long bones develop by endochondral ossification, through which growing cartilage at the epiphyseal plates is provisionally mineralized and then progressively resorbed and replaced by osteoid matrix that is mineralized to create bone (Fig. 9-27A).

When *hypocalcemia* occurs due to vitamin D deficiency (Fig. 9-28), PTH production is elevated, causing: (1) activation of renal 1α -hydroxylase, increasing the amount of active vitamin D and calcium absorption; (2) increased resorption of calcium from bone by osteoclasts; (3) decreased renal calcium excretion; and (4) increased renal excretion of phosphate. The latter is explained by increased synthesis in bone of fibroblast growth factor 23 (FGF-23), one of a group of agents known as *phosphatonins* that block phosphate absorption in the intestine and phosphate reabsorption in the kidney. Although a normal serum level of calcium may be restored, hypophosphatemia persists, impairing the mineralization of bone. Increased production of FGF-23 may be responsible for tumor-induced osteomalacia and some forms of hypophosphatemic rickets.

Deficiency States. The normal reference range for circulating 25-(OH)-D is 20 to 100 ng/mL; concentrations of less than 20 ng/mL constitute vitamin D deficiency.

Rickets in growing children and osteomalacia in adults are skeletal diseases with worldwide distributions. They may result from diets deficient in calcium and vitamin D, but an equally important cause of vitamin D deficiency is limited exposure to sunlight. This most often affects inhabitants of northern latitudes, but can even be a problem in tropical countries, in heavily veiled women, and in children born to mothers who have frequent pregnancies

Figure 9-28 Vitamin D deficiency. There is inadequate substrate for the renal 1α -hydroxylase (1), yielding a deficiency of $1,25(\text{OH})_2\text{D}$ (2), and deficient absorption of calcium and phosphorus from the gut (3), with consequently depressed serum levels of both (4). The hypocalcemia activates the parathyroid glands (5), causing mobilization of calcium and phosphorus from bone (6a). Simultaneously, the parathyroid hormone (PTH) induces wasting of phosphate in the urine (6b) and calcium retention. As a result, the serum levels of calcium are normal or nearly normal, but phosphate levels are low; hence, mineralization is impaired (7).

followed by lactation. In all of these situations, vitamin D deficiency can be prevented by a diet high in fish oils. Other, less common causes of rickets and osteomalacia include renal disorders causing decreased synthesis of $1,25$ -dihydroxyvitamin D, phosphate depletion, malabsorption disorders, and some rare inherited disorders. Although rickets and osteomalacia rarely occur outside high-risk groups, milder forms of vitamin D deficiency (also called *vitamin D insufficiency*), leading to an increased risk of bone loss and hip fractures, are quite common in older adults in the United States and Europe. Some genetically determined variants of the vitamin D receptors are also associated with an accelerated loss of bone minerals with aging and certain familial forms of osteoporosis (Chapter 26).

MORPHOLOGY

Vitamin D deficiency in both rickets and osteomalacia results in an **excess of unmineralized matrix**. The following sequence ensues in rickets:

- Overgrowth of epiphyseal cartilage due to inadequate provisional calcification and failure of the cartilage cells to mature and disintegrate
- Persistence of distorted, irregular masses of cartilage, which project into the marrow cavity
- Deposition of osteoid matrix on inadequately mineralized cartilaginous remnants
- Disruption of the orderly replacement of cartilage by osteoid matrix, with enlargement and lateral expansion of the osteochondral junction (Fig. 9-27B)

- Abnormal overgrowth of capillaries and fibroblasts in the disorganized zone resulting from microfractures and stresses on the inadequately mineralized, weak, poorly formed bone
- Deformation of the skeleton due to the loss of structural rigidity of the developing bones

The gross skeletal changes in rickets depend on the severity and duration of the process and, in particular, the stresses to which individual bones are subjected. During the nonambulatory stage of infancy, the head and chest sustain the greatest stresses. The softened occipital bones may become flattened, and the parietal bones can be buckled inward by pressure; with the release of the pressure, elastic recoil snaps the bones back into their original positions (**craniotabes**). An excess of osteoid produces **frontal bossing** and a **squared appearance to the head**. Deformation of the chest results from overgrowth of cartilage or osteoid tissue at the costochondral junction, producing the **“rachitic rosary.”** The weakened metaphyseal areas of the ribs are subject to the pull of the respiratory muscles and thus bend inward, creating anterior protrusion of the sternum (**pigeon breast deformity**). When an ambulating child develops rickets, deformities are likely to affect the spine, pelvis, and tibia, causing **lumbar lordosis** and **bowing of the legs** (Fig. 9-27C).

In adults with **osteomalacia**, the lack of vitamin D deranges the normal bone remodeling that occurs throughout life. The newly formed osteoid matrix laid down by osteoblasts is inadequately mineralized, thus producing the excess of persistent osteoid that is characteristic of osteomalacia. Although the contours of the bone are not affected, the bone is weak and vulnerable to gross fractures or microfractures, which are most likely to affect vertebral bodies and femoral necks. The unmineralized osteoid appears as a thickened layer of matrix (which stains pink in hematoxylin and eosin preparations) arranged about the more basophilic, normally mineralized trabeculae.

Nonskeletal Effects of Vitamin D. As mentioned earlier, the vitamin D receptor is present in various cells and tissues that do not participate in calcium and phosphorus homeostasis. In addition, macrophages, keratinocytes, and tissues such as breast, prostate, and colon can produce $1,25$ -dihydroxyvitamin D. Within macrophages, synthesis of $1,25$ -dihydroxyvitamin D occurs through the activity of CYP27B located in the mitochondria. It appears that pathogen-induced activation of Toll-like receptors in macrophages causes increased expression of vitamin D receptor and CYP27B, leading to local synthesis of $1,25$ -dihydroxyvitamin D and activation of vitamin-D-dependent gene expression in macrophages and other neighboring immune cells. The net effect of this altered gene expression on the immune response remains to be determined. One recent clinical trial in patients with tuberculosis showed that vitamin D supplements increased lymphocyte counts, altered circulating levels of multiple cytokines and chemokines, and enhanced clearance of *Mycobacterium tuberculosis* from sputum, suggesting the vitamin D has complex effects that may, on the whole, be beneficial in this setting. Other regulatory effects of vitamin D in the innate and adaptive immune system have been reported, but the data are often contradictory. It has also been reported that low levels of $1,25$ -dihydroxyvitamin D (<20 ng/mL) are associated with a 30% to 50% increase in

Figure 9-29 Major consequences of vitamin C deficiency caused by impaired formation of collagen.

the incidence of colon, prostate, and breast cancers, but whether vitamin D supplementation can reduce cancer risk has not been firmly established.

Vitamin D Toxicity. Prolonged exposure to normal sunlight does not produce an excess of vitamin D, but megadoses of orally administered vitamin can lead to hypervitaminosis. In children, hypervitaminosis D may

take the form of metastatic calcifications of soft tissues such as the kidney; in adults it causes bone pain and hypercalcemia. The toxic potential of this vitamin is so great that in sufficiently large doses it is a potent rodenticide.

Vitamin C (Ascorbic Acid)

A deficiency of water-soluble vitamin C leads to the development of *scurvy*, characterized principally by bone

Table 9-9 Vitamins: Major Functions and Deficiency Syndromes

Vitamin	Functions	Deficiency Syndromes
Fat-soluble		
Vitamin A	A component of visual pigment Maintenance of specialized epithelia Maintenance of resistance to infection	Night blindness, xerophthalmia, blindness Squamous metaplasia Vulnerability to infection, particularly measles
Vitamin D	Facilitates intestinal absorption of calcium and phosphorus and mineralization of bone	Rickets in children Osteomalacia in adults
Vitamin E	Major antioxidant; scavenges free radicals	Spinocerebellar degeneration
Vitamin K	Cofactor in hepatic carboxylation of procoagulants—factors II (prothrombin), VII, IX, and X; and protein C and protein S	Bleeding diathesis (Chapter 14)
Water-soluble		
Vitamin B ₁ (thiamine)	As pyrophosphate, is coenzyme in decarboxylation reactions	Dry and wet beriberi, Wernicke syndrome, Korsakoff syndrome (Chapter 28)
Vitamin B ₂ (riboflavin)	Converted to coenzymes flavin mononucleotide and flavin adenine dinucleotide, cofactors for many enzymes in intermediary metabolism	Ariboflavinosis, cheilosis, stomatitis, glossitis, dermatitis, corneal vascularization
Niacin	Incorporated into nicotinamide adenine dinucleotide (NAD) and NAD phosphate, involved in a variety of redox reactions	Pellagra—“three Ds”: dementia, dermatitis, diarrhea
Vitamin B ₆ (pyridoxine)	Derivatives serve as coenzymes in many intermediary reactions	Cheilosis, glossitis, dermatitis, peripheral neuropathy (Chapter 28) Maintenance of myelination of spinal cord tracts
Vitamin B ₁₂	Required for normal folate metabolism and DNA synthesis	Megaloblastic pernicious anemia and degeneration of posterolateral spinal cord tracts (Chapter 14)
Vitamin C	Serves in many oxidation-reduction (redox) reactions and hydroxylation of collagen	Scurvy
Folate	Essential for transfer and use of one-carbon units in DNA synthesis	Megaloblastic anemia, neural tube defects (Chapter 14)
Pantothenic acid	Incorporated in coenzyme A	No nonexperimental syndrome recognized
Biotin	Cofactor in carboxylation reactions	No clearly defined clinical syndrome

Table 9-10 Selected Trace Elements and Deficiency Syndromes

Element	Function	Basis of Deficiency	Clinical Features
Zinc	Component of enzymes, principally oxidases	Inadequate supplementation in artificial diets Interference with absorption by other dietary constituents Inborn error of metabolism	Rash around eyes, mouth, nose, and anus called acrodermatitis enteropathica Anorexia and diarrhea Growth retardation in children Depressed mental function Depressed wound healing and immune response Impaired night vision Infertility
Iron	Essential component of hemoglobin as well as several iron-containing metalloenzymes	Inadequate diet Chronic blood loss	Hypochromic microcytic anemia (Chapter 14)
Iodine	Component of thyroid hormone	Inadequate supply in food and water	Goiter and hypothyroidism (Chapter 24)
Copper	Component of cytochrome <i>c</i> oxidase, dopamine β -hydroxylase, tyrosinase, lysyl oxidase, and unknown enzymes involved in cross-linking collagen	Inadequate supplementation in artificial diet Interference with absorption	Muscle weakness Neurologic defects Abnormal collagen cross-linking
Fluoride	Mechanism unknown	Inadequate supply in soil and water Inadequate supplementation	Dental caries (Chapter 16)
Selenium	Component of glutathione peroxidase Antioxidant with vitamin E	Inadequate amounts in soil and water	Myopathy Cardiomyopathy (Keshan disease)

disease in growing children and by hemorrhages and healing defects in both children and adults. Sailors of the British Royal Navy were nicknamed “limeys,” because at the end of the eighteenth century the Navy began to provide lime and lemon juice (rich sources of vitamin C) to sailors to prevent scurvy during their long sojourn at sea. It was not until 1932 that ascorbic acid was identified and synthesized. Ascorbic acid is not synthesized endogenously in humans; therefore, we are entirely dependent on the diet for this nutrient. Vitamin C is present in milk and some animal products (liver, fish) and is abundant in a variety of fruits and vegetables. All but the most restricted diets provide adequate amounts of vitamin C.

Function. Ascorbic acid functions in a variety of biosynthetic pathways by accelerating hydroxylation and amidation reactions. The best established function of vitamin C is the activation of prolyl and lysyl hydroxylases from inactive precursors, providing for hydroxylation of procollagen. Inadequately hydroxylated procollagen cannot acquire a stable helical configuration, so it is poorly secreted from the fibroblast. Those molecules that are secreted are adequately cross-linked, lack tensile strength, and are more soluble and vulnerable to enzymatic degradation. Collagen, which normally has the highest content of hydroxyproline of any polypeptide, is most affected, particularly in blood vessels, accounting for the predisposition to hemorrhages in scurvy. In addition, a deficiency of vitamin C suppresses the rate of synthesis of procollagen, independent of effects on proline hydroxylation.

Vitamin C also has antioxidant properties. Vitamin C can scavenge free radicals directly and can act indirectly by regenerating the antioxidant form of vitamin E.

Deficiency States. Consequences of vitamin C deficiency (scurvy) are illustrated in Figure 9-29. Because of the abundance of ascorbic acid in many foods, scurvy has ceased to be a global problem. It is sometimes encountered even in affluent populations as a secondary deficiency, particularly among older individuals, persons who live alone, and

chronic alcoholics, groups that often have erratic and inadequate eating patterns. Occasionally, scurvy occurs in patients undergoing peritoneal dialysis and hemodialysis and among food faddists. The condition also sometimes appears in infants who are maintained on formulas of evaporated milk without supplementation of vitamin C.

Vitamin C Excess. The popular notion that megadoses of vitamin C protect against the common cold, or at least allay the symptoms, has not been borne out by controlled clinical studies. Such slight relief as may be experienced is probably due to the mild antihistamine action of ascorbic acid. Similarly, there is no evidence that large doses of vitamin C protect against cancer development. The physiologic availability of excess vitamin C is limited due to its inherent instability, poor intestinal absorption, and rapid urinary excretion. Fortunately, toxicities related to high doses of vitamin C are rare, consisting of possible iron overload (due to increase absorption), hemolytic anemia in those with glucose-6-phosphate dehydrogenase (G6PD) deficiency (Chapter 14), and calcium oxalate kidney stones.

Other vitamins and some essential minerals are listed and briefly described in Tables 9-9 and 9-10 and are discussed in other chapters.

KEY CONCEPTS

Nutritional Diseases

- Primary PEM is a common cause of childhood deaths in poor countries. The two main primary PEM syndromes are marasmus and kwashiorkor. Secondary PEM occurs in the chronically ill and in patients with advanced cancer (as a result of cachexia).
- Kwashiorkor is characterized by hypoalbuminemia, generalized edema, fatty liver, skin changes, and defects in immunity. It is caused by diets low in protein but normal in calories.
- Marasmus is characterized by emaciation resulting from loss of muscle mass and fat with relative preservation of

serum albumin. It is caused by diets severely lacking in calories—both protein and nonprotein.

- Anorexia nervosa is self-induced starvation; it is characterized by amenorrhea and multiple manifestations of low thyroid hormone levels. Bulimia is a condition in which food binges alternate with induced vomiting.
- Vitamins A and D are fat-soluble vitamins with a wide range of activities. Vitamin A is required for vision, epithelial differentiation, and immune function. Vitamin D is a key regulator of calcium and phosphate homeostasis.
- Vitamin C and members of the vitamin B family are water-soluble. Vitamin C is needed for collagen synthesis and collagen cross-linking and tensile strength. B vitamins have diverse roles in cellular metabolism.

Obesity

Excess adiposity (obesity) and excess body weight are associated with increased incidence of several of the most important diseases of humans, including type 2 diabetes, dyslipidemias, cardiovascular disease, hypertension, and cancer. Obesity is defined as an accumulation of adipose tissue that is of sufficient magnitude to impair health. As with weight loss, excess weight is best assessed by the *body mass index*, or BMI. For practical reasons, *body weight*, which generally correlates well with BMI, is often used as a surrogate for BMI measurements. The normal BMI range is 18.5 to 25 kg/m², although the range may differ for different countries. Individuals with BMI greater than 30 kg/m² are classified as obese; those with BMI between 25 kg/m² and 30 kg/m² are considered overweight. Unless otherwise noted, the term *obesity* herein applies to both the truly obese and the overweight.

Not only the total body weight but also the distribution of the stored fat is of importance in obesity. *Central, or visceral, obesity*, in which fat accumulates in the trunk and in the abdominal cavity (in the mesentery and around viscera), is associated with a much higher risk for several diseases than is excess accumulation of fat diffusely in subcutaneous tissue.

Obesity is a major public health problem in developed countries and an emerging health problem in developing nations, such as India. Globally, the World Health Organization estimates that by 2015, 700 million adults will be obese. In certain countries, obesity coexists with malnutrition in individual families. In the United States obesity has reached epidemic proportions. The prevalence of obesity increased from 13% to 32% between 1960 and 2004, and by 2010, 35.7% of adult in the United States were obese, as were 16.9% of children. Indeed, in 2009, it was estimated that the health care cost of obesity and related diseases had risen to \$147 billion annually in the United States, a price tag that appears bound to rise further as the nation's collective waistline expands. The increase in obesity in the United States has been associated with the higher caloric content of the diet, mostly caused by increased consumption of refined sugars, sweetened beverages, and vegetable oils.

At its simplest level, obesity is a disease of caloric imbalance that results from an excess intake of calories that exceeds their consumption by the body. However, the pathogenesis of obesity is complex and incompletely

understood. Ongoing research has identified intricate humoral and neural mechanisms that control appetite and satiety. These neurohumoral mechanisms respond to genetic, nutritional, environmental, and psychologic signals, and trigger a metabolic response through the stimulation of centers located in the hypothalamus. There is little doubt that genetic influences play an important role in weight control, but obesity is a disease that depends on the interaction between multiple factors. After all, regardless of genetic makeup, obesity would not occur without intake of food.

In a simplified way the neurohumoral mechanisms that regulate energy balance can be subdivided into three components (Figs. 9-30 and 9-31):

- The *peripheral or afferent system* generates signals from various sites. Its main components are *leptin* and *adiponectin* produced by fat cells, *ghrelin* from the stomach, *peptide YY (PYY)* from the ileum and colon, and *insulin* from the pancreas.
- The *arcuate nucleus in the hypothalamus* processes and integrates neurohumoral peripheral signals and generates efferent signals. It contains two subsets of first-order neurons: (1) *POMC* (pro-opiomelanocortin) and *CART* (cocaine and amphetamine-regulated transcripts) neurons, and (2) neurons containing *NPY* (neuropeptide Y) and *AgRP* (agouti-related peptide). These first-order neurons communicate with second-order neurons in the hypothalamus.
- The *efferent system* is organized along two pathways, anabolic and catabolic, that control food intake and energy expenditure, respectively. The hypothalamic system also communicates with forebrain and midbrain centers that control the autonomic nervous system.
- *POMC/CART* neurons enhance energy expenditure and weight loss through the production of the anorexigenic α -melanocyte-stimulating hormone (MSH), and the activation of the melanocortin receptors 3 and 4 (MC3/4R) in second-order neurons. These second order neurons are in turn responsible for producing factors such as thyroid releasing hormone (TSH) and corticotropin releasing hormone (CRH) that increase the basal metabolic rate and anabolic metabolism, thus favoring weight loss. By contrast, the *NPY/AgRP* neurons promote food intake (orexigenic effect) and weight gain, through the activation of Y1/5 receptors in secondary neurons. These secondary neurons then release factors such as melanin-concentrating hormone (MCH) and orexin, which stimulate appetite.

Three important components of the afferent system, which regulates appetite and satiety, are leptin, adiponectin, and gut hormones.

Leptin. The name *leptin* is derived from the Greek term *leptos*, meaning “thin.” Leptin, a 16-kD hormone synthesized by fat cells, is the product of the *ob* gene. The leptin receptor (OB-R) belongs to the type I cytokine receptor superfamily, which includes the gp130, granulocyte-colony-stimulating factor, IL-2, and IL-6 receptors. Mice genetically deficient in leptin (*ob/ob mice*) or leptin receptors (*db/db mice*) fail to sense the adequacy of fat stores, overeat, and gain weight, behaving as if they are undernourished. Thus, the obesity of these animals is a consequence of the

Figure 9-30 Regulation of energy balance. Adipose tissues generate afferent signals that influence the activity of the hypothalamus, which is the central regulator of appetite and satiety. These signals decrease food intake by inhibiting anabolic circuits, and enhance energy expenditure through the activation of catabolic circuits. PYY, Peptide YY. See text for details.

lack of the signal for energy sufficiency that is normally provided by leptin.

While the precise mechanisms that regulate the output of leptin from adipose tissue have not been completely defined, it has been established that leptin secretion is stimulated when fat stores are abundant. It is believed that insulin-stimulated glucose metabolism is an important factor in the regulation of leptin levels. Leptin levels are also regulated by multiple additional posttranscriptional mechanisms that affect its synthesis, secretion, and turnover. In the hypothalamus, leptin stimulates POMC/CART neurons that produce anorexigenic neuropeptides (primarily melanocyte-stimulating hormone) and inhibits NPY/AgRP neurons that produce feeding-inducing (orexigenic) neuropeptides (Figs. 9-30 and 9-31). In individuals with stable weight, the activities of the opposing POMC/CART and NPY/AgRP pathways are properly balanced. However, when there are inadequate stores of body fat, leptin secretion is diminished and food intake is increased.

Humans with loss-of-function mutations in the leptin system develop early-onset severe obesity, but this is a rare condition. Mutations of melanocortin receptor 4 (MC4R) and its downstream pathways are more frequent, being responsible for about 5% of massive obesity. In these individuals, sensing of satiety (anorexigenic signal) is not generated, and hence they behave as if they are undernourished. Haploinsufficiency of brain-derived neurotrophic factor

(BDNF), an important component of signaling downstream of MC4R in the hypothalamus, is associated with obesity in patients with the WAGR syndrome (a very rare condition that includes Wilms tumor, aniridia, genitourinary defects, and mental retardation in addition to obesity, Chapter 10). Although the defects in leptin and MC4R detected so far are uncommon, they underscore the importance of these systems in the control of energy balance and body weight. Perhaps other genetic or acquired defects in these pathways may have pathogenic effects in more common forms of obesity. For instance, it has been proposed that leptin resistance is prevalent in humans; it has also been noted that obese children have lower circulating levels of BDNF.

Leptin regulates not only food intake but also energy expenditure, through a distinct set of pathways. Thus, an abundance of leptin stimulates physical activity, heat production, and energy expenditure. The neurohumoral mediators of leptin-induced energy expenditure are less well defined. *Thermogenesis*, an important catabolic effect mediated by leptin, is controlled in part by hypothalamic signals that increase the release of norepinephrine from sympathetic nerve endings in adipose tissue. In addition to these effects, leptin can function as a proinflammatory cytokine and participates in the regulation of hematopoiesis and lymphopoiesis. The OB-R receptor is similar structurally to the IL-6 receptor and activates the JAK/STAT pathway.

Figure 9-31 Neurohumoral circuits in the hypothalamus that regulate energy balance. Shown are POMC/CART anorexigenic neurons and NPY/AgRP orexigenic neurons in the arcuate nucleus of the hypothalamus, and their pathways. See text for details.

Adiponectin. Injections of adiponectin in mice stimulate fatty acid oxidation in muscle, causing a decrease in fat mass. This hormone is produced mainly by adipocytes. Its levels in the blood are very high, about 1000 times higher than those of other polypeptide hormones, and are lower in obese than in lean individuals. Adiponectin, which has been called a “fat-burning molecule” and the “guardian angel against obesity,” directs fatty acids to muscle for their oxidation. It decreases the influx of fatty acids to the liver and the total hepatic triglyceride content, and also decreases the glucose production in the liver, causing an increase in insulin sensitivity and protecting against the metabolic syndrome (described later). Adiponectin circulates as a complex of three, six, or even more aggregates of the monomeric form, and binds to two receptors, AdipoR1 and AdipoR2. These receptors are found in many tissues, including the brain, but AdipoR1 and AdipoR2 are most highly expressed in skeletal muscle and liver, respectively. Binding of adiponectin to its receptors triggers signals that activate cAMP-dependent protein kinase (protein kinase A), which in turn phosphorylates and inactivates acetyl coenzyme A carboxylase, a key enzyme required for fatty acid synthesis.

Gut Hormones. Gut peptides act as short-term meal initiators and terminators. They include ghrelin, PYY, pancreatic polypeptide, insulin, and amylin among others. *Ghrelin* is produced in the stomach and in the arcuate nucleus of the hypothalamus. It is the only known gut hormone that increases food intake (orexigenic effect). Its injection in rodents elicits voracious feeding, even after repeated

administration. Long-term injections cause weight gain, by increasing caloric intake and reducing energy utilization. Ghrelin acts by binding the growth hormone secretagogue receptor, which is abundant in the hypothalamus and the pituitary. Although the precise mechanisms of ghrelin action have not been identified, it most likely stimulates NPY/AgRP neurons to increase food intake. Ghrelin levels rise before meals and fall between 1 and 2 hours after eating. In obese individuals the postprandial suppression of ghrelin is attenuated and may contribute to overeating.

PYY is secreted from endocrine cells in the ileum and colon. Plasma levels of PYY are low during fasting and increase shortly after food intake. Intravenous administration of PYY reduces energy intake, and its levels generally increase after gastric bypass surgery. By contrast, levels of PYY generally decrease in individuals with the *Prader-Willi syndrome* (caused by loss of imprinted genes on chromosome 15q11-q13), a disorder marked by hyperphagia and obesity. These observations have led to ongoing work to produce PYYs for the treatment of obesity. *Amylin*, a peptide secreted with insulin from pancreatic β -cells that reduces food intake and weight gain, is also being evaluated for the treatment of obesity and diabetes. Both PYY and amylin act centrally by stimulating POMC/CART neurons in the hypothalamus, causing a decrease in food intake.

Actions of Adipocytes. In addition to leptin and adiponectin, adipose tissue produces cytokines such as TNF, IL-6, IL-1, and IL-18, chemokines, and steroid hormones. The

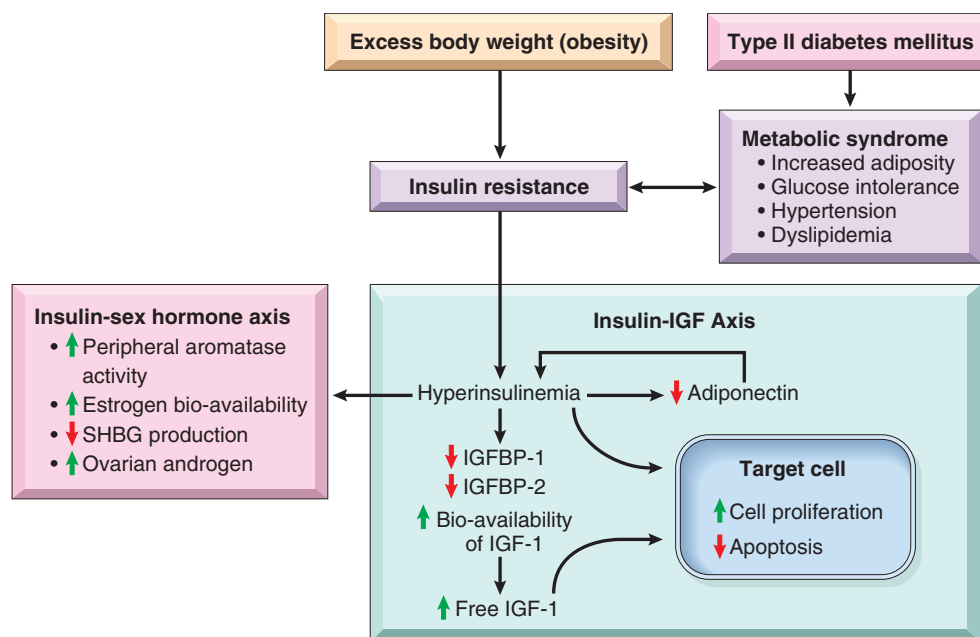

Figure 9-32 Obesity, metabolic syndrome, and cancer. Obesity and excessive weight are precursors of the metabolic syndrome, which is associated with insulin resistance, type 2 diabetes, and hormonal changes. Increases in insulin and IGF-1 (insulin-like growth factor-1) stimulate cell proliferation and inhibit apoptosis and may contribute to tumor development. IGF, Insulin-like growth factor; IGFBP, insulin-like growth factor-binding protein; SHBG, sex hormone-binding globulin. (Modified from Renehan AG, et al: Obesity and cancer risk: the role of the insulin-IGF axis. *Trends Endocrinol Metab* 17:328, 2006.)

increased production of cytokines and chemokines by adipose tissue in obese patients creates a chronic proinflammatory state marked by high levels of circulating C-reactive protein. This relationship may be more than a one-way street, as emerging evidence suggests that immune cells, particularly tissue macrophages, have important roles in regulating adipocyte function. Through this panoply of mediators, adipose tissue participates in the control of energy balance and energy metabolism, functioning as a link between lipid metabolism, nutrition, and inflammatory responses. Thus, the adipocyte, which was relegated to an obscure and passive role as the “Cinderella of cells of metabolism,” is now “the Belle of the Ball” at the forefront of metabolic research.

Regulation of adipocyte numbers. The total number of adipocytes is established during childhood and adolescence (yet another reason to be concerned about childhood obesity), and is higher in obese than in lean individuals. In adults, it is estimated that approximately 10% of adipocytes are renewed annually, regardless of the level of the individual’s body mass, but the number of adipocytes remains constant. Thus, adipocyte numbers are tightly controlled, and loss of fat mass in an adult person occurs through shrinkage of existing adipocytes. The well-known difficulty in maintaining weight losses from dieting is not well understood but appears to be related to homeostatic mechanisms that keep body fat constant over time. Thus, unless lowered caloric intake and/or increase energy expenditure is sustained, body weight inexorably returns to pre-diet levels. In a sense, therefore, the number of adipocytes create a set point for body weight.

Other emerging factors associated with obesity: role of the gut microbiome. A surprising and potentially important

new explanation for the development of obesity has focused on alterations in the gut microbiome. Diet has marked effects on the bacterial makeup of the colon, and the bacterial flora in turn can have large effects on the ability of the host to break down certain dietary constituents (e.g., fiber) and absorb nutrients, as well as on epithelial integrity and inflammation. In response to these changes, expression of gut factors such as PYY that feedback on central appetite centers may also be altered. The data showing that gut flora can influence obesity are strong in certain mouse models, but the relevance of these models to human obesity, although tantalizing, remain to be proven.

General Consequences of Obesity

Obesity, particularly *central obesity*, increases the risk for a number of conditions, including type 2 diabetes and cardiovascular disease (Fig. 9-32). Obesity is the main driver of a cluster of alterations known as the *metabolic syndrome* characterized by visceral or intra-abdominal adiposity, insulin resistance, hyperinsulinemia, glucose intolerance, hypertension, hypertriglyceridemia, and low HDL cholesterol (Chapter 11).

- Obesity is associated with *insulin resistance* and *hyperinsulinemia*, important features of type 2 diabetes (Chapter 24), and weight loss is associated with improvements in these abnormalities. Excess insulin, in turn, may play a role in the retention of sodium, expansion of blood volume, production of excess norepinephrine, and smooth muscle proliferation that are the hallmarks of hypertension. Regardless of the nature of the pathogenic mechanisms, the risk of developing *hypertension* among previously normotensive persons increases proportionately with weight.

- Obese persons generally have hypertriglyceridemia and low HDL, both of which increase the risk of *coronary artery disease*. It should be emphasized that the association between obesity and heart disease is not straightforward, and such linkage as there may be relates more to the associated diabetes and hypertension than to weight.
- Obesity is associated with *nonalcoholic fatty liver disease* (Chapter 18). This condition occurs most often in diabetic patients and can progress to fibrosis and cirrhosis.
- *Cholelithiasis* (gallstones) is six times more common in obese than in lean subjects. An increase in total body cholesterol, increased cholesterol turnover, and augmented biliary excretion of cholesterol all act to predispose to the formation of cholesterol-rich gallstones (Chapter 18).
- Obesity is associated with hypoventilation and hypersomnolence. *Hypoventilation syndrome* is a constellation of respiratory abnormalities in very obese persons. It has been called the *pickwickian syndrome*, after the fat lad who was constantly falling asleep in Charles Dickens' *Pickwick Papers*. *Hypersomnolence*, both at night and during the day, is often associated with apneic pauses during sleep (sleep apnea), polycythemia, and eventual right-sided heart failure (*cor pulmonale*).
- Marked adiposity predisposes to the development of degenerative joint disease (*osteoarthritis*). This form of arthritis, which typically appears in older persons, is attributed in large part to the cumulative effects of increased load on weight-bearing joints.

Obesity and Cancer

In 2007, the National Cancer Institute estimated that 4% of cancers in men and 7% of cancers in women were attributable to obesity, numbers that can be expected to rise as obesity increases. The clearest associations with increased risk were for cancers of the esophagus, pancreas, colon and rectum, breast, endometrium, kidney, thyroid, and gallbladder. The mechanisms by which obesity promotes cancer development are unknown, but several non-mutually exclusive possibilities have been proposed:

- **Elevated insulin levels.** Insulin resistance leads to hyperinsulinemia (Fig. 9-32), which has multiple effects that may directly or indirectly contribute to cancer. For example, hyperinsulinemia inhibits the production of the IGF-binding proteins IGFBP-1 and IGFBP-2, thereby causing a rise in levels of free insulin-like growth factor-1 (IGF-1). IGF-1 is a mitogen, and its receptor, IGFR-1, is highly expressed in many human cancers. It binds with high affinity to the IGFR-1 receptor, and with low affinity to the insulin receptor, which are also expressed on many cancers. Upon stimulation by IGF-1, IGFR-1 activates the RAS and PI3K/AKT pathways, which promote the growth of both normal and neoplastic cells (Chapter 7).
- Obesity has effects on *steroid hormones* that regulate cell growth and differentiation in the breast, uterus, and other tissues. Specifically, obesity increases the synthesis of estrogen from androgen precursors through an effect of adipose tissue aromatases, increases androgen

synthesis in ovaries and adrenals, and enhances estrogen availability in obese persons by inhibiting the production of sex-hormone-binding globulin (SHBG) in the liver (Fig. 9-32).

- As discussed earlier, *adiponectin*, secreted mostly from adipose tissue, is an abundant hormone that is inversely correlated with obesity and acts as an insulin-sensitizing agent. Thus, the decreased levels of adiponectin in obese persons contribute to hyperinsulinemia.
- The *proinflammatory state* that is associated with obesity may itself be carcinogenic, through mechanisms discussed in Chapter 7.

KEY CONCEPTS

Obesity

- Obesity is a disorder of energy regulation. It increases the risk for a number of important conditions such as insulin resistance, type 2 diabetes, hypertension, and hypertriglyceridemia, which are associated with the development of coronary artery disease, as well as certain cancers, nonalcoholic fatty liver disease, and gallstones.
- The regulation of energy balance is complex. It has three main components: (1) afferent signals, provided mostly by insulin, leptin, ghrelin, and peptide YY; (2) the central hypothalamic system, which integrates afferent signals and triggers the efferent signals; and (3) efferent signals, which control energy balance.
- Leptin plays a key role in energy balance. Its output from adipose tissues is regulated by the abundance of fat stores. Leptin binding to its receptors in the hypothalamus increases energy consumption by stimulating POMC/CART neurons and inhibiting NPY/AgRP neurons.

Diet, Cancer, and Atherosclerosis

Diet and Cancer

As you will recall from Chapter 7, the incidence of specific cancers varies as much as 100-fold in different geographic areas. It is well known that differences in incidence of various cancers are not fixed and can be modified by environmental factors, including changes in diet. For instance, the incidence of colon cancer in Japanese men and women 55 to 60 years of age was negligible about 50 years ago, but it is now higher than that in men of the same age in the United Kingdom. Studies have also shown a progressive increase in colon cancers in Japanese populations as they moved from Japan to Hawaii and from there to the continental United States. Nevertheless, despite extensive experimental and epidemiologic research, relatively few mechanisms that link diets and specific types of cancer have been established.

With respect to carcinogenesis, three aspects of the diet are of major concern: (1) the content of exogenous carcinogens, (2) the endogenous synthesis of carcinogens from dietary components, and (3) the lack of protective factors.

- Regarding *exogenous* substances, *aflatoxin* is involved in the development of hepatocellular carcinomas in parts of Asia and Africa, generally in cooperation with

hepatitis B virus. Exposure to aflatoxin causes a specific mutation in codon 249 of the *TP53* gene; when found in hepatocellular carcinomas, this mutation serves as a molecular signature for aflatoxin exposure. Debate continues about the carcinogenicity of food additives, artificial sweeteners, and contaminating pesticides.

- The concern about *endogenous* synthesis of carcinogens or enhancers of carcinogenicity from components of the diet relates principally to gastric carcinomas. *Nitrosamines* and *nitrosamides* are implicated in the generation of these tumors, as they have been clearly shown to induce gastric cancer in animals. These compounds can be formed in the body from nitrites and amines or amides derived from digested proteins. Sources of nitrites include sodium nitrite added to foods as a preservative, and nitrates, present in common vegetables, which are reduced in the gut by bacterial flora. There is, then, the potential for endogenous production of carcinogenic agents from dietary components, which might well have an effect on the stomach.
- *High animal fat intake combined with low fiber intake has been implicated in the causation of colon cancer.* It has been estimated that doubling the average level of total fiber consumption to about 40 gm/day per person in most populations decreases the risk of colon cancer by 50%. The most plausible explanation for this association is that high fat intake increases the level of bile acids in the gut, which in turn modifies intestinal flora, favoring the growth of microaerophilic bacteria. Bile acid metabolites produced by these bacteria may function as carcinogens. The *protective effect of a high-fiber diet* might relate to (1) increased stool bulk and decreased transit time, which decreases the exposure of mucosa to putative offenders, and (2) the capacity of certain fibers to bind carcinogens and thereby protect the mucosa. However, attempts to document these theories in clinical and experimental studies have not generated consistent results.
- Although epidemiologic data show a strong positive correlation between total dietary fat intake and breast cancer, it is still unclear whether increased fat consumption has a causal relationship to breast cancer development.
- Vitamins C and E, β -carotenes, and selenium have been assumed to have anticarcinogenic effects because of their antioxidant properties. However, thus far there is no convincing evidence that these antioxidants act as chemopreventive agents. As discussed earlier in this chapter, retinoids are effective agents in the therapy of acute promyelocytic leukemia, and associations between low levels of vitamin D and cancer of the colon, prostate, and breast have been reported.

Thus, despite many tantalizing trends and proclamations by “diet gurus,” thus far there is no definitive proof that a particular diet can cause or prevent cancer. On the other hand, given the relationships between obesity and cancer development, prevention of obesity through the consumption of a healthy diet is a commonsense measure that goes a long way in preserving good health. Concern persists that carcinogens lurk in things as pleasurable as a juicy steak, a rich ice cream, and in nuts contaminated with aflatoxin.

Diet and Atherosclerosis

The contribution of diet to atherogenesis is an important and controversial issue. The central question is “can dietary modification—specifically, reduction in the consumption of cholesterol and saturated animal fats (e.g., eggs, butter, beef)—reduce serum cholesterol levels and prevent or retard the development of atherosclerosis (most importantly, coronary heart disease)?” The average adult in the United States consumes a large amount of fat and cholesterol daily, with a ratio of saturated fatty acids to polyunsaturated fatty acids of about 3:1. Lowering this ratio to 1:1 causes a 10% to 15% reduction in the serum cholesterol level within a few weeks. Given the strong association of hypercholesterolemia with risk of atherosclerosis ([Chapter 11](#)), it is plausible that a low-fat diet might lower risk. A corollary of this idea is that supplementation of diet with “good” fats, for example, fish oil fatty acids belonging to the omega-3 family, might protect against atherosclerosis. However, recent studies have shown that omega-3 fatty acid supplements do not lower the risk of cardiovascular disease. Still, there remains much interest in the role that caloric restriction and special diets may play in the control of body weight and prevention of cardiovascular disease.

Caloric restriction has been convincingly demonstrated to decrease the incidence of some diseases and to increase life span in experimental animals. The basis of this striking observation is not entirely clear but seems to depend on activation of sirtuins and on lowering of insulin and IGF-1 levels ([Chapter 2](#)). In calorie-restricted animals there is also less age-related decline in immunologic functions, less oxidative damage, and greater resistance to carcinogenesis.

Not surprisingly, there are a large number of commercial diets that are reported by proponents to decrease the risk of heart disease. Among those are the low-carbohydrate diets (e.g., the Atkins Diet, the Zone, Sugar Busters, Protein Power) and others such as The Miami Diet/Hollywood 48-Hour Miracle Diet, and the South Beach Diet. The effect of these diets on heart disease, if any, is highly controversial.

Most diets dictate what you cannot eat (of course, your favorite foods!). A better strategy is to simply focus on eating an enjoyable and healthy diet rich in fish, vegetables, whole grains, fruits, olive and peanut oils (to replace saturated and *trans* fats), complex carbohydrates (instead of simple carbohydrates contained in sweets and soft drinks), and low in salt (to control hypertension).

Even lowly garlic has been touted to protect against heart disease (and also against, devils, werewolves, vampires, and, alas, kisses), although research has yet to prove this effect unequivocally. Of these, the effect on kisses is the best established!

Children are not merely little adults, and their diseases are not merely variants of adult diseases. Many childhood conditions are unique to, or at least take distinctive forms in, this stage of life and so are discussed separately in this chapter. Diseases originating in the perinatal period are important in that they account for significant morbidity and mortality. As would be expected, the chances for survival of live-born infants improve with each passing week. This progress represents, at least in part, a triumph of improved medical care. Better prenatal care, more effective methods of monitoring the condition of the fetus, and judicious resort to cesarean section before term when there is evidence of fetal distress, have all contributed toward bringing into this world live-born infants who in past years might have been stillborn. This has resulted in an increased number of *high-risk infants* in the population. Nonetheless, the infant mortality rate in the United States has shown a decline from a level of 20 deaths per 1000 live births in 1970 to about 6.1 deaths in 2010, the latest year for which complete data are available. Although the death rate has continued to decline for all infants, African Americans continue to have an infant mortality rate more than twice (12.4 deaths per 1000 live births) that of American whites (5.3 deaths). Worldwide, infant mortality rates vary widely, from as low as 1.8 deaths per 1000 live births in Luxembourg, to as high as 180 deaths in the African subcontinent. Rather

dismayingly, the United States ranks thirty-first in infant mortality rates among developed nations in the Western hemisphere.

Each stage of development of the infant and child is prey to a somewhat different group of disorders. The data available permit a survey of four time spans: (1) the neonatal period (the first 4 weeks of life), (2) infancy (the first year of life), (3) age 1 to 4 years, and (4) age 5 to 14 years.

The major causes of death in infancy and childhood are listed in [Table 10-1](#). Congenital anomalies, disorders relating to short gestation (prematurity) and low birth weight, and sudden infant death syndrome (SIDS) represent the leading causes of death in the first 12 months of life. Once the infant survives the first year of life, the outlook brightens measurably. In the next two age groups—1 to 4 years and 5 to 9 years—unintentional injuries resulting from accidents have become the leading cause of death. Among the natural diseases, in order of importance, congenital anomalies and malignant neoplasms assume major significance. It would appear then that, in a sense, life is an obstacle course. Thankfully for the great majority, the obstacles are comfortably overcome.

The following discussion looks at specific conditions encountered during the various stages of infant and child development.

Table 10-1 Cause of Death Related with Age

Causes*	Rate†
Younger than 1 year	660.6
Congenital malformations, deformations, and chromosomal anomalies	
Disorders related to short gestation and low birth weight	
Sudden infant death syndrome (SIDS)	
Newborn affected by maternal complications of pregnancy	
Accidents (unintentional injuries)	
Newborn affected by complications of placenta, cord, and membranes	
Bacterial sepsis of newborn	
Respiratory distress of newborn	
Diseases of the circulatory system	
Neonatal hemorrhage	
1-4 Years	28.3
Accidents (unintentional injuries)	
Congenital malformations, deformations, and chromosomal abnormalities	
Assault (homicide)	
Malignant neoplasms	
Diseases of the heart‡	
5-9 Years	12.5
Accidents (unintentional injuries)	
Malignant neoplasms	
Congenital malformations, deformations, and chromosomal abnormalities	
Assault (homicide)	
Influenza and pneumonia	
10-14 Years	15.7
Accidents (unintentional injuries)	
Malignant neoplasms	
Intentional self-harm (suicide)	
Assault (homicide)	
Congenital malformations, deformations, and chromosomal anomalies	

*Causes are listed in decreasing order of frequency. All causes and rates are based on 2008 (final) and 2009 (preliminary) data.
†Rates are expressed per 100,000 population from all causes within each age group.
‡Excludes congenital heart disease.
Data source: Centers for Disease Control and Prevention/NCHS, National Vital Statistics System: mortality, 2009 and 2008 (www.cdc.gov/nchs/nvss/mortality_tables.htm).

Congenital Anomalies

Congenital anomalies are anatomic defects that are present at birth, but some, such as cardiac defects and renal anomalies, may not become clinically apparent until years later. The term *congenital* means “born with,” but it does not imply or exclude a genetic basis for the birth defect. It is estimated that about 120,000 (1 in 33) babies are born with a birth defect each year in the United States. They are the most common cause of mortality in the first year and contribute significantly to morbidity and mortality throughout the early years of life. In a sense, anomalies found in live-born infants represent the less serious developmental failures in embryogenesis that are compatible with live birth. Perhaps 20% of fertilized ova are so anomalous that they are blighted from the outset. Others may be compatible with early fetal development, only to

lead to spontaneous abortion. Less severe anomalies allow more prolonged intrauterine survival, with some disorders terminating in stillbirth and those still less significant permitting live birth despite the handicaps imposed.

Definitions

The process of morphogenesis (organ and tissue development) can be impaired by a variety of different errors.

- *Malformations* represent primary errors of morphogenesis, in which there is an *intrinsically abnormal developmental process* (Fig. 10-1). Malformations can be the result of a single gene or chromosomal defect, but are more commonly multifactorial in origin. Malformations may present in several patterns. Some, such as congenital heart defects and anencephaly (absence of the brain), involve single body systems, whereas in other cases multiple malformations involving many organs may coexist.
- *Disruptions* result from secondary destruction of an organ or body region that was previously normal in development; thus, in contrast to malformations, disruptions arise from an *extrinsic disturbance in morphogenesis*. *Amniotic bands*, denoting rupture of amnion with resultant formation of “bands” that encircle, compress, or attach to parts of the developing fetus, are the classic example of a disruption (Fig. 10-2). A variety of environmental agents may cause disruptions (see later). Understandably, disruptions are not heritable and hence are not associated with risk of recurrence in subsequent pregnancies.
- *Deformations*, like disruptions, also represent an *extrinsic disturbance of development* rather than an intrinsic error of morphogenesis. Deformations are common problems, affecting approximately 2% of newborn infants to varying degrees. Fundamental to the pathogenesis of deformations is localized or generalized compression of the growing fetus by *abnormal biomechanical forces*, leading eventually to a variety of structural abnormalities. The most common underlying factor responsible for deformations is *uterine constraint*. Between the thirty-fifth and thirty-eighth weeks of gestation, rapid increase in the size of the fetus outpaces the growth of the uterus, and the relative amount of amniotic fluid (which normally acts as a cushion) also decreases. Thus, even the normal fetus is subjected to some form of uterine constraint. Several factors increase the likelihood of excessive compression of the fetus resulting in deformations. *Maternal factors* include first pregnancy, small uterus, malformed (bicornuate) uterus, and leiomyomas. *Fetal or placental factors* include oligohydramnios, multiple fetuses, and abnormal fetal presentation. An example of a deformation is clubfeet, often a component of Potter sequence, described later.
- A *sequence* is a cascade of anomalies triggered by one initiating aberration. Approximately half the time, congenital anomalies occur singly; in the remaining cases, multiple congenital anomalies are recognized. In some instances the constellation of anomalies may be explained by a single, localized aberration in organogenesis (malformation, disruption, or deformation) that

Figure 10-1 Examples of malformations. *Polydactyly* (one or more extra digits) and *syndactyly* (fusion of digits), both of which are illustrated in **A**, have little functional consequence when they occur in isolation. Similarly, *cleft lip* (**B**), with or without associated *cleft palate*, is compatible with life when it occurs as an isolated anomaly; in the present case, however, this neonate had an underlying *malformation syndrome* (trisomy 13) and died of severe cardiac defects. **C**, The stillbirth illustrated represents a severe and essentially lethal malformation, wherein the midface structures are fused or ill-formed; in almost all cases, this degree of external dysmorphogenesis is associated with severe internal anomalies such as maldevelopment of the brain and cardiac defects. (**A** and **C**, Courtesy Dr. Reade Quinton; **B**, Courtesy Dr. Beverly Rogers, Department of Pathology, University of Texas Southwestern Medical Center, Dallas, Texas.)

sets into motion secondary effects in other organs. A good example is the *oligohydramnios* (or *Potter*) *sequence* (**Fig. 10-3**). Oligohydramnios (decreased amniotic fluid) may be caused by a variety of unrelated maternal, placental, or fetal abnormalities. Causes of oligohydramnios include chronic leakage of amniotic fluid because of rupture of the amnion, uteroplacental insufficiency resulting from maternal hypertension or severe toxemia, and renal agenesis in the fetus (because fetal urine is a major constituent of amniotic fluid). The fetal compression associated with significant oligohydramnios, in

turn, results in a classic phenotype in the newborn infant, including flattened facies and positional abnormalities of the hands and feet (**Fig. 10-4**). The hips may be dislocated. Growth of the chest wall and the contained lungs is also compromised so that the lungs are frequently hypoplastic, occasionally to the degree that they are the cause of fetal demise. Nodules in the amnion (*amnion nodosum*) are frequently present.

- A *malformation syndrome* is a constellation of congenital anomalies, believed to be pathologically related, that, in contrast to a sequence, cannot be explained on the basis of a single, localized, initiating defect. Syndromes are most often caused by a single etiologic agent, such as a viral infection or specific chromosomal abnormality, which simultaneously affects several tissues.

In addition to the aforementioned general definitions, a few organ-specific terms should be defined. Agenesis

Figure 10-2 Disruption of morphogenesis by an amniotic band. Note the placenta at the right of the diagram and the band of amnion extending from the top portion of the amniotic sac to encircle the leg of the fetus. (Courtesy Dr. Theonia Boyd, Children’s Hospital of Boston, Boston, Mass.)

refers to the complete absence of an organ and its associated primordium. A closely related term, aplasia, also refers to the absence of an organ but one that occurs due to failure of growth of the existing primordium. *Atresia* describes the absence of an opening, usually of a hollow visceral organ, such as the trachea and intestine. *Hypoplasia* refers to incomplete development or decreased size of an organ with decreased numbers of cells, whereas *hyperplasia* refers to the converse, that is, the enlargement of an organ due to increased numbers of cells. An abnormality in an organ or a tissue as a result of an increase or a decrease in the size (rather than the number) of individual cells defines *hypertrophy* or *hypotrophy*, respectively. Finally, *dysplasia*, in the context of malformations (versus *neoplasia*) describes an abnormal organization of cells.

Causes of Anomalies

At one time, it was believed that the presence of a visible, external anomaly was divine punishment for wickedness, a belief that occasionally jeopardized the mother's life. Although we are learning a great deal about the molecular bases of some congenital anomalies, *the exact cause remains unknown in at least one half to three fourths of the cases. The common known causes of congenital anomalies can be grouped into three major categories: genetic, environmental, and multifactorial (Table 10-2).*

Genetic causes of malformations include all of the previously discussed mechanisms of genetic disease (Chapter 5). Virtually all chromosomal syndromes are associated with congenital malformations. Examples include Down syndrome and other trisomies, Turner syndrome, and Klinefelter syndrome. Most chromosomal disorders arise

during gametogenesis and hence are not familial. Single-gene mutations, characterized by mendelian inheritance, may underlie major malformations. For example, holoprosencephaly is the most common developmental defect of the forebrain and midface in humans; the Hedgehog signaling pathway plays a critical role in the morphogenesis of these structures, and loss-of-function mutations of individual components within this pathway are reported in families with a history of recurrent holoprosencephaly.

Environmental influences, such as viral infections, drugs, and irradiation to which the mother was exposed during pregnancy, may cause fetal anomalies. Among the viral infections listed in Table 10-2, rubella was a major scourge of the nineteenth and early twentieth centuries. Fortunately, maternal rubella and the resultant *rubella embryopathy* have been virtually eliminated in developed countries as a result of maternal rubella vaccination. A variety of drugs and chemicals have been suspected to be teratogenic, but perhaps less than 1% of congenital malformations are caused by these agents. The list includes thalidomide, alcohol, anticonvulsants, warfarin (oral anticoagulant), and 13-*cis*-retinoic acid, which is used in the treatment of severe acne. For example, *thalidomide*, once used as a tranquilizer in Europe, causes an extremely high incidence (50% to 80%) of limb malformations. *Alcohol*, when consumed even in modest amounts during pregnancy, is an important environmental teratogen. Affected infants show prenatal and postnatal growth retardation, facial anomalies (microcephaly, short palpebral fissures, maxillary

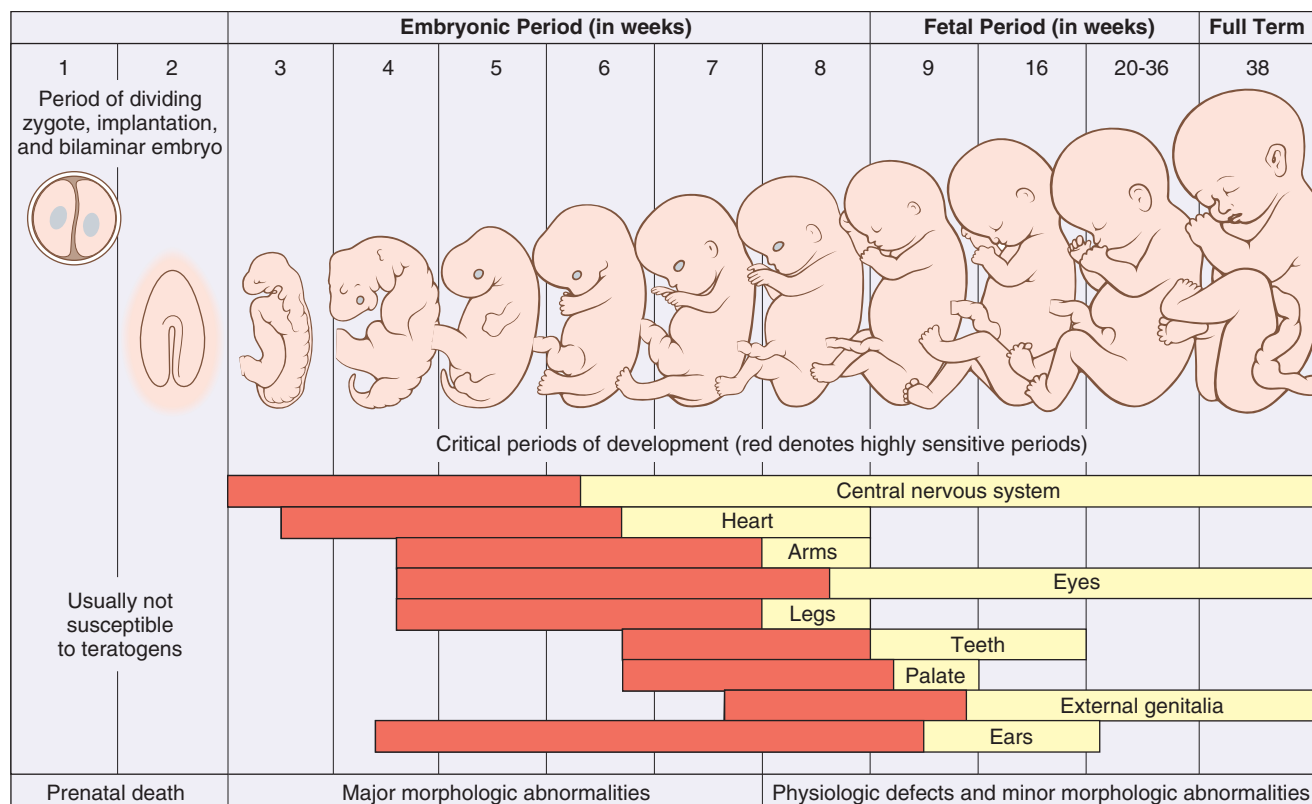

Figure 10-5 Critical periods of development for various organ systems and the resultant malformations. (Modified and redrawn from Moore KL: *The Developing Human*, 5th ed. Philadelphia, WB Saunders, 1993, p 156.)

hypoplasia), and psychomotor disturbances. These in combination are labeled the *fetal alcohol syndrome* (also discussed in [Chapter 9](#)). While cigarette smoke-derived nicotine has not been convincingly demonstrated to be a teratogen, there is a high incidence of spontaneous abortions, premature labor, and placental abnormalities in pregnant smokers; babies born to mothers who smoke often have a low birth weight and may be prone to the SIDS. *In light of these findings, it is best to avoid nicotine exposure altogether during pregnancy.* Among maternal conditions listed in [Table 10-2](#), *diabetes mellitus* is a common entity, and despite advances in antenatal obstetric monitoring and glucose control, the incidence of major malformations in infants of diabetic mothers stands between 6% and 10% in most series. Maternal hyperglycemia-induced fetal hyperinsulinemia results in fetal macrosomia (organomegaly and increased body fat and muscle mass); cardiac anomalies, neural tube defects, and other central nervous system (CNS) malformations are some of the major anomalies seen in *diabetic embryopathy*.

Multifactorial inheritance, which implies the interaction of environmental influences with two or more genes of small effect, is the most common genetic cause of congenital malformations. Included in this category are some relatively common malformations such as cleft lip, cleft palate and neural tube defects. The importance of environmental contributions to multifactorial inheritance is underscored by the dramatic reduction of the incidence of neural tube defects by periconceptional intake of folic acid in the diet.

Pathogenesis. The pathogenesis of congenital anomalies is complex and still poorly understood, but two general principles of developmental pathology are relevant regardless of the etiologic agent.

1. *The timing of the prenatal teratogenic insult has an important impact on the occurrence and the type of anomaly produced (Fig. 10-5).* The intrauterine development of humans can be divided into two phases: (1) the embryonic period occupying the first 9 weeks of pregnancy and (2) the fetal period terminating at birth.
 - In the *early embryonic period* (first 3 weeks after fertilization), an injurious agent damages either enough cells to cause death and abortion or only a few cells, presumably allowing the embryo to recover without developing defects. *Between the third and the ninth weeks, the embryo is extremely susceptible to teratogenesis, and the peak sensitivity during this period occurs between the fourth and the fifth weeks.* During this period organs are being crafted out of the germ cell layers.
 - The *fetal period* that follows organogenesis is marked chiefly by the further growth and maturation of the organs, with greatly reduced susceptibility to teratogenic agents. Instead, the fetus is susceptible to growth retardation or injury to already formed organs. It is therefore possible for a given agent to produce different anomalies if exposure occurs at different times of gestation.

2. The interplay between environmental teratogens and intrinsic genetic defects is exemplified by the fact that *features of dysmorphogenesis caused by environmental insults can often be recapitulated by genetic defects in the pathways targeted by these teratogens*. This is illustrated by the following representative examples.

- *Cyclopamine* is a plant teratogen and pregnant sheep who feed on this plant give birth to lambs that have severe craniofacial abnormalities including holoprosencephaly and “cyclopia” (single fused eye, hence the origin of the moniker cyclopamine). This compound is an inhibitor of Hedgehog signaling in the embryo, and as stated earlier, mutations of Hedgehog genes are present in subsets of patients with holoprosencephaly.
- *Valproic acid* is an antiepileptic and a recognized teratogen during pregnancy. Valproic acid disrupts expression of a family of highly conserved developmentally critical transcription factors known as *homeobox* (HOX) proteins. In vertebrates, HOX proteins have been implicated in the patterning of limbs, vertebrae, and craniofacial structures. Not surprisingly, mutations in *HOX* family of genes are responsible for congenital anomalies that mimic features observed in *valproic acid embryopathy*.
- The vitamin A (retinol) derivative *all-trans-retinoic acid* is essential for normal development and differentiation, and its absence during embryogenesis results in a constellation of malformations affecting multiple organ systems, including the eyes, genitourinary system, cardiovascular system, diaphragm, and lungs (see [Chapter 9](#) for effects of for vitamin A deficiency in the postnatal period). Conversely, *excessive exposure to retinoic acid is also teratogenic*. Infants born to mothers treated with retinoic acid for severe acne have a predictable phenotype (*retinoic acid embryopathy*), including CNS, cardiac, and craniofacial defects, such as *cleft lip and cleft palate*. The latter may stem from retinoic acid–mediated deregulation of components of the transforming growth factor- β (TGF- β) signaling pathway, which is involved in palatogenesis. Mice with knockout of the *Tgfb3* gene uniformly develop cleft palate, once again illustrating the functional relationship between teratogenic exposure and signaling pathways in the causation of congenital anomalies.

Prematurity and Fetal Growth Restriction

Prematurity, defined by a gestational age less than 37 weeks, is the second most common cause of neonatal mortality, behind only congenital anomalies (Table 10-1). The American College of Obstetrics and Gynecology estimates that 12% of all births in the United States are preterm deliveries, and despite extensive research into this area, this rate has increased over the last two decades. The major risk factors for prematurity include:

- *Preterm premature rupture of placental membranes* (PPROM): PPRM complicates about 3% of all

pregnancies and is responsible for as many as a third of all preterm deliveries. Rupture of membranes (ROM) before the onset of labor can be spontaneous or induced. PPRM refers to spontaneous ROM occurring *before 37 weeks' gestation* (hence the annotation “preterm”). In contrast, PROM refers to spontaneous ROM occurring *after 37 weeks' gestation*. This distinction is important because after 37 weeks the associated risk to the fetus is considerably decreased. Several clinical risk factors have been identified for PPRM, including a prior history of preterm delivery, preterm labor and/or vaginal bleeding during the current pregnancy, maternal smoking, low socioeconomic status, and poor maternal nutrition. The fetal and maternal outcome after PPRM depends on the gestation age of the fetus (second-trimester PPRM has a dismal prognosis), and the effective prophylaxis of infections in the exposed amniotic cavity.

- *Intrauterine infection*: This is a major cause of preterm labor with and without intact membranes. Intrauterine infection is present in approximately 25% of all preterm births, and the earlier the gestational age at delivery, the higher the frequency of intra-amniotic infection. The histologic correlates of intrauterine infection are inflammation of the placental membranes (*chorioamnionitis*) and inflammation of the fetal umbilical cord (*funisitis*). The most common microorganisms implicated in intrauterine infections leading to preterm labor are *Ureaplasma urealyticum*, *Mycoplasma hominis*, *Gardnerella vaginalis* (the dominant organism found in “bacterial vaginosis,” a polymicrobial infection), *Trichomonas*, gonorrhea, and *Chlamydia*. In developing countries, malaria and HIV are significant contributors to the burden of preterm labor and prematurity. Recent studies have begun to elucidate the molecular mechanisms of inflammation-induced preterm labor. Endogenous Toll-like receptors (TLRs), which bind bacterial components as natural ligands ([Chapter 6](#)), have emerged as key players in this process. It is postulated that signals produced by TLR engagement deregulate prostaglandin expression, which in turn induces uterine smooth muscle contractions.
- *Uterine, cervical, and placental structural abnormalities*: Uterine distortion (e.g., uterine fibroids), compromised structural support of the cervix (“cervical incompetence”), *placenta previa*, and *abruptio placentae* ([Chapter 22](#)) are associated with an increased risk of prematurity.
- *Multiple gestation* (twin pregnancy).

The hazards of prematurity are manifold for the newborn and may give rise to one or more of the following:

- Neonatal respiratory distress syndrome, also known as hyaline membrane disease
- Necrotizing enterocolitis
- Sepsis
- Intraventricular and germinal matrix hemorrhage

Fetal Growth Restriction

Although preterm infants have low birth weights, it is usually appropriate once adjusted for their gestational age. In contrast, as many as one third of infants who weigh less than 2500 gm are born at term and are therefore undergrown rather than immature. These

small-for-gestational-age (SGA) infants suffer from *fetal growth restriction*. Fetal growth restriction (FGR) may result from fetal, maternal, or placental abnormalities, although in many cases the specific cause is unknown.

Fetal Abnormalities. Fetal influences are those that intrinsically reduce growth potential of the fetus despite an adequate supply of nutrients from the mother. Prominent among such fetal conditions are *chromosomal disorders, congenital anomalies, and congenital infections*. Chromosomal abnormalities may be detected in up to 17% of fetuses sampled for FGR and in up to 66% of fetuses with documented ultrasonographic malformations. Among the first group, the abnormalities include triploidy (7%), trisomy 18 (6%), trisomy 21 (1%), trisomy 13 (1%), and a variety of deletions and translocations (2%). *Fetal infection* should be considered in all infants with FGR. Those most commonly responsible for FGR are the TORCH group of infections (toxoplasmosis, rubella, cytomegalovirus, herpesvirus, and other viruses and bacteria, such as syphilis). Infants who are SGA because of fetal factors usually have symmetric growth restriction (also referred to as *proportionate FGR*), meaning that all organ systems are similarly affected.

Placental Abnormalities. During the third trimester of pregnancy, vigorous fetal growth places particularly heavy demands on the uteroplacental blood supply. Therefore, the adequacy of placental growth in the preceding mid-trimester is extremely important, and *uteroplacental insufficiency is an important cause of growth restriction*. This insufficiency may result from *umbilical-placental vascular anomalies* (such as single umbilical artery, abnormal cord insertion, placental hemangioma), *placental abruptio*, *placenta previa*, *placental thrombosis and infarction*, *placental infection*, or *multiple gestations* (Chapter 22). In some cases the placenta may be small without any detectable underlying cause. Placental causes of FGR tend to result in *asymmetric* (or disproportionate) growth retardation of the fetus with relative sparing of the brain. Physiologically, this general type of FGR is viewed as a down-regulation of growth in the latter half of gestation because of limited availability of nutrients or oxygen.

Maternal Abnormalities. By far the most common factors associated with SGA infants are maternal conditions that result in decreased placental blood flow. Vascular diseases, such as *preeclampsia (toxemia of pregnancy)* and *chronic hypertension*, are often the underlying cause. Another class of maternal diseases increasingly being recognized in the setting of FGR are *thrombophilias*, such as the acquired antiphospholipid antibody syndrome (Chapter 6). Inherited diseases of hypercoagulability are also associated with recurrent early pregnancy losses. The list of other maternal conditions associated with SGA infants is long, but some of the avoidable factors worth mentioning are *maternal narcotic abuse, alcohol intake, and heavy cigarette smoking*. *Drugs* causing FGR include both classic teratogens, such as chemotherapeutic agents, and some commonly administered therapeutic agents, such as phenytoin (Dilantin). *Maternal malnutrition* (in particular, prolonged hypoglycemia) may also affect fetal growth, but the association between SGA infants and the nutritional status of the mother is complex.

The SGA infant faces a difficult course, not only during the struggle for survival in the perinatal period, but also in childhood and adult life. Depending on the underlying cause of FGR and, to a lesser extent, the degree of prematurity, there is a significant risk of morbidity in the form of a major handicap, cerebral dysfunction, learning disability, or hearing and visual impairment.

Neonatal Respiratory Distress Syndrome

There are many causes of respiratory distress in the newborn. The most common cause is respiratory distress syndrome (RDS), also known as hyaline membrane disease because of the deposition of a layer of hyaline proteinaceous material in the peripheral airspaces of infants who succumb to this condition. Others include excessive sedation of the mother, fetal head injury during delivery, aspiration of blood or amniotic fluid, and intra-uterine hypoxia brought about by coiling of the umbilical cord about the neck. An estimated 24,000 cases of RDS are reported annually in the United States. Thankfully, improvements in management of this condition have sharply decreased deaths due to respiratory insufficiency from as many as 5000 per year a decade earlier to less than 900 cases per year currently.

In untreated infants (not receiving surfactant), RDS generally presents in a stereotypical fashion, with characteristic clinical findings. The infant is almost always preterm but has weight appropriate for gestational age, and there are strong, but not invariable, associations with *male gender, maternal diabetes, and delivery by cesarean section*. Resuscitation may be necessary at birth, but usually within a few minutes rhythmic breathing and normal color are reestablished. Soon afterward, often within 30 minutes, breathing becomes more difficult, and within a few hours cyanosis becomes evident. Fine rales can now be heard over both lung fields. A chest x-ray film at this time usually reveals uniform minute reticulogranular densities, producing a so-called *ground-glass picture*. In the full-blown condition the respiratory distress persists, cyanosis increases, and even the administration of 80% oxygen by a variety of ventilatory methods fails to improve the situation. If therapy staves off death for the first 3 or 4 days, however, the infant has an excellent chance of recovery.

Pathogenesis. Immaturity of the lungs is the most important substrate on which RDS develops. It may be encountered in full-term infants but is much more frequent in those “born before their time into this breathing world.” The incidence of RDS is inversely proportional to gestational age. It occurs in about 60% of infants born at less than 28 weeks of gestation, 30% of those born between 28 to 34 weeks’ gestation, and less than 5% of those born after 34 weeks’ gestation.

The fundamental defect in RDS is a deficiency of pulmonary surfactant. As described in Chapter 15, surfactant consists predominantly of dipalmitoyl phosphatidylcholine (lecithin), smaller amounts of phosphatidylglycerol, and two groups of surfactant-associated proteins. The first group is composed of hydrophilic glycoproteins SP-A and SP-D, which play a role in pulmonary host defense (innate immunity). The second group consists of hydrophobic surfactant proteins SP-B and SP-C, which, in concert with the

surfactant lipids, are involved in the reduction of surface tension at the air-liquid barrier in the alveoli of the lung. With reduced surface tension in the alveoli, less pressure is required to keep them patent and hence aerated. The importance of surfactant proteins in normal lung function can be gauged by the occurrence of severe respiratory failure in neonates with congenital deficiency of surfactant caused by mutations in the *SFTPB* or *SFTBC* genes.

Surfactant production by type II alveolar cells is accelerated after the thirty-fifth week of gestation in the fetus. At birth, the first breath of life requires high inspiratory pressures to expand the lungs. With normal levels of surfactant, the lungs retain up to 40% of the residual air volume after the first breath; thus, subsequent breaths require far lower inspiratory pressures. With a deficiency of surfactant, the lungs collapse with each successive breath, and so infants must work as hard with each successive breath as they did with the first. The problem of *stiff* atelectatic lungs is compounded by the *soft* thoracic wall that is pulled in as the diaphragm descends. Progressive atelectasis and reduced lung compliance then lead to a train of events as depicted in Figure 10-6, resulting in protein-rich, fibrin-rich exudation into the alveolar spaces with the formation of hyaline membranes. The fibrin-hyaline membranes are barriers to gas exchange, leading to carbon dioxide retention and hypoxemia. The hypoxemia itself further impairs surfactant synthesis, and a vicious cycle ensues.

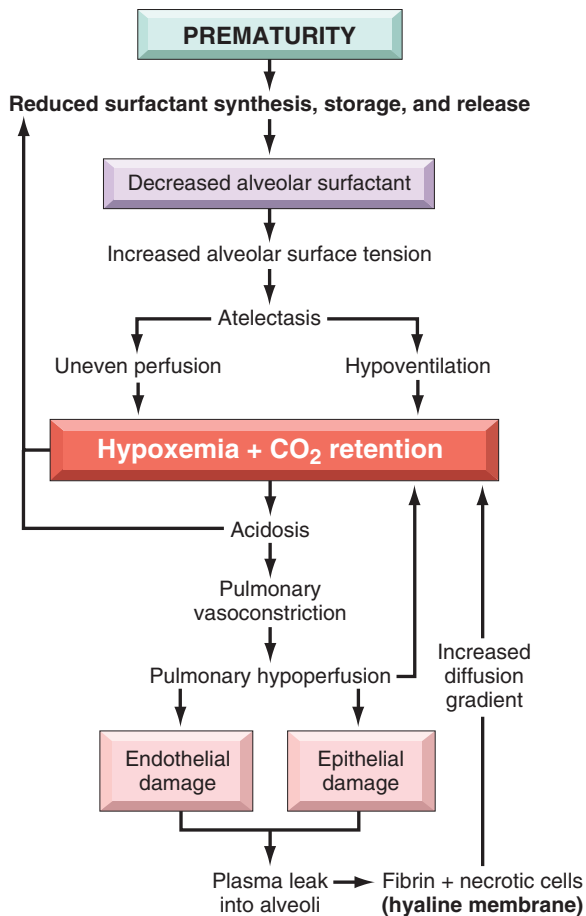

Figure 10-6 Schematic outline of the pathophysiology of respiratory distress syndrome (see text).

Figure 10-7 Hyaline membrane disease. There is alternating atelectasis and dilation of the alveoli. Note the eosinophilic thick hyaline membranes lining the dilated alveoli.

Surfactant synthesis is modulated by a variety of hormones and growth factors, including cortisol, insulin, prolactin, thyroxine, and TGF- β . The role of glucocorticoids is particularly important. Conditions associated with intrauterine stress and FGR that increase corticosteroid release lower the risk of developing RDS. Surfactant synthesis can be suppressed by the compensatory high blood levels of insulin in infants of diabetic mothers, which counteracts the effects of steroids. This may explain, in part, why infants of diabetic mothers have a higher risk of developing RDS. Labor is known to increase surfactant synthesis; hence, cesarean section before the onset of labor may increase the risk of RDS.

MORPHOLOGY

The lungs are distinctive on gross examination. Though of normal size, they are solid, airless, and reddish purple, similar to the color of the liver, and they usually sink in water. Microscopically, alveoli are poorly developed, and those that are present are collapsed (Fig. 10-7). When the infant dies early in the course of the disease, necrotic cellular debris can be seen in the terminal bronchioles and alveolar ducts. The necrotic material becomes incorporated within **eosinophilic hyaline membranes** lining the respiratory bronchioles, alveolar ducts, and alveoli. The membranes are largely made up of fibrin admixed with cell debris derived chiefly from necrotic type II pneumocytes. The sequence of events that leads to the formation of hyaline membranes is depicted in Figure 10-6. There is a remarkable paucity of neutrophilic inflammatory reaction associated with these membranes. The lesions of hyaline membrane disease are never seen in stillborn infants.

In infants who survive more than 48 hours, reparative changes occur in the lungs. The alveolar epithelium proliferates under the surface of the membrane, and may detach into the airspace where it undergoes partial digestion or phagocytosis by macrophages.

Clinical Features. The classic clinical presentation before the era of treatment with exogenous surfactant was described earlier. Currently, the actual clinical course and prognosis for neonatal RDS vary, depending on the maturity and birth weight of the infant and the promptness

of institution of therapy. A major thrust in the control of RDS focuses on prevention, either by delaying labor until the fetal lung reaches maturity or by inducing maturation of the lung in the fetus at risk. Critical to these objectives is the ability to assess fetal lung maturity accurately. Because pulmonary secretions are discharged into the amniotic fluid, analysis of amniotic fluid phospholipids provides a good estimate of the level of surfactant in the alveolar lining. Prophylactic administration of exogenous surfactant at birth to extremely premature infants (gestational age < 28 weeks) has been shown to be very beneficial, such that it is now uncommon for infants to die of acute RDS.

In uncomplicated cases, recovery begins to occur within 3 or 4 days. In affected neonates, oxygen is required. However, high concentration of ventilator-administered oxygen for prolonged periods is associated with two well-known complications: *retrolental fibroplasia* (also called *retinopathy of prematurity*) in the eyes, and *bronchopulmonary dysplasia*. Fortunately, both complications are now infrequent as a result of gentler ventilation techniques, antenatal glucocorticoid therapy, and prophylactic surfactant treatments.

- Retinopathy of prematurity has a two-phase pathogenesis. During the *hyperoxic* phase of RDS therapy (phase I), expression of the proangiogenic vascular endothelial growth factor (VEGF) is markedly decreased, causing endothelial cell apoptosis; VEGF levels rebound after return to relatively hypoxic room air ventilation (phase II), inducing retinal vessel proliferation (*neovascularization*) characteristic of the lesions in the retina.
- The major abnormality in *bronchopulmonary dysplasia* is striking decrease in alveolar septation (manifested as large, simplified alveolar structures) and a dysmorphic capillary configuration. Thus, the current view is that bronchopulmonary dysplasia is caused by a potentially reversible impairment in the development of alveolar septation at the so-called “saccular” stage. Multiple factors—hyperoxemia, hyperventilation, prematurity, inflammatory cytokines, and vascular maldevelopment—contribute to bronchopulmonary dysplasia and probably act additively or synergistically to promote injury. The levels of a variety of proinflammatory cytokines (TNF, interleukin-1 β [IL-1 β], IL-6, and IL-8) are increased in the alveoli of infants who develop bronchopulmonary dysplasia, suggesting a role for these cytokines in arresting pulmonary development.

Infants who recover from RDS are also at increased risk for developing a variety of other complications associated with preterm birth; most important among these are *patent ductus arteriosus*, *intraventricular hemorrhage*, and *necrotizing enterocolitis*. Thus, although technologic advances help save the lives of many infants with RDS, it also brings to the surface the exquisite fragility of the immature neonate.

Necrotizing Enterocolitis

Necrotizing enterocolitis is most common in premature infants, with the incidence of the disease being inversely proportional to the gestational age. It occurs in approximately 1 out of 10 very low birth weight infants (<1500 gm). Approximately 2500 cases occur annually in the United States.

The pathogenesis of necrotizing enterocolitis is uncertain, but is in all likelihood multifactorial. In addition to prematurity, most cases are associated with enteral feeding, suggesting that some postnatal insult (such as introduction of bacteria) sets in motion the cascade culminating in tissue destruction. While infectious agents likely play a role in the pathogenesis of necrotizing enterocolitis, no single bacterial pathogen has been linked to the disease. A large number of inflammatory mediators have been associated with necrotizing enterocolitis, and their discussion is beyond the scope of this book. One particular mediator, platelet activating factor (PAF), has been implicated in increasing mucosal permeability by promoting enterocyte apoptosis and compromising intercellular tight junctions, thus adding “fuel to the fire.” Stool and serum samples of infants with necrotizing enterocolitis demonstrate higher PAF levels than age-matched controls. Ultimately, breakdown of mucosal barrier functions permits transmural migration of gut bacteria, leading to a vicious cycle of inflammation, mucosal necrosis, and further bacterial entry, eventually culminating in sepsis and shock (Chapter 4).

The clinical course is fairly typical, with the onset of bloody stools, abdominal distention, and development of circulatory collapse. Abdominal radiographs often demonstrate gas within the intestinal wall (*pneumatosis intestinalis*).

MORPHOLOGY

Necrotizing enterocolitis typically involves the terminal ileum, cecum, and right colon, although any part of the small or large intestines may be involved. The involved segment is distended, friable, and congested, or it can be frankly gangrenous; intestinal perforation with accompanying peritonitis may be seen. Microscopically, mucosal or transmural coagulative necrosis, ulceration, bacterial colonization, and submucosal gas bubbles may be seen (Fig. 10-8). Reparative changes, such as the formation of granulation tissue and fibrosis, may begin shortly after the acute episode. When detected early on, necrotizing enterocolitis can be often managed conservatively, but many cases (20% to 60%) require resection of the necrotic segments of bowel. Necrotizing enterocolitis is associated with high perinatal mortality; those who survive often develop post-necrotizing enterocolitis strictures from fibrosis caused by the healing process.

Perinatal Infections

In general, fetal and perinatal infections are acquired through one of two primary routes—transcervically (also referred to as ascending) or transplacentally (hematologic). Occasionally, infections occur by a combination of the two routes in that an ascending microorganism infects the endometrium and then invades the fetal bloodstream via the chorionic villi.

Transcervical (Ascending) Infections

Most bacterial and a few viral (e.g., herpes simplex II) infections are acquired by the cervicovaginal route. Such infections may be acquired in utero or around the time of

Figure 10-8 Necrotizing enterocolitis (NEC). **A**, Postmortem examination in a severe case of NEC shows the entire small bowel is markedly distended with a perilously thin wall (usually this implies impending perforation). **B**, The congested portion of the ileum corresponds to areas of hemorrhagic infarction and transmural necrosis microscopically. Submucosal gas bubbles (*pneumatosis intestinalis*) can be seen in several areas (arrows).

birth. In general the fetus acquires the infection either by inhaling infected amniotic fluid into the lungs shortly before birth or by passing through an infected birth canal during delivery. As stated before, preterm birth is a common and unfortunate consequence of infection. Preterm birth due to infection may be related either to damage and rupture of the amniotic sac as a direct consequence of the inflammation or to the induction of labor by prostaglandins released from infiltrating neutrophils. Inflammation of the placental membranes and cord are usually seen, but the presence or absence and severity of chorioamnionitis do not necessarily correlate with the severity of the fetal infection. In the fetus infected by inhalation of amniotic fluid, pneumonia, sepsis, and meningitis are the most common sequelae.

Transplacental (Hematologic) Infections

Most parasitic (e.g., toxoplasma, malaria) and viral infections and a few bacterial infections (i.e., *Listeria*, *Treponema*) gain access to the fetal bloodstream transplacentally via the chorionic villi. This hematogenous transmission may occur at any time during gestation or occasionally, as may be the case with hepatitis B and HIV, at the time of delivery via maternal-to-fetal transfusion. The clinical manifestations of these infections are highly variable, depending largely on the gestational timing and microorganism involved.

Parvovirus B19, which causes erythema infectiosum or “fifth disease of childhood” in immunocompetent older children, can infect 1% to 5% of seronegative (non-immune) pregnant women, and the vast majority have a normal pregnancy outcome. Adverse pregnancy outcomes in a minority of intrauterine infections include spontaneous abortion (particularly in the second trimester), stillbirth, hydrops fetalis (see later), and congenital anemia. Parvovirus B19 has a particular tropism for erythroid cells, and diagnostic viral inclusions can be seen in early erythroid progenitors in infected infants (Fig. 10-9).

The *TORCH* group of infections (see earlier) are grouped together because they may evoke similar clinical and pathologic manifestations, including fever, encephalitis, chorioretinitis, hepatosplenomegaly, pneumonitis, myocarditis, hemolytic anemia, and vesicular or hemorrhagic skin lesions. Such infections occurring early in gestation may also cause chronic sequelae in the child, including growth and mental retardation, cataracts, congenital cardiac anomalies, and bone defects.

Sepsis

Perinatal sepsis can be grouped clinically based on early onset (within the first 7 days of life) versus late onset (from 7 days to 3 months). Most cases of early-onset sepsis are acquired at or shortly before birth and tend to result in clinical signs and symptoms of pneumonia, sepsis, and occasionally meningitis within 4 or 5 days of life. Group B

streptococcus is the most common cause of early-onset sepsis as well as early-onset bacterial meningitis. Infections with *Listeria* and *Candida* have longer latent periods between the time of microorganism inoculation and the appearance of clinical symptoms and present as late-onset sepsis.

Fetal Hydrops

Fetal hydrops refers to the accumulation of edema fluid in the fetus during intrauterine growth. Until recently, hemolytic anemia caused by Rh blood group incompatibility between mother and fetus (*immune hydrops*) was the most common cause, but with the successful prophylaxis of this disorder during pregnancy, causes of *nonimmune hydrops* have emerged as the principal culprits (Table 10-3). The intrauterine fluid accumulation can be quite variable, from progressive, generalized edema of the fetus (*hydrops fetalis*), a usually lethal condition, to more localized degrees of edema, such as isolated pleural and peritoneal effusions, or postnuchal fluid accumulation (*cystic hygroma*, see later) that are compatible with life.

Immune Hydrops

Immune hydrops is a hemolytic disease caused by blood group antigen incompatibility between mother and fetus. When the fetus inherits red cell antigenic determinants from the father that are foreign to the mother, a maternal

The cause of fetal hydrops may be undetermined ("idiopathic") in up to 20% of cases. Data from Machin GA: Hydrops, cystic hygroma, hydrothorax, pericardial effusions, and fetal ascites. In Gilbert-Barness E, et al (eds): *Potter's Pathology of the Fetus, Infant, and Child*. St. Louis, Mosby, 2007, p 33.

Figure 10-10 Pathogenesis of immune hydrops fetalis (see text).

immune reaction may occur. The major antigens known to induce clinically significant immunologic reactions are certain of the Rh antigens and the ABO blood groups. The reaction occurs in second and subsequent pregnancies in an Rh-negative mother with an Rh-positive father.

Etiology and Pathogenesis. The underlying basis of immune hydrops is the immunization of the mother by blood group antigens on fetal red cells and the free passage of antibodies from the mother through the placenta to the fetus (Fig. 10-10). Fetal red cells may reach the maternal circulation during the last trimester of pregnancy, when the cytotrophoblast is no longer present as a barrier, or during childbirth itself. The mother thus becomes sensitized to the foreign antigen. The initial exposure to Rh antigen evokes the formation of IgM antibodies, that unlike IgG antibodies, do not cross the placenta. Thus, Rh disease is uncommon with the first pregnancy. Exposure during a subsequent pregnancy generally leads to a brisk IgG antibody response and the risk of immune hydrops.

Of the numerous antigens included in the Rh system, only the D antigen is a major cause of Rh incompatibility. Several factors influence the immune response to Rh-positive fetal red cells that reach the maternal circulation.

- Concurrent ABO incompatibility protects the mother against Rh immunization, because the fetal red cells

are promptly coated and removed from the maternal circulation by anti-A or anti-B IgM antibodies that do not cross the placenta.

- The antibody response depends on the dose of immunizing antigen; hence, hemolytic disease develops only when the mother has experienced a significant transplacental bleed (>1 mL of Rh-positive fetal red cells).

The incidence of maternal Rh isoimmunization has decreased significantly since the use of Rhesus immune globulin (RhIg) containing anti-D antibodies. Administration of RhIg at 28 weeks and within 72 hours of delivery to Rh-negative mothers significantly decreases the risk for hemolytic disease in Rh-positive neonates and in subsequent pregnancies; RhIg is also administered following abortions, because these too can lead to immunization. Antenatal identification and management of the at-risk fetus have been greatly facilitated by amniocentesis and the advent of chorionic villus and fetal blood sampling. In addition, cloning of the *RHD* gene has resulted in efforts to determine fetal Rh status using maternal serum since it contains fetal DNA. When identified, cases of severe intrauterine hemolysis may be treated by fetal intravascular transfusions via the umbilical cord and early delivery.

The pathogenesis of fetal hemolysis caused by maternal-fetal ABO incompatibility is slightly different from that caused by differences in the Rh antigens. ABO incompatibility occurs in approximately 20% to 25% of pregnancies, but laboratory evidence of hemolytic disease occurs in only 1 in 10 of such infants, and the hemolytic disease is severe enough to require treatment in only 1 in 200 cases. Several factors account for this. First, as mentioned, most anti-A and anti-B antibodies are of the IgM type and hence do not cross the placenta. Second, neonatal red cells express blood group antigens A and B poorly. Third, many cells other than red cells express A and B antigens and thus absorb some of the transferred antibody. ABO hemolytic disease occurs almost exclusively in infants of group A or B who are born of group O mothers. For reasons unknown, certain group O women possess IgG antibodies directed against group A or B antigens (or both) even without prior sensitization. Therefore, the firstborn may be affected. Fortunately, even with transplacentally acquired antibodies, lysis of the infant's red cells is minimal. There is no effective protection against ABO reactions.

There are two consequences of excessive destruction of red cells in the neonate (Fig. 10-10). The severity of these changes varies considerably, depending on the degree of hemolysis and the maturity of the infant.

- **Anemia** is a direct result of red cell loss. If hemolysis is mild, increased red cell production may suffice to maintain near normal levels of red cells. However, with more severe hemolysis, progressive anemia develops and may result in hypoxic injury to the heart and liver. Because of liver injury, plasma protein synthesis decreases, and levels of these proteins may drop to as low as 2 to 2.5 mg/dL. Cardiac hypoxia may lead to cardiac decompensation and failure. The combination of reduced plasma oncotic pressure and increased hydrostatic pressure in the circulation (secondary to cardiac failure) results in generalized edema and anasarca, culminating in hydrops fetalis.

- **Jaundice** develops because hemolysis produces unconjugated bilirubin (Chapter 18). Bilirubin also passes through the infant's poorly developed blood-brain barrier. Being water insoluble, bilirubin binds to lipids in the brain, and can damage the CNS, causing *kernicterus* (see Fig. 10-13).

Nonimmune Hydrops

The three major causes of nonimmune hydrops include cardiovascular defects, chromosomal anomalies, and fetal anemia (Table 10-3). Both structural and functional cardiovascular defects, such as congenital malformations and arrhythmias, may result in intrauterine cardiac failure and hydrops. Among the chromosomal anomalies, 45,X karyotype (Turner syndrome) and the trisomies 21 and 18 are associated with fetal hydrops because of the accompanying structural cardiac anomalies. In Turner syndrome, abnormalities of lymphatic drainage from the neck may lead to postnuchal fluid accumulation (*cystic hygromas*) as well. Fetal anemia, not caused by Rh- or ABO-associated antibodies, can also result in hydrops. In fact, in some parts of the world (e.g., Southeast Asia), severe fetal anemia due to homozygous α -thalassemia, resulting from deletion of all four α -globin genes, is probably the most common cause of nonimmune hydrops (Chapter 14). Transplacental infection by parvovirus B19 is rapidly emerging as an important cause of hydrops (see earlier). The virus gains preferential entry into erythroid precursors (normoblasts), where it replicates, leading to apoptosis of red cell progenitors and isolated red cell aplasia. Parvoviral intranuclear inclusions can be seen within circulating and marrow erythroid precursors (Fig. 10-9). Approximately 10% of cases of nonimmune hydrops are related to monozygous twin pregnancies and twin-to-twin transfusion occurring through anastomoses between the two circulations.

MORPHOLOGY

The anatomic findings in fetuses with intrauterine fluid accumulation vary with both the severity of the disease and the underlying etiology. As previously noted, hydrops fetalis represents the most severe and generalized manifestation (Fig. 10-11), and lesser degrees of edema such as isolated pleural, peritoneal, or postnuchal fluid collections can occur. Accordingly, infants may be stillborn, die within the first few days, or recover completely. The presence of dysmorphic features suggests a chromosomal abnormality; postmortem examination may reveal an underlying cardiac anomaly.

In hydrops associated with fetal anemia, both fetus and placenta are characteristically pale; in most cases the liver and spleen are enlarged from cardiac failure and congestion. Additionally, the bone marrow demonstrates compensatory hyperplasia of erythroid precursors (parvovirus-associated red cell aplasia being a notable exception), and extramedullary hematopoiesis is present in the liver, spleen, and lymph nodes, and possibly other tissues such as the kidneys, lungs, and even the heart. The increased hematopoietic activity accounts for the presence in the peripheral circulation of large numbers of immature red cells, including reticulocytes, normoblasts, and erythroblasts (**erythroblastosis fetalis**) (Fig. 10-12).

Figure 10-11 Hydrops fetalis. **A**, There is generalized accumulation of fluid in the fetus. **B**, Fluid accumulation is particularly prominent in the soft tissues of the neck, and this condition has been termed *cystic hygroma*. Cystic hygromas are characteristically seen, but not limited to, constitutional chromosomal anomalies such as 45,X karyotypes. (Courtesy Dr. Beverly Rogers, Department of Pathology, University of Texas Southwestern Medical Center, Dallas, Texas.)

The most serious threat in fetal hydrops is CNS damage, known as **kernicterus** (Fig. 10-13). The affected brain is enlarged and edematous and, when sectioned, has a bright yellow color, particularly the basal ganglia, thalamus, cerebellum, cerebral gray matter, and spinal cord. The precise level of bilirubin that induces kernicterus is unpredictable, but neural damage usually requires a blood bilirubin level greater than 20 mg/dL in term infants; in premature infants this threshold may be considerably lower.

Clinical Features. The clinical manifestations of fetal hydrops vary with the severity of the disease and can be inferred from the preceding discussion. Minimally affected

Figure 10-12 Numerous islands of extramedullary hematopoiesis (small blue cells) are scattered among mature hepatocytes in the liver of this infant with nonimmune hydrops fetalis.

infants display pallor, possibly accompanied by hepatosplenomegaly (to which may be added jaundice with more severe hemolytic reactions), whereas the most gravely ill neonates present with intense jaundice, generalized edema, and signs of neurologic injury. These infants may be supported by a variety of measures, including phototherapy (visual light oxidizes toxic unconjugated bilirubin to harmless, readily excreted, water-soluble dipyrroles) and, in severe cases, total exchange transfusion of the infant.

Figure 10-13 Kernicterus. Note the yellow discoloration of the brain parenchyma due to bilirubin accumulation, which is most prominent in the basal ganglia deep to the ventricles.

Inborn Errors of Metabolism and Other Genetic Disorders

Inborn errors of metabolism are well-characterized genetic abnormalities that give rise to metabolic disorders. Since Sir Archibald Garrod coined the term in 1908, the number of such diseases that have been recognized has increased exponentially and a comprehensive discussion of these diseases is beyond the scope of this chapter. *Most inborn errors of metabolism are rare diseases that are generally inherited as autosomal recessive or X-linked traits (Chapter 5).* Mitochondrial disorders (Chapter 5) form a distinct entity by themselves. Some of the clinical features that suggest an underlying metabolic disorder in a neonate are listed in Table 10-4. Three genetic disorders of metabolism, phenylketonuria (PKU), galactosemia, and cystic fibrosis, are selected for discussion here. PKU and galactosemia are reviewed because their early diagnosis (via neonatal screening programs) is particularly important and with appropriate dietary regimens early death or mental retardation can be prevented. Cystic fibrosis is included because it is one of the most common, potentially lethal diseases occurring in individuals of Caucasian descent.

Phenylketonuria

There are several variants of this inborn error of metabolism, which affects 1 in 10,000 live-born Caucasian infants. The most common form, referred to as *classic phenylketonuria*, is quite common in persons of Scandinavian descent and is distinctly uncommon in African American and Jewish populations.

Figure 10-14 The phenylalanine hydroxylase system. Deficiency of PAH and DHPR can give rise to phenylketonuria.

Phenylketonuria (PKU) is an autosomal recessive disorder caused by a severe deficiency of the enzyme phenylalanine hydroxylase (PAH) and the resultant hyperphenylalaninemia. Affected infants are normal at birth but within a few weeks develop a rising plasma phenylalanine level, which impairs brain development. Usually by 6 months of life *severe mental retardation* becomes evident; fewer than 4% of untreated phenylketonuric children have IQs greater than 50 or 60. About one third of these children are never able to walk, and two thirds cannot talk. *Seizures*, other neurologic abnormalities, *decreased pigmentation of hair and skin*, and *eczema* often accompany the *mental retardation* in untreated children. Hyperphenylalaninemia and the resultant mental retardation can be avoided by restricting phenylalanine intake early in life. Hence, several screening procedures are routinely performed to detect PKU in the immediate postnatal period.

Many female PKU patients, if treated with dietary restriction early in life, reach childbearing age and are clinically asymptomatic. Most of them have marked hyperphenylalaninemia, because dietary treatment is discontinued after they reach adulthood. Between 75% and 90% of children born to such women are mentally retarded and microcephalic, and 15% have congenital heart disease, even though the infants themselves are heterozygotes. This syndrome, termed *maternal PKU*, results from the teratogenic effects of phenylalanine or its metabolites that cross the placenta and affect specific fetal organs during development. The presence and severity of the fetal anomalies directly correlate with the maternal phenylalanine level, so it is imperative that maternal dietary restriction of phenylalanine be initiated before conception and continued throughout pregnancy.

The biochemical abnormality in PKU is an inability to convert phenylalanine into tyrosine. In normal children, less than 50% of the dietary intake of phenylalanine is necessary for protein synthesis. The remainder is converted to tyrosine by the phenylalanine hydroxylase system (Fig. 10-14). When phenylalanine metabolism is blocked because of a lack of PAH enzyme, minor shunt pathways come into play, yielding several intermediates that are excreted in large amounts in the urine and in the sweat. These impart a *strong musty or mousy odor* to affected infants. It is believed that excess phenylalanine or its metabolites contribute to the brain damage in PKU. Concomitant lack of tyrosine (Fig. 10-14), a precursor of melanin, is responsible for the light color of hair and skin.

At the molecular level, approximately 500 mutant alleles of the *PAH* gene have been identified, only some of which cause a severe deficiency of the enzyme and thus result in classic PKU. Infants with mutations resulting in a complete lack of PAH activity present with the classic features of PKU, while those with up to 6% residual activity present

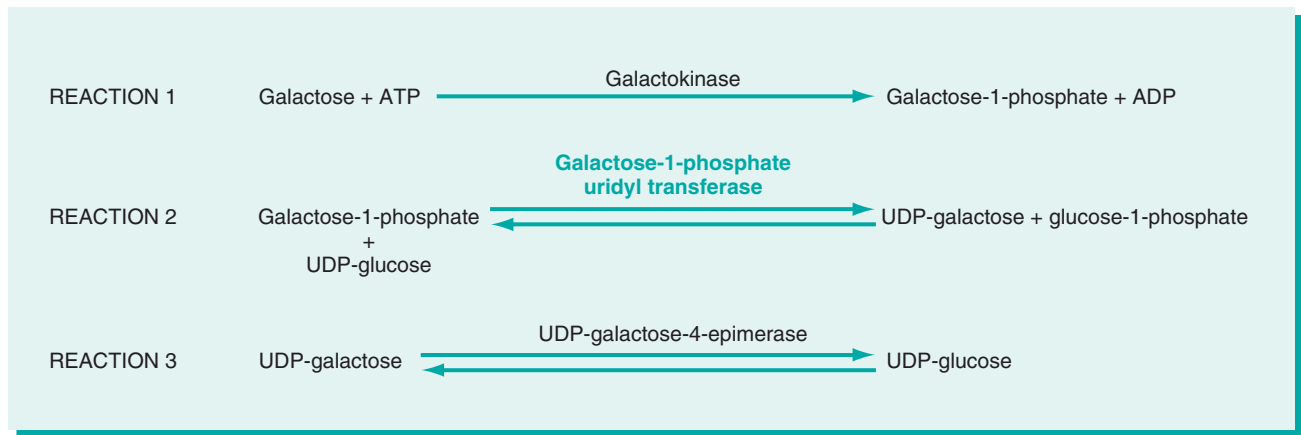

Figure 10-15 Pathways of galactose metabolism. ADP, Adenosine diphosphate; ATP, adenosine triphosphate; UDP, uridine diphosphate.

with milder disease. Moreover, some mutations result in only modest elevations of blood phenylalanine levels without associated neurologic damage. This latter condition, referred to as *benign hyperphenylalaninemia*, is important to recognize, because these individuals may well have positive screening tests but do not develop the stigmata of classic PKU. Because of the numerous disease-causing alleles of the phenylalanine hydroxylase gene, molecular diagnosis is not feasible, and measurement of serum phenylalanine levels is necessary to differentiate benign hyperphenylalaninemia from PKU; the levels in the latter are typically five-fold or more above normal. Once a biochemical diagnosis is established, the specific mutation causing PKU can be determined. With the identification of the mutation, carrier testing of at-risk family members can be performed.

While 98% of PKU is attributable to mutations in PAH, approximately 2% occur due to abnormalities in synthesis or recycling of the cofactor *tetrahydrobiopterin* BH₄ (Fig. 10-14). It is clinically important to recognize these variant forms of PKU, because they cannot be treated by dietary restriction of phenylalanine.

Galactosemia

Galactosemia is an autosomal recessive disorder of galactose metabolism resulting from accumulation of galactose-1-phosphate in tissues. Normally, lactose, the major carbohydrate of mammalian milk, is split into glucose and galactose in the intestinal microvilli by lactase. Galactose is then converted to glucose in three steps (Fig. 10-15). Two variants of galactosemia have been identified. In the more common variant there is a total lack of galactose-1-phosphate uridyl transferase (also known as GALT) involved in reaction 2. The rare variant arises from a deficiency of galactokinase, involved in reaction 1. Because galactokinase deficiency leads to a milder form of the disease not associated with mental retardation, it is not considered in this discussion. As a result of the transferase deficiency, galactose-1-phosphate accumulates in many locations, including the liver, spleen, lens of the eye, kidneys, heart muscle, cerebral cortex, and erythrocytes. Alternative metabolic pathways are activated, leading to the production of galactitol (a polyol metabolite of galactose) and galactonate, an oxidized by-product of excess galactose, both of which also accumulate in the tissues. Long-term toxicity in galactosemia has

been variously imputed to these metabolic intermediates. Heterozygotes may have a mild enzyme deficiency but are spared the clinical and pathologic consequences of the homozygous state.

The clinical picture is variable, probably reflecting the heterogeneity of mutations in the galactose-1-phosphate uridyl transferase gene. The liver, eyes, and brain bear the brunt of the damage. The early-to-develop *hepatomegaly* is due largely to fatty change, but in time widespread scarring that closely resembles the cirrhosis of alcohol abuse may supervene (Fig. 10-16). *Opacification of the lens (cataract)* develops, probably because the lens absorbs water and swells as galactitol, produced by alternative metabolic pathways, accumulates and increases osmotic pressure. Nonspecific alterations appear in the CNS, including *loss of nerve cells, gliosis, and edema, particularly in the dentate nuclei of the cerebellum and the olivary nuclei of the medulla*. Similar changes may occur in the cerebral cortex and white matter.

These infants *fail to thrive* almost from birth. *Vomiting and diarrhea* appear within a few days of milk ingestion. *Jaundice and hepatomegaly* usually become evident during the first week of life and may seem to be a continuation of the physiologic jaundice of the newborn. The *cataracts* develop within a few weeks, and within the first 6 to 12 months of life *mental retardation* may be detected. Even in

Figure 10-16 Galactosemia. The liver shows extensive fatty change and a delicate fibrosis. (Courtesy Dr. Wesley Tyson, The Children's Hospital, Denver, Colo.)

untreated infants, however, the mental deficit is usually not as severe as that seen in PKU. Accumulation of galactose and galactose-1-phosphate in the kidney impairs amino acid transport, resulting in *aminoaciduria*. There is an increased frequency of fulminant *Escherichia coli septicemia*, possibly arising from depressed neutrophil bactericidal activity. *Hemolysis* and *coagulopathy* in the newborn period can occur as well.

Many of the clinical and morphologic changes of galactosemia can be prevented or ameliorated by early removal of galactose from the diet for at least the first 2 years of life. Control instituted soon after birth prevents the cataracts and liver damage and permits almost normal development. Even with dietary restrictions, however, it is now established that older patients are frequently affected by a speech disorder and gonadal failure (especially premature ovarian failure) and, less commonly, ataxia.

Cystic Fibrosis (Mucoviscidosis)

Cystic fibrosis is an inherited disorder of ion transport that affects fluid secretion in exocrine glands and in the epithelial lining of the respiratory, gastrointestinal, and reproductive tracts. In many individuals this disorder leads to abnormally viscous secretions that obstruct organ passages, resulting in most of the clinical features of this disorder, such as *chronic lung disease secondary to recurrent infections, pancreatic insufficiency, steatorrhea, malnutrition, hepatic cirrhosis, intestinal obstruction, and male infertility*. These manifestations may appear at any point in life from before birth to much later in childhood or even in adolescence.

With an incidence of 1 in 2500 live births, *cystic fibrosis is the most common lethal genetic disease that affects Caucasian populations*. The carrier frequency in the United States is 1 in 20 among Caucasians but significantly lower in African Americans, Asians, and Hispanics. Although cystic fibrosis follows an *autosomal recessive* transmission pattern, recent data suggest that *even heterozygote carriers have a higher incidence of respiratory and pancreatic diseases* as compared with the general population. In addition, despite the classification of cystic fibrosis as a “mendelian” disorder, there is a wide degree of phenotypic variation that results from diverse mutations in the gene associated with cystic fibrosis, the tissue-specific effects of the encoded gene product, and the influence of so-called modifier genes.

Cystic Fibrosis Gene: Normal Structure and Function. In normal duct epithelia, chloride is transported by plasma membrane channels (chloride channels). **The primary defect in cystic fibrosis results from abnormal function of an epithelial chloride channel protein encoded by the cystic fibrosis transmembrane conductance regulator (CFTR) gene on chromosome 7q31.2.** The 1480-amino acid polypeptide encoded by CFTR has two transmembrane domains (each containing six α -helices), two cytoplasmic nucleotide-binding domains (NBDs), and a regulatory domain (R domain) that contains protein kinase A and C phosphorylation sites (Fig. 10-17). The two transmembrane domains form a channel through which chloride passes. Activation of the CFTR channel is mediated by agonist-induced increases in cyclic adenosine monophosphate (cAMP), followed by activation of a protein kinase A that

Figure 10-17 *Top*, Normal cystic fibrosis transmembrane conductance regulator (CFTR) structure and activation. CFTR consists of two transmembrane domains, two nucleotide-binding domains (NBDs), and a regulatory R domain. Agonists (e.g., acetylcholine) bind to epithelial cells and increase cyclic adenosine monophosphate (cAMP), which activates protein kinase A, the latter phosphorylating the CFTR at the R domain using ATP. This results in opening of the chloride channel. *Bottom*, CFTR from gene to protein. The most common mutation in the *CFTR* gene results in defective protein folding in the Golgi/endoplasmic reticulum and degradation of CFTR before it reaches the cell surface. Other mutations affect synthesis of CFTR, NBDs, and R domains, as well as membrane-spanning domains. (See text for details.)

phosphorylates the R domain. Adenosine triphosphate (ATP) binding and hydrolysis occurs at the NBD and is essential for the opening and closing of the channel pore in response to cAMP-mediated signaling. Several important facets of CFTR function have emerged in recent years:

- *CFTR regulates multiple additional ion channels and cellular processes.* Although initially characterized as a chloride-conductance channel, it is now recognized that CFTR can regulate multiple ion channels and cellular processes, primarily through interactions involving its NBDs. These include so-called outwardly rectified chloride channels, inwardly rectified potassium channels (Kir6.1), the epithelial sodium channel (ENaC), gap junction channels, and cellular processes involved in ATP transport and mucus secretion. Of these, the interaction of CFTR with the ENaC has possibly the most pathophysiologic relevance in cystic fibrosis. The ENaC is situated on the apical surface of exocrine epithelial cells and is responsible for sodium uptake from the

Figure 10-18 Chloride channel defect in the sweat duct (*top*) causes increased chloride and sodium concentration in sweat. In the airway (*bottom*), patients with cystic fibrosis have decreased chloride secretion and increased sodium and water reabsorption leading to dehydration of the mucus layer coating epithelial cells, defective mucociliary action, and mucus plugging of airways. CFTR, Cystic fibrosis transmembrane conductance regulator; ENaC, epithelial sodium channel.

luminal fluid, rendering it (the luminal fluid) hypotonic. The ENaC is *inhibited* by normally functioning CFTR; hence, *in cystic fibrosis*, ENaC activity increases, markedly augmenting sodium uptake across the apical membrane. The importance of this phenomenon is discussed later in the context of pulmonary and gastrointestinal pathology in cystic fibrosis. The one exception to this rule happens to be the human sweat ducts, where ENaC activity *decreases* as a result of CFTR mutations; therefore, a hypertonic luminal fluid containing high sweat sodium chloride (the *sine qua non* of classic cystic fibrosis) is formed. This is the basis for the “salty” sweat that mothers can often detect in their affected infants.

- The functions of CFTR are tissue-specific; therefore, the impact of a mutation in CFTR is also tissue-specific. The major function of CFTR in the sweat gland ducts is to reabsorb luminal chloride ions and augment sodium reabsorption via the ENaC (see earlier). Therefore, in the sweat ducts, loss of CFTR function leads to decreased reabsorption of sodium chloride and production of hypertonic sweat (Fig. 10-18). However, in the respiratory and intestinal epithelium, the CFTR is one of the most important avenues for active luminal secretion of chloride. At these sites, CFTR mutations result in loss or reduction of chloride secretion into the lumen (Fig. 10-18). Active luminal sodium absorption is increased (due to loss of inhibition of ENaC activity), and both of these ion changes increase passive water reabsorption from the lumen, lowering the water content of the surface fluid layer coating mucosal cells. Thus, unlike the sweat ducts,

there is no difference in the salt concentration of the surface fluid layer coating the respiratory and intestinal mucosal cells in normal individuals versus those with cystic fibrosis. Instead, the pathogenesis of respiratory and intestinal complications in cystic fibrosis seems to stem from an isotonic but low-volume surface fluid layer. In the lungs, this dehydration leads to defective mucociliary action and the accumulation of hyperconcentrated, viscid secretions that obstruct the air passages and predispose to recurrent pulmonary infections.

- CFTR regulates transport of bicarbonate ions. The bicarbonate transport function of CFTR is mediated by reciprocal interactions with a family of anion exchangers called SLC26, which are co-expressed on the apical surface with CFTR. In some CFTR mutants chloride transport is completely or substantially preserved, while bicarbonate transport is markedly abnormal. Alkaline fluids are secreted by normal tissues, in contrast fluids that are acidic (due to absence of bicarbonate ions) are secreted by epithelia harboring these mutant CFTR alleles. The acidity of secretions results in decreased luminal pH that can lead to a variety of adverse effects such as increased mucin precipitation and plugging of ducts, and increased binding of bacteria to plugged mucins. Pancreatic insufficiency, a feature of classic cystic fibrosis, is virtually always present when there are CFTR mutations with abnormal bicarbonate conductance.

Cystic Fibrosis Gene: Mutational Spectra and Genotype-Phenotype Correlation. Since the CFTR gene was cloned

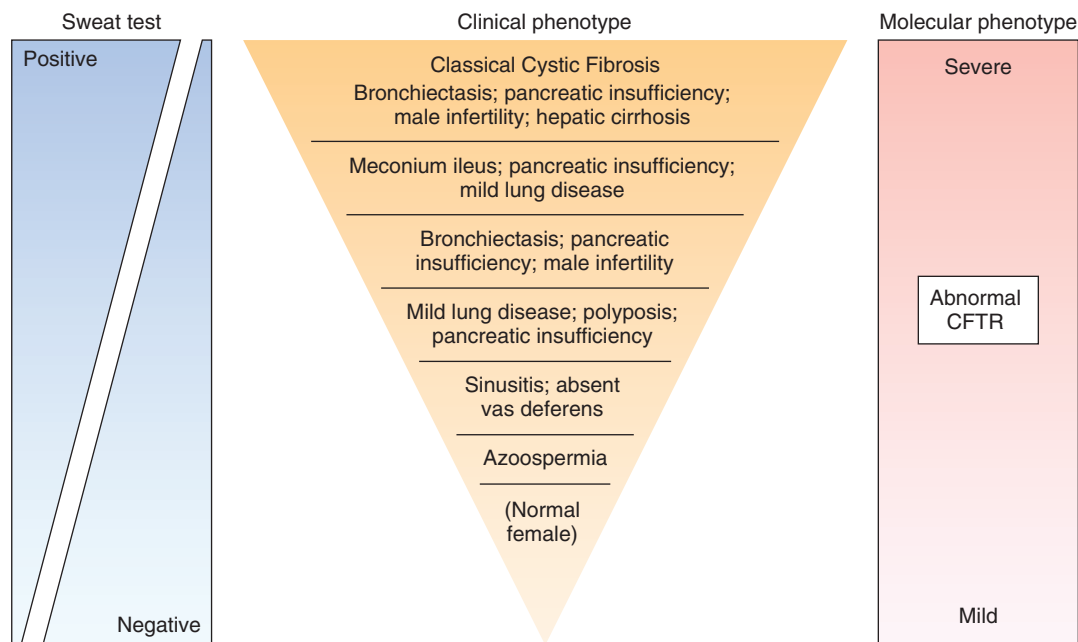

Figure 10-19 The many clinical manifestations of mutations in the cystic fibrosis gene, from most severe to asymptomatic. (Redrawn from Wallis C: Diagnosing cystic fibrosis: blood, sweat, and tears. *Arch Dis Child* 76:85, 1997.)

in 1989, more than 1800 disease-associated mutations have been identified. The mutations can be grouped into six classes based on their effect on the CFTR protein:

- Class I: *Defective protein synthesis*. These mutations are associated with complete lack of CFTR protein at the apical surface of epithelial cells.
- Class II: *Abnormal protein folding, processing, and trafficking*. These mutations result in defective processing of the protein from the endoplasmic reticulum to the Golgi apparatus; the protein does not become fully folded and glycosylated and is instead degraded before it reaches the cell surface. The most common class II mutation is a deletion of three nucleotides coding for phenylalanine at amino acid position 508 ($\Delta F508$). Worldwide, this mutation can be found in approximately 70% of cystic fibrosis patients. Class II mutations are also associated with complete lack of CFTR protein at the apical surface of epithelial cells.
- Class III: *Defective regulation*. Mutations in this class prevent activation of CFTR by abrogating ATP binding and hydrolysis, an essential prerequisite for ion transport (see earlier). Thus, there is a normal amount of CFTR on the apical surface, but it is nonfunctional.
- Class IV: *Decreased conductance*. These mutations typically occur in the transmembrane domain of CFTR, which forms the ionic pore for chloride transport. There is a normal amount of CFTR at the apical membrane, but with reduced function. This class is usually associated with a milder phenotype.
- Class V: *Reduced abundance*. These mutations typically affect intronic splice sites or the CFTR promoter, such that there is a reduced amount of normal protein. As discussed subsequently, class V mutations are also associated with a milder phenotype.
- Class VI: *Altered function in regulation of ion channels*. As previously described, CFTR is involved in the

regulation of multiple distinct cellular ion channels, of which its role in regulating bicarbonate secretion through relevant apical channels is required for maintaining luminal pH balance. Mutations in this class affect the regulatory role of CFTR. In some cases, a given mutation affects the conductance by CFTR as well as regulation of other ion channels. For example, the $\Delta F508$ mutation is both a class II and class VI mutation.

Because cystic fibrosis is an autosomal recessive disease, affected individuals harbor mutations on both alleles. However, the nature of mutations on each of the two alleles can have a remarkable effect on the overall phenotype, as well as on organ-specific manifestations (Fig. 10-19). Thus, two “severe” mutations (for example, a combination of Class I, II or III mutations in any permutation) that produce virtual absence of membrane CFTR function are associated with the classic cystic fibrosis phenotype (pancreatic insufficiency, sinopulmonary infections, and gastrointestinal symptoms), while the presence of a “mild” (class IV or V) mutation on one or both alleles results in a less severe phenotype. This general dictum of genotype-phenotype correlation is most consistent for pancreatic disease, wherein the presence of one allele with a mild mutation associated with some CFTR activity can prevent the pancreatic insufficiency that is virtually always seen with homozygosity for “severe” mutations. By contrast, genotype-phenotype correlations are far less consistent in pulmonary disease, due to the effect of secondary modifiers (see later). As genetic testing for CFTR mutations has expanded, it has become evident that some patients who present with clinical features apparently unrelated to cystic fibrosis may also harbor CFTR mutations. These include individuals with *idiopathic chronic pancreatitis*, *late-onset chronic pulmonary disease*, *idiopathic bronchiectasis*, and *obstructive azoospermia* caused by bilateral absence of the vas deferens (see detailed discussion of individual phenotypes later). Most of these

patients do not demonstrate other features of cystic fibrosis, despite the presence of bi-allelic *CFTR* mutations; these patients are classified as having *nonclassic* or *atypical cystic fibrosis*. Identifying these individuals is important not only for subsequent management, but also for genetic counseling.

Genetic and Environmental Modifiers. Although cystic fibrosis remains one of the best-known examples of the “one gene, one disease” axiom, there is now considerable evidence that genes other than *CFTR* modify the frequency and severity of certain organ-specific manifestations, especially pulmonary manifestations and neonatal meconium ileus. Not surprisingly, polymorphisms in genes whose products modulate neutrophil function in response to bacterial infections act as modifier loci for the severity of pulmonary disease in cystic fibrosis. Examples of such modifier genes include *mannose binding lectin 2 (MBL2)*, *transforming growth factor $\beta 1$ (TGFB1)* and *interferon related developmental regulator 1 (IFRD1)*. It is postulated that polymorphisms in these genes regulate the resistance of the lungs to exogenous infections with virulent microbes (see later), thus modifying the natural history of cystic fibrosis. Similarly, several other genetic modifiers appear to influence the incidence of meconium ileus in cystic fibrosis, although the degree of association is less stringent than that observed for pulmonary manifestations.

Environmental modifiers may also explain the significant phenotypic differences between individuals who share the same *CFTR* genotype. This is best exemplified in pulmonary disease, where *CFTR* genotype and phenotype correlations can be perplexing. As stated earlier, defective mucociliary action because of deficient hydration of the mucus results in an inability to clear bacteria from the airways. *Pseudomonas aeruginosa* species, in particular, colonize the lower respiratory tract, first intermittently and then chronically. Concurrent viral infections predispose to such colonization. The static mucus creates a hypoxic microenvironment in the airway surface fluid, which in turn favors the production of *alginate*, a mucoid polysaccharide capsule, by the colonizing bacteria. Alginate production permits the formation of a biofilm that protects the bacteria from antibodies and antibiotics, allowing them to evade host defenses, and produce a chronic destructive lung disease. Antibody- and cell-mediated immune reactions induced by the organisms result in further pulmonary destruction, but are ineffective against the organism. It is evident, therefore, that in addition to genetic factors (e.g., class of mutation), a plethora of environmental modifiers (e.g., virulence of organisms, efficacy of therapy, intercurrent and concurrent infections by other organisms, exposure to tobacco and allergens) can influence the severity and progression of lung disease in cystic fibrosis.

MORPHOLOGY

The anatomic changes are highly variable in distribution and severity. In individuals with nonclassic cystic fibrosis, the disease is quite mild and does not seriously disturb their growth and

Figure 10-20 Pancreas in cystic fibrosis. The ducts are dilated and plugged with eosinophilic mucin, and the parenchymal glands are atrophic and replaced by fibrous tissue.

development. In others, the pancreatic involvement is severe and impairs intestinal absorption because of the pancreatic insufficiency (Chapter 19), and so malabsorption stunts development and post-natal growth. In others, the mucus secretion defect leads to defective mucociliary action, obstruction of bronchi and bronchioles, and crippling fatal pulmonary infections. In all variants, the **sweat glands are morphologically unaffected**.

Pancreatic abnormalities are present in approximately 85% to 90% of patients with cystic fibrosis. In the milder cases, there may be only accumulations of mucus in the small ducts with some dilation of the exocrine glands. In more severe cases, usually seen in older children or adolescents, the ducts are completely plugged, causing atrophy of the exocrine glands and progressive fibrosis (Fig. 10-20). Atrophy of the exocrine portion of the pancreas may occur, leaving only the islets within a fibrofatty stroma. The loss of pancreatic exocrine secretion impairs fat absorption, and the associated avitaminosis A may contribute to squamous metaplasia of the lining epithelium of the ducts in the pancreas, which are already injured by the inspissated mucus secretions. Thick viscid plugs of mucus may also be found in the small intestine of infants. Sometimes these cause small-bowel obstruction, known as **meconium ileus**.

The **liver involvement** follows the same basic pattern. Bile canaliculi are plugged by mucus material, accompanied by ductular proliferation and portal inflammation. Hepatic **steatosis** is not an uncommon finding in liver biopsies. Over time, **focal biliary cirrhosis** develops in approximately a third of patients (Chapter 18), which can eventually involve the entire liver, resulting in diffuse hepatic nodularity. Such severe hepatic involvement is encountered in less than 10% of patients.

The **salivary glands** frequently show histologic changes similar to those described in the pancreas: progressive dilation of ducts, squamous metaplasia of the lining epithelium, and glandular atrophy followed by fibrosis.

The **pulmonary changes** are the most serious complications of this disease (Fig. 10-21). These stem from the viscous mucus secretions of the submucosal glands of the respiratory tree leading to secondary obstruction and infection of the air passages. The bronchioles are often distended with thick mucus associated with marked hyperplasia and hypertrophy of

Figure 10-21 Lungs of a patient dying of cystic fibrosis. There is extensive mucus plugging and dilation of the tracheobronchial tree. The pulmonary parenchyma is consolidated by a combination of both secretions and pneumonia—the green color associated with *Pseudomonas* infections. (Courtesy Dr. Eduardo Yunis, Children’s Hospital of Pittsburgh, Pittsburgh, Pa.)

the mucus-secreting cells. Superimposed infections give rise to severe chronic bronchitis and bronchiectasis (Chapter 15). In many instances, lung abscesses develop. *Staphylococcus aureus*, *Haemophilus influenzae*, and *Pseudomonas aeruginosa* are the three most common organisms responsible for lung infections. As mentioned earlier, a mucoid form of *P. aeruginosa* (alginate-producing) is particularly frequent and causes chronic inflammation. Even more sinister is the increasing frequency of infection with another group of pseudomonads, the *Burkholderia cepacia* complex, which includes at least nine different species; of these, infections with *B. cenocepacia* are the most common in cystic fibrosis patients. This opportunistic bacterium is particularly hardy, and infection with this organism has been associated with fulminant illness (“cepacia syndrome”), longer hospital stays, and increased mortality. Other opportunistic bacterial pathogens include *Stenotrophomonas maltophilia* and nontuberculous mycobacteria; allergic bronchopulmonary aspergillosis also occurs with increased frequency in cystic fibrosis.

Azoospermia and infertility are found in 95% of the males who survive to adulthood; **congenital bilateral absence of the vas deferens** is a frequent finding in these patients. In some males, bilateral absence of the vas deferens may be the only feature suggestive of an underlying *CFTR* mutation.

Clinical Features. Few childhood diseases are as protean as cystic fibrosis in clinical manifestations (Table 10-5). The symptoms are extremely varied and may appear at birth to years later, and involve one organ system or many. Approximately 5% to 10% of the cases come to clinical attention at birth or soon after because of *meconium ileus*. Distal intestinal obstruction can also occur in older individuals, manifesting as recurrent episodes of right lower

quadrant pain sometimes associated with a palpable mass of meconium, with or without associated intussusception, in the right iliac fossa.

Exocrine pancreatic insufficiency occurs in the majority (85% to 90%) of patients with cystic fibrosis and is associated with “severe” *CFTR* mutations on both alleles (e.g., $\Delta F508/\Delta F508$), whereas 10% to 15% of patients with one “severe” and one “mild” *CFTR* mutation ($\Delta F508/R117H$) or two “mild” *CFTR* mutations retain enough pancreatic exocrine function so as not to require enzyme supplementation (*pancreas-sufficient* phenotype). Pancreatic insufficiency is associated with protein and fat malabsorption and increased fecal loss. Manifestations of malabsorption (e.g., large, foul-smelling stools, abdominal distention, and poor weight gain) may appear during the first year of life. The faulty fat absorption may induce deficiency of the fat-soluble vitamins, resulting in manifestations of avitaminosis A, D, or K. Hypoproteinemia may be severe enough to cause generalized edema. Persistent diarrhea may result in rectal prolapse in up to 10% of children with this disease. The *pancreas-sufficient* phenotype is usually not associated with other gastrointestinal complications, and in general, these individuals demonstrate excellent growth and development. A subset of patients with *pancreas-sufficient* cystic fibrosis have recurrent bouts of pancreatitis associated with acute abdominal pain and

Table 10-5 Clinical Features and Diagnostic Criteria for Cystic Fibrosis

Clinical Features of Cystic Fibrosis

- Chronic sinopulmonary disease manifested by**
 - Persistent colonization/infection with typical cystic fibrosis pathogens, including *Staphylococcus aureus*, nontypeable *Haemophilus influenzae*, mucoid and nonmucoid *Pseudomonas aeruginosa*, *Burkholderia cepacia*
 - Chronic cough and sputum production
 - Persistent chest radiograph abnormalities (e.g., bronchiectasis, atelectasis, infiltrates, hyperinflation)
 - Airway obstruction manifested by wheezing and air trapping
 - Nasal polyps; radiographic or computed tomographic abnormalities of paranasal sinuses
 - Digital clubbing
- Gastrointestinal and nutritional abnormalities, including**
 - Intestinal: meconium ileus, distal intestinal obstruction syndrome, rectal prolapse
 - Pancreatic: pancreatic insufficiency, recurrent acute pancreatitis, chronic pancreatitis
 - Hepatic: chronic hepatic disease manifested by clinical or histologic evidence of focal biliary cirrhosis, or multilobular cirrhosis, prolonged neonatal jaundice
 - Nutritional: failure to thrive (protein-calorie malnutrition), hypoproteinemia, edema, complications secondary to fat-soluble vitamin deficiency
- Salt-loss syndromes: acute salt depletion, chronic metabolic alkalosis**
- Male urogenital abnormalities resulting in obstructive azoospermia (congenital bilateral absence of vas deferens)**

Criteria for Diagnosis of Cystic Fibrosis

One or more characteristic phenotypic features,
OR a history of cystic fibrosis in a sibling,
OR a positive newborn screening test result
AND

An increased sweat chloride concentration on two or more occasions
OR identification of two cystic fibrosis mutations,
OR demonstration of abnormal epithelial nasal ion transport

Adapted with permission from Rosenstein BJ, Cutting GR: The diagnosis of cystic fibrosis: a consensus statement. *J Pediatr* 132:589, 1998.

occasionally, life-threatening complications. These patients have other features of classic cystic fibrosis, such as pulmonary disease. By contrast, “idiopathic” chronic pancreatitis can also occur as an isolated late-onset finding in the absence of other stigmata of cystic fibrosis (Chapter 19); bi-allelic *CFTR* mutations (usually one “mild,” one “severe”) are demonstrable in the majority of these individuals who have nonclassic or atypical cystic fibrosis. Endocrine pancreatic insufficiency (i.e., diabetes) is uncommon in cystic fibrosis and is caused by severe destruction of pancreatic parenchyma including the islets.

Cardiorespiratory complications, such as persistent lung infections, obstructive pulmonary disease, and *cor pulmonale*, are the most common cause of death (~80%) in patients in the United States. By age 18, 80% of patients with classic cystic fibrosis harbor *P. aeruginosa*, and 3.5% harbor *B. cepacia*. With the indiscriminate use of antibiotic prophylaxis against *Staphylococcus*, there has been an unfortunate resurgence of resistant strains of *Pseudomonas* in many patients. Individuals who carry one “severe” and one “mild” *CFTR* mutation may develop late-onset mild pulmonary disease, another example of nonclassic or atypical cystic fibrosis. Patients with mild pulmonary disease usually have little or no pancreatic disease. Adult-onset “idiopathic” bronchiectasis, has been linked to *CFTR* mutations in a subset of cases. Recurrent sinonasal polyps can occur in 10% to 25% of individuals with cystic fibrosis; hence, children who present with this finding should be tested for cystic fibrosis.

Significant liver disease occurs late in the natural history of cystic fibrosis and is gaining in clinical importance as life expectancies increase. In fact, after cardiopulmonary and transplantation-related complications, liver disease is the most common cause of death in cystic fibrosis. Most studies suggest that symptomatic or biochemical liver disease has its onset at or around puberty, with a prevalence of approximately 13% to 17%. However, asymptomatic hepatomegaly may be present in up to a third of individuals. Obstruction of the common bile duct may occur due to stones or sludge; it presents with abdominal pain and the acute onset of jaundice. As previously noted, diffuse biliary cirrhosis develops in less than 10% of individuals with cystic fibrosis.

Approximately 95% of males with cystic fibrosis are infertile, as a result of obstructive azoospermia. As mentioned earlier, this is most commonly due to congenital bilateral absence of the vas deferens, which is caused in 80% of cases by bi-allelic *CFTR* mutations.

In most cases, the diagnosis of cystic fibrosis is based on persistently elevated sweat electrolyte concentrations (often the mother makes the diagnosis by recognizing her infant’s abnormally salty sweat), characteristic clinical findings (sinopulmonary disease and gastrointestinal manifestations), an abnormal newborn screening test, or a family history. A minority of patients with cystic fibrosis, especially those with at least one “mild” *CFTR* mutation, may have a normal or near-normal sweat test (<60 mM/L). Measurement of nasal transepithelial potential difference in vivo can be a useful adjunct under these circumstances; individuals with cystic fibrosis demonstrate a significantly more negative baseline nasal potential difference than controls. Sequencing the *CFTR* gene is the gold standard for diagnosis of cystic fibrosis. Therefore, in patients with

suggestive clinical findings or family history (or both), genetic analysis may be warranted.

There have been major improvements in the management of acute and chronic complications for cystic fibrosis, including more potent antimicrobial therapies, pancreatic enzyme replacement, and bilateral lung transplantation. New treatment modalities for restoring mutant *CFTR* function are being tested in clinical trials. For example, the first-in-class of a group of agents known as *CFTR* “potentiators” has been recently approved for use in a minority (~3%-5%) of cystic fibrosis patients that harbor a G155D mutation in the *CFTR* gene. This particular mutation is a class IV alteration, in which functionally defective *CFTR* is present in otherwise normal amounts at the cell membrane; the orally bioavailable *CFTR* “potentiator” partially restores the critical ion transport functions to the defective channel. Overall, improvements in the management of cystic fibrosis has extended the median life expectancy to close to 40 years and increasingly, a lethal disease of childhood is changing into a chronic disease of adults.

Sudden Infant Death Syndrome (SIDS)

According to the National Institute of Child Health and Human Development, SIDS is defined as “the sudden death of an infant under 1 year of age which remains unexplained after a thorough case investigation, including performance of a complete autopsy, examination of the death scene, and review of the clinical history.” It is important to emphasize that many cases of sudden death in infancy may have an unexpected anatomic or biochemical basis discernible at autopsy (Table 10-6), and these should not be labeled as SIDS, but rather as *sudden unexpected infant death (SUID)*. The Centers for Disease Control and Prevention estimates that SIDS accounts for approximately half of the cases of SUID in the United States. An aspect of SIDS that is not stressed in the definition is that the infant usually dies while asleep, mostly in the prone or side position, hence the pseudonyms of *crib death* or *cot death*.

Epidemiology. As infantile deaths due to nutritional problems and infections have come under control in developed countries, SIDS has assumed greater importance, including in the United States. SIDS is the leading cause of death between age 1 month and 1 year in this country and the third leading cause of death overall in infancy, after congenital anomalies and diseases of prematurity and low birth weight. Mostly because of nationwide SIDS awareness campaigns by organizations such as the American Academy of Pediatrics, there has been a significant drop in SIDS-related mortality in the past decade, from an estimated 120 deaths per 100,000 live births in 1992 to 54 per 100,000 in 2005. This number translates to about 2000 deaths due to SIDS in the US. Worldwide, in countries where unexpected infant deaths are diagnosed as SIDS only after postmortem examination, the death rates from SIDS range from 10 per 100,000 live births in the Netherlands to 80 per 100,000 in New Zealand.

Approximately 90% of all SIDS deaths occur during the first 6 months of life, most between ages 2 and 4 months. This narrow window of peak susceptibility is a unique characteristic that is independent of other risk factors (to

Table 10-6 Risk Factors and Postmortem Findings Associated with Sudden Infant Death Syndrome

Parental
Young maternal age (age younger than 20 years)
Maternal smoking during pregnancy
Drug abuse in <i>either</i> parent, specifically paternal marijuana and maternal opiate, cocaine use
Short intergestational intervals
Late or no prenatal care
Low socioeconomic group
African-American and American Indian ethnicity (? socioeconomic factors)
Infant
Brain stem abnormalities, associated with delayed development of arousal and cardiorespiratory control
Prematurity and/or low birth weight
Male sex
Product of a multiple birth
SIDS in a prior sibling
Antecedent respiratory infections
Germline polymorphisms in autonomic nervous system genes
Environment
Prone or side sleep position
Sleeping on a soft surface
Hyperthermia
Co-sleeping in first 3 months of life
Postmortem Abnormalities Detected in Cases of Sudden Unexpected Infant Death (SUID)*
Infections
Viral myocarditis
Bronchopneumonia
Unsuspected congenital anomaly
Congenital aortic stenosis
Anomalous origin of the left coronary artery from the pulmonary artery
Traumatic child abuse
Intentional suffocation (filicide)
Genetic and metabolic defects
Long QT syndrome (<i>SCN5A</i> and <i>KCNQ1</i> mutations)
Fatty acid oxidation disorders (<i>MCAD</i> , <i>LCHAD</i> , <i>SCHAD</i> mutations)
Histiocytoid cardiomyopathy (<i>MTCYB</i> mutations)
Abnormal inflammatory responsiveness (partial deletions in <i>C4a</i> and <i>C4b</i>)

*SIDS is not the only cause of SUIDs, but rather is a *diagnosis of exclusion*. Therefore, performance of an autopsy may often reveal findings that would explain the cause of an SUID. These cases should *not*, strictly speaking, be labeled as "SIDS." *SCN5A*, sodium channel, voltage-gated, type V, alpha polypeptide; *KCNQ1*, potassium voltage-gated channel, KQT-like subfamily, member 1; *MCAD*, medium-chain acyl coenzyme A dehydrogenase; *LCHAD*, long-chain 3-hydroxyacyl coenzyme A dehydrogenase; *SCHAD*, short-chain 3-hydroxyacyl coenzyme A dehydrogenase; *MTCYB*, mitochondrial cytochrome *b*; *C4*, complement component 4.

be described) and the geographic locale. Most infants who die of SIDS die at home, usually during the night after a period of sleep. For many years, prolonged apnea was considered to be a risk factor for SIDS. Infants who developed a so-called "apparent life-threatening event" (ALTE), characterized by some combination of apnea, marked change in color or muscle tone, choking or gagging, were considered at risk for subsequent SIDS. However, epidemiologic studies have demonstrated that these "life-threatening events" and SIDS have different risk factors and ages of onset, and are probably unrelated entities. Children experiencing ALTEs are often premature or have a mechanical basis for respiratory compromise. This distinction might explain why home apnea monitors, which have proliferated among American families for "SIDS prevention," have had minimal impact on reducing the risk of SIDS.

MORPHOLOGY

In infants who have died of suspected SIDS, a variety of findings have been reported at postmortem examination. They are usually subtle and of uncertain significance and are not present in all cases. Multiple petechiae are the most common finding (~80% of cases); these are usually present on the thymus, visceral and parietal pleura, and epicardium. Grossly, the lungs are usually congested, and vascular engorgement with or without pulmonary edema is demonstrable microscopically in the majority of cases. These changes possibly represent agonal events, because they are found with comparable frequencies in *explained* sudden deaths in infancy. Within the upper respiratory system (larynx and trachea), there may be some histologic evidence of recent infection (correlating with the clinical symptoms), although the changes are not sufficiently severe to account for death and should not detract from the diagnosis of SIDS. The CNS demonstrates astrogliosis of the brain stem and cerebellum. Sophisticated morphometric studies have revealed quantitative brain-stem abnormalities such as hypoplasia of the arcuate nucleus or a decrease in brain-stem neuronal populations in several cases; these observations are not uniform, however. Nonspecific findings include frequent persistence of hepatic extramedullary hematopoiesis and periadrenal brown fat; it is tempting to speculate that these latter findings relate to chronic hypoxemia, retardation of normal development, and chronic stress. Thus, autopsy usually fails to provide a clear cause of death, and this may well be related to the etiologic heterogeneity of SIDS. The importance of a postmortem examination rests in identifying other causes of SUID, such as unsuspected infection, congenital anomaly, or a genetic disorder (Table 10-6), the presence of any of which would *exclude* a diagnosis of SIDS; and in ruling out the unfortunate possibility of traumatic child abuse.

Pathogenesis. The circumstances surrounding SIDS have been explored in great detail, and it is generally accepted that it is a *multifactorial condition*, with a variable mixture of contributing factors. A "triple-risk" model of SIDS has been proposed, which postulates the intersection of three overlapping factors: (1) a vulnerable infant, (2) a critical developmental period in homeostatic control, and (3) an exogenous stressor. According to this model, several factors make the infant vulnerable to sudden death during the critical developmental period (i.e., the first 6 months of life). These vulnerability factors may relate to the parents or the infant, while the exogenous stressor(s) are environmental (Table 10-6).

While numerous factors have been proposed to account for a vulnerable infant, the most compelling hypothesis is that SIDS reflects a delayed development of "arousal" and cardiorespiratory control. The brain stem, and in particular the medulla oblongata, plays a critical role in the body's "arousal" response to noxious stimuli such as episodic hypercarbia, hypoxia, and thermal stress encountered during sleep. The serotonergic (5-HT) system of the medulla is implicated in these "arousal" responses, as well as regulation of other critical homeostatic functions such as respiratory drive, blood pressure, and upper airway reflexes. Abnormalities in serotonin-dependent signaling in the brain stem may be the underlying basis for SIDS in some infants.

Epidemiologic and genetic studies have identified additional vulnerability factors for SIDS in the “triple-risk” model. Infants who are born before term or who are low birth weight are at increased risk, and risk increases with decreasing gestational age or birth weight. As stated, male sex is associated with a slightly greater incidence of SIDS. SIDS in a prior sibling is associated with a fivefold relative risk of recurrence, highlighting the importance of a genetic predisposition; *traumatic child abuse must be carefully excluded under these circumstances*. Most SIDS babies have an immediate prior history of a mild respiratory tract infection, but no single causative organism has been isolated. These infections may predispose an already vulnerable infant to even greater impairment of cardiorespiratory control and delayed arousal. In this context, *laryngeal chemoreceptors* have emerged as a putative “missing link” between upper respiratory tract infections, the prone position, and SIDS. When stimulated, these laryngeal chemoreceptors typically elicit an inhibitory cardiorespiratory reflex. Stimulation of the chemoreceptors is augmented by respiratory tract infections, which increase the volume of secretions, and by the prone position, which impairs swallowing and clearing of the airways even in healthy infants. In a previously vulnerable infant with impaired arousal, the resulting inhibitory cardiorespiratory reflex may prove fatal. Genetic vulnerability factors in the infant include polymorphisms of genes related to serotonergic signaling and autonomic innervation, pointing to the importance of these processes in the pathophysiology of SIDS.

In addition to infant vulnerability factors, several maternal risk factors have also been identified. *Maternal smoking during pregnancy* has consistently emerged as a risk factor in epidemiologic studies of SIDS, with children exposed to in utero nicotine having more than double the risk of SIDS as compared with children born to nonsmokers. Young maternal age, frequent childbirths, and inadequate prenatal care are all risk factors associated with increased incidence of SIDS in the offspring.

Among the potential “environmental stressors,” prone or side sleeping positions, sleeping with parents in the first 3 months, sleeping on soft surfaces, and thermal stress are probably the most important modifiable risk factors for SIDS. The prone or side positions predispose an infant to one or more recognized noxious stimuli (hypoxia, hypercarbia, and thermal stress) during sleep. The side position was considered a reliable alternative to the prone sleeping position, but *the American Academy of Pediatrics now recognizes the supine sleeping position as the only safe position that reduces the risk of SIDS*. This “Back to Sleep” campaign has resulted in substantial reductions in SIDS-related deaths since its inception in 1994.

As has been stated, SIDS is far from the only cause of SUIDs. **In fact, SIDS is a diagnosis of exclusion, requiring careful examination of the death scene and a complete postmortem examination.** The latter can reveal an unsuspected cause of sudden death in as many as 20% or more of “SIDS” babies. Infections (e.g., viral myocarditis or bronchopneumonia) are the most common causes of sudden “unexpected” death, followed by unsuspected congenital anomalies. In part as a result of advancements in molecular diagnostics and knowledge of the human genome, several genetic causes of sudden “unexpected” infant death have emerged. For example, fatty

acid oxidation disorders, characterized by defects in mitochondrial fatty acid oxidative enzymes, may be responsible for as many as 5% of SUIDs. Other newly emerging genetic causes of sudden death are listed in Table 10-6.

Tumors and Tumor-like Lesions of Infancy and Childhood

Only 2% of all malignant tumors occur in infancy and childhood; nonetheless, cancer (including leukemia) accounts for about 9% of deaths in the United States in children older than age 4 and up to age 14 years, and only accidents cause significantly more deaths. Benign tumors are even more common than cancers. Most benign tumors are of little concern, but on occasion they cause serious complications by virtue of their location or rapid increase in size.

It is sometimes difficult to separate, on morphologic grounds, true tumors or neoplasms from tumor-like lesions in the infant and child. In this context, two special categories of tumor-like lesions should be distinguished from true tumors.

- The term *heterotopia* (or *choristoma*) is applied to microscopically normal cells or tissues that are present in abnormal locations. Examples of heterotopias include a rest of pancreatic tissue found in the wall of the stomach or small intestine, or a small mass of adrenal cells found in the kidney, lungs, ovaries, or elsewhere. These heterotopic rests are usually of little significance, but they can be confused clinically with neoplasms. Rarely, they are sites of origin of true neoplasms, producing paradoxes such as an adrenal carcinoma arising in the ovary.
- The term *hamartoma* refers to an excessive, focal overgrowth of cells and tissues native to the organ in which it occurs. Although the cellular elements are mature and identical to those found in the remainder of the organ, they do not reproduce the normal architecture of the surrounding tissue. The line of demarcation between a hamartoma and a benign neoplasm is often unclear, since both lesions can be clonal. Hemangiomas, lymphangiomas, rhabdomyomas of the heart, adenomas of the liver, and developmental cysts within the kidneys, lungs, or pancreas are interpreted by some as hamartomas and by others as true neoplasms. Their unequivocally benign histology, however, does not preclude bothersome and rarely life-threatening clinical problems in some cases.

Benign Tumors and Tumor-Like Lesions

Virtually any tumor may be encountered in children, but within this wide array hemangiomas, lymphangiomas, fibrous lesions, and teratomas deserve special mention. You will notice that the most common neoplasms of childhood are so-called soft-tissue tumors of mesenchymal derivation. This contrasts with adults, in whom the most common tumors, benign or malignant, have an epithelial origin. Benign tumors of various tissues are described in

Figure 10-22 Congenital capillary hemangioma at birth (A) and at age 2 years (B) after spontaneous regression. (Courtesy Dr. Eduardo Yunis, Children's Hospital of Pittsburgh, Pittsburgh, Pa.)

greater detail in appropriate chapters; here a few comments are made about their special features in childhood.

Hemangioma. Hemangiomas are the most common tumors of infancy (Chapter 11). Architecturally, they do not differ from those occurring in adults. Both cavernous and capillary hemangiomas may be encountered, although the latter are often more cellular than in adults, a feature that is deceptively worrisome. In children, most are located in the skin, particularly on the face and scalp, where they produce flat to elevated, irregular, red-blue masses; some of the flat, larger lesions (considered by some to represent vascular ectasias) are referred to as *port-wine stains*. Hemangiomas may enlarge along with the growth of the child, but in many instances they spontaneously regress (Fig. 10-22). In addition to their cosmetic significance, they can represent one facet of the hereditary disorder von Hippel-Lindau disease (Chapter 28). A subset of CNS cavernous hemangiomas can occur in the familial setting; these families harbor mutations in one of three *cerebral cavernous malformation* (CCM) genes.

Lymphatic Tumors. A wide variety of lesions are of lymphatic origin. Some of them—*lymphangiomas*—are hamartomatous or neoplastic, whereas others seem to represent abnormal dilations of preexisting lymph channels known

as *lymphangiectasis*. The *lymphangiomas* are usually characterized by cystic and cavernous spaces. Lesions of this nature may occur in the skin but are more often encountered in the deeper regions of the neck, axilla, mediastinum, retroperitoneal tissue, and elsewhere. Although histologically benign, they tend to increase in size after birth, owing to the accumulation of fluid and the budding of preexisting spaces. In this manner they may encroach on vital structures, such as those in the mediastinum or nerve trunks in the axilla, and give rise to clinical problems. *Lymphangiectasis*, in contrast, usually presents as a diffuse swelling of part or all of an extremity; considerable distortion and deformation may occur as a consequence of the spongy, dilated subcutaneous and deeper lymphatics. The lesion is not progressive, however, and does not extend beyond its original location. Nonetheless, it creates cosmetic problems that are often difficult to correct surgically.

Fibrous Tumors. Fibrous tumors occurring in infants and children range from sparsely cellular proliferations of spindle-shaped cells (designated as *fibromatosis*) to richly cellular lesions indistinguishable from fibrosarcomas occurring in adults (designated as *congenital-infantile fibrosarcomas*). Biologic behavior cannot be predicted based on histology alone, however, in that despite their histologic similarities with adult fibrosarcomas, the congenital-infantile variants have an excellent prognosis. A characteristic chromosomal translocation, $t(12;15)(p13;q25)$, has been described in congenital-infantile fibrosarcomas, which results in generation of an *ETV6-NTRK3* fusion transcript. The normal *ETV6* gene product is a transcription factor, while the *NTRK3* gene product (also known as TRKC) is a tyrosine kinase. Like other tyrosine kinase fusion proteins found in human neoplasms, *ETV6-TRKC* is constitutively active and stimulates signaling through the oncogenic RAS and PI-3K/AKT pathways (Chapter 7). Among soft-tissue tumors, the *ETV6-NTRK3* fusion transcript is unique to infantile fibrosarcomas, making it a useful diagnostic marker.

Teratomas. Teratomas illustrate the relationship of histologic maturity to biologic behavior. Teratomas may occur as benign, well-differentiated cystic lesions (mature teratomas), as lesions of indeterminate potential (immature teratomas), or as unequivocally malignant teratomas (usually admixed with another germ cell tumor component such as endodermal sinus tumor) (Chapter 21). They exhibit two peaks in incidence: the first at approximately 2 years of age and the second in late adolescence or early adulthood. The first peak is congenital neoplasms; the later occurring lesions may also be of prenatal origin but are more slowly growing. *Sacrocoxygeal teratomas* are the most common teratomas of childhood, accounting for 40% or more of cases (Fig. 10-23). They occur with a frequency of 1 in 20,000 to 40,000 live births, and are four times more common in girls than boys. In view of the overlap in the mechanisms underlying teratogenesis and oncogenesis, it is interesting that approximately 10% of sacrocoxygeal teratomas are associated with congenital anomalies, primarily defects of the hindgut and cloacal region and other midline defects (e.g., meningocele, spina bifida) not believed to result from local effects of the tumor.

Figure 10-23 Sacrococcygeal teratoma. Note the size of the lesion compared with that of the stillbirth.

Approximately 75% of these tumors are mature teratomas, and about 12% are unequivocally malignant and lethal. The remainder is immature teratomas; their malignant potential correlates with the amount of immature tissue, usually immature neuroepithelial elements, that are present. Most of the benign teratomas are encountered in younger infants (<4 months), whereas children with malignant lesions tend to be somewhat older. Other sites for teratomas in childhood include the testis (Chapter 21), ovaries (Chapter 22), and various midline locations, such as the mediastinum, retroperitoneum, and head and neck.

Malignant Tumors

Cancers of infancy and childhood differ biologically and histologically from their counterparts occurring later in life. The main differences, some of which have already been alluded to, include the following:

- Incidence and type of tumor
- Relatively frequent demonstration of a close relationship between abnormal development (teratogenesis) and tumor induction (oncogenesis)
- Prevalence of underlying familial or genetic aberrations spontaneously
- Tendency of fetal and neonatal malignancies to regress or differentiate spontaneously
- Improved survival or cure of many childhood tumors, so that more attention is now being devoted to minimizing the adverse delayed effects of chemotherapy and radiation therapy in survivors, including the development of second malignancies

Incidence and Types. The most frequent childhood cancers arise in the hematopoietic system, nervous tissue (including the central and sympathetic nervous system, adrenal medulla, and retina), soft tissues, bone, and kidney. This is in sharp contrast to adults, in whom the skin, lung, breast, prostate, and colon are the most common sites of tumors.

Neoplasms that exhibit sharp peaks in incidence in children younger than age 10 years include (1) leukemia (principally acute lymphoblastic leukemia), (2) neuroblastoma, (3) Wilms tumor, (4) hepatoblastoma, (5) retinoblastoma, (6) rhabdomyosarcoma, (7) teratoma, (8) Ewing sarcoma, and posterior fossa neoplasms—principally (9) juvenile astrocytoma, (10) medulloblastoma, and (11) ependymoma. Other forms of cancer are also common in childhood but do not have the same striking early peak. The approximate age distribution of these cancers is indicated in Table 10-7. Within this large array, leukemia alone accounts for more deaths in children younger than age 15 years than all of the other tumors combined.

Histologically, many of the malignant non-hematopoietic pediatric neoplasms are unique. In general, they tend to have a more primitive (*embryonal*) undifferentiated appearance, are often characterized by sheets of cells with small, round nuclei, and frequently show features of organogenesis specific to the site of tumor origin. Because of this latter characteristic, these tumors are frequently designated by the suffix *-blastoma*, for example, nephroblastoma (Wilms tumor), hepatoblastoma, and neuroblastoma. Because of their primitive histologic appearance, many childhood tumors have been collectively referred to as *small round blue cell tumors*. The differential diagnosis of such tumors includes neuroblastoma, Wilms tumor, lymphoma (Chapter 13), rhabdomyosarcoma (Chapter 27), Ewing sarcoma/primitive neuroectodermal tumor (Chapter 26), medulloblastoma (Chapter 28), and retinoblastoma (Chapter 29). If the anatomic site of origin is known, diagnosis is usually possible on histologic grounds alone. Occasionally, a combination of chromosome analysis, immunoperoxidase stains, or electron microscopy is required. Two of these tumors are particularly illustrative and are discussed here: the neuroblastic tumors, specifically neuroblastoma, and Wilms tumor. The remaining tumors are discussed in their respective organ-specific chapters.

Neuroblastic Tumors

The term neuroblastic tumor includes tumors of the sympathetic ganglia and adrenal medulla that are derived from primordial neural crest cells populating these sites. As a family, neuroblastic tumors demonstrate certain characteristic features including *spontaneous or therapy-induced*

Table 10-7 Common Malignant Neoplasms of Infancy and Childhood

0 to 4 Years	5 to 9 Years	10 to 14 Years
Leukemia	Leukemia	
Retinoblastoma	Retinoblastoma	
Neuroblastoma	Neuroblastoma	
Wilms tumor		
Hepatoblastoma	Hepatocellular carcinoma	Hepatocellular carcinoma
Soft tissue sarcoma (especially rhabdomyosarcoma)	Soft tissue sarcoma	Soft-tissue sarcoma
Teratomas		
Central nervous system tumors	Central nervous system tumors Ewing sarcoma Lymphoma	Osteogenic sarcoma Thyroid carcinoma Hodgkin disease

differentiation of primitive neuroblasts into mature elements, spontaneous tumor regression, and a wide range of clinical behavior and prognosis, which often mirror the extent of histologic differentiation. Neuroblastoma is the most important member of this family. It is the most common extracranial solid tumor of childhood, and the most frequently diagnosed tumor of infancy. The prevalence is about one case in 7000 live births, and there are approximately 700 cases diagnosed each year in the United States. The median age at diagnosis is 18 months; approximately 40% of cases are diagnosed in infancy. Most neuroblastomas occur sporadically, but 1% to 2% are familial, and in such cases the neoplasms may involve both of the adrenals or multiple primary autonomic sites. Germline mutations in the *anaplastic lymphoma kinase (ALK)* gene (Chapter 13) have recently been identified as a major cause of familial predisposition to neuroblastoma. Somatic gain-of-function *ALK* mutations are also observed in less than 10% of sporadic neuroblastomas. Tumors harboring *ALK* mutations in either the germline or somatic setting may be amenable to treatment using small molecule inhibitors that target the activity of this kinase.

Despite the remarkable progress made in the therapy of this disease, long-term prognosis for the high-risk subsets remains modest, with a 5-year survival in the range of 40%. As will be evident later, age and stage have a remarkable effect on prognosis, and, in general, children younger than 18 months of age tend to have a significantly better prognosis than older individuals at comparable disease burdens.

MORPHOLOGY

In childhood about 40% of neuroblastomas arise in the adrenal medulla. The remainder occur anywhere along the sympathetic chain, with the most common locations being the paravertebral region of the abdomen (25%) and posterior mediastinum (15%). Tumors may arise in numerous other sites, including the pelvis, the neck, and within the brain (cerebral neuroblastomas).

Neuroblastomas range in size from minute nodules (so-called **in situ lesions**) to large masses more than 1 kg in weight (Fig. 10-24). In situ neuroblastomas are reported to occur 40 times more frequently than clinically overt tumors. The great majority of these silent lesions spontaneously regress, leaving only a focus of fibrosis or calcification in the adult; this has led some to question the neoplastic connotation for the in situ lesions, arguing instead in favor of labeling them as developmental anomalies (“rests”).

Some neuroblastomas are often sharply demarcated by a fibrous pseudo-capsule, but others are far more infiltrative and invade surrounding structures, including the kidneys, renal vein, and vena cava, and envelop the aorta. On transection, they are composed of soft, gray-tan, tissue. Larger tumors have areas of necrosis, cystic softening, and hemorrhage. Occasionally, foci of punctate intra-tumoral calcification can be palpated.

Histologically, classic neuroblastomas are composed of small, primitive-appearing cells with dark nuclei, scant cytoplasm, and poorly defined cell borders growing in solid sheets. Such tumors may be difficult to differentiate morphologically from other small round blue cell tumors. Mitotic activity, nuclear breakdown (“karyorrhexis”), and pleomorphism may be prominent. The background often demonstrates a faintly eosinophilic

Figure 10-24 Adrenal neuroblastoma in a 6-month-old child. The hemorrhagic, partially encapsulated tumor has displaced the opened left kidney and is impinging on the aorta and left renal artery. (Courtesy Dr. Arthur Weinberg, University of Texas Southwestern Medical School, Dallas, Texas.)

Figure 10-25 Adrenal neuroblastoma. This tumor is composed of small cells embedded in a finely fibrillar matrix.

fibrillary material (**neuropil**) that corresponds to neuritic processes of the primitive neuroblasts. Typically, rosettes (**Homer-Wright pseudorosettes**) can be found in which the tumor cells are concentrically arranged about a central space filled with neuropil (Fig. 10-25). Other helpful features include positive immunohistochemical reactions for neuron-specific enolase and ultrastructural demonstration of small, membrane-bound, cytoplasmic catecholamine-containing secretory granules; the latter contain characteristic central dense cores surrounded by a peripheral halo (dense core granules). Some neoplasms show signs of maturation that can be spontaneous or therapy-induced. Larger cells having more abundant cytoplasm, large vesicular nuclei, and a prominent nucleolus, representing *ganglion cells* in various stages of maturation, may be found in tumors admixed with primitive neuroblasts (**ganglioneuroblastoma**). Even better differentiated lesions contain many more

Figure 10-26 Ganglioneuromas, arising from spontaneous or therapy-induced maturation of neuroblastomas, are characterized by clusters of large cells with vesicular nuclei and abundant eosinophilic cytoplasm, representing neoplastic ganglion cells (arrow). Spindle-shaped Schwann cells are present in the background stroma.

large cells resembling mature ganglion cells with few if any residual neuroblasts; such neoplasms merit the designation **ganglioneuroma** (Fig. 10-26). Maturation of neuroblasts into ganglion cells is usually accompanied by the appearance of **Schwann cells**. In fact, the presence of a so-called schwannian stroma composed of organized fascicles of neuritic processes, mature Schwann cells, and fibroblasts is a histologic prerequisite for the designation of ganglioneuroblastoma and ganglioneuroma; ganglion cells in and of themselves do not fulfill the criteria for maturation. The origin of Schwann cells in neuroblastoma remains an issue of contention; some investigators believe they represent a reactive population recruited by the tumor cells. However, studies using microdissection techniques have demonstrated that the Schwann cells harbor at least a subset of the same genetic alterations found in neuroblasts, and therefore are a component of the malignant clone. Irrespective of histogenesis, documenting the presence of schwannian stroma is essential, because its presence is associated with a **favorable outcome** (Table 10-8).

Metastases, when they develop, appear early and widely. In addition to local infiltration and lymph node spread, there is a pronounced tendency to spread through the bloodstream to the liver, lungs, bone marrow, and bones.

Staging. The International Neuroblastoma Staging System, which is the most widely used staging scheme worldwide, is detailed here:

- **Stage 1:** Localized tumor with complete gross excision, with or without microscopic residual disease; representative ipsilateral nonadherent lymph nodes negative for tumor (nodes adherent to the primary tumor may be positive for tumor).
- **Stage 2A:** Localized tumor with incomplete gross resection; representative ipsilateral nonadherent lymph nodes negative for tumor microscopically.
- **Stage 2B:** Localized tumor with or without complete gross excision; ipsilateral nonadherent lymph nodes positive for tumor; enlarged contralateral lymph nodes, which are negative for tumor microscopically.

- **Stage 3:** Unresectable unilateral tumor infiltrating across the midline with or without regional lymph node involvement; or localized unilateral tumor with contralateral regional lymph node involvement.
- **Stage 4:** Any primary tumor with dissemination to distant lymph nodes, bone, bone marrow, liver, skin, and/or other organs (except as defined for stage 4S).
- **Stage 4S** (“S” = special): Localized primary tumor (as defined for stages 1, 2A, or 2B) with dissemination limited to skin, liver, and/or bone marrow; stage 4S is limited to infants younger than 1 year.

Unfortunately, most (60% to 80%) children present with stage 3 or 4 tumors, and only 20% to 40% present with stage 1, 2A, 2B, or 4S neuroblastomas. The staging system is of paramount importance in determining prognosis.

Clinical Course and Prognostic Features. In young children, under age 2 years, neuroblastomas generally present with large abdominal masses, fever, and possibly weight loss. In older children, they may not come to attention until metastases produce manifestations, such as bone pain, respiratory symptoms, or gastrointestinal complaints. Neuroblastomas may metastasize widely through the hematogenous and lymphatic systems, particularly to liver, lungs, bones, and bone marrow. Proptosis and ecchymosis may also be present, due to spread to the periorbital region, a common metastatic site. Bladder and bowel dysfunction may be caused by paraspinal neuroblastomas that impinge on nerves. In neonates, disseminated neuroblastomas may present with multiple cutaneous metastases

Table 10-8 Prognostic Factors in Neuroblastomas

Variable	Favorable	Unfavorable
Stage*	Stage 1, 2A, 2B, 4S	Stage 3, 4
Age*	<18 months	>18 months
Histology*		
Evidence of schwannian stroma and gangliocytic differentiation†	Present	Absent
Mitosis-karyorrhexis index‡	<200/5000 cells	>200/5000 cells
DNA ploidy*	Hyperdiploid (whole chromosomal gains)	Near-diploid (Segmental chromosomal losses; chromothripsis)
MYCN*	Not amplified	Amplified
Chromosome 1p loss	Absent	Present
Chromosome 11q loss	Absent	Present
TRKA expression	Present	Absent
TRKB expression	Absent	Present
Mutations of neurotogenesis genes	Absent	Present

*Corresponds to the most commonly used parameters in clinical practice for assessment of prognosis and risk stratification.

†It is not only the presence but also the amount of schwannian stroma that confers the designation of a favorable histology. At least 50% or more schwannian stroma is required before a neoplasm can be classified as ganglioneuroblastoma or ganglioneuroma.

‡Mitotic karyorrhexis index (MKI) is defined as the number of mitotic or karyorrhectic cells per 5000 tumor cells in random foci.

that cause deep blue discoloration of the skin (earning the unfortunate designation of “blueberry muffin baby”). About 90% of neuroblastomas, regardless of location, produce catecholamines (similar to the catecholamines associated with pheochromocytomas), which are an important diagnostic feature (i.e., elevated blood levels of catecholamines and elevated urine levels of the metabolites vanillylmandelic acid [VMA] and homovanillic acid [HVA]). Despite the elaboration of catecholamines, hypertension is much less frequent with these neoplasms than with pheochromocytomas (Chapter 24). Ganglioneuromas, unlike their malignant counterparts, tend to produce either asymptomatic mass lesions or symptoms related to compression.

The course of neuroblastomas is extremely variable. Several clinical, histopathologic, molecular, and biochemical factors have been identified that have a bearing on prognosis (Table 10-8); based on the collection of prognostic factors present in a given patient, they are classified either as “low,” “intermediate,” or “high” risk. With improvements in therapy, long-term survival exceeds 90% of patients in the first two groups, while less than 50% of patients in the high-risk category are long-term survivors. The most pertinent prognostic factors include the following:

- *Age and stage are the most important determinants of outcome.* Neuroblastomas at stages 1, 2A, or 2B tend to have an excellent prognosis, irrespective of age (“low” or “intermediate” risk); the one notable exception to this rule are tumors exhibiting amplification of the *MYCN* oncogene. Infants with localized primary tumors and widespread metastases to the liver, bone marrow, and skin (stage 4S) represent a special subtype, wherein it is not uncommon for the disease to regress spontaneously. The biologic basis of this welcome behavior is not clear. *The age of 18 months has emerged as a critical point of dichotomy in terms of prognosis.* Children younger than 18 months of age, and especially those in the first year of life, have an excellent prognosis regardless of the stage of the neoplasm. Children older than 18 months fall into at least the “intermediate” risk category, while those with higher stage tumors or with confounding unfavorable prognostic variables like *MYCN* amplification in the neoplastic cells are considered “high” risk.
- *Morphology is an independent prognostic variable in neuroblastic tumors.* An age-linked morphologic classification of neuroblastic tumors has recently been proposed that divides them into *favorable* and *unfavorable* histologic subtypes. The specific morphologic features that bear on prognosis are listed in Table 10-8.
- *Amplification of the *MYCN* oncogene in neuroblastomas is a molecular event that has possibly the most profound impact on prognosis,* particularly when it occurs in tumors that would otherwise portend a good outcome. The presence of *MYCN* amplification “bumps” the tumor into a “high”-risk category, irrespective of age, stage, or histology. *MYCN* is located on the distal short arm of chromosome 2 (2p23-p24). Amplification of *MYCN* does not karyotypically manifest at the resident 2p23-p24 site, but rather as extrachromosomal double minute chromosomes or homogeneously staining regions on other chromosomes (Fig. 10-27). *MYCN* amplification is present in about 20% to 30% of primary tumors, most

Figure 10-27 **A**, Fluorescence in situ hybridization using a fluorescein-labeled cosmid probe for *N-myc* on a tissue section. Note the neuroblastoma cells on the upper half of the photo with large areas of staining (yellow-green); this corresponds to amplified *N-MYC* in the form of homogeneously staining regions. Renal tubular epithelial cells in the lower half of the photograph show no nuclear staining and background (green) cytoplasmic staining. **B**, A Kaplan-Meier survival curve of infants younger than 1 year of age with metastatic neuroblastoma. The 3-year event-free survival of infants whose tumors lacked *MYCN* amplification was 93%, whereas those with tumors that had *MYCN* amplification had only a 10% event free survival. (**A**, Courtesy Dr. Timothy Triche, Children’s Hospital, Los Angeles, Calif.; **B**, Reproduced with permission from Brodeur GM: Neuroblastoma: biological insights into a clinical enigma. *Nat Rev Cancer* 3:203-216; 2003.)

presenting as advanced-stage disease, and the degree of amplification correlates with worse prognosis. *MYCN* amplification is currently the most important genetic abnormality used in risk stratification of neuroblastic tumors (see later).

- *Ploidy of the tumor cells correlates with outcome in children less than 2 years of age but loses its independent prognostic significance in older children.* Broadly, neuroblastomas can be divided into two categories: *near-diploid* and *hyper-diploid (whole chromosome gains)*, with the latter being associated with a better prognosis. It is postulated that neuroblastomas with hyperdiploidy have an underlying defect in the mitotic machinery, leading to nondisjunction and whole chromosome gains, but otherwise relatively banal karyotypes. On the contrary, the more aggressive near-diploid tumors

harbor generalized genomic instability, with multiple segmental chromosomal aberrations that result in a complex karyotype with adverse prognostic implications. One peculiar form of segmental aberration described recently in aggressive neuroblastomas is called *chromothripsis* (Chapter 7), which involves localized fragmentation of a chromosome segment followed by random assembly of the fragments. In a subset of neuroblastomas, chromothripsis can result in amplification of *MYCN* or other oncogenes, or losses in tumor suppressor loci.

While *age, stage, histology, MYCN status, and DNA ploidy* are currently the “core” criteria used for the purposes of formal risk stratification and therapeutic decision, several emerging molecular variables have been described with prognostic implications. The most pertinent ones include the following:

- *Hemizygous deletion of the distal short arm of chromosome 1* in the region of band p36 has been demonstrated in 25% to 35% of primary tumors. Loss of 1p36 in neuroblastomas has a strong correlation with *MYCN* amplification, as well as advanced disease stage, and is associated with an increased risk of disease relapse in localized tumors. *Hemizygous loss of chromosome 11q* genetic material is another adverse prognostic factor, and may be the most common deletion event in neuroblastomas.
- *The expression of specific neurotrophin receptors* is also a prognostic marker for neuroblastoma. The neurotrophin receptors are a family of tyrosine kinase receptors, notably TrkA, TrkB, and TrkC (also known as NTRK3, see earlier), that regulate the growth, survival, and differentiation of neural cells. High TrkA expression is a favorable prognostic factor in neuroblastomas, generally associated with low-stage tumors lacking *MYCN* amplification that occur in younger patients. In contrast, elevated TrkB expression is associated with unfavorable biological characteristics, including *MYCN* amplification and a higher disease stage.
- Lastly, the application of next generation sequencing techniques to unravel the neuroblastoma genome has identified recurrent mutations in genes whose products are involved in *neuritogenesis* (a process in neuronal differentiation which includes the sprouting of neurites that will subsequently lead to the formation of axons). Selected examples of mutated genes within this functional class include *alpha thalassemia / mental retardation, X-linked (ATRX)* and *protein tyrosine phosphatase, receptor type D (PTPRD)*. Mutations of neuritogenesis associated genes were generally present in more aggressive, higher-stage neuroblastomas (including those arising in the absence of *MYCN* amplification), and these alterations are postulated to lead to defects in neuronal differentiation within the neoplastic cells, likely underlying their poorly differentiated histology.

Although discussion of the treatment modalities for neuroblastoma is beyond the scope of this book, we mention in passing two promising experimental approaches. The first involves the use of retinoids as an adjunct therapy for inducing the differentiation of neuroblastoma. Recall that the retinoic acid pathway plays a critical role in cellular differentiation during embryogenesis. The second is

focused on tumors harboring activating *ALK* mutations because they are potentially susceptible to targeted inhibitors of the encoded kinase, and such agents are currently undergoing evaluation in clinical trials.

Finally, we should mention the current status of screening programs for neuroblastoma. Because the vast majority of neuroblastomas release catecholamines into the circulation, detection of catecholamine metabolites (VMA and HVA) in urine could, in principle, form the basis for screening for asymptomatic tumors in children. However, two large studies in Europe and North America have failed to demonstrate improved mortality rates with population screening, because most tumors detected had favorable biologic characteristics. Therefore, community-based screening programs for neuroblastomas are not currently advocated.

Wilms Tumor

Wilms tumor afflicts approximately 1 in every 10,000 children in the United States, making it the most common primary renal tumor of childhood and the fourth most common pediatric malignancy in the United States. The peak incidence for Wilms tumor is between 2 and 5 years of age, and 95% of tumors occur before the age of 10 years. Approximately 5% to 10% of Wilms tumors involve both kidneys, either simultaneously (*synchronous*) or one after the other (*metachronous*). Bilateral Wilms tumors have a median age of onset approximately 10 months earlier than tumors restricted to one kidney, and these patients are presumed to harbor a germline mutation in one of the Wilms tumor-predisposing genes (see later). The biology of this tumor illustrates several important aspects of childhood neoplasms, such as the relationship between *malformations* and *neoplasia*, the histologic similarities between *organogenesis* and *oncogenesis*, the *two-hit theory* of recessive tumor suppressor genes (Chapter 7), the role of *pre-malignant lesions*, and perhaps most importantly, the potential for *judicious treatment modalities* to dramatically affect prognosis and outcome. Improvements in the cure rates for Wilms tumor (from as low as 30% a few decades ago, to approximately 90% currently) represent one of the greatest successes of pediatric oncology.

Pathogenesis and Genetics. *The risk of Wilms tumor is increased with at least three recognizable groups of congenital malformations associated with distinct chromosomal loci.* Although Wilms tumors arising in this setting account for no more than 10% of cases, these *syndromic tumors* have provided important insight into the biology of this neoplasm.

- The first group of patients has the *WAGR syndrome*, characterized by Wilms tumor, *aniridia*, genital anomalies, and mental retardation. Their lifetime risk of developing Wilms tumor is approximately 33%. Individuals with WAGR syndrome carry constitutional (germline) deletions of 11p13. Studies on these patients led to the identification of the first Wilms tumor-associated gene, *WT1*, and a contiguously deleted autosomal dominant gene for *aniridia*, *PAX6*, both located on chromosome 11p13. Patients with deletions restricted to *PAX6*, with normal *WT1* function, develop sporadic *aniridia*, but they are not at increased risk for Wilms tumors. The presence of germline *WT1* deletions in WAGR

syndrome represents the “first hit”; the development of Wilms tumor in these patients frequently correlates with the occurrence of a nonsense or frameshift mutation in the second *WT1* allele (“second hit”).

- A second group of patients at much higher risk for Wilms tumor (~90%) have the *Denys-Drash syndrome*, which is characterized by *gonadal dysgenesis* (male pseudohermaphroditism) and *early-onset nephropathy* leading to renal failure. The characteristic glomerular lesion in these patients is a *diffuse mesangial sclerosis* (Chapter 20). As in patients with WAGR, these patients also demonstrate germline abnormalities in *WT1*. In patients with the Denys-Drash syndrome, however, the genetic abnormality is a *dominant-negative missense mutation* in the zinc-finger region of the *WT1* protein that affects its DNA-binding properties. This mutation interferes with the function of the remaining wild-type allele, yet strangely, it is sufficient only in causing genitourinary abnormalities, but not tumorigenesis; Wilms tumors arising in Denys-Drash syndrome demonstrate bi-allelic inactivation of *WT1*. In addition to Wilms tumors, these individuals are also at increased risk for developing germ cell tumors called *gonadoblastomas* (Chapter 21), almost certainly a consequence of disruption in normal gonadal development.

WT1 encodes a DNA-binding transcription factor that is expressed within several tissues, including the kidney and gonads, during embryogenesis. The *WT1* protein is critical for normal renal and gonadal development. *WT1* has multiple binding partners, and the choice of this partner can affect whether *WT1* functions as a transcriptional activator or repressor in a given cellular context. Numerous transcriptional targets of *WT1* have been identified, including genes encoding glomerular podocyte-specific proteins and proteins involved in induction of renal differentiation. Despite the importance of *WT1* in nephrogenesis and its unequivocal role as a tumor suppressor gene, only about 10% of patients with sporadic (nonsyndromic) Wilms tumors demonstrate *WT1* mutations, suggesting that the majority of these tumors are caused by mutations in other genes.

- A third group, that is clinically distinct from these previous two groups of patients but also with an increased risk of developing Wilms tumor are children with *Beckwith-Wiedemann syndrome* (BWS), characterized by enlargement of body organs (organomegaly), macroglossia, hemihypertrophy, omphalocele, and abnormal large cells in the adrenal cortex (adrenal cytomegaly). BWS has served as a model for a nonclassical mechanism of tumorigenesis in humans—*genomic imprinting* (Chapter 5). The chromosomal region implicated in BWS has been localized to band 11p15.5 (“WT2”), distal to the *WT1* locus. This region contains multiple genes that are normally expressed from only one of the two parental alleles, with transcriptional silencing (i.e., imprinting) of the other parental homologue by methylation of the promoter region. Unlike WAGR or Denys-Drash syndromes, the genetic basis for BWS is considerably more heterogeneous in that no single 11p15.5 gene is involved in all cases. Moreover, the phenotype of BWS, including the predisposition to tumorigenesis, is influenced by the specific “WT2” imprinting abnormalities present. One of the genes in

this region—insulin-like growth factor-2 (*IGF2*)—is normally expressed solely from the *paternal allele*, while the maternal allele is silenced by imprinting. In some Wilms tumors, *loss of imprinting* (i.e., re-expression of the maternal *IGF2* allele) can be demonstrated, leading to overexpression of the IGF-2 protein. In other instances there is a selective deletion of the imprinted maternal allele, combined with duplication of the transcriptionally active paternal allele in the tumor (*uniparental paternal disomy*), which has an identical functional effect in terms of overexpression of IGF-2. Because the IGF-2 protein is an embryonal growth factor, it could conceivably explain the features of overgrowth associated with BWS, as well as the increased risk for Wilms tumors in these patients. Of all the “WT2” genes, imprinting abnormalities of *IGF2* have the strongest relationship to tumor predisposition in BWS. A subset of patients with BWS harbor mutations of the cell cycle regulator *CDKN1C* (also known as *p57* or *KIP2*); however, these patients have a significantly lower risk for developing Wilms tumors. In addition to Wilms tumors, patients with BWS are also at increased risk for developing hepatoblastoma, pancreatoblastoma, adrenocortical tumors, and rhabdomyosarcomas.

Recent genetic studies have also elucidated the role of β -catenin in Wilms tumor. It will be recalled (Chapter 7) that β -catenin belongs to the developmentally important *WNT* (*wingless*) signaling pathway. Gain-of-function mutations of the gene encoding β -catenin have been demonstrated in approximately 10% of sporadic Wilms tumors; there is a significant overlap between the presence of *WT1* and β -catenin mutations, suggesting a synergistic role for these events in the genesis of Wilms tumors.

Nephrogenic rests are putative precursor lesions of Wilms tumors and are seen in the renal parenchyma adjacent to approximately 25% to 40% of unilateral tumors; this frequency rises to nearly 100% in cases of bilateral Wilms tumors. In many instances the nephrogenic rests share genetic alterations with the adjacent Wilms tumor, pointing to their preneoplastic status. The appearance of nephrogenic rests varies from expansile masses that resemble Wilms tumors (hyperplastic rests) to sclerotic rests consisting predominantly of fibrous tissue and occasional admixed immature tubules or glomeruli. It is important to document the presence of nephrogenic rests in the resected specimen, because these patients are at an increased risk of developing Wilms tumors in the contralateral kidney and require frequent and regular surveillance for many years.

MORPHOLOGY

Grossly, Wilms tumor tends to present as a large, solitary, well-circumscribed mass, although 10% are either bilateral or multicentric at the time of diagnosis. On cut section, the tumor is soft, homogeneous, and tan to gray with occasional foci of hemorrhage, cyst formation, and necrosis (Fig. 10-28).

Microscopically, Wilms tumors are characterized by recognizable attempts to recapitulate different stages of nephrogenesis. **The classic triphasic combination of blastemal, stromal, and epithelial cell types is observed in the vast majority**

of lesions, although the percentage of each component is variable (Fig. 10-29A). Sheets of small blue cells with few distinctive features characterize the blastemal component. Epithelial differentiation is usually in the form of abortive tubules or glomeruli. Stromal cells are usually fibrocytic or myxoid in nature, although skeletal muscle differentiation is not uncommon. Rarely, other heterologous elements are identified, including squamous or mucinous epithelium, smooth muscle, adipose tissue, cartilage, and osteoid and neurogenic tissue. Approximately 5% of tumors reveal **anaplasia**, defined as the presence of cells with large, hyperchromatic, pleomorphic nuclei and abnormal mitoses (Fig. 10-29B). The presence of anaplasia correlates with the presence of *TP53* mutations and the emergence of resistance to chemotherapy. Recall that p53 elicits pro-apoptotic signals in response to DNA damage (Chapter 7). The loss of p53 function might explain the relative unresponsiveness of anaplastic cells to cytotoxic chemotherapy.

Clinical Features. Most children with Wilms tumors present with a large abdominal mass that may be unilateral or, when very large, may extend across the midline and down into the pelvis. Hematuria, pain in the abdomen after some traumatic incident, intestinal obstruction, and appearance of hypertension are other patterns of presentation. In a considerable number of these patients, pulmonary metastases are present at the time of primary diagnosis.

As stated, most patients with Wilms tumor can expect to be cured of their malignancy. Anaplastic histology remains a critical determinant of adverse prognosis. Even anaplasia restricted to the kidney (i.e., without extra-renal spread) confers an increased risk of recurrence and death, emphasizing the need for accurate identification of this histologic feature. Molecular parameters that correlate with adverse prognosis include loss of genetic material on chromosomes 11q and 16q, and gain of chromosome 1q in the tumor cells. Along with the increased survival of individuals with Wilms tumor have come reports of an increased risk of developing second primary tumors, including bone and soft-tissue sarcomas, leukemia and

Figure 10-28 Wilms tumor in the lower pole of the kidney with the characteristic tan-to-gray color and well-circumscribed margins.

Figure 10-29 **A**, Wilms tumor with tightly packed blue cells consistent with the blastemal component and interspersed primitive tubules, representing the epithelial component. Although multiple mitotic figures are seen, none are atypical in this field. **B**, Focal anaplasia was present in this Wilms tumor in other areas, characterized by cells with hyperchromatic, pleomorphic nuclei, and abnormal mitoses.

lymphomas, and breast cancers. While some of these neoplasms result from the presence of a germline mutation in a cancer predisposition gene, others are a consequence of therapy, most commonly radiation administered to the cancer field. This tragic, albeit uncommon, outcome has mandated that radiation therapy be used judiciously in the treatment of this and other childhood cancers.

Vascular pathology is responsible for more morbidity and mortality than any other category of human disease. Although the most clinically significant lesions involve arteries, venous disorders are not inconsequential. Two principal mechanisms underlie vascular disease:

- *Narrowing (stenosis) or complete obstruction* of vessel lumina, either progressively (e.g., by atherosclerosis) or precipitously (e.g., by thrombosis or embolism)
- *Weakening* of vessel walls, leading to dilation or rupture

To better appreciate the pathogenesis of vascular disorders, it is important to first understand normal blood vessels.

Vascular Structure and Function

The general architecture and cellular composition of blood vessels are similar throughout the cardiovascular system. However, structural specializations that reflect distinct functional roles characterize specific kinds of vessels

(Fig. 11-1). For example, arterial walls are thicker than corresponding veins at the same level of branching to accommodate pulsatile flow and higher blood pressures. Arterial wall thickness gradually diminishes as the vessels become smaller, but the ratio of wall thickness to lumen diameter increases, allowing these muscular vessels to exert control over blood flow and pressure. Many disorders of the vasculature only affect particular types of vessels and thus have characteristic anatomic distributions. Thus, atherosclerosis affects mainly elastic and muscular arteries, hypertension affects small muscular arteries and arterioles, and different varieties of vasculitis characteristically involve only vessels of a certain caliber.

The basic constituents of the walls of blood vessels are endothelial cells and smooth muscle cells, admixed with a variety of extracellular matrix, including elastin, collagen, and glycosaminoglycans. The relative amount and configuration of the basic constituents differ along the vasculature owing to local adaptations to mechanical or metabolic needs. In arteries and veins, these constituents are organized into three concentric layers, the *intima*, *media*, and

Figure 11-1 Regional specializations of the vasculature. Although the basic organization of the vasculature is constant, the thickness and composition of the various layers differ according to hemodynamic forces and tissue requirements. The aorta has substantial elastic tissue to accommodate high pulsatile forces, with the capacity to recoil and transmit energy into forward blood flow. The muscular arteries and arterioles have concentric rings of medial smooth muscle cells whose contractile state regulates vessel caliber and, thereby, blood flow and blood pressure. The venous system has relatively poorly developed medial layers that permit greater capacitance. The capillary wall permits ready diffusion of oxygen and nutrients because it is comprised only of an endothelial cell and sparse encircling pericytes. The differing structural and functional attributes leave the various parts of the vascular tree vulnerable to particular disorders. Thus, loss of aortic elastic tissue in a large artery may result in aneurysm, while stasis in a dilated venous bed may produce a thrombus.

adventitia, which are most anatomically distinct in the arteries.

- The *intima* normally consists of a single layer of endothelial cells sitting on a basement membrane underlaid by a thin layer of extracellular matrix; the intima is demarcated from the media by the *internal elastic lamina*.
- The *media* of vessels on the arterial side of the circulation varies in structure according to functional demands.
 - Arteries have several well-organized concentric layers of smooth muscle cells, while the smooth muscle cells of veins are arranged in a more haphazard fashion.
 - The media of elastic arteries (e.g., the aorta) has a high elastin content, allowing these vessels to expand during systole and recoil during diastole, a property that serves to propel the blood towards the tissues. With aging and the loss of elasticity, the aorta and larger arteries become less compliant, an alteration that tends to raise the systolic blood pressure. In addition, the arteries of older individuals often become progressively tortuous and dilated (*ectatic*).
- In *muscular arteries*, the media is composed predominantly of circumferentially oriented smooth muscle cells. Arteriolar smooth muscle cell contraction (*vasoconstriction*) or relaxation (*vasodilation*) are regulated by inputs from the autonomic nervous system, and local metabolic factors. These responses change the size of the lumen and thus regulate regional blood flow and blood pressure.
- *Arterioles are the principal points of physiologic resistance to blood flow*. Since the resistance to fluid flow is inversely proportional to the fourth power of the diameter (i.e., halving the diameter increases resistance 16-fold), small decreases in the lumen size of arterioles caused by structural changes or vasoconstriction can have profound effects on blood pressure.
- The *adventitia* lies external to the media and in many arteries is separated from the media by a well-defined *external elastic lamina*. The adventitia consists of loose connective tissue containing nerve fibers and the *vasa vasorum* (literally “vessels of the vessels”), small arterioles that are responsible for supplying the outer

portion of the media of large arteries with oxygen and nutrients.

As already alluded to, arteries are divided into three types based on their size and structural features: (1) large or *elastic arteries*, including the aorta, the major branches of the aorta (the innominate, subclavian, common carotid, and iliac arteries), and the pulmonary arteries; (2) medium-sized or *muscular arteries*, comprising smaller branches of the aorta (e.g., the coronary and renal arteries); and (3) small arteries (≤ 2 mm in diameter) and *arterioles* (20 to 100 μm in diameter), within tissues and organs.

Capillaries are approximately the diameter of a red cell (7 to 8 μm); they have an endothelial cell lining but no media, although variable numbers of *pericytes*, cells that resemble smooth muscle cells, typically lie just deep to the endothelium. Collectively, capillaries have a huge cross-sectional area, and also have a relative low flow rate. The combination of thin walls and slow flow make capillaries ideally suited for the exchange of diffusible substances between blood and tissues. Because functionally useful oxygen diffusion in tissues is limited to a distance of only approximately 100 μm , the capillary network of most tissues is very rich. Tissues with high metabolic rates, such as myocardium and brain, have the highest density of capillaries.

Blood from capillary beds flows into postcapillary venules and then sequentially through collecting venules and small, medium, and large veins. In most inflammatory reactions, vascular leakage and leukocyte exudation occur preferentially from postcapillary venules (Chapter 3).

Relative to arteries at the same level of branching, veins have larger diameters, larger lumens, and thinner and less organized walls (Fig. 11-1). These structural features augment the capacity of the venous side of the circulation, which on average contains about two-thirds of total blood volume. Less rigid walls means that *veins are subject to dilation and compression, as well as infiltration by tumors and inflammatory processes*. Reverse flow (due to gravity) is prevented in the extremities by venous valves.

Lymphatics are thin-walled channels lined by specialized endothelium; they provide conduits to return interstitial tissue fluid and inflammatory cells to the bloodstream. *Lymphatics can also transport microbes and tumor cells, thus constituting an important potential pathway for disease dissemination.*

KEY CONCEPTS

Vascular Structure and Function

- All vessels except capillaries share a three-layered architecture consisting of an endothelium lined intima, a surrounding smooth muscle media, and supportive adventitia, admixed with extracellular matrix.
- The smooth muscle cell and matrix content of arteries, veins, and capillaries vary according to hemodynamic demands (e.g., pressure, pulsatility) and functional requirements.
- The specific composition of the vessel wall at any given site within the vascular tree influences the nature and consequences of pathologic injuries.

Vascular Anomalies

Although rarely symptomatic, anatomic variants of the usual vascular supply are important for treating physicians to recognize, as the failure to do so may lead to surgical complications and impede attempted therapeutic interventions (e.g., placement of coronary artery stents). Among congenital vascular anomalies, three are of particular medical significance:

- *Developmental* or *berry aneurysms* occur in cerebral vessels; when ruptured, these can be causes of fatal intracerebral hemorrhage (Chapter 28).
- *Arteriovenous fistulas* are direct connections (usually small) between arteries and veins that bypass the intervening capillary bed. They occur most commonly as developmental defects but can also result from rupture of an arterial aneurysm into the adjacent vein, from penetrating injuries that pierce arteries and veins, or from inflammatory necrosis of adjacent vessels; surgically generated arteriovenous fistulas provide vascular access for chronic hemodialysis. Like berry aneurysms, arteriovenous fistulas may rupture, leading to intracerebral hemorrhage. Large or multiple arteriovenous fistulas can produce clinically significant effects by shunting blood from the arterial to the venous circulation, forcing the heart to pump additional volume and leading to high-output cardiac failure.
- *Fibromuscular dysplasia* is a focal irregular thickening in medium and large muscular arteries, including renal, carotid, splanchnic, and vertebral vessels. The cause is unknown, but is probably developmental; first-degree relatives of affected individuals have an increased incidence. Segments of the vessel wall are focally thickened by a combination of medial and intimal hyperplasia and fibrosis, resulting in luminal stenosis; in the renal arteries, this can be a cause of renovascular hypertension (Chapter 20). Immediately adjacent vessel segments can have markedly attenuated media (on angiography, the vessels are said to have a “string of beads” appearance), leading to vascular outpouchings (*aneurysms*) that can rupture. Fibromuscular dysplasia can manifest at any age; although it is seen most frequently in young women, there is no association with oral contraceptives or increased estrogen expression.

Vascular Wall Response to Injury

The integrated functioning of endothelial cells and smooth muscle cells impacts vessel development as well as the physiologic and pathophysiologic responses to hemodynamic and biochemical stimuli. Their function (and dysfunction) are described briefly, followed by discussion of specific vascular disorders.

Endothelial cells form a specialized lining for blood vessels. Although endothelial cells throughout the vascular tree share many attributes, populations that line different portions of the vascular tree (large vessels vs. capillaries, arteries vs. veins) have distinct gene expression profiles, behaviors, and morphologic appearances. Thus, endothelial cells in liver sinusoids or in renal glomeruli are

fenestrated (they have *holes*, presumably to facilitate filtration), while central nervous system endothelial cells (along with the associated perivascular cells) create an impermeable blood-brain barrier.

Endothelial cells are versatile multifunctional cells with a wealth of synthetic and metabolic properties. In the normal state they have several constitutive activities that are critical for vessel homeostasis and circulatory function. Endothelial cells have a nonthrombogenic surface that maintains blood in a fluid state (Chapter 4). They also modulate medial smooth muscle cell tone (thereby influencing vascular resistance), metabolize hormones such as angiotensin, regulate inflammation, and affect the growth of other cell types, particularly smooth muscle cells. Although interendothelial junctions are largely impermeable in normal vessels, vasoactive agents (e.g., histamine) allow the rapid egress of fluids, electrolytes and protein; in inflammation, even leukocytes can slip between adjacent endothelial cells (Chapter 3).

Endothelial cells can respond to various stimuli by adjusting their steady-state (constitutive) functions and by expressing newly acquired (inducible) properties—a process termed *endothelial activation* (Fig. 11-2). Inducers of endothelial activation include cytokines and bacterial products, which elicit inflammation and, in severe cases, septic shock (Chapter 4); hemodynamic stresses and lipid products, critical to the pathogenesis of atherosclerosis (see later); advanced glycation end-products (important in the pathologic sequelae of diabetes, Chapter 24); as well as viruses, complement components, and hypoxia. Activated endothelial cells, in turn, express adhesion molecules (Chapter 3) and produce cytokines and chemokines, growth factors, vasoactive molecules that result either in vasoconstriction or in vasodilation, major histocompatibility complex molecules, procoagulant and anticoagulant factors, and a variety of other biologically active products.

Figure 11-2 Basal and activated endothelial cell states. Normal blood pressure, laminar flow, and low growth factor levels promote a basal endothelial cell state that maintains a nonthrombotic, nonadhesive surface with appropriate vascular wall smooth muscle tone. Injury or exposure to certain mediators results in endothelial activation, a state where endothelial cells develop a procoagulant surface that can be adhesive for inflammatory cells, and also express factors that cause smooth muscle contraction and/or proliferation and matrix synthesis. VEGF, vascular endothelial growth factor.

Endothelial cells influence the vasoreactivity of the underlying smooth muscle cells through the production of both relaxing factors (e.g., nitric oxide [NO]) and contracting factors (e.g., endothelin). Normal endothelial cell function is characterized by a balance of these responses.

Endothelial dysfunction refers to an alteration in endothelial phenotype seen in many different conditions that is often both proinflammatory and prothrombogenic. It is responsible, at least in part, for the initiation of thrombus formation, atherosclerosis, and the vascular lesions of hypertension and other disorders. Certain forms of endothelial dysfunction are rapid in onset (within minutes), reversible, and independent of new protein synthesis (e.g., endothelial cell contraction induced by histamine and other vasoactive mediators that causes gaps in venular endothelium, Chapter 3). Other changes such as upregulation of adhesion molecules involve alterations in gene expression and protein synthesis and may require hours or even days to develop.

Vascular smooth muscle cells are the predominant cellular element of the vascular media, playing important roles in normal vascular repair and pathologic processes such as atherosclerosis. Smooth muscle cells have the capacity to proliferate when appropriately stimulated; they can also synthesize collagen, elastin, and proteoglycans and elaborate growth factors and cytokines. Smooth muscle cells are also responsible for the vasoconstriction or dilation that occurs in response to physiologic or pharmacologic stimuli.

Intimal Thickening: A Stereotyped Response to Vascular Injury

Vascular injury—associated with endothelial cell dysfunction or loss—stimulates smooth muscle cell recruitment and proliferation and associated matrix synthesis; the result is intimal thickening. Healing of injured vessels is analogous to the healing process that occurs in other damaged tissues (Chapter 3). Endothelial cells involved in repair may migrate from adjacent uninjured areas into denuded areas or may also be derived from circulating precursors. Medial smooth muscle cells or smooth muscle precursor cells also migrate into the intima, proliferate, and synthesize extracellular matrix in much the same way that fibroblasts fill in a wound (Fig. 11-3). The resulting neointima is typically completely covered by endothelial cells. This neointimal response occurs with any form of vascular damage or dysfunction, regardless of cause. *Thus, intimal thickening is the stereotypical response of the vessel wall to any insult.*

Neointimal smooth muscle cells have a phenotype that is distinct from that of medial smooth muscle cells. Specifically, rather than primarily functioning as contractile cells, neointimal smooth muscle cells are motile, undergo cell division, and acquire new biosynthetic capabilities. The function of neointimal smooth muscle cells is regulated by cytokines and growth factors derived from platelets, endothelial cells, and macrophages, as well as thrombin and activated complement factors. With time and restoration and/or normalization of the endothelial layer, intimal smooth muscle cells can return to a nonproliferative state. However, the healing response results in intimal thickening that may impede vascular flow.

Figure 11-3 Stereotypical response to vascular injury. Schematic diagram of intimal thickening, emphasizing intimal smooth muscle cell migration and proliferation associated with extracellular matrix synthesis. The new intimal cells are shown in a different color to emphasize that they have a proliferative, synthetic, and noncontractile phenotype distinct from medial smooth muscle cells.

KEY CONCEPTS

Response of Vascular Wall Cells to Injury

- All vessels are lined by endothelium; although all endothelial cells share certain homeostatic properties, endothelial cells in specific vascular beds have special features that allow for tissue-specific functions (e.g., fenestrated endothelial cells in renal glomeruli).
- Endothelial cell function is tightly regulated in both the basal and activated states. Various physiologic and pathophysiologic stimuli induce endothelial activation and dysfunction that alter the endothelial cell phenotype (e.g., procoagulative vs. anticoagulative, proinflammatory vs. antiinflammatory, and nonadhesive vs. adhesive).
- Injury (of almost any type) to the vessel wall results in a stereotyped healing response involving smooth muscle cell proliferation, extracellular matrix deposition, and intimal expansion.
- The recruitment and activation of the smooth muscle cell involves signals from cells (e.g., endothelial cells, platelets, and macrophages), as well as mediators derived from coagulation and complement cascades.
- Excessive thickening of the intima may result in luminal stenosis and vascular obstruction.

Hypertensive Vascular Disease

Systemic and local tissue blood pressures must be maintained within a narrow range to prevent untoward consequences. Low blood pressure (*hypotension*) results in inadequate organ perfusion and can lead to tissue dysfunction or death. Conversely, high blood pressure (*hypertension*) can cause end-organ damage and is one of the major risk factors for atherosclerosis (see later).

Like height and weight, blood pressure is a continuously distributed variable, and detrimental effects of elevated blood pressure increase continuously as blood pressure rises—no rigidly defined threshold level of blood pressure identifies those who are at risk for cardiovascular disease. Both the systolic and diastolic blood pressure are

important in determining risk; specifically, sustained diastolic pressures above 89 mm Hg or sustained systolic pressure above 139 mm Hg are associated with increased risk of atherosclerotic disease, and are thus considered clinically significant. Approximately 29% of individuals in the general population are hypertensive based on these criteria. However, such cutoffs do not reliably assess risk in all patients; for example, when other risk factors such as diabetes are present, lower thresholds are applicable.

Table 11-1 lists the major causes of hypertension. A small number of patients (approximately 5%) are said to have *secondary hypertension* resulting from an underlying renal or adrenal disease (e.g., primary aldosteronism, Cushing syndrome, or pheochromocytoma), renal artery stenosis, or other identifiable cause. *However, approximately 90% to 95% of hypertension is idiopathic—so-called essential hypertension.* Although the molecular pathways that regulate normal blood pressure are reasonably well understood, the causes of hypertension in most individuals remain unknown. It seems likely that hypertension is a multifactorial disorder, resulting from the cumulative effects of multiple genetic polymorphisms and interacting environmental factors.

The prevalence and vulnerability to complications of hypertension increase with age and are higher among African Americans. Besides increasing atherosclerotic risk, hypertension can cause cardiac hypertrophy and heart failure (*hypertensive heart disease*, Chapter 12), multi-infarct dementia (Chapter 28), aortic dissection (discussed later in this chapter), and renal failure (Chapter 20). Unfortunately, hypertension typically remains asymptomatic until late in its course and even severely elevated pressures can be clinically silent for years. Left untreated, roughly half of hypertensive patients die of ischemic heart disease (IHD) or congestive heart failure, and another third die of stroke. Treatment with blood pressure lowering drugs dramatically reduces the incidence and death rates attributable to all forms of hypertension-related pathology.

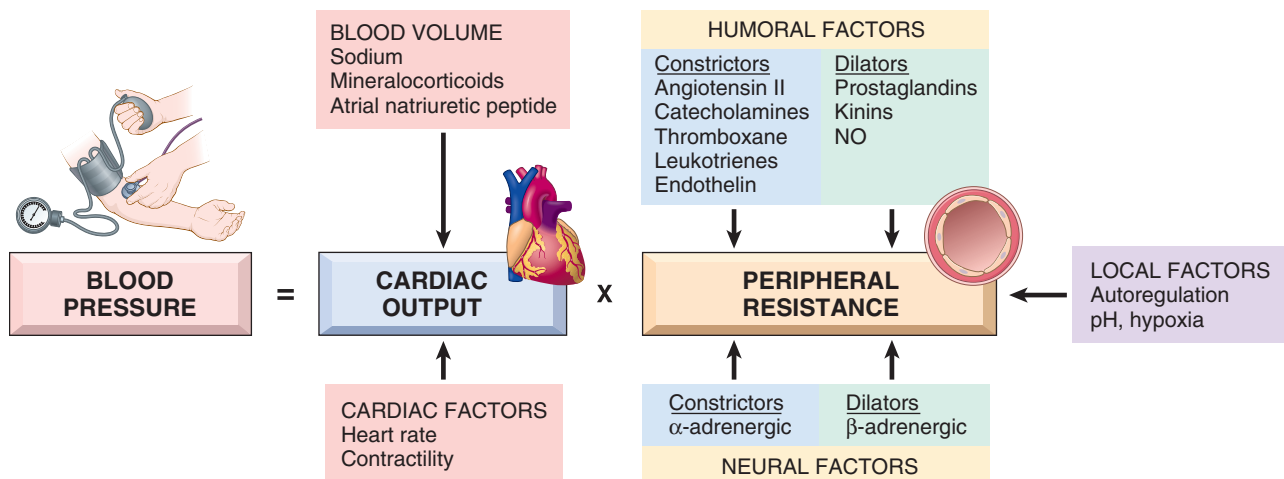

A small percentage of hypertensive persons (as much as 5%) show a rapidly rising blood pressure that, if untreated, leads to death within 1 to 2 years. This form of hypertension, called *malignant hypertension*, is characterized by severe hypertension (i.e., systolic pressure more than 200 mm Hg, diastolic pressure more than 120 mm Hg),

Table 11-1 Types and Causes of Hypertension (Systolic and Diastolic)

Essential hypertension
Accounts for 90% to 95% of all cases
Secondary hypertension
Renal
Acute glomerulonephritis
Chronic renal disease
Polycystic disease
Renal artery stenosis
Renal vasculitis
Renin-producing tumors
Endocrine
Adrenocortical hyperfunction (Cushing syndrome, primary aldosteronism, congenital adrenal hyperplasia, licorice ingestion)
Exogenous hormones (glucocorticoids, estrogen [including pregnancy-induced and oral contraceptives], sympathomimetics and tyramine-containing foods, monoamine oxidase inhibitors)
Pheochromocytoma
Acromegaly
Hypothyroidism (myxedema)
Hyperthyroidism (thyrotoxicosis)
Pregnancy-induced
Cardiovascular
Coarctation of aorta
Polyarteritis nodosa
Increased intravascular volume
Increased cardiac output
Rigidity of the aorta
Neurologic
Psychogenic
Increased intracranial pressure
Sleep apnea
Acute stress, including surgery

renal failure, and retinal hemorrhages and exudates, with or without papilledema. It can develop in previously normotensive persons but more often is superimposed on pre-existing “benign” hypertension.

This section briefly outlines normal blood pressure homeostasis, followed by a discussion of pathogenic mechanisms that underlie hypertension and a description of hypertension-associated pathologic changes in vessels.

**Figure 11-4** Blood pressure regulation. Diverse influences on cardiac output (e.g., blood volume and myocardial contractility) and peripheral resistance (neural, humoral, and local effectors) impact the output blood pressure.

Blood Pressure Regulation

Blood pressure is a function of cardiac output and peripheral vascular resistance, both of which are influenced by multiple genetic and environmental factors (Fig. 11-4). The integration of the various inputs ensures adequate systemic perfusion, despite differences in regional demand.

- *Cardiac output* is a function of stroke volume and heart rate. The most important determinant of stroke volume is the filling pressure, which is regulated through sodium homeostasis and its effect on blood volume. Heart rate and myocardial contractility (a second factor affecting stroke volume) are both regulated by the α - and β -adrenergic systems, which also have important effects on vascular tone.
- *Peripheral resistance* is regulated predominantly at the level of the arterioles by neural and hormonal inputs. Vascular tone reflects a balance between vasoconstrictors (including angiotensin II, catecholamines, and endothelin) and vasodilators (including kinins, prostaglandins, and nitric oxide). Resistance vessels also exhibit *autoregulation*, whereby increased blood flow induces vasoconstriction to protect tissues against hyperperfusion. Finally, blood pressure is fine-tuned by tissue pH and hypoxia to accommodate local metabolic demands.

Factors released from the kidneys, adrenals, and myocardium interact to influence vascular tone and to regulate blood volume by adjusting sodium balance (Fig. 11-5). The kidneys filter 170 L of plasma containing 23 moles of salt daily. Thus, with a typical daily diet containing 100 mEq of sodium, 99.5% of the filtered salt must be reabsorbed to maintain total body sodium levels. About 98% of the filtered sodium is reabsorbed by constitutively active sodium transporters. The small amount of remaining sodium is subject to resorption by the epithelial sodium channel (ENaC), which is tightly regulated by the renin-angiotensin system; it is this pathway that determines net sodium balance.

The kidneys and heart contain cells that sense changes in blood pressure or volume. In response, these cells

Figure 11-5 Interplay of renin-angiotensin-aldosterone and atrial natriuretic peptide in maintaining blood pressure homeostasis.

release circulating effectors that act in concert to maintain normal blood pressure. Kidneys influence peripheral resistance and sodium excretion/retention primarily through the renin-angiotensin system.

- *Renin* is a proteolytic enzyme produced by renal juxtaglomerular cells, myoepithelial cells that surround the glomerular afferent arterioles. Renin is released in response to low blood pressure in afferent arterioles, elevated levels of circulating catecholamines, or low sodium levels in the distal convoluted renal tubules. The latter occurs when the *glomerular filtration rate* falls (e.g., when the cardiac output is low), leading to increased sodium resorption by the proximal tubules.
- Renin cleaves *plasma angiotensinogen* to *angiotensin I*, which in turn is converted to *angiotensin II* by angiotensin-converting enzyme (ACE), mainly a product of vascular endothelium. Angiotensin II raises blood pressure by (1) inducing vascular contraction, (2) stimulating aldosterone secretion by the adrenal gland, and (3) increasing tubular sodium resorption. *Adrenal aldosterone* increases blood pressure by increasing sodium resorption (and thus water) in the distal convoluted tubule, which increases blood volume.

- The kidney also produces a variety of vascular relaxing substances (including prostaglandins and NO) that presumably counterbalance the vasopressor effects of angiotensin.

Myocardial natriuretic peptides are released from atrial and ventricular myocardium in response to volume expansion; these inhibit sodium resorption in the distal renal tubules, thus leading to sodium excretion and diuresis. They also induce systemic vasodilation.

KEY CONCEPTS

Blood Pressure Regulation

- Blood pressure is determined by vascular resistance and cardiac output.
- Vascular resistance is regulated at the level of the arterioles, influenced by neural and hormonal inputs.
- Cardiac output is determined by heart rate and stroke volume, which is strongly influenced by blood volume. Blood volume in turn is regulated mainly by renal sodium excretion or resorption.

- Renin, a major regulator of blood pressure, is secreted by the kidneys in response to decreased blood pressure in afferent arterioles. In turn, renin cleaves angiotensinogen to angiotensin I; subsequent peripheral catabolism produces angiotensin II, which regulates blood pressure by increasing vascular smooth muscle cell tone and by increasing adrenal aldosterone secretion and thereby renal sodium resorption.

Pathogenesis of Hypertension

Hypertension is a disorder with multiple genetic and environmental contributions. As already noted, **the vast majority (90% to 95%) of hypertension is idiopathic**. Even without knowing the specific lesions, it is reasonable to suppose that multiple small changes in renal sodium homeostasis and/or vessel wall tone or structure act in combination to cause essential hypertension (Fig. 11-5). Most other causes fall under the general rubric of renal disease, including renovascular hypertension (due to renal artery occlusion). Infrequently, hypertension has an underlying endocrine basis.

Pathogenesis of Secondary Hypertension. In many secondary forms of hypertension, the underlying pathways are reasonably well understood:

- In *renovascular hypertension*, renal artery stenosis causes decreased glomerular flow and pressure in the afferent arteriole of the glomerulus. This induces renin secretion, which, as already discussed, increases vascular tone and blood volume via the angiotensin-aldosterone pathway (Fig. 11-5).
- Single-gene disorders* cause severe but rare forms of hypertension:
 - Gene defects affecting enzymes involved in aldosterone metabolism* (e.g., *aldosterone synthase*, *11 β -hydroxylase*, *17 α -hydroxylase*). These lead to an increase in secretion of aldosterone, increased salt and water resorption, plasma volume expansion and, ultimately, hypertension. *Primary hyperaldosteronism* is one of the most common causes of secondary hypertension (Chapter 24).
 - Mutations affecting proteins that influence sodium reabsorption*. For example, the moderately severe form of salt-sensitive hypertension, called *Liddle syndrome*, is caused by gain-of-function mutations in an epithelial Na⁺ channel protein that increase distal tubular reabsorption of sodium in response to aldosterone.

Mechanisms of Essential Hypertension

- Genetic factors* influence blood pressure regulation, as shown by comparisons of monozygotic and dizygotic twins, and genetically related versus adopted children. Moreover, as noted earlier, several single-gene disorders cause relatively rare forms of hypertension (and hypotension) by altering net sodium reabsorption in the kidney. It is also suspected (but not yet proven) that variations in blood pressure may result from the cumulative effects of polymorphisms in several genes that affect blood pressure; for example, sequence variants in both the angiotensinogen and the angiotensin

receptor genes have been associated with hypertension in some studies.

- Reduced renal sodium excretion* in the presence of normal arterial pressure may be a key initiating event in essential hypertension and, indeed, a final common pathway for the pathogenesis of hypertension. Decreased sodium excretion may lead sequentially to an increase in fluid volume, increased cardiac output, and peripheral vasoconstriction, thereby elevating blood pressure. At the higher blood pressure, enough additional sodium is excreted by the kidneys to equal intake and prevent further fluid retention. Thus, a new steady state of sodium balance is achieved (“resetting of pressure natriuresis”), but at the expense of an increase in blood pressure.
- Vasoconstrictive influences*, such as factors that induce vasoconstriction or stimuli that cause structural changes in the vessel wall, can lead to an increase in peripheral resistance and may also play a role in essential hypertension.
- Environmental factors*, such as stress, obesity, smoking, physical inactivity, and heavy salt consumption are all implicated in hypertension. Indeed, the evidence linking dietary sodium intake with the prevalence of hypertension in different populations is particularly impressive.

Vascular Pathology in Hypertension

Hypertension not only accelerates atherogenesis (see later) but also causes degenerative changes in the walls of large and medium arteries that can lead to both aortic dissection and cerebrovascular hemorrhage. Hypertension is also associated with two forms of small blood vessel disease: hyaline arteriosclerosis and hyperplastic arteriosclerosis (Fig. 11-6).

MORPHOLOGY

Hyaline arteriosclerosis. Arterioles show homogeneous, pink hyaline thickening with associated luminal narrowing (Fig. 11-6A). These changes reflect both plasma protein leakage across injured endothelial cells, as well as increased smooth muscle cell matrix synthesis in response to the chronic hemodynamic stresses of hypertension. Although the vessels of older patients (either normotensive or hypertensive) also frequently exhibit hyaline arteriosclerosis, it is more generalized and severe in patients with hypertension. The same lesions are also a common feature of diabetic microangiopathy; in that case, the underlying etiology is hyperglycemia-induced endothelial cell dysfunction (Chapter 24). In **nephrosclerosis** due to chronic hypertension, the arteriolar narrowing of hyaline arteriosclerosis causes diffuse impairment of renal blood supply and glomerular scarring (Chapter 20).

Hyperplastic Arteriosclerosis. This lesion occurs in severe hypertension; vessels exhibit concentric, **laminated (“onion-skin”)** thickening of the walls with luminal narrowing (Fig. 11-6B). The laminations consist of smooth muscle cells with thickened, reduplicated basement membrane; in malignant hypertension, they are accompanied by fibrinoid deposits and vessel wall necrosis (**necrotizing arteriolitis**), particularly in the kidney (Chapter 20).

Figure 11-6 Vascular pathology in hypertension. **A**, Hyaline arteriosclerosis. The arteriolar wall is thickened with increased protein deposition (hyalinized), and the lumen is markedly narrowed. **B**, Hyperplastic arteriosclerosis (onion-skinning) causing luminal obliteration (periodic acid-Schiff [PAS] stain). KEY CONCEPTS

Hypertension

- Hypertension is a common disorder, affecting roughly 30% of adults in the U.S.; it is a major risk factor for atherosclerosis, congestive heart failure, and renal failure.
- Essential hypertension represents 90% to 95% of cases and is a complex, multifactorial disorder, involving both environmental influences and genetic polymorphisms that influence sodium resorption and the renin-angiotensin-aldosterone system.
- Hypertension is occasionally caused by single gene disorders or is secondary to diseases of the kidney, adrenal, or other endocrine organs.
- Sustained hypertension requires participation of the kidney, which normally responds to hypertension by eliminating salt and water. In established hypertension, both increased blood volume and increased peripheral resistance contribute to the increased blood pressure.
- Histologically, hypertension is associated with thickening of arterial walls caused by hyaline deposits and, in severe cases, by proliferation of smooth muscle cells and reduplication of basement membranes.

Arteriosclerosis

Arteriosclerosis literally means “hardening of the arteries”; it is a generic term for arterial wall thickening and loss of elasticity. There are three general patterns, with different clinical and pathologic consequences:

- *Arteriosclerosis* affects small arteries and arterioles, and may cause downstream ischemic injury. The two anatomic variants, hyaline and hyperplastic, are discussed earlier in relation to hypertension.
- *Mönckeberg medial sclerosis* is characterized by calcification of the walls of muscular arteries, typically involving the internal elastic membrane. Persons older than age 50 are most commonly affected. The calcifications

do not encroach on the vessel lumen and are usually not clinically significant.

- *Atherosclerosis*, from Greek root words for “gruel” and “hardening,” is the most frequent and clinically important pattern and is discussed here.

Atherosclerosis

Atherosclerosis underlies the pathogenesis of coronary, cerebral and peripheral vascular disease, and causes more morbidity and mortality (roughly half of all deaths) in the Western world than any other disorder. Because coronary artery disease is an important manifestation of the disease, epidemiologic data related to atherosclerosis mortality typically reflect deaths caused by ischemic heart disease ([Chapter 12](#)); indeed, myocardial infarction is responsible for almost a quarter of all deaths in the United States. Significant morbidity and mortality are also caused by aortic and carotid atherosclerotic disease and stroke.

The likelihood of atherosclerosis is determined by the combination of acquired (e.g., cholesterol levels, smoking, hypertension) and inherited (e.g., LDL receptor gene mutations) risk factors. Acting in concert they cause initial lesions called *atheromas* (also called *atheromatous* or *atherosclerotic plaques*) that protrude into vessel lumens. An atheromatous plaque consists of a raised lesion with a soft grumous core of lipid (mainly cholesterol and cholesterol esters) covered by a fibrous cap ([Fig. 11-7](#)). Besides mechanically obstructing blood flow, atherosclerotic plaques can rupture leading to catastrophic obstructive vascular thrombosis. Atherosclerotic plaque can also increase the diffusion distance from the lumen to the media, leading to ischemic injury and weakening of the vessel wall, changes that may result in aneurysm formation.

Epidemiology. Although atherosclerosis-associated ischemic heart disease is ubiquitous among most developed nations, risk reduction and improved therapies have combined to moderate the associated mortality. At the same time, reduced mortality from infectious diseases and the adoption of Western lifestyles has led to increased

Figure 11-7 Basic structure of an atherosclerotic plaque. Note that atherosclerosis is an intimal-based process.

prevalence of ischemic heart disease in developing nations. As a result, the death rate for coronary artery disease in the United States now lags behind the death rates in most of Africa, India, and Southeast Asia. The countries of the former Soviet Union hold the dubious distinction of having the highest ischemic heart disease-associated mortality rates, three to five times higher than the United States, and seven to 12 times greater than Japan.

The prevalence and severity of atherosclerosis and ischemic heart disease among individuals and groups are related to a number of risk factors. Some of these factors are constitutional (and therefore less controllable), but others are acquired or related to specific behaviors and potentially amenable to intervention (Table 11-2). Risk factors have been identified through a number of prospective analyses (e.g., the Framingham Heart Study). *These risk factors have roughly multiplicative effect.* Thus, two factors increase risk approximately four-fold, and three (i.e., hyperlipidemia, hypertension, and smoking), increase risk by a factor of seven (Fig. 11-8).

Constitutional Risk Factors

- **Genetics.** Family history is the most important independent risk factor for atherosclerosis. Certain Mendelian disorders are strongly associated with atherosclerosis (e.g., familial hypercholesterolemia; Chapter 5), but these account for only a small percentage of cases. The well-established familial predisposition to atherosclerosis and ischemic heart disease is usually polygenic, relating to familial clustering of other established risk factors, such as hypertension or diabetes, or to inherited variants that influence other pathophysiologic processes, such as inflammation.

Table 11-2 Major Risk Factors for Atherosclerosis

Nonmodifiable (Constitutional)
Genetic abnormalities
Family history
Increasing age
Male gender
Modifiable
Hyperlipidemia
Hypertension
Cigarette smoking
Diabetes
Inflammation

- **Age** is a dominant influence. Although the development of atherosclerotic plaque is typically a progressive process, it does not usually become clinically manifest until lesions reach a critical threshold in middle age or later (see later). Thus, between ages 40 and 60, the incidence of myocardial infarction increases five-fold. Death rates from ischemic heart disease rise with each decade even into advanced age.
- **Gender.** Other factors being equal, premenopausal women are relatively protected against atherosclerosis and its consequences compared to age-matched men. Thus, myocardial infarction and other complications of atherosclerosis are uncommon in premenopausal women unless they are otherwise predisposed by diabetes, hyperlipidemia, or severe hypertension. After menopause, however, the incidence of atherosclerosis-related diseases increases in women and at older ages actually exceeds that of men. Although a favorable influence of estrogen has long been proposed to explain this effect, clinical trials of estrogen replacement have not been shown to protect against vascular disease; indeed, in some studies, post-menopausal estrogen replacement actually *increased* cardiovascular risk. The atheroprotective effect of estrogens may be related to the age at which the therapy is initiated; in younger postmenopausal women, coronary atherosclerosis is diminished by estrogen therapy, while older women appear not to benefit.

Modifiable Major Risk Factors

- **Hyperlipidemia—and more specifically hypercholesterolemia—is a major risk factor for atherosclerosis; even in the absence of other risk factors, hypercholesterolemia is sufficient to initiate lesion development.** The major component of serum cholesterol associated with increased risk is low-density lipoprotein (LDL) cholesterol (“bad cholesterol”). LDL is the complex that delivers cholesterol to peripheral tissues; in contrast, high-density lipoprotein (HDL) is the complex that mobilizes cholesterol from the periphery (including atheromas) and transports it to the liver for excretion in the bile. Consequently, higher levels of HDL (“good cholesterol”) correlate with reduced risk.

Understandably, dietary and pharmacologic approaches that lower LDL or total serum cholesterol, or raise serum HDL, are of considerable interest. High

Figure 11-8 Estimated 10-year rate of coronary artery disease in 55-year old men and women as a function of established risk factors (hyperlipidemia, hypertension, smoking, and diabetes). BP, Blood pressure; ECG, electrocardiogram; HDL-C, high-density lipoprotein cholesterol; LVH, left ventricular hypertrophy. (From O'Donnell CJ, Kannel WB: Cardiovascular risks of hypertension: Lessons from observational studies. *J Hypertension* 16 (Suppl. 6):3, 1998.)

dietary intake of cholesterol and saturated fats (present in egg yolks, animal fats, and butter, for example) raises plasma cholesterol levels. Conversely, diets low in cholesterol and/or high in polyunsaturated fats lower plasma cholesterol levels. Omega-3 fatty acids (abundant in fish oils) are beneficial, whereas (trans)-unsaturated fats produced by artificial hydrogenation of polyunsaturated oils (used in baked goods and margarine) adversely affect cholesterol profiles. Exercise and moderate consumption of ethanol raise HDL levels whereas obesity and smoking lower it. *Statins* are a class of drugs that lower circulating cholesterol levels by inhibiting hydroxymethylglutaryl coenzyme A (HMG CoA) reductase, the rate-limiting enzyme in hepatic cholesterol biosynthesis (Chapter 5). In the past two decades, statins have been used widely to lower serum cholesterol levels, arguably one of the most significant success stories of translational research.

- **Hypertension** (see earlier) is another major risk factor for atherosclerosis; both systolic and diastolic levels are important. On its own, hypertension can increase the risk of ischemic heart disease by approximately 60% versus normotensive populations (Fig. 11-8). Chronic hypertension is the most common cause of left ventricular hypertrophy, and hence the latter is also a surrogate marker for cardiovascular risk.
- **Cigarette smoking** is a well-established risk factor in men and likely accounts for the increasing incidence and severity of atherosclerosis in women. Prolonged (years) smoking of one pack of cigarettes or more daily doubles the death rate from ischemic heart disease. Smoking cessation reduces that risk substantially.
- **Diabetes mellitus** induces hypercholesterolemia (Chapter 24) and markedly increases the risk of atherosclerosis. Other factors being equal, the incidence of myocardial

infarction is twice as high in patients with diabetes than in those without. There is also an increased risk of stroke and a 100-fold increased risk of atherosclerosis-induced gangrene of the lower extremities.

Additional Risk Factors

As many as 20% of all cardiovascular events occur in the absence of overt risk factors (e.g., hypertension, hyperlipidemia, smoking, or diabetes). Indeed, more than 75% of cardiovascular events in previously healthy women occur with LDL cholesterol levels below 160 mg/dL (levels generally considered to connote low risk). Clearly, other factors also contribute to risk; among those that are proven or suspected are the following:

- **Inflammation.** Inflammation is present during all stages of atherogenesis and is intimately linked with atherosclerotic plaque formation and rupture (see later). With the increasing recognition that inflammation plays a significant causal role in ischemic heart disease, assessment of systemic inflammation has become important in overall risk stratification. While a number of circulating markers of inflammation correlate with ischemic heart disease risk, *C-reactive protein (CRP)* has emerged as one of the simplest to measure and one of the most sensitive.

CRP is an acute phase reactant synthesized primarily by the liver. Its expression is increased by a number of inflammatory mediators, particularly IL-6, and it augments the innate immune response by binding to bacteria and activating the classical complement cascade. Whether CRP has any causal role in atherosclerosis is controversial. However, it is well established that plasma CRP is a strong, independent marker of risk for myocardial infarction, stroke, peripheral arterial disease,

Figure 11-9 C reactive protein (CRP) predicts cardiovascular risk. Relative risk (y-axis) refers to the risk of a cardiovascular event (e.g., myocardial infarction). The x-axis is the 10-year risk of a cardiovascular event derived from established risk factors identified in the Framingham Heart Study. In each risk group, CRP values further stratify patients. (Data from Ridker PM, et al: Comparison of C-reactive protein and low-density lipoprotein cholesterol levels in the prediction of first cardiovascular events. *N Engl J Med* 347:1557, 2002.)

and sudden cardiac death, even among apparently healthy individuals (Fig. 11-9). Accordingly, CRP levels have been incorporated into risk stratification algorithms. CRP is also a useful marker for gauging the effects of risk reduction measures, such as smoking cessation, weight loss, exercise, and statins; each one of these reduce CRP levels.

- **Hyperhomocystinemia.** Serum homocysteine levels correlate with coronary atherosclerosis, peripheral vascular disease, stroke, and venous thrombosis. *Homocystinuria*, due to rare inborn errors of metabolism, results in elevated circulating homocysteine (>100 $\mu\text{mol/L}$) and is associated with premature vascular disease. Although low folate and vitamin B₁₂ levels can increase homocysteine, supplemental vitamin ingestion does not affect the incidence of cardiovascular disease.
- **Metabolic syndrome.** Associated with central obesity (Chapter 9), this entity is characterized by insulin resistance, hypertension, dyslipidemia (elevated LDL and depressed HDL), hypercoagulability, and a proinflammatory state. The dyslipidemia, hyperglycemia, and hypertension are all cardiac risk factors, while the systemic hypercoagulable and proinflammatory state may contribute to endothelial dysfunction and/or thrombosis.
- **Lipoprotein a [Lp(a)]** is an altered form of LDL that contains the apolipoprotein B-100 portion of LDL linked to apolipoprotein A (apo A); Lp(a) levels are associated with coronary and cerebrovascular disease risk, independent of total cholesterol or LDL levels.
- **Factors affecting hemostasis.** Several markers of hemostatic and/or fibrinolytic function (e.g., elevated plasminogen activator inhibitor 1) are potent predictors of risk for major atherosclerotic events, including myocardial infarction and stroke. Platelet-derived factors, as well as thrombin—through both its procoagulant and

proinflammatory effects—are increasingly recognized as major contributors to vascular pathology.

- **Other factors.** Factors associated with a less pronounced and/or difficult-to-quantitate risk include lack of exercise; competitive, stressful life style (“type A” personality); and obesity (the latter also being complicated by hypertension, diabetes, hypertriglyceridemia, and decreased HDL).

Pathogenesis of Atherosclerosis

The clinical importance of atherosclerosis has stimulated enormous interest in understanding the mechanisms that underlie its evolution and complications. The contemporary view of atherogenesis integrates the risk factors previously discussed and is called the “response to injury” hypothesis. **This model views atherosclerosis as a chronic inflammatory and healing response of the arterial wall to endothelial injury. Lesion progression occurs through interaction of modified lipoproteins, monocyte-derived macrophages, and T lymphocytes with endothelial cells and smooth muscle cells of the arterial wall (Fig. 11-10).** According to this schema, atherosclerosis progresses in the following sequence:

- **Endothelial injury and dysfunction**, causing (among other things) increased vascular permeability, leukocyte adhesion, and thrombosis
- **Accumulation of lipoproteins** (mainly LDL and its oxidized forms) in the vessel wall
- **Monocyte adhesion to the endothelium**, followed by migration into the intima and transformation into *macrophages* and *foam cells*
- **Platelet adhesion**
- **Factor release** from activated platelets, macrophages, and vascular wall cells, inducing *smooth muscle cell recruitment*, either from the media or from circulating precursors
- **Smooth muscle cell proliferation, extracellular matrix production, and recruitment of T cells.**
- **Lipid accumulation** both extracellularly and within cells (macrophages and smooth muscle cell)

Endothelial Injury. Endothelial cell injury is the cornerstone of the response-to-injury hypothesis. Endothelial loss due to *any* kind of injury—induced experimentally by mechanical denudation, hemodynamic forces, immune complex deposition, irradiation, or chemicals—results in intimal thickening. However, *early human lesions begin at sites of morphologically intact endothelium.* Thus, non-denuding *endothelial dysfunction* underlies most human atherosclerosis; the intact but dysfunctional endothelial cells exhibit increased endothelial permeability, enhanced leukocyte adhesion, and altered gene expression.

The specific pathways of and factors contributing to endothelial cell dysfunction in early atherosclerosis are not completely understood: etiologic culprits include toxins from cigarette smoke, homocysteine, and even infectious agents, according to some (blame the bugs!). Inflammatory cytokines (e.g., tumor necrosis factor [TNF]) can also stimulate pro-atherogenic endothelial gene expression. However, **the two most important causes of endothelial dysfunction are hemodynamic disturbances and hypercholesterolemia.**

Figure 11-10 Evolution of arterial wall changes in the response to injury hypothesis. 1, Normal. 2, Endothelial injury with monocyte and platelet adhesion. 3, Monocyte and smooth muscle cell migration into the intima, with macrophage activation. 4, Macrophage and smooth muscle cell uptake of modified lipids, with further activation and recruitment of T cells. 5, Intimal smooth muscle cell proliferation with extracellular matrix production, forming a well-developed plaque.

Hemodynamic Disturbances. The importance of hemodynamic turbulence in atherogenesis is illustrated by the observation that plaques tend to occur at ostia of exiting vessels, branch points, and along the posterior wall of the abdominal aorta, where there are disturbed flow patterns. In vitro studies have demonstrated that nonturbulent laminar flow leads to the induction of endothelial genes whose products (e.g., the antioxidant superoxide dismutase) actually *protect* against atherosclerosis. Such “atheroprotective” genes could explain the nonrandom localization of early atherosclerotic lesions.

Lipids. Lipids are transported in the bloodstream bound to specific apoproteins (forming lipoprotein complexes). *Dyslipoproteinemias* are lipoprotein abnormalities that may be present in the general population (and indeed, are found in many myocardial infarction survivors) include (1) increased LDL cholesterol levels, (2) decreased HDL cholesterol levels, and (3) increased levels of the abnormal lipoprotein (a). These may result from mutations that lead to defects in apoproteins or lipoprotein receptors, or arise from other underlying disorders that affect circulating lipid levels, such as nephrotic syndrome, alcoholism, hypothyroidism, or diabetes mellitus. All of these abnormalities are associated with an increased risk of atherosclerosis.

The evidence implicating hypercholesterolemia in atherogenesis includes:

- The dominant lipids in atheromatous plaques are cholesterol and cholesterol esters.
- Genetic defects in lipoprotein uptake and metabolism that cause hyperlipoproteinemia are associated with accelerated atherosclerosis. For example, familial hypercholesterolemia, caused by defective LDL receptors and inadequate hepatic LDL uptake ([Chapter 5](#)), can precipitate myocardial infarctions before age 20. Similarly, accelerated atherosclerosis occurs in animal models with engineered deficiencies in apolipoproteins or LDL receptors.
- Other genetic or acquired disorders (e.g., diabetes mellitus, hypothyroidism) that cause hypercholesterolemia lead to premature atherosclerosis.
- Epidemiologic analyses demonstrate a significant correlation between the severity of atherosclerosis and the levels of total plasma cholesterol or LDL.
- Lowering serum cholesterol by diet or drugs slows the rate of progression of atherosclerosis, causes regression of some plaques, and reduces the risk of cardiovascular events.

The mechanisms by which hyperlipidemia contributes to atherogenesis include the following:

- Chronic hyperlipidemia, particularly hypercholesterolemia, can directly impair endothelial cell function

by increasing local reactive oxygen species production; besides causing membrane and mitochondrial damage, oxygen free radicals accelerate nitric oxide decay, damping its vasodilator activity.

- With chronic hyperlipidemia, lipoproteins accumulate within the intima, where they may aggregate or become oxidized by free radicals produced by inflammatory cells. Such modified LDL is then accumulated by macrophages through a variety of scavenger receptors (distinct from the LDL receptor). Because the modified lipoproteins cannot be completely degraded, chronic ingestion leads to the formation of lipid-filled macrophages called *foam cells*; smooth muscle cells can similarly transform into lipid-laden foam cells by ingesting modified lipids through LDL-receptor related proteins. Not only are the modified lipoproteins toxic to endothelial cells, smooth muscle cells, and macrophages, but their binding and uptake also stimulates the release of growth factors, cytokines, and chemokines that create a vicious cycle of monocyte recruitment and activation.

Inflammation. Chronic inflammation contributes to the initiation and progression of atherosclerotic lesions. It is believed that inflammation is triggered by the accumulation of cholesterol crystals and free fatty acids in macrophages and other cells. These cells sense the presence of abnormal materials via cytosolic innate immune receptors that are components of the inflammasome (Chapter 6). The resulting inflammasome activation leads to the production of the pro-inflammatory cytokine IL-1, which serves to recruit leukocytes, including monocytes. T lymphocytes are also activated, but what these T cells recognize and why these substances are detected as foreign “invaders” is not known. The net result of macrophage and T cell activation is the local production of cytokines and chemokines that recruit and activate more inflammatory cells. Activated macrophages produce reactive oxygen species that enhance LDL oxidation, and elaborate growth factors that drive smooth muscle cell proliferation. Activated T cells in the growing intimal lesions elaborate inflammatory cytokines, e.g., interferon- γ , which, in turn, can activate macrophages as well as endothelial cells and smooth muscle cells. These leukocytes and vascular wall cells release growth factors that promote smooth muscle cell proliferation and synthesis of extracellular matrix proteins. Thus, many of the lesions of atherosclerosis are attributable to the chronic inflammatory reaction in the vessel wall.

Infection. Although circumstantial evidence has been presented linking atherosclerosis to herpesvirus, cytomegalovirus, and *Chlamydomphila pneumoniae*, there is no established causal role for infection.

Smooth Muscle Proliferation and Matrix Synthesis. Intimal smooth muscle cell proliferation and extracellular matrix deposition convert a fatty streak into a mature atheroma and contribute to the progressive growth of atherosclerotic lesions (Fig. 11-10). Intimal smooth muscle cells have a proliferative and synthetic phenotype distinct from the underlying medial smooth muscle cells. Several growth factors are implicated in smooth muscle cell proliferation, including platelet-derived growth factor (PDGF, released by locally adherent platelets, as well as

macrophages, endothelial cells, and smooth muscle cells), fibroblast growth factor, and transforming growth factor- α (Chapter 1). These factors also stimulate smooth muscle cells to synthesize extracellular matrix (notably collagen), which stabilizes atherosclerotic plaques. In contrast, activated inflammatory cells in atheromas may increase the breakdown of extracellular matrix components, resulting in unstable plaques (see later).

Overview. Figure 11-11 summarizes the major pathogenic pathways in atherogenesis, emphasizing the multifactorial nature of the disease. This schematic highlights the concept of atherosclerosis as a chronic inflammatory response—and ultimately an attempt at vascular “healing”—driven by a variety of insults, including endothelial cell injury, lipid oxidation and accumulation, and inflammation. Atheromas are dynamic lesions consisting of dysfunctional endothelial cells, proliferating smooth muscle cells, and admixed T lymphocytes and macrophages. All four cell types are capable of liberating mediators that can influence atherogenesis. Thus, at early stages, intimal plaques are little more than aggregates of smooth muscle cells, macrophages, and foam cells; death of these cells releases lipids and necrotic debris. With progression, the atheroma is modified by extracellular matrix synthesized by smooth muscle cells; connective tissue is particularly prominent on the intimal aspect forming a fibrous cap, although lesions also typically retain a central core of lipid-laden cells and fatty debris that can become calcified. The intimal plaque may progressively encroach on the vessel lumen, or may compress the underlying media, leading to its degeneration; this in turn may expose thrombogenic factors such as tissue factor, resulting in thrombus formation and acute vascular occlusion.

MORPHOLOGY

Fatty streaks. Fatty streaks are composed of lipid-filled foamy macrophages. Beginning as multiple minute flat yellow spots, they eventually coalesce into elongated streaks 1 cm long or longer. These lesions are not sufficiently raised to cause any significant flow disturbances (Fig. 11-12). Although fatty streaks can evolve into plaques, not all are destined to become advanced lesions. Aortas of infants can exhibit fatty streaks, and such lesions are present in virtually all adolescents, even those without known risk factors. The observation that coronary fatty streaks begin to form in adolescence, at the same anatomic sites that later tend to develop plaques, suggests a temporal evolution of these lesions.

Atherosclerotic Plaque. The key processes in atherosclerosis are intimal thickening and lipid accumulation, which together form plaques (Figs. 11-7, 11-10, and 11-11). Atheromatous plaques are white-yellow and encroach on the lumen of the artery; superimposed thrombus over ulcerated plaques is red-brown. Plaques vary in size but can coalesce to form larger masses (Fig. 11-13).

Atherosclerotic lesions are patchy, usually involving only a portion of any given arterial wall and are rarely circumferential; on cross-section, the lesions therefore appear “eccentric” (see Fig. 11-14A). The focality of atherosclerotic lesions—despite the uniform exposure of vessel walls to such factors as cigarette

Figure 11-11 Sequence of cellular interactions in atherosclerosis. Hyperlipidemia, hyperglycemia, hypertension, and other influences cause endothelial dysfunction. This results in platelet adhesion and recruitment of circulating monocytes and T cells, with subsequent cytokine and growth factor release from inflammatory cells leading to smooth muscle cell migration and proliferation as well as further macrophage activation. Foam cells in atheromatous plaques derive from macrophages and smooth muscle cells that have accumulated modified lipids (e.g., oxidized and aggregated low density lipoprotein [LDL]) via scavenger and LDL-receptor-related proteins. Extracellular lipid is derived from insudation from the vessel lumen, particularly in the presence of hypercholesterolemia, as well as from degenerating foam cells. Cholesterol accumulation in the plaque reflects an imbalance between influx and efflux; high-density lipoprotein (HDL) likely helps clear cholesterol from these accumulations. In response to the elaborated cytokines and chemokines, smooth muscle cells migrate to the intima, proliferate, and produce extracellular matrix, including collagen and proteoglycans. IL-1, interleukin-1; MCP-1, monocyte chemoattractant protein-1.

(B, Courtesy Myron I. Cybulsky, MD, University of Toronto, Canada.)

Figure 11-13 Gross views of atherosclerosis in the aorta. **A**, Mild atherosclerosis composed of fibrous plaques, one of which is denoted by the arrow. **B**, Severe disease with diffuse and complicated lesions including an ulcerated plaque (*open arrow*), and a lesion with overlying thrombus (*closed arrow*).

smoke toxins, elevated LDL, and hyperglycemia—is attributable to the vagaries of vascular hemodynamics. Local flow disturbances, such as turbulence at branch points, make certain portions of a vessel wall more susceptible to plaque formation. Although focal and sparsely distributed at first, with time atherosclerotic lesions can become larger, more numerous, and more broadly distributed. Moreover, in any given vessel, lesions at various stages often coexist.

In descending order, **the most extensively involved vessels are the lower abdominal aorta, the coronary arteries, the popliteal arteries, the internal carotid arteries, and the vessels of the circle of Willis.** In humans, the abdominal aorta is typically involved to a much greater degree than the thoracic aorta. Vessels of the upper extremities are usually spared, as are the mesenteric and renal arteries, except at their ostia. Although most individuals tend to have a consistent degree of atherosclerotic burden in the affected vasculature, severity of disease in one arterial distribution does not always predict its severity in another.

Atherosclerotic plaques have three principal components: (1) smooth muscle cells, macrophages, and T cells; (2) extracellular matrix, including collagen, elastic fibers, and proteoglycans; and (3) intracellular and extracellular lipid (Fig. 11-14). These components occur in varying proportions and configurations in different lesions. Typically, there is a superficial fibrous cap composed of smooth muscle cells and relatively dense collagen. Beneath and to the side of the cap (the “shoulder”) is a more cellular area containing macrophages, T cells, and smooth muscle cells. Deep to the fibrous cap is a necrotic core, containing lipid (primarily cholesterol and cholesterol esters), debris from dead cells, foam cells (lipid-laden macrophages and smooth muscle cells), fibrin, variably organized thrombus, and other plasma proteins; the cholesterol content is frequently present as crystalline aggregates that are washed out during routine tissue processing and leave behind only empty “clefts.” The periphery of the lesions demonstrate **neovascularization** (proliferating small blood vessels; Fig. 11-14C). Most atheromas contain abundant lipid, but some

Figure 11-14 Histologic features of atheromatous plaque in the coronary artery. **A**, Overall architecture demonstrating fibrous cap (F) and a central necrotic core (C) containing cholesterol and other lipids. The lumen (L) has been moderately compromised. Note that a segment of the wall is plaque free (*arrow*); the lesion is therefore “eccentric.” In this section, collagen has been stained blue (Masson trichrome stain). **B**, Higher-power photograph of a section of the plaque shown in **A**, stained for elastin (black), demonstrating that the internal and external elastic laminae are attenuated and the media of the artery is thinned under the most advanced plaque (*arrow*). **C**, Higher magnification photomicrograph at the junction of the fibrous cap and core, showing scattered inflammatory cells, calcification (*arrowhead*), and neovascularization (*small arrows*).

Figure 11-15 Atherosclerotic plaque rupture. **A**, Plaque rupture without superimposed thrombus, in a patient who died suddenly. **B**, Acute coronary thrombosis superimposed on an atherosclerotic plaque with focal disruption of the fibrous cap, triggering fatal myocardial infarction. In both **A** and **B**, an arrow points to the site of plaque rupture. (**B**, Reproduced from Schoen FJ: *Interventional and Surgical Cardiovascular Pathology: Clinical Correlations and Basic Principles*. Philadelphia, WB Saunders, 1989, p 61.)

plaques (“fibrous plaques”) are composed almost exclusively of smooth muscle cells and fibrous tissue.

Plaques generally continue to change and progressively enlarge through cell death and degeneration, synthesis and degradation (remodeling) of extracellular matrix, and organization of any superimposed thrombus. Moreover, atheromas often undergo calcification (Fig. 11-14C). Patients with advanced coronary calcification have increased risk for coronary events.

Atherosclerotic plaques are susceptible to the following clinically important pathologic changes:

- **Rupture, ulceration, or erosion** of the surface of atheromatous plaques exposes highly thrombogenic substances and leads to **thrombosis**, which may partially or completely occlude the vessel lumen (Fig. 11-15). If the patient survives, the clot may become organized and incorporated into the growing plaque.
- **Hemorrhage into a plaque.** Rupture of the overlying fibrous cap, or of the thin-walled vessels in the areas of neovascularization, can cause intraplaque hemorrhage; a contained hematoma may expand the plaque or induce plaque rupture.

- **Atheroembolism.** Plaque rupture can discharge atherosclerotic debris into the bloodstream, producing microemboli.
- **Aneurysm formation.** Atherosclerosis-induced pressure or ischemic atrophy of the underlying media, with loss of elastic tissue, causes weakness and potential rupture.

Consequences of Atherosclerotic Disease

Large elastic arteries (e.g., aorta, carotid, and iliac arteries) and large and medium-sized muscular arteries (e.g., coronary and popliteal arteries) are the major targets of atherosclerosis. Symptomatic atherosclerotic disease most often involves the arteries supplying the heart, brain, kidneys, and lower extremities. **Myocardial infarction (heart attack), cerebral infarction (stroke), aortic aneurysms, and peripheral vascular disease (gangrene of the legs) are the major consequences of atherosclerosis.** The natural history, principal morphologic features, and main pathogenic events are schematized in Figure 11-16.

We next describe the features of atherosclerotic lesions that are typically responsible for the clinicopathologic manifestations.

Figure 11-16 The natural history, morphologic features, main pathogenic events, and clinical complications of atherosclerosis.

Atherosclerotic Stenosis. In small arteries, atherosclerotic plaques can gradually occlude vessel lumina, compromising blood flow and causing ischemic injury. At early stages of stenosis, outward remodeling of the vessel media tends to preserve the size of the lumen. However, there are limits on the extent of remodeling, and eventually the expanding atheroma impinges on the lumen to such a degree that blood flow is compromised. *Critical stenosis* is the stage at which the occlusion is sufficiently severe to produce tissue ischemia. In the coronary (and other) circulations, this typically occurs at when the occlusion produces a 70% decrease in luminal cross-sectional area; with this degree of stenosis, chest pain may develop with exertion (so-called *stable angina*; see Chapter 12). Although acute plaque rupture (see later) is the most dangerous consequence, atherosclerosis also takes a toll through chronically diminished arterial perfusion: *mesenteric occlusion and bowel ischemia, sudden cardiac death, chronic ischemic heart disease, ischemic encephalopathy, and intermittent claudication* (diminished perfusion of the extremities) are all consequences of flow-limiting stenoses. The effects of vascular occlusion ultimately depend on arterial supply and the metabolic demand of the affected tissue.

Acute Plaque Change. Plaque erosion or rupture is typically promptly followed by partial or complete vascular thrombosis (Fig. 11-15), resulting in acute tissue infarction (e.g., myocardial or cerebral infarction) (Fig. 11-16). Plaque changes fall into three general categories:

- *Rupture/fissuring*, exposing highly thrombogenic plaque constituents
- *Erosion/ulceration*, exposing the thrombogenic subendothelial basement membrane to blood
- *Hemorrhage into the atheroma*, expanding its volume

It is now recognized that plaques that are responsible for myocardial infarction and other acute coronary syndromes are often asymptomatic before the acute change. Thus, pathologic and clinical studies show that the majority of plaques that undergo abrupt disruption and coronary occlusion previously showed only mild to moderate noncritical luminal stenosis. The worrisome conclusion is that a large number of now asymptomatic adults may be at risk for a catastrophic coronary event. Unfortunately, it is presently impossible to identify such individuals.

Plaques rupture when they are unable to withstand mechanical stresses generated by vascular shear forces. The events that trigger abrupt changes in plaques and subsequent thrombosis are complex and include both intrinsic factors (e.g., plaque structure and composition) and extrinsic elements (e.g., blood pressure, platelet reactivity, vessel spasm).

The composition of plaques is dynamic and can contribute to risk of rupture. Thus, plaques that contain large areas of foam cells and extracellular lipid, and those in which the fibrous caps are thin or contain few smooth muscle cells or have clusters of inflammatory cells, are more likely to rupture; these are referred to as “vulnerable plaques” (Fig. 11-17).

The fibrous cap undergoes continuous remodeling that can stabilize the plaque, or conversely, render it more susceptible to rupture. Collagen is the major structural component of the fibrous cap, and accounts for its mechanical strength and

Figure 11-17 Vulnerable and stable atherosclerotic plaque. *Vulnerable* plaques have thin fibrous caps, large lipid cores, and greater inflammation. Stable plaques have thickened and densely collagenous fibrous caps with minimal inflammation and underlying atheromatous core. (Adapted from Libby P: *Circulation* 91:2844, 1995.)

stability. Thus, the balance of collagen synthesis versus degradation affects cap integrity. Collagen in atherosclerotic plaque is produced primarily by smooth muscle cells so that loss of these cells results in a less sturdy cap. Moreover, collagen turnover is controlled by metalloproteinases (MMPs), enzymes elaborated largely by macrophages and smooth muscle cells within the atheromatous plaque; conversely, tissue inhibitors of metalloproteinases (TIMPs) produced by endothelial cells, smooth muscle cells, and macrophages modulate MMP activity. In general, plaque inflammation results in a net increase in collagen degradation and reduced collagen synthesis, thereby destabilizing the mechanical integrity of the fibrous cap (see later). The inflammation induced by cholesterol deposits themselves may contribute to plaque destabilization. Conversely, statins may have a beneficial therapeutic effect not only by reducing circulating cholesterol levels, but also by stabilizing plaques through a reduction in plaque inflammation.

Influences extrinsic to plaques also contribute to acute plaque changes. Thus, adrenergic stimulation can increase systemic blood pressure or induce local vasoconstriction, thereby increasing the physical stresses on a given plaque. Indeed, the adrenergic stimulation associated with wakening and rising can cause blood pressure spikes (followed by heightened platelet reactivity) that have been causally linked to the pronounced circadian periodicity for onset of acute MI (peaking between 6 AM and noon). Intense emotional stress can also contribute to plaque disruption; this is most dramatically illustrated by the uptick in the incidence of sudden death associated with natural or other disasters, such as earthquakes and the September 11, 2001, attack on the World Trade Center.

It is also important to note that not all plaque ruptures result in occlusive thromboses with catastrophic consequences. Indeed, plaque disruption and an ensuing superficial platelet aggregation and thrombosis are probably common, repetitive, and often clinically silent complications of atheroma. Healing of these subclinical plaque disruptions—and resorption of their overlying thrombi—is an important mechanism in the growth of atherosclerotic lesions.

Thrombosis. As mentioned earlier, partial or total thrombosis superimposed on a disrupted plaque is a central factor in acute coronary syndromes. In its most serious form, thrombosis leads to total occlusion of the affected vessel. In contrast, in other coronary syndromes (Chapter 12), luminal obstruction by the thrombus is incomplete, and may even wax and wane with time.

Mural thrombi in a coronary artery can also embolize. Indeed, small embolic fragments of thrombus can often be found in the distal intramyocardial circulation or in association with microinfarcts in patients with atherosclerosis who die suddenly. Finally, thrombin and other factors associated with thrombosis are potent activators of smooth muscle cells and can thereby contribute to the growth of atherosclerotic lesions.

Vasoconstriction. Vasoconstriction compromises lumen size, and, by increasing the local mechanical forces, can potentiate plaque disruption. Vasoconstriction at sites of atheroma may be stimulated by (1) circulating adrenergic agonists, (2) locally released platelet contents, (3) endothelial cell dysfunction with impaired secretion of endothelial-derived relaxing factors (nitric oxide) relative to contracting factors (endothelin), and (4) mediators released from perivascular inflammatory cells.

KEY CONCEPTS

Atherosclerosis

- Atherosclerosis is an intimal-based lesion composed of a fibrous cap and an atheromatous core; the constituents of the plaque include smooth muscle cells, extracellular matrices, inflammatory cells, lipids, and necrotic debris.
- Atherogenesis is driven by an interplay of vessel wall injury and inflammation. The multiple risk factors for atherosclerosis all cause endothelial cell dysfunction and influence inflammatory cell and smooth muscle cell recruitment and stimulation.
- Atherosclerotic plaques develop and grow slowly over decades. Stable plaques can produce symptoms related to chronic ischemia by narrowing vessel lumens, whereas unstable plaques can cause dramatic and potentially fatal

ischemic complications related to acute plaque rupture, thrombosis, or embolization.

- Stable plaques tend to have a dense fibrous cap, minimal lipid accumulation and little inflammation, whereas “vulnerable” unstable plaques have thin caps, large lipid cores, and relatively dense inflammatory infiltrates.

Aneurysms and Dissection

An aneurysm is a localized abnormal dilation of a blood vessel or the heart that may be congenital or acquired (Fig. 11-18). When an aneurysm involves an attenuated but intact arterial wall or thinned ventricular wall of the heart, it is called a “true” aneurysm. Atherosclerotic, syphilitic, and congenital vascular aneurysms, as well as ventricular aneurysms that follow transmural myocardial infarctions are of this type. In contrast, a *false aneurysm* (also called *pseudo-aneurysm*) is a defect in the vascular wall leading to an extravascular hematoma that freely communicates with the intravascular space (“pulsating hematoma”). Examples include a ventricular rupture after myocardial infarction that is contained by a pericardial adhesion, or a leak at the sutured junction of a vascular graft with a natural artery. An arterial *dissection* arises when blood enters a defect in the arterial wall and tunnels between its layers. Dissections are often but not always aneurysmal (see later). Both true and false aneurysms as well as dissections can rupture, often with catastrophic consequences.

Descriptively, aneurysms are classified by macroscopic shape and size (Fig. 11-18). *Saccular aneurysms* are spherical outpouchings involving only a portion of the vessel wall; they vary from 5 to 20 cm in diameter and often contain thrombus. *Fusiform aneurysms* are diffuse, circumferential dilations of a long vascular segment; they vary in diameter (up to 20 cm) and in length and can involve extensive portions of the aortic arch, abdominal aorta, or even the iliacs. These types are not specific for any disease or clinical manifestations.

Pathogenesis of Aneurysms. To maintain their structural and functional integrity, arterial walls constantly remodel

Figure 11-18 Aneurysms. **A**, Normal vessel. **B**, True aneurysm, saccular type. The wall focally bulges outward and may be attenuated but is otherwise intact. **C**, True aneurysm, fusiform type. There is circumferential dilation of the vessel, without rupture. **D**, False aneurysm. The wall is ruptured, and there is a collection of blood (hematoma) that is bounded externally by adherent extravascular tissues. **E**, Dissection. Blood has entered (dissected) the wall of the vessel and separated the layers. Although this is shown as occurring through a tear in the lumen, dissections can also occur by rupture of the vessels of the vasa vasorum within the media.

by synthesizing, degrading, and repairing damage to their extracellular matrix constituents. Aneurysms can occur when the structure or function of the connective tissue within the vascular wall is compromised. Although we cite here examples of inherited defects in connective tissues, weakening of vessel walls is important in the more common, sporadic forms of aneurysms as well.

- *The intrinsic quality of the vascular wall connective tissue is poor.* In *Marfan syndrome*, for example (Chapter 5), defective synthesis of the scaffolding protein *fibrillin* leads to aberrant TGF- β activity and weakening of elastic tissue; in the aorta, this may result in progressive dilation. *Loeys-Dietz syndrome* is another cause of aneurysms; in this disorder, mutations in TGF- β receptors lead to defective synthesis of elastin and collagens I and III. Aneurysms in such individuals can rupture fairly easily (even at small size) and are thus considered to follow an “aggressive” course. Weak vessel walls due to defective type III collagen synthesis are also a hallmark of the vascular forms of *Ehlers-Danlos syndrome* (Chapter 5), and altered collagen cross-linking associated with vitamin C deficiency (scurvy) is an example of a nutritional basis for aneurysm formation, that is thankfully rare these days.
- *The balance of collagen degradation and synthesis is altered by inflammation and associated proteases.* In particular, increased matrix metalloprotease (MMP) expression, especially by macrophages in atherosclerotic plaque or in vasculitis, likely contributes to aneurysm development; these enzymes have the capacity to degrade virtually all components of the extracellular matrix in the arterial wall (collagens, elastin, proteoglycans, laminin, fibronectin). Decreased expression of tissue inhibitors of metalloproteases (TIMPs) can also contribute to the extracellular matrix degradation. The risk of aneurysm formation in the setting of inflammatory lesions (e.g., atherosclerosis) may be associated with MMP and/or TIMP polymorphisms, or altered by the nature of the local inflammatory response. For example, abdominal aortic aneurysms (AAA; see later) are associated with local production of cytokines (such as IL-4 and IL-10) that stimulate release of elastolytic MMP from macrophages.
- *The vascular wall is weakened through loss of smooth muscle cells or the synthesis of noncollagenous or nonelastic extracellular matrix.* Ischemia of the inner media occurs when there is atherosclerotic thickening of the intima, which increases the distance that oxygen and nutrients must diffuse. Systemic hypertension can also cause significant narrowing of arterioles of the vasa vasorum (e.g., in the aorta), which causes outer medial ischemia. Medial ischemia may lead to “degenerative changes” of the aorta, whereby smooth muscle cell loss—or change in synthetic phenotype—leads to scarring (and loss of elastic fibers), inadequate extracellular matrix synthesis, and production of increasing amounts of amorphous ground substance (glycosaminoglycan). Histologically, these changes are collectively recognized as *cystic medial degeneration* (Fig. 11-19), which can be seen in a variety of settings, including Marfan syndrome and scurvy.

Tertiary syphilis is another rare cause of aortic aneurysms. The obliterative endarteritis characteristic of late-stage syphilis shows a predilection for small vessels,

Figure 11-19 Cystic medial degeneration. **A**, Cross-section of aortic media from a patient with Marfan syndrome, showing elastin fragmentation and areas devoid of elastin that resemble cystic spaces but are actually filled with proteoglycans (asterisks). **B**, Normal media for comparison, showing the regular layered pattern of elastic tissue. In both **A** and **B**, elastin is stained black.

including those of the vasa vasorum of the thoracic aorta. This leads to ischemic injury of the aortic media and aneurysmal dilation, which sometimes involves the aortic valve annulus.

The two most important causes of aortic aneurysms are atherosclerosis and hypertension; atherosclerosis is a greater factor in AAAs, while hypertension is the most common etiology associated with ascending aortic aneurysms. Other factors that weaken vessel walls and lead to aneurysms include trauma, vasculitis (see later), congenital defects (e.g., fibromuscular dysplasia and *berry aneurysms* typically in the circle of Willis; Chapter 28), and infections (*mycotic aneurysms*). Mycotic aneurysms can originate (1) from embolization of a septic embolus, usually as a complication of infective endocarditis; (2) as an extension of an adjacent suppurative process; or (3) by circulating organisms directly infecting the arterial wall.

Abdominal Aortic Aneurysm (AAA)

Aneurysms occurring as a consequence of atherosclerosis form most commonly in the abdominal aorta and common iliac arteries. A variety of factors discussed earlier collaborate to weaken the media and predispose to aneurysm formation.

Figure 11-20 Abdominal aortic aneurysm. **A**, External view, gross photograph of a large aortic aneurysm that ruptured (rupture site is indicated by the arrow). **B**, Opened view, with the location of the rupture tract indicated by a probe. The wall of the aneurysm is exceedingly thin, and the lumen is filled by a large quantity of layered but largely unorganized thrombus.

AAAs occur more frequently in men and in smokers, rarely developing before age 50. Atherosclerosis is a major cause of AAA, but other factors clearly contribute since the incidence is less than 5% in men older than age 60 years, despite the almost universal presence of abdominal aortic atherosclerosis in this population.

MORPHOLOGY

Usually positioned below the renal arteries and above the bifurcation of the aorta, AAA can be saccular or fusiform, up to 15 cm in diameter, and up to 25 cm in length (Fig. 11-20). There is severe complicated atherosclerosis with destruction and thinning of the underlying aortic media; the aneurysm frequently contains a bland, laminated, poorly organized mural thrombus. AAA can occasionally affect the renal and superior or inferior mesenteric arteries, either by direct extension or by occluding vessel ostia with mural thrombi. Not infrequently, AAA is accompanied by smaller aneurysms of the iliac arteries.

Even though they are less common than the usual atherosclerotic aneurysm, three AAA variants merit special mention because of their unusual features:

- **Inflammatory AAA** account for 5% to 10% of all AAA; these typically occur in younger patients, who often present with back pain and elevated inflammatory markers (e.g., elevation of C-reactive protein). Inflammatory aneurysms are characterized by abundant lymphoplasmacytic inflammation with many macrophages (and even giant cells) associated with dense periaortic scarring that can extend into the anterior retroperitoneum. The cause is a presumed localized immune response to the abdominal aortic wall; remarkably, most cases are not associated with inflammation of other arteries.

- A subset of inflammatory AAA may be a vascular manifestation of a recently recognized entity called **immunoglobulin G4 (IgG4)-related disease**. This is a disorder marked by (in most cases) high plasma levels of IgG4 and tissue fibrosis associated with frequent infiltrating IgG4-expressing plasma cells. It may affect a variety of tissues, including pancreas, biliary system, and salivary gland. The affected individuals have aortitis and periaortitis that weaken the wall sufficiently in some cases to give rise to aneurysms. Recognition of this entity is important since it responds well to steroid therapy.
- **Mycotic AAA** are lesions that have become infected by the lodging of circulating microorganisms in the wall. In such cases, suppuration further destroys the media, potentiating rapid dilation and rupture.

Clinical Features. Most cases of AAA are asymptomatic and are discovered incidentally on physical exam as an abdominal mass (often palpably pulsating) that may mimic a tumor. The other clinical manifestations of AAA include:

- Rupture into the peritoneal cavity or retroperitoneal tissues with massive, potentially fatal hemorrhage
- Obstruction of a vessel branching off from the aorta, resulting in ischemic injury to the supplied tissue; for example, iliac (leg), renal (kidney), mesenteric (gastrointestinal tract), or vertebral arteries (spinal cord)
- Embolism from atheroma or mural thrombus
- Impingement on an adjacent structure, for example, compression of a ureter or erosion of vertebrae

The risk of rupture is directly related to the size of the aneurysm, varying from nil for AAA 4 cm or less in diameter, to 1% per year for AAA between 4 and 5 cm, 11% per year for AAA between 5 and 6 cm, and 25% per year for aneurysms larger than 6 cm. Most aneurysms expand at a rate of 0.2 to 0.3 cm/year, but 20% expand more rapidly. In general, aneurysms 5 cm or larger are managed aggressively, usually by surgical bypass with prosthetic grafts, although treatment via endoluminal approaches using stent grafts (expandable wire frames covered by a cloth sleeve) rather than surgery is now available for selected patients. Timely surgery is critical; operative mortality for unruptured aneurysms is approximately 5%, whereas emergency surgery after rupture carries a mortality rate of more than 50%. It is worth reiterating that because atherosclerosis is a systemic disease, a patient with AAA is also very likely to have atherosclerosis in other vascular beds and is at a significantly increased risk of IHD and stroke.

Thoracic Aortic Aneurysm

Thoracic aortic aneurysms are most commonly associated with hypertension, although other causes such as Marfan syndrome and Loeys-Dietz syndrome are increasingly recognized. These can present with signs and symptoms referable to (1) respiratory difficulties due to encroachment on the lungs and airways, (2) difficulty in swallowing due to compression of the esophagus, (3) persistent cough due to compression of the recurrent laryngeal nerves, (4) pain caused by erosion of bone (i.e., ribs and vertebral bodies), (5) cardiac disease as the aortic aneurysm leads to aortic valve dilation with valvular insufficiency or narrowing of

Figure 11-21 Aortic dissection. **A**, Gross photograph of an opened aorta with proximal dissection originating from a small, oblique intimal tear (probe), allowing blood to enter the media and creating a retrograde intramural hematoma (*narrow arrows*). Note that the intimal tear has occurred in a region largely free of atherosclerotic plaque and that propagation of the intramural hematoma distally is arrested where atherosclerosis begins (*broad arrow*). **B**, Histologic view of the dissection demonstrating an aortic intramural hematoma (*asterisk*). Aortic elastic layers are black and blood is red (Movat stain).

the coronary ostia causing myocardial ischemia, and (6) rupture. Most patients with syphilitic aneurysms die of heart failure secondary to aortic valvular incompetence.

Aortic Dissection

Aortic dissection occurs when blood separates the laminar planes of the media to form a blood-filled channel within the aortic wall (Fig. 11-21); this can be catastrophic if the dissection then ruptures through the adventitia and hemorrhages into adjacent spaces. Aortic dissection may or may not be associated with radiologically detectable aortic dilation.

Aortic dissection occurs principally in two groups of patients: (1) men aged 40 to 60 years with antecedent hypertension (more than 90% of cases) and (2) younger adults with systemic or localized abnormalities of connective tissue affecting the aorta (e.g., Marfan syndrome). Dissections can be iatrogenic, for example, following arterial cannulations during coronary catheterization procedures or cardiopulmonary bypass. Rarely, pregnancy is associated with aortic (or other vessel) dissection (roughly 10 to 20 cases per million births). This typically occurs during or after the third trimester, and may be related to hormone-induced vascular remodeling and the hemodynamic stresses of the perinatal period. Dissection is unusual in the presence of substantial atherosclerosis or other cause of medial scarring such as syphilis, presumably because the medial fibrosis inhibits propagation of the dissecting hematoma.

Pathogenesis. Hypertension is the major risk factor for aortic dissection. Aortas of hypertensive patients have medial hypertrophy of vasa vasorum associated with degenerative changes such as loss of medial smooth muscle cells and disorganized extracellular matrix, suggesting that ischemic injury (due to diminished flow through the vasa vasorum, possibly exacerbated by high wall pressures) is contributory. Other dissections occur in the setting of inherited or acquired connective tissue disorders with defective vascular extracellular matrix (e.g., Marfan syndrome, Ehlers-Danlos syndrome, defects in copper metabolism). However, recognizable medial damage appears to

be neither a prerequisite for dissection nor a reliable predictor of its occurrence. Regardless of the underlying etiology, the trigger for the intimal tear and initial intramural aortic hemorrhage is not known in most cases. Once a tear has occurred, blood flow under systemic pressure dissects through the media, leading to progression of the hematoma. Accordingly, aggressive pressure-reducing therapy may be effective in limiting an evolving dissection. In some cases, disruption of penetrating vessels of the vasa vasorum can give rise to an intramural hematoma *without* an intimal tear.

MORPHOLOGY

In most cases, no specific underlying causal pathology is identified in the aortic wall. The most frequent preexisting histologically detectable lesion is **cystic medial degeneration (Fig. 11-19)**, and inflammation is characteristically absent. However, since dissections can occur in the setting of rather trivial medial degeneration, and marked degenerative changes are frequently seen at autopsies of patients who are completely free from dissection, the relationship of the structural changes to the pathogenesis of dissection is uncertain.

An aortic dissection usually initiates with an intimal tear. In the vast majority of spontaneous dissections, the tear occurs in the ascending aorta, usually within 10 cm of the aortic valve (Fig. 11-21A). Such tears are typically transverse with sharp, jagged edges up to 1 to 5 cm in length. The dissection can extend retrograde toward the heart as well as distally, sometimes into the iliac and femoral arteries. The dissecting hematoma spreads characteristically along the laminar planes of the aorta, usually between the middle and outer thirds (Fig. 11-21B). It can rupture through the adventitia causing massive hemorrhage (e.g., into the thoracic or abdominal cavities) or cardiac tamponade (hemorrhage into the pericardial sac). In some (lucky) instances, the dissecting hematoma reenters the lumen of the aorta through a second distal intimal tear, creating a new false vascular channel (“double-barreled aorta”). This averts a fatal extraaortic hemorrhage, and over time, such false channels can be endothelialized to become recognizable **chronic dissections**.

Figure 11-22 Classification of dissections. Type A (proximal) involves the ascending aorta, either as part of a more extensive dissection (DeBakey I) or in isolation (DeBakey II). Type B (distal or DeBakey III) dissections arise after the take-off of the great vessels. Type A dissections typically have the most serious complications and greatest associated mortality.

Clinical Features. The morbidity and mortality associated with dissections depend on which part of the aorta is involved; the most serious complications occur with dissections between the aortic valve and the distal arch. Accordingly, aortic dissections are generally classified into two types (Fig. 11-22).

- The more common (and dangerous) *proximal* lesions (called *type A dissections*), involving either both the ascending and descending aorta or just the ascending aorta only (types I and II of the DeBakey classification)
- *Distal lesions not involving the ascending part* and usually beginning distal to the subclavian artery (called *type B dissections* or DeBakey type III)

The classic clinical symptoms of aortic dissection are the sudden onset of excruciating pain, usually beginning in the anterior chest, radiating to the back between the scapulae, and moving downward as the dissection progresses; the pain can be confused with that of myocardial infarction.

The most common cause of death is rupture of the dissection into the pericardial, pleural, or peritoneal cavities. Retrograde dissection into the aortic root can also disrupt the aortic valve annulus. Common clinical manifestations include cardiac tamponade and aortic insufficiency. Dissections can also extend into the great arteries of the neck, or into the coronary, renal, mesenteric, or iliac arteries, causing vascular obstruction and ischemic consequences such as myocardial infarction; involvement of spinal arteries can cause transverse myelitis.

In type A dissections, rapid diagnosis and institution of intensive antihypertensive therapy coupled with surgical plication of the aortic intimal tear can save 65% to 85% of patients. However, mortality approaches 70% in those who

present with hemorrhage or symptoms related to distal ischemia, and the overall 10-year survival is only 40% to 60%. Most type B dissections can be managed conservatively; patients have a 75% survival rate whether they are treated with surgery or antihypertensive medication only.

KEY CONCEPTS

Aneurysms and Dissections

- Aneurysms are congenital or acquired dilations of the heart or blood vessels that involve the entire thickness of the wall. Complications are related to rupture, thrombosis, and embolization.
- Dissections occur when blood enters the wall of a vessel and separates the various layers. Complications arise due to rupture or obstruction of vessels branching off the aorta.
- Aneurysms and dissections result from structural weakness of the vessel wall caused by loss of smooth muscle cells or insufficient extracellular matrix, which can result from ischemia, genetic defects, or defective matrix remodeling.

Vasculitis

Vasculitis is a general term for vessel wall inflammation. The clinical features of the various vasculitides are protean and largely depend on the vascular bed affected (e.g., CNS vs. heart vs. small bowel). Besides the findings referable to the specific tissues involved, the clinical manifestations typically include constitutional signs and symptoms such as fever, myalgias, arthralgias, and malaise.

Vessels of any type in virtually any organ can be affected, but most vasculitides affect small vessels ranging in size from arterioles to capillaries to venules. There are exceptions, however, and, several of the vasculitides tend to affect only vessels of a particular size or location. Thus, there are entities that primarily affect the aorta and medium-sized arteries, while others principally affect only smaller arterioles. Some 20 primary forms of vasculitis are recognized, and classification schemes attempt (with variable success) to group them according to vessel diameter, role of immune complexes, presence of specific auto-antibodies, granuloma formation, organ specificity, and even population demographics (Table 11-3 and Fig. 11-23). As we will see, there is considerable clinical and pathologic overlap among these entities.

The two common pathogenic mechanisms of vasculitis are immune-mediated inflammation and direct invasion of vascular walls by infectious pathogens. *Infections can also indirectly induce a noninfectious vasculitis*, for example, by generating immune complexes or triggering a cross-reactive immune response. In any given patient, it is critical to distinguish between infectious and immunologic mechanisms, because immunosuppressive therapy is appropriate for immune-mediated vasculitis but could very well be counter-productive for infectious vasculitides. Physical and chemical injury, such as from irradiation, mechanical trauma, and toxins, can also cause vasculitis.

Table 11-3 Primary Forms of Vasculitis

	Giant Cell Arteritis	Granulomatosis with Polyangiitis	Churg-Strauss Syndrome	Polyarteritis Nodosa	Leukocytoclastic Vasculitis	Buerger Disease	Behçet Disease
Sites of Involvement							
Aorta	+	-	-	-	-	-	-
Medium-sized arteries	+	+	+	+	-	+	+
Small-sized arteries	-	+	+	+	+	+	+
Capillaries	-	-	-	-	+	-	+
Veins	-	-	-	-	+	+	+
Inflammatory Cells Present							
Lymphocytes	+	+	+	±	±	±	±
Macrophages	+	+	+	±	±	±	±
Neutrophils	Rare	+	+	±	±	±	Required
Eosinophils	Very rare	±	Required	±	±	±	±
Other Features							
Granulomas	± *	Required *	±	-	-	-	-
Giant cells	Often; not required	±	-	-	-	-	-
Thrombosis	±	±	±	±	±	Required	±
Serum ANCA positivity	-	+	+	±	-	-	-
Clinical history	>40 y years old, ± polymyalgia rheumatica	Any	Asthma, atopy	Any	Any	Young male smoker	Orogenital ulcers

*The granulomas of giant cell arteritis are found within the vessel wall as part of the inflammation comprising the vasculitis, but need not be present to render the diagnosis. The granulomas of granulomatosis with polyangiitis are larger, spanning between vessels, and associated with areas of tissue necrosis. From Seidman MA, Mitchell RN: Surgical pathology of small-and medium-sized vessels. In Current Concepts in Cardiovascular Pathology, Philadelphia, Saunders, 2012.

Noninfectious Vasculitis

The major cause of noninfectious vasculitis is a local or systemic immune response. Immunologic injury in noninfectious vasculitis may be caused by:

- Immune complex deposition
- Antineutrophil cytoplasmic antibodies

- Antiendothelial cell antibodies
- Autoreactive T cells

Immune Complex-Associated Vasculitis

This form of vasculitis can be seen in systemic immunologic disorders such as systemic lupus erythematosus (Chapter 6) that are associated with autoantibody

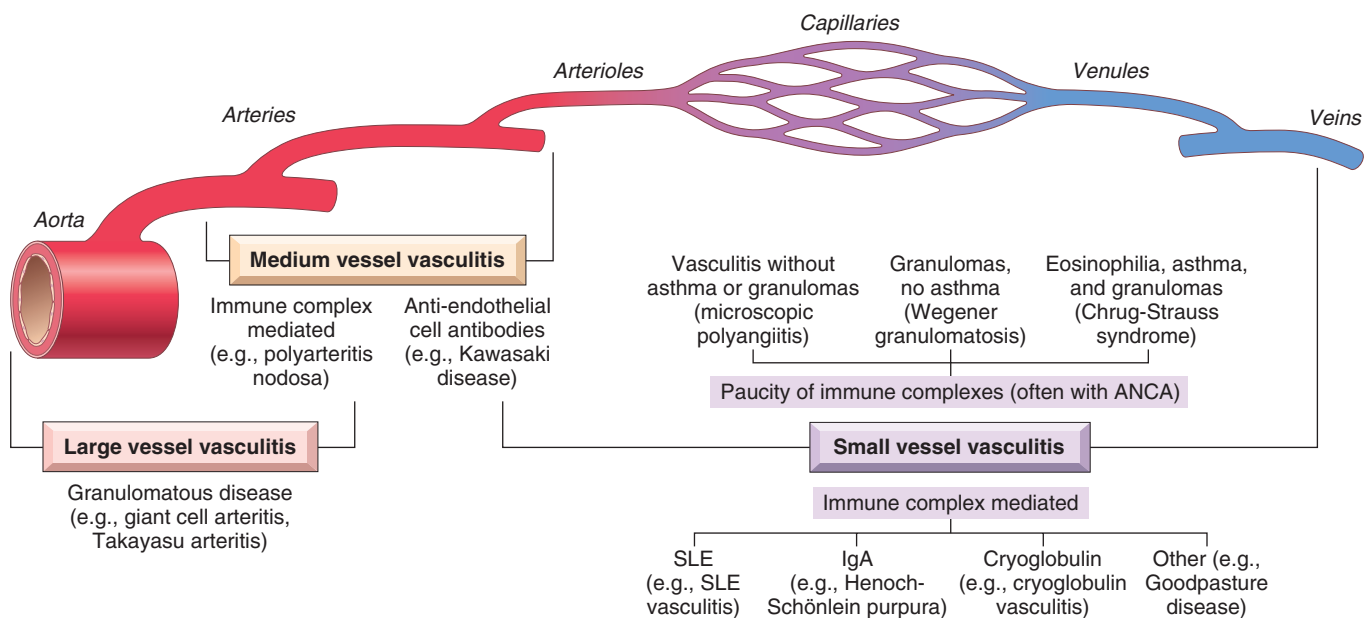

Figure 11-23 Vascular sites typically involved with the more common forms of vasculitis, as well as their presumptive etiologies. Note that there is a substantial overlap in distributions. ANCA, Antineutrophil cytoplasmic antibody; SLE, systemic lupus erythematosus.

production and formation of immune complexes that deposit in vessels. The vascular lesions resemble those found in experimental immune complex-mediated disorders, such as the Arthus phenomenon and serum sickness, and in many cases contain readily identifiable antibody and complement. Often, however, this type of vasculitis presents a number of diagnostic challenges. Only rarely is the specific antigen responsible for immune complex formation identified. Also, in most cases it is not clear whether the pathogenic antigen-antibody complexes are deposited from the circulation or form in situ. Indeed, the sensitivity and specificity of circulating immune complex assays in such diseases are extremely low. In many suspected cases, even the antigen-antibody deposits are scarce. In such instances, the immune complexes may have been degraded by the time of biopsy; alternatively, other mechanisms may underlie such "pauci-immune" vasculitides.

Immune complex deposition is also implicated in the following vasculitides:

- *Drug hypersensitivity vasculitis.* In some cases (e.g., penicillin), drugs act as haptens by binding to serum proteins or vessel wall constituents; other agents are themselves foreign proteins (e.g., streptokinase). Regardless, antibodies directed against the drug-modified proteins or foreign molecules result in immune complex formation. The clinical manifestations can be mild and self-limiting, or severe and even fatal; skin lesions are most common. It is always important to consider drug hypersensitivity as a cause of vasculitis since discontinuation of the offending agent usually leads to resolution.
- *Vasculitis secondary to infections.* Antibodies to microbial constituents can form immune complexes that circulate and deposit in vascular lesions. In up to 30% of patients with polyarteritis nodosa (see later), the vasculitis is attributable to immune complexes composed of hepatitis B surface antigens (HBsAg) and anti-HBsAg antibody.

Antineutrophil Cytoplasmic Antibodies

Many patients with vasculitis have circulating antibodies that react with neutrophil cytoplasmic antigens, so-called *antineutrophil cytoplasmic antibodies (ANCA)*. ANCAs are a heterogeneous group of autoantibodies directed against constituents (mainly enzymes) of neutrophil primary granules, monocyte lysosomes, and endothelial cells. ANCAs are very useful diagnostic markers; their titers generally mirror clinical severity, and a rise in titers after periods of quiescence is predictive of disease recurrence. Although a number of ANCAs have been described, two are most important. These were previously grouped according to the intracellular distribution of the target antigens (cytoplasmic [c-ANCA] or perinuclear [p-ANCA]), but are now classified according to their antigen specificity:

- *Anti-proteinase-3 (PR3-ANCA, previously c-ANCA).* PR3 is a neutrophil azurophilic granule constituent that shares homology with numerous microbial peptides, raising the possibility that the generation of PR3-ANCAs is triggered by certain infections. PR3-ANCAs are associated with polyangiitis (see later).

- *Anti-myeloperoxidase (MPO-ANCA, previously p-ANCA).* MPO is a lysosomal granule constituent involved in oxygen free radical generation (Chapter 3). MPO-ANCAs are induced by several therapeutic agents, particularly propylthiouracil. MPO-ANCAs are associated with microscopic polyangiitis and Churg-Strauss syndrome (see later).

The close association between ANCA titers and disease activity suggests a pathogenic role for these antibodies. Of note, ANCAs can directly activate neutrophils, stimulating the release of reactive oxygen species and proteolytic enzymes; in vascular beds, such activation also leads to destructive interactions between inflammatory cells and endothelial cells. While the antigenic targets of ANCA are primarily intracellular (and therefore not usually accessible to circulating antibodies), it is now clear that ANCA antigens (especially PR3) are either constitutively expressed at low levels on the plasma membrane or are translocated to the cell surface in activated and apoptotic leukocytes.

A plausible mechanism for ANCA vasculitis is the following:

- Drugs or cross-reactive microbial antigens induce ANCA formation; alternatively, leukocyte surface expression or release of PR3 and MPO (in the setting of infections) incites ANCA development in a susceptible host.
- Subsequent infection, endotoxin exposure, or inflammatory stimulus elicits cytokines such as TNF that upregulate the surface expression of PR3 and MPO on neutrophils and other cell types.
- ANCAs react with these cytokine-activated cells, causing either direct injury (e.g., to endothelial cells) or further activation (e.g., of neutrophils).
- ANCA-activated neutrophils cause tissue injury by releasing granule contents and reactive oxygen species.

Since ANCA autoantibodies are directed against cellular constituents and do not form circulating immune complexes, the vascular lesions do not typically contain demonstrable antibody and complement. Thus, ANCA-associated vasculitides are often described as "pauci-immune." Interestingly, ANCA directed against proteins other than PR3 and MPO are often seen in patients with nonvasculitic inflammatory disorders, such as inflammatory bowel disease, sclerosing cholangitis, and rheumatoid arthritis.

Antiendothelial Cell Antibodies

Antibodies to endothelial cells, perhaps induced by defects in immune regulation, may predispose to certain vasculitides, for example, Kawasaki disease (see later).

The following discussion presents several of the best characterized and generally recognized vasculitides; there is substantial overlap among the different entities. Moreover, it should be kept in mind that some patients with vasculitis do not have a classic constellation of findings that allows them to be neatly pigeon-holed into one specific diagnosis.

Giant Cell (Temporal) Arteritis

Giant cell (temporal) arteritis is the most common form of vasculitis among older individuals in the United States

and Europe. It is a chronic inflammatory disorder of large to small-sized arteries that principally affects arteries in the head—especially the temporal arteries—but also the vertebral and ophthalmic arteries. Ophthalmic arterial involvement can lead abruptly to permanent blindness; consequently, giant cell arteritis is a medical emergency requiring prompt recognition and treatment. Lesions also occur in other arteries, including the aorta (giant cell aortitis).

Pathogenesis. Most evidence suggests that giant cell arteritis stems from a T-cell-mediated immune response against one of handful of vessel wall antigens that drives subsequent proinflammatory cytokine production (particularly TNF). Anti-endothelial cell and anti-smooth muscle cell antibodies can also be demonstrated in roughly two thirds of patients, although it is unclear whether these are causal or a consequence of other immune injury. A cellular immune etiology is supported by the characteristic granulomatous response, a correlation with certain MHC class II haplotypes, and a prompt therapeutic response to steroids. The extraordinary predilection for a single vascular site (temporal artery) remains unexplained.

MORPHOLOGY

Involved arterial segments develop **intimal thickening** (with occasional thromboses) that reduces the luminal diameter. Classic lesions exhibit medial **granulomatous inflammation** centered on the internal elastic lamina that produce **elastic lamina fragmentation**; there is an infiltrate of T cells (CD4+ > CD8+) and macrophages. Although multinucleated giant cells are seen in approximately 75% of adequately biopsied specimens (Fig. 11-24), granulomas and giant cells can be rare or

absent. Inflammatory lesions are only focally distributed along the vessel and long segments of relatively normal artery may be interposed. The healed stage is marked by medial attenuation and scarring with intimal thickening, typically with residual elastic tissue fragmentation and adventitial fibrosis.

Clinical Features. Giant cell arteritis is rare before age 50. Symptoms may be only vague and constitutional—fever, fatigue, weight loss—or there may be facial pain or headache, most intense along the course of the superficial temporal artery, which can be painful to palpation. Ocular symptoms (associated with involvement of the ophthalmic artery) appear abruptly in about 50% of patients; these range from diplopia to complete vision loss. Diagnosis depends on biopsy and histologic confirmation. However, because giant cell arteritis can be extremely focal within an artery, adequate biopsy requires at least a 1-cm segment; even then, a negative biopsy result does not exclude the diagnosis. Corticosteroids or anti-TNF therapies are typically effective.

Takayasu Arteritis

This is a **granulomatous vasculitis of medium and larger arteries** characterized principally by ocular disturbances and marked weakening of the pulses in the upper extremities (hence the name *pulseless disease*). Takayasu arteritis manifests with transmural fibrous thickening of the aorta—particularly the aortic arch and great vessels—with severe luminal narrowing of the major branch vessels (Fig. 11-25). Takayasu aortitis shares many attributes with giant cell arteritis, including clinical features and histology. Indeed, the distinction is typically made based on the age of the patient: in patients older than 50, the diagnosis is giant cell arteritis, while in those younger than 50, it is Takayasu

Figure 11-24 Giant cell (temporal) arteritis. **A**, Hematoxylin and eosin stain of section of temporal artery showing giant cells at the degenerated internal elastic lamina in active arteritis (arrow). **B**, Elastic tissue stain demonstrating focal destruction of internal elastic lamina (arrow) and intimal thickening (IT) characteristic of long-standing or healed arteritis. **C**, The temporal artery of a patient with classic giant cell arteritis shows a thickened, nodular, and tender segment of a vessel on the surface of head (arrow). (C, From Salvarani C, et al. Polymyalgia rheumatica and giant-cell arteritis. *N Engl J Med* 347:261, 2002.)

Figure 11-25 Takayasu arteritis. **A**, Aortic arch angiogram showing narrowing of brachiocephalic, carotid, and subclavian arteries (arrows). **B**, Gross photograph of two cross-sections of the right carotid artery taken at autopsy of the patient shown in **A**, demonstrating marked intimal thickening and adventitial fibrosis with minimal residual lumen. **C**, Histologic appearance in active Takayasu arteritis, illustrating destruction and fibrosis of the arterial media associated with mononuclear infiltrates and inflammatory giant cells (arrows).

aortitis. Although historically associated with the Japanese population and a subset of HLA haplotypes, Takayasu aortitis has a global distribution. An autoimmune etiology is likely.

MORPHOLOGY

Takayasu arteritis classically involves the aortic arch. In a third of patients, it also affects the remainder of the aorta and its branches, with **pulmonary artery** involvement in half the cases; **coronary and renal arteries** may be similarly affected. There is irregular thickening of the vessel wall with intimal hyperplasia; when the aortic arch is involved, the great vessel lumina can be markedly narrowed or even obliterated (Fig. 11-25A and B). Histologically, the changes range from adventitial

mononuclear infiltrates with perivascular cuffing of the vasa vasorum, to intense mononuclear inflammation in the media, to granulomatous inflammation, replete with giant cells and patchy medial necrosis. The histology (Fig. 11-25C) is indistinguishable from giant cell (temporal) arteritis. As the disease progresses, collagenous scarring, with admixed chronic inflammatory infiltrates, occurs in all three layers of the vessel wall. Occasionally, aortic root involvement causes dilation and aortic valve insufficiency.

Clinical Features. Initial symptoms are usually nonspecific, including fatigue, weight loss, and fever. With progression, vascular symptoms appear and dominate the clinical picture, including reduced blood pressure and weak pulses in the carotids and the upper extremities; ocular disturbances, including visual defects, retinal hemorrhages, and total blindness; and neurologic deficits. Involvement of the more distal aorta may lead to claudication of the legs; pulmonary artery involvement can cause pulmonary hypertension. Narrowing of the coronary ostia may lead to myocardial infarction, and involvement of the renal arteries leads to systemic hypertension in roughly half of patients. The course of the disease is variable. In some there is rapid progression, while others enter a quiescent stage after 1 to 2 years, permitting long-term survival, albeit with visual or neurologic deficits.

Polyarteritis Nodosa

Polyarteritis nodosa (PAN) is a systemic vasculitis of small- or medium-sized muscular arteries, typically involving renal and visceral vessels but sparing the pulmonary circulation. There is no association with ANCA, but about 30% of patients with PAN have chronic hepatitis B and deposits containing HBsAg-HBsAb complexes in affected vessels, indicating an immune complex-mediated etiology in that subset. The cause remains unknown in the remaining cases; there may be etiologic and clinical distinctions between classic idiopathic PAN, the cutaneous forms of PAN, and the PAN associated with chronic hepatitis.

MORPHOLOGY

Classic polyarteritis nodosa is characterized by **segmental transmural necrotizing inflammation of small- to medium-sized arteries.** Vessels of the kidneys, heart, liver, and gastrointestinal tract are involved in descending order of frequency. Lesions usually involve only part of the vessel circumference with a predilection for branch points. The inflammatory process weakens the arterial wall and can lead to aneurysms or even rupture. Impaired perfusion with ulcerations, infarcts, ischemic atrophy, or hemorrhages may be the first sign of disease.

During the acute phase, there is transmural inflammation of the arterial wall with a mixed infiltrate of neutrophils, eosinophils, and mononuclear cells, frequently accompanied by **fibrinoid necrosis** (Fig. 11-26). Luminal thrombosis can occur. Later, the acute inflammatory infiltrate is replaced by fibrous (occasionally nodular) thickening of the vessel wall that can extend into the adventitia. Characteristically, all stages of activity (from early to late) may coexist in different vessels or even within the same vessel, suggesting ongoing and recurrent insults.

Figure 11-26 Polyarteritis nodosa. There is segmental fibrinoid necrosis and thrombotic occlusion of the lumen of this small artery. Note that part of the vessel wall at the upper right (arrow) is uninjured. (Courtesy Sidney Murphree, MD, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas.)

Clinical Features. Although typically a disease of young adults, PAN can also occur in pediatric and geriatric populations. Clinical manifestations result from ischemia and infarction of affected tissues and organs. The course is frequently remitting and episodic, with long symptom-free intervals. Because the vascular involvement is widely scattered, the clinical signs and symptoms of PAN can be quite variable. A “classic” presentation can involve some combination of rapidly accelerating hypertension due to renal artery involvement; abdominal pain and bloody stools caused by vascular gastrointestinal lesions; diffuse myalgias; and peripheral neuritis, predominantly affecting motor nerves. Renal involvement is often prominent and a major cause of mortality. Untreated, PAN is typically fatal; however, immunosuppression can yield remissions or cures in 90% of cases.

Kawasaki Disease

Kawasaki disease is an acute febrile, usually self-limited illness of infancy and childhood (80% of patients are 4 years old or younger); it is associated with an arteritis affecting large to medium-sized, and even small vessels. Its clinical significance stems primarily from a predilection for coronary artery involvement that can cause aneurysms that rupture or thrombose, resulting in acute myocardial infarctions. Originally described in Japan, the disease has a worldwide distribution and is the leading cause of acquired heart disease in children.

The pathogenesis of Kawasaki disease is unknown. A variety of infectious agents (mostly viral) have been implicated in triggering the disease in genetically susceptible individuals. The vascular damage is primarily mediated by activated T cells and monocytes/macrophages.

MORPHOLOGY

The vasculitis resembles that seen in polyarteritis nodosa. There is a dense transmural inflammatory infiltrate, although the fibrinoid necrosis is usually less prominent than in PAN. The acute

vasculitis typically subsides spontaneously or in response to treatment, but aneurysm formation due to wall damage can supervene. As with other arteritides, healed lesions can also exhibit obstructive intimal thickening. Pathologic changes outside the cardiovascular system are rarely significant.

Clinical Features. Kawasaki disease typically presents with conjunctival and oral erythema and blistering, edema of the hands and feet, erythema of the palms and soles, a desquamative rash, and cervical lymph node enlargement (hence its other name, *mucocutaneous lymph node syndrome*). Approximately 20% of untreated patients develop cardiovascular sequelae, ranging from asymptomatic coronary arteritis, to coronary artery ectasia, to giant coronary artery aneurysms (7 to 8 mm) leading to rupture or thrombosis, myocardial infarction, and sudden death. If the disease is recognized early in its course, treatment with intravenous immunoglobulin and aspirin sharply reduce the risk of symptomatic coronary artery disease.

Microscopic Polyangiitis

Microscopic polyangiitis is a *necrotizing vasculitis that generally affects capillaries, as well as small arterioles and venules*. It is also called hypersensitivity vasculitis or leukocytoclastic vasculitis. Unlike polyarteritis nodosa, *all lesions of microscopic polyangiitis tend to be of the same age in any given patient and are distributed more widely*. The skin, mucous membranes, lungs, brain, heart, gastrointestinal tract, kidneys, and muscle can all be involved; *necrotizing glomerulonephritis* (90% of patients) and pulmonary capillaritis are particularly common. Microscopic angitis can be a feature of a number of immune disorders, such as Henoch-Schönlein purpura, essential mixed cryoglobulinemia, and vasculitis associated with connective tissue disorders.

Pathogenesis. In some cases, antibody responses to antigens such as drugs (e.g., penicillin), microorganisms (e.g., streptococci), heterologous proteins, or tumor proteins have been implicated. These can either lead to immune complex deposition or trigger secondary immune responses (e.g., the development of ANCA) that are pathogenic. Indeed, most cases are associated with MPO-ANCA. Recruitment and activation of neutrophils within affected vascular beds is likely responsible for the disease manifestations.

MORPHOLOGY

Microscopic polyangiitis is characterized by segmental fibrinoid necrosis of the media and focal transmural necrotizing lesions; granulomatous inflammation is absent. These lesions morphologically resemble PAN but typically spare medium-sized and larger arteries; consequently, infarcts are uncommon. In some areas (typically postcapillary venules), only infiltrating neutrophils, many undergoing apoptosis, are seen, giving rise to the term **leukocytoclastic vasculitis** (Fig. 11-27A). Although immunoglobulins and complement components can be demonstrated in early skin lesions, little or no immunoglobulin are found in most lesions (so-called “pauci-immune injury”).

Figure 11-27 Small vessel vasculitis. **A**, Leukocytoclastic vasculitis (microscopic polyangiitis) with fragmentation of neutrophils in and around blood vessel walls. **B** and **C**, Granulomatosis with polyangiitis. **B**, Vasculitis of a small artery with adjacent granulomatous inflammation including epithelioid cells and giant cells (arrows). **C**, Gross photo from the lung of a patient with fatal granulomatosis with polyangiitis, demonstrating large nodular centrally cavitating lesions. (**A**, Courtesy Scott Granter, MD, Brigham and Women's Hospital, Boston, Mass.; **C**, Courtesy Sidney Murphree, MD, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas.)

Clinical Features. Depending on the vascular bed involved, major clinical features include hemoptysis, hematuria and proteinuria, bowel pain or bleeding, muscle pain or weakness, and palpable cutaneous purpura. Except in those in whom widespread renal or brain involvement develop, immunosuppression induces remission and markedly improves long-term survival.

Churg-Strauss Syndrome

Churg-Strauss syndrome is a small-vessel necrotizing vasculitis classically associated with asthma, allergic rhinitis, lung infiltrates, peripheral hypereosinophilia, and extravascular necrotizing granulomata. Also called allergic granulomatosis and angiitis, it is a relatively rare disease (roughly one in a million people). Vascular lesions can be histologically similar to polyarteritis nodosa or microscopic polyangiitis, but are also characteristically accompanied by granulomas and eosinophils. ANCA (mostly MPO-ANCA) are present in less than half the cases, and suggest that there are distinct subsets of patients with the syndrome. Nevertheless, when present, the ANCA are likely involved in the pathogenesis of the vascular lesions.

Churg-Strauss syndrome is a multisystem disease with cutaneous involvement (palpable purpura), gastrointestinal tract bleeding, and renal disease (primarily as focal and segmental glomerulosclerosis). Myocardial involvement may give rise to cardiomyopathy; the heart is involved in 60% of patients and accounts for almost half of the deaths in the syndrome. Involvement of the heart is associated with the presence of eosinophilic infiltrates. The syndrome may be a consequence of hyperresponsiveness to an allergic stimulus; in patients with asthma, leukotriene receptor antagonists have been reported to be a trigger.

Behçet Disease

Behçet disease is a small- to medium-vessel neutrophilic vasculitis that classically presents as a clinical triad of recurrent oral aphthous ulcers, genital ulcers, and uveitis.

There can also be gastrointestinal and pulmonary manifestations, with disease mortality related to severe neurologic involvement or rupture of vascular aneurysms. There is an association with certain HLA haplotypes (HLA-B51, in particular) and a cross-reactive immune response to certain microorganisms is implicated. T_H17 cells (Chapter 6) play a significant role by contributing to the recruitment of neutrophils, which are seen infiltrating vessel walls. However, the findings are nonspecific and the diagnosis requires an appropriate clinical story. Immunosuppression with steroids or TNF-antagonist therapies are generally effective.

Granulomatosis with Polyangiitis

Previously called Wegener granulomatosis, granulomatosis with polyangiitis is a necrotizing vasculitis characterized by a triad of:

- *Necrotizing granulomas* of the upper respiratory tract (ear, nose, sinuses, throat) or the lower respiratory tract (lung) or both.
- *Necrotizing or granulomatous vasculitis* affecting small- to medium-sized vessels (e.g., capillaries, venules, arterioles, and arteries), most prominent in the lungs and upper airways but involving other sites as well.
- *Focal necrotizing, often crescentic, glomerulonephritis.*

"Limited" forms of this disease may be restricted to the respiratory tract. Conversely, a widespread form of the disease can affect eyes, skin, and other organs, notably the heart; clinically, this resembles PAN except that there is also respiratory involvement.

Pathogenesis. Granulomatosis with polyangiitis likely represents a form of T-cell-mediated hypersensitivity response to normally "innocuous" inhaled microbial or other environmental agents; such a pathogenesis is supported by the presence of granulomas and a dramatic response to immunosuppressive therapy. PR3-ANCA are also present in up to 95% of cases; they are a useful marker of disease activity and may participate in disease

pathogenesis. Following immunosuppression, a rising PR3-ANCA titer is often a harbinger of relapse; most patients in remission have a negative test or falling titers.

MORPHOLOGY

Upper respiratory tract lesions range from inflammatory sinusitis with mucosal granulomas to ulcerative lesions of the nose, palate, or pharynx, rimmed by **granulomas with geographic patterns of central necrosis and accompanying vasculitis** (Fig. 11-27B). The necrotizing granulomas are surrounded by a zone of proliferating fibroblasts associated with giant cells and leukocytic infiltrate, reminiscent of mycobacterial or fungal infections. Multiple granulomas can coalesce to produce radiographically visible nodules that can also cavitate; late stage disease may be marked by extensive necrotizing granulomatous involvement of the parenchyma (Fig. 11-27C), and alveolar hemorrhage may be prominent. Lesions may ultimately undergo progressive fibrosis and organization.

A spectrum of renal lesions can be seen (Chapter 20). In early stages, glomeruli exhibit only focal necrosis with isolated capillary loop thrombosis (**focal and segmental necrotizing glomerulonephritis**); there is minimal parietal cell proliferation in the Bowman capsule. More advanced glomerular lesions are characterized by diffuse necrosis with exuberant parietal cell proliferation resulting in crescent formation (**crescentic glomerulonephritis**).

Clinical Features. Males are affected more often than females, at an average age of about 40 years. Classic features include persistent pneumonitis with bilateral nodular and cavitory infiltrates (95%), chronic sinusitis (90%), mucosal ulcerations of the nasopharynx (75%), and evidence of renal disease (80%). Other features include rashes, myalgias, articular involvement, neural inflammation, and fever. Left untreated, the disease is usually rapidly fatal, with 80% mortality within 1 year. Treatment with steroids, cyclophosphamide, and more recently TNF antagonists have turned this formerly fatal condition into a chronic relapsing and remitting disease.

Thromboangiitis Obliterans (Buerger Disease)

Thromboangiitis obliterans (Buerger disease) is characterized by segmental, thrombosing, acute and chronic inflammation of medium-sized and small arteries, principally the tibial and radial arteries, with occasional secondary extension into the veins and nerves of the extremities. It is a distinctive disease that often leads to vascular insufficiency, typically of the extremities. It occurs almost exclusively in heavy cigarette smokers, usually before age 35.

Pathogenesis. The strong relationship with cigarette smoking may stem from either a direct idiosyncratic endothelial cell toxicity caused by some component of tobacco, or an immune response to components of tobacco smoke that modify host vascular wall proteins. Most patients have hypersensitivity to intradermally injected tobacco extracts, and their vessels exhibit impaired endothelium-dependent vasodilation when challenged with acetylcholine. There is an increased prevalence in certain ethnic groups (Israeli, Indian subcontinent, Japanese) and an association with particular HLA haplotypes.

Figure 11-28 Thromboangiitis obliterans (Buerger disease). The lumen is occluded by a thrombus containing abscesses (arrow), and the vessel wall is infiltrated with leukocytes.

MORPHOLOGY

Thromboangiitis obliterans is characterized by a **focal acute and chronic vasculitis of small- and medium-sized arteries**, predominantly of the extremities. On histology, there is acute and chronic inflammation, accompanied by luminal thrombosis. The thrombus can contain small **microabscesses** composed of neutrophils surrounded by granulomatous inflammation (Fig. 11-28); the thrombus may eventually organize and recanalize. The inflammatory process extends into contiguous veins and nerves (rare with other forms of vasculitis), and with time all three structures can be encased in fibrous tissue.

Clinical Features. Early manifestations include cold-induced Raynaud phenomenon (see later), leg pain induced by exercise that is relieved on rest (*intermittent claudication*), instep foot pain induced by exercise (*instep claudication*), and a superficial nodular phlebitis (venous inflammation). The vascular insufficiency of Buerger disease tends to be accompanied by severe pain—even at rest—undoubtedly due to the neural involvement. Chronic extremity ulcerations develop, progressing over time (occasionally precipitously) to frank gangrene. Smoking abstinence in the early stages of the disease can often ameliorate further attacks; however, once established, the vascular lesions typically do not respond to smoking abstinence.

Vasculitis Associated with Other Noninfectious Disorders

Vasculitis resembling hypersensitivity angiitis or classic polyarteritis nodosa can sometimes be associated with other disorders, such as rheumatoid arthritis, systemic lupus erythematosus, malignancy, or systemic illnesses such as mixed cryoglobulinemia, antiphospholipid antibody syndrome (Chapter 4), and Henoch-Schönlein purpura. *Rheumatoid vasculitis* occurs predominantly in the setting of long-standing, severe rheumatoid arthritis and usually affects small- and medium-sized arteries, leading to visceral infarction; it may also cause a clinically significant aortitis. Identifying the underlying pathology has therapeutic significance. For example, although

lupus vasculitis and antiphospholipid antibody syndrome can be morphologically and clinically similar, immunosuppressive therapy is required in the former, and anticoagulant therapy is indicated in the latter.

Infectious Vasculitis

Arteritis can be caused by the direct invasion of infectious agents, usually bacteria (*Pseudomonas* being the classic example) or fungi, in particular *Aspergillus* and *Mucor* species. Vascular invasion can be part of a localized tissue infection (e.g., bacterial pneumonia or adjacent abscesses), or—less commonly—can arise from hematogenous spread of microorganisms during septicemia or embolization from infective endocarditis.

Vascular infections can weaken arterial walls and culminate in *mycotic aneurysms* (see earlier), or can induce thrombosis and infarction. Thus, inflammation-induced thrombosis of meningeal vessels in bacterial meningitis can eventually cause infarction of the underlying brain.

KEY CONCEPTS

Vasculitis

- Vasculitis is defined as inflammation of vessel walls; it is frequently associated with systemic manifestations (including fever, malaise, myalgias, and arthralgias) and organ dysfunction that depends on the pattern of vascular involvement.
- Vasculitis can result from infections, but more commonly has an immunologic basis, including immune complex deposition, formation of anti-neutrophil antibodies (ANCA), or T cell responses to vascular wall antigens.
- Different forms of vasculitis tend to specifically affect vessels of a particular caliber and location, and the clinical manifestations depend on the pattern of vessel involvement.

Disorders of Blood Vessel Hyperreactivity

Several disorders are characterized by inappropriate or exaggerated vasoconstriction of blood vessels.

Raynaud Phenomenon

Raynaud phenomenon results from exaggerated vasoconstriction of arteries and arterioles in the extremities, particularly the fingers and toes, but also occasionally the nose, earlobes, or lips. The restricted blood flow induces paroxysmal pallor, and even cyanosis in severe cases; involved digits classically show “red, white, and blue” color changes from most proximal to most distal, correlating with proximal vasodilation, central vasoconstriction, and more distal cyanosis (Fig. 11-29). Raynaud phenomenon can be a primary entity or secondary to other disorders.

Primary Raynaud phenomenon (previously called Raynaud disease) is caused by exaggerated central and local vasomotor responses to cold or emotion; it affects 3% to 5% of the general population and has a predilection for young women. It tends to symmetrically affect the extremities, and the severity and extent of involvement typically remains static over time. Structural changes in the arterial walls are absent except in long-standing disease, when intimal thickening can develop. The course is usually benign, but chronicity can lead to atrophy of the skin, subcutaneous tissues, and muscles. Ulceration and ischemic gangrene are rare.

Secondary Raynaud phenomenon refers to vascular insufficiency due to arterial disease caused by other entities including SLE, scleroderma, Buerger disease, or even atherosclerosis. Clinically, secondary Raynaud phenomenon tends to have asymmetric involvement of the extremities and progressively worsens in extent and severity over time.

Since Raynaud phenomenon may be the first manifestation of immune-mediated vasculitides, any patient with

Figure 11-29 Raynaud phenomenon. **A**, Sharply demarcated pallor of the distal fingers resulting from spasm of the digital arteries. **B**, Cyanosis of the fingertips. (Reproduced from Salvarani C, et al: Polymyalgia rheumatica and giant-cell arteritis. *N Engl J Med* 347:261, 2002.)

new symptoms should be evaluated. Of these, some 10% will eventually manifest an underlying disorder.

Myocardial Vessel Vasospasm

Excessive constriction of coronary arteries or myocardial arterioles may cause ischemia, and persistent vasospasm can even cause myocardial infarction. In addition to intrinsic hyper-reactivity of medial smooth muscle cells, as described earlier for primary Raynaud disease, high levels of vasoactive mediators can precipitate prolonged myocardial vessel contraction. Such agents can be endogenous (e.g., epinephrine released by pheochromocytomas) or exogenous (cocaine or phenylephrine). Elevated thyroid hormone causes a similar effect by increasing the sensitivity of vessels to circulating catecholamines, while autoantibodies and T cells in scleroderma (Chapter 6) can cause vascular instability and vasospasm. In some individuals, extreme psychological stress and the attendant release of catecholamines can lead to pathologic vasospasm.

When vasospasm of cardiac arterial or arteriolar beds (so-called *cardiac Raynaud*) is of sufficient duration (20 to 30 minutes), myocardial infarction occurs. Elevated levels of catechols also increase heart rate and myocardial contractility, exacerbating ischemia caused by the vasospasm. The outcome may be sudden cardiac death (likely caused by a fatal arrhythmia) or an ischemic dilated cardiomyopathy, so-called *Takotsubo cardiomyopathy* (also called “broken heart syndrome” because of the association with emotional duress; Chapter 12). Histologically, acute cases may show microscopic areas of necrosis characterized by myocyte hypercontraction (*contraction band necrosis*); subacute and chronic cases may exhibit microscopic foci of granulation tissue and/or scar.

Veins and Lymphatics

Varicose veins and phlebothrombosis/thrombophlebitis together account for at least 90% of clinical venous disease.

Varicose Veins

Varicose veins are abnormally dilated, tortuous veins produced by prolonged, increased intraluminal pressure leading to vessel dilation and incompetence of the venous valves. The *superficial veins* of the upper and lower leg are commonly involved because venous pressures in these sites can be markedly elevated (up to 10 times normal) by prolonged dependent posture. Roughly 10% to 30% of adults develop lower extremity varicosities; obesity and pregnancy increase risk by creating mass effects that impede venous drainage. A familial predilection to varicose veins reflects defective venous wall development.

Clinical Features. Incompetence of the venous valves leads to stasis, congestion, edema, pain, and thrombosis. Secondary tissue ischemia results from chronic venous congestion and poor vessel drainage leading to *stasis dermatitis* (also called “brawny induration”; the brawny color comes from the hemolysis of extravasated red cells) and ulcerations; poor wound healing and superimposed infections are common additional complications. *Notably,*

embolism from these superficial veins is very rare, in contrast to the relatively frequent thromboembolism that arises from thrombosed deep veins (see later and Chapter 4).

Varicosities in two other sites also deserve mention:

- *Esophageal varices.* Liver cirrhosis (less frequently, portal vein obstruction or hepatic vein thrombosis) causes portal vein hypertension (Chapter 18). Portal hypertension leads to the opening of portosystemic shunts that increase blood flow into veins at the gastroesophageal junction (forming *esophageal varices*), the rectum (forming *hemorrhoids*), and periumbilical veins of the abdominal wall (forming a *caput medusa*). Esophageal varices are the most important since their rupture can lead to massive (even fatal) upper gastrointestinal hemorrhage.
- *Hemorrhoids* can also result from primary varicose dilation of the venous plexus at the anorectal junction (e.g., through prolonged pelvic vascular congestion due to pregnancy or straining to defecate). Hemorrhoids are uncomfortable and may be a source of bleeding; they can also thrombose and are prone to painful ulceration.

Thrombophlebitis and Phlebothrombosis

Thrombophlebitis and phlebothrombosis are largely interchangeable designations for venous thrombosis and inflammation; involvement of deep leg veins accounts for more than 90% of cases. The periprostatic venous plexus in males and the pelvic venous plexus in females are additional sites, as are the large veins in the skull and the dural sinuses (especially in the setting of infection or inflammation). Portal vein thrombosis may occur with peritoneal infections (peritonitis, appendicitis, salpingitis, and pelvic abscesses), as well as certain thrombophilic conditions associated with platelet hyperactivity (e.g., polycythemia vera, Chapter 13).

Prolonged immobilization resulting in venous stasis is the most important risk factor for deep venous thrombosis (DVT) in the lower extremities. This can occur with extended bedrest or even sitting during lengthy trips in an airplane or automobile; postoperative patients are also at risk, in part, due to immobilization. Clearly, DVT can develop in the setting of any other mechanical factor that slows venous return; these include congestive heart failure, pregnancy, and obesity.

Systemic hypercoagulability, including genetic hypercoagulability syndromes (Chapter 4), often also plays a role in potentiating thrombophlebitis. In patients with cancer, particularly adenocarcinomas, hypercoagulability occurs as a paraneoplastic syndrome related to elaboration of procoagulant factors by tumor cells (Chapter 7). In this setting, venous thromboses classically appear in one location, disappear, and then occur in another site, so-called *migratory thrombophlebitis (Trousseau sign)*.

Thrombi in the legs tend to produce few, if any, reliable signs or symptoms. Indeed, local manifestations, including vein dilation, edema, cyanosis, heat, erythema, or pain may be entirely absent, especially in bedridden patients. In some cases, pain can be elicited by pressure over affected veins, squeezing the calf muscles, or forced dorsiflexion of the foot (*Homan sign*). However, these findings are

notoriously unreliable; hence their absence does not exclude a diagnosis of DVT.

Pulmonary embolism is the most common serious clinical complication of DVT, and is often the first manifestation of thrombophlebitis (Chapter 4). It results from fragmentation or detachment of the venous thrombus. Depending on the size and number of emboli, the outcome can range from no symptoms to death.

Superior and Inferior Vena Cava Syndromes

The *superior vena cava syndrome* is usually caused by neoplasms that compress or invade the superior vena cava, such as bronchogenic carcinoma or mediastinal lymphoma. Less commonly, other space occupying lesions in the mediastinum such as aortic aneurysms can be the cause of compression. The resulting obstruction produces a characteristic clinical complex including marked dilation of the veins of the head, neck, and arms with cyanosis. Pulmonary vessels can also be compressed, inducing respiratory distress.

The *inferior vena cava syndrome* can be caused by neoplasms that compress or invade the inferior vena cava (IVC) or by thrombosis of the hepatic, renal, or lower extremity veins that propagates cephalad. Certain neoplasms—particularly hepatocellular carcinoma and renal cell carcinoma—show a striking tendency to grow within veins, and these can ultimately occlude the IVC. IVC obstruction induces marked lower extremity edema, distention of the superficial collateral veins of the lower abdomen, and—with renal vein involvement—massive proteinuria.

Lymphangitis and Lymphedema

Although primary disorders of lymphatic vessels are extremely uncommon, secondary processes frequently develop in association with inflammation or malignancies.

Lymphangitis represents acute inflammation elicited by the spread of bacterial infections into lymphatics; group A β -hemolytic streptococci are the most common agent, although any microbe can be causal. Affected lymphatics are dilated and filled with an exudate of neutrophils and monocytes; the infiltrates can extend through the vessel wall, and in severe cases, can produce cellulitis or focal abscesses. Lymphangitis is manifested by red, painful subcutaneous streaks (the inflamed lymphatics), and painful enlargement of the draining lymph nodes (*lymphadenitis*). If bacteria are not successfully contained within the lymph nodes, subsequent escape into the venous circulation can result in bacteremia or sepsis.

Primary lymphedema can occur as an isolated congenital defect (simple congenital lymphedema) or as the familial *Milroy disease (heredofamilial congenital lymphedema)*, which results in lymphatic agenesis or hypoplasia. *Secondary* or *obstructive lymphedema* stems from blockage of a previously normal lymphatic; examples include:

- Malignant tumors obstructing lymphatic channels or the regional lymph nodes
- Surgical procedures that remove regional groups of lymph nodes (e.g., axillary lymph nodes in radical mastectomy)
- Postirradiation fibrosis

- Filariasis
- Postinflammatory thrombosis and scarring

Regardless of the cause, lymphedema increases the hydrostatic pressure in the lymphatics distal to the obstruction and causes increased interstitial fluid accumulation. Persistent edema and subsequent deposition of interstitial connective tissue leads to a *peau d'orange* (orange peel) appearance of the overlying skin, seen typically in skin overlying breast cancers after the draining lymphatics are clogged with tumor cells; ulcers may develop due to inadequate tissue perfusion. Rupture of dilated lymphatics (e.g., secondary to obstruction from a tumor) leads to milky accumulations of lymph designated as *chylous ascites* (abdomen), *chylothorax*, and *chylopericardium*.

Vascular Tumors

Tumors of blood vessels and lymphatics constitute a spectrum from benign hemangiomas to intermediate lesions that are locally aggressive but infrequently metastasize, to rare, highly malignant angiosarcomas (Table 11-4). Congenital or developmental malformations and nonneoplastic reactive vascular proliferations (e.g., *bacillary angiomatosis*) can also present as tumor-like lesions. Because the growth of vascular neoplasms appears to depend on the same signaling pathways that regulate angiogenesis, treatment with inhibitors of blood vessel formation (antiangiogenic therapy) is a rational therapy that is being explored.

Vascular neoplasms can be endothelial-derived (e.g., hemangioma, lymphangioma, angiosarcoma) or can arise from cells that support or surround blood vessels (e.g., glomus tumor, hemangiopericytoma). Primary tumors of large vessels (aorta, pulmonary artery, and vena cava) are mostly connective tissue sarcomas. Although a benign well-differentiated hemangioma can usually be readily discriminated from an anaplastic high-grade angiosarcoma, the distinction between benign and malignant can

Table 11-4 Classification of Vascular Tumors and Tumor-Like Conditions

Benign Neoplasms, Developmental and Acquired Conditions
Hemangioma
Capillary hemangioma
Cavernous hemangioma
Pyogenic granuloma
Lymphangioma
Simple (capillary) lymphangioma
Cavernous lymphangioma (cystic hygroma)
Glomus tumor
Vascular ectasias
Nevus flammeus
Spider telangiectasia (arterial spider)
Hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu disease)
Reactive vascular proliferations
Bacillary angiomatosis
Intermediate-Grade Neoplasms
Kaposi sarcoma
Hemangioendothelioma
Malignant Neoplasm
Angiosarcoma
Hemangiopericytoma

occasionally be difficult. Two general rules of thumb are helpful:

- Benign tumors usually produce obvious vascular channels filled with blood cells (e.g. capillaries filled with red cells) lined by a monolayer of normal-appearing endothelial cells.
- Malignant tumors are more cellular and more proliferative, and exhibit cytologic atypia; they usually do not form well-organized vessels. The endothelial derivation of neoplastic proliferations that do not form distinct vascular lumina can usually be confirmed by immunohistochemical demonstration of endothelial cell-specific markers such as CD31 or von Willebrand factor.

Benign Tumors and Tumor-Like Conditions

Vascular Ectasias. *Ectasia* is a generic term for any local dilation of a structure, while *telangiectasia* is used to describe a permanent dilation of preexisting small vessels (capillaries, venules, and arterioles) that form a discrete red lesion—usually in the skin or mucous membranes. These can be congenital or acquired and *are not true neoplasms*; some of them are malformations and others are hamartomas:

- *Nevus flammeus* (a “birthmark”), the most common form of vascular ectasia, is a light pink to deep purple flat lesion on the head or neck composed of dilated vessels. Most ultimately regress spontaneously.
- The so-called *port wine stain* is a special form of nevus flammeus. These lesions tend to grow during childhood, thicken the skin surface, and do not fade with time. Such lesions in the distribution of the trigeminal nerve are associated with the *Sturge-Weber syndrome* (also called *encephalotrigeminal angiomatosis*). This uncommon congenital disorder is associated with facial port wine nevi, ipsilateral venous angiomas in the cortical leptomeninges, mental retardation, seizures, hemiplegia, and skull radio-opacities. Thus, a large facial telangiectasia in a child with mental deficiency may indicate the presence of additional vascular malformations.
- *Spider telangiectasias* are nonneoplastic vascular lesions grossly resembling a spider. These manifest as radial, often pulsatile arrays of dilated subcutaneous arteries or arterioles (resembling spider legs) about a central core (resembling a spider’s body) that blanch with pressure. These commonly occur on the face, neck, or upper chest and are most frequently associated with hyperestrogenic states, such as pregnancy or liver cirrhosis.
- *Hereditary hemorrhagic telangiectasia* (*Osler-Weber-Rendu disease*) is an autosomal dominant disorder caused by mutations in genes that encode components of the TGF- β signaling pathway. The telangiectasias are malformations composed of dilated capillaries and veins that are present at birth. They are widely distributed over the skin and oral mucous membranes, as well as in the respiratory, gastrointestinal, and urinary tracts. The lesions can spontaneously rupture, causing serious epistaxis (nosebleed), gastrointestinal bleeding, or hematuria.

Hemangioma. Hemangiomas are very common tumors characterized by increased numbers of normal or abnor-

mal vessels filled with blood (Fig. 11-30). These lesions constitute 7% of all benign tumors of infancy and childhood; most are present from birth and initially increase in size, but many eventually regress spontaneously. While hemangiomas typically are localized lesions confined to the head and neck, they can occasionally be more extensive (*angiomatosis*) and can occur internally. Nearly one third of these internal lesions are found in the liver. Malignant transformation is rare. Several histologic and clinical variants have been described:

- *Capillary hemangiomas* are the most common type; these occur in the skin, subcutaneous tissues, and mucous membranes of the oral cavities and lips, as well as in the liver, spleen, and kidneys (Fig. 11-30A). Histologically, they are composed of thin-walled capillaries with scant stroma (Fig. 11-30B).
- *Juvenile hemangiomas* (so-called “strawberry type” hemangiomas) of the newborn are extremely common (1 in 200 births) and can be multiple. These arise in the skin and grow rapidly for a few months, but then fade by 1 to 3 years of age and completely regress by age 7 in the vast majority of cases.
- *Cavernous hemangiomas* are composed of large, dilated vascular channels. As compared to capillary hemangiomas, *cavernous hemangiomas* are more infiltrative, frequently involve deep structures, and do not spontaneously regress. On histologic examination, the mass is unencapsulated, has infiltrative borders, and is composed of large, cavernous blood-filled vascular spaces separated by connective tissue stroma (Fig. 11-30C). Intravascular thrombosis and associated dystrophic calcification are common. They can be locally destructive, and as a result some may require surgery. More often the tumors are of little clinical significance, but they can be cosmetically troublesome and are vulnerable to traumatic ulceration and bleeding. Moreover, cavernous hemangiomas detected by imaging studies may be difficult to distinguish from their malignant counterparts. Brain hemangiomas are also problematic, as they can cause symptoms related to compression of adjacent tissue or rupture. Cavernous hemangiomas are one component of *von Hippel-Lindau disease* (Chapter 28), in which vascular lesions are commonly found in the cerebellum, brain stem, retina, pancreas, and liver.
- *Pyogenic granulomas* are capillary hemangiomas that present as rapidly growing red pedunculated lesions on the skin, gingival, or oral mucosa. They bleed easily and are often ulcerated (Fig. 11-30D). Roughly a quarter of lesions develop after trauma, reaching a size of 1 to 2 cm within a few weeks. Curettage and cautery is usually curative. *Pregnancy tumor* (*granuloma gravidarum*) is a pyogenic granuloma that occurs infrequently (1% of patients) in the gingiva of pregnant women. These lesions may spontaneously regress (especially after pregnancy), or undergo fibrosis, but occasionally require surgical excision.

Lymphangiomas. Lymphangiomas are the benign lymphatic counterparts of hemangiomas.

- *Simple (capillary) lymphangiomas* are slightly elevated or sometimes pedunculated lesions up to 1 to 2 cm in diameter that occur predominantly in the head,

Figure 11-30 Hemangiomas. **A**, Hemangioma of the tongue. **B**, Histology of juvenile capillary hemangioma. **C**, Histology of cavernous hemangioma. **D**, Pyogenic granuloma of the lip. (**A** and **D**, Courtesy John Sexton, MD, Beth Israel Hospital, Boston, Mass.; **B**, courtesy Christopher DM Fletcher, MD, Brigham and Women's Hospital, Boston, Mass.; **C**, courtesy Thomas Rogers, MD, University of Texas Southwestern Medical School, Dallas, Texas.)

neck, and axillary subcutaneous tissues. Histologically, lymphangiomas exhibit networks of endothelium-lined spaces that can be distinguished from capillary channels only by the absence of red cells.

- **Cavernous lymphangiomas (cystic hygromas)** are typically found in the neck or axilla of children, and more rarely in the retroperitoneum. Cavernous lymphangiomas can occasionally be enormous (up to 15 cm in diameter) and may fill the axilla or produce gross deformities about the neck. Of note, cavernous lymphangiomas of the neck are common in Turner syndrome. These lesions are composed of massively dilated lymphatic spaces lined by endothelial cells and separated by intervening connective tissue stroma containing lymphoid aggregates. The tumor margins are indistinct and unencapsulated, making definitive resection difficult.

Glomus Tumor (Glomangioma). Glomus tumors are benign but exquisitely painful tumors arising from modified smooth muscle cells of the glomus bodies, arteriovenous structures involved in thermoregulation. Although they may superficially resemble hemangiomas, glomangiomas arise from smooth muscle cells rather than endothelial cells. They are most commonly found in the distal portion of the digits, especially under the fingernails. Excision is curative.

Bacillary Angiomatosis. Bacillary angiomatosis is a vascular proliferation in immunocompromised hosts (e.g.,

patients with AIDS) caused by opportunistic gram-negative bacilli of the *Bartonella* family. Lesions can involve the skin, bone, brain, and other organs. Two species are implicated:

- *Bartonella henselae*, whose principal reservoir is the domestic cat; this organism causes *cat-scratch disease* (a necrotizing granulomatous disorder of lymph nodes) in immunocompetent hosts.
- *Bartonella quintana*, which is transmitted by human body lice; this microbe was the cause of "trench fever" in World War I.

MORPHOLOGY

Skin lesions are red papules and nodules, or rounded subcutaneous masses; histologically, there is capillary proliferation with prominent epithelioid endothelial cells exhibiting nuclear atypia and mitoses (Fig. 11-31). Lesions contain stromal neutrophils, nuclear dust, and the causal bacteria.

Although difficult to cultivate in the laboratory, the *Bartonella* culprits can be unequivocally demonstrated using molecular methods such as polymerase chain reaction with species-specific primers. All the species are able to adhere to endothelial cells and are internalized in vacuoles. With *B. henselae* infection, the vascular proliferation results from induction of host hypoxia-inducible factor-1 (HIF-1) by the bacteria, which in turn drives

Figure 11-31 Bacillary angiomatosis. **A**, Characteristic cutaneous lesion. **B**, Histologic appearance with acute neutrophilic inflammation and vascular (capillary) proliferation. vascular endothelial growth factor (VEGF) production. The infections (and lesions) are cleared by macrolide antibiotics (including erythromycin).

Intermediate-Grade (Borderline) Tumors

Kaposi Sarcoma. Kaposi sarcoma (KS) is vascular neoplasm caused by human herpesvirus 8 (HHV8) that is highly associated with acquired immunodeficiency syndrome (AIDS). It also occurs much less commonly in other settings. Four forms of KS are recognized, based on population demographics and risks:

- **Classic KS** is a disorder of older men of Mediterranean, Middle Eastern, or Eastern European descent (especially Ashkenazic Jews); it is uncommon in the United States. It can be associated with malignancy or altered immunity, but is not associated with HIV infection. Classic KS manifests as multiple red-purple skin plaques or nodules, usually in the distal lower extremities; these progressively increase in size and number and spread proximally. Although persistent, the tumors are typically asymptomatic and remain localized to the skin and subcutaneous tissue.
- **Endemic African KS** typically occurs in HIV-seronegative individuals younger than age 40 and can follow an indolent or aggressive course; it involves lymph nodes much more frequently than the classic variant. In combination with AIDS-associated KS (see later), KS is now the most common tumor in central Africa. A particularly severe form, with prominent lymph node and visceral involvement, occurs in prepubertal children; the prognosis is poor, with an almost 100% mortality within 3 years.
- **Transplant-associated KS** occurs in solid organ transplant recipients in the setting of T-cell immunosuppression. The risk of KS is increased 100-fold in transplant recipients, pursuing an aggressive course that characteristically involves lymph nodes, mucosa, and viscera; cutaneous lesions may be absent. Lesions often regress with attenuation of immunosuppression, but at the risk of organ rejection.
- **AIDS-associated (epidemic) KS** is an AIDS-defining illness, and worldwide, it represents the most common HIV-related

malignancy (Chapter 6). Although the incidence of KS has fallen more than 80% with the advent of aggressive antiretroviral therapies, it still occurs in HIV-infected individuals at a rate over a thousand-fold greater than in the general population, and affects 2-3% of the HIV-infected population in the US. AIDS-associated KS often involves lymph nodes and disseminates widely to viscera early in its course. Most patients eventually die of opportunistic infections rather than KS.

Pathogenesis. Virtually all KS lesions are infected by human herpesvirus 8 (HHV8), also known as Kaposi sarcoma herpesvirus. Like Epstein-Barr virus, HHV8 is a γ -herpesvirus. It is transmitted sexually and by poorly understood nonsexual routes potentially including oral secretions and cutaneous exposures (of note, the prevalence of endemic African KS is inversely related to the wearing of shoes). HHV8 and altered T-cell immunity are likely required for KS development; in older adults, diminished T-cell immunity may be related to aging. Because the development and progression of KS are tightly linked to immune function, its molecular pathogenesis is discussed in detail in Chapter 6.

MORPHOLOGY

In **classic KS** (and sometimes in other variants), the cutaneous lesions progress through three stages:

- **Patches** are red-purple macules typically confined to the distal lower extremities (Fig. 11-32A). Histology shows only dilated irregular endothelial cell-lined vascular spaces with interspersed lymphocytes, plasma cells, and macrophages (sometimes containing hemosiderin). The lesions can be difficult to distinguish from granulation tissue.
- With time, lesions spread proximally and become larger, violaceous, **raised plaques** (Fig. 11-32A) composed of dermal accumulations of dilated, jagged vascular channels lined and surrounded by plump spindle cells. Scattered between the vascular channels are extravasated erythrocytes, hemosiderin-laden macrophages, and other mononuclear inflammatory cells.

Figure 11-32 Kaposi sarcoma. **A**, Gross photograph, illustrating coalescent red-purple macules and plaques of the skin. **B**, Histologic appearance of the nodular stage of KS, demonstrating sheets of plump, proliferating spindle cells. (**B**, Courtesy Christopher DM Fletcher, MD, Brigham and Women's Hospital, Boston, Mass.)

- Eventually, lesions become **nodular** and more distinctly neoplastic. These lesions are composed of sheets of plump, proliferating spindle cells, mostly in the dermis or subcutaneous tissues (Fig. 11-32B), encompassing small vessels and slitlike spaces containing red cells. Marked hemorrhage, hemosiderin pigment, and mononuclear inflammation are present; mitotic figures are common, as are round, pink, cytoplasmic globules representing degenerating red cells within phagolysosomes. The nodular stage often heralds nodal and visceral involvement, particularly in the African and AIDS-associated variants.

Clinical Features. The course of KS varies widely and is significantly influenced by the clinical setting. Most primary KSHV infections are asymptomatic. Classic KS is—at least initially—largely restricted to the surface of the body, and surgical resection is usually adequate for an excellent prognosis. Radiation can be used for multiple lesions in a restricted area and chemotherapy yields satisfactory results for more disseminated disease, including nodal involvement. In immunosuppression-associated KS, withdrawal of immunosuppression (perhaps with adjunct chemotherapy or radiotherapy) is often effective. Anti-retroviral therapy treatment has greatly decreased that frequency of KS in HIV infected patients, emphasizing the central role that T cell immunodeficiency has in the disease. Interferon- α and angiogenesis inhibitors are variably effective, while newer strategies aimed at specific kinases that lie downstream of VEGF receptors show promise.

Hemangioendothelioma. *Hemangioendotheliomas* encompass a spectrum of vascular neoplasms with clinical behaviors *intermediate between benign, well-differentiated hemangiomas and frankly anaplastic angiosarcomas*, described later.

Epithelioid hemangioendothelioma is an example; it is a vascular tumor of adults occurring around medium- and large-sized veins. Well-defined vascular channels are inconspicuous, and neoplastic cells are plump and often cuboidal (resembling epithelial cells). The clinical behavior is extremely variable; most are cured by excision, but up to 40% recur, 20% to 30% eventually metastasize, and perhaps 15% of patients die of their tumor.

Malignant Tumors

Angiosarcoma. *Angiosarcoma* is a malignant endothelial neoplasm that primarily affects older adults. There is equal gender predilection, and the tumor may occur at any site, but most often involves skin, soft tissue, breast, and liver.

Hepatic angiosarcoma is associated with carcinogenic exposures, including arsenic (e.g., in pesticides), Thorotrast (a radioactive contrast agent formerly used for radiologic imaging), and polyvinyl chloride (a widely used plastic). All of these agents have long latencies between initial exposure and eventual tumor development. The increased frequency of angiosarcoma among polyvinyl chloride workers is one of the well-documented instances of human chemical carcinogenesis.

Angiosarcoma can also arise in the setting of lymphedema, classically in the ipsilateral upper extremity several years after radical mastectomy (i.e., with lymph node resection) for breast cancer; the tumor presumably arises from lymphatic vessels (*lymphangiosarcoma*). Angiosarcoma has also been induced by radiation and are rarely associated with foreign material introduced into the body either iatrogenically or accidentally.

Angiosarcomas are locally invasive and can readily metastasize; 5-year survival rates approach 30%.

MORPHOLOGY

Cutaneous angiosarcoma can begin as multiple deceptively small and asymptomatic red papules or nodules; these eventually become large, fleshy masses of red-tan to gray-white tissue with margins blurring imperceptibly into surrounding structures (Fig. 11-33A). Central areas of necrosis and hemorrhage are frequent.

Microscopically, **all degrees of differentiation can be seen**, from plump, atypical endothelial cells forming vascular channels (Fig. 11-33B) to wildly undifferentiated tumors with a solid spindled appearance and no discernible blood vessels that may be difficult to distinguish from carcinomas and melanomas. The endothelial origin of these tumors can be demonstrated by immunohistochemical staining for CD31 or von Willebrand factor (Fig. 11-33C).

Figure 11-33 Angiosarcoma. **A**, Angiosarcoma involving the right ventricle. **B**, Moderately differentiated angiosarcoma with dense clumps of atypical cells lining distinct vascular lumens. **C**, Immunohistochemical staining for the endothelial cell marker CD31, demonstrating the endothelial nature of the tumor cells.

Hemangiopericytoma. Hemangiopericytomas have been considered tumors that arise from pericytes, the myofibroblast-like cells associated with capillaries and venules. Recent studies suggest that tumors of pericytes are very rare and the vast majority of those previously assigned to this group are derived from other cells such as fibroblasts and are classified as such. One example is the solitary fibrous tumor that arises on the pleura.

KEY CONCEPTS

Vascular Tumors

- Vascular ectasias are not neoplasms, but rather dilations of existing vessels.
- Vessel neoplasms can derive from either blood vessels or lymphatics, and can be composed of endothelial cells (hemangioma, lymphangioma, angiosarcoma) or other components of vascular wall cells
- Most vascular tumors are benign (e.g., hemangiomas), some have an intermediate, locally aggressive behavior (e.g., Kaposi sarcoma), and others are highly malignant (e.g., angiosarcoma).
- Benign tumors typically form obvious vascular channels lined by normal-appearing endothelial cells. Malignant tumors are more often solid and cellular, exhibit cytologic atypia, and lack well-defined vessels.

Pathology of Vascular Intervention

The morphologic changes that occur in vessels following therapeutic intervention (e.g., stenting or bypass surgery) largely recapitulate the changes that occur in the setting of any vascular insult. Local trauma or thrombosis (e.g., due

to a stent), or abnormal mechanical forces (e.g., a saphenous vein inserted into the arterial circulation as a coronary artery bypass graft), all induce the same stereotypical healing responses. Analogous to the various insults that drive atherosclerosis, any therapeutic intervention that injures the endothelium also tends to induce intimal thickening by recruiting smooth muscle cells and promoting extracellular matrix deposition.

Endovascular Stenting

Arterial stenoses (especially those in coronary arteries) can be dilated by transiently inflating a balloon catheter to pressures sufficient to rupture the occluding plaque (*balloon angioplasty*); in doing so, a (hopefully) limited *arterial dissection* is also induced. Although most patients improve symptomatically following angioplasty alone, *abrupt reclosure* can occur as a result of compression of the lumen by an extensive circumferential or longitudinal dissection, by vessel wall spasm, or by thrombosis. Thus, more than 90% of endovascular coronary procedures now involve both angioplasty and concurrent *coronary stent* placement.

Coronary stents are expandable tubes of metallic mesh. They provide a larger and more regular lumen, “tack down” the intimal flaps and dissections that occur during angioplasty, and mechanically limit vascular spasm. Nevertheless, due to endothelial injury, *thrombosis* is an important immediate post-stenting complication, and patients must receive potent antithrombotic agents (primarily platelet antagonists) to prevent acute catastrophic thrombotic occlusions. The *long-term* success of angioplasty is limited by the development of *proliferative in-stent restenosis*. This intimal thickening is due to smooth muscle cell ingrowth, proliferation, and matrix synthesis, all driven by the initial vascular wall injury; it causes clinically

Figure 11-34 Restenosis after angioplasty and stenting. **A**, Gross view demonstrating residual yellow atherosclerotic plaque (arrows) and a new, tan-white concentric intimal lesion inside of that plaque. **B**, Histologic view shows a thickened neointima separating and overlying the stent wires (the black diamond indicated by the arrow), which encroaches on the lumen (indicated by the asterisk); Movat stain with matrix staining gray-green. (B, Reproduced from Schoen FJ, Edwards WD. Pathology of cardiovascular interventions, including endovascular therapies, revascularization, vascular replacement, cardiac assist/replacement, arrhythmia control, and repaired congenital heart disease. In Silver MD, Gotlieb AI, Schoen FJ (eds): Cardiovascular Pathology, 3rd ed. Philadelphia, Churchill Livingstone, 2001.)

significant luminal occlusion in up to a third of patients within 6 to 12 months of stenting (Fig. 11-34).

The newest generation of *drug-eluting stents* is designed to avoid this complication by leaching antiproliferative drugs (e.g., paclitaxel or sirolimus) into the adjacent vessel wall to block smooth muscle cell activation. Although the duration of drug elution is short (days to weeks), these drug-eluting stents nevertheless reduce the incidence of restenosis at 1 year by 50% to 80%. However, because of the antiproliferative effect of the drug-eluting stents, the time to reendothelialization is prolonged and patients

require extended courses of anticoagulation to prevent stent thrombosis.

Vascular Replacement

Synthetic or autologous vascular grafts are increasingly used to replace damaged vessels or bypass diseased arteries. Large-bore (12- to 18-mm) synthetic conduits function well in high-flow locations such as the aorta; unfortunately, small-diameter artificial grafts (≤ 8 mm in diameter) generally fail as a result of early thrombosis or late intimal hyperplasia, the latter at the junction of the graft with the native vasculature (Fig. 11-35).

Consequently, when small-bore vessel replacement is required (e.g., in coronary bypass surgeries), the grafts are fashioned from saphenous veins (taken from the patient's own leg) or left internal mammary arteries. The long-term patency of saphenous vein grafts is only 50% at 10 years; grafts occlude due to thrombosis (typically early), intimal thickening (months to years postoperatively), and vein graft atherosclerosis—sometimes with superimposed plaque rupture, thrombi, or aneurysms (usually more than 2 to 3 years). By contrast, 90% or more of internal mammary artery grafts are patent at 10 years. With the advent of stenting (and better control of risk factors such as hyperlipidemia), the frequency of coronary arterial bypass surgery has decreased in recent years.

The human heart is a remarkably efficient, durable, and reliable pump, distributing more than 6000 liters of blood through the body each day, and beating 30 to 40 million times a year—providing tissues with vital nutrients and facilitating waste excretion. Consequently, cardiac dysfunction can have devastating physiologic consequences. Cardiovascular disease (including coronary artery disease, stroke, and peripheral vascular disease) is the number one cause of worldwide mortality, with about 80% of the burden occurring in developing countries. In the United States alone, cardiovascular disease accounts for roughly a third of all deaths, totaling about 800,000 individuals—or nearly 1.5 times the number of deaths caused by all forms of cancer combined.

Disruption of *any* element of the heart—myocardium, valves, conduction system, and coronary vasculature—can adversely affect pumping efficiency, thus leading to morbidity and mortality. The major categories of cardiac disease

described in this chapter include congenital heart abnormalities, ischemic heart disease, hypertensive heart disease, diseases of the cardiac valves, and primary myocardial disorders. A few comments about pericardial diseases and cardiac neoplasms, as well as cardiac transplantation, are also presented. This chapter begins with a brief review of the normal heart since most cardiac diseases manifest as structural and/or functional changes in one or more cardiac components. General principles underlying cardiac hypertrophy and failure—common end points of several of the different forms of heart disease—are also discussed.

Cardiac Structure and Specializations

Heart weight varies with body habitus, averaging approximately 0.4% to 0.5% of body weight (250 to 320 gm in females and 300 to 360 gm in males); the right ventricle

wall thickness is usually 0.3 to 0.5 cm, while the left ventricle wall is 1.3 to 1.5 cm thick. Increases in heart weight or ventricular thickness above these normal limits indicates *hypertrophy*, and an enlarged chamber size implies *dilation*; both can represent compensatory changes in response to heart disease and to volume and/or pressure overloads (see later). Increased cardiac weight or size (or both)—resulting from hypertrophy and/or dilation—is called *cardiomegaly*.

Myocardium

The pumping function of the heart is accomplished via the coordinated contraction (during *systole*) and relaxation (during *diastole*) of the cardiac myocytes that comprise the *myocardium*. Left ventricular myocytes are arranged circumferentially in a spiral orientation that helps to generate a coordinated wave of contraction that spreads from the apex to the base of the heart. In contrast, right ventricular myocytes have a somewhat less structured organization. The contractile apparatus within myocytes is organized into a series of subunits called *sarcomeres*, composed of highly ordered networks of thick filaments (primarily *myosin* in the center of the sarcomere) interlaced with thin filaments (largely *actin*, attached to the end of the sarcomere) and regulatory proteins such as troponin and tropomyosin. The actin and myosin filaments partially overlap with each other, giving rise to the striated appearance of cardiac myocytes (overlapping areas of actin and myosin are dark while the intervening areas are light).

Contraction results as myosin filaments ratchet adjacent actin filaments toward the center—shortening individual sarcomeres, and collectively leading to myocyte shortening. The amount of force generated is determined by the distance each sarcomere contracts. Thus, moderate ventricular dilation during diastole creates a greater distance over which the sarcomere can subsequently shorten and augment the force of systolic contraction. This compensatory mechanism serves to accommodate differing volume and pressure demands. Unfortunately, there is an upper limit to the benefit of increased stretching during diastole. With excessive dilation, the overlap of the actin and myosin filaments is reduced and the force of contraction decreases sharply, leading to heart failure.

Atrial myocytes are relatively haphazardly arranged, and thus generate weaker contractile forces than the ventricles. Some atrial cells have distinctive cytoplasmic electron-dense storage granules that contain *atrial natriuretic peptide*; this is a peptide hormone that promotes arterial vasodilation and stimulates renal salt and water elimination (*natriuresis* and *diuresis*), actions that are beneficial in the setting of hypertension and congestive heart failure.

The coordinated beating of cardiac myocytes depends on *intercalated discs*—specialized intercellular junctions that facilitate cell-to-cell mechanical and electrical (ionic) coupling. Within the intercalated discs (and at the lateral borders of adjacent myocytes), *gap junctions* facilitate synchronized waves of myocyte contraction by permitting rapid movement of ions (e.g., sodium, potassium, calcium) between adjoining cells. Abnormalities in the spatial distribution of gap junctions in a variety of heart diseases can cause electromechanical dysfunction (*arrhythmia*) and/or heart failure.

Valves

The four cardiac valves—tricuspid, pulmonary, mitral, and aortic—maintain unidirectional blood flow. Valve function depends on the mobility, pliability, and structural integrity of the *leaflets* of the *atrioventricular* valves (tricuspid and mitral) or *cusps* of the *semilunar valves* (aortic and pulmonary). Cardiac valves are lined by endothelium and share a similar, tri-layered architecture:

- A dense collagenous core (*fibrosa*) at the outflow surface and connected to the valvular supporting structures
- A central core of loose connective tissue (*spongiosa*)
- A layer rich in elastin (*ventricularis* or *atrialis* depending on which chamber it faces) on the inflow surface

The collagen of the *ventricularis* is largely responsible for the mechanical integrity of a valve, while the elastic tissue of the *atrialis/ventricularis* imparts a rapid recoil to achieve prompt valve closure. The proteoglycan-rich *spongiosa* facilitates the interactions of the collagenous (relatively stiff) and elastic layers during the cardiac cycle. Crucial to function are the valvular interstitial cells, the most abundant cell type in the heart valves, and distributed throughout all of its layers. Valvular interstitial cells synthesize extracellular matrix (ECM) and express matrix degrading enzymes (including matrix metalloproteinases [MMPs], along with inhibitors that remodel collagen and other matrix components. Valvular interstitial cells comprise a diverse and dynamic population of resident cells that can alter their phenotypes and functions in response to changing hemodynamic stresses.

The function of the semilunar valves depends on the integrity and coordinated movements of the cuspal attachments. Thus, dilation of the aortic root can hinder coaptation of the aortic valve cusps during closure and result in valvular regurgitation. In contrast, the competence of the atrioventricular valves depends on the proper function not only the leaflets but also the tendinous cords and the attached papillary muscles of the ventricular wall. Left ventricular dilation, a ruptured tendinous cord, or papillary muscle dysfunction can all interfere with valve closure, causing valvular insufficiency.

Because they are thin enough to be nourished by diffusion from the blood, normal leaflets and cusps have only scant blood vessels limited to the proximal portion. **Pathologic changes of valves are largely of three types: damage to collagen that weakens the leaflets, exemplified by mitral valve prolapse; nodular calcification beginning in interstitial cells, as in calcific aortic stenosis; and fibrotic thickening, the key feature in rheumatic heart disease** (see later).

Conduction System

Coordinated contraction of the cardiac muscle depends on propagation of electrical impulses—accomplished through specialized excitatory and conducting myocytes within the cardiac conduction system that regulate heart rate and rhythm. The frequency of electrical impulses that course through the conduction system is sensitive to neural inputs (e.g., vagal stimulation), extrinsic adrenergic agents (e.g., adrenaline), hypoxia, and potassium concentration (i.e., hyperkalemia can block signal transmission

altogether). Inputs from the autonomic nervous system can increase the heart rate to twice normal within seconds, and are important for physiologic responses to exercise or other states associated with increased oxygen demand.

The components of the conduction system include:

- *Sinoatrial (SA) node* pacemaker (at the junction of the right atrial appendage and superior vena cava)
- *Atrioventricular (AV) node* (located in the right atrium along the atrial septum)
- *Bundle of His*, connecting the right atrium to the ventricular septum
- Subsequent divisions into the right and left bundle branches that stimulate their respective ventricles via further arborization into the *Purkinje network*

The cells of the cardiac conduction system depolarize spontaneously, enabling them to function as cardiac pacemakers. Because the normal rate of spontaneous depolarization in the SA node (60 to 100 beats/minute) is faster than the other components, it normally sets the pace. The AV node has a gatekeeper function; by delaying the transmission of signals from the atria to the ventricles, it ensures that atrial contraction precedes ventricular systole.

Blood Supply

Cardiac myocytes rely almost exclusively on oxidative phosphorylation for their energy needs. Besides a high density of mitochondria (20% to 30% of myocyte volume), myocardial energy generation also requires a constant supply of oxygenated blood—rendering myocardium extremely vulnerable to ischemia. Nutrients and oxygen are delivered via the *coronary arteries*, with takeoffs immediately distal to the aortic valve. These initially course along the external surface of the heart (*epicardial coronary arteries*) and then penetrate the myocardium (*intramural arteries*), subsequently branching into arterioles, and eventually forming a rich arborizing vascular network so that each myocyte contacts roughly three capillaries.

There are three major epicardial coronary arteries (so-called because they form a crown or *corona* at the base of the heart):

- Left anterior descending (LAD) and left circumflex (LCX) arteries arise from the left (main) coronary artery
- Right coronary artery

The divisions of the LAD are called *diagonal branches*, and those of the LCX are *marginal branches*. The right and left coronary arteries function as end arteries, although anatomically most hearts have numerous intercoronary anastomoses (connections called collateral circulation). Blood flow to the myocardium occurs during ventricular diastole, following closure of the aortic valve, and when the microcirculation is not compressed by cardiac contraction. At rest, diastole comprises approximately two thirds of the cardiac cycle; with tachycardia (increased heart rate), the relative duration of diastole also shortens, thus potentially compromising cardiac perfusion.

Cardiac Stem Cells

Although cardiac regeneration in metazoans (e.g., newts and zebrafish) is well described, the myocardium of higher

order animals is classically depicted as a permanent cell population without replicative potential. However, increasing evidence points to the presence of bone marrow-derived precursors—as well as a small population of stem cells within the myocardium—that are capable of repopulating the mammalian heart. Besides self-renewal, these cardiac stem cells generate all cell lineages seen within the myocardium. They constitute up to 5% to 10% of normal atrial cellularity, but represent only roughly 1 in 100,000 cells in a normal ventricle.

Cardiac stem cells have a very slow rate of proliferation, which is greatest in neonates, and decreases with age. The human adult heart replaces roughly 1% of its total population each year, so that by the age of 50 years, almost 45% of the total cardiomyocytes have been renewed. While stem cell numbers and progeny increase after myocardial injury or hypertrophy, albeit to a limited extent, hearts that suffer myocardial cell loss (e.g., due to infarction) do not recover any significant function in the necrotic zone (one of several features that distinguish humans from fish and newts). Nevertheless, the potential for stimulating proliferation and differentiation of these cells *in vivo* is tantalizing since it could facilitate recovery of myocardial function following irreversible myocardial damage. Similarly, *ex vivo* expansion and subsequent administration of stem cells is another strategy being explored in the unfulfilled quest to heal a broken heart. Until then a trip to the local jewelry store will have to suffice!

Effects of Aging on the Heart

The prevalence of most forms of heart disease increases with each advancing decade. Consequently, as the average population in developed countries ages, changes in the cardiovascular system that accrue with aging become increasingly significant (Table 12-1).

Epicardial fat increases, while the detritus of years of intracellular catabolism and oxidant stress accumulate in the form of intracellular lipofuscin. *Basophilic degeneration*, a gray-blue byproduct of glycogen metabolism within cardiac myocytes, is also increased. The size of the left ventricular cavity, particularly in the base-to-apex dimension, is reduced; this volume change is exacerbated by systemic hypertension and bulging of the basal ventricular septum into the left ventricular outflow tract (termed *sigmoid septum*).

Valvular aging changes include calcification of the mitral annulus and aortic valve, the latter frequently leading to aortic stenosis. In addition, the valves can develop fibrous thickening, and the mitral leaflets tend to buckle back toward the left atrium during ventricular systole, simulating a prolapsing (myxomatous) mitral valve. As this happens, increasing volume and pressure overloads lead to left atrial dilation, and with it, an increased incidence of atrial arrhythmias (e.g., fibrillation). With time, small filiform processes (*Lambl excrescences*) form on the closure lines of aortic and mitral valves, probably resulting from the organization of small thrombi.

The aorta becomes progressively stiffer, owing to the fragmentation and loss of elastic tissue and increased collagen deposition, along with the accumulation of atherosclerotic plaque. The result is less elasticity, and increased

Table 12-1 Changes in the Aging Heart

Chambers
Increased left atrial cavity size Decreased left ventricular cavity size Sigmoid-shaped ventricular septum
Valves
Aortic valve calcific deposits Mitral valve annular calcific deposits Fibrous thickening of leaflets Buckling of mitral leaflets toward the left atrium Lambd excrescences

Decreased mass Increased subepicardial fat Brown atrophy Lipofuscin deposition Basophilic degeneration Amyloid deposits
Aorta
Dilated ascending aorta with rightward shift Elongated (tortuous) thoracic aorta Sinotubular junction calcific deposits Elastic fragmentation and collagen accumulation Atherosclerotic plaque

pressure spikes with each cardiac contraction that are transmitted to distal organs.

Compared with younger myocardium, “elderly” myocardium has fewer myocytes, increased collagenized connective tissue and, often the deposition of extracellular amyloid (most commonly due to poorly catabolized transthyretin; see [Chapter 6](#)).

Most importantly, the progressive atherosclerosis ([Chapter 11](#))—over a period of 50 to 60 years—finally ends up causing significant stenosis, or weakens the wall sufficiently to give rise to catastrophic dissection of the aortic wall (see later).

Overview of Cardiac Pathophysiology

Cardiovascular dysfunction can be attributed to one (or more) of six principal mechanisms:

- **Pump failure.** In some conditions, the myocardium contracts weakly during systole and there is inadequate cardiac output. Conversely, myocardium may relax insufficiently during diastole to permit adequate ventricular filling.
- **Flow obstruction.** Lesions can obstruct blood flow through a vessel (e.g., atherosclerotic plaque) or prevent valve opening or otherwise cause increased ventricular chamber pressure (e.g., aortic valvular stenosis, systemic hypertension, or aortic coarctation). In the case of a valvular blockage, the increased pressure overloads the chamber that pumps against the obstruction.
- **Regurgitant flow.** A portion of the output from each contraction flows backward through an incompetent valve, adding a volume overload to the affected atria or ventricles (e.g., left ventricle in aortic regurgitation; left atrium and left ventricle in mitral regurgitation).
- **Shunted flow.** Blood can be diverted from one part of the heart to another (e.g., from the left ventricle to the right ventricle), through defects that can be congenital or acquired (e.g., following myocardial infarction). Shunted flow can also occur between blood vessels, as in patent ductus arteriosus (PDA).
- **Disorders of cardiac conduction.** Conduction defects or arrhythmias due to uncoordinated generation or transmission of impulses (e.g., atrial or ventricular fibrillation) lead to nonuniform and inefficient myocardial contractions, and may in fact be lethal.
- **Rupture of the heart or a major vessel.** In such circumstances (e.g., gunshot to the left ventricle, or aortic dissection and rupture), there is cataclysmic exsanguination, either into body cavities or externally.

Most cardiovascular disease results from a complex interplay of genetics and environmental factors; these may disrupt signaling pathways that control morphogenesis, impact myocyte survival after injury, or affect contractility or electrical conduction in the face of biomechanical stressors. Indeed, the pathogenesis of many congenital heart defects involves an underlying genetic abnormality whose expression is modified by environmental or maternal factors (see later). Moreover, genes that control the development of the heart may also regulate the response to various forms of injury including aging. Subtle polymorphisms can significantly impact the risk of many forms of heart disease, and, as discussed later, a number of adult-onset heart disorders have a fundamentally genetic basis. Thus, cardiovascular genetics provides an important window on the pathogenesis of heart disease and increasingly molecular diagnoses are becoming a critical part of its classification.

Heart Failure

Heart failure, often called *congestive heart failure (CHF)*, is a common, usually progressive condition with a poor prognosis. Each year in the United States, CHF affects more than 5 million individuals (approximately 2% of the population), necessitating more than a million hospitalizations, and contributing to the death of nearly 300,000 people.

CHF occurs when the heart is unable to pump blood at a rate sufficient to meet the metabolic demands of the tissues or can do so only at an elevated filling pressure. It is the common end stage of many forms of chronic heart disease, often developing insidiously from the cumulative effects of chronic work overload (e.g., in valve disease or hypertension) or ischemic heart disease (e.g., following myocardial infarction with heart damage). However, acute hemodynamic stresses, such as fluid overload, abrupt valvular dysfunction, or myocardial infarction, can all precipitate sudden CHF.

When cardiac workload increases or cardiac function is compromised, several physiologic mechanisms maintain arterial pressure and organ perfusion:

- *Frank-Starling mechanism*, in which increased filling volumes dilate the heart and thereby increase subsequent actin-myosin cross-bridge formation, enhancing contractility and stroke volume
- *Myocardial adaptations, including hypertrophy with or without cardiac chamber dilation*. In many pathologic states, heart failure is preceded by cardiac hypertrophy, the compensatory response of the myocardium to increased mechanical work. The collective molecular, cellular, and structural changes that occur as a response to injury or changes in loading conditions are called *ventricular remodeling*.
- *Activation of neurohumoral systems* to augment heart function and/or regulate filling volumes and pressures
 - Release of norepinephrine by adrenergic cardiac nerves of the autonomic nervous system (which increases heart rate and augments myocardial contractility and vascular resistance)
 - Activation of the renin-angiotensin-aldosterone system
 - Release of atrial natriuretic peptide. The latter two factors act to adjust filling volumes and pressures.

These adaptive mechanisms may be adequate to maintain normal cardiac output in the face of acute perturbations, but their capacity to do so may ultimately be overwhelmed. Moreover, superimposed pathologic changes, such as myocyte apoptosis, intracellular cytoskeletal alterations, and extracellular matrix deposition, may cause further structural and functional disturbances. Heart failure can result from progressive deterioration of myocardial contractile function (*systolic dysfunction*)—reflected as a decrease in ejection fraction (EF, the percentage of blood volume ejected from the ventricle during systole; normal is approximately 45% to 65%). Reduction in EF can occur with ischemic injury, inadequate adaptation to pressure or volume overload due to hypertension or valvular disease, or ventricular dilation. Increasingly, heart failure is recognized as resulting from an inability of the heart chamber to expand and fill sufficiently during diastole (*diastolic dysfunction*), for example, due to left ventricular hypertrophy, myocardial fibrosis, constrictive pericarditis, or amyloid deposition.

Cardiac Hypertrophy: Pathophysiology and Progression to Heart Failure

Sustained increase in mechanical work due to pressure or volume overload (e.g., systemic hypertension or aortic stenosis) or trophic signals (e.g., those mediated through the activation of β -adrenergic receptors) cause myocytes to increase in size (*hypertrophy*); cumulatively, this increases the size and weight of the heart (Fig. 12-1). Hypertrophy requires increased protein synthesis, thus enabling the assembly of additional sarcomeres, as well as increasing the numbers of mitochondria. Hypertrophic myocytes also have enlarged nuclei, attributable to increased DNA ploidy resulting from DNA replication in the absence of cell division. The pattern of hypertrophy reflects the nature of the stimulus. In *pressure-overload*

hypertrophy (e.g., due to hypertension or aortic stenosis), new sarcomeres are predominantly assembled in parallel to the long axes of cells, expanding the cross-sectional area of myocytes in ventricles and causing a concentric increase in wall thickness. In contrast, *volume-overload hypertrophy* is characterized by new sarcomeres being assembled in series within existing sarcomeres, leading primarily to ventricular dilation. As a result, in dilation due to volume overload, or dilation that accompanies failure of a previously pressure-overloaded heart, the wall thickness may be increased, normal, or less than normal. Consequently, heart weight, rather than wall thickness, is the best measure of hypertrophy in dilated hearts.

Cardiac hypertrophy can be substantial in clinical heart disease. Heart weights of two to three times normal are common in patients with systemic hypertension, ischemic heart disease, aortic stenosis, mitral regurgitation, or dilated cardiomyopathy, and heart weights can be three- to four-fold greater than normal in those with aortic regurgitation or hypertrophic cardiomyopathy.

Important changes at the tissue and cell level occur with cardiac hypertrophy. Importantly, myocyte hypertrophy is not accompanied by a proportional increase in capillary numbers. As a result, the supply of oxygen and nutrients to the hypertrophied heart, particularly one undergoing pressure overload hypertrophy, is more tenuous than in the normal heart. At the same time, oxygen consumption by the hypertrophied heart is elevated due to the increased workload that drives the process. Hypertrophy is also often accompanied by deposition of fibrous tissue (interstitial fibrosis). Molecular changes include the expression of immediate-early genes (e.g., *FOS*, *JUN*, *MYC*, and *EGR1*) (Chapter 2). With prolonged hemodynamic overload, there may be a shift to a gene expression pattern resembling that seen during fetal cardiac development (including selective expression of embryonic/fetal forms of β -myosin heavy chain, natriuretic peptides, and collagen).

At a functional level, cardiac hypertrophy is associated with heightened metabolic demands due to increases in mass, heart rate, and contractility (inotropic state, or force of contraction), all of which increase cardiac oxygen consumption. *As a result of these changes, the hypertrophied heart is vulnerable to ischemia-related decompensation*, which can evolve to cardiac failure and eventually lead to death.

The proposed sequence of initially beneficial—and later harmful—events in response to increased cardiac work is summarized in Figure 12-2. *The molecular and cellular changes in hypertrophied hearts that initially mediate enhanced function may themselves contribute to the development of heart failure.* This can occur through:

- Abnormal myocardial metabolism
- Alterations of intracellular handling of calcium ions
- Myocyte apoptosis
- Reprogramming of gene expression, which may occur in part through changes in expression of miRNAs, small noncoding RNAs that inhibit gene expression (Chapter 1).

The degree of structural abnormality of the heart in CHF does not always reflect the severity of dysfunction, and the structural, biochemical, and molecular basis for myocardial contractile failure can be obscure.

Figure 12-1 Left ventricular hypertrophy. **A**, Pressure hypertrophy due to left ventricular outflow obstruction. The left ventricle is on the lower right in this apical four-chamber view of the heart. **B**, Left ventricular hypertrophy with and without dilation, viewed in transverse heart sections. Compared with a normal heart (*center*), the pressure-hypertrophied hearts (*left* and in **A**) have increased mass and a thick left ventricular wall, while the hypertrophied, dilated heart (*right*) has increased mass and a normal wall thickness. **C**, Normal myocardium. **D**, Hypertrophied myocardium (panels **C** and **D** are photomicrographs at the same magnification). Note the increases in both cell size and nuclear size in the hypertrophied myocytes. (**A**,**B**, Reproduced with permission from Edwards WD: Cardiac anatomy and examination of cardiac specimens. In Emmanouilides GC, et al [eds]: Moss and Adams Heart Disease in Infants, Children, and Adolescents: Including the Fetus and Young Adults, 5th ed. Philadelphia, Williams & Wilkins, 1995, p 86.)

At autopsy, the hearts of patients with CHF are generally heavy and dilated, and may be relatively thin-walled; they exhibit microscopic evidence of hypertrophy, but the extent of these changes is extremely variable. In hearts that have suffered myocardial infarction, loss of pumping capacity due to myocyte death leads to work-related hypertrophy of the surrounding viable myocardium. In valvular heart disease, the increased pressure or volume overloads the myocardium globally. Increased heart mass owing to disease is correlated with excess cardiac mortality and morbidity; indeed, cardiomegaly is an independent risk factor for sudden death.

In contrast to pathologic hypertrophy (which is often associated with contractile impairment), hypertrophy induced by regular strenuous exercise has varied effects on the heart depending on the type of exercise. Aerobic exercise (e.g., long distance running) tends to be associated with volume-load hypertrophy that may be accompanied by increases in capillary density (unlike other forms of hypertrophy) and decreases in resting heart rate and blood pressure—effects that are all beneficial. These changes are

sometimes referred to as *physiologic hypertrophy*. Static exercise (e.g., weight lifting) is associated with pressure hypertrophy and appears more likely to be associated with deleterious changes.

Whatever its basis, CHF is characterized by variable degrees of decreased cardiac output and tissue perfusion (sometimes called forward failure), as well as pooling of blood in the venous capacitance system (backward failure); the latter may cause pulmonary edema, peripheral edema, or both. As a result, many of the significant clinical features and morphologic changes noted in CHF are actually secondary to injuries induced by hypoxia and congestion in tissues away from the heart.

The cardiovascular system is a closed circuit. Thus, although left-sided and right-sided failure can occur independently, failure of one side (particularly the left) often produces excessive strain on the other, terminating in global heart failure. Despite this interdependence, it is easiest to understand the pathology of heart failure by considering right- and left-sided heart failure separately.

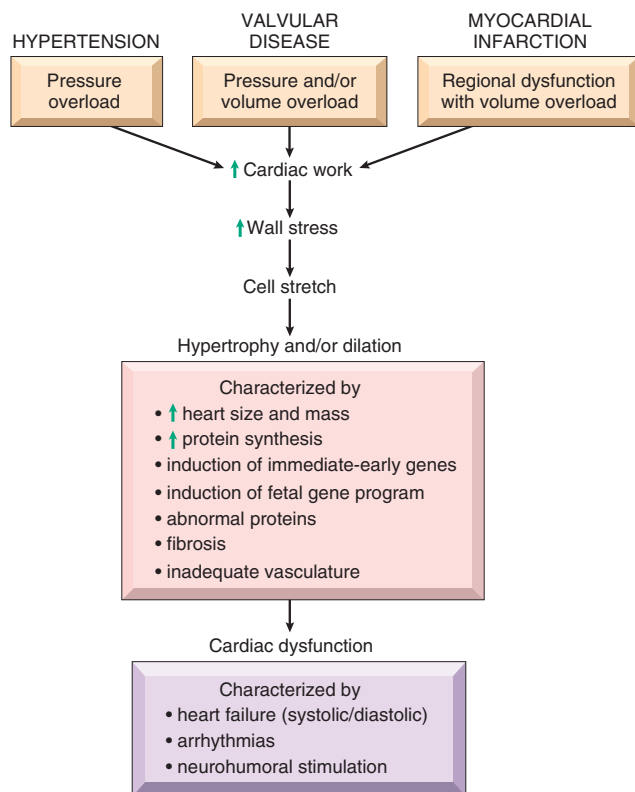

Figure 12-2 Schematic representation of the causes and consequences of cardiac hypertrophy.

Left-Sided Heart Failure

Left-sided heart failure is most often caused by:

- Ischemic heart disease
- Hypertension
- Aortic and mitral valvular diseases
- Primary myocardial diseases

The clinical and morphologic effects of left-sided CHF are a consequence of passive congestion (blood backing up in the pulmonary circulation), stasis of blood in the left-sided chambers, and inadequate perfusion of downstream tissues leading to organ dysfunction.

MORPHOLOGY

Heart. The heart findings depend on the disease process, ranging from myocardial infarcts, to stenotic or regurgitant valves, to intrinsic myocardial pathology. Except for failure caused by mitral valve stenosis or unusual restrictive cardiomyopathies (described later), the left ventricle is usually hypertrophied and often dilated, sometimes massively. The microscopic changes are nonspecific: primarily myocyte hypertrophy and variable degrees of interstitial fibrosis. Impaired left ventricular function usually causes secondary dilation of the left atrium, which increases the risk of atrial fibrillation. This in turn results in stasis of blood, particularly in the atrial appendage, which is a common site of thrombus formation.

Lungs. Pulmonary congestion and **edema** produce heavy, wet lungs, as described elsewhere (Chapters 4 and 15). Pulmonary changes—from mildest to most severe—include (1)

perivascular and interstitial edema, particularly in the interlobular septa, responsible for the characteristic Kerley B and C lines noted on chest X-ray study in CHF, (2) progressive edematous widening of alveolar septa, and (3) accumulation of edema fluid in the alveolar spaces. Some red cells and plasma proteins extravasate into the edema fluid within the alveolar spaces, where they are phagocytosed and digested by macrophages, which store the iron recovered from hemoglobin in the form of hemosiderin. These *hemosiderin-laden macrophages* (also known as **heart failure cells**) are telltale signs of previous episodes of pulmonary edema. Pleural effusions arise from elevated pleural capillary pressure and the resultant transudation of fluid into the pleural cavities.

Early left-sided heart failure symptoms are related to pulmonary congestion and edema and may be subtle. Initially, cough and *dyspnea* (breathlessness) may occur only with exertion. As CHF progresses, worsening pulmonary edema may cause *orthopnea* (dyspnea when supine, relieved by sitting or standing) or *paroxysmal nocturnal dyspnea* (dyspnea usually occurring at night that is so severe that it induces a feeling of suffocation). Dyspnea at rest may follow. *Atrial fibrillation*, an uncoordinated, chaotic contraction of the atrium, exacerbates CHF owing to the loss of the atrial “kick” and its 10% to 15% contribution to ventricular filling.

A reduced ejection fraction leads to diminished renal perfusion, causing activation of the renin-angiotensin-aldosterone system as a compensatory mechanism to correct the “perceived” hypotension. This leads to salt and water retention, with expansion of the interstitial and intravascular fluid volumes (Chapters 4 and 11) that then exacerbate the ongoing pulmonary edema. If the hypoperfusion of the kidney becomes sufficiently severe, impaired excretion of nitrogenous products may cause azotemia (called *prerenal azotemia* because of its vascular origin; Chapter 20). In far-advanced CHF, cerebral hypoperfusion can give rise to *hypoxic encephalopathy* (Chapter 28), with irritability, loss of attention span, and restlessness that can progress to stupor and coma with ischemic cerebral injury.

Left-sided heart failure can be divided into systolic and diastolic failure:

- *Systolic failure* is defined by insufficient ejection fraction (pump failure), and can be caused by any of the many disorders that damage or derange the contractile function of the left ventricle.
- In *diastolic failure*, the left ventricle is abnormally stiff and cannot relax during diastole. Thus, although cardiac function is relatively preserved at rest, the heart is unable to increase its output in response to increases in the metabolic demands of peripheral tissues (e.g., during exercise). Moreover, because the left ventricle cannot expand normally, any increase in filling pressure is immediately transferred back into the pulmonary circulation, producing rapid onset pulmonary edema (*flash pulmonary edema*). Diastolic failure predominantly occurs in patients older than age 65 years and for unclear reasons is more common in women. Hypertension is the most common underlying etiology; diabetes mellitus, obesity, and bilateral renal artery stenosis may also

contribute to risk. Reduced left ventricular relaxation may stem from myocardial fibrosis (e.g., in cardiomyopathies and ischemic heart disease), and infiltrative disorders associated with restrictive cardiomyopathies (e.g., cardiac amyloidosis). Diastolic failure may appear in older patients without any known predisposing factors, possibly as an exaggeration of the normal stiffening of the heart with age. Constrictive pericarditis (discussed later) can also limit myocardial relaxation and therefore mimics primary diastolic dysfunction.

Right-Sided Heart Failure

Right-sided heart failure is most commonly caused by left-sided heart failure, as any increase in pressure in the pulmonary circulation from left-sided failure inevitably burdens the right side of the heart. Consequently, the causes of right-sided heart failure include all of those that induce left-sided heart failure. Isolated right-sided heart failure is infrequent and typically occurs in patients with one of a variety of disorders affecting the lungs; hence it is often referred to as *cor pulmonale*. Besides parenchymal lung diseases, *cor pulmonale* can also arise secondary to disorders that affect the pulmonary vasculature, for example, primary pulmonary hypertension (Chapter 15), recurrent pulmonary thromboembolism (Chapter 4), or conditions that cause pulmonary vasoconstriction (obstructive sleep apnea, altitude sickness). *The common feature of these disorders is pulmonary hypertension* (discussed later), which results in hypertrophy and dilation of the right side of the heart. In extreme cases, leftward bulging of the interventricular septum can even cause left ventricular dysfunction. The major morphologic and clinical effects of primary right-sided heart failure differ from those of left-sided heart failure in that pulmonary congestion is minimal while engorgement of the systemic and portal venous systems is pronounced.

MORPHOLOGY

Heart. As in left-heart failure, the cardiac morphology varies with cause. Rarely, structural defects such as tricuspid or pulmonary valvular abnormalities or endocardial fibrosis (as in carcinoid heart disease) may be present. However, since isolated right heart failure is most often caused by lung disease, most cases exhibit only hypertrophy and dilation of the right atrium and ventricle.

Liver and Portal System. Congestion of the hepatic and portal vessels may produce pathologic changes in the liver, the spleen, and the GI tract. The liver is usually increased in size and weight (**congestive hepatomegaly**) due to prominent **passive congestion**, greatest around the central veins (Chapter 4). Grossly, this is reflected as congested red-brown pericentral zones, with relatively normal-colored tan periportal regions, producing the characteristic “nutmeg liver” appearance (Chapter 4). In some instances, especially when left-sided heart failure with hypoperfusion is also present, severe centrilobular hypoxia produces **centrilobular necrosis**. With long-standing severe right-sided heart failure, the central areas can become fibrotic, eventually culminating in **cardiac cirrhosis** (Chapter 18). Portal venous hypertension also causes enlargement of the spleen with platelet sequestration (**congestive**

splenomegaly), and can also contribute to chronic congestion and edema of the bowel wall. The latter may be sufficiently severe as to interfere with nutrient (and/or drug) absorption.

Pleural, Pericardial, and Peritoneal Spaces. Systemic venous congestion can lead to fluid accumulation in the pleural, pericardial, or peritoneal spaces (**effusions**; peritoneal effusions are also called **ascites**). Large pleural effusions can impact lung inflation, causing atelectasis, and substantial ascites can also limit diaphragmatic excursion, causing dyspnea on a purely mechanical basis.

Subcutaneous Tissues. Edema of the peripheral and dependent portions of the body, especially ankle (pedal) and pretibial edema, is a hallmark of right-sided heart failure. In chronically bedridden patients presacral edema may predominate. Generalized massive edema (**anasarca**) may also occur.

The kidney and the brain are also prominently affected in right-sided heart failure. Renal congestion is more marked with right-sided than left-sided heart failure, leading to greater fluid retention and peripheral edema, and more pronounced azotemia. Venous congestion and hypoxia of the central nervous system can also produce deficits of mental function akin to those seen in left-sided heart failure with poor systemic perfusion.

Although we have discussed right and left heart failure separately, it is again worth emphasizing that in many cases of chronic cardiac decompensation, patients present in biventricular CHF with symptoms reflecting both right-sided and left-sided heart failure.

Standard therapy for CHF is mainly pharmacologic. Drugs that relieve fluid overload (e.g., diuretics), that block the renin-angiotensin-aldosterone axis (e.g., angiotensin converting enzyme inhibitors), and that lower adrenergic tone (e.g., beta-1 adrenergic blockers) are all particularly beneficial. The efficacy of the latter two classes of drugs supports the concept that neurohumoral changes in CHF (e.g., renin and norepinephrine elevations) are maladaptive contributions to heart failure.

Newer approaches to improving cardiac function include mechanical assist devices, and resynchronization of electrical impulses to maximize cardiac efficiency. Interestingly, some patients treated by mechanical assist can recover sufficient function to be weaned from the device. There is also considerable enthusiasm for novel therapies, including cell-based approaches, although several hurdles remain in their implementation.

KEY CONCEPTS

Heart Failure

- CHF occurs when the heart is unable to provide adequate perfusion to meet the metabolic requirements of peripheral tissues; inadequate cardiac output is usually accompanied by increased congestion of the venous circulation.
- Left-sided heart failure is most commonly due to ischemic heart disease, systemic hypertension, mitral or aortic valve disease, and primary diseases of the myocardium; symptoms are mainly a consequence of pulmonary congestion and edema, although systemic hypoperfusion can cause secondary renal and cerebral dysfunction.

- Right heart failure is most often due to left heart failure, and less commonly to primary pulmonary disorders; symptoms are chiefly related to peripheral edema and visceral congestion.

Congenital Heart Disease

Congenital heart disease (CHD) is a general term designating abnormalities of the heart or great vessels that are present at birth. Most congenital heart disease arises from faulty embryogenesis during gestational weeks 3 through 8, when major cardiovascular structures form and begin to function. The most severe anomalies are incompatible with intrauterine survival and significant heart malformations are common among premature infant and stillborns. On the other hand, defects that affect individual chambers or discrete regions of the heart are often compatible with embryologic maturation and eventual live birth. In this category are septation defects, unilateral obstructions, and outflow tract anomalies. Septal defects, or “holes in the heart”, include atrial septal defects (ASDs) or ventricular septal defects (VSDs). Stenotic lesion can be at the level of the cardiac valve or entire cardiac chamber, as in hypoplastic left heart syndrome. Outflow tract anomalies include inappropriate routing of the great vessels from the ventricular mass. These forms of congenital heart disease usually produce clinically important manifestations only after birth—unveiled by the transition from fetal to perinatal circulation.

Incidence. With an incidence of up to 5%, congenital cardiovascular malformations are among the most prevalent birth defects and are the most common type of pediatric heart disease. Approximately 1% of individuals have significant forms of congenital heart disease that are diagnosed in the first year of life. However, milder forms of congenital heart disease such as bicuspid semilunar valves, with an incidence itself of 1-2%, may not become evident until adulthood. Twelve disorders account for about 85% of cases; their frequencies are listed in [Table 12-2](#).

The number of individuals who survive into adulthood with congenital heart disease is increasing rapidly and is estimated at nearly 1 million individuals in the United States. Many have benefited from advances in early post-natal (and even intrauterine) surgical repair of their structural defects. In some cases, however, surgical repairs fail to restore complete normalcy; patients may have already sustained pulmonary or myocardial changes that are no longer reversible, or may suffer from arrhythmias due to surgical scarring. Other factors that impact the long-term outcome include risks associated with the use of prosthetic materials and devices (e.g., substitute valves or myocardial patches), and the cardiovascular stressors associated with childbearing that may tip a repaired heart into failure.

Cardiac Development. The diverse malformations seen in congenital heart disease are caused by errors that occur during cardiac morphogenesis ([Fig. 12-3](#)). The earliest cardiac precursors originate in lateral mesoderm and move to the midline in two migratory waves to create a crescent of cells consisting of the first and second heart fields by about day 15 of development. Both fields contain

Table 12-2 Frequencies of Congenital Cardiac Malformations*

Malformation	Incidence per Million Live Births	%
Ventricular septal defect	4482	42
Atrial septal defect	1043	10
Pulmonary stenosis	836	8
Patent ductus arteriosus	781	7

multipotent progenitor cells that can produce all of the major cell types of the heart: endocardium, myocardium, and smooth muscle cells. However, each heart field is differentially marked by the expression of distinct gene sets. Thus, the first heart field expresses the transcription factor *Hand1*, whereas the second heart field expresses the transcription factor *Hand2* and the secreted protein fibroblast growth factor-10.

Even at this very early stage of development, each heart field is destined to give rise to particular portions of the heart. Thus, the left ventricle largely derives from cells originating in the first heart field, whereas cells from the second heart field become the outflow tract, right ventricle, and most of the atria. By day 20, the initial cell crescent develops into a beating tube, which loops to the right and begins to form the basic heart chambers roughly 8 days later. At the same time, two other critical events occur: (1) neural crest-derived cells migrate into the outflow tract, where they participate in the septation of the outflow tract and the formation of the aortic arches, and (2) interstitial connective tissue that will become the future atrioventricular canal and outflow tract enlarges to produce swellings known as endocardial cushions. By day 50, further septation of the ventricles, atria, and atrioventricular valves produces a four-chambered heart.

Proper orchestration of these remarkable transformations depends on a network of transcription factors that are regulated by a number of signaling pathways, particularly the Wnt, hedgehog, vascular endothelial growth factor (VEGF), bone morphogenetic factor, TGF β , fibroblast growth factor, and Notch pathways ([Chapter 1](#)). In addition, specific micro-RNAs play critical roles in cardiac development by coordinating patterns and levels of transcription factor expression. The heart is a mechanical organ that generates pulsatile blood from its earliest stages of development. It is therefore likely that hemodynamic forces play an important role in cardiac development, just as they influence adaptations in the adult heart such as hypertrophy and dilation.

Figure 12-3 Human cardiac development, emphasizing three main sources of cells. **A**, Day 15. First heart field (FHF) cells (shown in red) form a crescent shape in the anterior embryo with second heart field (SHF) cells (shown in yellow) near the FHF. **B**, Day 21. SHF cells lie dorsal to the straight heart tube and begin to migrate (arrows) into the anterior and posterior ends of the tube to form the right ventricle, conotruncus (CT), and part of the atria (A). **C**, Day 28. Following rightward looping of the heart tube, cardiac neural crest cells (shown in blue) also migrate (arrow) into the outflow tract from the neural folds to septate the outflow tract and pattern the bilaterally symmetric aortic arch arteries. **D**, Day 50. Septation of the ventricles, atria, and atrioventricular valves (AVV) results in the appropriately configured four-chambered heart. Ao, Aorta; AS, aortic sac; DA, ductus arteriosus; LA, left atrium; LCA, left carotid artery; LSCA, left subclavian artery; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RCA, right carotid artery; RSCA, right subclavian artery; V, ventricle. (Modified with permission from Srivastava D: Making or breaking the heart: from lineage determination to morphogenesis. Cell 126:1037, 2006.)

Many of the inherited defects that affect heart development involve genes that encode transcription factors; these typically cause partial loss of function and are autosomal dominant (discussed later). Even relatively minor decrements in activity can result in significant defects. Moreover, transient environmental stresses during the first trimester of pregnancy that alter the activity of these same genes could conceivably lead to acquired defects that mimic those produced by heritable mutations.

Etiology and Pathogenesis. Sporadic genetic abnormalities are the major known causes of congenital heart disease. They can take the form of single gene mutations, small chromosomal losses, and additions or deletions of whole chromosomes (trisomies and monosomies). In the case of single gene mutations, the affected genes encode proteins belonging to several different functional classes (Table 12-3); as noted earlier, many of these involve transcription factors. Since affected patients are heterozygous for such mutations, it follows that a 50% reduction in the activity of these factors (or even less) may be sufficient to derange cardiac development.

Moreover, many of the transcription factors interact in large protein complexes, providing a rationale for why mutations in any one of several genes can produce similar defects. Thus, GATA4, TBX5, and NKX2-5, three transcription factors that are mutated in some patients with atrial and ventricular septal defects, all bind to one another and co-regulate the expression of target genes required for proper cardiac development. Of further interest, GATA4 and TBX20 are also mutated in rare forms of adult-onset cardiomyopathy (discussed later), indicating important roles not only in development but also in maintaining normal function of the postnatal heart.

Table 12-3 Selected Examples of Gene Defects Associated with Congenital Heart Disease*

Disorder	Gene(s)	Gene Product Function
Nonsyndromic		
ASD or conduction defects	<i>NKX2.5</i>	Transcription factor
ASD or VSD	<i>GATA4</i>	Transcription factor
Tetralogy of Fallot	<i>ZFPM2</i> or <i>NKX2.5</i>	Transcription factors
Syndromic[†]		
Alagille syndrome—pulmonary artery stenosis or tetralogy of Fallot	<i>JAG1</i> or <i>NOTCH2</i>	Signaling proteins or receptors
Char syndrome—PDA	<i>TFAP2B</i>	Transcription factor
CHARGE syndrome—ASD, VSD, PDA, or hypoplastic right side of the heart	<i>CHD7</i>	Helicase-binding protein
DiGeorge syndrome—ASD, VSD, or outflow tract obstruction	<i>TBX1</i>	Transcription factor
Holt-Oram syndrome—ASD, VSD, or conduction defect	<i>TBX5</i>	Transcription factor
Noonan syndrome—pulmonary valve stenosis, VSD, or hypertrophic cardiomyopathy	<i>PTPN11</i> , <i>KRAS</i> , <i>SOS1</i>	Signaling proteins

ASD, Atrial septal defect; CHARGE, posterior coloboma, heart defect, choanal atresia, retardation, genital and ear anomalies; PDA, patent ductus arteriosus; VSD, ventricular septal defect. *Different mutations can cause the same phenotype, and mutations in some genes can cause multiple phenotypes (e.g., *NKX2.5*). Many of these congenital lesions also can occur sporadically, without specific genetic mutation.

[†]Only the cardiac manifestations of the syndrome are listed; the other skeletal, facial, neurologic, and visceral changes are not.

Other single gene mutations associated with congenital heart disease can alter structural proteins or affect signaling pathway molecules. Thus, mutations in genes encoding various components of the Notch pathway (Chapter 1) are associated with a variety of congenital heart defects, including bicuspid aortic valve (*NOTCH1*, discussed later) and tetralogy of Fallot (*JAG1* and *NOTCH2*). As described in Chapter 11, fibrillin mutations underlie Marfan syndrome—associated with valvular defects and aortic aneurysms. Although fibrillin is an important structural protein in the ECM, it is also an important negative regulator of TGF- β signaling, and hyperactive TGF- β signaling contributes to the cardiovascular abnormalities in Marfan syndrome and Loeys-Dietz syndrome.

A notable example of a small chromosomal lesion causing congenital heart disease is deletion of chromosome 22q11.2, occurring in up to 50% of patients with DiGeorge syndrome. In this syndrome, the fourth branchial arch and the derivatives of the third and fourth pharyngeal pouches (which contribute to the formation of the thymus, parathyroids, and heart) develop abnormally. The syndrome is therefore associated with multiple deficits (memorable through the mnemonic CATCH-22: cardiac abnormality, abnormal facies, thymic aplasia, cleft palate, and hypocalcemia, all on chromosome 22). Of the 30 or so genes present on this chromosome segment, deletion specifically of the *TBX1* transcription factor gene is probably the culprit lesion. *TBX1* regulates neural crest migration, as well as the expansion of cardiac progenitors in the second heart field. Interestingly, deletions in this region are also associated with mental illness, including schizophrenia.

Other important genetic causes of congenital heart disease include chromosomal aneuploidies, particularly Turner syndrome (monosomy X) and trisomies 13, 18, and 21. Indeed, the most common genetic cause of congenital heart disease is trisomy 21 (Down syndrome); roughly 40% of patients with Down syndrome have one or more heart defects, most often affecting structures derived from the second heart field (e.g., the atrioventricular septae). The mechanisms by which aneuploidy causes congenital heart disease likely involve the dysregulated expression of multiple genes.

Despite these genetic advances, our understanding of the mechanisms underlying congenital heart disease remains rudimentary. Most affected patients have no identifiable genetic risk, and even in those that do, the nature and severity of the defect are highly variable. Thus, environmental factors, alone or in combination with genetic factors, are also increasingly implicated in congenital heart disease. Examples include congenital rubella infection, gestational diabetes, and teratogen exposure (including some therapeutic drugs). Nutritional factors may also influence risk. For instance, folate supplementation during early pregnancy may reduce congenital heart disease risk.

Clinical Features. Most of the various structural anomalies in congenital heart disease can be organized into three major categories:

- Malformations causing a *left-to-right shunt*
- Malformations causing a *right-to-left shunt*
- Malformations causing an *obstruction*

A *shunt* is an abnormal communication between chambers or blood vessels. Abnormal channels permit blood

flow down pressure gradients from the left (systemic) side to the right (pulmonary) side of the circulation or vice versa. When blood from the right side of the circulation flows directly into the left side (*right-to-left shunt*), hypoxemia and *cyanosis* (a dusky blueness of the skin and mucous membranes) result because the pulmonary circulation is bypassed and poorly oxygenated venous blood shunts directly into the systemic arterial supply. In addition, right-to-left shunts can allow emboli from the peripheral veins to bypass the lungs and directly enter the systemic circulation (*paradoxical embolism*). Severe, long-standing cyanosis also causes a peculiar distal blunting and enlargement (“clubbing”) of the tips of the fingers and toes (called *hypertrophic osteoarthropathy*), as well as *polycythemia*. The most important causes of right-to-left shunts are Tetralogy of Fallot, transposition of the great arteries, persistent truncus arteriosus, tricuspid atresia, and total anomalous pulmonary venous connection.

In contrast, *left-to-right shunts* (e.g., ASD, VSD, and patent ductus arteriosus [PDA]) increase pulmonary blood flow, but are not *initially* associated with cyanosis. However, left-to-right shunts chronically elevate both volume and pressure in the normally low-pressure, low-resistance pulmonary circulation. To maintain relatively normal distal pulmonary capillary and venous pressures, the muscular pulmonary arteries (<1 mm in diameter) initially respond by undergoing medial hypertrophy and vasoconstriction. However, prolonged pulmonary arterial vasoconstriction stimulates the development of irreversible obstructive intimal lesions analogous to the arteriolar changes seen in systemic hypertension; pulmonary arteries can even develop frank atherosclerotic lesions (Chapter 11). The right ventricle also responds to the pulmonary vascular changes by undergoing progressive right ventricular hypertrophy. Eventually, pulmonary vascular resistance approaches systemic levels, and the original left-to-right shunt becomes a right-to-left shunt that introduces poorly oxygenated blood into the systemic circulation (*Eisenmenger syndrome*).

Once irreversible pulmonary hypertension develops, the structural defects of congenital heart disease are considered irreparable; subsequent right heart failure can lead to the patient’s death. This provides the rationale for early intervention to close significant left-to-right shunts.

Obstructive congenital heart disease occurs when there is abnormal narrowing of chambers, valves, or blood vessels; these include coarctation of the aorta, aortic valvular stenosis, and pulmonary valvular stenosis. A complete obstruction is called an *atresia*. In some disorders (e.g., Tetralogy of Fallot [TOF]), an obstruction (pulmonary stenosis) and a shunt (right-to-left through a VSD) are both present.

The altered hemodynamics of congenital heart disease usually cause cardiac dilation or hypertrophy (or both). However, some defects induce a decrease in the volume and muscle mass of a cardiac chamber; this is called *hypoplasia* if it occurs before birth and *atrophy* if it develops postnatally.

Left-to-Right Shunts

Left-to-right shunts are the most common congenital heart disease; these include ASD, VSD, and PDA as shown in

Figure 12-4 Common congenital left-to-right shunts (arrows indicate the direction of blood flow). **A**, Atrial septal defect (ASD). **B**, Ventricular septal defect (VSD). With VSD the shunt is left-to-right, and the pressures are the same in both ventricles. Pressure hypertrophy of the right ventricle and volume hypertrophy of the left ventricle are generally present. **C**, Patent ductus arteriosus (PDA). Ao, Aorta; LA, left atrium; LV, left ventricle; PT, pulmonary trunk; RA, right atrium; RV, right ventricle.

Figure 12-4. ASD typically increases only right ventricular and pulmonary outflow volumes, while VSD and PDA cause both increased pulmonary blood flow and pressure. Depending on their size and location, manifestations of these shunts range in severity from no symptoms at all to fulminant heart failure.

Atrial Septal Defect

ASDs are abnormal, fixed openings in the atrial septum caused by incomplete tissue formation that allows communication of blood between the left and right atria; ASDs are usually asymptomatic until adulthood (Table 12-2 and Fig. 12-4A). ASD should not be confused with *patent foramen ovale* (PFO; see later), which represents the failure to close a foramen (hole) that is part of normal development. Both ASD and PFO result from defects in the formation of the interatrial septum; a brief summary of the developmental stages of this structure follows:

- The *septum primum* is a crescent-shaped membranous ingrowth that sits posteriorly between the right and left atria and partially separates them; the remaining anterior opening, called the *ostium primum*, allows movement of blood from the right to left atrium during fetal development.

- Before the growing *septum primum* completely obliterates the *ostium primum*, it develops a second posterior opening called the *ostium secundum*.
- The *septum secundum* is a subsequent membranous ingrowth located to the right and anterior of the *septum primum*.
- As the *septum secundum* grows, it also leaves a small opening called the *foramen ovale* that is continuous with the *ostium secundum*—the *foramen ovale/ostium secundum* permits continued right-to-left shunting of blood during intrauterine development.
- The *septum secundum* continues to enlarge until it forms a flap of tissue that covers the *foramen ovale* on its left side.

This flap of tissue opens and closes in response to pressure gradients between the left and right atria; the valve opens only when the pressure is greater in the right atrium. In fetal life, the lungs are nonfunctional, and the pressure in the *pulmonary circulation* is greater than that of the *systemic circulation*; thus, the right atrium is under higher pressures than the left atrium, and the valve of the *foramen ovale* is normally open. At birth, with lung expansion, the pulmonary vascular pressures drop, and the right atrial pressures fall below those in the left atrium. As a result, the valve of the *foramen ovale* closes—and usually permanently seals (see later).

MORPHOLOGY

ASDs are classified according to their location. **Secundum ASD** (90% of all ASD) result from a deficient *septum secundum* formation near the center of the atrial septum. These are usually not associated with other anomalies, may be of any size, and can be multiple or fenestrated. **Primum anomalies** (5% of ASD) occur adjacent to the AV valves and are often associated with AV valve abnormalities and/or a VSD. **Sinus venosus defects** (5%) are located near the entrance of the superior vena cava and can be associated with anomalous pulmonary venous return to the right atrium.

Clinical Features. ASDs result in a left-to-right shunt, largely because pulmonary vascular resistance is considerably less than systemic vascular resistance and because the compliance (distensibility) of the right ventricle is much greater than that of the left. Pulmonary blood flow may be two to eight times normal. A murmur is often present as a result of excessive flow through the pulmonary valve and/or through the ASD. Despite the right-sided volume overload, ASDs are generally well tolerated and usually do not become symptomatic before age 30; irreversible pulmonary hypertension is unusual. ASD closure (surgical or catheter-based) reverses the hemodynamic abnormalities and prevents the complications, including heart failure, paradoxical embolization, and irreversible pulmonary vascular disease. Mortality is low, and long-term survival is comparable to that of the normal population.

Patent Foramen Ovale. The *foramen ovale* closes permanently in approximately 80% of people by 2 years of age. However, in the remaining 20%, the unsealed flap can open if right-sided pressures become elevated. Thus, sustained pulmonary hypertension or even transient increases in

right-sided pressures, for example, during a bowel movement, coughing, or sneezing, can produce brief periods of right-to-left shunting, with the possibility of paradoxical embolism.

Ventricular Septal Defect

VSDs are incomplete closures of the ventricular septum, allowing free communication of blood between the left to right ventricles; they are the most common form of congenital heart disease (Table 12-2 and Fig. 12-4B).

MORPHOLOGY

VSDs are classified according to their size and location. Most are about the size of the aortic valve orifice, and about 90% occur in the region of the membranous interventricular septum (**membranous VSD**; Fig. 12-5). The remainder occur below the pulmonary valve (**infundibular VSD**) or within the muscular septum. Although most VSDs are single, those in the muscular septum may be multiple.

Clinical Features. Most VSDs that clinically manifest in the pediatric age group are associated with other congenital cardiac anomalies such as Tetralogy of Fallot; only 20% to 30% are isolated. Conversely, if a VSD is first detected only in an adult, it is usually an isolated defect. The functional consequences of a VSD depend on the size of the defect and whether there are associated right-sided malformations. Thus, large VSDs cause difficulties virtually from birth; smaller lesions are generally well tolerated for years and may not be recognized until much later in life. Moreover, approximately 50% of small muscular VSDs close spontaneously. Large defects are usually membranous or infundibular, and they generally cause significant left-to-right shunting, leading to early right ventricular hypertrophy and pulmonary hypertension. Over time, large unclosed VSDs almost universally lead to irreversible pulmonary vascular disease, ultimately resulting in shunt reversal, cyanosis, and death. Surgical or catheter-based closure of asymptomatic VSD is generally delayed beyond infancy, in hope of spontaneous closure. Early correction, however, must be performed for large defects to prevent

Figure 12-5 A ventricular septal defect (membranous type), denoted by the arrow. (Courtesy William D. Edwards, MD, Mayo Clinic, Rochester, Minn.)

the development of irreversible obstructive pulmonary vascular disease.

Patent Ductus Arteriosus

The *ductus arteriosus* arises from the pulmonary artery and joins the aorta just distal to the origin of the left subclavian artery. During intrauterine life, it permits blood flow from the pulmonary artery to the aorta, thereby bypassing the unoxygenated lungs. Shortly after birth in healthy term infants, the ductus constricts and is functionally closed after 1 to 2 days; this occurs in response to increased arterial oxygenation, decreased pulmonary vascular resistance, and declining local levels of prostaglandin E₂. Complete structural obliteration occurs within the first few months of extrauterine life to form the *ligamentum arteriosum*. Ductal closure is often delayed (or even absent) in infants with hypoxia (due to respiratory distress or heart disease), or when PDA occurs in association with other congenital defects, particularly VSDs that increase pulmonary vascular pressures. PDAs account for about 7% of cases of congenital heart disease (Table 12-2 and Fig. 12-4C), and 90% of these are isolated defects.

PDA produces a characteristic continuous harsh “machinery-like” murmur. The clinical impact of a PDA depends on its diameter and the cardiovascular status of the individual. PDA is usually asymptomatic at birth, and a narrow PDA may have no effect on the child’s growth and development. Because the shunt is initially left-to-right, there is no cyanosis. However, with large shunts, the additional volume and pressure overloads eventually produce obstructive changes in small pulmonary arteries, leading to reversal of flow and its associated consequences. In general, isolated PDA should be closed as early in life as is feasible. Conversely, preservation of ductal patency (by administering prostaglandin E) may be life saving for infants with various congenital malformations that obstruct the pulmonary or systemic outflow tracts. In aortic valve atresia, for example, a PDA may provide the entire systemic blood flow.

Right-to-Left Shunts

The diseases in this group cause cyanosis early in postnatal life (*cyanotic congenital heart disease*). Tetralogy of Fallot, the most common in this group, and transposition of the great arteries are illustrated schematically in Figure 12-6. The others include persistent truncus arteriosus, tricuspid atresia, and total anomalous pulmonary venous connection.

Tetralogy of Fallot

The four cardinal features of TOF are (1) VSD, (2) obstruction of the right ventricular outflow tract (subpulmonary stenosis), (3) an aorta that overrides the VSD, and (4) right ventricular hypertrophy (Fig. 12-6A). All of these features result embryologically from anterosuperior displacement of the infundibular septum.

MORPHOLOGY

The heart is typically enlarged and is classically “boot-shaped” due to marked right ventricular hypertrophy. The VSD is usually large with the aortic valve at the superior border, thereby

Figure 12-6 Common congenital right-to-left shunts (*cyanotic congenital heart disease*). **A**, Tetralogy of Fallot. The direction of shunting across the ventricular septal defect (VSD) depends on the degree of the subpulmonary stenosis; when severe, a right-to-left shunt results (*arrow*). **B**, Transposition of the great arteries with and without VSD. Ao, Aorta; LA, left atrium; LV, left ventricle; PT, pulmonary trunk; RA, right atrium; RV, right ventricle.

overriding the defect and both ventricular chambers. The obstruction to right ventricular outflow is most often due to narrowing of the infundibulum (subpulmonary stenosis) but can be accompanied by pulmonary valvular stenosis. Sometimes there is complete atresia of the pulmonary valve and variable portions of the pulmonary arteries, such that blood flow through a PDA, dilated bronchial arteries, or both, is necessary for survival. Aortic valve insufficiency or an ASD may also be present; a right aortic arch is present in about 25% of cases.

Clinical Features. Even untreated, patients with TOF can survive into adult life; 10% of untreated patients are alive at 20 years and 3% survive for 40 years. The clinical consequences depend primarily on the severity of the subpulmonary stenosis, since this determines the direction of blood flow. If the subpulmonary stenosis is mild, the abnormality resembles an isolated VSD, and the shunt may be left-to-right, without cyanosis (so-called “pink tetralogy”). With more severe right ventricular outflow obstruction, right-sided pressures approach or exceed left-sided pressures, and right-to-left shunting develops, producing cyanosis (classic TOF). Most infants with TOF are cyanotic from birth or

soon thereafter. The more severe the subpulmonary stenosis, the more hypoplastic are the pulmonary arteries (i.e., smaller and thinner-walled), and the larger is the overriding aorta. As the child grows and the heart increases in size, the pulmonic orifice does not expand proportionally, making the obstruction progressively worse. The subpulmonary stenosis, however, protects the pulmonary vasculature from pressure overload, and right ventricular failure is rare because the right ventricle is decompressed by the shunting of blood into the left ventricle and aorta. Complete surgical repair is possible but becomes complicated for individuals with pulmonary atresia and dilated bronchial arteries.

Transposition of the Great Arteries

TGA produces ventriculoarterial discordance. Thus, the aorta lies anterior and arises from the right ventricle, while the pulmonary artery is relatively posterior and emanates from the left ventricle (Fig. 12-7; see also Fig. 12-6B). The atrium-to-ventricle connections are normal (concordant), with the right atrium joining the right ventricle and the left atrium emptying into the left ventricle. The embryologic defect in complete TGA stems from abnormal formation of the truncal and aortopulmonary septa. The result is separation of the systemic and pulmonary circulations, a condition incompatible with postnatal life unless a shunt exists for adequate mixing of blood.

The outlook for infants with TGA depends on the degree of blood “mixing,” the magnitude of tissue hypoxia, and the ability of the right ventricle to maintain the systemic circulation. Patients with TGA and a VSD (approximately 35%) often have a stable shunt. However, dependence on a patent foramen ovale or ductus arteriosus for blood mixing (approximately 65%) is problematic. These systemic-to-pulmonary connections tend to close early and thus require intervention to create a new shunt within the first few days of life (e.g., balloon atrial septostomy). With

Figure 12-7 Transposition of the great arteries. (Courtesy William D. Edwards, MD, Mayo Clinic, Rochester, Minn.)

time, right ventricular hypertrophy becomes prominent, because this chamber functions as the systemic ventricle. Concurrently, the left ventricle becomes thin-walled (atrophic) as it supports the low-resistance pulmonary circulation. Without surgery, most patients die within months. However, improving surgical interventions allow many patients with TGA to survive into adulthood.

Tricuspid Atresia

Tricuspid atresia represents complete occlusion of the tricuspid valve orifice. It results embryologically from unequal division of the AV canal; thus, the mitral valve is larger than normal, and there is right ventricular underdevelopment (hypoplasia). The circulation can be maintained by right-to-left shunting through an interatrial communication (ASD or patent foramen ovale), in addition to a VSD that affords communication between the left ventricle and the pulmonary artery arising from the hypoplastic right ventricle. Cyanosis is present virtually from birth, and there is a high early mortality.

Obstructive Lesions

Congenital obstruction to blood flow can occur at the level of the heart valves or within a great vessel. Common examples include aortic or pulmonary valve stenosis or atresia, and coarctation of the aorta. Obstruction can also occur within a chamber, as with subpulmonary stenosis in TOF.

Coarctation of the Aorta

Coarctation (narrowing, constriction) of the aorta ranks high in frequency among the common structural anomalies. It is twice as common in males as in females; interestingly, females with Turner syndrome are also frequently affected (Chapter 5). There are two classic forms: (1) an “infantile” form—often symptomatic in early childhood—with tubular hypoplasia of the aortic arch proximal to a PDA, and (2) an “adult” form with a discrete ridgelike infolding of the aorta just opposite the closed ductus arteriosus (*ligamentum arteriosum*) distal to the arch vessels (Fig. 12-8). Encroachment on the aortic lumen is variable, sometimes leaving only a small channel and at other times

producing only minimal narrowing. Although coarctation of the aorta may occur as a solitary defect, in 50% of cases it is accompanied by a bicuspid aortic valve and may also be associated with congenital aortic stenosis, ASD, VSD, mitral regurgitation, or berry aneurysms of the circle of Willis.

Clinical manifestations depend on the severity of the narrowing and the patency of the ductus arteriosus. *Coarctation of the aorta with a PDA* usually manifests early in life; indeed, it may cause signs and symptoms immediately after birth. In such cases, the delivery of unsaturated blood through the PDA produces cyanosis localized to the lower half of the body. Many such infants do not survive the neonatal period without surgical or catheter-based intervention to occlude the PDA.

The outlook is different with *coarctation of the aorta without a PDA*, unless the aortic constriction is severe. Most children are asymptomatic, and the disease may go unrecognized until well into adult life. Typically there is hypertension in the upper extremities with weak pulses and hypotension in the lower extremities, associated with manifestations of arterial insufficiency (i.e., claudication and coldness). Particularly characteristic is the development of collateral circulation between the pre-coarctation and post-coarctation arteries through enlarged intercostal and internal mammary arteries, often producing radiographically visible erosions (“notching”) of the undersurfaces of the ribs.

With significant coarctations, murmurs are present throughout systole; sometimes a vibratory “thrill” is also present. The long-standing pressure overload leads to concentric left ventricular hypertrophy. With uncomplicated coarctation of the aorta, surgical resection and end-to-end anastomosis or replacement of the affected aortic segment by a prosthetic graft yields excellent results.

Pulmonary Stenosis and Atresia

Pulmonary stenosis or atresia is a relatively frequent malformation leading to obstruction at the level of the pulmonary valve. This can be mild to severe; the lesion can also be isolated or part of a more complex anomaly—either TOF or TGA. Right ventricular hypertrophy typically develops, and there is sometimes poststenotic dilation of the pulmonary artery due to injury of the wall by “jetting” blood. With coexistent subpulmonary stenosis (as in TOF), the pulmonary trunk is not dilated and may in fact be hypoplastic. When the valve is entirely atretic, there is no communication between the right ventricle and lungs. In such cases the anomaly is associated with a hypoplastic right ventricle and an ASD; blood reaches the lungs through a PDA. Mild stenosis may be asymptomatic and compatible with long life, whereas symptomatic cases require surgical correction.

Aortic Stenosis and Atresia

Congenital narrowing and obstruction of the aortic valve can occur at three locations: valvular, subvalvular, and supravalvular. Congenital aortic stenosis is an isolated lesion in 80% of cases. With *valvular aortic stenosis* the cusps may be hypoplastic (small), dysplastic (thickened, nodular), or abnormal in number (usually acommisural or unicommissural). In severe congenital aortic stenosis or atresia, obstruction of the left ventricular outflow tract leads to

Figure 12-8 Schematic of aortic coarctation with and without patent ductus arteriosus (PDA). Ao, Aorta; LA, left atrium; LV, left ventricle; PT, pulmonary trunk; RA, right atrium; RV, right ventricle; PDA, patent ductus arteriosus. (Courtesy William D. Edwards, MD, Mayo Clinic, Rochester, Minn.)

hypoplasia of the left ventricle and ascending aorta, sometimes accompanied by dense, porcelain-like left ventricular endocardial fibroelastosis. The ductus must be open to allow blood flow to the aorta and coronary arteries, and the constellation of findings is called the *hypoplastic left heart syndrome*. Unless a palliative procedure is done to preserve PDA patency, duct closure in the first week of life is generally lethal. However, less severe congenital aortic stenosis can be compatible with long survival.

Subaortic stenosis is caused by a thickened ring or collar of dense endocardial fibrous tissue below the level of the cusps. *Supraaortic stenosis* is a congenital aortic dysplasia with thickening of ascending aortic wall and consequent luminal constriction. In some cases it is a component of a multiorgan developmental disorder resulting from deletions on chromosome 7 that include the gene for elastin. Other features of the syndrome include hypercalcemia, cognitive abnormalities, and characteristic facial anomalies (*Williams-Beuren syndrome*). Elastin gene mutations may cause supraaortic stenosis by disrupting elastin-smooth muscle cell interactions during aortic morphogenesis.

Subaortic stenosis is usually associated with a prominent systolic murmur and sometimes a thrill. Pressure hypertrophy of the left ventricle develops as a consequence of the obstruction to blood flow, but congenital stenoses are well tolerated unless very severe. Although mild stenoses can often be managed conservatively with antibiotic prophylaxis (to prevent endocarditis) and avoidance of strenuous activity, the resulting left ventricular hypertrophy still carries a risk of sudden death with exertion.

KEY CONCEPTS

Congenital Heart Disease

- Congenital heart disease represents defects of cardiac chambers or the great vessels; these either result in shunting of blood between the right and left circulation or cause outflow obstructions. Lesions range from relatively asymptomatic to rapidly fatal. Environmental (toxic or infectious) and genetic causes both contribute, and the manifestations depend on the timing of the environmental insult or which step in cardiac development is affected.
- Left-to-right shunts are most common and are typically associated with ASDs, VSDs, or a PDA. These lesions result in chronic right-sided pressure and volume overloads that eventually cause pulmonary hypertension with reversal of flow and right-to-left shunts with cyanosis (*Eisenmenger syndrome*).
- Right-to-left shunts are most commonly caused by TOF or TGA. These are cyanotic lesions from the outset and are associated with polycythemia, hypertrophic osteoarthropathy, and paradoxical emboli.
- Obstructive lesions include aortic coarctation; the clinical severity of the lesion depends on the degree of stenosis and the patency of the ductus arteriosus.

Ischemic Heart Disease

Ischemic heart disease (IHD) represents a group of pathophysiologically related syndromes resulting from

***myocardial ischemia*—an imbalance between myocardial supply (perfusion) and cardiac demand for oxygenated blood.** Ischemia not only limits tissue oxygenation (and thus ATP generation), but also reduces the availability of nutrients and the removal of metabolic wastes (Chapter 2). Thus, cardiac ischemia is generally less well tolerated than hypoxia *per se*, such as may occur with severe anemia, cyanotic heart disease, or advanced lung disease.

In more than 90% of cases, myocardial ischemia results from reduced blood flow due to obstructive atherosclerotic lesions in the epicardial coronary arteries; consequently, IHD is frequently referred to as coronary artery disease (CAD). In most cases there is a long period (up to decades) of silent, slow progression of coronary lesions before the sudden onset of symptoms. Thus, IHD is often the late manifestation of coronary atherosclerosis that began during childhood or adolescence (Chapter 11).

IHD can present as one or more of the following clinical syndromes:

- *Myocardial infarction (MI)*, where ischemia causes frank cardiac necrosis
- *Angina pectoris* (literally “chest pain”), where ischemia is not severe enough to cause infarction, but the symptoms nevertheless portend infarction risk
- *Chronic IHD with heart failure*
- *Sudden cardiac death (SCD)*.

In addition to coronary atherosclerosis, myocardial ischemia can be caused by coronary emboli, myocardial vessel inflammation, or vascular spasm. Moreover, otherwise modest vascular occlusions may become consequential in the setting of increased cardiac energy demand (e.g., myocardial hypertrophy or increased heart rate), hypoxemia, or systemic hypotension (e.g., shock). Some conditions can have multiple deleterious effects. Thus, tachycardia increases oxygen demand (because of more contractions per unit time) while decreasing functional supply (by decreasing the relative time spent in diastole, when cardiac perfusion occurs).

Epidemiology. IHD is the leading cause of death in the United States (one of every six deaths in 2008; more than 400,000 individuals) and other developed nations (approximately 7 million total per year). As high as these numbers are, they represent a substantial improvement relative to just one to two generations ago. Since peaking in 1963, the overall death rate from IHD has fallen in the United States by approximately 50%. This remarkable improvement can be attributed to:

- *Prevention*, achieved by modifying important risk factors, such as smoking, blood cholesterol, and hypertension. Additional risk reduction and prevention may potentially be achieved by maintenance of normal blood glucose levels in diabetic patients, control of obesity, and exercise.
- *Diagnostic and therapeutic advances*, allowing earlier and more effective treatments. The latter include new medications, including the use of cholesterol lowering drugs such as statins, coronary care units, thrombolysis for MI, percutaneous transluminal coronary angioplasty, endovascular stents, coronary artery bypass graft (CABG) surgery, and improved control of heart

failure and arrhythmias via left ventricular assist devices, implantable defibrillators, and cardiac resynchronization with pacemakers. Even a simple daily prophylactic aspirin can have therapeutic benefit.

Continuing this encouraging trend will be challenging, particularly in view of the increased longevity of “baby boomers” (which will lead to a doubling of individuals older than age 65 by 2050), the “obesity epidemic,” and other factors. Increasingly, new therapeutic advances will depend on understanding the genetic determinants of coronary atherosclerosis and IHD. For example, the observation that MIs occur in only a fraction of individuals with coronary disease suggests that simple control of atherosclerotic risk factors is only part of the story. For example, MI risk—but not coronary atherosclerosis—is associated with genetic variants that modify leukotriene B4 metabolism.

Pathogenesis. The dominant cause of IHD syndromes is insufficient coronary perfusion relative to myocardial demand; in the vast majority of cases, this is due to chronic, progressive atherosclerotic narrowing of the epicardial coronary arteries, and variable degrees of superimposed acute plaque change, thrombosis, and vasospasm. The individual elements and their interactions are discussed next.

Chronic Vascular Occlusion. More than 90% of patients with IHD have atherosclerosis involving one or more of the epicardial coronary arteries (Chapter 11). The clinical manifestations of coronary atherosclerosis are generally due to progressive narrowing of the lumen leading to stenosis (“fixed” obstructions), or to acute plaque erosion or rupture with thrombosis, all of which compromise blood flow. A fixed lesion obstructing greater than 75% of vascular cross-sectional area defines significant coronary artery disease; this is generally the threshold for symptomatic ischemia precipitated by exercise (typically manifesting as angina). With this degree of obstruction, compensatory coronary arterial vasodilation is no longer sufficient to meet even moderate increases in myocardial demand. Obstruction of 90% of the cross-sectional area of the lumen can lead to inadequate coronary blood flow even at rest. Progressive myocardial ischemia induced by slowly developing occlusions may stimulate the formation of collateral vessels over time, which can often protect against myocardial ischemia and infarction and mitigate the effects of high-grade stenoses.

Although only a single major coronary epicardial vessel may be affected, two or all three—the LAD, LCX, and RCA—are often involved by obstructive atherosclerosis. Clinically significant plaques can be located anywhere along the course of the vessels, particularly the RCA, although they tend to predominate within the first several centimeters of the LAD and LCX. Sometimes the major epicardial branches are also involved (i.e., LAD diagonal branches, LCX obtuse marginal branches, or posterior descending branch of the RCA), but atherosclerosis of the intramural (penetrating) branches is rare.

Acute Plaque Change. The risk of an individual developing clinically important IHD depends in part on the number, distribution, structure, and degree of obstruction

of atheromatous plaques. However, the varied clinical manifestations of IHD cannot be explained by the anatomic disease burden alone. This is particularly true for the so-called acute coronary syndromes, namely unstable angina, acute MI, and sudden death. These acute coronary syndromes are typically initiated by an unpredictable and abrupt conversion of a stable atherosclerotic plaque to an unstable and potentially life-threatening atherothrombotic lesion through rupture, superficial erosion, ulceration, fissuring, or deep hemorrhage (Chapter 11). In most instances, plaque changes—typically associated with intralumenal inflammation—precipitate the formation of a superimposed thrombus that partially or completely occludes the artery.

Consequences of Myocardial Ischemia. The common feature of the acute coronary syndromes is downstream myocardial ischemia.

- *Stable angina* results from increases in myocardial oxygen demand that outstrip the ability of stenosed coronary arteries to increase oxygen delivery; it is usually not associated with plaque disruption.
- *Unstable angina* is caused by plaque disruption that results in thrombosis and vasoconstriction, and leads to severe but transient reductions in coronary blood flow. In some cases, microinfarcts can occur distal to disrupted plaques due to thromboemboli.
- *Myocardial infarction (MI)* is often the result of acute plaque change that induces an abrupt thrombotic occlusion, resulting in myocardial necrosis.
- *Sudden cardiac death* may be caused by regional myocardial ischemia that induces a fatal ventricular arrhythmia.

Each of these important syndromes is discussed in detail next, followed by an examination of the important myocardial consequences.

Angina Pectoris

Angina pectoris is characterized by paroxysmal and usually recurrent attacks of substernal or precordial chest discomfort caused by transient (15 seconds to 15 minutes) myocardial ischemia that is insufficient to induce myocyte necrosis. The pain itself is likely a consequence of the ischemia-induced release of adenosine, bradykinin, and other molecules that stimulate sympathetic and vagal afferent nerves. There are three overlapping patterns of angina pectoris caused by varying combinations of decreased perfusion, increased demand, and coronary arterial pathology. Importantly, not all ischemic events are perceived by patients; silent ischemia is particularly common in the geriatric population and in the setting of diabetic neuropathy.

- *Stable (typical) angina* is the most common form of angina; it is caused by an imbalance in coronary perfusion (due to chronic stenosing coronary atherosclerosis) relative to myocardial demand, such as that produced by physical activity, emotional excitement or psychological stress. Typical angina pectoris is variously described as a deep, poorly localized pressure, squeezing, or burning sensation (like indigestion), but unusually as pain, and is

usually relieved by rest (decreasing demand) or administering vasodilators, such as nitroglycerin and calcium channel blockers (increasing perfusion).

- *Prinzmetal variant angina is an uncommon form of episodic myocardial ischemia; it is caused by coronary artery spasm.* Although individuals with Prinzmetal variant angina may well have significant coronary atherosclerosis, the anginal attacks are unrelated to physical activity, heart rate, or blood pressure. Prinzmetal angina generally responds promptly to vasodilators.
- *Unstable or crescendo angina refers to a pattern of increasingly frequent, prolonged (>20 min), or severe angina or chest discomfort that is described as frank pain, precipitated by progressively lower levels of physical activity or even occurring at rest.* In most patients, unstable angina is caused by the disruption of an atherosclerotic plaque with superimposed partial thrombosis and possibly embolization or vasospasm (or both). Approximately one-half of patients with unstable angina have evidence of myocardial necrosis; for others, acute MI may be imminent.

Myocardial Infarction

Myocardial infarction, also commonly referred to as “heart attack,” is the death of cardiac muscle due to prolonged severe ischemia. Roughly 1.5 million individuals in the United States suffer an MI annually.

Incidence and Risk Factors. MI can occur at virtually any age; nearly 10% of myocardial infarcts occur in people younger than age 40, and 45% occur in people younger than age 65. Nevertheless, MI frequency rises progressively with increasing age. The incidence of MI also strongly correlates with genetic and behavioral predispositions to atherosclerosis. Blacks and whites are equally affected. Through middle age, male gender increases the relative risk of MI; indeed, women are generally protected against MI during their reproductive years. However, postmenopausal decline in estrogen production is usually associated with accelerated CAD, and IHD is the most common cause of death in older women. Unfortunately, postmenopausal hormonal replacement therapy has not been shown to be protective, and in fact, in some cases, may be detrimental.

Pathogenesis

Coronary Arterial Occlusion. The following sequence of events likely underlies most MIs (see [Chapter 11](#) for additional details):

- A coronary artery atheromatous plaque undergoes an acute change consisting of intraplaque hemorrhage, erosion or ulceration, or rupture or fissuring.
- When exposed to subendothelial collagen and necrotic plaque contents, platelets adhere, become activated, release their granule contents, and aggregate to form microthrombi.
- Vasospasm is stimulated by mediators released from platelets.
- Tissue factor activates the coagulation pathway, adding to the bulk of the thrombus.
- Within minutes, the thrombus can expand to completely occlude the vessel lumen.

Compelling evidence for this sequence derives from (1) autopsy studies of patients dying of acute MI; (2) angiographic studies demonstrating a high frequency of thrombotic occlusion early after MI; (3) the high success rate of coronary revascularization following MI (i.e., thrombolysis, angioplasty, stent placement, and surgery); and (4) the demonstration of residual disrupted atherosclerotic lesions by angiography after thrombolysis. Coronary angiography performed within 4 hours of MI onset shows coronary thrombosis in almost 90% of cases. However, angiography after 12 to 24 hours reveals thrombosis only about 60% of the time, suggesting resolution due to fibrinolysis, relaxation of spasm, or both.

In approximately 10% of cases, transmural MI occurs in the absence of the typical coronary atherothrombosis. In such situations, other mechanisms may be responsible for the reduced coronary blood flow, including:

- *Vasospasm* with or without coronary atherosclerosis, perhaps in association with platelet aggregation or due to drug ingestion (e.g., cocaine or ephedrine)
- *Emboli* from the left atrium in association with atrial fibrillation, a left-sided mural thrombus, vegetations of infective endocarditis, intracardiac prosthetic material; or *paradoxical emboli* from the right side of the heart or the peripheral veins, traversing a patent foramen ovale and into the coronary arteries
- *Ischemia without detectable or significant coronary atherosclerosis and thrombosis* may be caused by disorders of small intramural coronary vessels (e.g., vasculitis), hematologic abnormalities (e.g., sickle cell disease), amyloid deposition in vascular walls, vascular dissection, marked hypertrophy (e.g., aortic stenosis), lowered systemic blood pressure (e.g., shock), or inadequate myocardial “protection” during cardiac surgery.

Myocardial Response. Coronary arterial obstruction diminishes blood flow to a region of myocardium ([Fig. 12-9](#)), causing ischemia, rapid myocardial dysfunction, and eventually—with prolonged vascular compromise—myocyte death. The anatomic region supplied by that artery is referred to as the *area at risk*. The outcome depends predominantly on the severity and duration of flow deprivation ([Fig. 12-10](#)).

The early biochemical consequence of myocardial ischemia is the cessation of aerobic metabolism within seconds, leading to inadequate production of high-energy phosphates (e.g., creatine phosphate and adenosine triphosphate) and accumulation of potentially noxious metabolites (e.g., lactic acid) ([Fig. 12-10A](#)). Because of the exquisite dependence of myocardial function on oxygen and nutrients, myocardial contractility ceases within a minute or so of the onset of severe ischemia. Such loss of function actually precipitates heart failure long before myocyte death occurs.

As detailed in [Chapter 2](#), ultrastructural changes (including myofibrillar relaxation, glycogen depletion, cell and mitochondrial swelling) also develop within a few minutes of the onset of ischemia. Nevertheless, these early manifestations of ischemic injury are potentially reversible. Indeed, experimental and clinical evidence shows that only severe ischemia (blood flow 10% or less of normal) lasting 20 to 30 minutes or longer leads to irreversible damage (necrosis) of cardiac myocytes. This delay in the onset of

Figure 12-9 Postmortem angiogram showing the posterior aspect of the heart of a patient who died during the evolution of acute myocardial infarction, demonstrating total occlusion of the distal right coronary artery by an acute thrombus (*arrow*) and a large zone of myocardial hypoperfusion involving the posterior left and right ventricles, as indicated by *arrowheads*, and having almost absent filling of capillaries. The heart has been fixed by coronary arterial perfusion with glutaraldehyde and cleared with methyl salicylate, followed by intracoronary injection of silicone polymer (yellow). Philadelphia, WB Saunders, 1989, p. 60.)

permanent myocardial injury provides the rationale for rapid diagnosis in acute MI—to permit early coronary intervention to establish reperfusion and salvage as much “at risk” myocardium as possible.

The earliest detectable feature of myocyte necrosis is the disruption of the integrity of the sarcolemmal membrane, allowing intracellular macromolecules to leak out of necrotic cells into the cardiac interstitium and ultimately into the microvasculature and lymphatics. This escape of

Table 12-4 Approximate Time of Onset of Key Events in Ischemic Cardiac Myocytes

Feature	Time
Onset of ATP depletion	Seconds
Loss of contractility	<2 min
ATP reduced to 50% of normal	10 min
ATP reduced to 10% of normal	40 min
Irreversible cell injury	20-40 min
Microvascular injury	>1 hr

ATP, Adenosine triphosphate.

intracellular myocardial proteins into the circulation forms the basis for blood tests that can sensitively detect irreversible myocyte damage, and are important for managing MI (see later). With prolonged severe ischemia, injury to the microvasculature follows injury to the cardiac myocytes. The temporal progression of these events is summarized in [Table 12-4](#).

The progression of ischemic necrosis in the myocardium is summarized in [Figure 12-11](#). Due to the myocardial perfusion pattern from epicardium to endocardium, ischemia is most pronounced in the subendocardium; thus, irreversible injury of ischemic myocytes occurs first in the subendocardial zone. With more extended ischemia, a *wavefront* of cell death moves through the myocardium to encompass progressively more of the transmural thickness and breadth of the ischemic zone. The precise location, size, and specific morphologic features of an acute MI depend on:

- The location, severity, and rate of development of coronary obstructions due to atherosclerosis and thromboses
- The size of the vascular bed perfused by the obstructed vessels
- The duration of the occlusion
- The metabolic and oxygen needs of the myocardium at risk

Figure 12-10 Temporal sequence of early biochemical findings and progression of necrosis after onset of severe myocardial ischemia. **A**, Early changes include loss of adenosine triphosphate (ATP) and accumulation of lactate. **B**, For approximately 30 minutes after the onset of even the most severe ischemia, myocardial injury is potentially reversible. Thereafter, progressive loss of viability occurs that is complete by 6 to 12 hours. The benefits of reperfusion are greatest when it is achieved early, and are progressively lost when reperfusion is delayed. (Modified with permission from Antman E: *Acute myocardial infarction*. In Braunwald E, et al [eds]: *Heart Disease: A Textbook of Cardiovascular Medicine*, 6th ed. Philadelphia, WB Saunders, 2001, pp 1114-1231.)

Figure 12-11 Progression of myocardial necrosis after coronary artery occlusion. Necrosis begins in a small zone of the myocardium beneath the endocardial surface in the center of the ischemic zone. The area that depends on the occluded vessel for perfusion is the “at risk” myocardium (*shaded*). Note that a very narrow zone of myocardium immediately beneath the endocardium is spared from necrosis because it can be oxygenated by diffusion from the ventricle.

- The extent of collateral blood vessels
- The presence, site, and severity of coronary arterial spasm
- Other factors, such as heart rate, cardiac rhythm, and blood oxygenation

Necrosis involves approximately half of the thickness of the myocardium in 2 to 3 hours of the onset of severe myocardial ischemia, and is usually transmural within 6 hours. However, in instances where chronic sublethal ischemia has induced a more well-developed coronary collateral circulation, the progression of necrosis may follow a more protracted course (12 hours or longer).

Knowledge of the areas of myocardium perfused by the major coronary arteries allows correlation of specific vascular obstructions with their corresponding areas of myocardial infarction. Typically, the LAD branch of the left coronary artery supplies most of the apex of the heart, the anterior wall of the left ventricle, and the anterior two thirds of the ventricular septum. By convention, the coronary artery—either RCA or LCX—that perfuses the posterior third of the septum is called

“dominant” (even though the LAD and LCX collectively perfuse the majority of the left ventricular myocardium). In a *right dominant circulation* (present in approximately 80% of individuals), the RCA supplies the entire right ventricular free wall, the posterobasal wall of the left ventricle, and the posterior third of the ventricular septum, while the LCX generally perfuses only the lateral wall of the left ventricle. Thus, RCA occlusions can potentially lead to left ventricular damage. Although most hearts have numerous intercoronary anastomoses (collateral circulation), relatively little blood normally courses through these. However, when a coronary artery is progressively narrowed over time, blood flows via the collaterals from the high- to the low-pressure circulating causing the channels to enlarge. Through such progressive dilation and growth of collaterals, stimulated by ischemia, blood flow is provided to areas of myocardium that would otherwise be deprived of adequate perfusion. Indeed, in the setting of extensive collateralization, the normal epicardial perfusion territories may be so expanded that subsequent occlusion leads to infarction in paradoxical distributions.

Figure 12-12 Distribution of myocardial ischemic necrosis correlates with the location and nature of decreased perfusion. *Left*, The positions of transmural acute infarcts resulting from occlusions of the major coronary arteries; *top to bottom*, left anterior descending, left circumflex, and right coronary arteries. *Right*, The types of infarcts that result from a partial or transient occlusion, global hypotension, or intramural small vessel occlusions.

Patterns of Infarction. The distribution of myocardial necrosis correlates with the location and cause of the decreased perfusion (Fig. 12-12).

- **Transmural infarction.** Myocardial infarcts caused by occlusion of an epicardial vessel (in the absence of any therapeutic intervention) are typically transmural—the necrosis involves virtually the full thickness of the ventricular wall in the distribution of the affected coronary. This pattern of infarction is usually associated with a combination of chronic coronary atherosclerosis, acute plaque change, and superimposed thrombosis (discussed earlier).
- **Subendocardial (nontransmural) infarction.** As the subendocardial zone is normally the least perfused region of myocardium, this area is most vulnerable to any reduction in coronary flow. A subendocardial infarct—typically involving roughly the inner third of the ventricular wall—can occur as a result of a plaque disruption followed by a coronary thrombus that becomes lysed (therapeutically or spontaneously) before myocardial necrosis extends across the full thickness of the wall. Subendocardial infarcts can also result from prolonged, severe reduction in systemic blood pressure, as in shock superimposed on chronic, otherwise noncritical, coronary stenoses. In the subendocardial infarcts that occur as a result of global hypotension, myocardial damage is usually circumferential, rather than being limited to the distribution of a single major coronary artery.
- **Multifocal microinfarction.** This pattern is seen when there is pathology involving only smaller intramural vessels. This may occur in the setting of microembolization, vasculitis, or vascular spasm, for example, due to

endogenous catechols (epinephrine) or drugs (cocaine or ephedrine). Elevated levels of catechols also increase heart rate and myocardial contractility, exacerbating ischemia caused by the vasospasm. The outcome of such vasospasm can be sudden cardiac death (usually caused by a fatal arrhythmia) or an ischemic dilated cardiomyopathy, so-called *takotsubo cardiomyopathy* (also called “broken heart syndrome” because of the association with emotional duress).

Owing to the characteristic electrocardiographic changes resulting from myocardial ischemia or necrosis in various distributions, a transmural infarct is sometimes referred to as an “ST elevation myocardial infarct” (STEMI) and a subendocardial infarct as a “non-ST elevation infarct” (NSTEMI). Depending on the extent and location of the vascular involvement, microinfarctions show nonspecific changes or can even be electrocardiographically silent.

MORPHOLOGY

The temporal evolution of the morphologic changes in acute MI and subsequent healing are summarized in Table 12-5.

Nearly all transmural infarcts involve at least a portion of the left ventricle (comprising the free wall and ventricular septum) and encompass nearly the entire perfusion zone of the occluded coronary artery save for a narrow rim (approximately 0.1 mm) of preserved subendocardial myocardium that is preserved by diffusion of oxygen and nutrients from the ventricular lumen.

Of MIs caused by a right coronary obstruction, 15% to 30% extend from the posterior free wall of the septal portion of the left ventricle into the adjacent right ventricular wall. Isolated

Table 12-5 Evolution of Morphologic Changes in Myocardial Infarction

Time	Gross Features	Light Microscope	Electron Microscope
Reversible Injury			
0-½ hr	None	None	Relaxation of myofibrils; glycogen loss; mitochondrial swelling
Irreversible Injury			
½-4 hr	None	Usually none; variable waviness of fibers at border	Sarcolemmal disruption; mitochondrial amorphous densities
4-12 hr	Dark mottling (occasional)	Early coagulation necrosis; edema; hemorrhage	
12-24 hr	Dark mottling	Ongoing coagulation necrosis; pyknosis of nuclei; myocyte hypereosinophilia; marginal contraction band necrosis; early neutrophilic infiltrate	
1-3 days	Mottling with yellow-tan infarct center	Coagulation necrosis, with loss of nuclei and striations; brisk interstitial infiltrate of neutrophils	
3-7 days	Hyperemic border; central yellow-tan softening	Beginning disintegration of dead myofibers, with dying neutrophils; early phagocytosis of dead cells by macrophages at infarct border	
7-10 days	Maximally yellow-tan and soft, with depressed red-tan margins	Well-developed phagocytosis of dead cells; granulation tissue at margins	
10-14 days	Red-gray depressed infarct borders	Well-established granulation tissue with new blood vessels and collagen deposition	
2-8 wk	Gray-white scar, progressive from border toward core of infarct	Increased collagen deposition, with decreased cellularity	
>2 mo	Scarring complete	Dense collagenous scar	

infarction of the right ventricle is unusual (only 1% to 3% of cases), as is infarction of the atria.

The frequencies of involvement of each of the three main arterial trunks and the corresponding sites of myocardial lesions resulting in infarction (in the typical right dominant heart) are as follows (Fig. 12-12A):

- Left anterior descending coronary artery (40% to 50%): infarcts involving the anterior wall of left ventricle near the apex; the anterior portion of ventricular septum; and the apex circumferentially
- Right coronary artery (30% to 40%): infarcts involving the inferior/posterior wall of left ventricle; posterior portion of ventricular septum; and the inferior/posterior right ventricular free wall in some cases
- Left circumflex coronary artery (15% to 20%): infarcts involving the lateral wall of left ventricle except at the apex

Other locations of critical coronary arterial lesions causing infarcts are sometimes encountered, such as the left main coronary artery, the secondary (diagonal) branches of the left anterior descending coronary artery, or the marginal branches of the left circumflex coronary artery.

The gross and microscopic appearance of an infarct depends on the duration of survival of the patient following the MI. Areas of damage undergo a progressive sequence of morphologic changes involving typical ischemic coagulative necrosis (the predominant mechanism of cell death in MI, although apoptosis may also occur), followed by inflammation and repair that closely parallels responses to injury in other tissues.

Early morphologic recognition of acute MI can be difficult, particularly when death occurs within a few hours of the onset of symptoms. MIs less than 12 hours old are usually not apparent on gross examination. However, if the infarct preceded death by 2 to 3 hours, it is possible to highlight the area of

necrosis by immersion of tissue slices in a solution of **triphenyltetrazolium chloride**. This gross histochemical stain imparts a brick-red color to intact, noninfarcted myocardium where lactate dehydrogenase activity is preserved. Because dehydrogenases leak out through the damaged membranes of dead cells, an infarct appears as an unstained pale zone (Fig. 12-13). By 12 to 24 hours after infarction, an MI can usually be identified grossly as a reddish-blue area of discoloration caused by stagnated, trapped blood. Thereafter, the infarct becomes

Figure 12-13 Acute myocardial infarct, predominantly of the posterolateral left ventricle, demonstrated histochemically by a lack of staining by triphenyltetrazolium chloride in areas of necrosis (*arrow*). The staining defect is due to the lactate dehydrogenase leakage that follows cell death. Note the myocardial hemorrhage at one edge of the infarct that was associated with cardiac rupture, and the anterior scar (*arrowhead*), indicative of old infarct. Specimen is oriented with the posterior wall at the top.

progressively more sharply defined, yellow-tan, and soft. By 10 days to 2 weeks, it is rimmed by a hyperemic zone of highly vascularized granulation tissue. Over the succeeding weeks, the injured region evolves to a fibrous scar.

The histopathologic changes also proceed in a fairly predictable sequence (Fig. 12-14). The typical changes of coagulative necrosis become detectable in the first 6 to 12 hours. “Wavy fibers” may be present at the periphery of the infarct; these changes probably result from the forceful systolic tugs of the viable fibers on immediately adjacent, noncontractile dead fibers, causing stretching and folding. An additional sublethal ischemic change may be seen in the margins of infarcts: so-called myocyte vacuolization or **myocytolysis**, which reflects intracellular accumulations of salt and water within the sarcoplasmic reticulum. The necrotic muscle elicits acute inflammation (most prominent between 1 and 3 days). Thereafter, macrophages remove the necrotic myocytes (most noticeable by 3 to 7 days), and the damaged zone is progressively replaced by the ingrowth of highly vascularized granulation tissue (most prominent at 1 to 2 weeks); as healing progresses, this is replaced by fibrous tissue. In most instances, scarring is well advanced by the end of the sixth week, but the efficiency of repair depends on the size of the original lesion, as well as the relative metabolic and inflammatory state of the host.

Since healing requires the participation of inflammatory cells, immune suppression (e.g., due to steroids) can impair the vigor of the healing response. Moreover, delivering inflammatory cells to the site of necrosis requires intact vasculature; since blood vessels often survive only at the edges of an infarct, MIs typically

heal from the margins toward the center. Consequently, a large infarct may not heal as quickly or as completely as a small one. A healing infarct can also appear nonuniform, with the most advanced healing at the periphery. Once a lesion is completely healed, it is impossible to determine its age (i.e., the dense fibrous scar of 8-week-old and 10-year-old infarcts looks virtually identical).

The following discussion considers the changes that result from interventions that can limit infarct size by salvaging myocardium that is not yet necrotic.

Infarct Modification by Reperfusion. Reperfusion is the restoration of blood flow to ischemic myocardium threatened by infarction; the goal is to salvage cardiac muscle at risk and limit infarct size. The cardiology adage that “time is myocardium” succinctly captures the impetus to intervene promptly once ongoing infarction is diagnosed; patient outcome materially worsens with progressively larger infarcts. Not only does reperfusion improve short- and long-term survival, but it also impacts short- and long-term myocardial function. Thus, prompt reperfusion is the preeminent objective for treatment of patients with MI. This can be accomplished by a host of coronary interventions, that is, thrombolysis, angioplasty, stent placement, or coronary artery bypass graft [CABG] surgery. The goal is to dissolve, mechanically alter, or bypass the lesion that precipitated the acute infarction. The benefits of reperfusion correlate with (1) the rapidity of reestablishing

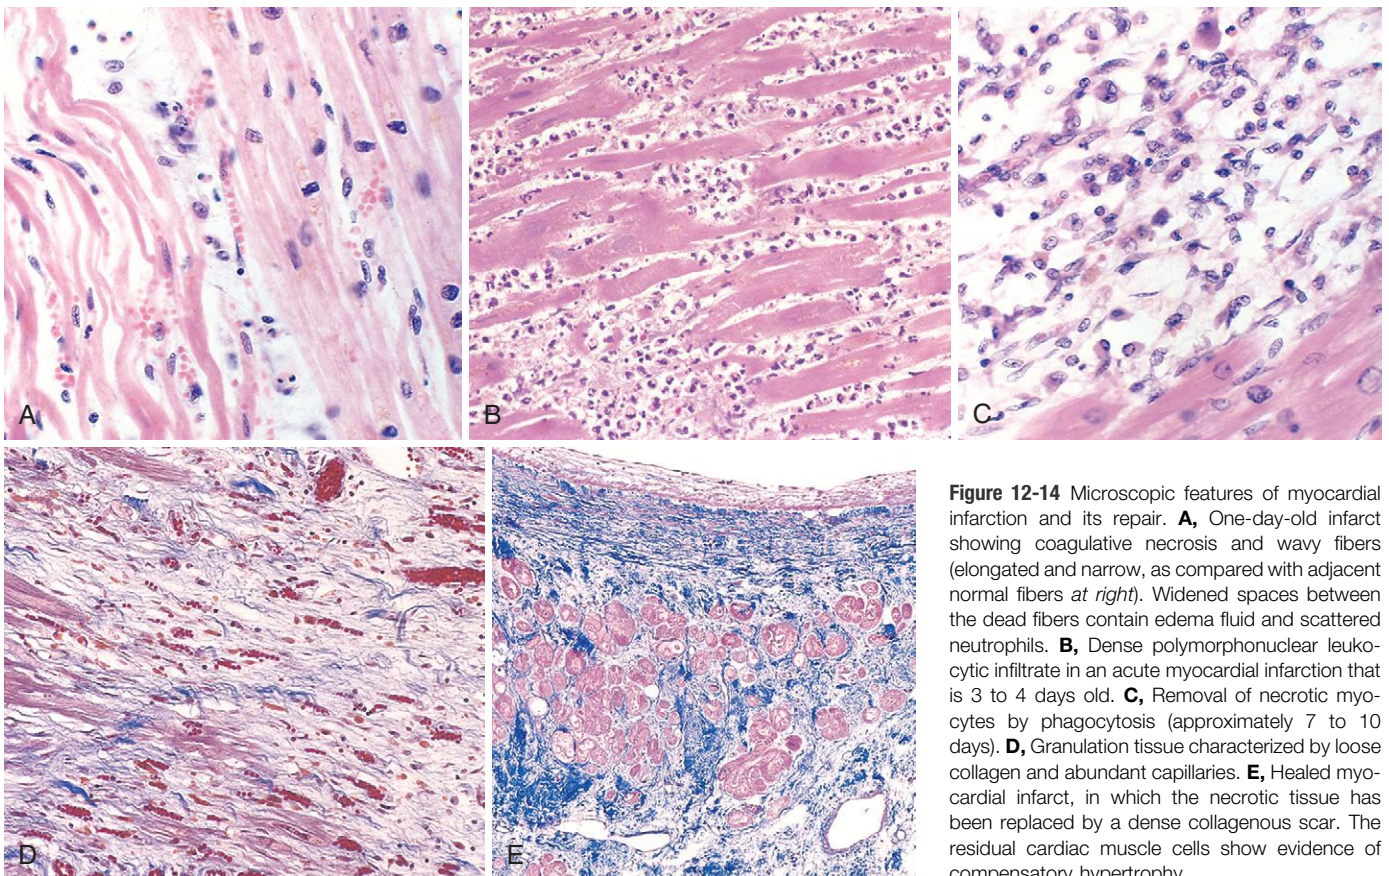

Figure 12-14 Microscopic features of myocardial infarction and its repair. **A**, One-day-old infarct showing coagulative necrosis and wavy fibers (elongated and narrow, as compared with adjacent normal fibers at right). Widened spaces between the dead fibers contain edema fluid and scattered neutrophils. **B**, Dense polymorphonuclear leukocytic infiltrate in an acute myocardial infarction that is 3 to 4 days old. **C**, Removal of necrotic myocytes by phagocytosis (approximately 7 to 10 days). **D**, Granulation tissue characterized by loose collagen and abundant capillaries. **E**, Healed myocardial infarct, in which the necrotic tissue has been replaced by a dense collagenous scar. The residual cardiac muscle cells show evidence of compensatory hypertrophy.

Figure 12-15 Consequences of myocardial ischemia followed by reperfusion. Gross (**A**) and microscopic (**B**) appearance of myocardium modified by reperfusion. **A**, Large, densely hemorrhagic, anterior wall acute myocardial infarction in a patient with left anterior descending artery thrombus treated with streptokinase, a fibrinolytic agent (triphenyl tetrazolium chloride-stained heart slice). Specimen oriented with posterior wall at top. **B**, Myocardial necrosis with hemorrhage and contraction bands, visible as dark bands spanning some myofibers (*arrow*).

coronary blood flow (the first 3 to 4 hours following obstruction are critical) and (2) the extent of restoration of blood flow and correction of the underlying causal lesion. Indeed, thrombolysis can remove a thrombus occluding a coronary artery, but does not alter the underlying atherosclerotic plaque that initiated it. In contrast, percutaneous transluminal coronary angioplasty (PTCA) with stent placement not only eliminates a thrombotic occlusion but also relieves some of the original obstruction and instability caused by the underlying disrupted plaque. CABG provides a new conduit for flow bypassing the area of vessel blockage.

The typical appearance of reperfused myocardium is illustrated in [Figure 12-15](#). Reperfused infarcts are usually hemorrhagic because the vasculature is injured during ischemia and there is bleeding after flow is restored. Microscopic examination reveals that irreversibly injured myocytes exhibit *contraction bands*, intensely eosinophilic intracellular “stripes” composed of closely packed

sarcomeres. These result from the exaggerated contraction of sarcomeres when perfusion is reestablished, at which time the interior of cells with damaged membranes is exposed to a high concentration of calcium ions from the plasma. Thus, *reperfusion not only salvages reversibly injured cells but also alters the morphology of lethally injured cells*.

The effects of reperfusion on myocardial viability and function are discussed later and summarized in [Figure 12-16](#). Although clearly beneficial, reperfusion can trigger deleterious complications, including arrhythmias as well as damage superimposed on the original ischemia, so-called *reperfusion injury*. This term encompasses various forms of damage that can occur after restoration of flow to “vulnerable” myocardium that is ischemic but not yet irreversibly damaged ([Fig. 12-16B](#)). As discussed in [Chapter 2](#), reperfusion injury may be mediated by oxidative stress, calcium overload, and inflammatory cells recruited after tissue reperfusion. Reperfusion-induced microvascular injury not only results in hemorrhage but can also cause

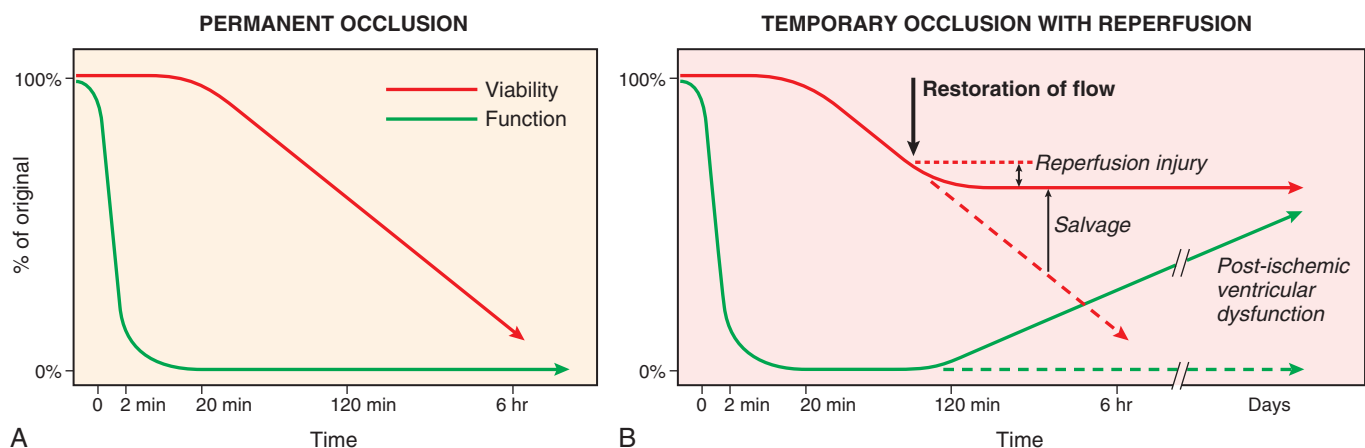

Figure 12-16 Effects of reperfusion on myocardial viability and function. Following coronary occlusion, contractile function is lost within 2 minutes and viability begins to diminish after approximately 20 minutes. If perfusion is not restored (**A**), then nearly all myocardium in the affected region suffers death. **B**, If flow is restored, then some necrosis is prevented, myocardium is salvaged, and at least some function can return. The earlier reperfusion occurs, the greater the degree of salvage. However, the process of reperfusion itself may induce some damage (*reperfusion injury*), and return of function of salvaged myocardium may be delayed for hours to days (*postischemic ventricular dysfunction* or *stunning*).

endothelial swelling that occludes capillaries and may limit the reperfusion of critically injured myocardium (called *no-reflow*). Although the clinical significance of myocardial reperfusion injury is debated, it has been estimated that up to 50% (or more) of the ultimate infarct size can be attributed to its effects.

Biochemical abnormalities (and their functional consequences) may also persist for days to weeks in reperfused myocytes. Such changes are thought to underlie a phenomenon referred to as *stunned myocardium*, a state of prolonged cardiac failure induced by short-term ischemia that usually recovers after several days. Myocardium that is subjected to chronic, sublethal ischemia may also enter into a state of lowered metabolism and function called *hibernation*. Subsequent revascularization (e.g., by CABG surgery, angioplasty, or stenting) often restores normal function to such hibernating myocardium.

Clinical Features. MI is diagnosed by clinical symptoms, laboratory tests for the presence of myocardial proteins in the plasma, and characteristic electrocardiographic changes. Patients with MI classically present with prolonged (more than 30 minutes) chest pain described as crushing, stabbing, or squeezing, associated with a rapid, weak pulse; profuse sweating (diaphoresis), and nausea and vomiting are common, and can suggest involvement of the posterior-inferior ventricle with secondary vagal stimulation. Dyspnea due to impaired contractility of the ischemic myocardium and the resultant pulmonary congestion and edema is a frequent symptom. However, in as many as 25% of patients the onset is entirely asymptomatic (e.g., in the setting of diabetic neuropathy) and the disease is discovered only by electrocardiographic changes or laboratory tests that show evidence of myocardial damage (see later).

The laboratory evaluation of MI is based on measuring the blood levels of proteins that leak out of irreversibly damaged myocytes; the most useful of these molecules are cardiac-specific troponins T and I (cTnT and cTnI), and the MB

fraction of creatine kinase (CK-MB) (Fig. 12-17). The diagnosis of myocardial injury is established when blood levels of these cardiac biomarkers are elevated. The rate of appearance of these markers in the peripheral circulation depends on several factors, including their intracellular location and molecular weight, the blood flow and lymphatic drainage in the area of the infarct, and the rate of elimination of the marker from the blood.

The most sensitive and specific biomarkers of myocardial damage are cardiac-specific proteins, particularly cTnT and cTnI (proteins that regulate calcium-mediated contraction of cardiac and skeletal muscle). *Troponins I and T* are not normally detectable in the circulation. Following an MI, levels of both begin to rise at 3-12 hours; cTnT levels peak somewhere between 12-48 hours while cTnI levels are maximal at 24 hours. *Creatine kinase* is an enzyme expressed in brain, myocardium, and skeletal muscle; it is a dimer composed of two isoforms designated "M" and "B." While MM homodimers are found predominantly in cardiac and skeletal muscle, and BB homodimers in brain, lung, and many other tissues, MB heterodimers are principally localized to cardiac muscle (with considerably lesser amounts found in skeletal muscle). Thus, the MB form of creatine kinase (CK-MB) is sensitive but not specific, since it can also be elevated after skeletal muscle injury. CK-MB begins to rise within 3 to 12 hours of the onset of MI, peaks at about 24 hours, and returns to normal within approximately 48 to 72 hours.

To summarize:

- Time to elevation of CKMB, cTnT and cTnI is 3 to 12 hrs
- CK-MB and cTnI peak at 24 hours
- CK-MB returns to normal in 48-72 hrs, cTnI in 5-10 days, and cTnT in 5 to 14 days

Consequences and Complications of Myocardial Infarction. Extraordinary progress has been made in the treatment of patients with acute MI. Concurrent with the decrease in the overall mortality of IHD since the 1960s,

Figure 12-17 Release of myocyte proteins in myocardial infarction. Some of these proteins, for example, troponin I or troponin T, and creatine kinase, MB fraction (CK-MB) are routinely used as diagnostic biomarkers.

the in-hospital death rate has declined from around 30% to approximately 5% in patients receiving timely therapy. Factors associated with a poorer prognosis include advanced age, female gender, diabetes mellitus, and—due to the cumulative loss of functional myocardium—previous MI. Half of the deaths associated with acute MI occur within 1 hour of onset, most commonly due to a fatal arrhythmia; most of these individuals never reach the hospital. MI therapeutic interventions include:

- Morphine to relieve pain and improve dyspneic symptoms
 - Prompt reperfusion to salvage myocardium
 - Antiplatelet agents such as aspirin, P2Y₁₂ receptor inhibitors, and GPIIb/IIIa inhibitors
 - Anticoagulant therapy with unfractionated heparin, low-molecular-weight heparin, direct thrombin inhibitors, and/or factor Xa inhibitors to prevent coronary artery clot propagation
 - Nitrates to induce vasodilation and reverse vasospasm
 - Beta blockers to decrease myocardial oxygen demand and to reduce risk of arrhythmias
 - Antiarrhythmics to manage arrhythmias
- Angiotensin-converting enzyme (ACE) inhibitors to limit ventricular dilation
 - Oxygen supplementation to improve blood oxygen saturation

Despite these interventions, many patients have one or more complications following acute MI (Fig. 12-18):

- *Contractile dysfunction.* Myocardial infarcts produce abnormalities in left ventricular function roughly proportional to their size. There is usually some degree of left ventricular failure with hypotension, pulmonary vascular congestion, and interstitial pulmonary transudates, which can progress to pulmonary edema and respiratory impairment. Severe “pump failure” (*cardiogenic shock*) occurs in 10% to 15% of patients following acute MI, generally with large infarcts involving more than 40% of the left ventricle. Cardiogenic shock has a nearly 70% mortality rate; it accounts for two thirds of in-hospital deaths in those patients admitted for MI.

Right ventricular infarcts can cause right-sided heart failure associated with pooling of blood in the venous circulation and systemic hypotension.

- *Arrhythmias*. Many patients have *myocardial irritability* and/or conduction disturbances following MI that lead to potentially fatal arrhythmias. MI-associated arrhythmias include sinus bradycardia, atrial fibrillation, heart block, tachycardia, ventricular premature contractions, ventricular tachycardia, and ventricular fibrillation. Because of the location of portions of the atrioventricular conduction system (bundle of His) in the inferoseptal myocardium, infarcts involving this site can also be associated with heart block (see also the discussion concerning arrhythmias).
 - *Myocardial rupture*. The various forms of cardiac rupture typically occur when there is transmural necrosis of a ventricle. These include:
 - Rupture of the ventricular free wall (most common), with hemopericardium and cardiac tamponade (Fig. 12-18A)
 - Rupture of the ventricular septum (less common), leading to an *acute VSD* and left-to-right shunting (Fig. 12-18B)
 - Papillary muscle rupture (least common), resulting in the acute onset of severe mitral regurgitation (Fig. 12-18C)

Free-wall rupture occurs most frequently 2 to 4 days after MI, when coagulative necrosis, neutrophilic infiltration, and lysis of the myocardial connective tissue have appreciably weakened the infarcted myocardium; the anterolateral wall at the mid-ventricular level is the most common site. Risk factors for free-wall rupture include age older than 60, first MI, large, transmural and anterior MI, absence of left ventricular hypertrophy, and preexisting hypertension. Ventricular rupture occurs less frequently in patients with prior MI because associated fibrotic scarring tends to inhibit myocardial tearing. While acute free-wall ruptures are usually rapidly fatal, a fortuitously located pericardial adhesion can abort a rupture and result in a *false aneurysm* (localized hematoma communicating with the ventricular cavity). The wall of a false aneurysm consists only of epicardium and adherent parietal pericardium and thus many still ultimately rupture.
 - *Ventricular aneurysm*. In contrast to the *false aneurysms* mentioned earlier, *true aneurysms* of the ventricular wall are bounded by myocardium that has become scarred. Aneurysms of the ventricular wall are a late complication of large transmural infarcts that experience early expansion. The thin scar tissue wall of an aneurysm paradoxically bulges during systole (Fig. 12-18F). Complications of ventricular aneurysms include mural thrombus, arrhythmias, and heart failure; rupture of the tough fibrotic wall does not usually occur.
 - *Pericarditis*. A fibrinous or fibrinohemorrhagic pericarditis usually develops about the second or third day following a transmural infarct as a result of underlying myocardial inflammation (*Dressler syndrome*; Fig. 12-18D).
 - *Infarct expansion*. As a result of the weakening of necrotic muscle, there may be disproportionate stretching, thinning, and dilation of the infarct region (especially with anteroseptal infarcts), which is often associated with mural thrombus (Fig. 12-18E).
 - *Mural thrombus*. With any infarct, the combination of a local abnormality in contractility (causing stasis) and endocardial damage (creating a thrombogenic surface) can foster *mural thrombosis* and potentially *thromboembolism*.
 - *Papillary muscle dysfunction*. Although papillary muscle rupture after an MI may certainly result in precipitous onset of mitral (or tricuspid) valve incompetence, most post-infarct regurgitation results from ischemic dysfunction of a papillary muscle (and underlying myocardium), or later from ventricular dilation or from papillary muscle fibrosis and shortening.
 - *Progressive late heart failure* (chronic IHD) is discussed later.
- The risk of postinfarct complications and the prognosis of the patient depend primarily on the infarct size, location, and fraction of the wall thickness involved (subendocardial or transmural). Thus, large transmural infarcts yield a higher probability of cardiogenic shock, arrhythmias, and late CHF. Patients with anterior transmural infarcts are at greatest risk for free-wall rupture, expansion, mural thrombi, and aneurysm. In contrast, posterior transmural infarcts are more likely to be complicated by conduction blocks, right ventricular involvement, or both; when acute VSDs occur in this area they are more difficult to manage. Moreover, female gender, age older than 70 years, diabetes mellitus and previous MI are poor prognostic factors in patients with ST elevation myocardial infarcts. With subendocardial infarcts, only rarely do pericarditis, rupture, and aneurysms occur.
- In addition to the sequence of repair in the infarcted tissues described earlier, the noninfarcted segments of the ventricle undergo hypertrophy and dilation; collectively, these changes are termed *ventricular remodeling*. The compensatory hypertrophy of noninfarcted myocardium is initially hemodynamically beneficial. However, this adaptive effect may be overwhelmed by ventricular dilation (with or without ventricular aneurysm) and increased oxygen demand, which can exacerbate ischemia and depress cardiac function. There may also be changes in ventricular shape and stiffening of the ventricle due to scar formation and hypertrophy that further diminish cardiac output. Some of these deleterious effects appear to be reduced by ACE inhibitors, which lessen the ventricular remodeling that can occur after infarction.
- Long-term prognosis after MI depends on many factors, the most important of which are the residual left ventricular function and the extent of any vascular obstructions in vessels that perfuse the remaining viable myocardium. The overall total mortality within the first year can be as high as 30%; thereafter, each passing year is associated with an additional 3% to 4% mortality among survivors. Infarct prevention (through control of risk factors) in individuals who have never experienced MI (*primary prevention*) and prevention of reinfarction in MI survivors (*secondary prevention*) are important strategies that have received much attention and achieved considerable success.
- The relationship of the causes, pathophysiology, and consequences of MI are summarized in Figure 12-19, including the possible outcomes of chronic IHD and sudden death, discussed below.

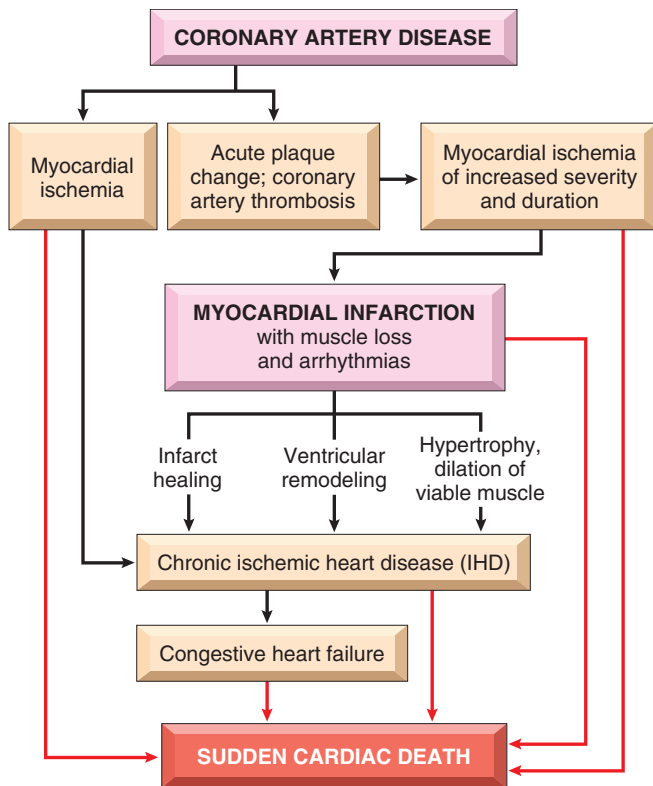

Figure 12-19 Schematic for the causes and outcomes of ischemic heart disease (IHD), showing the interrelationships among coronary artery disease, acute plaque change, myocardial ischemia, myocardial infarction, chronic IHD, congestive heart failure, and sudden cardiac death.

Chronic Ischemic Heart Disease

The designation chronic IHD (often called *ischemic cardiomyopathy* by clinicians) is used here to describe progressive congestive heart failure as a consequence of accumulated ischemic myocardial damage and/or inadequate compensatory responses. In most instances there has been prior MI and sometimes previous coronary arterial interventions and/or bypass surgery. Chronic IHD usually appears postinfarction due to the functional decompensation of hypertrophied noninfarcted myocardium (see earlier discussion of cardiac hypertrophy). However, in other cases severe obstructive coronary artery disease may present as chronic congestive heart failure in the absence of prior infarction. Patients with chronic IHD account for almost 50% of cardiac transplant recipients.

MORPHOLOGY

Hearts from patients with chronic IHD have cardiomegaly, with left ventricular hypertrophy and dilation. Invariably there is some degree of stenotic coronary atherosclerosis. Discrete scars representing healed infarcts are usually present. The mural endocardium often has patchy fibrous thickenings (due to abnormal wall shear forces), and mural thrombi may be present. Microscopic findings include myocardial hypertrophy, diffuse subendocardial vacuolization, and fibrosis.

KEY CONCEPTS

Ischemic Heart Disease

- The vast majority of ischemic heart disease is due to coronary artery atherosclerosis; vasospasm, vasculitis, or embolism are less common causes.
- Cardiac ischemia results from a mismatch in coronary supply and myocardial demand, and presents as different, albeit overlapping syndromes:
 - *Angina pectoris* is chest pain due to inadequate perfusion, and is typically due to atherosclerotic disease with greater than 70% fixed stenosis (so-called critical stenosis).
 - *Unstable angina* results from a small fissure or rupture of atherosclerotic plaque triggering platelet aggregation, vasoconstriction, and formation of a mural thrombus that need not necessarily be occlusive.
 - *Acute myocardial infarction* typically results from acute thromboses after plaque disruption; most occur in plaques that did not previously exhibit critical stenosis.
 - *Sudden cardiac death* usually results from a fatal arrhythmia, typically without significant acute myocardial damage.
 - *Chronic ischemic heart disease* is progressive heart failure due to ischemic injury, either from prior infarctions or chronic low-grade ischemia.
- Myocardial ischemia leads to loss of function within 1 to 2 minutes, but causes necrosis only after 20 to 40 minutes. Myocardial infarction is diagnosed based on symptoms, electrocardiographic changes, and measurement of serum CK-MB and troponins. Gross and histologic changes of infarction require hours to days to develop.
- Infarction can be modified by therapeutic intervention (e.g., thrombolysis or stenting), which salvages myocardium at risk, but potentially induces reperfusion-related injury.
- Complications of infarction include: ventricular rupture, papillary muscle rupture, aneurysm formation, mural thrombus, arrhythmia, pericarditis, and CHF.

Arrhythmias

Abnormalities in myocardial conduction can be sustained or sporadic (*paroxysmal*). Aberrant rhythms can be initiated anywhere in the conduction system, from SA node down to the level of an individual myocyte; they are typically designated as originating from the atrium (*supraventricular*) or within the ventricular myocardium. Arrhythmias can manifest as *tachycardia* (fast heart rate), *bradycardia* (slow heart rate), an irregular rhythm with normal ventricular contraction, chaotic depolarization without functional ventricular contraction (*ventricular fibrillation*), or no electrical activity at all (*asystole*). Patients may be unaware of a rhythm disorder, or may note a “racing heart” or *palpitations* (irregular rhythm); loss of adequate cardiac output due to sustained arrhythmia can produce light-headedness (near syncope), loss of consciousness (*syncope*), or *sudden cardiac death* (see later)

Ischemic injury is the most common cause of rhythm disorders, either through direct damage, or through the dilation of heart chambers that alters conduction system firing.

- If the SA node is damaged (e.g., *sick sinus syndrome*), other fibers or even the AV node can take over pacemaker function, albeit at a much slower intrinsic rate (causing bradycardia).
- If the atrial myocytes become “irritable” and depolarize independently and sporadically (as occurs with atrial dilation), the signals are variably transmitted through the AV node leading to the random “irregularly irregular” heart rate of *atrial fibrillation*.
- If the AV node is dysfunctional, varying degrees of *heart block* occur, ranging from simple prolongation of the P-R interval on the electrocardiogram (ECG; *first degree heart block*), to intermittent transmission of the signal (*second degree heart block*), to complete failure (*third degree heart block*).

As already discussed, coordinated cardiac contraction depends on the orderly transmission of electrical currents from myocyte to myocyte via gap junctions. Thus, abnormalities in the structure or spatial distribution of gap junctions, which are seen in a variety of disorders (e.g., IHD and dilated cardiomyopathies), can cause arrhythmias. Ischemia, myocyte hypertrophy, and inflammation (e.g., myocarditis or sarcoidosis) also promote increased “irritability” that leads to spontaneous aberrant myocyte depolarization; because of the electrical interconnection of myocytes, such random events can cause inappropriate firing of adjacent cells and create abnormal electrical circuits (so-called reentry circuits) that lead to *ventricular tachycardia*, which may progress to fatal ventricular fibrillation. Likewise, deposition of nonconducting material (e.g., amyloid), and even small areas of fibrosis, can disrupt myocyte-to-myocyte signaling, again sowing the seeds for development of reentry circuits that can give rise to potentially fatal arrhythmias.

Heritable conditions associated with arrhythmias are important to recognize, since they may alert physicians to the need for intervention to prevent sudden cardiac death (discussed later) in the proband and their family members. Some of these disorders are associated with recognizable anatomic abnormalities (e.g., congenital anomalies, hypertrophic cardiomyopathy, mitral valve prolapse). However, other heritable disorders precipitate arrhythmias and sudden death in the absence of structural cardiac pathology (so-called primary electrical disorders). These syndromes can only be diagnosed by genetic testing, which is performed in those with a positive family history or an unexplained nonlethal arrhythmia.

The primary electrical abnormalities of the heart that predispose to arrhythmias are listed in [Table 12-6](#). The most important of these are the so-called *channelopathies*, which are caused by mutations in genes that are required for normal ion channel function. These disorders (mostly with autosomal dominant inheritance) either involve genes that encode the structural components of ion channels (including Na⁺, K⁺, and Ca²⁺ channels), or accessory proteins that are essential for normal channel function. Ion channels are responsible for conducting the electrical currents that mediate contraction of the heart, and it is thus not surprising that defects in these channels may provoke arrhythmias. The prototype is the *long QT syndrome*, characterized by prolongation of the QT segment in ECGs and susceptibility to malignant ventricular arrhythmias. Ion channels are

Table 12-6 Selected Examples of Causal Genes in Inherited Arrhythmogenic Diseases*

Disorder	Gene	Function
Long QT syndrome [†]	<i>KCNQ1</i>	K ⁺ channel (LOF)
	<i>KCNH2</i>	K ⁺ channel (LOF)
	<i>SCN5A</i>	Na ⁺ channel (GOF)
	<i>CAV3</i>	Caveolin, Na ⁺ current (GOF)
Short QT syndrome [†]	<i>KCNQ1</i>	K ⁺ channel (GOF)
	<i>KCNH2</i>	K ⁺ channel (GOF)
Brugada syndrome [†]	<i>SCN5A</i>	Na ⁺ channel (LOF)
	<i>CACNB2b</i>	Ca ²⁺ channel (LOF)
	<i>SCN1b</i>	Na ⁺ channel (LOF)*
CPVT syndrome [†]	<i>RYR2</i>	Diastolic Ca ²⁺ release (GOF)
	<i>CASQ2</i>	Diastolic Ca ²⁺ release (LOF)

*Different mutations can cause the same general syndrome and mutations in some genes can cause multiple different phenotypes; thus, loss of function (LOF) mutations may cause long QT intervals, whereas gain of function (GOF) mutations result in short repolarization intervals.

[†]**Long QT syndrome** manifests as arrhythmias associated with excessive prolongation of the cardiac repolarization; patients often present with stress-induced syncope or sudden cardiac death (SCD), and some forms are associated with swimming. **Short QT syndrome** patients have arrhythmias associated with abbreviated repolarization intervals; they can present with palpitations, syncope, and SCD. **Brugada syndrome** manifests as ECG abnormalities (ST segment elevations and right bundle branch block) in the absence of structural heart disease; patients classically present with syncope or SCD during rest or sleep, or after large meals. **CPVT** does not have characteristic ECG changes; patients often present in childhood with life-threatening arrhythmias due to adrenergic stimulation (stress-related).

LOF, Loss of function mutations; GOF, gain of function mutations; CPVT, catecholaminergic polymorphic ventricular tachycardia.

Modified from Cerrone M, Priori SG: Genetics of sudden death: focus on inherited channelopathies. *Eur Heart J*, 2011;32, 2109-2118.

needed for the normal function of many tissues, and certain channelopathies are also associated with skeletal muscle disorders and diabetes. Nevertheless, the most common channelopathies are isolated disorders of the heart, and their most feared consequence is sudden cardiac death (discussed below).

Sudden Cardiac Death (SCD)

SCD is most commonly defined as unexpected death from cardiac causes either without symptoms, or within 1 to 24 hours of symptom onset (different authors use different criteria); this happens in some 300,000 to 400,000 individuals each year in the United States alone. Coronary artery disease is the leading cause of SCD, responsible for 80% to 90% of cases; unfortunately, SCD is often the first manifestation of IHD. Interestingly, there is typically only chronic severe atherosclerotic disease; acute plaque disruption is found in only 10% to 20% of cases. Healed remote MIs are present in about 40%.

With younger victims, other nonatherosclerotic causes are more common etiologies for SCD:

- Hereditary or acquired abnormalities of the cardiac conduction system
- Congenital coronary arterial abnormalities
- Mitral valve prolapse
- Myocarditis or sarcoidosis
- Dilated or hypertrophic cardiomyopathy
- Pulmonary hypertension
- Myocardial hypertrophy. Increased cardiac mass is an independent risk factor for SCD; thus, some young individuals who die suddenly—including athletes—have

hypertensive hypertrophy or unexplained increased cardiac mass as the only finding.

- Other miscellaneous causes, such as pericardial tamponade, pulmonary embolism, systemic metabolic and hemodynamic alterations, catecholamines, and drugs of abuse, particularly cocaine and methamphetamine.

The mechanism of SCD is most often a lethal arrhythmia (e.g., asystole or ventricular fibrillation). Notably, infarction need not occur; 80% to 90% of patients who suffer SCD but are successfully resuscitated do not show any enzymatic or ECG evidence of myocardial necrosis—even when the original cause was ischemic heart disease. Although ischemic injury (and other pathologies) can directly affect the major components of the conduction system, most cases of fatal arrhythmia are triggered by electrical irritability of myocardium distant from the major elements of the conduction system.

The prognosis of patients vulnerable to SCD is markedly improved by pharmaceutical intervention, and particularly by implantation of automatic cardioverter defibrillators that can sense and electrically counteract episodes of ventricular fibrillation.

MORPHOLOGY

Marked coronary atherosclerosis with a critical (>75% cross-sectional area) stenosis involving one or more of the three major vessels is present in 80% to 90% of SCD victims; only 10% to 20% of cases are of nonatherosclerotic origin. Usually there are high-grade stenoses (>90% of area); in approximately one half, acute plaque disruption is observed, and in approximately 25% diagnostic changes of acute MI are seen. This suggests that many patients who die suddenly are suffering an MI, but the short interval from onset to death precludes the development of diagnostic myocardial changes. However, in one study of those who had been successfully resuscitated from a sudden cardiac arrest, a new MI occurred in only 39% of the patients. Thus, most SCD is not associated with acute MI; most of these deaths are thought to result from myocardial ischemia-induced irritability that initiates malignant ventricular arrhythmias. Scars of previous infarcts and subendocardial myocyte vacuolization indicative of severe chronic ischemia are common in such patients.

KEY CONCEPTS

Arrhythmias

- Arrhythmias can be caused by ischemic or structural changes in the conduction system or by intrinsic myocyte electrical instability. In structurally normal hearts, arrhythmias are more often due to mutations in ion channels that cause aberrant repolarization or depolarization.
- SCD typically results from ventricular fibrillation, and is most frequently a consequence of coronary artery disease. Myocardial irritability typically results from nonlethal ischemia or from preexisting fibrosis from previous myocardial injury. SCD is less often due to acute plaque rupture with thrombosis that induces a rapidly fatal arrhythmia.

Hypertensive Heart Disease

Hypertensive heart disease (HHD) is a consequence of the increased demands placed on the heart by hypertension, causing pressure overload and ventricular hypertrophy. Although most commonly seen in the left heart as the result of systemic hypertension, pulmonary hypertension can cause right-sided HHD, or *cor pulmonale*.

Systemic (Left-Sided) Hypertensive Heart Disease

Hypertrophy of the heart is an adaptive response to the pressure overload of chronic hypertension. However, such compensatory changes may be ultimately maladaptive and can lead to myocardial dysfunction, cardiac dilation, CHF, and in some cases sudden death. *The minimal pathologic criteria for the diagnosis of systemic HHD are the following: (1) left ventricular hypertrophy (usually concentric) in the absence of other cardiovascular pathology and (2) a clinical history or pathologic evidence of hypertension in other organs (e.g., kidney).* The Framingham Study established unequivocally that even mild hypertension (levels only slightly above 140/90 mm Hg)—if sufficiently prolonged—induces left ventricular hypertrophy. Approximately 30% of the population of the United States suffers from hypertension of at least this degree. The pathogenesis of hypertension is discussed in [Chapter 11](#).

MORPHOLOGY

Hypertension induces left ventricular pressure overload hypertrophy, initially without ventricular dilation. As a result, the left ventricular wall thickening increases the weight of the heart disproportionately to the increase in overall cardiac size ([Fig. 12-20A](#)). The thickness of the left ventricular wall may exceed 2.0 cm, and the heart weight may exceed 500 gm. In time the increased thickness of the left ventricular wall, often associated with increased interstitial connective tissue, imparts a stiffness that impairs diastolic filling, frequently with consequent left atrial enlargement.

Microscopically, the earliest change of systemic HHD is an increase in the transverse diameter of myocytes, which may be difficult to appreciate on routine microscopy. At a more advanced stage variable degrees of cellular and nuclear enlargement become apparent, often accompanied by interstitial fibrosis.

Compensated systemic HHD may be asymptomatic, producing only electrocardiographic or echocardiographic evidence of left ventricular enlargement. In many patients, systemic HHD comes to attention due to new atrial fibrillation induced by left atrial enlargement, or by progressive CHF. Depending on the severity, duration, and underlying basis of the hypertension, and on the adequacy of therapeutic control, the patient may (1) enjoy normal longevity and die of unrelated causes, (2) develop IHD due to both the potentiating effects of hypertension on coronary atherosclerosis and the ischemia induced by increased oxygen demand from the hypertrophic muscle, (3) suffer renal damage or cerebrovascular stroke as direct effects of

Figure 12-20 Hypertensive heart disease, systemic and pulmonary. **A**, Systemic (left-sided) hypertensive heart disease. There is marked concentric thickening of the left ventricular wall causing reduction in lumen size. The left ventricle and left atrium (*asterisk*) are on the *right* in this apical four-chamber view of the heart. A pacemaker is present in the right ventricle (*arrow*). **B**, Pulmonary (right-sided) hypertensive heart disease (*cor pulmonale*). The right ventricle is markedly dilated and has a thickened free wall and hypertrophied trabeculae (apical four-chamber view of heart, right ventricle on *left*). The shape of the left ventricle (to the *right*) has been distorted by the enlarged right ventricle.

hypertension, or (4) experience progressive heart failure or SCD. Effective control of hypertension can prevent cardiac hypertrophy, or can lead to its regression; with normalization of the blood pressure, the associated risks of HHD are diminished.

Pulmonary (Right-Sided) Hypertensive Heart Disease (Cor Pulmonale)

Normally, because the pulmonary vasculature is the low pressure side of the circulation, the right ventricle has a thinner and more compliant wall than the left ventricle. Isolated pulmonary HHD, or *cor pulmonale*, stems from right ventricular pressure overload. Chronic *cor pulmonale* is characterized by right ventricular hypertrophy, dilation, and potentially right-sided failure. Typical causes of *chronic cor pulmonale* are disorders of the lungs, especially chronic parenchymal diseases such as emphysema, and primary pulmonary hypertension (Table 12-7; see also Chapter 15). *Acute cor pulmonale* can follow massive pulmonary embolism. Nevertheless, it should also be remembered that pulmonary hypertension *most commonly occurs as a complication of left-sided heart disease*.

MORPHOLOGY

In acute *cor pulmonale* there is marked dilation of the right ventricle without hypertrophy. On cross-section the normal crescent shape of the right ventricle is transformed to a dilated ovoid. In chronic *cor pulmonale* the right ventricular wall thickens, sometimes up to 1.0 cm or more (Fig. 12-20B). More subtle right ventricular hypertrophy may take the form of thickening of the muscle bundles in the outflow tract, immediately below the pulmonary valve, or thickening of the moderator band, the muscle bundle that connects the ventricular septum to the anterior right ventricular papillary muscle. Sometimes, the hypertrophied right ventricle compresses the left ventricular chamber, or leads to regurgitation and fibrous thickening of the tricuspid valve.

Table 12-7 Disorders Predisposing to Cor Pulmonale

Diseases of the Pulmonary Parenchyma
Chronic obstructive pulmonary disease
Diffuse pulmonary interstitial fibrosis
Pneumoconioses
Cystic fibrosis
Bronchiectasis
Diseases of the Pulmonary Vessels
Recurrent pulmonary thromboembolism
Primary pulmonary hypertension
Extensive pulmonary arteritis (e.g., granulomatosis with polyangiitis)
Drug-, toxin-, or radiation-induced vascular obstruction
Extensive pulmonary tumor microembolism
Disorders Affecting Chest Movement
Kyphoscoliosis
Marked obesity (sleep apnea, pickwickian syndrome)
Neuromuscular diseases
Disorders Inducing Pulmonary Arterial Constriction
Metabolic acidosis
Hypoxemia
Chronic altitude sickness
Obstruction of major airways
Idiopathic alveolar hypoventilation

KEY CONCEPTS

Hypertensive Heart Disease

- Hypertensive heart disease can affect either the left ventricle or the right ventricle; the latter is called *cor pulmonale*. Elevated pressures induce myocyte hypertrophy and interstitial fibrosis that increases wall thickness and myocardial stiffness.
- The chronic pressure overload of systemic hypertension causes left ventricular concentric hypertrophy, often associated with left atrial dilation due to impaired diastolic filling of the ventricle. Persistently elevated pressure overload can cause ventricular failure with dilation.
- *Cor pulmonale* results from pulmonary hypertension due to primary lung parenchymal or vascular disorders. There is commonly right ventricular and right atrial hypertrophy; right ventricular and atrial dilation can occur.

Valvular Heart Disease

Valvular disease can come to clinical attention due to stenosis, insufficiency (synonyms: regurgitation or incompetence), or both. *Stenosis is the failure of a valve to open completely, which impedes forward flow. Insufficiency results from failure of a valve to close completely, thereby allowing reversed flow.* These abnormalities can be present alone or coexist, and may involve only a single valve, or more than one valve. *Functional regurgitation* is used to describe the incompetence of a valve stemming from an abnormality in one of its support structures, as opposed to a primary valve defect. For example, dilation of the right or left ventricle can pull the ventricular papillary muscles down and outward, thereby preventing proper closure of otherwise normal mitral or tricuspid leaflets. Functional mitral valve regurgitation is particularly common and clinically important in IHD, as well as in dilated cardiomyopathy.

The clinical consequences of valve dysfunction vary depending on the valve involved, the degree of impairment, the tempo of disease onset, and the rate and quality of compensatory mechanisms. For example, sudden destruction of an aortic valve cusp by infection (infective endocarditis; see later) can cause acute, massive, and rapidly fatal regurgitation. In contrast, rheumatic mitral stenosis typically develops indolently over years, and its clinical effects can be well tolerated for extended periods. Certain conditions can complicate valvular heart disease by increasing the demands on the heart; for example, the increased output demands of pregnancy can exacerbate valve disease and lead to unfavorable maternal or fetal outcomes. Valvular stenosis or insufficiency often produces secondary changes, both proximal and distal to the affected valve, particularly in the myocardium. Generally, valvular stenosis leads to pressure overload cardiac hypertrophy, whereas mitral or aortic valvular insufficiency leads to volume overload; both situations can culminate in heart failure. In addition, the ejection of blood through narrowed stenotic valves can produce high speed “jets” of blood that injure the endocardium where they impact.

Valvular abnormalities can be congenital (discussed earlier) or acquired. *Acquired valvular stenosis* has relatively few causes; it is almost always a consequence of a remote or chronic injury of the valve cusps that declares itself clinically only after many years. In contrast, *acquired valvular insufficiency* can result from intrinsic disease of the valve cusps or damage to or distortion of the supporting structures (e.g., the aorta, mitral annulus, tendinous cords, papillary muscles, ventricular free wall). Thus, valvular insufficiency has many causes and may appear acutely, as with rupture of the cords, or chronically in disorders associated with leaflet scarring and retraction.

The causes of acquired heart valve diseases are summarized in [Table 12-8](#). The most frequent causes of the major functional valvular lesions are:

- *Aortic stenosis*: calcification and sclerosis of anatomically normal or congenitally bicuspid aortic valves
- *Aortic insufficiency*: dilation of the ascending aorta, often secondary to hypertension and/or aging
- *Mitral stenosis*: rheumatic heart disease

Table 12-8 Major Etiologies of Acquired Heart Valve Disease

Mitral Valve Disease	Aortic Valve Disease

- *Mitral insufficiency*: myxomatous degeneration (*mitral valve prolapse*)

Calcific Valvular Degeneration

Heart valves are subjected to high levels of repetitive mechanical stress, particularly at the hinge points of the cusps and leaflets; this is a consequence of (1) 30 to 40 million or more cardiac contractions per year, (2) substantial tissue deformations during each contraction, and (3) transvalvular pressure gradients in the closed phase of each contraction of approximately 120 mm Hg for the mitral and 80 mm Hg for the aortic valve. It is therefore not surprising that these delicate structures can suffer cumulative damage and calcification that lead to clinically important dysfunction.

Calcific Aortic Stenosis

The most common of all valvular abnormalities, calcific aortic stenosis is usually the consequence of age-associated “wear and tear” of either anatomically normal valves or congenitally bicuspid valves (in approximately 1% of the population). The prevalence of aortic stenosis is estimated at 2% and is increasing as the general population ages. Aortic stenosis of previously normal valves (termed senile calcific aortic stenosis) usually comes to clinical attention in the seventh to ninth decades of life, whereas stenotic bicuspid valves tend to become clinically significant 1 to 2 decades earlier.

Aortic valve calcification is likely a consequence of recurrent chronic injury due to hyperlipidemia, hypertension, inflammation, and other factors similar to those implicated in atherosclerosis. Bicuspid valves incur greater

mechanical stress than normal tricuspid valves, which may explain their accelerated stenosis. The chronic progressive injury leads to valvular degeneration and incites the deposition of hydroxyapatite (the same calcium salt found in bone). Although this model provides a good starting point for understanding calcific degeneration, it is increasingly clear that the valve injury of calcific aortic stenosis differs in some important respects from atherosclerosis. Most notably, the abnormal valves contain cells resembling osteoblasts that synthesize bone matrix proteins and promote the deposition of calcium salts. Moreover, interventions that improve atherosclerotic risk (e.g., statins), do not appear to significantly impact valvular calcific degeneration.

MORPHOLOGY

The gross morphologic hallmark of nonrheumatic, calcific aortic stenosis (involving either tricuspid or bicuspid valves) is rounded calcified masses within the aortic cusps that ultimately protrude through the outflow surfaces into the sinuses of Valsalva, and prevent cuspal opening. The free edges of the cusps are usually not involved (Fig. 12-21A). Microscopically, the layered architecture of the valve is largely preserved. The calcific process begins in the valvular fibrosa on the outflow surface of the valve, at the points of maximal cusp flexion (near the margins of attachment). Inflammation is variable, and metaplastic bone (and even bone marrow) may be seen. In aortic stenosis, the functional valve area is decreased by large nodular calcific deposits that can eventually cause measurable outflow obstruction; this subjects the left ventricular myocardium to progressively increasing pressure overload.

In contrast to rheumatic (and congenital) aortic stenosis (see Fig. 12-23E), commissural fusion is not usually seen. The mitral valve is generally normal, although some patients may have direct extension of aortic valve calcific deposits onto the anterior mitral leaflet. In contrast, virtually all patients with rheumatic aortic stenosis also have concomitant and characteristic structural abnormalities of the mitral valve (see later discussion).

Clinical Features. In calcific aortic stenosis (superimposed on a previously normal or bicuspid aortic valve), the obstruction to left ventricular outflow leads to gradual

narrowing of the valve orifice (valve area approximately 0.5 to 1 cm² in severe aortic stenosis; normal approximately 4 cm²) and an increasing pressure gradient across the calcified valve, reaching 75 to 100 mm Hg in severe cases. Left ventricular pressures rise to 200 mm Hg or more in such instances, producing concentric left ventricular (pressure overload) hypertrophy. The hypertrophied myocardium tends to be ischemic (as a result of diminished microcirculatory perfusion, often complicated by coronary atherosclerosis), and angina pectoris may occur. Both systolic and diastolic myocardial function may be impaired; eventually, cardiac decompensation and CHF can ensue. The onset of symptoms (angina, CHF, or syncope) in aortic stenosis heralds cardiac decompensation and carries an extremely poor prognosis. If untreated, most patients with aortic stenosis will die within 5 years of developing angina, within 3 years of developing syncope, and within 2 years of CHF onset. Treatment requires surgical valve replacement, as medical therapy is ineffective in severe symptomatic aortic stenosis.

Calcific Stenosis of Congenitally Bicuspid Aortic Valve

Bicuspid aortic valve (BAV) is a developmental abnormality with prevalence in the population of approximately 1%. Some cases of BAV show familial clustering, often with associated aorta or left ventricular outflow tract malformations. While the heritability of BAV is well-established, and three loci on chromosomes 18q, 5q, and 13q have been identified in kindred studies, the specific genes that are responsible for the disorder remain largely unknown. Thus far, only loss-of-function mutations in *NOTCH1* (mapping to chromosome 9q34.3) have been specifically associated with BAV in a few families; tantalizingly, modulation of Notch activity in animal models also impacts valvular calcification.

In a congenitally bicuspid aortic valve, there are only two functional cusps, usually of unequal size, with the larger cusp having a midline *raphe*, resulting from incomplete commissural separation during development; less frequently the cusps are of equal size and the raphe is absent. The raphe is frequently a major site of calcific deposits. Once stenosis is present, the clinical course is similar to that described earlier for calcific aortic stenosis. Valves that become bicuspid because of an acquired deformity (e.g., rheumatic valve disease) have a

Figure 12-21 Calcific valvular degeneration. **A**, Calcific aortic stenosis of a previously normal valve (viewed from aortic aspect). Nodular masses of calcium are heaped up within the sinuses of Valsalva (arrow). Note that the commissures are not fused, as occurs with post-rheumatic aortic valve stenosis (see Fig. 12-23E). **B**, Calcific aortic stenosis of a congenitally bicuspid valve. One cusp has a partial fusion at its center, called a *raphe* (arrow). **C** and **D**, Mitral annular calcification, with calcific nodules at the base (attachment margin) of the anterior mitral leaflet (arrows). **C**, Left atrial view. **D**, Cut section of myocardium showing the lateral wall with dense calcification that extends into the underlying myocardium (arrow).

fused commissure that produces a conjoined cusp that is generally twice the size of the nonconjoined cusp. BAVs may also become incompetent as a result of aortic dilation, cusp prolapse, or infective endocarditis. The mitral valve is generally normal in patients with a congenitally bicuspid aortic valve.

Although BAV is usually asymptomatic early in life, late complications include aortic stenosis or regurgitation, infective endocarditis, and aortic dilation and/or dissection. In particular, BAVs are predisposed to progressive calcification, similar to that occurring in aortic valves with initially normal anatomy (Fig. 12-21B); calcified BAV comprise approximately 50% of cases of aortic stenosis in adults. Structural abnormalities of the aortic wall also commonly accompany BAV, even when the valve is hemodynamically normal, and this may potentiate aortic dilation or aortic dissection (see later).

Mitral Annular Calcification

As opposed to the predominantly cuspal involvement in aortic valve calcification, degenerative calcific deposits in the mitral valve typically develop in the fibrous annulus. Grossly, these appear as irregular, stony hard, occasionally ulcerated nodules (2 to 5 mm in thickness) at the base of the leaflets (Fig. 12-21C, D). Mitral annular calcification usually does not affect valvular function. However, in exceptional cases it can lead to:

- Regurgitation by interfering with physiologic contraction of the valve ring
- Stenosis by impairing opening of the mitral leaflets
- Arrhythmias and occasionally sudden death by penetration of calcium deposits to a depth sufficient to impinge on the atrioventricular conduction system.

Because calcific nodules may also provide a site for thrombus formation, patients with mitral annular calcification have an increased risk of embolic stroke, and the calcific nodules can become a nidus for infective endocarditis. Heavy calcific deposits are sometimes visualized on echocardiography or seen as distinctive, ringlike opacities on chest radiographs. Mitral annular calcification is most common in women older than age 60 and individuals with mitral valve prolapse (see later).

Mitral Valve Prolapse (Myxomatous Degeneration of the Mitral Valve)

In mitral valve prolapse (MVP), one or both mitral valve leaflets are “floppy” and *prolapse*, or balloon back, into the left atrium during systole. MVP affects approximately 2-3% of adults in the United States with an approximate 7:1 female-to-male ratio; it is most often an incidental finding on physical examination, but in a small minority of affected individuals may lead to serious complications.

Pathogenesis. The etiologic basis for the changes that weaken the valve leaflets and associated structures is unknown in most cases. Uncommonly, MVP is associated with heritable disorders of connective tissue including Marfan syndrome, caused by fibrillin-1 (*FBN-1*) mutations (Chapter 5). Fibrillin-1 defects alter cell-matrix

interactions and dysregulate TGF- β signaling. Interestingly, mice with mutated *FBN-1* develop a form of mitral valve prolapse that is prevented by TGF- β inhibitors, indicating that excess TGF- β activity can cause the characteristic structural laxity and myxomatous changes. Whether similar mechanisms contribute to sporadic MVP is unknown. Genetic linkage analyses have also mapped inherited forms of MVP to loci involved in the remodeling of valvular extracellular matrix and cell:cell adhesion.

MORPHOLOGY

The characteristic anatomic change in MVP is interchordal ballooning (hooding) of the mitral leaflets or portions thereof (Fig. 12-22A-C). The affected leaflets are often enlarged, redundant, thick, and rubbery. The associated tendinous cords may be elongated, thinned, or even ruptured, and the annulus may be dilated. The tricuspid, aortic, or pulmonary valves may also be affected. The key histologic change in the tissue is marked thickening of the spongiosa layer with deposition of mucoid (myxomatous) material, called **myxomatous degeneration**; there is also attenuation of the collagenous fibrosa layer of the valve, on which the structural integrity of the leaflet depends (Fig. 12-22E). Secondary changes reflect the stresses and tissue injury incident to the billowing leaflets: (1) fibrous thickening of the valve leaflets, particularly where they rub against each other; (2) linear fibrous thickening of the left ventricular endocardial surface where the abnormally long cords snap or rub against it; (3) thickening of the mural endocardium of the left ventricle or atrium as a consequence of friction-induced injury induced by the prolapsing, hypermobile leaflets; (4) thrombi on the atrial surfaces of the leaflets or the atrial walls (Fig. 12-22B); and (5) focal calcifications at the base of the posterior mitral leaflet (Fig. 12-22C). Notably, mitral valve myxomatous degeneration can also occur as a secondary consequence of regurgitation of other etiologies (e.g., ischemic dysfunction).

Clinical Features. Most individuals diagnosed with MVP are asymptomatic; in such cases, the condition is discovered incidentally by auscultation of mid-systolic clicks, sometimes followed by a mid to late systolic murmur. The diagnosis is confirmed by echocardiography. A minority of patients have chest pain mimicking angina (although not exertional in nature), and a subset has dyspnea, presumably related to valvular insufficiency. Although the great majority of persons with MVP have no untoward effects, approximately 3% develop one of four serious complications: (1) infective endocarditis; (2) mitral insufficiency, sometimes with chordal rupture; (3) stroke or other systemic infarct, resulting from embolism of leaflet thrombi; or (4) arrhythmias, both ventricular and atrial. Rarely, MVP is the only finding in sudden cardiac death.

The risk of serious complications is very low in MVP discovered incidentally in young asymptomatic patients; the risk is higher for men, older patients, and those with arrhythmias or mitral regurgitation. Valve repair or replacement surgery can be done for symptomatic patients or those with increased risk for significant complications; indeed, in the United States, MVP is the most common cause for mitral valve surgery.

Figure 12-22 Myxomatous degeneration of the mitral valve. **A**, Long axis view (left ventricle is on the *right*) demonstrating hooding with prolapse of the posterior mitral leaflet into the left atrium (*arrow*). **B**, Opened valve, showing pronounced hooding of the posterior mitral leaflet with thrombotic plaques at sites of leaflet-left atrium contact (*arrows*). **C**, Opened valve with pronounced hooding (*double arrows*) in a patient who died suddenly. Note also mitral annular calcification (*arrowhead*). Normal heart valve (**D**) and myxomatous mitral valve (**E**). In myxomatous valves, collagen in the fibrosa is loose and disorganized, proteoglycan deposition (*asterisk*) in the spongiosa is markedly expanded, and elastin in the atrialis is disorganized. (**A**, Courtesy William D. Edwards, MD, Mayo Clinic, Rochester, Minn; **D, E**, Movat pentachrome stain, in which collagen is yellow, elastin is black, and proteoglycans are blue). From Rabkin E, et al: Activated interstitial myofibroblasts express catabolic enzymes and mediate matrix remodeling in myxomatous heart valves. *Circulation* 104:2525-2532, 2001.)

Rheumatic Fever and Rheumatic Heart Disease

Rheumatic fever (RF) is an acute, immunologically mediated, multisystem inflammatory disease classically occurring a few weeks after an episode of group A streptococcal pharyngitis; occasionally, RF can follow streptococcal infections at other sites, such as the skin. Acute rheumatic carditis is a common manifestation of active RF and may progress over time to chronic rheumatic heart disease (RHD), mainly manifesting as valvular abnormalities.

RHD is characterized principally by deforming fibrotic valvular disease, particularly involving the mitral valve; *indeed, RHD is virtually the only cause of mitral stenosis.* The incidence and mortality rate of RF and RHD have declined remarkably in many parts of the world over the past century, as a result of improved sanitation, and rapid diagnosis and treatment of streptococcal pharyngitis. Nevertheless, in developing countries, and in many crowded, economically depressed urban areas, RHD remains an important public health problem, affecting an estimated 15 million people.

Pathogenesis. Acute rheumatic fever results from host immune responses to group A streptococcal antigens that cross-react with host proteins. In particular, antibodies and CD4+ T cells directed against streptococcal M proteins can also in some cases recognize cardiac self-antigens. Antibody binding can activate complement, as well as recruit Fc-receptor bearing cells (neutrophils and macrophages); cytokine production by the stimulated T cells leads to macrophage activation (e.g., within Aschoff bodies). Damage to heart tissue may thus be caused by a combination of antibody- and T cell-mediated reactions (Chapter 6).

MORPHOLOGY

Key pathologic features of acute RF and chronic RHD are shown in Figure 12-23. During acute RF, focal inflammatory lesions are found in various tissues. Distinctive lesions occur in the heart, called **Aschoff bodies**, consisting of foci of T lymphocytes, occasional plasma cells, and plump activated macrophages called **Anitschkow cells** (pathognomonic for RF). These macrophages have abundant cytoplasm and central

round-to-ovoid nuclei (occasionally binucleate) in which the chromatin condenses into a central, slender, wavy ribbon (hence the designation “caterpillar cells”).

During acute RF, diffuse inflammation and Aschoff bodies may be found in any of the three layers of the heart, resulting in pericarditis, myocarditis, or endocarditis (**pancarditis**).

Inflammation of the endocardium and the left-sided valves typically results in fibrinoid necrosis within the cusps or tendinous cords. Overlying these necrotic foci and along the lines of closure are small (1 to 2 mm) vegetations, called **verrucae**. Thus, RHD is one of the forms of vegetative valve disease, each of which exhibit their own characteristic morphologic features (Fig. 12-24). Subendocardial lesions, perhaps exacerbated by regurgitant jets, can induce irregular thickenings called **MacCallum plaques**, usually in the left atrium.

The cardinal anatomic changes of the mitral valve in chronic RHD are **leaflet thickening, commissural fusion and shortening, and thickening and fusion of the tendinous cords** (Fig. 12-23D). In chronic disease the mitral valve is virtually always involved. The mitral valve is affected in isolation in roughly two thirds of RHD, and along with the aortic valve in another 25% of cases. Tricuspid valve involvement is

Figure 12-23 Acute and chronic rheumatic heart disease. **A**, Acute rheumatic mitral valvulitis superimposed on chronic rheumatic heart disease. Small vegetations (verrucae) are visible along the line of closure of the mitral valve leaflet (arrows). Previous episodes of rheumatic valvulitis have caused fibrous thickening and fusion of the chordae tendineae. **B**, Microscopic appearance of an *Aschoff body* in a patient with acute rheumatic carditis. The myocardium exhibits a circumscribed nodule of mixed mononuclear inflammatory cells with associated necrosis; within the inflammation, large activated macrophages show prominent nucleoli, as well as chromatin condensed into long, wavy ribbons (caterpillar cells; arrows). **C** and **D**, Mitral stenosis with diffuse fibrous thickening and distortion of the valve leaflets and commissural fusion (arrows, **C**), and thickening of the chordae tendineae (**D**). Note neovascularization of anterior mitral leaflet (arrow, **D**). **E**, Surgically resected specimen of rheumatic aortic stenosis, demonstrating thickening and distortion of the cusps with commissural fusion. (**E**, Reproduced from Schoen FJ, St. John-Sutton M: Contemporary issues in the pathology of valvular heart disease. *Hum Pathol* 18:568, 1967.)

infrequent, and the pulmonary valve is only rarely affected. Because of the increase in calcific aortic stenosis (see earlier) and the reduced frequency of RHD, rheumatic aortic stenosis now accounts for a small fraction of cases of acquired aortic stenosis.

In rheumatic mitral stenosis, calcification and fibrous bridging across the valvular commissures create “fish mouth” or “buttonhole” stenoses. With tight mitral stenosis, the left atrium progressively dilates and may harbor mural thrombi that can embolize. Long-standing congestive changes in the lungs may induce pulmonary vascular and parenchymal changes; over time, these can lead to right ventricular hypertrophy. The left ventricle is largely unaffected by isolated pure mitral stenosis. Microscopically, valves show organization of the acute inflammation, with post-inflammatory neovascularization and transmural fibrosis that obliterate the leaflet architecture. Aschoff bodies are rarely seen in surgical specimens or autopsy tissue from patients with chronic RHD, as a result of the long intervals between the initial insult and the development of the chronic deformity.

Clinical Features. RF is characterized by a constellation of findings: (1) migratory polyarthritis of the large joints, (2) pancarditis, (3) subcutaneous nodules, (4) erythema marginatum of the skin, and (5) Sydenham chorea, a neurologic disorder with involuntary rapid, purposeless movements. The diagnosis is established by the so-called Jones criteria: evidence of a preceding group A streptococcal infection, with the presence of two of the major manifestations listed earlier or one major and two minor manifestations (nonspecific signs and symptoms that include fever, arthralgia, or elevated blood levels of acute-phase reactants).

Acute RF typically appears 10 days to 6 weeks after a group A streptococcal infection in about 3% of patients. It occurs most often in children between ages 5 and 15, but first attacks can occur in middle to later life. Although pharyngeal cultures for streptococci are negative by the time the illness begins, antibodies to one or more streptococcal enzymes, such as streptolysin O and DNase B, can be detected in the sera of most patients with RF. The predominant clinical manifestations are carditis and arthritis, the latter more common in adults than in children. Arthritis typically begins with migratory polyarthritis (accompanied by fever) in which one large joint after another becomes painful and swollen for a period of days and then subsides spontaneously, leaving no residual disability. Clinical features related to *acute carditis* include pericardial friction rubs, tachycardia, and arrhythmias. Myocarditis can cause cardiac dilation that may culminate in functional mitral valve insufficiency or even heart failure. Approximately 1% of affected individuals die of fulminant RF involvement of the heart.

After an initial attack there is increased vulnerability to reactivation of the disease with subsequent pharyngeal infections, and the same manifestations are likely to appear with each recurrent attack. Damage to the valves is cumulative. Turbulence induced by ongoing valvular deformities leads to additional fibrosis. Clinical manifestations appear years or even decades after the initial episode of RF and depend on which cardiac valves are involved. In addition to various cardiac murmurs, cardiac hypertrophy and dilation, and

heart failure, individuals with chronic RHD may suffer from arrhythmias (particularly atrial fibrillation in the setting of mitral stenosis), thromboembolic complications, and infective endocarditis (see later). The long-term prognosis is highly variable. Surgical repair or prosthetic replacement of diseased valves has greatly improved the outlook for persons with RHD.

Infective Endocarditis

Infective endocarditis (IE) is a microbial infection of the heart valves or the mural endocardium that leads to the formation of vegetations composed of thrombotic debris and organisms, often associated with destruction of the underlying cardiac tissues. The aorta, aneurysms, other blood vessels, and prosthetic devices can also become infected. Although fungi and other classes of microorganisms can be responsible, most infections are bacterial (*bacterial endocarditis*). Prompt diagnosis, identification of the offending agent, and effective treatment of IE is important in limiting morbidity and mortality.

Traditionally, IE has been classified on clinical grounds into acute and subacute forms. This subdivision reflects the range of the disease severity and tempo, which are determined in large part by the virulence of the infecting microorganism and whether underlying cardiac disease is present. *Acute infective endocarditis* is typically caused by infection of a previously normal heart valve by a highly virulent organism (e.g., *Staphylococcus aureus*) that rapidly produces necrotizing and destructive lesions. These infections may be difficult to cure with antibiotics alone, and usually require surgery. Despite appropriate treatment, death can ensue within days to weeks. In contrast, *subacute IE* is characterized by organisms with lower virulence (e.g., viridans streptococci) that cause insidious infections of deformed valves with overall less destruction. In such cases the disease may pursue a protracted course of weeks to months, and cures can be achieved with antibiotics.

Pathogenesis. Although highly virulent organisms can infect previously normal valves, a variety of cardiac and vascular abnormalities increase the risk of developing IE. Rheumatic heart disease with valvular scarring has historically been the major antecedent disorder; as RHD becomes less common, it has been supplanted by mitral valve prolapse, degenerative calcific valvular stenosis, bicuspid aortic valve (whether calcified or not), artificial (prosthetic) valves, and unrepaired and repaired congenital defects.

The causal organisms differ among the major high-risk groups. Endocarditis of native but previously damaged or otherwise abnormal valves is caused most commonly (50% to 60% of cases) by *Streptococcus viridans*, a normal component of the oral cavity flora. In contrast, more virulent *S. aureus* organisms commonly found on the skin can infect either healthy or deformed valves and are responsible for 20% to 30% of cases overall; notably, *S. aureus* is the major offender in IE among intravenous drug abusers. Other bacterial causes include enterococci and the so-called HACEK group (*Haemophilus*, *Actinobacillus*, *Cardiobacterium*, *Eikenella*, and *Kingella*), all commensals in the oral cavity. Prosthetic valve endocarditis is caused most commonly by coagulase-negative staphylococci (e.g., *S. epidermidis*). Other agents causing endocarditis include gram-negative

Figure 12-24 Comparison of the four major forms of vegetative endocarditis. The rheumatic fever phase of rheumatic heart disease (RHD) is marked by small, warty vegetations along the lines of closure of the valve leaflets. Infective endocarditis (IE) is characterized by large, irregular masses on the valve cusps that can extend onto the chordae (see Fig. 12-25A). Nonbacterial thrombotic endocarditis (NBTE) typically exhibits small, bland vegetations, usually attached at the line of closure. One or many may be present (see Figure 12-26). Libman-Sacks endocarditis (LSE) has small or medium-sized vegetations on either or both sides of the valve leaflets.

bacilli and fungi. In about 10% of all cases of endocarditis, no organism can be isolated from the blood (“culture-negative” endocarditis); reasons include prior antibiotic therapy, difficulties in isolating the offending agent, or because deeply embedded organisms within the enlarging vegetation are not released into the blood.

Foremost among the factors predisposing to endocarditis are those that cause microorganism seeding into the blood stream (bacteremia or fungemia). The source may be an obvious infection elsewhere, a dental or surgical procedure, a contaminated needle shared by intravenous drug users, or seemingly trivial breaks in the epithelial barriers of the gut, oral cavity, or skin. In patients with valve abnormalities, or with known bacteremia, IE risk can be lowered by antibiotic prophylaxis.

common sites of infection, although the valves of the right heart may also be involved, particularly in intravenous drug abusers. Vegetations can be single or multiple and may involve more than one valve; they can occasionally erode into the underlying myocardium and produce an abscess (ring abscess; Fig. 12-25B). Vegetations are prone to embolization; because the embolic fragments often contain virulent organisms, abscesses frequently develop where they lodge, leading to sequelae such as septic infarcts or mycotic aneurysms.

The vegetations of subacute endocarditis are associated with less valvular destruction than those of acute endocarditis, although the distinction can be subtle. Microscopically, the vegetations of subacute IE typically exhibit granulation tissue at their bases indicative of healing. With time, fibrosis, calcification, and a chronic inflammatory infiltrate can develop.

MORPHOLOGY

Vegetations on heart valves are the classic hallmark of IE; these are friable, bulky, potentially destructive lesions containing fibrin, inflammatory cells, and bacteria or other organisms (Figs. 12-24 and 12-25). The aortic and mitral valves are the most

Clinical Features. Acute endocarditis has a stormy onset with rapidly developing fever, chills, weakness, and lassitude. Although fever is the most consistent sign of IE, it can be slight or absent, particularly in older adults, and the only manifestations may be nonspecific fatigue, loss of

Figure 12-25 Infective (bacterial) endocarditis. **A**, Endocarditis of mitral valve (subacute, caused by *Streptococcus viridans*). The large, friable vegetations are denoted by arrows. **B**, Acute endocarditis of congenitally bicuspid aortic valve (caused by *Staphylococcus aureus*) with extensive cuspal destruction and ring abscess (arrow).

Table 12-9 Diagnostic Criteria for Infective Endocarditis*

Pathologic Criteria	
Microorganisms, demonstrated by culture or histologic examination, in a vegetation, embolus from a vegetation, or intracardiac abscess	
Histologic confirmation of active endocarditis in vegetation or intracardiac abscess	
Clinical Criteria	
Major	
Blood culture(s) positive for a characteristic organism or persistently positive for an unusual organism	
Echocardiographic identification of a valve-related or implant-related mass or abscess, or partial separation of artificial valve	
New valvular regurgitation	
Minor	
Predisposing heart lesion or intravenous drug use	
Fever	
Vascular lesions, including arterial petechiae, subungual/splinter hemorrhages, emboli, septic infarcts, mycotic aneurysm, intracranial hemorrhage, Janeway lesions [†]	
Immunological phenomena, including glomerulonephritis, Osler nodes, [‡] Roth spots, [§] rheumatoid factor	
Microbiologic evidence, including a single culture positive for an unusual organism	
Echocardiographic findings consistent with but not diagnostic of endocarditis, including worsening or changing of a preexistent murmur	

*Diagnosis by these guidelines, often called the Duke Criteria, requires either pathologic or clinical criteria; if clinical criteria are used, 2 major, 1 major + 3 minor, or 5 minor criteria are required for diagnosis.

[†]Janeway lesions are small erythematous or hemorrhagic, macular, nontender lesions on the palms and soles and are the consequence of septic embolic events.

[‡]Osler nodes are small, tender subcutaneous nodules that develop in the pulp of the digits or occasionally more proximally in the fingers and persist for hours to several days.

[§]Roth spots are oval retinal hemorrhages with pale centers.

Modified from Durack DT, et al: New criteria for diagnosis of infective endocarditis: utilization of specific echocardiographic findings. *Am J Med*, 96:200, 1994, and Karchmer AW: Infective Endocarditis. In Braunwald E, Zipes DP, Libby P (eds): *Heart Disease. A Textbook of Cardiovascular Medicine*, 6th ed. Philadelphia, WB Saunders, 2001, p 1723.

weight, and a flulike syndrome. Murmurs are present in 90% of patients with left-sided IE, either from a new valvular defect or from a preexisting abnormality. The so-called modified Duke criteria (Table 12-9) facilitate evaluation of individuals with suspected IE that takes into account predisposing factors, physical findings, blood

culture results, echocardiographic findings, and laboratory information.

Complications of IE generally begin within the first few weeks of onset, and can include glomerular antigen-antibody complex deposition causing glomerulonephritis (Chapter 20). Earlier diagnosis and effective treatment has nearly eliminated some previously common clinical manifestations of long-standing IE—for example, microthromboemboli (manifest as splinter or subungual hemorrhages), erythematous or hemorrhagic nontender lesions on the palms or soles (Janeway lesions), subcutaneous nodules in the pulp of the digits (Osler nodes), and retinal hemorrhages in the eyes (Roth spots).

Noninfected Vegetations

Noninfected (sterile) vegetations occur in nonbacterial thrombotic endocarditis and the endocarditis of systemic lupus erythematosus (SLE), called Libman-Sacks endocarditis (see later).

Nonbacterial Thrombotic Endocarditis

Nonbacterial thrombotic endocarditis (NBTE) is characterized by the deposition of small sterile thrombi on the leaflets of the cardiac valves (Figs. 12-24 and 12-26). The lesions are 1 to 5 mm in size, and occur as single or multiple vegetations along the line of closure of the leaflets or cusps. Histologically, they comprise bland thrombi that are loosely attached to the underlying valve; the vegetations are not invasive and do not elicit any inflammatory reaction. Thus, although the local effect of the vegetations is usually trivial, they can be the source of systemic emboli that produce significant infarcts in the brain, heart, or elsewhere.

NBTE is often encountered in debilitated patients, such as those with cancer or sepsis—hence the previous term *marantic endocarditis* (root word *marasmus*, relating to malnutrition). It frequently occurs concomitantly with deep venous thromboses, pulmonary emboli, or other findings suggesting an underlying systemic hypercoagulable state (Chapter 4). Indeed, there is a striking association with mucinous adenocarcinomas, potentially relating to the procoagulant effects of tumor-derived mucin or tissue

Figure 12-26 Nonbacterial thrombotic endocarditis (NBTE). **A**, Nearly complete row of thrombotic vegetations along the line of closure of the mitral valve leaflets (arrows). **B**, Photomicrograph of NBTE, showing bland thrombus, with virtually no inflammation in the valve cusp (c) or the thrombotic deposit (t). The thrombus is only loosely attached to the cusp (arrow).

factor that can also cause migratory thrombophlebitis (Trousseau syndrome, [Chapter 4](#)). Endocardial trauma, as from an indwelling catheter, is another well-recognized predisposing condition, and right-sided valvular and endocardial thrombotic lesions frequently track along the course of pulmonary artery catheters.

Endocarditis of Systemic Lupus Erythematosus (Libman-Sacks Disease)

Mitral and tricuspid valvulitis with small, sterile vegetations, called *Libman-Sacks endocarditis*, is occasionally encountered in systemic lupus erythematosus. Due to the use of steroids, the incidence of this complication has been greatly reduced. The lesions are small (1 to 4 mm in diameter), single or multiple, sterile, pink vegetations with a warty (verrucous) appearance. They may be located on the undersurfaces of the atrioventricular valves, on the valvular endocardium, on the chords, or on the mural endocardium of atria or ventricles. Histologically the vegetations consist of a finely granular, fibrinous eosinophilic material containing cellular debris including nuclear remnants. Vegetations are often associated with an intense valvulitis, characterized by fibrinoid necrosis of the valve substance and reflecting the activation of complement and recruitment of Fc-receptor-bearing cells.

Thrombotic heart valve lesions with sterile vegetations or rarely fibrous thickening can occur in the setting of the antiphospholipid syndrome, which can also induce a hypercoagulable state ([Chapter 4](#)). The mitral valve is more frequently involved than the aortic valve, and regurgitation is the usual functional abnormality.

Carcinoid Heart Disease

The *carcinoid syndrome* refers to a systemic disorder marked by flushing, diarrhea, dermatitis, and bronchoconstriction that is caused by bioactive compounds such as serotonin released by *carcinoid tumors* ([Chapter 17](#)). *Carcinoid heart disease* refers to the cardiac manifestations caused by the bioactive compounds and occurs in roughly half of the patients in whom the systemic syndrome develops. Cardiac lesions do not typically occur until there is a

massive hepatic metastatic burden, since the liver normally catabolizes circulating mediators before they can affect the heart. Classically, endocardium and valves of the right heart are primarily affected since they are the first cardiac tissues bathed by the mediators released by gastrointestinal carcinoid tumors. The left side of the heart is afforded some measure of protection because the pulmonary vascular bed degrades the mediators. However, left heart carcinoid lesions can occur in the setting of atrial or septal defects and right-to-left flow, or can be elicited by primary pulmonary carcinoid tumors.

Pathogenesis. The mediators elaborated by carcinoid tumors include serotonin (5-hydroxytryptamine), kallikrein, bradykinin, histamine, prostaglandins, and tachykinins. Although it is not clear which of these is causal, plasma levels of serotonin and urinary excretion of the serotonin metabolite 5-hydroxyindoleacetic acid correlate with the severity of the cardiac lesions. The valvular plaques in carcinoid syndrome are also similar to lesions that occur in patients taking fenfluramine (an appetite suppressant) or ergot alkaloids (for migraine headaches); interestingly, these agents affect systemic serotonin metabolism. Similarly, left-sided plaques have been reported following methysergide or ergotamine therapy for migraines; notably, these drugs are metabolized to serotonin as they pass through the pulmonary vasculature. Despite this tantalizing evidence, however, it is not known how serotonin might induce the observed cardiac changes, nor has it been proven that treatment with serotonin inhibitors has any effect on the development or progression of heart lesions.

MORPHOLOGY

The cardiovascular lesions associated with the carcinoid syndrome are distinctive, glistening white intimal plaque-like thickenings of the endocardial surfaces of the cardiac chambers and valve leaflets ([Fig. 12-27](#)). The lesions are composed of smooth muscle cells and sparse collagen fibers embedded in an acid mucopolysaccharide-rich matrix material. Underlying structures are intact. With right-sided involvement, typical findings are tricuspid insufficiency and pulmonary stenosis.

Figure 12-27 Carcinoid heart disease. **A**, Characteristic endocardial fibrotic lesion involving the right ventricle and tricuspid valve. **B**, Microscopic appearance of carcinoid heart disease with intimal thickening. Movat stain shows myocardial elastic tissue (black) underlying the acid mucopolysaccharide-rich lesion (blue-green). The underlying myocardium is unaffected.

Complications of Prosthetic Valves

Replacement of damaged cardiac valves with prostheses is a common and often lifesaving mode of therapy. There are two types of valvular prostheses:

- *Mechanical valves.* These consist of different configurations of rigid nonphysiologic material, such as caged balls, tilting disks, or hinged semicircular flaps (bi-leaflet tilting disk valves).
- *Tissue valves (bioprostheses).* Porcine aortic valves or bovine pericardium are preserved in a dilute glutaraldehyde solution and then mounted on a prosthetic frame. Alternatively, frozen human valves from deceased donors (called cryopreserved “homografts”) can also be used. Tissue valves are flexible and function similarly to natural semilunar valves. However, the chemical treatment of the animal valves cross-links the valvular proteins, especially collagen, and renders the tissue nonviable. Similarly, the freezing and thawing of human homografts may also render them largely nonviable.

Approximately 60% of substitute valve recipients develop a serious prosthesis-related problem within 10 years after the surgery. The complications that occur depend on which type of valve has been implanted (Table 12-10 and Fig. 12-28).

- *Thromboembolism* is the major consideration with mechanical valves (Fig. 12-28A); this may take the form of either thrombotic occlusion of the prosthesis or emboli released from thrombi formed on the valve. Because blood flow in all mechanical devices is non-laminar, foci of turbulence and stasis are produced by prostheses that predispose to thrombus formation. The risk of such complications necessitates long-term anticoagulation in all individuals with mechanical valves,

Table 12-10 Complications of Cardiac Valve Prostheses

Thrombosis/thromboembolism
Anticoagulant-related hemorrhage
Prosthetic valve endocarditis
Structural deterioration (intrinsic)
Wear, fracture, poppet failure in ball valves, cuspal tear, calcification
Other forms of dysfunction
Inadequate healing (paravalvular leak), exuberant healing (obstruction), hemolysis

with the attendant risk of hemorrhagic stroke or other forms of serious bleeding.

- *Structural deterioration* rarely causes failure of mechanical valves in current use. However, virtually all bioprostheses eventually become incompetent due to calcification and/or tearing (Fig. 12-28B).
- *Infective endocarditis* is a potentially serious complication of any valve replacement. The vegetations of prosthetic valve endocarditis are usually located at the prosthesis-tissue interface, and often cause the formation of a ring abscess, which can eventually lead to a paravalvular regurgitant blood leak. In addition, vegetations may directly involve the tissue of bioprosthetic valvular cusps. The major organisms causing such infections are staphylococcal skin contaminants (e.g., *S. epidermidis*), *S. aureus*, streptococci, and fungi.
- Other complications include paravalvular leak due to inadequate healing, obstruction due to overgrowth of fibrous tissue during healing, valve-orifice disproportion (where the effective valve area is too small for the needs of the patient, leading to a relative stenosis), intravascular hemolysis due to high shear forces, or excessive noise owing to hard contacts of moving rigid parts.

Figure 12-28 Complications of artificial heart valves. **A**, Thrombosis of a mechanical prosthetic valve. **B**, Calcification with secondary tearing of a porcine bioprosthetic heart valve, viewed from the inflow aspect.

KEY CONCEPTS

Valvular Heart Disease

- Valve pathology can lead to occlusion (*stenosis*) and/or to regurgitation (*insufficiency*); acquired aortic and mitral valves stenoses account for approximately two thirds of all valve disease.
- Valve calcification is a degenerative process that typically results in stenosis; abnormal matrix synthesis and turnover result in myxomatous degeneration and insufficiency.
- Inflammatory valve diseases lead to post-inflammatory neovascularization and scarring. Rheumatic heart disease results from anti-streptococcal antibodies that cross-react with cardiac tissues; it most commonly affects the mitral valve and is responsible for 99% of acquired mitral stenoses.
- Infective endocarditis can be aggressive and rapidly destroy normal valves (acute IE), or can be indolent and minimally destructive of previously abnormal valves (sub-acute IE). Systemic embolization can produce septic infarcts.
- Nonbacterial thrombotic endocarditis occurs on previously normal valves due to hypercoagulable states; embolization is an important complication.
- Mechanical prosthetic valves have thrombotic or hemorrhagic complications related to the nonlaminar flow of blood and the need for chronic anti-coagulation. Bioprosthetic valves are nonviable and are therefore susceptible to long-term calcification and/or degeneration with tearing. Both types of valves have an increased risk of developing endocarditis relative to native valves.

Cardiomyopathies

Although the term *cardiomyopathy* (literally, heart muscle disease) has been historically applied to any cardiac dysfunction resulting from a myocardial abnormality, a more nuanced definition is probably appropriate. Thus—stimulated by the recognition of new phenotypes and the advent of more sophisticated molecular characterization—an expert panel has suggested: “[C]ardiomyopathies are a heterogeneous group of diseases of the myocardium associated with mechanical and/or electrical dysfunction that usually (but not invariably) exhibit inappropriate ventricular hypertrophy or dilatation and are due to a variety of causes that frequently are genetic. Cardiomyopathies either are confined to the heart or are part of generalized systemic disorders, often leading to cardiovascular death or progressive heart failure-related disability.”

Thus, cardiomyopathies manifest as failure of myocardial performance; this can be mechanical (e.g., diastolic or systolic dysfunction) leading to CHF, or can culminate in life-threatening arrhythmias. *Primary* cardiomyopathies can be genetic or acquired diseases of myocardium, whereas *secondary* cardiomyopathies have myocardial involvement as a component of a systemic or multiorgan disorder. A major advance in our understanding of cardiomyopathies stems from the frequent identification of underlying genetic causes, including mutations in myocardial proteins involved in contraction, cell-cell contacts, and the cytoskeleton. These, in turn, lead to abnormal

contraction or relaxation, or to dysregulated ion transport across cell membranes. Although chronic myocardial dysfunction secondary to ischemia, valvular abnormalities, or hypertension can cause significant ventricular dysfunction (as described previously), these conditions should not be denoted as cardiomyopathies.

Cardiomyopathies can be classified according to a variety of criteria, including the underlying genetic basis of dysfunction; indeed, we have already discussed a number of the arrhythmia-inducing channelopathies, which may be included in cardiomyopathies. However, we will confine our list of cardiomyopathies to disorders that produce anatomic abnormalities in the heart. These fall into three pathologic patterns (Fig. 12-29 and Table 12-11):

- Dilated cardiomyopathy (including arrhythmogenic right ventricular cardiomyopathy)
- Hypertrophic cardiomyopathy
- Restrictive cardiomyopathy

Among the three major patterns, dilated cardiomyopathy is most common (90% of cases), and restrictive cardiomyopathy is the least frequent. Within each pattern, there is a spectrum of clinical severity, and in some cases clinical features overlap among the groups. In addition, each of these patterns can be caused by a specific identifiable cause, or can be idiopathic (Tables 12-11 and 12-12).

Figure 12-29 The three major morphologic patterns of cardiomyopathy. Dilated cardiomyopathy leads primarily to systolic dysfunction, whereas restrictive and hypertrophic cardiomyopathies result in diastolic dysfunction. Note the changes in atrial and/or ventricular wall thickness. Ao, Aorta; LA, left atrium; LV, left ventricle.

Table 12-11 Cardiomyopathy and Indirect Myocardial Dysfunction: Functional Patterns and Causes

Functional Pattern	Left Ventricular Ejection Fraction*	Mechanisms of Heart Failure	Causes of Phenotype	Indirect Myocardial Dysfunction (Mimicking Cardiomyopathy)
Dilated	<40%	Impairment of contractility (systolic dysfunction)	Genetic; alcohol; peripartum; myocarditis; hemochromatosis; chronic anemia; doxorubicin (Adriamycin) toxicity; sarcoidosis; idiopathic	Ischemic heart disease; valvular heart disease; hypertensive heart disease; congenital heart disease
Hypertrophic	50% to 80%	Impairment of compliance (diastolic dysfunction)	Genetic; Friedreich ataxia; storage diseases; infants of diabetic mother	Hypertensive heart disease; aortic stenosis
Restrictive	45% to 90%	Impairment of compliance (diastolic dysfunction)	Amyloidosis; radiation-induced fibrosis; idiopathic	Pericardial constriction

*Normal, approximately 50% to 65%.

Dilated Cardiomyopathy

Dilated cardiomyopathy (DCM) is characterized morphologically and functionally by progressive cardiac dilation and contractile (systolic) dysfunction, usually with concomitant hypertrophy. Many cases are familial, but the

DCM phenotype can result from diverse causes, both primary and secondary.

Pathogenesis. By the time of diagnosis, DCM has typically progressed to end-stage disease; the heart is dilated and poorly contractile. Unfortunately, at that point, even an exhaustive evaluation frequently fails to suggest a specific etiology. Increasingly, familial (genetic) forms of DCM are recognized, but the final pathology can also result from various acquired myocardial insults; as this implies, several different pathways can lead to DCM (Fig. 12-31).

- **Genetic Influences.** DCM is familial in at least 30% to 50% of cases, in which it is caused by mutations in a diverse group of more than 20 genes encoding proteins involved in the cytoskeleton, sarcolemma, and nuclear envelope (laminin A/C). In particular, mutations in *TTN*, a gene that encodes titin (so-called because it is the largest protein expressed in humans), may account for approximately 20% of all cases of DCM (Fig. 12-30).

In the genetic forms of DCM, autosomal dominant inheritance is the predominant pattern; X-linked, autosomal recessive, and mitochondrial inheritance are less common. In some families there are deletions in mitochondrial genes that result in defects in oxidative phosphorylation; in others there are mutations in genes encoding enzymes involved in β -oxidation of fatty acids. Mitochondrial defects typically manifest in the pediatric population, while X-linked DCM typically presents after puberty and into early adulthood. X-linked cardiomyopathy can also be associated with mutations affecting the membrane-associated dystrophin protein that couples cytoskeleton to the extracellular matrix; recall that dystrophin is mutated in the most common skeletal myopathies (i.e., Duchenne and Becker muscular dystrophies; Chapter 27). Some patients and families with dystrophin gene mutations have DCM as the primary clinical feature. Interestingly, and probably resulting from the common developmental origin of contractile myocytes and conduction elements, congenital abnormalities of conduction may also be associated with DCM.

- **Myocarditis.** Sequential endomyocardial biopsies have documented progression from myocarditis to DCM. In other studies, the detection of the genetic fingerprints of coxsackie B and other viruses within myocardium of patients with DCM suggests that viral myocarditis can be causal (see later discussion).
- **Alcohol and other toxins.** Alcohol abuse is strongly associated with the development of DCM, raising the

Figure 12-30 Schematic of a myocyte, showing key proteins mutated in dilated cardiomyopathy (red labels), hypertrophic cardiomyopathy (blue labels), or both (green labels). Mutations in titin (the largest known human protein at approximately 30,000 amino acids) account for approximately 20% of all dilated cardiomyopathy. Titin spans the sarcomere and connects the Z and M bands thereby limiting the passive range of motion of the sarcomere as it is stretched. Titin also functions like a molecular spring, with domains that unfold when the protein is stretched and refold when the tension is removed, thereby impacting the passive elasticity of striated muscle.

possibility that ethanol toxicity (Chapter 9) or a secondary nutritional disturbance can underlie myocardial injury. Alcohol or its metabolites (especially acetaldehyde) have a direct toxic effect on the myocardium. Moreover, chronic alcoholism may be associated with thiamine deficiency, which can lead to beriberi heart disease (also indistinguishable from DCM). Nevertheless, no morphologic features serve to distinguish *alcoholic cardiomyopathy* from DCM of other causes.

In other cases, some other toxic insult can progress to eventual myocardial failure. Particularly important is myocardial injury caused by certain chemotherapeutic agents, including doxorubicin (Adriamycin), and even targeted cancer therapeutics (e.g., tyrosine kinase inhibitors). Cobalt is an example of a heavy metal with cardiotoxicity and has caused DCM in the setting of inadvertent tainting (e.g., in beer production).

- **Childbirth.** A special form of DCM, termed *peripartum cardiomyopathy*, can occur late in pregnancy or up to months postpartum. The mechanism underlying this entity is poorly understood but is probably multifactorial. Pregnancy-associated hypertension, volume overload, nutritional deficiency, other metabolic derangements, or an as yet poorly characterized immunological reaction have been proposed as causes. Recent work suggests that the primary defect is a microvascular angiogenic imbalance within the myocardium leading to functional ischemic injury. Thus, peripartum

cardiomyopathy can be elicited in mouse models by increased levels of circulating antiangiogenic mediators including vascular endothelial growth factor inhibitors (e.g., sFLT1, as occurs with preeclampsia) or antiangiogenic cleavage products of the hormone prolactin (which rises late in pregnancy). Proangiogenic approaches, including the blockade of prolactin secretion by bromocriptine, represent new therapeutic strategies for treating this disease.

- **Iron overload** in the heart can result from either hereditary hemochromatosis (Chapter 18) or from multiple transfusions. DCM is the most common manifestation of such iron excess, and may be caused by interference with metal-dependent enzyme systems or to injury from iron-mediated production of reactive oxygen species.
- **Supraphysiologic stress** can also result in DCM. This can happen with persistent tachycardia, hyperthyroidism, or even during development, as in the fetuses of insulin-dependent diabetic mothers. *Excess catecholamines*, in particular, may result in multifocal myocardial contraction band necrosis that can eventually progress to DCM. This can happen in individuals with *pheochromocytomas*, tumors that elaborate epinephrine (Chapter 24); use of cocaine or vasopressor agents such as dopamine can have similar consequences. Such “catecholamine effect” also occurs in the setting of intense autonomic stimulation, for example, secondary to intracranial

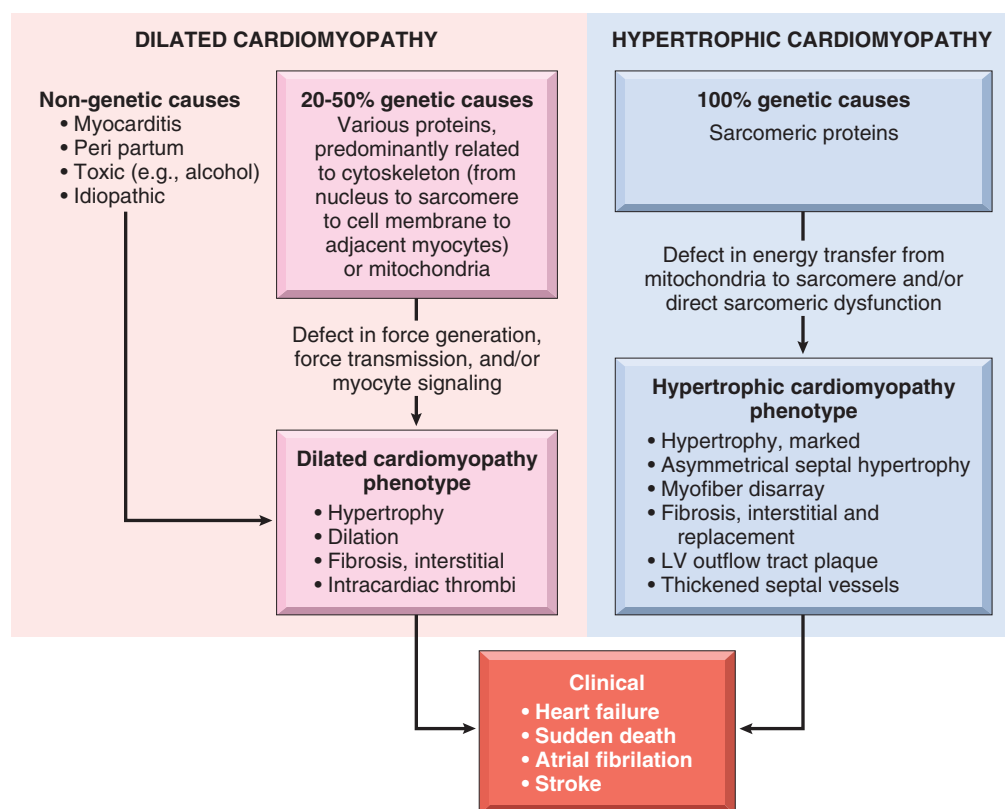

Figure 12-31 Causes and consequences of dilated and hypertrophic cardiomyopathy. Some dilated cardiomyopathies and virtually all hypertrophic cardiomyopathies are genetic in origin. The genetic causes of dilated cardiomyopathy involve mutations in any of a wide range of genes. They encode proteins predominantly of the cytoskeleton, but also the sarcomere, mitochondria, and nuclear envelope. In contrast, all of the mutated genes that cause hypertrophic cardiomyopathy encode proteins of the sarcomere. Although these two forms of cardiomyopathy differ greatly in subcellular basis and morphologic phenotypes, they share a common set of clinical complications. LV, left ventricle.

lesions or emotional duress. Thus, *takotsubo cardiomyopathy* is an entity characterized by left ventricular contractile dysfunction following extreme psychological stress; affected myocardium may be stunned or show multifocal contraction band necrosis. For unclear reasons, the left ventricular apex is most often affected leading to “apical ballooning” that resembles a “takotsubo,” Japanese for “fishing pot for trapping octopus” (hence, the name).

The mechanism of catecholamine cardiotoxicity is uncertain, but likely relates either to direct myocyte toxicity due to calcium overload or to focal vasoconstriction in the coronary arterial macro- or microcirculation in the face of an increased heart rate. Similar changes may be encountered in individuals who have recovered from hypotensive episodes or have been resuscitated from a cardiac arrest; in such cases, the damage is a result of ischemia-reperfusion (see earlier) with subsequent inflammation.

regurgitation). Either the coronary arteries are free of significant narrowing or the obstructions present are insufficient to explain the degree of cardiac dysfunction.

The histologic abnormalities in DCM are nonspecific and usually do not point to a specific etiology. Most muscle cells are hypertrophied with enlarged nuclei, but some are attenuated, stretched, and irregular. Interstitial and endocardial fibrosis of variable degree is present, and small subendocardial scars may replace individual cells or groups of cells, probably reflecting healing of previous ischemic necrosis of myocytes caused by hypertrophy-induced imbalance between perfusion and demand. Moreover, the severity of morphologic changes may not reflect either the degree of dysfunction or the patient’s prognosis.

MORPHOLOGY

In DCM the heart is usually enlarged, heavy (often weighing two to three times normal), and flabby, due to dilation of all chambers (Fig. 12-32). Mural thrombi are common and may be a source of thromboemboli. There are no primary valvular alterations; if mitral (or tricuspid) regurgitation is present, it results from left (or right) ventricular chamber dilation (*functional*

Clinical Features. DCM can occur at any age, including in childhood, but it most commonly affects individuals between the ages of 20 and 50. **It presents with slowly progressive signs and symptoms of CHF including dyspnea, easy fatigability, and poor exertional capacity. At the end stage, ejection fractions are typically less than 25% (normal = 50% to 65%).** Secondary mitral regurgitation and abnormal cardiac rhythms are common, and embolism from intracardiac thrombi can occur. Death usually results from progressive cardiac failure or arrhythmia, and can occur suddenly. Although the annual mortality is high (10% to 50%), some severely affected patients respond well to pharmacologic therapy. Cardiac transplantation is also

Figure 12-32 Dilated cardiomyopathy. **A**, Four-chamber dilatation and hypertrophy are evident. There is a mural thrombus (*arrow*) at the apex of the left ventricle (on the *right* in this apical four-chamber view). The coronary arteries were patent. **B**, Histologic section demonstrating variable myocyte hypertrophy and interstitial fibrosis (collagen is highlighted as blue in this Masson trichrome stain).

increasingly performed, and long-term ventricular assist can be beneficial. Interestingly, in some patients, relatively short-term mechanical cardiac support can induce durable improvement of cardiac function.

Arrhythmogenic Right Ventricular Cardiomyopathy

Arrhythmogenic right ventricular cardiomyopathy (ARVC) is an inherited disease of myocardium causing right ventricular failure and rhythm disturbances (particularly ventricular tachycardia or fibrillation) with sudden death. Left-sided involvement with left-sided heart failure may also occur. Morphologically, the right ventricular wall is severely thinned due to loss of myocytes, accompanied by extensive

fatty infiltration and fibrosis (*Fig. 12-33*). Although myocardial inflammation may be present, ARVC is not considered an inflammatory cardiomyopathy. Classical ARVC has autosomal dominant inheritance with a variable penetrance. The disease has been attributed to defective cell adhesion proteins in the desmosomes that link adjacent cardiac myocytes. *Naxos syndrome* is a disorder characterized by arrhythmogenic right ventricular cardiomyopathy and hyperkeratosis of plantar palmar skin surfaces specifically associated with mutations in the gene encoding the desmosome-associated protein plakoglobin.

Hypertrophic Cardiomyopathy

Hypertrophic cardiomyopathy (HCM) is a common (incidence, 1 in 500), clinically heterogeneous, genetic

Figure 12-33 Arrhythmogenic right ventricular cardiomyopathy. **A**, Gross photograph, showing dilation of the right ventricle and near-transmural replacement of the right ventricular free-wall by fat and fibrosis. The left ventricle has a virtually normal configuration in this case, but can also be involved by the disease process. **B**, Histologic section of the right ventricular free wall, demonstrating replacement of myocardium (red) by fibrosis (blue, *arrow*) and fat (Masson trichrome stain).

disorder characterized by myocardial hypertrophy, poorly compliant left ventricular myocardium leading to abnormal diastolic filling, and (in about one third of cases) intermittent ventricular outflow obstruction. It is the leading cause of left ventricular hypertrophy unexplained by other clinical or pathologic causes. The heart is thick-walled, heavy, and *hypercontracting*, in striking contrast to the flabby, *hypocontracting* heart of DCM. HCM causes primarily diastolic dysfunction; systolic function is usually preserved. The two most common diseases that must be distinguished clinically from HCM are deposition diseases (e.g., amyloidosis, Fabry disease) and hypertensive heart disease coupled with age-related subaortic septal hypertrophy (see earlier discussion under Hypertensive Heart Disease). Occasionally, valvular or congenital subvalvular aortic stenosis can also mimic HCM.

Pathogenesis. In most cases, the pattern of transmission is autosomal dominant with variable penetrance. HCM is caused by mutations in any one of several genes that encode sarcomeric proteins; there are more than 400 different known mutations in nine different genes, most being missense mutations. Mutations causing HCM are found most commonly in the gene encoding β -myosin heavy chain (β -MHC), followed by the genes coding for cardiac TnT, α -tropomyosin, and myosin-binding protein C (MYBP-C); overall, these account for 70% to 80% of all cases. Different affected families may have distinct mutations involving the same protein. For example, approximately 50 different mutations of β -MHC are known to cause HCM. The prognosis of HCM varies widely and correlates strongly with specific mutations. Although it is clear that these genetic defects are critical to the etiology of HCM, the sequence of events leading from mutations to disease is still poorly understood.

As discussed above, HCM is a disease caused by mutations in proteins of the sarcomere. Although such sarcomeric alterations have been thought to be pathologic on the basis of abnormal cardiac contraction causing a secondary compensatory hypertrophy, newer evidence suggests that HCM may instead arise from defective energy transfer

from its source of generation (mitochondria) to its site of use (sarcomeres). In addition, the interstitial fibrosis in HCM probably occurs secondary to exaggerated responses of the myocardial fibroblasts to the primary myocardial dysfunction. In contrast, DCM is mostly associated with abnormalities of cytoskeletal proteins (Fig. 12-30), and can be conceptualized as a disease of abnormal force generation, force transmission, or myocyte signaling. To complicate matters, mutations in certain genes, depicted in Figure 12-30, can give rise to either HCM or DCM, depending on the site and nature of the mutation.

MORPHOLOGY

The essential feature of HCM is **massive myocardial hypertrophy, usually without ventricular dilation** (Fig. 12-34). The classic pattern involves disproportionate thickening of the ventricular septum relative to the left ventricle free wall (with a ratio of septum to free wall greater than 3:1), termed **asymmetric septal hypertrophy**. In about 10% of cases, the hypertrophy is concentric and symmetrical. On longitudinal sectioning, the normally round-to-ovoid left ventricular cavity may be compressed into a “banana-like” configuration by bulging of the ventricular septum into the lumen (Fig. 12-34A). Although marked hypertrophy can involve the entire septum, it is usually most prominent in the subaortic region. The left ventricular outflow tract often exhibits a fibrous endocardial plaque associated with thickening of the anterior mitral leaflet. Both findings result from contact of the anterior mitral leaflet with the septum during ventricular systole; they correlate with the echocardiographic “systolic anterior motion” of the anterior leaflet, with functional left ventricular outflow tract obstruction during mid-systole.

The most important histologic features of HCM myocardium are (1) massive myocyte hypertrophy, with transverse myocyte diameters frequently greater than 40 μ m (normal, approximately 15 μ m); (2) haphazard disarray of bundles of myocytes, individual myocytes, and contractile elements in sarcomeres within cells (termed **myofiber disarray**); and (3) interstitial and replacement fibrosis (Fig. 12-34B).

Figure 12-34 Hypertrophic cardiomyopathy with asymmetric septal hypertrophy. **A**, The septal muscle bulges into the left ventricular outflow tract, and the left atrium is enlarged. The anterior mitral leaflet has been reflected away from the septum to reveal a fibrous endocardial plaque (arrow) (see text). **B**, Histologic appearance demonstrating myocyte disarray, extreme hypertrophy, and exaggerated myocyte branching, as well as the characteristic interstitial fibrosis (collagen is blue in this Masson trichrome stain).

Clinical Features. The central abnormality in HCM is reduced stroke volume due to impaired diastolic filling. This is a consequence of a reduced chamber size, as well as the reduced compliance of the massively hypertrophied left ventricle. In addition, approximately 25% of patients with HCM have dynamic obstruction to the left ventricular outflow. The compromised cardiac output in conjunction with a secondary increase in pulmonary venous pressure explains the exertional dyspnea seen in these patients. Auscultation discloses a harsh systolic ejection murmur, caused by the ventricular outflow obstruction as the anterior mitral leaflet moves toward the ventricular septum during systole. Because of the massive hypertrophy, high left ventricular chamber pressure, and frequently thick-walled intramural arteries, focal myocardial ischemia commonly results, even in the absence of concomitant coronary artery disease. Major clinical problems in HCM are atrial fibrillation, mural thrombus formation leading to embolization and possible stroke, intractable cardiac failure, ventricular arrhythmias, and, not infrequently, sudden death, especially with certain specific mutations. Indeed, HCM is one of the most common causes of sudden, otherwise unexplained death in young athletes.

The natural history of HCM is highly variable. Most patients can be helped by pharmacologic intervention (e.g., β -adrenergic blockade) to decrease heart rate and contractility. Some benefit can also be gained by reducing the septal myocardial mass, thus relieving the outflow tract obstruction. This can be achieved either by surgical excision of muscle or by carefully controlled septal infarction through a catheter-based infusion of alcohol.

Restrictive Cardiomyopathy

Restrictive cardiomyopathy is characterized by a primary decrease in ventricular compliance, resulting in impaired ventricular filling during diastole. Because the contractile (systolic) function of the left ventricle is usually unaffected, the functional abnormality can be confused with that of constrictive pericarditis or HCM. Restrictive cardiomyopathy can be idiopathic or associated with distinct diseases or processes that affect the myocardium, principally radiation fibrosis, amyloidosis, sarcoidosis, metastatic tumors, or the deposition of metabolites that accumulate due to inborn errors of metabolism.

The morphologic features are not distinctive. The ventricles are of approximately normal size or slightly enlarged, the cavities are not dilated, and the myocardium is firm and noncompliant. Biatrial dilation is commonly observed. Microscopically, there may be only patchy or diffuse interstitial fibrosis, which can vary from minimal to extensive. Endomyocardial biopsy can often reveal a specific etiology. An important specific subgroup is amyloidosis (described later).

Several other restrictive conditions merit brief mention.

- *Endomyocardial fibrosis* is principally a disease of children and young adults in Africa and other tropical areas, characterized by fibrosis of the ventricular endocardium and subendocardium that extends from the apex upward, often involving the tricuspid and mitral valves. The fibrous tissue markedly diminishes the volume and compliance of affected chambers and so

causes a restrictive functional defect. Ventricular mural thrombi sometimes develop, and indeed the endocardial fibrosis may result from thrombus organization. The etiology is unknown.

- *Loeffler endomyocarditis* also results in endomyocardial fibrosis, typically with large mural thrombi, with an overall morphology similar to the tropical disease. However, in addition to the cardiac changes, there is often a peripheral eosinophilia and eosinophilic infiltrates in multiple organs, including the heart. The release of toxic products of eosinophils, especially major basic protein, is postulated to initiate endomyocardial necrosis, followed by scarring of the necrotic area, layering of the endocardium by thrombus, and finally organization of the thrombus. Many patients with Loeffler endomyocarditis have a myeloproliferative disorder associated with chromosomal rearrangements involving either the platelet-derived growth factor receptor (PDGFR)- α or - β genes (Chapter 13). These rearrangements produce fusion genes that encode constitutively active PDGFR tyrosine kinases. Treatment of such patients with the tyrosine kinase inhibitor imatinib has resulted in hematologic remissions associated with reversal of the endomyocarditis, which is otherwise often rapidly fatal.
- *Endocardial fibroelastosis* is an uncommon heart disease characterized by fibroelastic thickening that typically involves the left ventricular endocardium. It is most common in the first 2 years of life; in a third of cases, it is accompanied by aortic valve obstruction or other congenital cardiac anomalies. Endocardial fibroelastosis may actually represent a common morphologic endpoint of several different insults including viral infections (e.g., intrauterine exposure to mumps) or mutations in the gene for tafazzin, which affects mitochondrial inner membrane integrity. Diffuse involvement may be responsible for rapid and progressive cardiac decompensation and death.

Myocarditis

Myocarditis is a diverse group of pathologic entities in which infectious microorganisms and/or a primary inflammatory process cause myocardial injury. Myocarditis should be distinguished from conditions such as ischemic heart disease, where myocardial inflammation is secondary to other causes.

Pathogenesis. In the United States, *viral infections* are the most common cause of myocarditis. *Coxsackie viruses A and B* and other enteroviruses probably account for most of the cases. Other less common etiologic agents include cytomegalovirus, HIV, and influenza (Table 12-13). In some (but not all) cases, the responsible virus can be ascertained by serologic studies or by identifying viral nucleic acid sequences in myocardial biopsies. Depending on the pathogen and the host, viruses can potentially cause myocardial injury either as a direct cytopathic effect, or by eliciting a destructive immune response. Inflammatory cytokines produced in response to myocardial injury can also cause *myocardial dysfunction* that is out of proportion to the degree of actual myocyte damage.

Table 12-13 Major Causes of Myocarditis

Infections
Viruses (e.g., coxsackievirus, ECHO, influenza, HIV, cytomegalovirus)
Chlamydiae (e.g., <i>Chlamydothyla psittaci</i>)
Rickettsiae (e.g., <i>Rickettsia typhi</i> , typhus fever)
Bacteria (e.g., <i>Corynebacterium diphtheriae</i> , <i>Neisseria meningococcus</i> , <i>Borrelia</i> (Lyme disease))
Fungi (e.g., <i>Candida</i>)
Protozoa (e.g., <i>Trypanosoma cruzi</i> [Chagas disease], toxoplasmosis)
Helminths (e.g., trichinosis)
Immune-Mediated Reactions
Postviral
Poststreptococcal (rheumatic fever)
Systemic lupus erythematosus
Drug hypersensitivity (e.g., methyl dopa, sulfonamides)
Transplant rejection
Unknown
Sarcoidosis
Giant cell myocarditis
<small>HIV, Human immunodeficiency virus.</small>

Nonviral agents are also important causes of infectious myocarditis, particularly the protozoan *Trypanosoma cruzi*, the agent of Chagas disease. Chagas disease is endemic in some regions of South America, with myocardial involvement in most infected individuals. About 10% of patients die during an acute attack; others develop a chronic immune-mediated myocarditis that may progress to cardiac insufficiency in 10 to 20 years. Trichinosis (*Trichinella spiralis*) is the most common helminthic disease associated with myocarditis. Parasitic diseases, including toxoplasmosis, and bacterial infections such as Lyme disease and diphtheria, can also cause myocarditis. In the case of diphtheritic myocarditis, the myocardial injury is a consequence of diphtheria toxin release by the causal organism, *Corynebacterium diphtheriae* (Chapter 8). Myocarditis occurs in approximately 5% of patients with Lyme disease, a systemic illness caused by the bacterial spirochete *Borrelia burgdorferi* (Chapter 8); it manifests primarily as a self-limited conduction system disorder that may require a temporary pacemaker. AIDS-associated myocarditis may reflect inflammation and myocyte damage without a clear etiologic agent, or a myocarditis attributable directly to HIV or to an opportunistic pathogen.

There are also noninfectious causes of myocarditis. Broadly speaking they are either immunologically mediated (*hypersensitivity myocarditis*) or idiopathic conditions with distinctive morphology (*giant cell myocarditis*) suspected to be of immunologic origin (Table 12-13).

MORPHOLOGY

Grossly, the heart in myocarditis may appear normal or dilated; some hypertrophy may be present depending on disease duration. In advanced stages the ventricular myocardium is flabby and often mottled by either pale foci or minute hemorrhagic lesions. Mural thrombi may be present.

Active myocarditis is characterized by an interstitial inflammatory infiltrate associated with focal myocyte necrosis (Fig. 12-35). A diffuse, mononuclear, predominantly lymphocytic infiltrate is most common (Fig. 12-35A). Although endomyocardial

biopsies are diagnostic in some cases, they can be spuriously negative because inflammatory involvement of the myocardium may be focal or patchy. If the patient survives the acute phase of myocarditis, the inflammatory lesions either resolve, leaving no residual changes, or heal by progressive fibrosis.

Hypersensitivity myocarditis has interstitial infiltrates, principally perivascular, composed of lymphocytes, macrophages, and a high proportion of eosinophils (Fig. 12-35B). A morphologically distinctive form of myocarditis, called **giant-cell myocarditis**, is characterized by a widespread inflammatory cellular infiltrate containing multinucleate giant cells (fused macrophages) interspersed with lymphocytes, eosinophils, plasma cells, and macrophages. Focal to frequently extensive necrosis is present (Fig. 12-35C). This variant likely represents the fulminant end of the myocarditis spectrum and carries a poor prognosis.

The myocarditis of **Chagas disease** is distinctive by virtue of the parasitization of scattered myofibers by trypanosomes accompanied by a mixed inflammatory infiltrate of neutrophils, lymphocytes, macrophages, and occasional eosinophils (Fig. 12-35D).

Clinical Features. The clinical spectrum of myocarditis is broad. At one end, the disease is entirely asymptomatic, and patients can expect a complete recovery without sequelae; at the other extreme is the precipitous onset of heart failure or arrhythmias, occasionally with sudden death. Between these extremes are the many levels of involvement associated with symptoms such as fatigue, dyspnea, palpitations, precordial discomfort, and fever. The clinical features of myocarditis can mimic those of acute MI. As noted previously, patients can develop dilated cardiomyopathy as a late complication of myocarditis.

Other Causes of Myocardial Disease

Cardiotoxic Drugs. Cardiac complications of cancer therapy are an important clinical problem; cardiotoxicity has been associated with conventional chemotherapeutic agents, tyrosine kinase inhibitors, and certain forms of immunotherapy. The anthracyclines doxorubicin and daunorubicin are the chemotherapeutic agents most often associated with toxic myocardial injury; they cause dilated cardiomyopathy with heart failure attributed primarily to peroxidation of lipids in myocyte membranes. Anthracycline toxicity is dose-dependent, with the cardiotoxicity risk increasing when cumulative life-time doses exceed 500 mg/m².

Many other therapeutic agents, including lithium, phenothiazines, and chloroquine can idiosyncratically induce myocardial injury and sometimes sudden death. Common findings in affected myocardium include myofiber swelling, cytoplasmic vacuolization, and fatty change. Discontinuing the offending agent often leads to prompt resolution, without apparent sequelae. Occasionally, however, more extensive damage produces myocyte necrosis that can evolve to a dilated cardiomyopathy.

Amyloidosis. Amyloidosis results from the extracellular accumulation of protein fibrils that are prone to forming insoluble β -pleated sheets (Chapter 6). Cardiac

Figure 12-35 Myocarditis. **A**, Lymphocytic myocarditis, associated with myocyte injury. **B**, Hypersensitivity myocarditis, characterized by interstitial inflammatory infiltrate composed largely of eosinophils and mononuclear inflammatory cells, predominantly localized to perivascular and expanded interstitial spaces. **C**, Giant-cell myocarditis, with mononuclear inflammatory infiltrate containing lymphocytes and macrophages, extensive loss of muscle, and multinucleated giant cells (fused macrophages). **D**, The myocarditis of Chagas disease. A myofiber distended with trypanosomes (arrow) is present along with individual myofiber necrosis, and modest amounts of inflammation.

amyloidosis can appear as a consequence of systemic amyloidosis (e.g., due to myeloma or inflammation-associated amyloid) or can be restricted to the heart, particularly in the aged (*senile cardiac amyloidosis*). Senile cardiac amyloidosis characteristically occurs in individuals 70 years and older, and has a far better prognosis than systemic amyloidosis. Senile cardiac amyloid deposits are largely composed of *transthyretin*, a normal serum protein synthesized in the liver that transports *thyroxine* and *retinol-binding protein*. Mutant forms of transthyretin can accelerate the cardiac (and associated systemic) amyloid deposition; 4% of African-Americans have a transthyretin mutation substituting isoleucine for valine at position 122 that produces a particularly amyloidogenic protein, responsible for autosomal dominant familial transthyretin amyloidosis. Isolated atrial amyloidosis can also occur secondary to deposition of atrial natriuretic peptide, but its clinical significance is uncertain.

Cardiac amyloidosis most frequently produces a restrictive cardiomyopathy, but it can also be asymptomatic, manifest as dilation or arrhythmias, or mimic ischemic or valvular disease. The varied presentations depend on the predominant location of the deposits, for example, interstitium, conduction system, vasculature, or valves.

MORPHOLOGY

In cardiac amyloidosis the heart varies in consistency from normal to firm and rubbery. The chambers are usually of normal size, but can be dilated and have thickened walls. Small, semitranslucent nodules resembling drips of wax may be seen on the atrial endocardial surface, particularly on the left. Histologically, hyaline eosinophilic deposits of amyloid may be found in the interstitium, conduction tissue, valves, endocardium, pericardium, and small intramural coronary arteries (Fig. 12-36); they can be distinguished from other deposits by special stains such as Congo red, which produces classic apple-green birefringence when viewed under polarized light (Fig. 12-36B). Intramural arteries and arterioles may have sufficient amyloid in their walls to compress and occlude their lumens, inducing myocardial ischemia ("small-vessel disease").

KEY CONCEPTS

Cardiomyopathy

- Cardiomyopathy is intrinsic cardiac muscle disease; there may be specific causes, or it can be idiopathic.

Figure 12-36 Cardiac amyloidosis. **A**, Hematoxylin and eosin stain, showing amyloid appearing as amorphous pink material around myocytes. **B**, Congo red stain viewed under polarized light, in which amyloid shows characteristic apple-green birefringence (compared with collagen, which appears white).

- There are three general pathophysiologic categories of cardiomyopathy: dilated (90%), hypertrophic, and restrictive (least common).
- Dilated cardiomyopathy results in systolic (contractile) dysfunction. Causes include myocarditis, toxic exposures (e.g., alcohol), and pregnancy. In 20% to 50% of cases, genetic cytoskeletal protein defects are causal, with titin mutations representing up to 20% of cases of dilated cardiomyopathy.
- Hypertrophic cardiomyopathy results in diastolic (relaxation) dysfunction. Virtually all cases are due to autosomal dominant mutations in the proteins comprising the contractile apparatus, in particular β -myosin heavy chain.
- Restrictive cardiomyopathy results in a stiff, noncompliant myocardium and can be due to deposition (e.g., amyloid), increased interstitial fibrosis (e.g., due to radiation), or endomyocardial scarring.
- Myocarditis is myocardial damage caused by inflammatory infiltrates secondary to infections or immune reactions. Coxsackie A and B viruses are the most common causes in the United States. Clinically, myocarditis can be asymptomatic, give rise to acute heart failure, or evolve into dilated cardiomyopathy.

Pericardial Disease

The most important pericardial disorders cause fluid accumulation, inflammation, fibrous constriction, or some combination of these processes, usually in association with other cardiac pathology or a systemic disease; isolated pericardial disease is unusual.

Pericardial Effusion and Hemopericardium

Normally, the pericardial sac contains less than 50 mL of thin, clear, straw-colored fluid. Under various circumstances the parietal pericardium may be distended by serous fluid (*pericardial effusion*), blood (*hemopericardium*),

or pus (*purulent pericarditis*). With long-standing cardiac enlargement or with slowly accumulating fluid, the pericardium has time to dilate. This permits a slowly accumulating pericardial effusion to become quite large without interfering with cardiac function. Thus, with chronic effusions of less than 500 mL in volume, the only clinical significance is a characteristic globular enlargement of the heart shadow on chest radiographs. In contrast, rapidly developing fluid collections of as little as 200 to 300 mL—e.g., due to hemopericardium caused by a ruptured MI or aortic dissection—can produce clinically devastating compression of the thin-walled atria and venae cavae, or the ventricles themselves; cardiac filling is thereby restricted, producing potentially fatal *cardiac tamponade*.

Pericarditis

Pericardial inflammation can occur secondary to a variety of cardiac, thoracic, or systemic disorders, metastases from remote neoplasms, or cardiac surgical procedures. Primary pericarditis is unusual and almost always of viral origin. The major causes of pericarditis are listed in [Table 12-14](#). Most evoke an acute pericarditis, but a few, such as tuberculosis and fungi, produce chronic reactions.

Acute Pericarditis

Serous pericarditis is characteristically produced by non-infectious inflammatory diseases, including rheumatic fever, SLE, and scleroderma, as well as tumors and uremia. An infection in the tissues contiguous to the pericardium—for example, a bacterial pleuritis—may incite sufficient irritation of the parietal pericardial serosa to cause a sterile serous effusion that can progress to serofibrinous pericarditis and ultimately to a frank suppurative reaction. In some instances a well-defined viral infection elsewhere—upper respiratory tract infection, pneumonia, parotitis—antedates the pericarditis and serves as the primary focus of infection. Infrequently, usually in young adults, a viral pericarditis occurs as an apparent primary infection that may be accompanied by myocarditis (*myopericarditis*). Tumors can cause a serous pericarditis by lymphatic

invasion or direct contiguous extension into the pericardium. Histologically, serous pericarditis elicits a mild inflammatory infiltrate in the epipericardial fat consisting predominantly of lymphocytes; tumor-associated pericarditis may also exhibit neoplastic cells. Organization into fibrous adhesions rarely occurs.

Fibrinous and serofibrinous pericarditis are the most frequent types of pericarditis; these are composed of serous fluid variably admixed with a fibrinous exudate. Common causes include acute MI (Fig. 12-18D), postinfarction (Dressler) syndrome (an autoimmune response appearing days-weeks after an MI), uremia, chest radiation, rheumatic fever, SLE, and trauma. A fibrinous reaction also follows routine cardiac surgery.

MORPHOLOGY

In fibrinous pericarditis the surface is dry, with a fine granular roughening. In serofibrinous pericarditis a more intense inflammatory process induces the accumulation of larger amounts of yellow to brown turbid fluid, containing leukocytes, erythrocytes, and fibrin. As with all inflammatory exudates, fibrin may be lysed with resolution of the exudate, or can become organized (Chapter 3).

Symptoms of fibrinous pericarditis characteristically include pain (sharp, pleuritic, and position dependent) and fever; congestive failure may also be present. A *loud pericardial friction rub* is the most striking clinical finding. However, the collection of serous fluid can actually prevent rubbing by separating the two layers of the pericardium.

Purulent or suppurative pericarditis reflects an active infection caused by microbial invasion of the pericardial space; this can occur through:

- Direct extension from neighboring infections, such as an empyema of the pleural cavity, lobar pneumonia, mediastinal infections, or extension of a ring abscess through the myocardium or aortic root

- Seeding from the blood
- Lymphatic extension
- Direct introduction during cardiomy

The exudate ranges from a thin cloudy fluid to frank pus up to 400 to 500 mL in volume. The serosal surfaces are reddened, granular, and coated with the exudate (Fig. 12-37). Microscopically there is an acute inflammatory reaction, which sometimes extends into surrounding structures to induce *mediastinopericarditis*. Complete resolution is infrequent, and organization by scarring is the usual outcome. The intense inflammatory response and the subsequent scarring frequently produce *constrictive pericarditis*, a serious consequence (see later). Clinical findings in the active phase resemble those seen in fibrinous pericarditis, although the frank infection leads to more marked systemic symptoms including spiking fevers and rigors.

Hemorrhagic pericarditis has an exudate composed of blood mixed with a fibrinous or suppurative effusion; it is most commonly caused by the spread of a malignant neoplasm to the pericardial space. In such cases, cytologic examination of fluid removed through a pericardial tap often reveals neoplastic cells. Hemorrhagic pericarditis can also be found in bacterial infections, in persons with an underlying bleeding diathesis, and in tuberculosis. Hemorrhagic pericarditis often follows cardiac surgery and is occasionally responsible for significant blood loss or even tamponade, requiring re-operation. The clinical significance is similar to that of fibrinous or suppurative pericarditis.

Caseous pericarditis is, until proved otherwise, tuberculous in origin; infrequently, fungal infections evoke a similar reaction. Pericardial involvement occurs by direct spread from tuberculous foci within the tracheobronchial nodes. Caseous pericarditis is a common antecedent of disabling, fibrocalcific, chronic constrictive pericarditis.

Figure 12-37 Acute suppurative pericarditis arising from direct extension of an adjacent pneumonia. Extensive purulent exudate is evident.

Chronic or Healed Pericarditis. In some cases organization merely produces plaque-like fibrous thickenings of the serosal membranes (“soldier’s plaque”) or thin, delicate adhesions that rarely cause impairment of cardiac function. In other cases, fibrosis in the form of mesh-like stringy adhesions completely obliterates the pericardial sac. In most instances, this *adhesive pericarditis* has no effect on cardiac function.

Adhesive mediastinopericarditis may follow infectious pericarditis, previous cardiac surgery, or mediastinal irradiation. The pericardial sac is obliterated, and adherence of the external aspect of the parietal layer to surrounding structures strains cardiac function. With each systolic contraction, the heart pulls not only against the parietal pericardium but also against the attached surrounding structures. Systolic retraction of the rib cage and diaphragm, pulsus paradoxus, and a variety of other characteristic clinical findings may be observed. The increased workload causes occasionally severe cardiac hypertrophy and dilation.

In *constrictive pericarditis* the heart is encased in a dense, fibrous or fibrocalcific scar that limits diastolic expansion and cardiac output, features that mimic a restrictive cardiomyopathy. A prior history of pericarditis may or may not be present. The fibrous scar can be up to a centimeter in thickness, obliterating the pericardial space and sometimes calcifying; in extreme cases it can resemble a plaster mold (*concretio cordis*). Because of the dense enclosing scar, cardiac hypertrophy and dilation cannot occur. Cardiac output may be reduced at rest, but more importantly the heart has little if any capacity to increase its output in response to increased systemic demands. Signs of constrictive pericarditis include distant or muffled heart sounds, elevated jugular venous pressure, and peripheral edema. Treatment consists of surgical resection of the shell of constricting fibrous tissue (pericardiectomy).

Heart Disease Associated with Rheumatologic Disorders

The heart (vessels, myocardium, valves, or pericardium) can be significantly impacted by chronic rheumatologic diseases (e.g., rheumatoid arthritis, SLE, systemic sclerosis, ankylosing spondylitis, and psoriatic arthritis). Indeed, as improved therapies lead to longer life expectancies, the cardiovascular manifestations of such systemic inflammation are increasingly recognized. In addition, ischemic heart disease can be accelerated in the setting of systemic inflammation.

Although rheumatoid arthritis is primarily a joint disorder, it also has several extra-articular manifestations, including subcutaneous rheumatoid nodules, vasculitis, and neutropenia (Chapter 26). The heart is also involved in 20-40% of severe cases. The most common finding is a *fibrinous pericarditis* that may progress to fibrous thickening of the visceral and parietal pericardium and dense adhesions. Granulomatous rheumatoid nodules resembling the subcutaneous nodules may also occur in the myocardium, endocardium, valves, and aortic root. *Rheumatoid valvulitis* can lead to marked fibrous thickening and secondary calcification of the aortic valve cusps, producing changes

resembling those of chronic rheumatic valvular disease. The Libman-Sacks valvular lesions associated with SLE were discussed previously.

Tumors of the Heart

Primary tumors of the heart are rare; in contrast, metastatic tumors to the heart occur in about 5% of persons dying of cancer. The most common primary cardiac tumors, in descending order of frequency (overall, including adults and children) are myxomas, fibromas, lipomas, papillary fibroelastomas, rhabdomyomas, and angiosarcomas. The five most common tumors are all benign and collectively account for 80% to 90% of primary tumors of the heart.

Primary Cardiac Tumors

Myxomas are the most common primary tumor of the adult heart (Fig. 12-38). These are benign neoplasms thought to arise from primitive multipotent mesenchymal cells. Although sporadic myxomas do not show consistent genetic alterations, familial syndromes associated with myxomas have activating mutations in the *GNAS1* gene, encoding a subunit of G protein (G_{α}) (in association with McCune-Albright syndrome) or null mutations in *PRKARIA*, encoding a regulatory subunit of a cyclic-AMP-dependent protein kinase (*Carney complex*). About 90% of myxomas arise in the atria, with a left-to-right ratio of approximately 4:1.

MORPHOLOGY

The tumors are usually single, but can rarely be multiple. The region of the fossa ovalis in the atrial septum is the favored site of origin. Myxomas range from small (<1 cm) to large (≥ 10 cm), and can be sessile or pedunculated lesions (Fig. 12-38A). They vary from globular hard masses mottled with hemorrhage to soft, translucent, papillary, or villous lesions having a gelatinous appearance. The pedunculated form is often sufficiently mobile to move during systole into the atrioventricular valve

Figure 12-38 Atrial myxoma. **A**, A large pedunculated lesion arises from the region of the fossa ovalis and extends into the mitral valve orifice. **B**, Abundant amorphous extracellular matrix contains scattered multinucleate myxoma cells (arrowheads) in various groupings, including abnormal vessel-like formations (arrow).

opening, causing intermittent obstruction that may be position-dependent. Sometimes mobile tumors exert a “wrecking-ball” effect, causing damage to the valve leaflets.

Histologically, myxomas are composed of stellate or globular myxoma cells embedded within an abundant acid mucopolysaccharide ground substance (Fig. 12-38B). Peculiar vessel-like or gland-like structures are characteristic. Hemorrhage and mononuclear inflammation are usually present.

The major clinical manifestations are due to valvular “ball-valve” obstruction, embolization, or a syndrome of constitutional symptoms, such as fever and malaise. Sometimes fragmentation and systemic embolization calls attention to these lesions. Constitutional symptoms are probably due to the elaboration by some myxomas of the cytokine interleukin-6, a major mediator of the acute-phase response. Echocardiography provides the opportunity to identify these masses noninvasively. Surgical removal is usually curative; rarely, presumably with incomplete excision, the neoplasm can recur months to years later.

Lipoma. Lipomas are localized, well-circumscribed, benign tumors composed of mature fat cells that can occur in the subendocardium, subepicardium, or myocardium. They may be asymptomatic, or produce ball-valve obstructions or arrhythmias. Lipomas are most often located in the left ventricle, right atrium, or atrial septum. In the atrial septum, nonneoplastic depositions of fat sometimes occur that are called “lipomatous hypertrophy.” These lesions include white and brown adipose tissue, as well as small interspersed areas of myocardium.

Papillary Fibroelastoma. Papillary fibroelastomas are curious, usually incidental, sea-anemone-like lesions, most often identified at autopsy. They may embolize and thereby become clinically important. Clonal cytogenetic abnormalities have been reported, suggesting that fibroelastomas are unusual benign neoplasms. They resemble the much smaller, usually trivial, *Lambl excrescences* that may represent remotely organized thrombus on the aortic valves of older individuals.

MORPHOLOGY

Papillary fibroelastomas are usually (>80%) located on valves, particularly the ventricular surfaces of semilunar valves and the atrial surfaces of atrioventricular valves. Each lesion, typically 1 to 2 cm in diameter, consists of a distinctive cluster of hairlike projections up to 1 cm in length. Histologically, the projections are covered by a surface endothelium surrounding a core of myxoid connective tissue with abundant mucopolysaccharide matrix and elastic fibers.

Rhabdomyoma. Rhabdomyomas are the most frequent primary tumor of the pediatric heart, and are commonly discovered in the first years of life because of obstruction of a valvular orifice or cardiac chamber. Approximately half of cardiac rhabdomyomas are due to sporadic mutations; the other 50% of cases are associated with tuberous sclerosis (Chapter 28), with mutations in the *TSC1* or *TSC2* tumor suppressor gene. The *TSC1* and *TSC2* proteins

(hamartin and tuberin, respectively) function in a complex that inhibits the activity of the mammalian target of rapamycin (mTOR), a kinase that stimulates cell growth and regulates cell size. *TSC1* or *TSC2* expression is often absent in tuberous sclerosis-associated rhabdomyomas, providing a mechanism for myocyte overgrowth. Because rhabdomyomas often regress spontaneously, they may be considered as hamartomas rather than true neoplasms.

MORPHOLOGY

Rhabdomyomas are gray-white myocardial masses that can be small or up to several centimeters in diameter. They are usually multiple and involve the ventricles preferentially, protruding into the lumen. Microscopically, they are composed of bizarre, markedly enlarged myocytes. Routine histologic processing often artifactually reduces the abundant cytoplasm to thin strands that stretch from the nucleus to the surface membrane, an appearance referred to as “spider” cells.

Sarcoma. Cardiac *angiosarcomas* and other sarcomas are not clinically or morphologically distinctive from their counterparts in other locations, and so require no further comment here.

Cardiac Effects of Noncardiac Neoplasms

With enhanced patient survival due to diagnostic and therapeutic advances, significant cardiovascular effects of noncardiac neoplasms and their therapy are increasingly encountered (Table 12-15). The pathologic consequences include direct tumor infiltration, effects of circulating mediators, and therapeutic complications.

The most frequent metastatic tumors involving the heart are carcinomas of the lung and breast, melanomas, leukemias, and lymphomas. Metastases can reach the heart and pericardium by retrograde lymphatic extension (most carcinomas), by hematogenous seeding (many tumors), by direct contiguous extension (primary carcinoma of the lung, breast, or esophagus), or by venous extension (tumors of the kidney or liver). Clinical symptoms are most often associated with pericardial spread, which can cause

Table 12-15 Cardiovascular Effects of Noncardiac Neoplasms

Evidence for chronic immune reaction to activated graft endothelial cells. *Am J Pathol* 138:791, 1991.)

symptomatic pericardial effusions or a mass-effect that is sufficient to restrict cardiac filling. Myocardial metastases are usually clinically silent or have nonspecific features, such as a generalized defect in ventricular contractility or compliance. Bronchogenic carcinoma or malignant lymphoma may infiltrate the mediastinum extensively, causing encasement, compression, or invasion of the superior vena cava with resultant obstruction to blood coming from the head and upper extremities (*superior vena cava syndrome*). Renal cell carcinoma often invades the renal vein, and may grow as a continuous column of tumor up the inferior vena cava and into the right atrium, blocking venous return to the heart.

Noncardiac tumors may also affect cardiac function indirectly, sometimes via circulating tumor-derived substances. The consequences include nonbacterial thrombotic endocarditis, carcinoid heart disease, pheochromocytoma-associated myocardial damage and myeloma-associated AL-type amyloidosis.

Complications of chemotherapy were discussed earlier in this chapter. Radiation used to treat breast, lung, or mediastinal neoplasms can cause pericarditis, pericardial effusion, myocardial fibrosis, and chronic pericardial disorders. Other cardiac effects of radiation therapy include accelerated coronary artery disease and mural and valvular endocardial fibrosis.

Cardiac Transplantation

Transplantation of cardiac allografts is now frequently performed (approximately 3000 per year worldwide) for severe, intractable heart failure of diverse causes—most commonly DCM and IHD. Three major factors have contributed to the improved outcome of cardiac transplantation since the first human to human transplant in 1967: (1) more effective immunosuppressive therapy (including the use of cyclosporin A, glucocorticoids, and other agents), (2) careful selection of candidates, and (3) early histopathologic diagnosis of acute allograft rejection by endomyocardial biopsy.

Of the major complications, allograft rejection is the primary problem requiring surveillance; routine endomyocardial biopsy is the only reliable means of diagnosing acute cardiac rejection before substantial myocardial damage has occurred and at a stage that is reversible in the majority of instances. Classic *cellular rejection* is characterized by interstitial lymphocytic inflammation with associated myocyte damage; the histology resembles myocarditis (Fig. 12-39A). There may also be interstitial edema due to vascular injury, and local cytokine elaboration can impact myocardial contractility without necessarily eliciting myocyte damage. Increasingly, *antibody-mediated rejection* is also recognized as a pathologic mechanism of injury; donor-specific antibodies directed against major histocompatibility complex proteins lead to complement activation and the recruitment of Fc-receptor-bearing cells. Mild rejection may resolve spontaneously, while prompt recognition of more severe episodes allows successful treatment by augmenting baseline levels of immunosuppression; occasionally aggressive anti-T cell or anti-B cell immunotherapy, with or without plasmapheresis may be necessary.

Allograft arteriopathy is the single most important long-term limitation for cardiac transplantation. It is a late, progressive, diffusely stenosing intimal proliferation in the coronary arteries (Fig. 12-39B), leading to ischemic injury. Within 5 years of transplantation, 50% of patients develop significant allograft arteriopathy, and virtually all patients have lesions within 10 years. The pathogenesis of allograft arteriopathy involves immunologic responses that induce local production of growth factors that promote intimal smooth muscle cell recruitment and proliferation with ECM synthesis. Allograft arteriopathy is a particularly vexing problem because it can lead to silent MI (transplant patients have denervated hearts and do not experience angina), progressive CHF, or sudden cardiac death.

Other postoperative problems include infection and malignancies, particularly Epstein-Barr virus-associated B-cell lymphomas that arise in the setting of chronic T-cell immunosuppression. Despite these problems, the overall outlook is good; the 1-year survival is 90% and 5-year survival is greater than 60%.

The components of the hematopoietic system have been traditionally divided into the *myeloid tissues*, which include the bone marrow and the cells derived from it (e.g., red cells, platelets, granulocytes, and monocytes), and the *lymphoid tissues*, consisting of the thymus, lymph nodes, and spleen. It is important to recognize, however, that this subdivision is artificial with respect to both the normal physiology of hematopoietic cells and the diseases affecting them. For example, although bone marrow contains relatively few lymphocytes, it is the source of all lymphoid progenitors, and the home of long-lived plasma cells and memory lymphocytes. Similarly, neoplastic disorders of myeloid progenitor cells (myeloid leukemias) originate in the bone marrow but secondarily involve the spleen and (to a lesser degree) the lymph nodes. Some red cell disorders (e.g., immunohemolytic anemia, discussed in [Chapter 14](#)) result from the formation of autoantibodies, indicating a primary disorder of lymphocytes. Thus, it is not possible to draw neat lines between diseases involving the myeloid and lymphoid tissues.

Recognizing this difficulty, we somewhat arbitrarily divide diseases of the hematopoietic tissues into two chapters. In this chapter we discuss white cell diseases and disorders affecting the spleen and thymus. In [Chapter 14](#)

we consider diseases of red cells and those affecting hemostasis. Before delving into specific diseases, we will briefly discuss the origins of hematopoietic cells, since many disorders of white cells and red cells involve disturbances of their normal development and maturation.

Development and Maintenance of Hematopoietic Tissues

Blood cell progenitors first appear during the third week of embryonic development in the yolk sac. Cells derived from the yolk sac are the source of long-lived tissue macrophages, such as microglial cells in the brain and Kupffer cells in the liver ([Chapter 3](#)), but the contribution of the yolk sac to blood formation, mainly in the form of embryonic red blood cells, is only transient. Definitive *hematopoietic stem cells* (HSCs) arise several weeks later in the mesoderm of the intraembryonic aorta/gonad/mesonephros region. During the third month of embryogenesis, HSCs migrate to the liver, which becomes the chief site of blood cell formation until shortly before birth. HSCs also take up residence in the fetal placenta; this pool of HSCs is of uncertain physiologic relevance, but has taken on

Figure 13-1 Differentiation of blood cells. CFU, Colony forming unit; LIN⁻, negative for lineage-specific markers.

substantial clinical importance, as HSCs harvested at birth from umbilical cord blood are being used increasingly in therapeutic hematopoietic stem cell transplantation. By the fourth month of development, HSCs shift in location yet again, taking up residence in the bone marrow. By birth, marrow throughout the skeleton is hematopoietically active and hepatic hematopoiesis dwindles to a trickle, persisting only in widely scattered foci that become inactive soon after birth. Until puberty, hematopoietically active marrow is found throughout the skeleton, but soon thereafter it becomes restricted to the axial skeleton. Thus, in normal adults, only about half of the marrow space is hematopoietically active.

The formed elements of blood—red cells, granulocytes, monocytes, platelets, and lymphocytes—have a common origin from HSCs, pluripotent cells that sit at the apex of a hierarchy of bone marrow progenitors (Fig. 13-1). Most evidence supporting this scheme comes from studies in mice, but human hematopoiesis is believed to proceed in a similar way. HSCs give rise to several kinds of early progenitor cells with a restricted differentiation potential, such that they ultimately produce mainly myeloid cells or lymphoid cells. The origins of lymphoid cells are revisited when tumors derived from these cells are discussed. These early progenitors in turn give “birth” to progenitors that are further constrained to differentiation

along particular lineages. Some of these cells are referred to as *colony-forming units* (CFUs) (Fig. 13-1), because they produce colonies composed of specific kinds of mature cells when grown in culture. From the various committed progenitors are derived the morphologically recognizable precursors, such as myeloblasts, proerythroblasts, and megakaryoblasts, which are the immediate progenitors of mature granulocytes, red cells, and platelets.

HSCs have two essential properties that are required for the maintenance of hematopoiesis: pluripotency and the capacity for self-renewal. Pluripotency refers to the ability of a single HSC to generate all mature blood cells. When an HSC divides, at least one daughter cell must self-renew to avoid stem cell depletion. Self-renewing divisions occur within a specialized marrow niche, in which stromal cells and secreted factors nurture and protect the HSCs. As one might surmise from their ability to migrate during embryonic development, HSCs are not sessile. Particularly under conditions of marked stress, such as severe anemia or acute inflammation, HSCs are mobilized from the bone marrow and appear in the peripheral blood. In fact, HSCs used in transplantation are now mainly collected from the peripheral blood of donors treated with granulocyte colony stimulating factor (G-CSF), one of the factors that can mobilize a fraction of marrow HSCs from their stem cell niches.

The marrow response to short-term physiologic needs is regulated by hematopoietic growth factors through effects on the committed progenitors. Because mature blood elements are terminally differentiated cells with finite life spans, their numbers must be constantly replenished. In current models of hematopoiesis, some divisions of HSCs give rise to cells referred to as *multipotent progenitors*, which are more proliferative than HSCs but have a lesser capacity for self-renewal (Fig. 13-1). Division of multipotent progenitors gives rise to at least one daughter cell that leaves the stem cell pool and begins to differentiate. Once past this threshold, these newly committed cells lose the capacity for self-renewal and commence an inexorable journey down a road that leads to terminal differentiation and death. However, as these progenitors differentiate, they also begin to proliferate more rapidly in response to growth factors, expanding their numbers. Some growth factors, such as stem cell factor (also called *KIT ligand*) and FLT3-ligand, act through receptors that are expressed on very early committed progenitors. Others, such as erythropoietin, granulocyte-macrophage colony-stimulating factor (GM-CSF), G-CSF, and thrombopoietin, act through receptors that are only expressed on committed progenitors with more restricted differentiation potentials. Feedback loops involving these lineage-specific growth factors tune the marrow output, allowing the numbers of formed blood elements (red cells, white cells, and platelets) to be maintained within appropriate ranges (Table 13-1).

Many diseases alter the production of blood cells. The marrow is the ultimate source of most cells of the innate and adaptive immune system and responds to infectious or inflammatory challenges by increasing its output of granulocytes under the direction of specific growth factors and cytokines. By contrast, many other disorders are associated with defects in hematopoiesis that lead to deficiencies of one or more types of blood cells. Primary tumors of

Table 13-1 Adult Reference Ranges for Blood Cells*

Cell Type	Reference Range
White cells ($\times 10^3/\mu\text{L}$)	4.8-10.8
Granulocytes (%)	40-70
Neutrophils ($\times 10^3/\mu\text{L}$)	1.4-6.5
Lymphocytes ($\times 10^3/\mu\text{L}$)	1.2-3.4
Monocytes ($\times 10^3/\mu\text{L}$)	0.1-0.6
Eosinophils ($\times 10^3/\mu\text{L}$)	0-0.5
Basophils ($\times 10^3/\mu\text{L}$)	0-0.2
Red cells ($\times 10^3/\mu\text{L}$)	4.3-5, men; 3.5-5, women
Platelets ($\times 10^3/\mu\text{L}$)	150-450

*Reference ranges vary among laboratories. The reference ranges for the laboratory providing the result should always be used.

hematopoietic cells are among the most important diseases that interfere with marrow function, but certain genetic diseases, infections, toxins, and nutritional deficiencies, as well as chronic inflammation from any cause, can also decrease the production of blood cells by the marrow.

Tumors of hematopoietic origin are often associated with mutations that block progenitor cell maturation or abrogate their growth factor dependence. The net effect of such derangements is an unregulated clonal expansion of hematopoietic elements, which replace normal marrow progenitors and often spread to other hematopoietic tissues. In some instances, these tumors originate from transformed HSCs that retain the ability to differentiate along multiple lineages, whereas in other instances the origin is a more differentiated progenitor that has acquired an abnormal capacity for self-renewal (Chapter 7).

MORPHOLOGY

The bone marrow is a unique microenvironment that supports the orderly proliferation, differentiation, and release of blood cells. It is filled with a network of thin-walled sinusoids lined by a single layer of endothelial cells, which are underlaid by a discontinuous basement membrane and adventitial cells. Within the interstitium lie clusters of hematopoietic cells and fat cells. Differentiated blood cells enter the circulation by transcellular migration through the endothelial cells.

The normal marrow is organized in subtle, but important, ways. For example, normal **megakaryocytes** lie next to sinusoids and extend cytoplasmic processes that bud off into the bloodstream to produce platelets, while red cell precursors often surround macrophages (so-called *nurse cells*) that provide some of the iron needed for the synthesis of hemoglobin. Processes that distort the marrow architecture, such as deposits of metastatic cancer or granulomatous disorders, can cause the abnormal release of immature precursors into the peripheral blood, a finding that is referred to as **leukoerythroblastosis**.

Marrow aspirate smears provide the best assessment of the morphology of hematopoietic cells. The most mature marrow precursors can be identified based on their morphology alone. Immature precursors ("blast" forms) of different types are morphologically similar and must be identified definitively using lineage-specific antibodies and histochemical markers (described later under white cell neoplasms). Biopsies are a

good means for estimating marrow activity. In normal adults, the ratio of fat cells to hematopoietic elements is about 1:1. In hypoplastic states (e.g., aplastic anemia) the proportion of fat cells is greatly increased; conversely, fat cells often disappear when the marrow is involved by hematopoietic tumors and in

diseases characterized by compensatory hyperplasias (e.g., hemolytic anemias), and neoplastic proliferations such as leukemias. Other disorders (e.g., metastatic cancers and granulomatous diseases) induce local marrow fibrosis. Such lesions are usually inappreciable and best seen in biopsies.

DISORDERS OF WHITE CELLS

Disorders of white blood cells can be classified into two broad categories: *proliferative disorders*, in which there is an expansion of leukocytes, and *leukopenias*, which are defined as a deficiency of leukocytes. Proliferations of white cells can be *reactive* or *neoplastic*. Reactive proliferations in the setting of infections or inflammatory processes, when leukocytes are needed for an effective host response, are fairly common. Neoplastic disorders, though less frequent, are much more important clinically. In the following discussion we will first describe the leukopenic states and summarize the common reactive disorders, and then consider in some detail the malignant proliferations of white cells.

Leukopenia

The number of circulating white cells may be markedly decreased in a variety of disorders. An abnormally low white cell count (*leukopenia*) usually results from reduced numbers of neutrophils (*neutropenia*, *granulocytopenia*). *Lymphopenia* is less common; in addition to congenital immunodeficiency diseases (Chapter 6), it is most commonly observed in advanced human immunodeficiency virus (HIV) infection, following therapy with glucocorticoids or cytotoxic drugs, autoimmune disorders, malnutrition, and certain acute viral infections. In the latter setting lymphopenia actually stems from lymphocyte redistribution rather than a decrease in the number of lymphocytes in the body. Acute viral infections induce production of type I interferons, which activate T lymphocytes and change the expression of surface proteins that regulate T cell migration. These changes result in the sequestration of activated T cells in lymph nodes and increased adherence to endothelial cells, both of which contribute to lymphopenia. Granulocytopenia is more common and is often associated with diminished granulocyte function, and thus merits further discussion.

Neutropenia, Agranulocytosis

Neutropenia, a reduction in the number of neutrophils in the blood, occurs in a wide variety of circumstances. *Agranulocytosis*, a clinically significant reduction in neutrophils, has the serious consequence of making individuals susceptible to bacterial and fungal infections.

Pathogenesis. Neutropenia can be caused by (1) **inadequate or ineffective granulopoiesis**, or (2) **increased destruction or sequestration of neutrophils in the periphery**. Inadequate or ineffective granulopoiesis is observed in the setting of:

- *Suppression of hematopoietic stem cells*, as occurs in aplastic anemia (Chapter 14) and a variety of infiltrative marrow disorders (e.g., tumors, granulomatous disease); in these conditions granulocytopenia is accompanied by anemia and thrombocytopenia
- *Suppression of committed granulocytic precursors* by exposure to certain drugs (discussed later)
- Disease states associated with *ineffective hematopoiesis*, such as megaloblastic anemias (Chapter 14) and myelodysplastic syndromes, in which defective precursors die in the marrow
- Rare *congenital conditions* (e.g., Kostmann syndrome) in which inherited defects in specific genes impair granulocytic differentiation

Accelerated destruction or sequestration of neutrophils occurs with

- *Immunologically mediated injury* to neutrophils, which can be idiopathic, associated with a well-defined immunologic disorder (e.g., systemic lupus erythematosus), or caused by exposure to drugs
- *Splenomegaly*, in which splenic enlargement leads to sequestration of neutrophils and modest neutropenia, sometimes associated with anemia and often with thrombocytopenia
- *Increased peripheral utilization*, which can occur in overwhelming bacterial, fungal, or rickettsial infections

The most common cause of agranulocytosis is drug toxicity. Certain drugs, such as alkylating agents and antimetabolites used in cancer treatment, produce agranulocytosis in a predictable, dose-related fashion. Because such drugs cause a generalized suppression of hematopoiesis, production of red cells and platelets is also affected. Agranulocytosis can also occur as an idiosyncratic reaction to a large variety of agents. The roster of implicated drugs includes aminopyrine, chloramphenicol, sulfonamides, chlorpromazine, thiouracil, and phenylbutazone. The neutropenia induced by chlorpromazine and related phenothiazines results from a toxic effect on granulocytic precursors in the bone marrow. In contrast, agranulocytosis following administration of other drugs, such as sulfonamides, probably stems from antibody-mediated destruction of mature neutrophils through mechanisms similar to those involved in drug-induced immunohemolytic anemias (Chapter 14).

In some patients with acquired idiopathic neutropenia, autoantibodies directed against neutrophil-specific antigens are detected. Severe neutropenia can also occur in association with monoclonal proliferations of large granular lymphocytes (so-called *LGL leukemia*). The mechanism

of this neutropenia is not clear; suppression of granulocytic progenitors by products of the neoplastic cell (usually a CD8+ cytotoxic T cell) is considered most likely.

MORPHOLOGY

The alterations in the **bone marrow** vary with cause. With excessive destruction of neutrophils in the periphery, the marrow is usually hypercellular due to a compensatory increase in granulocytic precursors. Hypercellularity is also the rule with neutropenias caused by ineffective granulopoiesis, as occurs in megaloblastic anemias and myelodysplastic syndromes. Agranulocytosis caused by agents that suppress or destroy granulocytic precursors is understandably associated with marrow hypocellularity.

Infections are a common consequence of agranulocytosis. Ulcerating necrotizing lesions of the gingiva, floor of the mouth, buccal mucosa, pharynx, or elsewhere in the oral cavity (agranulocytic angina) are quite characteristic. These are typically deep, undermined, and covered by gray to green-black necrotic membranes from which numerous bacteria or fungi can be isolated. Less frequently, similar ulcerative lesions occur in the skin, vagina, anus, or gastrointestinal tract. Severe life-threatening invasive bacterial or fungal infections may occur in the lungs, urinary tract, and kidneys. The neutropenic patient is at particularly high risk for deep fungal infections caused by *Candida* and *Aspergillus*. Sites of infection often show a massive growth of organisms with little leukocytic response. In the most dramatic instances, bacteria grow in colonies (botryomycosis) resembling those seen on agar plates.

Clinical Features. The symptoms and signs of neutropenia are related to infection, and include malaise, chills, and fever, often followed by marked weakness and fatigability. With agranulocytosis, infections are often overwhelming and may cause death within hours to days.

Serious infections are most likely when the neutrophil count falls below 500 per mm³. Because infections are often fulminant, broad-spectrum antibiotics must be given expeditiously whenever signs or symptoms appear. In some instances, such as following myelosuppressive chemotherapy, neutropenia is treated with G-CSF, a growth factor that stimulates the production of granulocytes from marrow precursors.

Reactive Proliferations of White Cells and Lymph Nodes

Leukocytosis

Leukocytosis refers to an increase in the number of white cells in the blood. It is a common reaction to a variety of inflammatory states.

Pathogenesis. The peripheral blood leukocyte count is influenced by several factors, including:

- The size of the myeloid and lymphoid precursor and storage cell pools in the bone marrow, thymus, circulation, and peripheral tissues

Table 13-2 Mechanisms and Causes of Leukocytosis

Increased Production in the Marrow
Chronic infection or inflammation (growth factor-dependent)
Paraneoplastic (e.g., Hodgkin lymphoma; growth factor-dependent)
Myeloproliferative disorders (e.g., chronic myeloid leukemia; growth factor-independent)
Increased Release from Marrow Stores
Endotoxemia
Infection
Hypoxia
Decreased Margination
Exercise
Catecholamines
Decreased Extravasation into Tissues
Glucocorticoids

- The rate of release of cells from the storage pools into the circulation
- The proportion of cells that are adherent to blood vessel walls at any time (the marginal pool)
- The rate of extravasation of cells from the blood into tissues

As discussed in [Chapter 3](#), leukocyte homeostasis is maintained by cytokines, growth factors, and adhesion molecules through their effects on the commitment, proliferation, differentiation, and extravasation of leukocytes and their progenitors. [Table 13-2](#) summarizes the major mechanisms of neutrophilic leukocytosis and its causes, the most important of which is infection. In acute infection there is a rapid increase in the egress of mature granulocytes from the bone marrow pool, an alteration that may be mediated through the effects of tumor necrosis factor (TNF) and interleukin-1 (IL-1). If the infection or an inflammatory process is prolonged, IL-1, TNF, and other inflammatory mediators stimulate macrophages, bone marrow stromal cells and T cells to produce increased amounts of hematopoietic growth factors. These factors enhance the proliferation and differentiation of committed granulocytic progenitors and, over several days, cause a sustained increase in neutrophil production.

Some growth factors preferentially stimulate the production of a single type of leukocyte. For example, IL-5 mainly stimulates eosinophil production, while G-CSF induces neutrophilia. Such factors are differentially produced in response to various pathogenic stimuli and, as a result, the five principal types of leukocytosis (neutrophilia, eosinophilia, basophilia, monocytosis, and lymphocytosis) tend to be observed in different clinical settings ([Table 13-3](#)).

In sepsis or severe inflammatory disorders (e.g., Kawasaki disease), leukocytosis is often accompanied by morphologic changes in the neutrophils, such as toxic granulations, Döhle bodies, and cytoplasmic vacuoles ([Fig. 13-2](#)). *Toxic granules*, which are coarser and darker than the normal neutrophilic granules, represent abnormal azurophilic (primary) granules. *Döhle bodies* are patches of dilated endoplasmic reticulum that appear as sky-blue cytoplasmic “puddles.”

In most instances it is not difficult to distinguish reactive and neoplastic leukocytoses, but uncertainties may arise in two settings. Acute viral infections, particularly in

Table 13-3 Causes of Leukocytosis

Type of Leukocytosis	Causes
Neutrophilic leukocytosis	Acute bacterial infections, especially those caused by pyogenic organisms; sterile inflammation caused by, for example, tissue necrosis (myocardial infarction, burns)
Eosinophilic leukocytosis (eosinophilia)	Allergic disorders such as asthma, hay fever, parasitic infestations; drug reactions; certain malignancies (e.g., Hodgkin and some non-Hodgkin lymphomas); automimmune disorders (e.g., pemphigus, dermatitis herpetiformis) and some vasculitides; atheroembolic disease (transient)
Basophilic leukocytosis (basophilia)	Rare, often indicative of a myeloproliferative disease (e.g., chronic myelogenous leukemia)
Monocytosis	Chronic infections (e.g., tuberculosis), bacterial endocarditis, rickettsiosis, and malaria; autoimmune disorders (e.g., systemic lupus erythematosus); inflammatory bowel diseases (e.g., ulcerative colitis)
Lymphocytosis	Accompanies monocytosis in many disorders associated with chronic immunologic stimulation (e.g., tuberculosis, brucellosis); viral infections (e.g., hepatitis A, cytomegalovirus, Epstein-Barr virus); <i>Bordetella pertussis</i> infection

children, can cause the appearance of large numbers of activated lymphocytes that resemble neoplastic lymphoid cells. At other times, particularly in severe infections, many immature granulocytes appear in the blood, mimicking a myeloid leukemia (*leukemoid reaction*). Special laboratory studies (discussed later) are helpful in distinguishing reactive and neoplastic leukocytoses.

Lymphadenitis

Following their initial development from precursors in the central (also called primary) lymphoid organs,—the bone marrow for B cells and the thymus for T cells—, lymphocytes circulate through the blood and, under the influence of specific cytokines and chemokines, home to lymph nodes, spleen, tonsils, adenoids, and Peyer's patches, which constitute the peripheral (secondary) lymphoid tissues. Lymph nodes, the most widely distributed and easily accessible lymphoid tissue, are frequently examined for diagnostic purposes. They are discrete encapsulated structures that contain well-organized B-cell and T-cell zones, which are richly invested with phagocytes and antigen-presenting cells (see Fig. 6-8, Chapter 6).

The activation of resident immune cells leads to morphologic changes in lymph nodes. Within several days of antigenic stimulation, the primary follicles enlarge and develop pale-staining *germinal centers*, highly dynamic

structures in which B cells acquire the capacity to make high-affinity antibodies against specific antigens. Paracortical T-cell zones may also undergo hyperplasia. The degree and pattern of the morphologic changes are dependent on the inciting stimulus and the intensity of the response. Trivial injuries and infections induce subtle changes, while more significant infections inevitably produce nodal enlargement and sometimes leave residual scarring. For this reason, lymph nodes in adults are almost never “normal” or “resting,” and it is often necessary to distinguish morphologic changes secondary to past experience from those related to present disease. Infections and inflammatory stimuli often elicit regional or systemic immune reactions within lymph nodes. Some that produce distinctive morphologic patterns are described in other chapters. Most, however, cause stereotypical patterns of lymph node reaction designated acute and chronic nonspecific lymphadenitis.

Acute Nonspecific Lymphadenitis

Acute lymphadenitis in the cervical region is most often due to drainage of microbes or microbial products from infections of the teeth or tonsils, while in the axillary or inguinal regions it is most often caused by infections in the extremities. Acute lymphadenitis also occurs in mesenteric lymph nodes draining acute appendicitis. Other self-limited infections may also cause acute mesenteric adenitis and induce symptoms mimicking acute appendicitis, a differential diagnosis that plagues the surgeon. Systemic viral infections (particularly in children) and bacteremia often produce acute generalized lymphadenopathy.

Figure 13-2 Reactive changes in neutrophils. Neutrophils containing coarse purple cytoplasmic granules (toxic granulations) and blue cytoplasmic patches of dilated endoplasmic reticulum (Döhle bodies, *arrow*) are observed in this peripheral blood smear prepared from a patient with bacterial sepsis.

MORPHOLOGY

The nodes are swollen, gray-red, and engorged. Microscopically, there is prominence of large reactive germinal centers containing numerous mitotic figures. Macrophages often contain particulate debris derived from dead bacteria or necrotic cells. When pyogenic organisms are the cause, neutrophils are prominent and the centers of the follicles may undergo necrosis; sometimes the entire node is converted to a bag of pus. With less severe reactions, scattered neutrophils infiltrate about the follicles and accumulate within the lymphoid sinuses. The endothelial cells lining the sinuses undergo hyperplasia.

Nodes involved by acute lymphadenitis are enlarged and painful. When abscess formation is extensive the nodes become fluctuant. The overlying skin is red. Sometimes, suppurative infections penetrate through the capsule of the

node and track to the skin to produce draining sinuses. Healing of such lesions is associated with scarring.

Chronic Nonspecific Lymphadenitis

Chronic immunologic stimuli produce several different patterns of lymph node reaction, as described later.

MORPHOLOGY

Follicular hyperplasia is caused by stimuli that activate humoral immune responses. It is defined by the presence of large oblong germinal centers (secondary follicles), which are surrounded by a collar of small resting naive B cells (the mantle zone) (Fig. 13-3). Germinal centers are normally polarized, consisting of two distinct regions: (1) a dark zone containing proliferating blastlike B cells (centroblasts) and (2) a light zone composed of B cells with irregular or cleaved nuclear contours (centrocytes). Interspersed between the germinal B centers is an inconspicuous network of antigen-presenting follicular dendritic cells and macrophages (often referred to as **tingible-body macrophages**) containing the nuclear debris of B cells, which undergo apoptosis if they fail to produce an antibody with a high affinity for antigen.

Causes of follicular hyperplasia include rheumatoid arthritis, toxoplasmosis, and early stages of infection with HIV. This form of hyperplasia is morphologically similar to follicular lymphoma (discussed later). Features favoring a reactive (nonneoplastic) hyperplasia include (1) preservation of the lymph node architecture, including the interfollicular T-cell zones and the sinusoids; (2) marked variation in the shape and size of the follicles; and (3) the presence of frequent mitotic figures, phagocytic macrophages, and recognizable light and dark zones, all of which tend to be absent from neoplastic follicles.

Paracortical hyperplasia is caused by stimuli that trigger T-cell-mediated immune responses, such as acute viral infections (e.g., infectious mononucleosis). The T-cell regions typically contain immunoblasts, activated T cells three to four times the size of resting lymphocytes that have round nuclei, open chromatin, several prominent nucleoli, and moderate amounts of pale cytoplasm. The expanded T-cell zones encroach on and, in particularly exuberant reactions, efface the B-cell follicles. In such cases immunoblasts may be so numerous that special studies are needed to exclude a lymphoid neoplasm. In addition, there is often a hypertrophy of sinusoidal and vascular endothelial cells, sometimes accompanied by infiltrating macrophages and eosinophils.

Sinus histiocytosis (also called *reticular hyperplasia*) refers to an increase in the number and size of the cells that line lymphatic sinusoids. Although nonspecific, this form of hyperplasia may be particularly prominent in lymph nodes draining cancers such as carcinoma of the breast. The lining lymphatic endothelial cells are markedly hypertrophied and macrophages are greatly increased in numbers, resulting in the expansion and distension of the sinuses.

Characteristically, lymph nodes in chronic reactions are nontender, as nodal enlargement occurs slowly over time and acute inflammation with associated tissue damage is absent. Chronic lymphadenitis is particularly common in inguinal and axillary nodes, which drain relatively large areas of the body and are frequently stimulated by immune reactions to trivial injuries and infections of the extremities.

Figure 13-3 Follicular hyperplasia. **A**, Low-power view showing a reactive follicle and surrounding mantle zone. The dark-staining mantle zone is more prominent adjacent to the germinal-center light zone in the left half of the follicle. The right half of the follicle consists of the dark zone. **B**, High-power view of the dark zone shows several mitotic figures and numerous macrophages containing phagocytosed apoptotic cells (tingible bodies).

Furthermore, chronic immune reactions can promote the appearance of organized collections of immune cells in nonlymphoid tissues. These collections are sometimes called tertiary lymphoid organs. A classic example is that of chronic gastritis caused by *Helicobacter pylori*, in which aggregates of mucosal lymphocytes are seen that simulate the appearance of Peyer patches. A similar phenomenon occurs in rheumatoid arthritis, in which B-cell follicles often appear in the inflamed synovium. Lymphotoxin, a cytokine required for the formation of normal Peyer patches, is probably involved in the establishment of these “extranodal” inflammation-induced collections of lymphoid cells.

Hemophagocytic Lymphohistiocytosis

Hemophagocytic lymphohistiocytosis (HLH) is a reactive condition marked by cytopenias and signs and symptoms of systemic inflammation related to macrophage activation. For this reason, it is also sometimes referred to as *macrophage activation syndrome*. Some forms are familial and may appear early in life, even in infants, while other forms are sporadic and may affect people of any age.

Pathogenesis. The common feature of all forms of HLH is systemic activation of macrophages and CD8+ cytotoxic

T cells. The activated macrophages phagocytose blood cell progenitors in the marrow and formed elements in the peripheral tissues, while the “stew” of mediators released from macrophages and lymphocytes suppress hematopoiesis and produce symptoms of systemic inflammation. These effects lead to cytopenias and a shock-like picture, sometimes referred to as “cytokine storm” or the systemic inflammatory response syndrome (Chapter 4).

Familial forms of HLH are associated with several different mutations, all of which impact the ability of cytotoxic T cells and NK to properly form or deploy cytotoxic granules. How these defects lead to HLH is not known. One idea with some experimental support is based on the premise that cytotoxic T cells keep immune responses in check by lysing antigen-bearing dendritic cells or activated macrophages; if this regulatory mechanism fails, hyperactivation of the immune system and the clinical syndrome of HLH ensue. Unbridled HLH is associated with extremely high levels of inflammatory mediators such as interferon- γ , TNF α , IL-6, and IL-12, as well as soluble IL-2 receptor. Some “sporadic” cases in adults also prove to have mutations in the same set of genes, while in other adult-onset patients the cause is unknown. The most common trigger for HLH is infection, particularly with Epstein-Barr virus (EBV).

Clinical Features. Most patients present with an acute febrile illness associated with splenomegaly and hepatomegaly. Hemophagocytosis is usually seen on bone marrow examination, but is neither sufficient nor required to make the diagnosis. Laboratory studies typically reveal anemia, thrombocytopenia, and very high levels of plasma ferritin and soluble IL-2 receptor, both indicative of severe inflammation, as well as elevated liver function tests and triglyceride levels, both related to hepatitis. Coagulation studies may show evidence of disseminated intravascular coagulation. If untreated, this picture can progress rapidly to multiorgan failure, shock, and death.

Treatment involves the use of immunosuppressive drugs and “mild” chemotherapy. Patients with germline mutations that cause HLH or who have persistent/resistant disease are candidates for hematopoietic stem cell transplantation. Without treatment, the prognosis is grim, particularly in those with familial forms of the disease, who typically survive for less than 2 months. With prompt treatment, with or without subsequent hematopoietic stem cell transplantation, roughly half of patients survive, though many do so with significant sequelae, such as renal damage in adults and growth and mental retardation in children.

Neoplastic Proliferations of White Cells

Malignancies are clinically the most important disorders of white cells. These diseases fall into several broad categories:

- *Myeloid neoplasms* arise from early hematopoietic progenitors. Three categories of myeloid neoplasia are recognized: *acute myeloid leukemias*, in which immature progenitor cells accumulate in the bone marrow; *myelodysplastic syndromes*, which are associated with ineffective hematopoiesis and resultant peripheral blood cytopenias; and *chronic myeloproliferative disorders*, in which increased production of one or more terminally differentiated myeloid elements (e.g., granulocytes) usually leads to elevated peripheral blood counts.
- The *histiocytoses* are uncommon proliferative lesions of macrophages and dendritic cells. Although “histiocyte” (literally, “tissue cell”) is an archaic morphologic term, it is still often used. A special type of immature dendritic cell, the Langerhans cell, gives rise to a spectrum of neoplastic disorders referred to as the *Langerhans cell histiocytoses*.

Etiologic and Pathogenetic Factors in White Cell Neoplasia: Overview

As discussed see in the following sections, the neoplastic disorders of white cells are extremely varied. Before we delve into this complexity, it is worth considering a few themes of general relevance to their etiology and pathogenesis.

Chromosomal Translocations and Other Acquired Mutations. Nonrandom chromosomal abnormalities, most commonly translocations, are present in the majority of white cell neoplasms. Many specific rearrangements are associated with particular neoplasms, suggesting a critical role in their genesis (Chapter 7).

- **The genes that are mutated or otherwise altered often play crucial roles in the development, growth, or survival of the normal counterpart of the malignant cell.** As a consequence, certain mutations are strongly associated with specific tumor types, so much so that in some instances they are required for particular diagnoses. In some instances, the mutation produces a “dominant-negative” protein that interferes with a normal function (a loss of function); in others the result is an inappropriate increase in some normal activity (a gain of function).
- **Oncoproteins created by genomic aberrations often block normal maturation, turn on pro-growth signaling pathways, or protect cells from apoptotic cell death.** Figure 13-4 highlights some of the more common or better characterized oncogenic events that serve as oncogenic driver mutations in particular kinds of white cell malignancies.
 - Many oncoproteins cause an arrest in differentiation, often at a stage when cells are proliferating rapidly. The importance of this block in maturation is most evident in the acute leukemias, in which dominant-negative oncogenic mutations involving transcription factors are often present that interfere with early stages of lymphoid or myeloid cell differentiation.
 - Other mutations in transcriptional regulators seem to directly enhance the self-renewal of tumors cells,

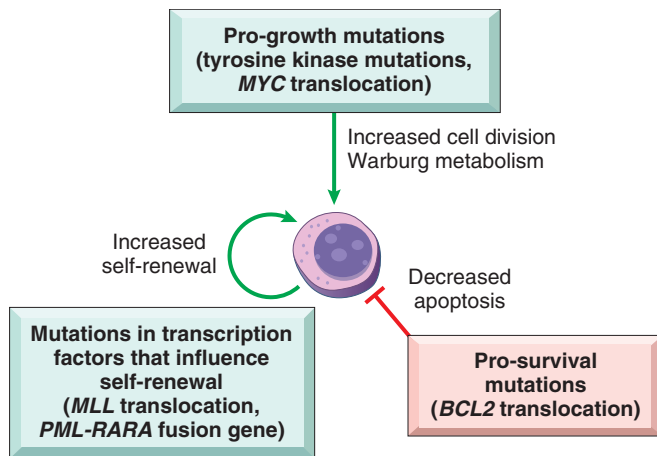

Figure 13-4 Pathogenesis of white cell malignancies. Various tumors harbor mutations that principally effect maturation or enhance self-renewal, drive growth, or prevent apoptosis. Exemplary examples of each type of mutation are listed; details are provided later under specific tumor types.

giving such cells stem-cell-like properties. These types of mutations often collaborate with mutations that produce a constitutively active tyrosine kinase; oncogenic tyrosine kinases activate RAS and its two downstream signaling arms, the PI3K/AKT and MAPK pathways (Chapter 7), and thereby drive cell growth and Warburg metabolism.

- Finally, mutations that inhibit apoptosis are prevalent in certain hematologic malignancies.
- **Proto-oncogenes are often activated in lymphoid cells by errors that occur during antigen receptor gene rearrangement and diversification.** Among lymphoid cells, potentially oncogenic mutations occur most frequently in germinal center B cells during attempted antibody diversification. After antigen stimulation, B cells enter germinal centers and upregulate the expression of activation-induced cytosine deaminase (AID), a specialized DNA-modifying enzyme that is essential for two types of immunoglobulin (Ig) gene modifications: *class switching*, an intragenic recombination event in which the IgM heavy-chain constant gene segment is replaced with a different constant segment (e.g., IgG₃), leading to a switch in the class (isotype) of antibody produced; and *somatic hypermutation*, which creates point mutations within Ig genes that may increase antibody affinity for antigen (Chapter 6). Certain proto-oncogenes, such as *MYC*, are activated in germinal center B-cell lymphomas by translocations to the transcriptionally active Ig locus. Remarkably, AID expression is sufficient to induce *MYC/Ig* translocations in normal germinal center B cells, apparently because AID creates lesions in DNA that lead to chromosomal breaks. Other proto-oncogenes, such as *BCL6*, a transcription factor that has an important role in many B cell malignancies, are frequently activated in germinal center B-cell lymphomas by point mutations that also seem to stem from “mistargeted” DNA breaks induced by AID. A different type of regulated genomic instability is unique to precursor B and T cells, which express a V(D)J recombinase that cuts DNA at specific sites

within the Ig and T-cell receptor loci, respectively. This process is essential for the assembly of productive antigen receptor genes, but sometimes goes awry, leading to the joining of portions of other genes to antigen receptor gene regulatory elements. Particularly in tumors of precursor T cells, proto-oncogenes are often deregulated by their involvement in such aberrant recombination events.

Inherited Genetic Factors. As discussed in Chapter 7, individuals with genetic diseases that promote genomic instability, such as Bloom syndrome, Fanconi anemia, and ataxia telangiectasia, are at increased risk of acute leukemia. In addition, both Down syndrome (trisomy 21) and type I neurofibromatosis are associated with an increased incidence of childhood leukemia.

Viruses. Three lymphotropic viruses—human T-cell leukemia virus-1 (HTLV-1), Epstein-Barr virus (EBV), and Kaposi sarcoma herpesvirus/human herpesvirus-8 (KSHV/HHV-8)—have been implicated as causative agents in particular lymphomas. The possible mechanisms of transformation by viruses are discussed in Chapter 7. HTLV-1 is associated with adult T-cell leukemia/lymphoma. EBV is found in a subset of Burkitt lymphoma, 30% to 40% of Hodgkin lymphoma (HL), many B-cell lymphomas arising in the setting of T-cell immunodeficiency, and rare NK-cell lymphomas. In addition to Kaposi sarcoma (Chapter 11), KSHV is associated with an unusual B-cell lymphoma that presents as a malignant effusion, often in the pleural cavity.

Chronic Inflammation. Several agents that cause localized chronic inflammation predispose to lymphoid neoplasia, which almost always arises within the inflamed tissue. Examples include the associations between *H. pylori* infection and gastric B-cell lymphomas (Chapter 17), gluten-sensitive enteropathy and intestinal T-cell lymphomas, and even breast implants, which are associated with an unusual subtype of T cell lymphoma. This can be contrasted with HIV infection, which is associated with an increased risk of B-cell lymphomas that may arise within virtually any organ. Early in the course, T-cell dysregulation by HIV infection causes a systemic hyperplasia of germinal center B cells that is associated with an increased incidence of germinal center B-cell lymphomas. In advanced infection (acquired immunodeficiency syndrome), severe T-cell immunodeficiency further elevates the risk for B-cell lymphomas, particularly those associated with EBV and KSHV/HHV-8. These relationships are discussed in more detail in Chapter 6.

Iatrogenic Factors. Ironically, radiation therapy and certain forms of chemotherapy used to treat cancer increase the risk of subsequent myeloid and lymphoid neoplasms. This association stems from the mutagenic effects of ionizing radiation and chemotherapeutic drugs on hematolymphoid progenitor cells.

Smoking. The incidence of acute myeloid leukemia is increased 1.3- to 2-fold in smokers, presumably because of exposure to carcinogens, such as benzene, in tobacco smoke.

Lymphoid Neoplasms

Definitions and Classifications

One confusing aspect of the lymphoid neoplasms concerns the use of the terms *lymphocytic leukemia* and *lymphoma*. *Leukemia* is used for neoplasms that present with widespread involvement of the bone marrow and (usually, but not always) the peripheral blood. *Lymphoma* is used for proliferations that arise as discrete tissue masses. Originally these terms were attached to what were considered distinct entities, but with time and increased understanding these divisions have blurred. Many entities called “lymphoma” occasionally have leukemic presentations, and evolution to “leukemia” is not unusual during the progression of incurable “lymphomas.” Conversely, tumors identical to “leukemias” sometimes arise as soft-tissue masses without detectable bone marrow disease. Hence, when applied to particular neoplasms, the terms *leukemia* and *lymphoma* merely reflect the usual tissue distribution of each disease at presentation.

Within the large group of lymphomas, *Hodgkin lymphoma* is segregated from all other forms, which constitute the *non-Hodgkin lymphomas (NHLs)*. Hodgkin lymphoma has distinctive pathologic features and is treated in a unique fashion. Another special group of B cell tumors, which differs from most lymphomas, is the *plasma cell neoplasms*. These most often arise in the bone marrow and only infrequently involve lymph nodes or the peripheral blood. Taken together, the diverse lymphoid neoplasms constitute a complex, clinically important group of cancers, with about 100,000 new cases being diagnosed each year in the United States.

The clinical presentation of the various lymphoid neoplasms is most often determined by the anatomic distribution of disease. Two thirds of NHLs and virtually all Hodgkin lymphomas present as enlarged nontender lymph nodes (often > 2 cm). The remaining one third of NHLs present with symptoms related to the involvement of extranodal sites (e.g., skin, stomach, or brain). The lymphocytic leukemias most often come to attention because of signs and symptoms related to the suppression of normal hematopoiesis by tumor cells in the bone marrow. Finally, the most common plasma cell neoplasm, multiple myeloma, causes bony destruction of the skeleton and often presents with pain due to pathologic fractures. Other symptoms related to lymphoid tumors are frequently caused by proteins secreted from the tumor cells or from immune cells that are responding to the tumor. Specific examples include the plasma cell tumors, in which much of the pathophysiology is related to the secretion of whole antibodies or Ig fragments; Hodgkin lymphoma, which is often associated with fever related to the release of cytokines from inflammatory cells responding to the tumor cells; and peripheral T-cell lymphomas, tumors of functional T cells that often release a number of inflammatory cytokines and chemokines.

Historically, few areas of pathology evoked as much controversy as the classification of lymphoid neoplasms, but consensus has been reached through use of objective molecular diagnostic tools. The current World Health Organization (WHO) classification scheme (Table 13-4) uses morphologic, immunophenotypic, genotypic, and

Table 13-4 World Health Organization Classification of Lymphoid Neoplasms

I. Precursor B-Cell Neoplasms
B-cell acute lymphoblastic leukemia/lymphoma (B-ALL)
II. Peripheral B-Cell Neoplasms
Chronic lymphocytic leukemia/small lymphocytic lymphoma
B-cell prolymphocytic leukemia
Lymphoplasmacytic lymphoma
Splenic and nodal marginal zone lymphomas
Extranodal marginal zone lymphoma
Mantle cell lymphoma
Follicular lymphoma
Marginal zone lymphoma
Hairy cell leukemia
Plasmacytoma/plasma cell myeloma
Diffuse large B-cell lymphoma
Burkitt lymphoma
III. Precursor T-Cell Neoplasms
T-cell acute lymphoblastic leukemia/lymphoma (T-ALL)
IV. Peripheral T-Cell and NK-Cell Neoplasms
T-cell prolymphocytic leukemia
Large granular lymphocytic leukemia
Mycosis fungoides/Sézary syndrome
Peripheral T-cell lymphoma, unspecified
Anaplastic large-cell lymphoma
Angioimmunoblastic T-cell lymphoma
Enteropathy-associated T-cell lymphoma
Panniculitis-like T-cell lymphoma
Hepatosplenic $\gamma\delta$ T-cell lymphoma
Adult T-cell leukemia/lymphoma
Extranodal NK/T-cell lymphoma
NK-cell leukemia
V. Hodgkin Lymphoma
Classical subtypes
Nodular sclerosis
Mixed cellularity
Lymphocyte-rich
Lymphocyte depletion
Lymphocyte predominance

NK, Natural killer.

clinical features to sort the lymphoid neoplasms into five broad categories, which are separated according to the cell of origin:

1. Precursor B-cell neoplasms (neoplasms of immature B cells)
2. Peripheral B-cell neoplasms (neoplasms of mature B cells)
3. Precursor T-cell neoplasms (neoplasms of immature T cells)
4. Peripheral T-cell and NK-cell neoplasms (neoplasms of mature T cells and NK cells)
5. Hodgkin lymphoma (neoplasms of Reed-Sternberg cells and variants)

Before discussing the specific entities of the WHO classification, some important principles relevant to the lymphoid neoplasms should be emphasized.

- Lymphoid neoplasia can be suspected from the clinical features, but histologic examination of lymph nodes or other involved tissues is required for diagnosis.

Figure 13-5 Origin of lymphoid neoplasms. Stages of B- and T-cell differentiation from which specific lymphoid tumors emerge are shown. CLP, Common lymphoid precursor; BLB, pre-B lymphoblast; DN, CD4/CD8 double-negative pro-T cell; DP, CD4/CD8 double-positive pre-T cell; GC, germinal-center B cell; MC, mantle B cell; MZ, marginal zone B cell; NBC, naive B cell; PTC, peripheral T cell.

- **Antigen receptor gene rearrangement generally precedes transformation of lymphoid cells; hence, all daughter cells derived from the malignant progenitor share the same antigen receptor gene configuration and sequence, and synthesize identical antigen receptor proteins (either Igs or T-cell receptors).** In contrast, normal immune responses are comprised of polyclonal populations of lymphocytes that express many different antigen receptors. Thus, analyses of antigen receptor genes and their protein products can be used to distinguish reactive (polyclonal) and malignant (monoclonal) lymphoid proliferations. In addition, each antigen receptor gene rearrangement produces a unique DNA sequence that constitutes a highly specific clonal marker, which can be used to detect small numbers of residual malignant lymphoid cells after therapy.
- **Most lymphoid neoplasms resemble some recognizable stage of B- or T-cell differentiation (Fig. 13-5),** a feature that is used in their classification. The vast majority (85% to 90%) of lymphoid neoplasms are of B-cell origin, with most of the remainder being T-cell tumors; only rarely are tumors of NK cell origin encountered. Markers recognized by antibodies that are helpful in the characterization of lymphomas and leukemias are listed in [Table 13-5](#).
- **Lymphoid neoplasms are often associated with immune abnormalities.** Both a loss of protective immunity (susceptibility to infection) and a breakdown of tolerance (autoimmunity) can be seen, sometimes in the same patient. In a further ironic twist, individuals with inherited or acquired immunodeficiency are themselves at high risk of developing certain lymphoid neoplasms, particularly those caused by oncogenic viruses (e.g., EBV).
- **Neoplastic B and T cells tend to recapitulate the behavior of their normal counterparts.** Like normal lymphocytes, neoplastic B and T cells home to certain tissue sites, leading to characteristic patterns of involvement. For example, follicular lymphomas home to germinal centers in lymph nodes, whereas cutaneous T-cell lymphomas home to the skin. Like their normal counterparts, particular adhesion molecules and chemokine receptors govern the homing of the neoplastic lymphoid cells. Variable numbers of neoplastic B and T

Table 13-5 Some Immune Cell Antigens Detected by Monoclonal Antibodies

Antigen Designation	Normal Cellular Distribution
Primarily T-Cell Associated	
CD1	Thymocytes and Langerhans cells
CD3	Thymocytes, mature T cells
CD4	Helper T cells, subset of thymocytes
CD5	T cells and a small subset of B cells
CD8	Cytotoxic T cells, subset of thymocytes, and some NK cells
Primarily B-Cell Associated	
CD10	Pre-B cells and germinal-center B cells
CD19	Pre-B cells and mature B cells but not plasma cells
CD20	Pre-B cells after CD19 and mature B cells but not plasma cells
CD21	EBV receptor; mature B cells and follicular dendritic cells
CD23	Activated mature B cells
CD79a	Marrow pre-B cells and mature B cells
Primarily Monocyte or Macrophage Associated	
CD11c	Granulocytes, monocytes, and macrophages; also expressed by hairy cell leukemias
CD13	Immature and mature monocytes and granulocytes
CD14	Monocytes
CD15	Granulocytes; Reed-Sternberg cells and variants
CD33	Myeloid progenitors and monocytes
CD64	Mature myeloid cells
Primarily NK-Cell Associated	
CD16	NK cells and granulocytes
CD56	NK cells and a subset of T cells
Primarily Stem Cell and Progenitor Cell Associated	
CD34	Pluripotent hematopoietic stem cells and progenitor cells of many lineages
Activation Markers	
CD30	Activated B cells, T cells, and monocytes; Reed-Sternberg cells and variants
Present on All Leukocytes	
CD45	All leukocytes; also known as leukocyte common antigen (LCA)

CD, Cluster designation; EBV, Epstein-Barr virus; NK, natural killer.

lymphoid cells also recirculate through the lymphatics and peripheral blood to distant sites; as a result most lymphoid tumors are widely disseminated at the time of diagnosis. Notable exceptions to this rule include Hodgkin lymphomas, which are sometimes restricted to one group of lymph nodes, and marginal zone B-cell lymphomas, which are often restricted to sites of chronic inflammation.

- **Hodgkin lymphoma spreads in an orderly fashion, whereas most forms of NHL spread widely early in their course in a less predictable fashion.** Hence, while lymphoma staging provides generally useful prognostic information, it is of most utility in guiding therapy in Hodgkin lymphoma.

We now turn to the specific entities of the WHO classification. We will begin with neoplasms of immature lymphoid cells, and then discuss the more common Non-Hodgkin lymphomas and plasma cell neoplasms, followed by a selection of rarer lymphoid neoplasms that are pathogenetically informative or of particular clinical importance. Some of the salient molecular and clinical features of these neoplasms are summarized in Table 13-6. We will finish by discussing the Hodgkin lymphomas.

Precursor B- and T-Cell Neoplasms

Acute Lymphoblastic Leukemia/Lymphoma

Acute lymphoblastic leukemia/lymphomas (ALLs) are neoplasms composed of immature B (pre-B) or T (pre-T) cells, which are referred to as lymphoblasts. About 85% are B-ALLs, which typically manifest as childhood acute “leukemias.” The less common T-ALLs tend to present in adolescent males as thymic “lymphomas.” There is, however, considerable overlap in the clinical behavior of B- and T-ALL; for example, B-ALL uncommonly presents as a mass in the skin or a bone, and many T-ALLs present with or evolve to a leukemic picture. Because of their morphologic and clinical similarities, the various forms of ALL will be considered here together.

ALL is the most common cancer of children. Approximately 2500 new cases are diagnosed each year in the United States, most occurring in individuals younger than 15 years of age. ALL is almost three times as common in whites as in blacks and is slightly more frequent in boys than in girls. Hispanics have the highest incidence of any ethnic group. B-ALL peaks in incidence at about the age of 3, perhaps because the number of normal bone marrow pre-B cells (the cell of origin) is greatest very early in life. Similarly the peak incidence of T-ALL is in adolescence, the age when the thymus reaches maximum size. B- and T-ALL also occur less frequently in adults of all ages.

Pathogenesis. Many of the chromosomal aberrations seen in ALL dysregulate the expression and function of transcription factors required for normal B- and T-cell development. Up to 70% of T-ALLs have gain-of-function mutations in *NOTCH1*, a gene that is essential for T-cell development. On the other hand, a high fraction of B-ALLs have loss-of-function mutations in genes that are required for B-cell development, such as *PAX5*, *E2A*, and *EBF*, or a balanced t(12;21) involving the genes *ETV6* and *RUNX1*, two genes that are needed in very early hematopoietic precursors. All of these varied mutations disturb the differentiation of lymphoid precursors and promote maturation arrest, and in doing they induce increased self-renewal, a stem cell-like phenotype. Similar themes are relevant in the genesis of AML (discussed later).

In keeping with the multistep origin of cancer (Chapter 7), single mutations are not sufficient to produce ALL. The identity of these complementary mutations is incomplete, but aberrations that drive cell growth, such as mutations that increase tyrosine kinase activity and RAS signaling, are commonly present. Emerging data from deep sequencing of ALL genomes is rapidly filling in the remaining gaps. Early returns suggest that fewer than 10 mutations are sufficient to produce full-blown ALL; hence, compared to solid tumors, ALL is a genetically simple tumor.

Table 13-6 Summary of Major Types of Lymphoid Leukemias and Non-Hodgkin Lymphomas

Diagnosis	Cell of Origin	Genotype	Salient Clinical Features
Neoplasms of Immature B and T Cells			
B-cell acute lymphoblastic leukemia/lymphoma*	Bone marrow precursor B cell	Diverse chromosomal translocations; t(12;21) involving <i>RUNX1</i> and <i>ETV6</i> present in 25%	Predominantly children; symptoms relating to marrow replacement and pancytopenia; aggressive
T-cell acute lymphoblastic leukemia/lymphoma	Precursor T cell (often of thymic origin)	Diverse chromosomal translocations, <i>NOTCH1</i> mutations (50%-70%)	Predominantly adolescent males; thymic masses and variable bone marrow involvement; aggressive
Neoplasms of Mature B Cells			
Burkitt lymphoma*	Germinal-center B cell	Translocations involving <i>MYC</i> and Ig loci, usually t(8;14); subset EBV-associated	Adolescents or young adults with extranodal masses; uncommonly presents as "leukemia"; aggressive
Diffuse large B-cell lymphoma†	Germinal-center or postgerminal center B cell	Diverse chromosomal rearrangements, most often of <i>BCL6</i> (30%), <i>BCL2</i> (10%), or <i>MYC</i> (5%)	All ages, but most common in older adults; often appears as a rapidly growing mass; 30% extranodal; aggressive
Extranodal marginal zone lymphoma	Memory B cell	t(11;18), t(1;14), and t(14;18) creating <i>MALT1-IAP2</i> , <i>BCL10-IgH</i> , and <i>MALT1-IgH</i> fusion genes, respectively	Arises at extranodal sites in adults with chronic inflammatory diseases; may remain localized; indolent
Follicular lymphoma†	Germinal-center B cell	t(14;18) creating <i>BCL2-IgH</i> fusion gene	Older adults with generalized lymphadenopathy and marrow involvement; indolent
Hairy cell leukemia	Memory B cell	Activating <i>BRAF</i> mutations	Older males with pancytopenia and splenomegaly; indolent
Mantle cell lymphoma	Naive B cell	t(11;14) creating <i>CyclinD1-IgH</i> fusion gene	Older males with disseminated disease; moderately aggressive
Multiple myeloma/solitary plasmacytoma†	Post-germinal-center bone marrow homing plasma cell	Diverse rearrangements involving <i>IgH</i> ; 13q deletions	Myeloma: older adults with lytic bone lesions, pathologic fractures, hypercalcemia, and renal failure; moderately aggressive Plasmacytoma: isolated plasma cell masses in bone or soft tissue; indolent
Small lymphocytic lymphoma/chronic lymphocytic leukemia	Naive B cell or memory B cell	Trisomy 12, deletions of 11q, 13q, and 17p	Older adults with bone marrow, lymph node, spleen, and liver disease; autoimmune hemolysis and thrombocytopenia in a minority; indolent
Neoplasms of Mature T Cells or NK Cells			
Adult T-cell leukemia/lymphoma	Helper T cell	HTLV-1 provirus present in tumor cells	Adults with cutaneous lesions, marrow involvement, and hypercalcemia; occurs mainly in Japan, West Africa, and the Caribbean; aggressive
Peripheral T-cell lymphoma, unspecified	Helper or cytotoxic T cell	No specific chromosomal abnormality	Mainly older adults; usually presents with lymphadenopathy; aggressive
Anaplastic large-cell lymphoma	Cytotoxic T cell	Rearrangements of <i>ALK</i> (anaplastic large cell lymphoma kinase) in a subset	Children and young adults, usually with lymph node and soft-tissue disease; aggressive
Extranodal NK/T-cell lymphoma	NK-cell (common) or cytotoxic T cell (rare)	EBV-associated; no specific chromosomal abnormality	Adults with destructive extranodal masses, most commonly sinonasal; aggressive
Mycosis fungoides/Sézary syndrome	Helper T cell	No specific chromosomal abnormality	Adult patients with cutaneous patches, plaques, nodules, or generalized erythema; indolent
Large granular lymphocytic leukemia	Two types: cytotoxic T cell and NK cell	Point mutations in <i>STAT3</i>	Adult patients with splenomegaly, neutropenia, and anemia, sometimes, accompanied by autoimmune disease

*Most common tumors in children

†Most common tumors in adults.

EBV, Epstein-Barr virus; HTLV, human immunodeficiency virus; Ig, immunoglobulin; NK, natural killer.

Approximately 90% of ALLs have numerical or structural chromosomal changes. Most common is hyperploidy (>50 chromosomes), but hypoploidy and a variety of balanced chromosomal translocations are also seen. Changes in chromosome numbers are of uncertain pathogenic significance, but are important because they frequently correlate with immunophenotype and sometimes prognosis. For example, hyperdiploidy and hypodiploidy are seen only in B-ALL. In addition, B- and T-ALL are associated with completely different sets of translocations, indicating that they are pathogenetically distinct.

MORPHOLOGY

In leukemic presentations, **the marrow is hypercellular and packed with lymphoblasts**, which replace the normal marrow elements. Mediastinal thymic masses occur in 50% to 70% of T-ALLs, which are also more likely to be associated with lymphadenopathy and splenomegaly. In both B- and T-ALL, the tumor cells have scant basophilic cytoplasm and nuclei somewhat larger than those of small lymphocytes (Fig. 13-6A). The nuclear chromatin is delicate and finely stippled, and nucleoli are usually small and often demarcated by a rim of

condensed chromatin. In many cases the nuclear membrane is deeply subdivided, imparting a convoluted appearance. In keeping with the aggressive clinical behavior, the mitotic rate is high. As with other rapidly growing lymphoid tumors, interspersed macrophages ingesting apoptotic tumor cells may impart a “starry sky” appearance (shown in Fig. 13-15).

Because of their different responses to chemotherapy, ALL must be distinguished from acute myeloid leukemia (AML), a neoplasm of immature myeloid cells that can cause identical signs and symptoms. **Compared with myeloblasts, lymphoblasts have more condensed chromatin, less conspicuous nucleoli, and smaller amounts of cytoplasm that usually lacks granules.** However, these morphologic distinctions are not absolute and definitive diagnosis relies on stains performed with antibodies specific for B- and T-cell antigens (Fig. 13-6B and C). Histochemical stains are also helpful, in that (in contrast to myeloblasts) lymphoblasts are myeloperoxidase-negative and often contain periodic acid-Schiff-positive cytoplasmic material.

Figure 13-6 A, Acute lymphoblastic leukemia/lymphoma. Lymphoblasts with condensed nuclear chromatin, small nucleoli, and scant agranular cytoplasm. B and C represent the phenotype of the ALL shown in A, analyzed by flow cytometry. B, Note that the lymphoblasts represented by the red dots express terminal deoxynucleotidyl-transferase (TdT) and the B-cell marker CD22. C, The same cells are positive for two other markers, CD10 and CD19, commonly expressed on pre-B lymphoblasts. Thus, this is a B-ALL. (A, Courtesy Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas; B and C, courtesy Dr. Louis Picker, Oregon Health Science Center, Portland, Ore.)

Immunophenotype. Immunostaining for terminal deoxynucleotidyl transferase (TdT), a specialized DNA polymerase that is expressed only in pre-B and pre-T lymphoblasts, is positive in more than 95% of cases (Fig. 13-6B). B- and T-ALLs are distinguished with stains for B- and T-cell-specific markers (summarized later).

B-ALLs are arrested at various stages of pre-B-cell development. The lymphoblasts usually express the pan B-cell marker CD19 and the transcription factor PAX5, as well as CD10. In very immature B-ALLs, CD10 is negative. Alternatively, more mature “late pre-B” ALLs express CD10, CD19, CD20, and cytoplasmic IgM heavy chain (μ chain).

Similarly, T-ALLs are arrested at various stages of pre-T-cell development. In most cases the cells are positive for CD1, CD2, CD5, and CD7. The more immature tumors are usually negative for surface CD3, CD4, and CD8, whereas “late” pre-T-cell tumors are positive for these markers.

Clinical Features. Although ALL and AML are genetically and immunophenotypically distinct, they are clinically very similar. In both, the accumulation of neoplastic “blasts” in the bone marrow suppresses normal hematopoiesis by physical crowding, competition for growth factors, and other poorly understood mechanisms. The common features and those more characteristic of ALL are the following:

- *Abrupt stormy onset* within days to a few weeks of the first symptoms
- *Symptoms related to depression of marrow function*, including fatigue due to anemia; fever, reflecting infections secondary to neutropenia; and bleeding due to thrombocytopenia
- *Mass effects caused by neoplastic infiltration* (which are more common in ALL), including bone pain resulting from marrow expansion and infiltration of the subperiosteum; generalized lymphadenopathy, splenomegaly, and hepatomegaly; testicular enlargement; and in T-ALL, complications related to compression of large vessels and airways in the mediastinum
- *Central nervous system manifestations* such as headache, vomiting, and nerve palsies resulting from meningeal spread, all of which are also more common in ALL

Prognosis. Pediatric ALL is one of the great success stories of oncology. With aggressive chemotherapy about 95% of children with ALL obtain a complete remission, and 75% to 85% are cured. Despite these achievements, however, ALL remains the leading cause of cancer deaths in children, and only 35% to 40% of adults are cured. Several factors are associated with a worse prognosis: (1) age younger than 2 years, largely because of the strong association of infantile ALL with translocations involving the *MLL* gene; (2) presentation in adolescence or adulthood; and (3) peripheral blood blast counts greater than 100,000, which probably reflects a high tumor burden. Favorable prognostic markers include (1) age between 2 and 10 years, (2) a low white cell count, (3) hyperdiploidy, (4) trisomy of chromosomes 4, 7, and 10, and (5) the presence of a $t(12;21)$. Notably, the molecular detection of residual disease after therapy is predictive of a worse outcome in both B- and T-ALL and is being used to guide new clinical trials.

Although most chromosomal aberrations in ALL alter the function of transcription factors, the t(9;22) instead creates a fusion gene that encodes a constitutively active BCR-ABL tyrosine kinase (described in more detail under chronic myelogenous leukemia). In B-ALL, the BCR-ABL protein is usually 190 kDa in size and has stronger tyrosine kinase activity than the form of BCR-ABL that is found in chronic myelogenous leukemia, in which a BCR-ABL protein of 210 kDa in size is usually seen. Treatment of t(9;22)-positive ALLs with BCR-ABL kinase inhibitors in combination with conventional chemotherapy is highly effective and has greatly improved the outcome for this molecular subtype of B-ALL in children. The outlook for adults with ALL remains more guarded, in part because of differences in the molecular pathogenesis of adult and childhood ALL, but also because older adults cannot tolerate the very intensive chemotherapy regimens that are curative in children.

Peripheral B-Cell Neoplasms

Chronic Lymphocytic Leukemia,
Small Lymphocytic Lymphoma

Chronic lymphocytic leukemia (CLL) and small lymphocytic lymphoma (SLL) differ only in the degree of peripheral blood lymphocytosis. Most affected patients have sufficient lymphocytosis to fulfill the diagnostic requirement for CLL (absolute lymphocyte count > 5000 per mm³). **CLL is the most common leukemia of adults in the Western world.** There are about 15,000 new cases of CLL each year in the United States. The median age at diagnosis is 60 years, and there is a 2:1 male predominance. In contrast, SLL constitutes only 4% of NHLs. CLL/SLL is much less common in Japan and other Asian countries than in the West.

Pathogenesis. Unlike most other lymphoid malignancies, chromosomal translocations are rare in CLL/SLL. **The most common genetic anomalies are deletions of 13q14.3, 11q, and 17p, and trisomy 12q.** Molecular characterization of the region deleted on chromosome 13 has implicated two microRNAs, miR-15a and miR-16-1, as possible tumor suppressor genes. DNA sequencing has revealed that the Ig genes of some CLL/SLL are somatically hypermutated,

whereas others are not, suggesting that the cell of origin may be either a postgerminal center memory B cell or a naive B cell. For unclear reasons, tumors with unmutated Ig segments (those putatively of naive B-cell origin) pursue a more aggressive course. Deep sequencing of CLL genomes has also revealed gain-of-function mutations involving the NOTCH1 receptor in 10% to 18% of tumors, as well as frequent mutations in genes that regulate RNA splicing.

The growth of CLL/SLL cells is largely confined to proliferation centers (described below), where tumor cells receive critical cues from the microenvironment. Stromal cells in proliferation centers seem to express a variety of factors that stimulate the activity of the transcription factor NF- κ B, which promotes cell growth and survival. In addition, experimental models of CLL suggest that tumor cells rely on signals generated by the B-cell receptor (membrane bound immunoglobulin) for growth and survival. These signals are transduced by a cascade of kinases that include the Bruton tyrosine kinase (BTK), which is defective in patients with congenital X-linked agammaglobulinemia (Chapter 6). Of note, BTK inhibitors now being tested in clinical trials have produced sustained responses in a high fraction of CLL patients, indicating that human CLL cells are also dependent on this signaling pathway.

MORPHOLOGY

Lymph nodes are diffusely effaced by an infiltrate of predominantly small lymphocytes 6 to 12 μ m in diameter with round to slightly irregular nuclei, condensed chromatin, and scant cytoplasm (Fig. 13-7). Admixed are variable numbers of larger activated lymphocytes that often gather in loose aggregates referred to as **proliferation centers**, which contain mitotically active cells. When present, **proliferation centers are pathognomonic for CLL/SLL.** The blood contains large numbers of small round lymphocytes with scant cytoplasm (Fig. 13-8). Some of these cells are usually disrupted in the process of making smears, producing so-called **smudge cells**. The bone marrow is almost always involved by interstitial infiltrates or aggregates of tumor cells. Infiltrates are also virtually always seen in the splenic white and red pulp and the hepatic portal tracts (Fig. 13-9).

Figure 13-7 Small lymphocytic lymphoma/chronic lymphocytic leukemia (lymph node). **A**, Low-power view shows diffuse effacement of nodal architecture. **B**, At high power the majority of the tumor cells are small round lymphocytes. A “prolymphocyte,” a larger cell with a centrally placed nucleolus, is also present in this field (arrow). (**A**, Courtesy Dr. José Hernandez, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas.)

Figure 13-8 Chronic lymphocytic leukemia. This peripheral blood smear is flooded with small lymphocytes with condensed chromatin and scant cytoplasm. A characteristic finding is the presence of disrupted tumor cells (smudge cells), two of which are present in this smear. A coexistent autoimmune hemolytic anemia (Chapter 14) explains the presence of spherocytes (hyperchromatic, round erythrocytes). A nucleated erythroid cell is present in the lower left-hand corner of the field. In this setting, circulating nucleated red cells could stem from premature release of progenitors in the face of severe anemia, marrow infiltration by tumor (leukoerythroblastosis), or both.

Immunophenotype. CLL/SLL has a distinctive immunophenotype. The tumor cells express the pan B-cell markers CD19 and CD20, as well as CD23 and CD5, the latter a marker that is found on a small subset of normal B cells. Low-level expression of surface Ig (usually IgM or IgM and IgD) is also typical.

Clinical Features. Patients are often asymptomatic at diagnosis. When symptoms appear, they are nonspecific and include easy fatigability, weight loss, and anorexia. Generalized lymphadenopathy and hepatosplenomegaly are present in 50% to 60% of symptomatic patients. The leukocyte count is highly variable; leukopenia can be seen in individuals with SLL and marrow involvement, while counts in excess of 200,000/mm³ are sometimes seen in CLL patients with heavy tumor burdens. A small monoclonal Ig “spike” is present in the blood of some patients.

Figure 13-9 Small lymphocytic lymphoma/chronic lymphocytic leukemia involving the liver. Low-power view of a typical periportal lymphocytic infiltrate. (Courtesy Dr. Mark Fleming, Department of Pathology, Children’s Hospital, Boston, Mass.)

At the other end of the spectrum are asymptomatic patients with monoclonal B cells in their peripheral blood but in numbers that are too few to merit the diagnosis of CLL. These abnormal B cells often have some of the same genetic aberrations that are seen in CLL, such as 13q deletions and trisomy 12, yet only about 1% of such patients progress to symptomatic CLL per year, presumably due to acquisition of additional genetic lesions.

CLL/SLL disrupts normal immune function through uncertain mechanisms. Hypogammaglobulinemia is common and contributes to an increased susceptibility to infections, particularly those caused by bacteria. Conversely, 10% to 15% of patients develop hemolytic anemia or thrombocytopenia due to autoantibodies made by non-neoplastic B cells.

The course and prognosis are extremely variable and depend primarily on the clinical stage. Overall median survival is 4 to 6 years, but is more than 10 years in individuals with minimal tumor burdens at diagnosis. Other variables that correlate with a worse outcome include (1) the presence of deletions of 11q and 17p, (2) a lack of somatic hypermutation, (3) the expression of ZAP-70, a protein that augments signals produced by the Ig receptor, and (4) the presence of *NOTCH1* mutations. Symptomatic patients are generally treated with “gentle” chemotherapy and immunotherapy with antibodies against proteins found on the surface of CLL/SLL cells, particularly CD20. Hematopoietic stem cell transplantation is being offered to the relatively young. The most promising new therapy is BTK inhibitors, described earlier.

Another factor that impacts patient survival is the tendency of CLL/SLL to transform to a more aggressive tumor. Most commonly this takes the form of a transformation to diffuse large B-cell lymphoma, so-called *Richter syndrome* (approximately 5% to 10% of patients). Transformation to diffuse large B-cell lymphoma is often heralded by the development of a rapidly enlarging mass within a lymph node or the spleen. Transformation probably stems from the acquisition of additional, still mutations that increase growth. Large-cell transformation is an ominous event, with most patients surviving less than 1 year.

Follicular Lymphoma

Follicular lymphoma is the most common form of indolent NHL in the United States, affecting 15,000 to 20,000 individuals per year. It usually presents in middle age and afflicts males and females equally. It is less common in Europe and rare in Asian populations.

Pathogenesis. Follicular lymphoma likely arises from germinal center B cells and is strongly associated with chromosomal translocations involving *BCL2*. Its hallmark is a (14;18) translocation that juxtaposes the *IGH* locus on chromosome 14 and the *BCL2* locus on chromosome 18. The t(14;18) is seen in up to 90% of follicular lymphomas, and leads to overexpression of *BCL2* (see Fig. 13-12). *BCL2* antagonizes apoptosis (Chapter 7) and promotes the survival of follicular lymphoma cells. Notably, while normal germinal centers contain numerous B cells undergoing apoptosis, follicular lymphoma is characteristically devoid of apoptotic cells. Deep sequencing of follicular lymphoma genomes have identified mutations in the *MLL2* gene in about 90% of cases as well. *MLL2* encodes a histone

Figure 13-10 Follicular lymphoma (lymph node). **A**, Nodular aggregates of lymphoma cells are present throughout lymph node. **B**, At high magnification, small lymphoid cells with condensed chromatin and irregular or cleaved nuclear outlines (centrocytes) are mixed with a population of larger cells with nucleoli (centroblasts). (**A**, Courtesy Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas.)

methyltransferase that regulates gene expression, suggesting that epigenetic abnormalities have an important role in this neoplasm; however, the functional significance of *MLL2* mutations has yet to be deciphered.

Particularly early in the disease, follicular lymphoma cells growing in lymph nodes are found within a network of reactive follicular dendritic cells admixed with macrophages and T cells. Expression profiling studies have shown that differences in the genes expressed by these reactive cells are predictive of outcome, implying that the response of follicular lymphoma cells to therapy is influenced by the surrounding microenvironment.

MORPHOLOGY

In most cases, a predominantly nodular or nodular and diffuse growth pattern is observed in involved lymph nodes (Fig. 13-10A). Two principal cell types are present in varying proportions: (1) small cells with irregular or cleaved nuclear contours and scant cytoplasm, referred to as **centrocytes** (small cleaved cells); and (2) larger cells with open nuclear chromatin, several nucleoli, and modest amounts of cytoplasm, referred to as **centroblasts** (Fig. 13-10B). In most follicular lymphomas, small cleaved cells are in the majority. Peripheral blood involvement sufficient to produce lymphocytosis (usually less than 20,000 cells/mm³) is seen in about 10% of cases. Bone marrow involvement occurs in 85% of cases and characteristically takes the form of paratrabecular lymphoid aggregates. The splenic white pulp (Fig. 13-11) and hepatic portal triads are also frequently involved.

Immunophenotype. The neoplastic cells closely resemble normal germinal center B cells, expressing CD19, CD20, CD10, surface Ig, and BCL6. Unlike CLL/SLL and mantle cell lymphoma, CD5 is not expressed. BCL2 is expressed in more than 90% of cases, in distinction to normal follicular center B cells, which are BCL2-negative (Fig. 13-12).

Clinical Features. Follicular lymphoma tends to present with painless, generalized lymphadenopathy. Involvement of extranodal sites, such as the gastrointestinal tract, central nervous system, or testis, is relatively uncommon.

Although incurable, it usually follows an indolent waxing and waning course. Survival (median, 7 to 9 years) is not improved by aggressive therapy; hence, the usual approach is to palliate patients with low-dose chemotherapy or immunotherapy (e.g., anti-CD20 antibody) when they become symptomatic.

Histologic transformation occurs in 30% to 50% of follicular lymphomas, most commonly to diffuse large B-cell lymphoma. Less commonly, tumors resembling Burkitt lymphoma emerge that are associated with chromosomal translocations involving *MYC*. Like normal germinal center B cells, follicular lymphomas have ongoing somatic hypermutation, which may promote transformation by causing point mutations or chromosomal aberrations. The median survival is less than 1 year after transformation.

Diffuse Large B-Cell Lymphoma

Diffuse large B-cell lymphoma (DLBCL) is the most common form of NHL. Each year in the United States there are about 25,000 new cases. There is a slight male

Figure 13-11 Follicular lymphoma (spleen). Prominent nodules represent white pulp follicles expanded by follicular lymphoma cells. Other indolent B-cell lymphomas (small lymphocytic lymphoma, mantle cell lymphoma, marginal zone lymphoma) can produce an identical pattern of involvement. (Courtesy Dr. Jeffrey Jorgenson, Department of Hematopathology, MD Anderson Cancer Center, Houston, Texas.)

Figure 13-12 BCL2 expression in reactive and neoplastic follicles. BCL2 protein was detected by using an immunohistochemical technique that produces a brown stain. In reactive follicles (**A**), BCL2 is present in mantle zone cells but not follicular-center B cells, whereas follicular lymphoma cells (**B**) show strong BCL2 staining. (Courtesy Dr. Jeffrey Jorgenson, Department of Hematopathology, MD Anderson Cancer Center, Houston, Texas.)

predominance. The median patient age is about 60 years, but DLBCL also occurs in young adults and children.

Pathogenesis. Genetic, gene expression profiling, and immunohistochemical studies indicate that DLBCL is molecularly heterogeneous. One frequent pathogenic event is dysregulation of *BCL6*, a DNA-binding zinc-finger transcriptional repressor that is required for the formation of normal germinal centers. About 30% of DLBCLs contain various translocations that have in common a breakpoint in *BCL6* at chromosome 3q27. Acquired mutations in *BCL6* promoter sequences that abrogate *BCL6* autoregulation (an important negative-regulatory mechanism) are seen even more frequently. It is hypothesized that both types of lesions are inadvertent byproducts of somatic hypermutation that result in overexpression of *BCL6*, which has several important consequences. *BCL6* represses the expression of factors that normally serve to promote germinal center B-cell differentiation, growth arrest, and apoptosis, and each of these effects is believed to contribute to the development of DLBCL. Mutations similar to those found in *BCL6* are also seen in multiple other oncogenes, including *MYC*, suggesting that somatic hypermutation in DLBCL cells is “mistargeted” to a wide variety of loci.

Another 10% to 20% of tumors are associated with the t(14;18) (discussed earlier under Follicular Lymphoma), which leads to the overexpression of the antiapoptotic protein BCL2. Tumors with *BCL2* rearrangements usually lack *BCL6* rearrangements, suggesting that these rearrangements define two distinct molecular classes of DLBCL. Some tumors with *BCL2* rearrangements may arise from unrecognized underlying follicular lymphomas, which frequently transform to DLBCL. Roughly 5% of DLBCLs are associated with translocations involving *MYC*; these tumors may have a distinctive biology and are discussed further under Burkitt Lymphoma (later). Finally, deep sequencing of DLBCL genomes has identified frequent mutations in genes encoding histone acetyltransferases such as p300 and CREBP, proteins that regulate gene expression by modifying histones and altering chromatin

structure. This association has sparked interest in using drugs that target the epigenome as therapies for DLBCL.

MORPHOLOGY

The common features are a relatively **large cell size** (usually four to five times the diameter of a small lymphocyte) and a **diffuse pattern of growth** (Fig. 13-13). In other respects, substantial morphologic variation is seen. Most commonly, the tumor cells have a round or oval nucleus that appears vesicular due to margination of chromatin to the nuclear membrane, but large multilobated or cleaved nuclei are prominent in some cases. Nucleoli may be two to three in number and located adjacent to the nuclear membrane, or single and centrally placed. The cytoplasm is usually moderately abundant and may be pale or basophilic. More anaplastic tumors may even contain multinucleated cells with large inclusion-like nucleoli that resemble Reed-Sternberg cells (the malignant cell of Hodgkin lymphoma).

Immunophenotype. These mature B-cell tumors express CD19 and CD20 and show variable expression of germinal center B-cell markers such as CD10 and BCL6. Most have surface Ig.

Special Subtypes. Several subtypes of DLBCL are sufficiently distinctive to merit brief discussion.

- **Immunodeficiency-associated large B-cell lymphoma** occurs in the setting of severe T-cell immunodeficiency (e.g., advanced HIV infection and allogeneic bone marrow transplantation). The neoplastic B cells are usually infected with EBV, which plays a critical pathogenic role. Restoration of T-cell immunity may lead to regression of these proliferations.
- **Primary effusion lymphoma** presents as a malignant pleural or ascitic effusion, mostly in patients with advanced HIV infection or older adults. The tumor cells are often anaplastic in appearance and typically fail to express surface B- or T-cell markers, but have clonal IgH gene rearrangements. In all cases the tumor cells are infected with KSHV/HHV-8, which appears to have a causal role.

Clinical Features. DLBCL typically presents as a rapidly enlarging mass at a nodal or extranodal site. It can arise

Figure 13-13 Diffuse large B-cell lymphoma. Tumor cells have large nuclei, open chromatin, and prominent nucleoli. (Courtesy Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas.)

Figure 13-14 Diffuse large B-cell lymphoma involving the spleen. The isolated large mass is typical. In contrast, indolent B-cell lymphomas usually produce multifocal expansion of white pulp (see Fig. 13-11). (Courtesy Dr. Mark Fleming, Department of Pathology, Children's Hospital, Boston, Mass.)

virtually anywhere in the body. Waldeyer ring, the oropharyngeal lymphoid tissue that includes the tonsils and adenoids, is involved commonly. Primary or secondary involvement of the liver and spleen may take the form of large destructive masses (Fig. 13-14). Extranodal sites include the gastrointestinal tract, skin, bone, brain, and other tissues. Bone marrow involvement is relatively uncommon and usually occurs late in the course. Rarely, a leukemic picture emerges.

DLBCLs are aggressive tumors that are rapidly fatal without treatment. With intensive combination chemotherapy, 60% to 80% of patients achieve a complete remission, and 40% to 50% are cured. Adjuvant therapy with anti-CD20 antibody improves both the initial response and the overall outcome. Individuals with limited disease fare better than those with widespread disease or bulky tumor masses. Expression profiling has identified distinct molecular subtypes with differing clinical outcomes and has provided the rationale for new therapies directed at inhibiting the NF- κ B and B cell receptor signaling pathways. Of note, about 5% of DLBCLs have *MYC* translocations, and these cases of DLBCL may be difficult to distinguish from Burkitt lymphoma (described later) by conventional diagnostic tests. In fact, recent data suggest that DLBCLs with *MYC* translocations have a worse prognosis than those without and may be better treated with chemotherapy regimens that are now standard for Burkitt lymphoma.

Burkitt Lymphoma

Within the category of Burkitt Lymphoma fall (1) African (endemic) Burkitt lymphoma, (2) sporadic (nonendemic) Burkitt lymphoma, and (3) a subset of aggressive lymphomas occurring in individuals infected with HIV. Burkitt lymphomas occurring in each of these settings are histologically identical but differ in some clinical, genotypic, and virologic characteristics.

Pathogenesis. All forms of Burkitt lymphoma are highly associated with translocations of the *MYC* gene on chromosome 8 that lead to increased *MYC* protein levels. *MYC* is a master transcriptional regulator that increases the expression of genes that are required for aerobic glycolysis, the so-called Warburg effect (Chapter 7). When nutrients such as glucose and glutamine are available, Warburg metabolism allow cells to biosynthesize all of the building blocks—nucleotides, lipids, proteins—that are

needed for growth and cell division. Consequently, Burkitt lymphoma is believed to be the fastest growing human tumor. The translocation partner for *MYC* is usually the IgH locus [t(8;14)] but may also be the Ig κ [t(2;8)] or λ [t(8;22)] light chain loci. The breakpoints in the IgH locus in sporadic Burkitt lymphoma are usually found in the class switch regions, whereas the breakpoints in endemic Burkitt lymphoma tend to lie within more 5' V(D)J sequences. The basis for this subtle molecular distinction is not known, but both types of translocations can be induced in germinal center B cells by AID, a specialized DNA-modifying enzyme required for both Ig class switching and somatic hypermutation (see earlier). The net effect of these translocations is similar; the *MYC* coding sequence is repositioned adjacent to strong Ig promoter and enhancer elements, which drive increased *MYC* expression. In addition, the translocated *MYC* allele often harbors point mutations that further increase its activity.

Essentially all endemic Burkitt lymphomas are latently infected with EBV, which is also present in about 25% of HIV-associated tumors and 15% to 20% of sporadic cases. The configuration of the EBV DNA is identical in all tumor cells within individual cases, indicating that infection precedes transformation. Although this places EBV at the “scene of the crime,” its precise role in the genesis of Burkitt lymphoma remains poorly understood.

MORPHOLOGY

Involved tissues are effaced by a diffuse infiltrate of intermediate-sized lymphoid cells 10 to 25 μ m in diameter with round or oval nuclei, coarse chromatin, several nucleoli, and a moderate amount of cytoplasm (Fig. 13-15). **The tumor exhibits a high mitotic index and contains numerous apoptotic cells**, the nuclear remnants of which are phagocytosed by interspersed benign macrophages. These phagocytes have abundant clear cytoplasm, creating a characteristic “starry sky” pattern. When the bone marrow is involved, aspirates reveal tumor cells with slightly clumped nuclear chromatin, two to five distinct nucleoli, and **royal blue cytoplasm containing clear cytoplasmic vacuoles**.

Immunophenotype. These are tumors of mature B cells that express surface IgM, CD19, CD20, CD10, and BCL6, a phenotype consistent with a germinal center B-cell origin. Unlike other tumors of germinal center origin, Burkitt lymphoma almost always fails to express the antiapoptotic protein BCL2.

Clinical Features. Both endemic and sporadic Burkitt lymphomas are found mainly in children or young adults; overall, it accounts for about 30% of childhood NHLs in the United States. Most tumors manifest at extranodal sites. Endemic Burkitt lymphoma often presents as a mass involving the mandible and shows an unusual predilection for involvement of abdominal viscera, particularly the kidneys, ovaries, and adrenal glands. In contrast, sporadic Burkitt lymphoma most often appears as a mass involving the ileocecum and peritoneum. Involvement of the bone marrow and peripheral blood is uncommon, especially in endemic cases.

Burkitt lymphoma is very aggressive but responds well to intensive chemotherapy. Most children and young adults can be cured. The outcome is more guarded in older adults.

Figure 13-15 Burkitt lymphoma. **A**, At low power, numerous pale tingible body macrophages are evident, producing a “starry sky” appearance. **B**, At high power, tumor cells have multiple small nucleoli and high mitotic index. The lack of significant variation in nuclear shape and size lends a monotonous appearance. (**B**, Courtesy Dr. José Hernandez, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Tex.)

KEY CONCEPTS

Common Forms of Lymphoid Leukemia and Lymphoma

Acute Lymphoblastic Leukemia/Lymphoblastic Lymphoma

- Most common type of cancer in children, may be derived from either precursor B or T cells
- Highly aggressive tumors manifest with signs and symptoms of bone marrow failure, or as rapidly growing masses.
- Tumor cells contain genetic lesions that block differentiation, leading to the accumulation of immature, nonfunctional blasts.

Small Lymphocytic Lymphoma/Chronic Lymphocytic Leukemia

- Most common leukemia of adults
- Tumor of mature B cells that usually manifests with bone marrow and lymph node involvement
- Indolent course, commonly associated with immune abnormalities, including an increased susceptibility to infection and autoimmune disorders

Follicular Lymphoma

- Most common indolent lymphoma of adults
- Tumor cells recapitulate the growth pattern of normal germinal center B cells; most cases are associated with a (14;18) translocation that results in the overexpression of BCL2.

Diffuse Large B-Cell Lymphoma

- Most common lymphoma of adults
- Heterogeneous group of mature B-cell tumors that shares a large cell morphology and aggressive clinical behavior
- Rearrangements or mutations of *BCL6* gene are recognized associations; one third carry a (14;18) translocation involving *BCL2* and may arise from follicular lymphomas.

Burkitt Lymphoma

- Very aggressive tumor of mature B cells that usually arises at extranodal sites.
- Strongly associated with translocations involving the *MYC* proto-oncogene
- Tumor cells often are latently infected by EBV.

Plasma Cell Neoplasms and Related Disorders

These B-cell proliferations contain neoplastic plasma cells that virtually always secrete a monoclonal Ig or Ig fragment, which serve as tumor markers and often have pathologic consequences. Collectively, the plasma cell neoplasms (often referred to as *dyscrasias*) account for about 15% of the deaths caused by lymphoid neoplasms. The most common and deadly of these neoplasms is multiple myeloma, of which there are about 15,000 new cases per year in the United States.

A monoclonal Ig identified in the blood is referred to as an *M component*, in reference to myeloma. Because complete M components have molecular weights of 160,000 or higher, they are restricted to the plasma and extracellular fluid and excluded from the urine in the absence of glomerular damage. However, **neoplastic plasma cells often synthesize excess light chains along with complete Igs.** Occasionally only light chains are produced, and rare tumors secrete only heavy chains. Highly sensitive tests for free light chains in the blood are now available. In patients with plasma cell tumors, the level of free light chains is usually elevated and is markedly skewed toward one light chain (e.g., kappa) at the expense of the second (e.g., lambda). Because free light chains are small in size, they are also excreted in the urine, where they are referred to as *Bence-Jones proteins*.

Terms used to describe the abnormal Igs associated with plasma cell neoplasms include *monoclonal gammopathy*, *dysproteinemia*, and *paraproteinemia*. These abnormal proteins are associated with the following clinicopathologic entities:

- *Multiple myeloma (plasma cell myeloma)*, the most important plasma cell neoplasm, usually presents as tumorous masses scattered throughout the skeletal system. *Solitary myeloma (plasmacytoma)* is an infrequent variant that presents as a single mass in bone or soft tissue. *Smoldering myeloma* refers to another uncommon variant defined by a lack of symptoms and a high plasma M component.
- *Waldenström macroglobulinemia* is a syndrome in which high levels of IgM lead to symptoms related to hyperviscosity of the blood. It occurs in older adults, most commonly in association with lymphoplasmacytic lymphoma (described later).

- *Heavy-chain disease* is a rare monoclonal gammopathy that is seen in association with a diverse group of disorders, including lymphoplasmacytic lymphoma and an unusual small bowel marginal zone lymphoma that occurs in malnourished populations (so-called *Mediterranean lymphoma*). The common feature is the synthesis and secretion of free heavy-chain fragments.
- *Primary or immunocyte-associated amyloidosis* results from a monoclonal proliferation of plasma cells secreting light chains (usually of λ isotype) that are deposited as amyloid. Some patients have overt multiple myeloma, but others have only a minor clonal population of plasma cells in the marrow.
- *Monoclonal gammopathy of undetermined significance (MGUS)* is applied to patients without signs or symptoms who have small to moderately large M components in their blood. MGUS is very common in older adults and has a low but constant rate of transformation to symptomatic monoclonal gammopathies, most often multiple myeloma.

With this background, we now turn to some of the specific clinicopathologic entities. Primary amyloidosis was discussed along with other disorders of the immune system in [Chapter 6](#).

Multiple Myeloma. Multiple myeloma is a plasma cell neoplasm commonly associated with lytic bone lesions, hypercalcemia, renal failure, and acquired immune abnormalities. Although bony disease dominates, it can spread late in its course to lymph nodes and extranodal sites. Multiple myeloma causes 1% of all cancer deaths in Western countries. Its incidence is higher in men and people of African descent. It is chiefly a disease of older adults, with a peak age of incidence of 65 to 70 years.

Pathogenesis. Multiple myeloma is associated with frequent rearrangements involving the IgH locus and various proto-oncogenes. Included among the loci that are recurrently involved in translocations with the Ig heavy-chain gene on chromosome 14q32 are the cell cycle-regulatory genes cyclin D1 on chromosome 11q13 and cyclin D3 on chromosome 6p21. Deletions of chromosome 17p that involve the *TP53* tumor suppressor locus also occur and are associated with a poor outcome. Late-stage, highly aggressive forms of the disease such as plasma cell leukemia are associated with acquisition of rearrangements involving *MYC*. More recent deep sequencing of myeloma genomes has identified frequent mutations involving components of the NF- κ B pathway, which supports B-cell survival. Based on these studies, it is evident that myeloma molecularly heterogeneous.

The proliferation and survival of myeloma cells are dependent on several cytokines, most notably IL-6. IL-6 is an important growth factor for plasma cells. It is produced by the tumor cells themselves and by resident marrow stromal cells. High serum levels of IL-6 are seen in patients with active disease and are associated with a poor prognosis. Myeloma cell growth and survival are also augmented by direct physical interactions with bone marrow stromal cells, which is a focus of new therapeutic approaches.

Factors produced by neoplastic plasma cells mediate bone destruction, the major pathologic feature of

multiple myeloma. Of particular importance, myeloma-derived MIP1 α up-regulates the expression of the receptor activator of NF- κ B ligand (RANKL) by bone marrow stromal cells, which in turn activates osteoclasts. Other factors released from tumor cells, such as modulators of the Wnt pathway, are potent inhibitors of osteoblast function. The net effect is a marked increase in bone resorption, which leads to hypercalcemia and pathologic fractures.

MORPHOLOGY

Multiple myeloma usually presents as destructive plasma cell tumors (plasmacytomas) involving the axial skeleton.

The bones most commonly affected (in descending order of frequency) are the vertebral column, ribs, skull, pelvis, femur, clavicle, and scapula. Lesions begin in the medullary cavity, erode cancellous bone, and progressively destroy the bony cortex, often leading to pathologic fractures; these are most common in the vertebral column, but may occur in any affected bone. **The bone lesions appear radiographically as punched-out defects, usually 1 to 4 cm in diameter (Fig. 13-16)**, and consist of soft, gelatinous, red tumor masses. Less commonly, widespread myelomatous bone disease produces diffuse demineralization (osteopenia) rather than focal defects.

Even away from overt tumor masses, the marrow contains an increased number of plasma cells, which usually constitute more than 30% of the cellularity. The plasma cells may infiltrate the interstitium or be present in sheets that completely replace normal elements. Like their benign counterparts, malignant plasma cells have a perinuclear clearing due to a prominent Golgi apparatus and an eccentrically placed nucleus (Fig. 13-17). Relatively normal-appearing plasma cells, **plasmablasts** with vesicular nuclear chromatin and a prominent single nucleolus, or **bizarre, multinucleated cells** may predominate. Other cytologic variants stem from the dysregulated synthesis and secretion of Ig, which often leads to intracellular accumulation of intact or partially degraded protein. Such variants include **flame cells** with fiery red cytoplasm, **Mott cells** with multiple grapelike cytoplasmic droplets, and cells containing a variety of other inclusions, including **fibrils, crystalline rods, and globules**. The globular inclusions are referred to as **Russell bodies** (if cytoplasmic) or **Dutcher bodies** (if nuclear). In advanced disease, plasma cell infiltrates may be present in the spleen, liver, kidneys, lungs, lymph nodes, and other soft tissues.

Commonly, the high level of M proteins causes red cells in peripheral blood smears to stick to one another in linear arrays, a finding referred to as **rouleaux formation**. Rouleaux formation is characteristic but not specific, as it may be seen in other conditions in which Ig levels are elevated, such as lupus erythematosus and early HIV infection. Rarely, tumor cells flood the peripheral blood, giving rise to **plasma cell leukemia**.

Bence Jones proteins are excreted in the kidney and contribute to a form of renal disease called **myeloma kidney**. This important complication is discussed in detail in [Chapter 20](#).

Immunophenotype. Plasma cell tumors are positive for CD138, an adhesion molecule also known as syndecan-1, and often express CD56, a feature that can be helpful in identifying small populations of neoplastic cells.

Clinical Features. The clinical features of multiple myeloma stem from (1) the effects of plasma cell growth in

Figure 13-16 Multiple myeloma of the skull (radiograph, lateral view). The sharply punched-out bone lesions are most obvious in the calvarium.

tissues, particularly the bones; (2) the production of excessive Igs, which often have abnormal physicochemical properties; and (3) the suppression of normal humoral immunity.

Bone resorption often leads to *pathologic fractures* and *chronic pain*. The attendant *hypercalcemia* can give rise to neurologic manifestations, such as confusion, weakness, lethargy, constipation, and polyuria, and contributes to renal dysfunction. Decreased production of normal Igs sets the stage for *recurrent bacterial infections*. Cellular immunity is relatively unaffected. Of great significance is *renal insufficiency*, which trails only infections as a cause of death. The pathogenesis of renal failure (**Chapter 20**), which occurs in up to 50% of patients, is multifactorial. However, the single most important factor seems to be *Bence-Jones proteinuria*, as the excreted light chains are toxic to renal tubular

Figure 13-17 Multiple myeloma (bone marrow aspirate). Normal marrow cells are largely replaced by plasma cells, including forms with multiple nuclei, prominent nucleoli, and cytoplasmic droplets containing Ig.

Figure 13-18 M protein detection in multiple myeloma. Serum protein electrophoresis (SP) is used to screen for a monoclonal immunoglobulin (M protein). Polyclonal IgG in normal serum (*arrow*) appears as a broad band; in contrast, serum from a patient with multiple myeloma contains a single sharp protein band (*arrowhead*) in this region of the electropherogram. The suspected monoclonal Ig is confirmed and characterized by immunofixation. In this procedure, proteins separated by electrophoresis within a gel are reacted with specific antisera. After extensive washing, proteins that are cross-linked by antisera are retained and detected with a protein stain. Note the sharp band in the patient serum is cross-linked by antisera specific for IgG heavy chain (G) and kappa light chain (κ), indicating the presence of an IgG κ M protein. Levels of polyclonal IgG, IgA (A), and lambda light chain (λ) are also decreased in the patient serum relative to normal, a finding typical of multiple myeloma. (Courtesy Dr. David Sacks, Department of Pathology, Brigham and Women's Hospital, Boston, Mass.)

epithelial cells. Certain light chains (particularly those of the $\lambda 6$ and $\lambda 3$ families) are prone to cause *amyloidosis* of the AL type (**Chapter 6**), which can exacerbate renal dysfunction and deposit in other tissues as well.

In 99% of patients, laboratory analyses reveal increased levels of Igs in the blood and/or light chains (Bence-Jones proteins) in the urine. The monoclonal Igs are usually first detected as abnormal protein “spikes” in serum or urine electrophoresis and then further characterized by immunofixation (**Fig. 13-18**). Most myelomas are associated with more than 3 gm/dL of serum Ig and/or more than 6 mg/dL of urine Bence-Jones protein. The most common monoclonal Ig (“M protein”) is IgG (approximately 55% of patients), followed by IgA (approximately 25% of cases). Myelomas expressing IgM, IgD, or IgE occur but are rare. Excessive production and aggregation of M proteins, usually of the IgA and or IgG₃ subtype, leads to symptoms related to hyperviscosity (described under lymphoplastic lymphoma) in about 7% of patients. Both free light chains and a serum M protein are observed together in 60% to 70% of patients. However, in about 20% of patients only free light chains are present. Around 1% of myelomas are nonsecretory; hence, the absence of detectable M proteins does not completely exclude the diagnosis.

The clinicopathologic diagnosis of multiple myeloma rests on radiographic and laboratory findings. It can be strongly suspected when the distinctive radiographic changes are present, but definitive diagnosis requires a bone marrow examination. Marrow involvement often gives rise to a normocytic normochromic anemia, sometimes accompanied by moderate leukopenia and thrombocytopenia.

The prognosis is variable, but has improved in recent years with new therapeutic approaches. The median survival is 4 to 7 years, and cures have yet to be achieved. Patients with multiple bony lesions, if untreated, rarely survive for more than 6 to 12 months, whereas patients with “smoldering myeloma” may be asymptomatic for many years. Translocations involving cyclin D1 are associated with a good outcome, whereas deletions of 13q, deletions of 17p, and the t(4;14) all portend a more aggressive course.

New therapies are bringing hope. Myeloma cells are sensitive to inhibitors of the proteasome, a cellular organelle that degrades unwanted and misfolded proteins. As discussed in [Chapter 2](#), misfolded proteins activate apoptotic pathways. Myeloma cells are prone to the accumulation of misfolded, unpaired Ig chains. Proteasome inhibitors may induce cell death by exacerbating this inherent tendency, and also seem to retard bone resorption through effects on stromal cells. Thalidomide and related compounds such as lenalidomide also have activity against myeloma. Interestingly, this may also involve changes in protein degradation, as lenalidomide appears to activate ubiquitin ligases, thereby targeting proteins for proteolysis that are required for myeloma growth. Biphosphonates, drugs that inhibit bone resorption, reduce pathologic fractures and limit the hypercalcemia. Hematopoietic stem cell transplantation prolongs life but has not yet proven to be curative.

Solitary Myeloma (Plasmacytoma). About 3% to 5% of plasma cell neoplasms present as a solitary lesion of bone or soft tissue. The bone lesions tend to occur in the same locations as in multiple myeloma. Extrasosseous lesions are often located in the lungs, oronasopharynx, or nasal sinuses. Modest elevations of M proteins in the blood or urine may be found in some patients. Solitary osseous plasmacytoma almost inevitably progresses to multiple myeloma, but this can take 10 to 20 years or longer. In contrast, extrasosseous plasmacytomas, particularly those involving the upper respiratory tract, are frequently cured by local resection.

Smoldering Myeloma. This entity defines a middle ground between multiple myeloma and monoclonal gammopathy of uncertain significance. Plasma cells make up 10% to 30% of the marrow cellularity, and the serum M protein level is greater than 3 gm/dL, but patients are asymptomatic. About 75% of patients progress to multiple myeloma over a 15-year period.

Monoclonal Gammopathy of Uncertain Significance. MGUS is the most common plasma cell dyscrasia, occurring in about 3% of persons older than 50 years of age and in about 5% of individuals older than 70 years of age. By definition, patients are asymptomatic and the serum M protein level is less than 3 gm/dL. **Approximately 1% of patients**

with MGUS develop a symptomatic plasma cell neoplasm, usually multiple myeloma, per year, a rate of conversion that remains roughly constant over time. The clonal plasma cells in MGUS contain many of the same chromosomal translocations and deletions that are found in full-blown multiple myeloma, indicating that MGUS is an early stage of myeloma development. As in patients with smoldering myeloma, progression to multiple myeloma is unpredictable; hence, periodic assessment of serum M component levels and Bence Jones proteinuria is warranted.

Lymphoplasmacytic Lymphoma. Lymphoplasmacytic lymphoma is a B-cell neoplasm of older adults that usually presents in the sixth or seventh decade of life. Although bearing a superficial resemblance to CLL/SLL, it differs in that a substantial fraction of the tumor cells undergo terminal differentiation to plasma cells. Most commonly, the plasma cell component secretes monoclonal IgM, often in amounts sufficient to cause a hyperviscosity syndrome known as *Waldenström macroglobulinemia*. Unlike multiple myeloma, complications stemming from the secretion of free light chains (e.g., renal failure and amyloidosis) are relatively rare and bone destruction does not occur.

Pathogenesis. Recent deep sequencing studies have shown that virtually all cases of lymphoplasmacytic lymphoma are associated with acquired mutations in *MYD88*. The *MYD88* gene encodes an adaptor protein that participates in signaling events that activate NF- κ B and also augment signals downstream of the B-cell receptor (Ig) complex, both of which may promote the growth and survival of the tumor cells.

MORPHOLOGY

Typically, the marrow contains an infiltrate of lymphocytes, plasma cells, and plasmacytoid lymphocytes in varying proportions, often accompanied by mast cell hyperplasia ([Fig. 13-19](#)). Some tumors also contain a population of larger lymphoid cells with more vesicular nuclear chromatin and prominent nucleoli. Periodic acid-Schiff-positive inclusions containing Ig are frequently seen in the cytoplasm (**Russell bodies**) or the nucleus (**Dutcher bodies**) of some of the plasma cells. At diagnosis the tumor has usually disseminated to the lymph nodes, spleen, and liver. Infiltration of the nerve roots, meninges, and more rarely the brain can also occur with disease progression.

Immunophenotype. The lymphoid component expresses B-cell markers such as CD20 and surface Ig, whereas the plasma cell component secretes the same Ig that is expressed on the surface of the lymphoid cells. This is usually IgM but can also be IgG or IgA.

Clinical Features. The dominant presenting complaints are nonspecific and include weakness, fatigue, and weight loss. Approximately half the patients have *lymphadenopathy, hepatomegaly, and splenomegaly*. Anemia caused by marrow infiltration is common. About 10% of patients have *autoimmune hemolysis* caused by *cold agglutinins*, IgM antibodies that bind to red cells at temperatures of less than 37°C ([Chapter 14](#)).

Figure 13-19 Lymphoplasmacytic lymphoma. Bone marrow biopsy shows a characteristic mixture of small lymphoid cells exhibiting various degrees of plasma cell differentiation. In addition, a mast cell with purplish red cytoplasmic granules is present at the left-hand side of the field.

Patients with IgM-secreting tumors have additional signs and symptoms stemming from the physicochemical properties of IgM. Because of its large size, at high concentrations IgM greatly increases the viscosity of the blood, giving rise to a *hyperviscosity syndrome* characterized by the following:

- *Visual impairment* associated with venous congestion, which is reflected by striking tortuosity and distention of retinal veins; retinal hemorrhages and exudates can also contribute to the visual problems
- *Neurologic problems* such as headaches, dizziness, deafness, and stupor, all stemming from sluggish blood flow and sludging
- *Bleeding* related to the formation of complexes between macroglobulins and clotting factors as well as interference with platelet functions
- *Cryoglobulinemia* resulting from the precipitation of macroglobulins at low temperatures, which produces symptoms such as Raynaud phenomenon and cold urticaria

Lymphoplasmacytic lymphoma is an incurable progressive disease. Because most IgM is intravascular, symptoms caused by the high IgM levels (e.g., hyperviscosity and hemolysis) can be alleviated by plasmapheresis. Tumor growth can be controlled for a time with low doses of chemotherapeutic drugs and immunotherapy with anti-CD20 antibody. Transformation to large-cell lymphoma occurs but is uncommon. Median survival is about 4 years.

KEY CONCEPTS

Plasma Cell Neoplasms

Multiple Myeloma

- Plasma cell tumor that manifests with multiple lytic bone lesions associated with pathologic fractures and hypercalcemia
- Neoplastic plasma cells suppress normal humoral immunity and secrete partial immunoglobulins that are nephrotoxic
- Associated with diverse translocations involving the IgH locus; frequent dysregulation and overexpression of D cyclins

- May be associated with AL amyloidosis (as may other neoplasms later)

Other Plasma Cell Neoplasms

- MGUS (monoclonal gammopathy of unknown significance): common in older adults, progresses to myeloma at a rate of 1% per year
- Smoldering myeloma: disseminated disease that pursues an unusually indolent course
- Solitary osseous plasmacytoma: solitary bone lesion identical to disseminated myeloma; most progress to myeloma within 7 to 10 years
- Extramedullary plasmacytoma: solitary mass, usually in the upper aerodigestive tract; rarely progresses to systemic disease
- Lymphoplasmacytic lymphoma: B cell lymphoma that exhibits plasmacytic differentiation; clinical symptoms dominated by hyperviscosity related to high levels of tumor-derived IgM; highly associated with mutations in the *MYD88* gene

Mantle Cell Lymphoma

Mantle cell lymphoma is an uncommon lymphoid neoplasm that makes up about 2.5% of NHL in the United States and 7% to 9% of NHL in Europe. It usually presents in the fifth to sixth decades of life and shows a male predominance. As the name implies, the tumor cells closely resemble the normal mantle zone B cells that surround germinal centers.

Pathogenesis. Virtually all mantle cell lymphomas have an (11;14) translocation involving the IgH locus on chromosome 14 and the cyclin D1 locus on chromosome 11 that leads to overexpression of cyclin D1. This translocation is detected in about 70% of cases by standard karyotyping and in virtually all tumors by fluorescence in situ hybridization. The resulting up-regulation of cyclin D1 promotes G1- to S-phase progression during the cell cycle, as was described in [Chapter 7](#).

MORPHOLOGY

At diagnosis the majority of patients have generalized lymphadenopathy, and 20% to 40% have peripheral blood involvement. Frequent sites of extranodal involvement include the bone marrow, spleen, liver, and gut. Occasionally, mucosal involvement of the small bowel or colon produces polyp-like lesions (lymphomatoid polyposis); of all forms of NHL, mantle cell lymphoma is most likely to spread in this fashion.

Nodal tumor cells may surround reactive germinal centers to produce a nodular appearance at low power, or diffusely efface the node. **Typically, the proliferation consists of a homogeneous population of small lymphocytes with irregular to occasionally deeply clefted (cleaved) nuclear contours (Fig. 13-20).** Large cells resembling centroblasts and proliferation centers are absent, distinguishing mantle cell lymphoma from follicular lymphoma and CLL/SLL, respectively. In most cases the nuclear chromatin is condensed, nucleoli are inconspicuous, and the cytoplasm is scant. Occasionally, tumors composed of intermediate-sized cells with more open chromatin and a brisk mitotic rate are observed; immunophenotyping is necessary to distinguish these “blastoid” variants from ALL.

Figure 13-20 Mantle cell lymphoma. **A**, At low power, neoplastic lymphoid cells surround a small, atrophic germinal center, producing a mantle zone pattern of growth. **B**, High-power view shows a homogeneous population of small lymphoid cells with somewhat irregular nuclear outlines, condensed chromatin, and scant cytoplasm. Large cells resembling prolymphocytes (seen in chronic lymphocytic leukemia) and centroblasts (seen in follicular lymphoma) are absent.

Immunophenotype. Mantle cell lymphomas express high levels of cyclin D1. Most tumors also express CD19, CD20, and moderately high levels of surface Ig (usually IgM and IgD with κ or λ light chain). It is usually CD5+ and CD23-, which help to distinguish it from CLL/SLL. The IgH genes lack somatic hypermutation, supporting an origin from a naive B cell.

Clinical Features. The most common presentation is painless lymphadenopathy. Symptoms related to involvement of the spleen (present in ~50% of cases) and gut are also common. The prognosis is poor; the median survival is only 3 to 4 years. This lymphoma is not curable with conventional chemotherapy, and most patients eventually succumb to organ dysfunction caused by tumor infiltration. The blastoid variant and a “proliferative” expression profiling signature are associated with even shorter survivals. Hematopoietic stem cell transplantation and proteasome inhibitors are newer therapeutic approaches that show some promise.

Marginal Zone Lymphomas

The category of marginal zone lymphoma encompasses a heterogeneous group of B-cell tumors that arise within lymph nodes, spleen, or extranodal tissues. The extranodal tumors were initially recognized at mucosal sites and are often referred to as mucosa-associated lymphoid tumors (or “MALTomas”). In most cases, the tumor cells show evidence of somatic hypermutation and are considered to be of memory B-cell origin.

Although all marginal zone lymphomas share certain features, those occurring at extranodal sites deserve special attention because of their unusual pathogenesis and three exceptional characteristics.

- They often arise within tissues involved by chronic inflammatory disorders of autoimmune or infectious etiology; examples include the salivary gland in Sjögren disease, the thyroid gland in Hashimoto thyroiditis, and the stomach in *Helicobacter* gastritis.
- They remain localized for prolonged periods, spreading systemically only late in their course.
- They may regress if the inciting agent (e.g., *Helicobacter pylori*) is eradicated.

These characteristics suggest that **extranodal marginal zone lymphomas arising in chronically inflamed tissues lie on a continuum between reactive lymphoid hyperplasia and full-blown lymphoma**. The disease begins as a polyclonal immune reaction. With the acquisition of still-unknown initiating mutations, a B-cell clone emerges that still depends on antigen-stimulated T-helper cells for signals that drive growth and survival. At this stage, withdrawal of the responsible antigen causes tumor involution. A clinically relevant example is found in gastric “MALToma,” in which antibiotic therapy directed against *H. pylori* often leads to tumor regression (Chapter 17). With time, however, tumors may acquire additional mutations that render their growth and survival antigen-independent, such as the (11;18), (14;18), or (1;14) chromosomal translocations, which are relatively specific for extranodal marginal zone lymphomas. All of these translocations up-regulate the expression and function of BCL10 or MALT1, protein components of a signaling complex that activates NF- κ B and promotes the growth and survival of B cells. With further clonal evolution, spread to distant sites and transformation to diffuse large B-cell lymphoma may occur. This theme of polyclonal to monoclonal transition during lymphomagenesis is also applicable to the pathogenesis of EBV-induced lymphoma and is discussed more fully in Chapter 7.

Hairy Cell Leukemia

This rare but distinctive B-cell neoplasm constitutes about 2% of all leukemias. It is predominantly a disease of middle-aged white males, with a median age of 55 and a male-to-female ratio of 5:1.

Pathogenesis. Hairy cell leukemias are associated in more than 90% of cases with activating point mutations in the serine/threonine kinase BRAF, which is positioned immediately downstream of RAS in the MAPK signaling cascade (Chapter 7). The specific mutation, a valine to glutamate substitution at residue 600, is also found in diverse other neoplasms, including many melanomas and Langerhans cell histiocytosis (discussed later).

MORPHOLOGY

Hairy cell leukemia derives its picturesque name from the appearance of the leukemic cells, which have **fine hairlike projections** that are best recognized under the phase-contrast microscope (Fig. 13-21). On routine peripheral blood smears, hairy cells have round, oblong, or reniform nuclei and moderate amounts of pale blue cytoplasm with threadlike or bleblike extensions. The number of circulating cells is highly variable. The marrow is involved by a diffuse interstitial infiltrate of cells with oblong or reniform nuclei, condensed chromatin, and pale cytoplasm. Because these cells are enmeshed in an extracellular matrix composed of reticulin fibrils, they usually cannot be aspirated (a clinical difficulty referred to as a “dry tap”) and are only seen in marrow biopsies. The splenic red pulp is usually heavily infiltrated, leading to obliteration of white pulp and a beefy red gross appearance. Hepatic portal triads are also involved frequently.

Immunophenotype. Hairy cell leukemias typically express the pan-B-cell markers CD19 and CD20, surface Ig (usually IgG), and certain relatively distinctive markers, such as CD11c, CD25, CD103, and annexin A1.

Clinical Features. Clinical manifestations result largely from infiltration of the bone marrow, liver, and spleen. *Splenomegaly*, often massive, is the most common and sometimes the only abnormal physical finding. *Hepatomegaly* is less common and not as marked; lymphadenopathy is rare. *Pancytopenia* resulting from marrow involvement and splenic sequestration is seen in more than half the cases. About one third of those affected present with *infections*. There is an increased incidence of atypical mycobacterial infections, possibly related to frequent unexplained monocytopenia.

Hairy cell leukemia follows an indolent course. For unclear reasons, this tumor is exceptionally sensitive to “gentle” chemotherapeutic regimens, which produce long-lasting remissions. Tumors often relapse after 5 or more years, yet generally respond well when retreated with the same agents, a feature that is highly unusual among human cancers. BRAF inhibitors appear to produce excellent responses in tumors that have failed conventional chemotherapy. The overall prognosis is excellent.

Peripheral T-Cell and NK-Cell Neoplasms

These categories include a heterogeneous group of neoplasms having phenotypes resembling mature T cells or NK cells. Peripheral T-cell tumors make up about 5% to 10% of NHLs in the United States and Europe, while NK cell tumors are rare. By contrast, for unknown reasons both T cell and NK cell tumors are relatively more common in the Far East. Only the most common diagnoses and those of particular pathogenetic interest will be discussed.

Peripheral T-Cell Lymphoma, Unspecified

Although the WHO classification includes a number of distinct peripheral T-cell neoplasms, many of these lymphomas are not easily categorized and are lumped into a “wastebasket” diagnosis, *peripheral T-cell lymphoma, unspecified*. As might be expected, no morphologic feature is pathognomonic, but certain findings are characteristic. These tumors efface lymph nodes diffusely and are typically composed of a pleomorphic mixture of variably sized malignant T cells (Fig. 13-22). There is often a prominent infiltrate of reactive cells, such as eosinophils and macrophages, probably attracted by tumor-derived cytokines. Brisk neoangiogenesis may also be seen.

By definition, all peripheral T-cell lymphomas are derived from mature T cells. They usually express CD2, CD3, CD5, and either $\alpha\beta$ or $\gamma\delta$ T-cell receptors. Some also express CD4 or CD8; such tumors are taken to be of helper or cytotoxic T-cell origin, respectively. However, many tumors have phenotypes that do not resemble any known normal T cell. In difficult cases where the differential diagnosis lies between lymphoma and a florid reactive process, DNA analysis is used to confirm the presence of clonal T-cell receptor rearrangements.

Most patients present with generalized lymphadenopathy, sometimes accompanied by eosinophilia, pruritus, fever, and weight loss. Although cures of peripheral T-cell lymphoma have been reported, these tumors have a significantly worse prognosis than comparably aggressive mature B-cell neoplasms (e.g., diffuse large B-cell lymphoma).

Anaplastic Large-Cell Lymphoma (ALK Positive)

This uncommon entity is defined by the presence of rearrangements in the *ALK* gene on chromosome 2p23. These

Figure 13-21 Hairy cell leukemia (peripheral blood smear). **A**, Phase-contrast microscopy shows tumor cells with fine hairlike cytoplasmic projections. **B**, In stained smears, these cells have round or folded nuclei and modest amounts of pale blue, agranular cytoplasm.

Figure 13-22 Peripheral T-cell lymphoma, unspecified (lymph node). A spectrum of small, intermediate, and large lymphoid cells, many with irregular nuclear contours, is visible.

rearrangements break the *ALK* locus and lead to the formation of chimeric genes encoding *ALK* fusion proteins, constitutively active tyrosine kinases that trigger the RAS and JAK/STAT signaling pathways.

As the name implies, this tumor is typically composed of large anaplastic cells, some containing horseshoe-shaped nuclei and voluminous cytoplasm (so-called *hallmark cells*) (Fig. 13-23A). The tumor cells often cluster about venules and infiltrate lymphoid sinuses, mimicking the appearance of metastatic carcinoma. *ALK* is not expressed in normal lymphocytes; thus, the detection of *ALK* protein in tumor cells (Fig. 13-23B) is a reliable indicator of an *ALK* gene rearrangement.

T-cell lymphomas with *ALK* rearrangements tend to occur in children or young adults, frequently involve soft tissues, and carry a very good prognosis (unlike other aggressive peripheral T-cell neoplasms). The cure rate with chemotherapy is 75% to 80%. Inhibitors of *ALK* have been developed and are being evaluated as a form of selective, targeted therapy. Morphologically similar tumors lacking *ALK* rearrangements occur in older adults and have a

substantially worse prognosis. Both the *ALK*⁺ and *ALK*⁻ tumors usually express CD30, a member of the TNF receptor family; of note, recombinant antibodies that bind and kill CD30-expressing cells have produced promising responses in patients with anaplastic large cell lymphoma and Hodgkin lymphoma, another CD30⁺ tumor (described later).

Adult T-Cell Leukemia/Lymphoma

This neoplasm of CD4⁺ T cells is only observed in adults infected by human T-cell leukemia retrovirus type 1 (HTLV-1), which was discussed in Chapter 7. It occurs mainly in regions where HTLV-1 is endemic, namely southern Japan, West Africa, and the Caribbean basin. Common findings include skin lesions, generalized lymphadenopathy, hepatosplenomegaly, peripheral blood lymphocytosis, and hypercalcemia. The appearance of the tumor cells varies, but cells with multilobated nuclei (“cloverleaf” or “flower” cells) are frequently observed. The tumor cells contain clonal HTLV-1 provirus, which is believed to play a critical pathogenic role. Notably, HTLV-1 encodes a protein called Tax that is a potent activator of NF- κ B, which, as previously discussed, enhances lymphocyte growth and survival.

Most patients present with rapidly progressive disease that is fatal within months to 1 year despite aggressive chemotherapy. Less commonly, the tumor involves only the skin and follows a much more indolent course, like that of *mycosis fungoides* (described below). It should be noted that in addition to adult T-cell leukemia/lymphoma, HTLV-1 infection sometimes gives rise to a progressive demyelinating disease of the central nervous system and spinal cord (Chapter 28).

Mycosis Fungoides/Sézary Syndrome

Mycosis fungoides and Sézary syndrome are different manifestations of a tumor of CD4⁺ helper T cells that home to the skin. Clinically, the cutaneous lesions of *mycosis fungoides* typically progress through three somewhat distinct stages, an inflammatory *premycotic phase*, a *plaque phase*, and a *tumor phase* (Chapter 25). Histologically,

Figure 13-23 Anaplastic large-cell lymphoma. **A**, Several “hallmark” cells with horseshoe-like or “embryoid” nuclei and abundant cytoplasm lie near the center of the field. **B**, Immunohistochemical stain demonstrating the presence of *ALK* fusion protein. (Courtesy Dr. Jeffrey Kutok, Department of Pathology, Brigham and Women’s Hospital, Boston, Mass.)

the epidermis and upper dermis are infiltrated by neoplastic T cells, which often have a cerebriform appearance due to marked infolding of the nuclear membrane. Late disease progression is characterized by extracutaneous spread, most commonly to lymph nodes and bone marrow.

Sézary syndrome is a variant in which skin involvement is manifested as a *generalized exfoliative erythroderma*. In contrast to *mycosis fungoides*, the skin lesions rarely proceed to tumefaction, and there is an associated leukemia of “Sézary” cells with characteristic cerebriform nuclei.

The tumor cells express the adhesion molecule cutaneous leukocyte antigen (CLA) and the chemokine receptors CCR4 and CCR10, all of which contribute to the homing of normal CD4+ T cells to the skin. Although cutaneous disease dominates the clinical picture, sensitive molecular analyses have shown that the tumor cells circulate through the blood, marrow, and lymph nodes even early in the course. Nevertheless, these are indolent tumors, with a median survival of 8 to 9 years. Transformation to aggressive T-cell lymphoma occurs occasionally as a terminal event.

Large Granular Lymphocytic Leukemia

T-cell and NK-cell variants of this rare neoplasm are recognized, both of which occur mainly in adults. Individuals with T-cell disease usually present with mild to moderate lymphocytosis and splenomegaly. Lymphadenopathy and hepatomegaly are usually absent. NK-cell disease often presents in an even more subtle fashion, with little or no lymphocytosis or splenomegaly.

Recent work has shown that 30% to 40% of large granular lymphocytic leukemias have acquired mutations in the transcription factor STAT3, which functions downstream of cytokine receptors. These mutations occur in both T-cell and NK-cell forms of the disease and appear to result in cytokine-independent activation of STAT3, which is now postulated to have a major role in the pathogenesis of these heretofore mysterious proliferations.

The tumor cells are large lymphocytes with abundant blue cytoplasm and a few coarse azurophilic granules, best seen in peripheral blood smears. The marrow usually contains sparse interstitial lymphocytic infiltrates, which can be difficult to appreciate without immunohistochemical stains. Infiltrates are also usually present in the spleen and liver. As might be expected, T-cell variants are CD3+, whereas NK-cell large granular lymphocytic leukemias are CD3–, CD56+.

Despite the relative paucity of marrow infiltration, **neutropenia and anemia dominate the clinical picture**. Neutropenia is often accompanied by a striking decrease in late myeloid forms in the marrow. Rarely, *pure red cell aplasia* is seen. There is also an increased incidence of rheumatologic disorders. Some patients with *Felty syndrome*, a triad of rheumatoid arthritis, splenomegaly, and neutropenia, have this disorder as an underlying cause. The basis for these varied clinical abnormalities is unknown, but autoimmunity, provoked in some way by the tumor, seems likely.

The course is variable, being largely dependent on the severity of the cytopenias and their responsiveness to low-dose chemotherapy or steroids. In general, tumors of T-cell origin pursue an indolent course, whereas NK-cell tumors behave more aggressively.

Extranodal NK/T-Cell Lymphoma

This neoplasm is rare in the United States and Europe, but constitutes as many as 3% of NHLs in Asia. It presents most commonly as a destructive nasopharyngeal mass; less common sites of presentation include the testis and the skin. The tumor cell infiltrate typically surrounds and invades small vessels, leading to extensive *ischemic necrosis*. In touch preparations, *large azurophilic granules* are seen in the cytoplasm of the tumor cells that resemble those found in normal NK cells.

Extranodal NK/T-cell lymphoma is highly associated with EBV. Within individual patients, all of the tumor cells contain identical EBV episomes, indicating that the tumor originates from a single EBV-infected cell. How EBV gains entry is uncertain, since the tumor cells do not express CD21, the surface protein that serves as the B-cell EBV receptor. Most tumors are CD3– and lack T-cell receptor rearrangements and express NK-cell markers, supporting an NK-cell origin. No consistent chromosome aberration has been described.

Most extranodal NK/T-cell lymphomas are highly aggressive neoplasms that respond well to radiation therapy but are resistant to chemotherapy. Thus, the prognosis is poor in patients with advanced disease.

KEY CONCEPTS

Uncommon Lymphoid Neoplasms

Mantle cell lymphoma: Tumor of naive B cells that pursues a moderately aggressive course and is highly associated with translocations involving the cyclin D1 gene

Marginal zone lymphoma: Indolent tumors of antigen-primed B cells that arise at sites of chronic immune stimulation and often remain localized for long periods of time

Hairy cell leukemia: Morphologically distinct, very indolent tumor of mature B cells that is highly associated with mutations in the BRAF serine/threonine kinase

Peripheral NK/T cell lymphomas and leukemias

- Anaplastic large cell lymphoma: Aggressive T cell tumor, associated in a subset with activating mutations in the ALK tyrosine kinase
- Adult T cell leukemia/lymphoma: Aggressive tumor of CD4+ T cells that is uniformly associated with HTLV-1 infection
- Large granular lymphocytic leukemia: Indolent tumor of cytotoxic T cells or NK cells that is associated with mutations in the transcription factor STAT3 and with autoimmune phenomena and cytopenias
- Extranodal NK/T cell lymphoma: Aggressive tumor, usually derived from NK cells, that is strongly associated with EBV infection

Hodgkin Lymphoma

Hodgkin lymphoma (HL) encompasses a group of lymphoid neoplasms that differ from NHL in several respects (Table 13-7). While NHLs frequently occur at extranodal sites and spread in an unpredictable fashion, **HL arises in a single node or chain of nodes and spreads first to**

Table 13-7 Differences between Hodgkin and Non-Hodgkin Lymphomas

Hodgkin Lymphoma	Non-Hodgkin Lymphoma
More often localized to a single axial group of nodes (cervical, mediastinal, para-aortic)	More frequent involvement of multiple peripheral nodes
Orderly spread by contiguity	Noncontiguous spread
Mesenteric nodes and Waldeyer ring rarely involved	Waldeyer ring and mesenteric nodes commonly involved
Extranodal presentation rare	Extranodal presentation common

anatomically contiguous lymphoid tissues. HL also has distinctive morphologic features. It is characterized by the presence of neoplastic giant cells called Reed-Sternberg cells. These cells release factors that induce the accumulation of reactive lymphocytes, macrophages, and granulocytes, which typically make up greater than 90% of the tumor cellularity. In the vast majority of HLs, the neoplastic Reed-Sternberg cells are derived from germinal center or postgerminal center B cells.

Hodgkin lymphoma accounts for 0.7% of all new cancers in the United States; there are about 8000 new cases each year. The average age at diagnosis is 32 years. It is one of the most common cancers of young adults and adolescents, but also occurs in the aged. It was the first human cancer to be successfully treated with radiation therapy and chemotherapy, and is curable in most cases.

Classification. The WHO classification recognizes five subtypes of HL:

1. Nodular sclerosis
2. Mixed cellularity
3. Lymphocyte-rich
4. Lymphocyte depletion
5. Lymphocyte predominance

In the first four subtypes—nodular sclerosis, mixed cellularity, lymphocyte-rich, and lymphocyte depletion—the Reed-Sternberg cells have a similar immunophenotype. These subtypes are often lumped together as *classical* forms of HL. In the remaining subtype, lymphocyte predominance, the Reed-Sternberg cells have a distinctive B-cell immunophenotype that differs from that of the “classical” types.

Pathogenesis. The origin of the neoplastic Reed-Sternberg cells of classical HL has been explained through elegant studies relying on molecular analysis of single isolated Reed-Sternberg cells and variants. In the vast majority of cases, the Ig genes of Reed-Sternberg cells have undergone both V(D)J recombination and somatic hypermutation, establishing an origin from a germinal center or postgerminal center B cell. Despite having the genetic signature of a B cell, the Reed-Sternberg cells of classical HL fail to express most B-cell-specific genes, including the Ig genes. The cause of this wholesale reprogramming of gene expression has yet to be fully explained, but presumably is the result of widespread epigenetic changes of uncertain etiology.

Activation of the transcription factor NF- κ B is a common event in classical HL. This can occur by several mechanisms:

- NF- κ B may be activated either by EBV infection or by some other mechanism and turns on genes that promote lymphocyte survival and proliferation.
- EBV⁺ tumor cells express latent membrane protein-1 (LMP-1), a protein encoded by the EBV genome that transmits signals that up-regulate NF- κ B.
- Activation of NF- κ B may occur in EBV-tumors as a result of acquired loss-of-function mutations in I κ B or A20 (also known as *TNF alpha-induced protein 3*, or *TNFAIP3*), which are both negative regulators of NF- κ B.
- It is hypothesized that activation of NF- κ B by EBV or other mechanisms rescues “crippled” germinal center B cells that cannot express Igs from apoptosis, setting the stage for the acquisition of other unknown mutations that collaborate to produce Reed-Sternberg cells.

Little is known about the basis for the morphology of Reed-Sternberg cells and variants, but it is intriguing that EBV-infected B cells resembling Reed-Sternberg cells are found in the lymph nodes of individuals with infectious mononucleosis, strongly suggesting that EBV-encoded proteins play a part in the remarkable metamorphosis of B cells into Reed-Sternberg cells.

The florid accumulation of reactive cells in tissues involved by classical HL occurs in response to a wide variety of cytokines (e.g., IL-5, IL-10, and M-CSF) chemokines (e.g., eotaxin), and other factors (e.g., immunomodulatory factor galectin-1) that are secreted by Reed-Sternberg cells. Once attracted, the reactive cells produce factors that support the growth and survival of the tumor cells and further modify the reactive cell response. For example, eosinophils and T cells express ligands that activate the CD30 and CD40 receptors found on Reed-Sternberg cells, producing signals that up-regulate NF- κ B. Other examples of “cross-talk” between Reed-Sternberg cells and surrounding reactive cells are provided in [Figure 13-28](#). Some of the factors produced by RS cells give rise to a state of immunodeficiency by impairment of T helper and cytotoxic cells and enhancing the generation of regulatory T cells (as discussed later).

Reed-Sternberg cells are aneuploid and possess diverse clonal chromosomal aberrations. Copy number gains in the *REL* proto-oncogene on chromosome 2p are particularly common and may also contribute to increases in NF- κ B activity.

MORPHOLOGY

Identification of Reed-Sternberg cells and their variants is essential for the diagnosis. **Diagnostic Reed-Sternberg cells are large cells (45 μ m in diameter) with multiple nuclei or a single nucleus with multiple nuclear lobes, each with a large inclusion-like nucleolus about the size of a small lymphocyte (5 to 7 μ m in diameter) (Fig. 13-24A).** The cytoplasm is abundant. Several Reed-Sternberg cell variants are also recognized. **Mononuclear variants** contain a single nucleus with a large inclusion-like nucleolus (Fig. 13-24B). **Lacunar cells** (seen in the nodular sclerosis subtype) have more delicate, folded, or multilobate nuclei and abundant pale cytoplasm that is often disrupted during the cutting of sections, leaving the nucleus sitting in an empty hole (a lacuna) (Fig.

Figure 13-24 Reed-Sternberg cells and variants. **A**, Diagnostic Reed-Sternberg cell, with two nuclear lobes, large inclusion-like nucleoli, and abundant cytoplasm, surrounded by lymphocytes, macrophages, and an eosinophil. **B**, Reed-Sternberg cell, mononuclear variant. **C**, Reed-Sternberg cell, lacunar variant. This variant has a folded or multilobated nucleus and lies within an open space, which is an artifact created by disruption of the cytoplasm during tissue sectioning. **D**, Reed-Sternberg cell, lymphohistiocytic variant. Several such variants with multiply infolded nuclear membranes, small nucleoli, fine chromatin, and abundant pale cytoplasm are present. (**A**, Courtesy Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Tex.)

13-24C). In classical forms of HL, Reed-Sternberg cells undergo a peculiar form of cell death in which the cells shrink and become pyknotic, a process described as “mummification.” **Lymphohistiocytic variants** (L&H cells) with polyploid nuclei, inconspicuous nucleoli, and moderately abundant cytoplasm are characteristic of the lymphocyte predominance subtype (Fig. 13-24D).

HL must be distinguished from other conditions in which cells resembling Reed-Sternberg cells can be seen, such as infectious mononucleosis, solid tissue cancers, and large-cell NHLs. The diagnosis of HL depends on the identification of Reed-Sternberg cells in a background of non-neoplastic inflammatory cells. The Reed-Sternberg cells of HL also have a characteristic immunohistochemical profile.

With this as background, we turn to the subclasses of HL, pointing out some of the salient morphologic and immunophenotypic features of each (Table 13-8). The clinical manifestations common to all are presented later.

Nodular Sclerosis Type. This is the most common form of HL, constituting 65% to 70% of cases. It is characterized by the presence of lacunar variant Reed-Sternberg cells and the **deposition of collagen in bands that divide involved lymph nodes into circumscribed nodules** (Fig. 13-25). The fibrosis may be scant or abundant. The Reed-Sternberg cells are found in a polymorphous background of T cells, eosinophils, plasma cells, and macrophages. Diagnostic Reed-Sternberg cells are

often uncommon. The Reed-Sternberg cells in this and other “classical” HL subtypes have a characteristic immunophenotype; they are positive for PAX5 (a B-cell transcription factor), CD15, and CD30, and negative for other B-cell markers, T-cell markers, and CD45 (leukocyte common antigen). As in other forms of HL, involvement of the spleen, liver, bone marrow, and other organs and tissues can appear in due course in the form of irregular tumor nodules resembling those seen in lymph nodes. This subtype is uncommonly associated with EBV.

The nodular sclerosis type occurs with equal frequency in males and females. It has a propensity to involve the lower cervical, supraclavicular, and mediastinal lymph nodes of adolescents or young adults. The prognosis is excellent.

Mixed-Cellularity Type. This form of HL constitutes about 20% to 25% of cases. Involved lymph nodes are diffusely effaced by a heterogeneous cellular infiltrate, which includes T cells, eosinophils, plasma cells, and benign macrophages admixed with Reed-Sternberg cells (Fig. 13-26). **Diagnostic Reed-Sternberg cells and mononuclear variants are usually plentiful. The Reed-Sternberg cells are infected with EBV in about 70% of cases.** The immunophenotype is identical to that observed in the nodular sclerosis type.

Mixed-cellularity HL is more common in males. Compared with the lymphocyte predominance and nodular sclerosis subtypes, it is more likely to be associated with older age, systemic symptoms such as night sweats and weight loss, and

Table 13-8 Subtypes of Hodgkin Lymphoma

Subtype	Morphology and Immunophenotype	Typical Clinical Features
Nodular sclerosis	Frequent lacunar cells and occasional diagnostic RS cells; background infiltrate composed of T lymphocytes, eosinophils, macrophages, and plasma cells; fibrous bands dividing cellular areas into nodules. RS cells CD15+, CD30+; usually EBV-	Most common subtype; usually stage I or II disease; frequent mediastinal involvement; equal occurrence in males and females (F = M), most patients young adults
Mixed cellularity	Frequent mononuclear and diagnostic RS cells; background infiltrate rich in T lymphocytes, eosinophils, macrophages, plasma cells; RS cells CD15+, CD30+; 70% EBV+	More than 50% present as stage III or IV disease; M greater than F; biphasic incidence, peaking in young adults and again in adults older than 55
Lymphocyte rich	Frequent mononuclear and diagnostic RS cells; background infiltrate rich in T lymphocytes; RS cells CD15+, CD30+; 40% EBV-	Uncommon; M greater than F; tends to be seen in older adults
Lymphocyte depletion	Reticular variant: Frequent diagnostic RS cells and variants and a paucity of background reactive cells; RS cells CD15+, CD30+; most EBV+	Uncommon; more common in older males, HIV-infected individuals, and in developing countries; often presents with advanced disease
Lymphocyte predominance	Frequent L&H (popcorn cell) variants in a background of follicular dendritic cells and reactive B cells; RS cells CD20+, CD15-, CD30-, EB-	Uncommon; young males with cervical or axillary lymphadenopathy; mediastinal

L&H, lymphohistiocytic; RS cell, Reed-Sternberg cell.

advanced tumor stage. Nonetheless, the overall prognosis is very good.

Lymphocyte-Rich Type. This is an uncommon form of classical HL in which **reactive lymphocytes make up the vast majority of the cellular infiltrate**. In most cases, involved lymph nodes are diffusely effaced, but vague nodularity due to the presence of residual B-cell follicles is sometimes seen. This entity is distinguished from the lymphocyte predominance type by the presence of frequent mononuclear variants and diagnostic Reed-Sternberg cells with a “classical” immunophenotypic profile. It is associated with EBV in about 40% of cases and has a very good to excellent prognosis.

Lymphocyte Depletion Type. This is the least common form of HL, amounting to less than 5% of cases. It is characterized by a paucity of lymphocytes and a relative abundance of Reed-Sternberg cells or their pleomorphic variants. The immunophenotype of the Reed-Sternberg cells is identical to that seen in other classical types of HL. Immunophenotyping is essential, since most tumors suspected of being lymphocyte depletion HL actually prove to be large-cell NHLs. **The Reed-Sternberg cells are infected with EBV in over 90% of cases.**

Lymphocyte depletion HL occurs predominantly in older adults, in HIV+ individuals of any age, and in nonindustrialized countries. Advanced stage and systemic symptoms are frequent, and the overall outcome is somewhat less favorable than in the other subtypes.

Lymphocyte Predominance Type. This uncommon “nonclassical” variant of HL accounts for about 5% of cases. Involved nodes are effaced by a nodular infiltrate of small lymphocytes admixed with variable numbers of macrophages (Fig. 13-27). “Classical” Reed-Sternberg cells are usually difficult to find. Instead, this tumor contains so-called L&H (lymphocytic and histiocytic) variants, which have a multilobed nucleus resembling a popcorn kernel (“popcorn cell”). Eosinophils and plasma cells are usually scant or absent.

In contrast to the Reed-Sternberg cells found in classical forms of HL, **L&H variants express B-cell markers typical of germinal-center B cells**, such as CD20 and BCL6, and are usually negative for CD15 and CD30. The typical nodular pattern of growth is due to the presence of expanded B-cell follicles, which are populated with L&H variants, numerous reactive B cells, and follicular dendritic cells. The IgH genes of

Figure 13-26 Hodgkin lymphoma, mixed-cellularity type. A diagnostic, binucleate Reed-Sternberg cell is surrounded by reactive cells, including eosinophils (bright red cytoplasm), lymphocytes, and histiocytes. (Courtesy Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Tex.)

Figure 13-27 Hodgkin lymphoma, lymphocyte predominance type. Numerous mature-looking lymphocytes surround scattered, large, pale-staining lymphohistiocytic variants (“popcorn” cells). (Courtesy Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Tex.)

the L&H variants show evidence of ongoing somatic hypermutation, a modification that occurs only in germinal center B cells. In 3% to 5% of cases, this type transforms into a tumor resembling diffuse large B-cell lymphoma. EBV is not associated with this subtype.

A majority of patients are males, usually younger than 35 years of age, who typically present with cervical or axillary lymphadenopathy. Mediastinal and bone marrow involvement is rare. In some series, this form of HL is more likely to recur than the classical subtypes, but the prognosis is excellent.

Clinical Features. HL most commonly present as painless lymphadenopathy. Patients with the nodular sclerosis or lymphocyte predominance types tend to have stage I-II disease and are usually free of systemic manifestations. Patients with disseminated disease (stages III-IV) or the mixed-cellularity or lymphocyte depletion subtypes are more likely to have constitutional symptoms, such as fever, night sweats, and weight loss. Cutaneous immune unresponsiveness (also called anergy) resulting from depressed cell-mediated immunity is seen in most cases. The mix of factors released from Reed-Sternberg cells (Fig. 13-28) suppress T_H1 immune responses and may contribute to immune dysregulation.

The spread of HL is remarkably stereotyped: nodal disease first, then splenic disease, hepatic disease, and finally involvement of the marrow and other tissues. Staging involves physical examination, radiologic imaging of the abdomen, pelvis, and chest, and biopsy of the bone marrow (Table 13-9). With current treatment protocols, tumor stage rather than histologic type is the most important prognostic variable. The cure rate of patients with stages I and IIA is close to 90%. Even with advanced disease (stages IVA and IVB), disease-free survival at 5 years is 60% to 70%.

Low-stage localized HL can be cured with involved field radiotherapy, and indeed cure of such patients was one of the early success stories in oncology. However, it was subsequently recognized that long-term survivors treated with radiotherapy had a much higher incidence of certain malignancies, including lung cancer, melanoma, and breast cancer. Patients treated with early chemotherapy regimens containing alkylating agents also had a high

Table 13-9 Clinical Staging of Hodgkin and Non-Hodgkin Lymphomas (Ann Arbor Classification)

Stage	Distribution of Disease
I	Involvement of a single lymph node region (I) or a single extralymphatic organ or site (IE)
II	Involvement of two or more lymph node regions on the same side of the diaphragm alone (II) or localized involvement of an extralymphatic organ or site (IIE)
III	Involvement of lymph node regions on both sides of the diaphragm without (III) or with (IIIE) localized involvement of an extralymphatic organ or site
IV	Diffuse involvement of one or more extralymphatic organs or sites with or without lymphatic involvement
All stages are further divided on the basis of the absence (A) or presence (B) of the following symptoms: unexplained fever, drenching night sweats, and/or unexplained weight loss of greater than 10% of normal body weight.	

Data from Carbone PT, et al: Symposium (Ann Arbor): Staging in Hodgkin's disease. *Cancer Res* 31:1707, 1971.

incidence of secondary tumors, particularly acute myeloid leukemia. These sobering results spurred the development of current treatment regimens, which minimize the use of radiotherapy and employ less genotoxic chemotherapeutic agents; as a result, the incidence of secondary tumors appears to have been reduced markedly, without any loss of therapeutic efficacy. Anti-CD30 antibodies have produced excellent responses in patients with disease that has failed conventional treatments and represent a promising targeted therapy.

KEY CONCEPTS

Hodgkin Lymphoma

- Unusual tumor consisting mostly of reactive lymphocytes, macrophages, eosinophils, plasma cells and stromal cells mixed with rare tumor giant cells called Reed-Sternberg cells and variants
- Two broad types, classical (which has several subtypes) and lymphocyte predominant, which are distinguished based on morphologic and immunophenotypic grounds
- Reed-Sternberg cells of classical types make multiple cytokines and chemokines that influence the host response, and the host response in turn makes factors that support the growth of the tumor cells
- Classical forms are frequently associated with acquired mutations that activate the transcription factor NF- κ B and with EBV infection
- Lymphocyte predominance type expresses B cell markers and is not associated with EBV

Myeloid Neoplasms

The common feature of this heterogeneous group of neoplasms is an origin from hematopoietic progenitor cells. These diseases primarily involve the marrow and to a lesser degree the secondary hematopoietic organs (the spleen, liver, and lymph nodes), and usually present with symptoms related to altered hematopoiesis. Three broad categories of myeloid neoplasia exist:

- *Acute myeloid leukemias*, in which an accumulation of immature myeloid forms (blasts) in the bone marrow suppresses normal hematopoiesis
- *Myelodysplastic syndromes*, in which defective maturation of myeloid progenitors gives rise to ineffective hematopoiesis, leading to cytopenias
- *Myeloproliferative disorders*, in which there is usually increased production of one or more types of blood cells

The pathogenesis of myeloid neoplasms is best understood in the context of normal hematopoiesis, which involves a hierarchy of hematopoietic stem cells, committed progenitors, and more differentiated elements (Fig. 13-1). Normal hematopoiesis is finely tuned by homeostatic feedback mechanisms involving cytokines and growth factors that modulate the production of red cells, white cells, and platelets in the marrow. These mechanisms are deranged in marrows involved by myeloid neoplasms, which “escape” from normal homeostatic controls and suppress the function of residual normal stem cells. The specific manifestations of the different myeloid neoplasms are influenced by

- *The position of the transformed cell within the hierarchy of progenitors* (i.e., a pluripotent hematopoietic stem cell versus a more committed progenitor)
- *The effect of the transforming events on differentiation*, which may be inhibited, skewed, or deranged by particular oncogenic mutations

Given that all myeloid neoplasms originate from transformed hematopoietic progenitors, it is not surprising that divisions between these neoplasms are sometimes blurred. Myeloid neoplasms, like other malignancies, tend to evolve over time to more aggressive forms of disease. In particular, both myelodysplastic syndromes and myeloproliferative disorders often “transform” to AML. In one of the most important myeloproliferative disorders, chronic myelogenous leukemia (CML), transformation to acute lymphoblastic leukemia is also seen, indicating that it originates from a transformed pluripotent hematopoietic stem cell.

Acute Myeloid Leukemia

Acute myeloid leukemia (AML) is a tumor of hematopoietic progenitors caused by acquired oncogenic mutations that impede differentiation, leading to the accumulation of immature myeloid blasts in the marrow. The replacement of the marrow with blasts produces marrow failure and complications related to anemia, thrombocytopenia, and neutropenia. AML occurs at all ages, but the incidence rises throughout life, peaking after 60 years of age. There are about 13,000 new cases each year in the United States.

Classification. AML is quite heterogeneous, reflecting the complexities of myeloid cell differentiation. The current WHO classification subdivides AML into four categories (Table 13-10). The first includes forms of AML that are associated with particular genetic aberrations, which are important because they correlate with prognosis and guide therapy. Also included are categories of AML arising after a myelodysplastic disorder (MDS) or with MDS-like features, and therapy-related AML. AMLs in these two categories have distinct genetic features and respond poorly to

Table 13-10 Major Subtypes of AML in the WHO Classification

Class	Prognosis	Morphology/Comments
I. AML with Genetic Aberrations		
AML with t(8;21)(q22;q22); <i>RUNX1/ETO</i> fusion gene	Favorable	Full range of myelocytic maturation; Auer rods easily found; abnormal cytoplasmic granules
AML with inv(16)(p13;q22); <i>CBFB/MYH11</i> fusion gene	Favorable	Myelocytic and monocytic differentiation; abnormal eosinophilic precursors with abnormal basophilic granules
AML with t(15;17)(q22;11-12); <i>RARA/PML</i> fusion gene	Intermediate	Numerous Auer rods, often in bundles within individual progranulocytes; primary granules usually very prominent, but inconspicuous in microgranular variant; high incidence of DIC
AML with t(11q23;q); diverse <i>MLL</i> fusion genes	Poor	Usually some degree of monocytic differentiation
AML with normal cytogenetics and mutated <i>NPM</i>	Favorable	Detected by immunohistochemical staining for NPM
II. AML with MDS-like Features		
With prior MDS	Poor	Diagnosis based on clinical history
AML with multilineage dysplasia	Poor	Maturing cells with dysplastic features typical of MDS
AML with MDS-like cytogenetic aberrations	Poor	Associated with 5q-, 7q-, 20q-aberrations
III. AML, therapy-related		
	Very poor	If following alkylator therapy or radiation therapy, 2- to 8-year latency period, MDS-like cytogenetic aberrations (e.g., 5q-, 7q-); if following topoisomerase II inhibitor (e.g., etoposide) therapy, 1- to 3-year latency, translocations involving <i>MLL</i> (11q23)
IV. AML, Not Otherwise Specified		
AML, minimally differentiated	Intermediate	Negative for myeloperoxidase; myeloid antigens detected on blasts by flow cytometry
AML without maturation	Intermediate	>3% of blasts positive for myeloperoxidase
AML with myelocytic maturation	Intermediate	Full range of myelocytic maturation
AML with myelomonocytic maturation	Intermediate	Myelocytic and monocytic differentiation
AML with monocytic maturation	Intermediate	Nonspecific esterase-positive monoblasts and pro-monocytes predominate in marrow; may see monoblasts or mature monocytes in the blood
AML with erythroid maturation	Intermediate	Erythroid/myeloid subtype defined by >50% dysplastic maturing erythroid precursors and >20% myeloblasts; pure erythroid subtype defined by >80% erythroid precursors without myeloblasts
AML with megakaryocytic maturation	Intermediate	Blasts of megakaryocytic lineage predominate; detected with antibodies against megakaryocyte-specific markers (GPIIb/IIIa or vWF); often associated with marrow fibrosis; most common AML in Down syndrome

AML, Acute myeloid leukemia; DIC, disseminated intravascular coagulation; MDS, myelodysplasia; NPM, nucleophosmin; vWF, von Willebrand factor.

therapy. A fourth “wastebasket” category includes AMLs lacking any of these features. These are classified based on the degree of differentiation and the lineage of the leukemic blasts. Given the increasing role of cytogenetic and molecular features in directing therapy, a further shift toward genetic classification of AML is both inevitable and desirable.

Pathogenesis. Many of the recurrent genetic aberrations seen in AML disrupt genes encoding transcription factors that are required for normal myeloid differentiation. For example, the two most common chromosomal rearrangements, t(8;21) and inv(16), disrupt the *RUNX1* and *CBFB* genes, respectively. These two genes encode polypeptides that bind one another to form a *RUNX1/CBF1β* transcription factor that is required for normal hematopoiesis. The t(8;21) and the inv(16) create chimeric genes encoding fusion proteins that interfere with the function of *RUNX1/CBF1β* and block the maturation of myeloid cells. However, experiments in mouse models indicate that genetic lesions that merely block the maturation of myeloid progenitors are not sufficient to cause AML. Thus other genetic changes (discussed next) are also essential.

There is increasing evidence that mutations that lead to activation of growth factor signaling pathways collaborate with transcription factor aberrations to produce

AML. One example is found in AML with the t(15;17), acute promyelocytic leukemia. The t(15;17) creates yet another fusion gene encoding a chimeric protein consisting of the retinoic acid receptor- α (*RARα*) fused to a portion of a protein called PML (after the tumor). As discussed in Chapter 7, this fusion protein interferes with the terminal differentiation of granulocytes, an effect that can be overcome by treatment with either all-trans retinoic acid or arsenic trioxide. However, expression of the PML-*RARα* fusion protein in the bone marrow cells of mice produces disease only in aged mice, suggesting that PML-*RARα* is not sufficient. Indeed, AMLs with the t(15;17) (a subtype referred to as acute promyelocytic leukemia) also have frequent activating mutations in *FLT3*, a receptor tyrosine kinase that transmits signals that mimic normal growth factor signaling, thereby increasing cellular proliferation and survival. As might be predicted, the combination of PML-*RARα* and activated *FLT3* is a potent inducer of AML in mice. Other similar observations in human AML and in mouse models indicate that aberrant activation of growth factor signaling pathways is a common feature of AML.

Deep sequencing of AML genomes has also revealed unexpectedly frequent mutations affecting factors that impact the state of the “epigenome,” suggesting the epigenetic alterations have a central role in AML.

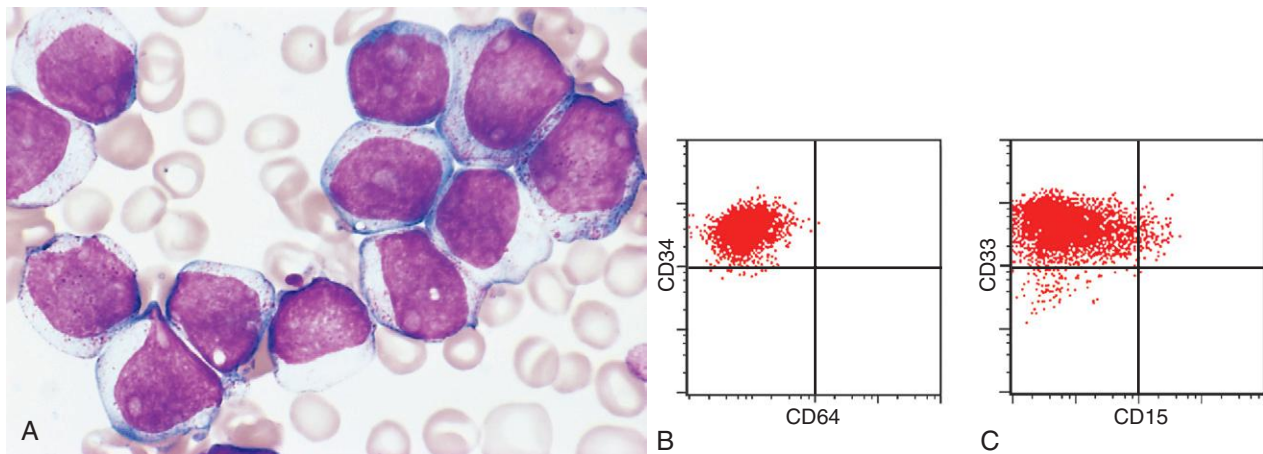

Figure 13-29 **A**, Acute myeloid leukemia without maturation (FAB M1 subtype). Myeloblasts have delicate nuclear chromatin, prominent nucleoli, and fine azurophilic granules in the cytoplasm. **B**, In the flow cytometric analysis shown, the myeloid blasts, represented by the red dots, express CD34, a marker of multipotent stem cells, but do not express CD64, a marker of mature myeloid cells. **C**, The same myeloid blasts express CD33, a marker of immature myeloid cells, and a subset express CD15, a marker of more mature myeloid cells. Thus, these blasts are myeloid cells showing limited maturation. (**A**, Courtesy Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Tex; **B** and **C**, courtesy Dr. Louis Picker, Oregon Health Science Center, Portland, Ore.)

Gene expression is regulated by two types of epigenetic modifications, DNA methylation and posttranslational modifications of histones (e.g., acetylation, methylation, phosphorylation). Some of the most commonly mutated genes in AML encode factors that influence DNA methylation or histone modifications. Another 15% of tumors have mutations involving genes encoding components of the cohesin complex, proteins that regulate the three-dimensional structure of chromatin. The precise mechanism by which these mutations contribute to the development of AML remains to be determined and is a “hot” area of current research.

MORPHOLOGY

The diagnosis of AML is based on the presence of at least 20% myeloid blasts in the bone marrow. Several types of myeloid blasts are recognized, and individual tumors may have more than one type of blast or blasts with hybrid features.

Myeloblasts have delicate nuclear chromatin, two to four nucleoli, and more voluminous cytoplasm than lymphoblasts (Fig. 13-29A). The cytoplasm often contains fine, peroxidase-positive azurophilic granules. **Auer rods**, distinctive needle-like azurophilic granules, are present in many cases; they are particularly numerous in AML with the t(15;17) (acute promyelocytic leukemia) (Fig. 13-30A). **Monoblasts** (Fig. 13-30B) have folded or lobulated nuclei, lack Auer rods, and are nonspecific esterase-positive. In some AMLs, blasts show megakaryocytic differentiation, which is often accompanied by marrow fibrosis caused by the release of fibrogenic cytokines. Rarely, the blasts of AML show erythroid differentiation.

The number of leukemic cells in the blood is highly variable. Blasts may be more than 100,000/mm³, but are under 10,000/mm³ in about 50% of patients. **Occasionally, blasts are entirely absent from the blood (aleukemic leukemia).** For this reason, a bone marrow examination is essential to exclude acute leukemia in pancytopenic patients.

Figure 13-30 Acute myeloid leukemia subtypes. **A**, Acute promyelocytic leukemia with the t(15;17) (FAB M3 subtype). Bone marrow aspirate shows neoplastic promyelocytes with abnormally coarse and numerous azurophilic granules. Other characteristic findings include the presence of several cells with bilobed nuclei and a cell in the center of the field that contains multiple needle-like Auer rods. **B**, Acute myeloid leukemia with monocytic differentiation (FAB M5b subtype). Peripheral smear shows one monoblast and five promonocytes with folded nuclear membranes. (Courtesy Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Tex.)

Immunophenotype. Because it can be difficult to distinguish myeloblasts and lymphoblasts morphologically, the diagnosis of AML is confirmed by performing stains for myeloid-specific antigens (Fig. 13-29B,C).

Cytogenetics. Cytogenetic analysis has a central role in the classification of AML. Karyotypic aberrations are detected in 50% to 70% of cases with standard techniques and in approximately 90% of cases using special high-resolution banding. Particular chromosomal abnormalities correlate with certain clinical features. AMLs arising de novo in younger adults are commonly associated with balanced chromosomal translocations, particularly t(8;21), inv(16), and t(15;17). In contrast, AMLs following myelodysplastic syndromes or exposure to DNA-damaging agents (such as chemotherapy or radiation therapy) often have deletions or monosomies involving chromosomes 5 and 7 and usually lack chromosomal translocations. The exception to this rule is AML occurring after treatment with topoisomerase II inhibitors, which is strongly associated with translocations involving the *MLL* gene on chromosome 11q23. AML in older adults is also more likely to be associated with “bad” aberrations, such as deletions of chromosomes 5q and 7q.

Clinical Features. Most patients present within weeks or a few months of the onset of symptoms with complaints related to *anemia, neutropenia, and thrombocytopenia*, most notably fatigue, fever, and spontaneous mucosal and cutaneous bleeding. You will remember that these findings are very similar to those produced by ALL. Thrombocytopenia results in a bleeding diathesis, which is often prominent. Cutaneous petechiae and ecchymoses, serosal hemorrhages into the linings of the body cavities and viscera, and mucosal hemorrhages into the gingivae and urinary tract are common. Procoagulants and fibrinolytic factors released by leukemic cells, especially in AML with the t(15;17), exacerbate the bleeding tendency. Infections are frequent, particularly in the oral cavity, skin, lungs, kidneys, urinary bladder, and colon, and are often caused by opportunists such as fungi, *Pseudomonas*, and commensals.

Signs and symptoms related to involvement of tissues other than the marrow are usually less striking in AML than in ALL, but tumors with monocytic differentiation often infiltrate the skin (leukemia cutis) and the gingiva; this probably reflects the normal tendency of monocytes to extravasate into tissues. Central nervous system spread is less common than in ALL. AML occasionally presents as a localized soft-tissue mass known variously as a myeloblastoma, granulocytic sarcoma, or chloroma. Without systemic treatment, such tumors inevitably progress to full-blown AML over time.

Prognosis. AML is generally a difficult disease to treat; about 60% of patients achieve complete remission with chemotherapy, but only 15% to 30% remain free of disease for 5 years. However, the outcome varies markedly among different molecular subtypes. With targeted therapy using all-trans retinoic acid and arsenic salts (described in Chapter 7), AMLs with the t(15;17) now have the best prognosis of any type, being curable in more than 80% of patients. AMLs with t(8;21) or inv(16) have a relatively good prognosis with conventional chemotherapy,

particularly in the absence of *KIT* mutations. In contrast, the prognosis is dismal for AMLs that follow MDS or genotoxic therapy, or that occur in older adults, possibly because in these contexts the disease arises out of a background of hematopoietic stem cell damage or depletion. These “high-risk” forms of AML (as well as relapsed AML of all types) are treated with hematopoietic stem cell transplantation when possible.

Sequencing of AML genomes has recently revealed new molecular predictors of outcome. It is certain that insights gained from DNA sequencing will have an increasingly important role in selecting therapy and stratifying patients in clinical trials of new therapeutics, such as drugs that target the tumor epigenome.

Myelodysplastic Syndromes

The term “myelodysplastic syndrome” (MDS) refers to a group of clonal stem cell disorders characterized by maturation defects that are associated with ineffective hematopoiesis and a high risk of transformation to AML. In MDS the bone marrow is partly or wholly replaced by the clonal progeny of a neoplastic multipotent stem cell that retains the capacity to differentiate but does so in an ineffective and disordered fashion. These abnormal cells stay within the bone marrow and hence the patients have peripheral blood cytopenias.

MDS may be either primary (idiopathic) or secondary to previous genotoxic drug or radiation therapy (t-MDS). t-MDS usually appears from 2 to 8 years after the genotoxic exposure. All forms of MDS can transform to AML, but transformation occurs with highest frequency and most rapidly in t-MDS. Although characteristic morphologic changes are typically seen in the marrow and the peripheral blood, the diagnosis frequently requires correlation with other laboratory tests. Cytogenetic analysis is particularly helpful, since certain chromosomal aberrations (discussed later) are often observed.

Pathogenesis. The pathogenesis of MDS is poorly understood, but important new insights have come from recent deep sequencing of MDS genomes, which has identified a number of recurrently mutated genes. These genes can be lumped into three major functional categories, as follows:

- **Epigenetic factors.** Frequent mutations are seen involving many of the same epigenetic factors that are mutated in AML, including factors that regulate DNA methylation and histone modifications; thus, like AML, dysregulation of the epigenome appears to be important in the genesis of MDS.
- **RNA splicing factors.** A subset of tumors has mutations involving components of the 3' end of the RNA splicing machinery. The impact of these mutations on RNA splicing and other nuclear functions is not yet known.
- **Transcription factors.** These mutations affect transcription factors that are required for normal myelopoiesis and may contribute to the deranged differentiation that characterizes MDS.

In addition, roughly 10% of MDS cases have loss-of-function mutations in the tumor suppressor gene *TP53*, which correlate with the presence of a complex karyotype and particularly poor clinical outcomes. Both primary MDS and t-MDS are associated with similar recurrent

Figure 13-31 Myelodysplasia. Characteristic forms of dysplasia are shown. **A**, Nucleated red cell progenitors with multilobated or multiple nuclei. **B**, Ringed sideroblasts, erythroid progenitors with iron-laden mitochondria seen as blue perinuclear granules (Prussian blue stain). **C**, Pseudo-Pelger-Hüet cells, neutrophils with only two nuclear lobes instead of the normal three to four, are observed at the top and bottom of this field. **D**, Megakaryocytes with multiple nuclei instead of the normal single multilobated nucleus. (**A, B, D**, Marrow aspirates; **C**, peripheral blood smear.)

chromosomal abnormalities, including monosomies 5 and 7, deletions of 5q, 7q, and 20q, and trisomy 8.

As with aneuploidy in other cancers, it is not known how these aberrations contribute to MDS. One idea with some experimental support is that the gain or loss of single copies of key genes is sufficient to give cells a growth advantage, and that aneuploidy is one way to achieve this result. For example, subtle increases in the notorious oncoprotein MYC is sufficient to stimulate cell growth. Notably, the MYC gene is located on chromosome 8, and trisomy 8 is one of the most common forms of aneuploidy in a wide range of myeloid tumors. Similarly, the region that is commonly lost on chromosome 5q contains a gene encoding the ribosomal protein RPS14. In experimental systems, loss of one copy of RPS14 produces ineffective erythropoiesis, one of the hallmarks of MDS.

MORPHOLOGY

Although the marrow is usually hypercellular at diagnosis, it is sometimes normocellular or, less commonly, hypocellular. The most characteristic finding is disordered (dysplastic) differentiation affecting the erythroid, granulocytic, monocytic, and megakaryocytic lineages to varying degrees (Fig. 13-31). Within the erythroid series, common abnormalities include **ring sideroblasts**, erythroblasts with iron-laden mitochondria visible as

perinuclear granules in Prussian blue-stained aspirates or biopsies; **megaloblastoid maturation**, resembling that seen in vitamin B₁₂ and folate deficiency (Chapter 14); and **nuclear budding abnormalities**, recognized as nuclei with misshapen, often polyploid, outlines. Neutrophils frequently contain decreased numbers of secondary granules, toxic granulations, and/or Döhle bodies. **Pseudo-Pelger-Hüet cells**, neutrophils with only two nuclear lobes, are commonly observed, and neutrophils are seen occasionally that completely lack nuclear segmentation. Megakaryocytes with single nuclear lobes or multiple separate nuclei (**pawn ball megakaryocytes**) are also characteristic. **Myeloid blasts** may be increased but make up less than 20% of the overall marrow cellularity. The blood often contains pseudo-Pelger-Hüet cells, giant platelets, macrocytes, and poikilocytes, accompanied by a relative or absolute monocytosis. Myeloid blasts usually make up less than 10% of the leukocytes in the blood.

Clinical Features. Primary MDS is predominantly a disease of older adults; the mean age of onset is 70 years. In up to half of the cases, it is discovered incidentally on routine blood testing. When symptomatic, it presents with weakness, infections, and hemorrhages, all due to pancytopenia.

Primary MDS is divided into eight categories based on morphologic and cytogenetic features in the WHO

Table 13-11 Tyrosine Kinase Mutations in Myeloproliferative Disorders

Disorder	Mutation	Frequency*	Consequences†
Chronic myelogenous leukemia	<i>BCR-ABL</i> fusion gene	100%	Constitutive ABL kinase activation‡
Polycythemia vera	<i>JAK2</i> point mutations	>95%	Constitutive <i>JAK2</i> kinase activation
Essential thrombocythemia	<i>JAK2</i> point mutations	50% to 60%	Constitutive <i>JAK2</i> kinase activation
	<i>MPL</i> point mutations	5% to 10%	Constitutive <i>MPL</i> kinase activation
Primary myelofibrosis	<i>JAK2</i> point mutations	50% to 60%	Constitutive <i>JAK2</i> kinase activation
	<i>MPL</i> point mutations	5% to 10%	Constitutive <i>MPL</i> kinase activation
Systemic mastocytosis	<i>KIT</i> point mutations	>90%	Constitutive <i>KIT</i> kinase activation
Chronic eosinophilic leukemia§	<i>FIP1L1-PDGFRα</i> fusion gene	Common	Constitutive <i>PDGFRα</i> kinase activation
	<i>PDE4DIP-PDGFRβ</i> fusion gene	Rare	Constitutive <i>PDGFRβ</i> kinase activation†
Stem cell leukemia	Various <i>FGFR1</i> fusion genes	100%	Constitutive <i>FGFR1</i> kinase activation¶

*Refers to frequency within a diagnostic category.

†All stimulate ligand-independent pro-growth and survival signals.

classification, details of which are beyond our scope. A prognostic scoring system has been developed that groups patients into 5 major prognostic groups. In brief, worse outcomes are (understandably) predicted by higher blast counts and more severe cytopenias, as well as the presence of multiple clonal chromosomal abnormalities.

The median survival in primary MDS varies from 9 to 29 months, but some individuals in good prognostic groups may live for 5 years or more. Overall, progression to AML occurs in 10% to 40% of individuals and is usually accompanied by the appearance of additional cytogenetic abnormalities. Patients often succumb to the complications of thrombocytopenia (bleeding) and neutropenia (infection). The outlook is even grimmer in t-MDS, which has a median survival of only 4 to 8 months. In t-MDS, cytopenias tend to be more severe and progression to AML is often rapid.

Treatment options are fairly limited. In younger patients, allogeneic hematopoietic stem cell transplantation offers hope for reconstitution of normal hematopoiesis and possible cure. Older patients with MDS are treated supportively with antibiotics and blood product transfusions. Thalidomide-like drugs (see prior discussion in myeloma) and DNA methylation inhibitors improve the effectiveness of hematopoiesis and the peripheral blood counts in a subset of patients. The presence of isolated 5q- is correlated with a hematologic response to thalidomide-like drugs, but as yet response to DNA methylation inhibitors is unpredictable.

Myeloproliferative Disorders

The common pathogenic feature of the myeloproliferative disorders is the presence of mutated, constitutively activated tyrosine kinases or other acquired aberrations in signaling pathways that lead to growth factor independence. Hematopoietic growth factors act on normal progenitors by binding to surface receptors and activating tyrosine kinases, which turn on pathways that promote growth and survival (Chapter 7). The mutated tyrosine kinases found in the myeloproliferative disorders circumvent normal controls and lead to the growth factor-independent proliferation and survival of marrow

progenitors. Because the tyrosine kinase mutations underlying the various myeloproliferative disorders do not impair differentiation, the most common consequence is an increase in the production of one or more mature blood elements. Most myeloproliferative disorders originate in multipotent myeloid progenitors, whereas others arise in pluripotent stem cells that give rise to both lymphoid and myeloid cells.

There is a considerable degree of clinical and morphologic overlap among the myeloproliferative disorders. The common features include:

- *Increased proliferative drive* in the bone marrow
- Homing of the neoplastic stem cells to secondary hematopoietic organs, producing *extramedullary hematopoiesis*
- Variable transformation to a spent phase characterized by *marrow fibrosis* and peripheral blood *cytopenias*
- Variable transformation to *acute leukemia*

Certain myeloproliferative disorders are strongly associated with activating mutations in specific tyrosine kinases. This insight and the availability of kinase inhibitors have increased the importance of molecular tests for tyrosine kinase mutations, both for purposes of diagnosis and the selection of therapy. This discussion is confined to the more common myeloproliferative disorders, which are classified based on clinical, laboratory, and molecular criteria. Systemic mastocytosis, a distinctive myeloproliferative disorder that is associated with mutations in the *KIT* tyrosine kinase, is discussed under disorders of the skin (Chapter 25). The association of various myeloproliferative disorders with specific tyrosine kinase mutations (including rare disorders not discussed here) is summarized in Table 13-11.

Chronic Myelogenous Leukemia

Chronic myelogenous leukemia (CML) is distinguished from other myeloproliferative disorders by the presence of a chimeric *BCR-ABL* gene derived from portions of the *BCR* gene on chromosome 22 and the *ABL* gene on chromosome 9. *BCR-ABL* directs the synthesis of a constitutively active *BCR-ABL* tyrosine kinase (Fig. 13-32), which

Figure 13-32 Pathogenesis of chronic myeloid leukemia. Breakage and joining of *BCR* and *ABL* creates a chimeric *BCR-ABL* fusion gene that encodes a constitutively active BCR-ABL tyrosine kinase. BCR-ABL activates multiple downstream pathways, which drive growth factor-independent proliferation and survival of bone marrow progenitors. Because BCR-ABL does not interfere with differentiation, the net result is an increase in mature elements in the peripheral blood, particularly granulocytes and platelets.

in CML is usually 210 kDa in size. In more than 90% of cases, *BCR-ABL* is created by a reciprocal (9;22)(q34;q11) translocation (the so-called *Philadelphia chromosome* [Ph]). In the remaining cases the *BCR-ABL* fusion gene is formed by cytogenetically complex or cryptic rearrangements and must be detected by other methods, such as fluorescence in situ hybridization or polymerase chain reaction (PCR)-based tests. The cell of origin is a pluripotent hematopoietic stem cell.

Pathogenesis. Tyrosine kinases are normally regulated by ligand-mediated dimerization and autophosphorylation, which creates an activated kinase capable of phosphorylating other protein substrates (Chapters 3 and 7). The BCR moiety of BCR-ABL contains a dimerization domain that self-associates, leading to the activation of the ABL tyrosine kinase moiety. The ABL kinase in turn phosphorylates proteins that induce signaling through the same pro-growth and pro-survival pathways that are turned on by hematopoietic growth factors, including the RAS and JAK/STAT pathways. For unknown reasons, BCR-ABL preferentially drives the proliferation of granulocytic and megakaryocytic progenitors, and also causes the abnormal release of immature granulocytic forms from the marrow into the blood.

Figure 13-33 Chronic myelogenous leukemia. Peripheral blood smear shows many mature neutrophils, some metamyelocytes, and a myelocyte. (Courtesy Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Tex.)

MORPHOLOGY

The marrow is markedly **hypercellular** because of massively increased numbers of maturing granulocytic precursors, which usually include an elevated proportion of eosinophils and basophils. Megakaryocytes are also increased and usually include small, dysplastic forms. Erythroid progenitors are present in normal or mildly decreased numbers. A characteristic finding is the presence of scattered macrophages with abundant wrinkled, green-blue cytoplasm so-called sea-blue histiocytes. Increased deposition of reticulin is typical, but overt marrow fibrosis is rare early in the course. The blood reveals a **leukocytosis, often exceeding 100,000 cells/mm³** (Fig. 13-33), which consists predominantly of neutrophils, band forms, metamyelocytes, myelocytes, eosinophils, and basophils. Blasts usually make up less than 10% of the circulating cells. Platelets are also usually increased, sometimes markedly. The spleen is often greatly enlarged as a result of extensive extramedullary hematopoiesis (Fig. 13-34) and often contains infarcts of varying age. Extramedullary hematopoiesis can also produce mild hepatomegaly and lymphadenopathy.

Clinical Features. CML is primarily a disease of adults but also occurs in children and adolescents. The peak incidence is in the fifth to sixth decades of life. There are about 4500 new cases per year in the United States.

Figure 13-34 Chronic myeloid leukemia (spleen). Enlarged spleen (2630 gm; normal: 150 to 200 gm) with greatly expanded red pulp stemming from neoplastic hematopoiesis. (Courtesy Dr. Daniel Jones, Department of Pathology, MD Anderson Cancer Center, Houston, Tex.)

The onset is insidious. Mild-to-moderate anemia and hypermetabolism due to increased cell turnover lead to fatigability, weakness, weight loss, and anorexia. Sometimes the first symptom is a dragging sensation in the abdomen caused by splenomegaly, or the acute onset of left upper quadrant pain due to splenic infarction. CML is best differentiated from other myeloproliferative disorders by detection of the *BCR-ABL* fusion gene through either chromosomal analysis or PCR-based tests.

The natural history is one of slow progression; even without treatment, the median survival is about 3 years. After a variable period averaging 3 years, about 50% of patients enter an “accelerated phase” marked by increasing anemia and thrombocytopenia, sometimes accompanied by a rise in the number of basophils in the blood. Additional clonal cytogenetic abnormalities, such as trisomy 8, isochromosome 17q, or duplication of the Ph chromosome, often appear. Within 6 to 12 months, the accelerated phase terminates in a picture resembling acute leukemia (*blast crisis*). In the other 50% of patients, blast crises occur abruptly without an accelerated phase. In 70% of crises, the blasts are of myeloid origin (myeloid blast crisis), whereas in most of the remainder the blasts are of pre-B cell origin (lymphoid blast crisis). This is taken as evidence that CML originates from a pluripotent stem cell with both myeloid and lymphoid potential.

Given that we have seen that acute leukemias often stem from complementary mutations involving a transcription factor and a tyrosine kinase, it might be predicted that blast crisis would be caused by an acquired mutation in a key transcriptional regulator. This prediction has been realized in lymphoid blast crisis, in which 85% of cases are associated with mutations that interfere with the activity of Ikaros, a transcription factor that regulates the differentiation of hematopoietic progenitors. The same types of Ikaros mutations are also seen in *BCR-ABL*-positive B-ALL, suggesting that these two varieties of aggressive leukemia have a similar pathogenic basis.

Understanding of the pathogenesis of CML has led to the use of drugs that target *BCR-ABL*. Treatment with *BCR-ABL* inhibitors results in sustained hematologic remissions in greater than 90% of patients, with generally tolerable side effects. These inhibitors markedly decrease the number of *BCR-ABL*-positive cells in the marrow and elsewhere, but do not extinguish the CML “stem cell,” which persists at low levels. As a result, it is not clear if *BCR-ABL* inhibitors are ever truly curative. However, this form of targeted therapy controls blood counts and substantially decreases the risk of transformation to the accelerated phase and blast crisis, which is the greatest threat to the patient. It may be that by lowering the proliferative drive of the *BCR-ABL*-positive progenitors, *BCR-ABL* inhibitors decrease the rate at which these cells acquire mutations that lead to disease progression.

The other major threat to the patient is the emergence of resistance to first generation *BCR-ABL* inhibitors, which in about 50% of cases stems from mutations in *BCR-ABL* and in the remaining cases mutations in other kinases. This problem has been overcome in part by development of second and third generation kinase inhibitors that are active against mutated forms of *BCR-ABL*. For relatively young patients, hematopoietic stem cell transplantation performed in the stable phase is curative in about 75% of

cases. The outlook is less favorable once the accelerated phase or blast crisis supervenes, as transplantation and treatment with *BCR-ABL* inhibitors are both less effective in these settings.

Polycythemia Vera

Polycythemia vera is strongly associated with activating point mutations in the tyrosine kinase *JAK2*. Polycythemia vera (PCV) is characterized by increased marrow production of red cells, granulocytes, and platelets (panmyelosis), but it is the increase in red cells (polycythemia) that is responsible for most of the clinical symptoms. PCV must be differentiated from relative polycythemia resulting from hemoconcentration and other causes of absolute polycythemia (Chapter 14).

Pathogenesis. *JAK2* participates in the *JAK/STAT* pathway, which lies downstream of multiple hematopoietic growth factor receptors, including the erythropoietin receptor. In PCV the transformed progenitor cells have markedly decreased requirements for erythropoietin and other hematopoietic growth factors due to constitutive *JAK2* signaling. Accordingly, serum erythropoietin levels in PCV are low, whereas secondary forms of polycythemia have high erythropoietin levels. The elevated hematocrit leads to increased blood viscosity and sludging. These hemodynamic factors, together with thrombocytosis and abnormal platelet function, make patients with PCV prone to both thrombosis and bleeding.

More than 97% of cases are associated with a mutation in *JAK2* that results in a valine-to-phenylalanine substitution at residue 617; other *JAK2* mutations are found in most (and perhaps all) of the remaining cases. The mutated forms of *JAK2* found in PCV render hematopoietic cell lines growth factor-independent, and when expressed in murine bone marrow progenitors cause a PCV-like syndrome that is associated with marrow fibrosis. In 25% to 30% of cases the tumor cells contain two mutated copies of *JAK2*, a genotype that is associated with higher white cell counts, more significant splenomegaly, symptomatic pruritus, and a greater rate of progression to the spent phase.

The proliferative drive in PCV (and other myeloproliferative disorders associated with *JAK2* mutations) is less than in CML, which is associated with more pronounced marrow hypercellularity, leukocytosis, and splenomegaly. Presumably, *JAK2* signals are quantitatively weaker or qualitatively different from those produced by *BCR-ABL* (Fig. 13-32).

MORPHOLOGY

The marrow is hypercellular, but some residual fat is usually present. **The increase in red cell progenitors is subtle and usually accompanied by an increase in granulocytic precursors and megakaryocytes as well.** At diagnosis, a moderate to marked increase in reticulin fibers is seen in about 10% of marrows. Mild organomegaly is common, being caused early in the course largely by congestion; at this stage extramedullary hematopoiesis is minimal. The peripheral blood often contains increased numbers of basophils and abnormally large platelets.

Late in the course, PCV often progresses to a **spent phase** characterized by extensive marrow fibrosis that displaces hematopoietic cells. This is accompanied by increased extramedullary hematopoiesis in the spleen and liver, often leading to prominent organomegaly (Fig. 13-35). Transformation to AML, with its typical features, occurs in about 1% of patients.

Clinical Features. PCV is uncommon, having an incidence of 1 to 3 per 100,000 per year. It appears insidiously, usually in adults of late middle age. Most symptoms are related to the increased red cell mass and hematocrit. Usually, there is also an increased total blood volume. Together, these factors cause abnormal blood flow, particularly on the low-pressure venous side of the circulation, which becomes greatly distended. Patients are plethoric and cyanotic due to stagnation and deoxygenation of blood in peripheral vessels. Headache, dizziness, hypertension, and gastrointestinal symptoms are common. Intense pruritus and peptic ulceration may occur, both possibly resulting from the release of histamine from basophils. High cell turnover gives rise to hyperuricemia; symptomatic gout is seen in 5% to 10% of cases.

More ominously, the abnormal blood flow and platelet function lead to an increased risk of both major bleeding and thrombotic episodes. About 25% of patients first come to attention due to deep venous thrombosis, myocardial infarction, or stroke. Thromboses sometimes also occur in the hepatic veins (producing Budd-Chiari syndrome) and the portal and mesenteric veins (leading to bowel infarction). It should be remembered that thrombotic complications sometimes precede the appearance of the typical hematologic findings. Minor hemorrhages (epistaxis, bleeding gums) are common, and life-threatening hemorrhages occur in 5% to 10% of cases.

The hemoglobin concentration ranges from 14 to 28 gm/dL, and the hematocrit is usually 60% or more. Sometimes chronic bleeding leads to iron deficiency, which can suppress erythropoiesis sufficiently to lower the hematocrit into the normal range, an example of two defects counteracting one another to “correct” a laboratory

Figure 13-35 Polycythemia vera, spent phase. Massive splenomegaly (3020 gm; normal: 150 to 200 gm) largely due to extramedullary hematopoiesis occurring in the setting of advanced marrow myelofibrosis. (Courtesy Dr. Mark Fleming, Department of Pathology, Children’s Hospital, Boston, Mass.)

abnormality. The white cell count ranges from 12,000 to 50,000 cells/mm³, and the platelet count is often greater than 500,000 platelets/mm³. The platelets usually exhibit morphologic abnormalities such as giant forms and are often defective in functional aggregation studies.

Without treatment, death from bleeding or thrombosis occurs within months of diagnosis. However, simply maintaining the red cell mass at nearly normal levels by phlebotomy extends the median survival to about 10 years. JAK2 inhibitors are in preclinical development and represent a promising form of targeted therapy.

Extended survival with treatment has revealed that PCV tends to evolve to a “spent phase,” during which clinical and anatomic features of primary myelofibrosis develop. The disease undergoes this transition in about 15% to 20% of patients after an average period of 10 years. It is marked by the appearance of obliterative fibrosis in the bone marrow (myelofibrosis) and extensive extramedullary hematopoiesis, principally in the spleen, which enlarges greatly. The mechanisms underlying the progression to the spent phase are not known.

In about 2% of patients, PCV transforms to AML. Surprisingly, the AML clone often lacks JAK2 mutations, suggesting that the causative JAK2 mutations occur in an abnormal stem cell that already harbors potentially oncogenic mutations, and therefore is “at risk” for giving rise to several different myeloid tumors. Unlike CML, transformation to ALL is rarely observed, consistent with the cell of origin being a progenitor committed to myeloid differentiation.

Essential Thrombocytosis

Essential thrombocytosis (ET) is often associated with activating point mutations in JAK2 (50% of cases) or MPL (5% to 10% of cases), a receptor tyrosine kinase that is normally activated by thrombopoietin. In addition, recent DNA sequencing studies have revealed that most of the remaining cases have mutations in calreticulin, a protein with several described functions in the endoplasmic reticulum and the cytoplasm. Since JAK2 and calreticulin mutations are mutually exclusive, it is hypothesized that the calreticulin mutations also increase JAK-STAT signaling through currently unknown mechanisms.

ET manifests clinically with elevated platelet counts and is separated from PCV and primary myelofibrosis based on the absence of polycythemia and marrow fibrosis, respectively. In those cases without tyrosine kinase mutations, causes of reactive thrombocytosis, such as inflammatory disorders and iron deficiency, must be excluded before the diagnosis can be established.

Constitutive JAK2 or MPL signaling renders the progenitors thrombopoietin-independent and leads to hyperproliferation. The JAK2 mutation is the same as that found in almost all cases of PCV. Why some patients with JAK2 mutations present with PCV and others with ET is not understood. Some cases of “ET” may in fact be PCV disguised by iron deficiency (which is more common in individuals diagnosed with ET), but this is probably true of only a small fraction of patients. As mentioned, most cases without JAK2 or MPL mutations have calreticulin mutations instead.

Bone marrow cellularity is usually only mildly increased, but megakaryocytes are often markedly increased in

Figure 13-36 Essential thrombocythosis. Peripheral blood smear shows marked thrombocytosis, including giant platelets approximating the size of surrounding red cells.

number and include abnormally large forms. Delicate reticulin fibrils are often seen, but the overt fibrosis of primary myelofibrosis (see later) is absent. Peripheral smears usually reveal abnormally large platelets (Fig. 13-36), often accompanied by mild leukocytosis. Modest degrees of extramedullary hematopoiesis may occur, producing mild organomegaly in about 50% of patients. Uncommonly, a spent phase of marrow fibrosis or transformation to AML supervenes.

The incidence of ET is 1 to 3 per 100,000 per year. It usually occurs past the age of 60 but may also be seen in young adults. Dysfunctions of platelets derived from the neoplastic clone can lead to thrombosis and hemorrhage, the major clinical manifestations. Platelets are not only increased in numbers but also frequently demonstrate qualitative abnormalities in functional tests. The types of thrombotic events resemble those observed in PCV; they include deep venous thrombosis, portal and hepatic vein thrombosis, and myocardial infarction. One characteristic symptom is *erythromelalgia*, a throbbing and burning of hands and feet caused by occlusion of small arterioles by platelet aggregates, which may also be seen in PCV.

ET is an indolent disorder with long asymptomatic periods punctuated by occasional thrombotic or hemorrhagic crises. Median survival times are 12 to 15 years. Thrombotic complications are most likely in patients with very high platelet counts and homozygous *JAK2* mutations. Therapy consists of “gentle” chemotherapeutic agents that suppress thrombopoiesis.

Primary Myelofibrosis

The hallmark of primary myelofibrosis is the development of obliterative marrow fibrosis. The replacement of the marrow by fibrous tissue reduces bone marrow hematopoiesis, leading to cytopenias and extensive extramedullary hematopoiesis. Histologically, the appearance is identical to the spent phase that occurs occasionally late in the course of other myeloproliferative disorders. This similarity also extends to the underlying pathogenesis.

Activating *JAK2* mutations are present in 50% to 60% of cases and activating *MPL* mutations in an additional 1% to 5% of cases of primary myelofibrosis. As with ET, most of the remaining cases have been recently observed to have

mutations in calreticulin that are hypothesized to give rise to increased *JAK-STAT* signaling.

The chief pathologic feature is the extensive deposition of collagen in the marrow by non-neoplastic fibroblasts. The fibrosis inexorably displaces hematopoietic elements, including stem cells, from the marrow and eventually leads to marrow failure. It is probably caused by the inappropriate release of fibrogenic factors from neoplastic megakaryocytes. Two factors synthesized by megakaryocytes have been implicated: *platelet-derived growth factor* and *TGF-β*. As you recall, platelet-derived growth factor and *TGF-β* are fibroblast mitogens. In addition, *TGF-β* promotes collagen deposition and causes angiogenesis, both of which are observed in myelofibrosis.

As marrow fibrosis progresses, circulating hematopoietic stem cells take up residence in niches in secondary hematopoietic organs, such as the spleen, the liver, and the lymph nodes, leading to the appearance of extramedullary hematopoiesis. For incompletely understood reasons, red cell production at extramedullary sites is disordered. This factor and the concomitant suppression of marrow function result in moderate to severe anemia. It is not clear whether primary myelofibrosis is truly distinct from PCV and ET, or merely reflects unusually rapid progression to the spent phase.

MORPHOLOGY

Early in the course, the marrow is often hypercellular due to increases in maturing cells of all lineages, a feature reminiscent of PCV. Morphologically, the erythroid and granulocytic precursors appear normal, but megakaryocytes are large, dysplastic, and abnormally clustered. At this stage fibrosis is minimal, and the blood may show leukocytosis and thrombocytosis. **With progression, the marrow becomes more hypocellular and diffusely fibrotic.** Clusters of atypical megakaryocytes with unusual nuclear shapes (described as “cloud-like”) are seen, and hematopoietic elements are often found within dilated sinusoids, which is a manifestation of severe architectural distortion caused by the fibrosis. Very late in the course, the fibrotic marrow space may be converted into bone, a change called “osteosclerosis.” These features are identical to those seen in the spent phase of other myeloproliferative disorders.

Fibrotic obliteration of the marrow space leads to extensive extramedullary hematopoiesis, principally in the spleen, which is usually markedly enlarged, sometimes up to 4000 gm. Grossly, such spleens are firm and diffusely red to gray. As in CML, subcapsular infarcts are common (see Fig. 13-40). Initially, extramedullary hematopoiesis is confined to the sinusoids, but later it expands into the cords. The liver may be enlarged moderately by sinusoidal foci of extramedullary hematopoiesis. Hematopoiesis can also appear within lymph nodes, but significant lymphadenopathy is uncommon.

The marrow fibrosis is reflected in several characteristic blood findings (Fig. 13-37). Marrow distortion leads to the premature release of nucleated erythroid and early granulocyte progenitors (**leukoerythroblastosis**), and immature cells also enter the circulation from sites of extramedullary hematopoiesis. **Teardrop-shaped red cells** (dacrocytes), cells that were probably damaged during the birthing process in the fibrotic marrow, are also often seen. Although characteristic of primary

Figure 13-37 Primary myelofibrosis (peripheral blood smear). Two nucleated erythroid precursors and several teardrop-shaped red cells (dacrocytes) are evident. Immature myeloid cells were present in other fields. An identical picture can be seen in other diseases producing marrow distortion and fibrosis.

myelofibrosis, leukoerythroblastosis and teardrop red cells are seen in many infiltrative disorders of the marrow, including granulomatous diseases and metastatic tumors. Other common, albeit nonspecific, blood findings include abnormally large platelets and basophilia.

Clinical Features. Primary myelofibrosis is less common than PCV and ET and usually occurs in individuals older than 60 years of age. Except when preceded by another myeloproliferative disorder, it comes to attention because of progressive anemia and splenomegaly, which produces a sensation of fullness in the left upper quadrant. Nonspecific symptoms such as fatigue, weight loss, and night sweats result from an increase in metabolism associated with the expanding mass of hematopoietic cells. Hyperuricemia and secondary gout due to a high rate of cell turnover can complicate the picture.

Laboratory studies typically show a moderate to severe normochromic normocytic anemia accompanied by leukoerythroblastosis. The white cell count is usually normal or mildly reduced, but can be markedly elevated (80,000 to 100,000 cells/mm³) early in the course. The platelet count is usually normal or elevated at the time of diagnosis, but thrombocytopenia may supervene as the disease progresses. These blood findings are not specific; bone marrow biopsy is essential for diagnosis.

Primary myelofibrosis is a much more difficult disease to treat than PCV or ET. The course is variable, but the median survival is in the range of 3 to 5 years. Threats to life include intercurrent infections, thrombotic episodes, bleeding related to platelet abnormalities, and transformation to AML, which occurs in 5% to 20% of cases. When myelofibrosis is extensive, AML sometimes arises at extramedullary sites, including lymph nodes and soft tissues. JAK2 inhibitors have recently been approved to treat this disease and are effective at decreasing the splenomegaly and constitutional symptoms. Hematopoietic stem cell transplantation offers some hope for cure in those young and fit enough to withstand the procedure.

KEY CONCEPTS

Myeloid Neoplasms

Myeloid tumors occur mainly in adults and fall into three major groups:

Acute myeloid leukemias (AMLs)

- Aggressive tumors comprised of immature myeloid lineage blasts, which replace the marrow and suppress normal hematopoiesis
- Associated with diverse acquired mutations that lead to expression of abnormal transcription factors, which interfere with myeloid differentiation
- Often also associated with mutations in genes encoding growth factor receptor signaling pathway components or regulators of the epigenome

Myeloproliferative disorders

- Myeloid tumors in which production of formed myeloid elements is initially increased, leading to high blood counts and extramedullary hematopoiesis
- Commonly associated with acquired mutations that lead to constitutive activation of tyrosine kinases, which mimic signals from normal growth factors. The most common pathogenic kinases are BCR-ABL (associated with CML) and mutated JAK2 (associated with polycythemia vera and primary myelofibrosis).
- All can transform to acute leukemia and to a spent phase of marrow fibrosis associated with anemia, thrombocytopenia, and splenomegaly.

Myelodysplastic Syndromes

- Poorly understood myeloid tumors characterized by disordered and ineffective hematopoiesis and dysmaturation
- Recently shown to frequently harbor mutations in splicing factors and epigenetic regulators
- Manifest with one or more cytopenias and progress in 10% to 40% of cases to AML

Langerhans Cell Histiocytosis

The term *histiocytosis* is an “umbrella” designation for a variety of proliferative disorders of dendritic cells or macrophages. Some, such as rare “histiocytic” lymphomas, are clearly malignant, whereas others, such as reactive proliferations of macrophages in lymph nodes, are clearly benign. Lying between these two extremes are the Langerhans cell histiocytoses, a spectrum of proliferations of a special type of immature dendritic cell called the Langerhans cell ([Chapter 6](#)).

The origin and nature of the proliferating cells in Langerhans cell histiocytosis has been controversial, leading to discussion of whether it is better considered a neoplasm or a reactive process. Recent sequencing has largely settled this score, as the majority of cases have mutations that are known to be oncogenic in other contexts. The most common mutation is an activating valine-to-glutamate substitution at residue 600 in BRAF, already discussed for its role in hairy cell leukemia, which is present in 55% to 60% of cases. Less common mutations have also been detected in TP53, RAS, and the tyrosine kinase MET. Thus, there seems no doubt that many of these proliferations are neoplastic in origin.

Figure 13-38 Langerhans cell histiocytosis. **A**, Langerhans cells with folded or grooved nuclei and moderately abundant pale cytoplasm are mixed with a few eosinophils. **B**, An electron micrograph shows rodlike Birbeck granules with characteristic periodicity and dilated terminal end. (**B**, Courtesy Dr. George Murphy, Department of Pathology, Brigham and Women's Hospital, Boston, Mass.)

Regardless of the clinical picture, the proliferating Langerhans cells have abundant, often vacuolated cytoplasm and vesicular nuclei containing linear grooves or folds (Fig. 13-38A). The presence of *Birbeck granules* in the cytoplasm is characteristic. Birbeck granules are pentalaminar tubules, often with a dilated terminal end producing a tennis racket-like appearance (Fig. 13-38B), which contain the protein langerin. In addition, the tumor cells also typically express HLA-DR, S-100, and CD1a.

Langerhans cell histiocytosis presents as several clinicopathologic entities:

- *Multifocal multisystem Langerhans cell histiocytosis (Letterer-Siwe disease)* occurs most frequently before 2 years of age but occasionally affects adults. A dominant clinical feature is the development of cutaneous lesions resembling a seborrheic eruption, which is caused by infiltrates of Langerhans cells over the front and back of the trunk and on the scalp. Most of those affected have concurrent hepatosplenomegaly, lymphadenopathy, pulmonary lesions, and (eventually) destructive osteolytic bone lesions. Extensive infiltration of the marrow often leads to anemia, thrombocytopenia, and a predisposition to recurrent infections, such as otitis media and mastoiditis. In some instances the tumor cells are quite anaplastic; such tumors are sometimes referred to as Langerhans cell sarcoma. The course of untreated disease is rapidly fatal. With intensive chemotherapy, 50% of patients survive 5 years.
- *Unifocal and multifocal unisystem Langerhans cell histiocytosis (eosinophilic granuloma)* is characterized by proliferations of Langerhans cells admixed with variable numbers of eosinophils, lymphocytes, plasma cells, and neutrophils. Eosinophils are usually, but not always, a prominent component of the infiltrate. It typically arises within the medullary cavities of bones, most commonly the calvarium, ribs, and femur. Less commonly, unisystem lesions of identical histology arise in the skin, lungs, or stomach. *Unifocal lesions* most commonly affect the skeletal system in older children or adults. Bone lesions can be asymptomatic or cause pain, tenderness, and, in some instances, pathologic fractures. Unifocal disease is indolent and may heal spontaneously or be cured by local excision or irradiation. *Multifocal unisystem disease* usually affects young children, who present with multiple erosive bony masses that sometimes expand into adjacent soft tissue. Involvement of the posterior pituitary stalk of the hypothalamus leads to diabetes insipidus in about 50% of patients. The combination of calvarial bone defects, diabetes insipidus, and exophthalmos is referred to as the *Hand-Schüller-Christian triad*. Many patients experience spontaneous regression; others can be treated successfully with chemotherapy.
- *Pulmonary Langerhans cell histiocytosis* represents a special category of disease, most often seen in adult smokers, which may regress spontaneously upon cessation of smoking. These lesions have been described as reactive proliferations of Langerhans cells, but fully 40% are associated with BRAF mutations, suggesting that in many instances, they too are neoplastic in origin.

One factor that contributes to the homing of neoplastic Langerhans cells is the aberrant expression of chemokine receptors. For example, while normal epidermal Langerhans cells express CCR6, their neoplastic counterparts express both CCR6 and CCR7. This allows the neoplastic cells to migrate into tissues that express the relevant chemokines—CCL20 (a ligand for CCR6) in skin and bone, and CCL19 and 21 (ligands for CCR7) in lymphoid organs.

SPLEEN

The spleen is an ingeniously designed filter for the blood and a site of immune responses to blood-borne antigens. Normally in the adult it weighs about 150 gm and is enclosed within a thin, glistening, slate-gray connective tissue capsule. Its cut surface reveals extensive red pulp dotted with gray specks, which are the white pulp follicles. These consist of an artery with an eccentric collar of T lymphocytes, the so-called periarteriolar lymphatic sheath. At intervals this sheath expands to form lymphoid nodules composed mainly of B lymphocytes, which are capable of developing into germinal centers identical to those seen in lymph nodes in response to antigenic stimulation (Fig. 13-39).

The red pulp of the spleen is traversed by numerous thin-walled vascular sinusoids, separated by the splenic cords or “cords of Billroth.” The endothelial lining of the sinusoid is discontinuous, providing a passage for blood cells between the sinusoids and cords. The cords contain a labyrinth of macrophages loosely connected through long dendritic processes to create both a physical and a functional filter. As it traverses the red pulp, the blood takes two routes to reach the splenic veins. Some flows through capillaries into the cords, from which blood cells squeeze through gaps in the discontinuous basement of the endothelial lining to reach the sinusoids; this is the so-called open circulation or slow compartment. In the other “closed circuit,” blood passes rapidly and directly from the capillaries to the splenic veins. Although only a

small fraction of the blood pursues the “open” route, during the course of a day the entire blood volume passes through the cords, where it is closely examined by macrophages.

The spleen has four functions that impact disease states:

1. *Phagocytosis of blood cells and particulate matter.* As is discussed under the hemolytic anemias (Chapter 14), red cells undergo extreme deformation during passage from the cords into the sinusoids. In conditions in which red cell deformability is decreased, red cells become trapped in the cords and are more readily phagocytosed by macrophages. Splenic macrophages are also responsible for “pitting” of red cells, the process by which inclusions such as *Heinz bodies* and *Howell-Jolly bodies* are excised, and for the removal of particles, such as bacteria, from the blood.
2. *Antibody production.* Dendritic cells in the periarterial lymphatic sheath trap antigens and present them to T lymphocytes. T- and B-cell interaction at the edges of white pulp follicles leads to the generation of antibody-secreting plasma cells, which are found mainly within the sinuses of the red pulp. The spleen seems to be an important site of production of antibodies against microbial polysaccharides, as well as autoantibodies against a variety of self antigens.
3. *Hematopoiesis.* During fetal development, the spleen may be a minor site of hematopoiesis, but this normally disappears by birth. However, the spleen can become a major site of compensatory extramedullary hematopoiesis in the setting of severe chronic anemia (e.g., in patients with thalassemia, described in Chapter 14) and in patients with myeloproliferative disorders, such as chronic myelogenous leukemia and primary myelofibrosis.
4. *Sequestration of formed blood elements.* The normal spleen contains only about 30 to 40 mL of red cells, but this volume increases greatly with splenomegaly. The normal spleen also harbors approximately 30% to 40% of the total platelet mass in the body. With splenomegaly up to 80% to 90% of the total platelet mass can be sequestered in the interstices of the red pulp, producing thrombocytopenia. Similarly, the enlarged spleen can trap white cells and thereby induce leukopenia.

As the largest unit of the mononuclear phagocyte system, the spleen is involved in all systemic inflammations, generalized hematopoietic disorders, and many metabolic disturbances. In each, the spleen undergoes enlargement (*splenomegaly*), which is the major manifestation of disorders of this organ. It is rarely the primary site of disease. Splenic insufficiency due to splenectomy or autoinfarction (as in sickle-cell disease) has one major clinical manifestation, an increased susceptibility to sepsis caused by encapsulated bacteria such as pneumococci, meningococci, and *Haemophilus influenzae*. The decrease in phagocytic capacity and antibody production that result from asplenia both contribute to the increased risk of sepsis, which may be fatal. All asplenic individuals should be vaccinated against these agents to reduce the risk of this tragic complication.

Figure 13-39 Normal splenic architecture. (Modified from Faller DV: Diseases of the spleen. In Wyngaarden JB, Smith LH (eds): *Cecil Textbook of Medicine*, 18th ed. Philadelphia, WB Saunders, 1988, p 1036.)

Splenomegaly

When sufficiently enlarged, the spleen causes a dragging sensation in the left upper quadrant and, through pressure on the stomach, discomfort after eating. In addition, enlargement can cause a syndrome known as *hypersplenism*, which is characterized by anemia, leukopenia, thrombocytopenia, alone or in combination. The probable cause of the cytopenias is increased sequestration of formed elements and the consequent enhanced phagocytosis by the splenic macrophages.

Table 13-12 lists major disorders associated with splenomegaly. Splenomegaly in virtually all the conditions mentioned has been discussed elsewhere. A few disorders are left to consider.

Nonspecific Acute Splenitis

Enlargement of the spleen occurs in any blood-borne infection. The nonspecific splenic reaction in these infections

Table 13-12 Disorders Associated with Splenomegaly

I. Infections
Nonspecific splenitis of various blood-borne infections (particularly infectious endocarditis)
Infectious mononucleosis
Tuberculosis
Typhoid fever
Brucellosis
Cytomegalovirus
Syphilis
Malaria
Histoplasmosis
Toxoplasmosis
Kala-azar
Trypanosomiasis
Schistosomiasis
Leishmaniasis
Echinococcosis
II. Congestive States Related to Portal Hypertension
Cirrhosis of the liver
Portal or splenic vein thrombosis
Cardiac failure
III. Lymphohematogenous Disorders
Hodgkin lymphoma
Non-Hodgkin lymphomas and lymphocytic leukemias
Multiple myeloma
Myeloproliferative disorders
Hemolytic anemias
IV. Immunologic-Inflammatory Conditions
Rheumatoid arthritis
Systemic lupus erythematosus
V. Storage Diseases
Gaucher disease
Niemann-Pick disease
Mucopolysaccharidoses
VI. Miscellaneous Disorders
Amyloidosis
Primary neoplasms and cysts
Secondary neoplasms

is caused both by the microbiologic agents themselves and by cytokines that are released as part of the immune response.

MORPHOLOGY

The spleen is enlarged (200 to 400 gm) and soft. Microscopically, the major feature is acute congestion of the red pulp, which may encroach on and virtually efface the lymphoid follicles. Neutrophils, plasma cells, and occasionally eosinophils are usually present throughout the white and red pulp. At times the white pulp follicles may undergo necrosis, particularly when the causative agent is a hemolytic streptococcus. Rarely, abscess formation occurs.

Congestive Splenomegaly

Chronic venous outflow obstruction causes a form of splenic enlargement referred to as *congestive splenomegaly*. Venous obstruction may be caused by intrahepatic disorders that retard portal venous drainage, or arise from extrahepatic disorders that directly impinge upon the portal or splenic veins. All of these disorders ultimately lead to portal or splenic vein hypertension. *Systemic, or central, venous congestion* is encountered in cardiac decompensation involving the right side of the heart, as can occur in tricuspid or pulmonic valvular disease, chronic cor pulmonale, or following left-sided heart failure. Systemic congestion is associated with only moderately enlarged spleens that rarely exceed 500 gm in weight.

Cirrhosis of the liver is the main cause of massive congestive splenomegaly. The “pipe-stem” hepatic fibrosis of schistosomiasis causes particularly severe congestive splenomegaly, while the diffuse fibrous scarring of alcoholic cirrhosis and pigment cirrhosis also evokes profound enlargements. Other forms of cirrhosis are less commonly implicated.

Congestive splenomegaly is also caused by obstruction of the extrahepatic portal vein or splenic vein. This can stem from *spontaneous portal vein thrombosis*, which is usually associated with some intrahepatic obstructive disease, or inflammation of the portal vein (*pylephlebitis*), such as follows intraperitoneal infections. Thrombosis of the splenic vein can be caused by infiltrating tumors arising in neighboring organs, such as carcinomas of the stomach or pancreas.

MORPHOLOGY

Long-standing splenic congestion produces marked enlargement (1000 to 5000 gm). The organ is firm, and the capsule is usually thickened and fibrous. Microscopically, the red pulp is congested early in the course but becomes increasingly fibrotic and cellular with time. The elevated portal venous pressure stimulates the deposition of collagen in the basement membrane of the sinusoids, which appear dilated because of the rigidity of their walls. The resultant slowing of blood flow from the cords to the sinusoids prolongs the exposure of the blood cells to macrophages, resulting in excessive destruction (hypersplenism).

Splenic Infarcts

Splenic infarcts are common lesions caused by the occlusion of the major splenic artery or any of its branches. The lack of extensive collateral blood supply predisposes to infarction following vascular occlusion. The spleen, along with kidneys and brain, ranks as one of the most frequent sites where emboli lodge. In normal-sized spleens, infarcts are most often caused by emboli that arise from the heart. The infarcts can be small or large, single or multiple, or even involve the entire organ. They are usually bland, except in individuals with infectious endocarditis of the mitral or aortic valves, in whom septic infarcts are common. Infarcts are also common in markedly enlarged spleens, regardless of cause, presumably because the blood supply is tenuous and easily compromised.

MORPHOLOGY

Bland infarcts are characteristically pale, wedge-shaped, and subcapsular in location. The overlying capsule is often covered with fibrin (Fig. 13-40). In septic infarcts this appearance is modified by the development of suppurative necrosis. In the course of healing, large depressed scars often develop.

Figure 13-40 Splenic infarcts. Multiple well-circumscribed infarcts are present in this spleen, which is massively enlarged (2820 gm; normal: 150 to 200 gm) by extramedullary hematopoiesis secondary to a myeloproliferative disorder (myelofibrosis). Recent infarcts are hemorrhagic, whereas older, more fibrotic infarcts are a pale yellow-gray color.

THYMUS

Once an organ buried in obscurity, the thymus now has a starring role in cell-mediated immunity (Chapter 6). Here, our interest centers on the disorders of the gland itself.

The thymus is embryologically derived from the third and, inconstantly, the fourth pair of pharyngeal pouches. At birth it weighs 10 to 35 gm. It grows until puberty, when it achieves a maximum weight of 20 to 50 gm, and thereafter undergoes progressive involution to little more than 5 to 15 gm in older adults. The thymus can also involute in children and young adults in response to severe illness and HIV infection.

Neoplasms

Neoplastic involvement of the spleen is rare except in myeloid and lymphoid tumors, which often cause splenomegaly (discussed earlier). Benign fibromas, osteomas, chondromas, lymphangiomas, and hemangiomas may arise in the spleen. Of these, lymphangiomas and hemangiomas are most common and often cavernous in type.

Congenital Anomalies

Complete absence of the spleen is rare and is usually associated with other congenital abnormalities, such as situs inversus and cardiac malformations. *Hypoplasia* is a more common finding.

Accessory spleens (spleniculi) are common, being present singly or multiply in 20% to 35% of postmortem examinations. They are small, spherical structures that are histologically and functionally identical to the normal spleen. They can be found at any place within the abdominal cavity. Accessory spleens are of great clinical importance in some hematologic disorders, such as hereditary spherocytosis and immune thrombocytopenia purpura, where splenectomy is used as a treatment. If an accessory spleen is overlooked, the therapeutic benefit of removal of the definitive spleen may be reduced or lost entirely.

Rupture

Splenic rupture is usually precipitated by blunt trauma. Much less often, it occurs in the apparent absence of a physical blow. Such “spontaneous ruptures” never involve truly normal spleens but rather stem from some minor physical insult to a spleen made fragile by an underlying condition. The most common predisposing conditions are infectious mononucleosis, malaria, typhoid fever, and lymphoid neoplasms, which may cause the spleen to enlarge rapidly, producing a thin, tense capsule that is susceptible to rupture. This dramatic event often precipitates intraperitoneal hemorrhage, which must be treated by prompt splenectomy to prevent death from blood loss. Chronically enlarged spleens are unlikely to rupture because of the toughening effect of extensive reactive fibrosis.

interconnecting processes. Whorls of medullary epithelial cells create *Hassall corpuscles*, with their characteristic keratinized cores.

As you know from the earlier consideration of the thymus in relation to immunity, progenitor cells migrate from the marrow to the thymus and mature into T cells, which are exported to the periphery, but only after they have been educated in the “thymic university” to distinguish between self and non-self antigens. During adulthood the thymic production of T cells slowly declines as the organ atrophies.

Macrophages, dendritic cells, a minor population of B lymphocytes, rare neutrophils and eosinophils, and scattered myoid (muscle-like) cells are also found within the thymus. The myoid cells are of particular interest because of the suspicion that they play some role in the development of myasthenia gravis, a musculoskeletal disorder of immune origin.

Pathologic changes within the thymus are limited and will be described here. The changes associated with myasthenia gravis are considered in [Chapter 27](#).

Developmental Disorders

Thymic hypoplasia or *aplasia* is seen in DiGeorge syndrome, which is marked by severe defects in cell-mediated immunity and variable abnormalities of parathyroid development associated with hypoparathyroidism. As discussed in [Chapter 5](#), DiGeorge syndrome is often associated with other developmental defects as part of the 22q11 deletion syndrome.

Isolated *thymic cysts* are uncommon lesions that are usually discovered incidentally postmortem or during surgery. They rarely exceed 4 cm in diameter, can be spherical or arborizing, and are lined by stratified to columnar epithelium. The fluid contents can be serous or mucinous and are often modified by hemorrhage.

While isolated cysts are not clinically significant, neoplastic thymic masses (whatever their origin) compress and distort adjacent normal thymus and sometimes cause

cysts to form. Therefore, the presence of a cystic thymic lesion in a symptomatic patient should provoke a thorough search for a neoplasm, particularly a lymphoma or a thymoma.

Thymic Hyperplasia

The term *thymic hyperplasia* is a bit misleading, since it usually applies to the appearance of B-cell germinal centers within the thymus, a finding that is referred to as *thymic follicular hyperplasia*. Such B-cell follicles are present in only small numbers in the normal thymus. Although follicular hyperplasia can occur in a number of chronic inflammatory and immunologic states, it is most frequently encountered in myasthenia gravis, in which it is found in 65% to 75% of cases ([Chapter 27](#)). Similar thymic changes are sometimes encountered in Graves disease, systemic lupus erythematosus, scleroderma, rheumatoid arthritis, and other autoimmune disorders.

In other instances, a morphologically normal thymus is simply large for the age of the patient. As mentioned, the size of the thymus varies widely, and whether this constitutes a true hyperplasia or is merely a variant of normal is unclear. The main significance of this form of thymic “hyperplasia” is that it may be mistaken radiologically for a thymoma, leading to unnecessary surgical procedures.

Thymomas

A diversity of neoplasms may arise in the thymus—germ cell tumors, lymphomas, carcinoids, and others—but the designation “**thymoma**” is restricted to tumors of thymic epithelial cells. Such tumors typically also contain benign immature T cells (thymocytes).

The WHO has created a classification system based on histology for thymomas, but its clinical utility remains uncertain. We will instead use a classification that relies on the most important prognostic features, the surgical stage and the presence or absence of overt cytologic features of

Figure 13-41 Thymoma. **A**, Benign thymoma (medullary type). The neoplastic epithelial cells are arranged in a swirling pattern and have bland, oval to elongated nuclei with inconspicuous nucleoli. Only a few small, reactive lymphoid cells are interspersed. **B**, Malignant thymoma, type I. The neoplastic epithelial cells are polygonal and have round to oval, bland nuclei with inconspicuous nucleoli. Numerous small, reactive lymphoid cells are interspersed. The morphologic appearance of this tumor is identical to that of benign thymomas of the cortical type. In this case, however, the tumor was locally aggressive, invading adjacent lung and pericardium.

malignancy. In this simple system there are only three histologic subtypes:

- Tumors that are cytologically benign and noninvasive
- Tumors that are cytologically benign but invasive or metastatic
- Tumors that are cytologically malignant (thymic carcinoma)

In all categories, the tumors usually occur in adults older than 40 years of age; thymomas are rare in children. Males and females are affected equally. Most arise in the anterior superior mediastinum, but sometimes they occur in the neck, thyroid, pulmonary hilus, or elsewhere. They are uncommon in the posterior mediastinum. Thymomas account for 20% to 30% of tumors in the anterosuperior mediastinum, which is also a common location for certain lymphomas.

MORPHOLOGY

Macroscopically, thymomas are lobulated, firm, gray-white masses of up to 15 to 20 cm in size. They sometimes have areas of cystic necrosis and calcification. Most are encapsulated, but 20% to 25% of the tumors penetrate the capsule and infiltrate perithymic tissues and structures.

Noninvasive thymomas are most often composed of medullary-type epithelial cells or a mixture of medullary and cortical type epithelial cells. The medullary type epithelial cells are elongated or spindle-shaped (Fig. 13-41A). There is usually a sparse infiltrate of thymocytes, which often recapitulate the phenotype of medullary thymocytes. In mixed thymomas there is an admixture of polygonal cortical type epithelial cells and a denser infiltrate of thymocytes. The medullary and mixed patterns together account for about 50% of all thymomas. Tumors that have a substantial proportion of medullary-type epithelial cells are usually noninvasive.

Invasive thymoma refers to a tumor that is cytologically benign but locally invasive. These tumors are much more likely to metastasize. The epithelial cells are most commonly of the cortical variety, with abundant cytoplasm and rounded vesicular nuclei (Fig. 13-41B), and are usually mixed with numerous thymocytes. In some cases, the neoplastic cells show cytologic atypia, a feature that correlates with a propensity for more aggressive behavior. These tumors account for about 20% to 25% of all thymomas. **By definition, invasive thymomas penetrate through the capsule into surrounding structures.** The extent of invasion has been subdivided into various stages, which are beyond our scope. With minimal invasion, complete excision yields a 5-year survival rate of greater than 90%, whereas extensive invasion is associated with a 5-year survival rate of less than 50%.

Thymic carcinoma represents about 5% of thymomas. Macroscopically, they are usually fleshy, obviously invasive masses, sometimes accompanied by metastases to sites such as the lungs. Microscopically, most are **squamous cell carcinomas**. The next most common variant is **lymphoepithelioma-like carcinoma**, a tumor composed of sheets of cells with indistinct borders that bears a close histologic resemblance to nasopharyngeal carcinoma. About 50% of lymphoepithelioma-like carcinomas contain monoclonal EBV genomes, consistent with a role for EBV in their pathogenesis. A variety of other less common histologic patterns of thymic carcinoma have been described; all exhibit cytologic atypia seen in other carcinomas.

Clinical Features. About 40% of thymomas present with symptoms stemming from impingement on mediastinal structures. Another 30% to 45% are detected in the course of evaluating patients with myasthenia gravis. The rest are discovered incidentally during imaging studies or cardiothoracic surgery. In addition to myasthenia gravis, other associated autoimmune disorders include hypogammaglobulinemia, pure red cell aplasia, Graves disease, pernicious anemia, dermatomyositis-polymyositis, and Cushing syndrome. The basis for these associations is still obscure, but the thymocytes that arise within thymomas give rise to long-lived CD4+ and CD8+ T cells, and cortical thymomas rich in thymocytes are more likely to be associated with autoimmune disease. Hence, it seems likely that abnormalities in the selection or “education” of T cells maturing within the environment of the neoplasm contribute to the development of diverse autoimmune disorders.

Infectious Complications 666

In this chapter we will first consider diseases of red cells. By far, the most common and important are the anemias, red cell deficiency states that usually have a nonneoplastic basis. We will then complete our review of blood diseases by discussing the major bleeding disorders and complications of blood transfusion.

Anemias

Anemia is defined as a reduction of the total circulating red cell mass below normal limits. Anemia reduces the oxygen-carrying capacity of the blood, leading to tissue hypoxia. In practice, the measurement of red cell mass is not easy, and anemia is usually diagnosed based on a reduction in the *hematocrit* (the ratio of packed red cells to total blood volume) and the *hemoglobin concentration* of the blood to levels that are below the normal range. These values correlate with the red cell mass except when there are changes in plasma volume caused by fluid retention or dehydration.

There are many classifications of anemia. We will follow one based on underlying mechanisms that is presented in **Table 14-1**. A second clinically useful approach classifies anemia according to alterations in red cell morphology, which often point to particular causes. Morphologic characteristics providing etiologic clues include red cell size (normocytic, microcytic, or macrocytic); degree of hemoglobinization, reflected in the color of red cells (normochromic or hypochromic); and shape. In general, microcytic hypochromic anemias are caused by disorders of hemoglobin synthesis (most often iron deficiency), while macrocytic anemias often stem from abnormalities that impair the maturation of erythroid precursors in the bone marrow. Normochromic, normocytic anemias have diverse etiologies; in some of these anemias, specific abnormalities of red cell shape (best appreciated through visual inspection of peripheral smears) provide an important clue as to the cause. The other indices can also be assessed qualitatively in smears, but precise measurement is carried out in clinical laboratories with special instrumentation. The most useful red cell indices are as follows:

Table 14-1 Classification of Anemia According to Underlying Mechanism

Mechanism	Specific Examples
Blood Loss	
Acute blood loss	Trauma
Chronic blood loss	Gastrointestinal tract lesions, gynecologic disturbances*
Increased Red Cell Destruction (Hemolysis)	
Inherited genetic defects	
Red cell membrane disorders	Hereditary spherocytosis, hereditary elliptocytosis
Enzyme deficiencies	
Hexose monophosphate shunt enzyme deficiencies	G6PD deficiency, glutathione synthetase deficiency
Glycolytic enzyme deficiencies	Pyruvate kinase deficiency, hexokinase deficiency
Hemoglobin abnormalities	
Deficient globin synthesis	Thalassemia syndromes
Structurally abnormal globins (hemoglobinopathies)	Sickle cell disease, unstable hemoglobins
Acquired genetic defects	
Deficiency of phosphatidylinositol-linked glycoproteins	Paroxysmal nocturnal hemoglobinuria
Antibody-mediated destruction	
	Hemolytic disease of the newborn (Rh disease), transfusion reactions, drug-induced, autoimmune disorders
Mechanical trauma	
Microangiopathic hemolytic anemias	Hemolytic uremic syndrome, disseminated intravascular coagulation, thrombotic thrombocytopenia purpura
Cardiac traumatic hemolysis	Defective cardiac valves
Repetitive physical trauma	Bongo drumming, marathon running, karate chopping
Infections of red cells	
	Malaria, babesiosis
Toxic or chemical injury	
	Clostridial sepsis, snake venom, lead poisoning
Membrane lipid abnormalities	
	Abetalipoproteinemia, severe hepatocellular liver disease
Sequestration	
	Hypersplenism
Decreased Red Cell Production	
Inherited genetic defects	
Defects leading to stem cell depletion	Fanconi anemia, telomerase defects
Defects affecting erythroblast maturation	Thalassemia syndromes
Nutritional deficiencies	
Deficiencies affecting DNA synthesis	B ₁₂ and folate deficiencies
Deficiencies affecting hemoglobin synthesis	Iron deficiency anemia
Erythropoietin deficiency	
	Renal failure, anemia of chronic disease
Immune-mediated injury of progenitors	
	Aplastic anemia, pure red cell aplasia
Inflammation-mediated iron sequestration	
	Anemia of chronic disease
Primary hematopoietic neoplasms	
	Acute leukemia, myelodysplasia, myeloproliferative disorders (Chapter 13)
Space-occupying marrow lesions	
	Metastatic neoplasms, granulomatous disease
Infections of red cell progenitors	
	Parvovirus B19 infection
Unknown mechanisms	
	Endocrine disorders, hepatocellular liver disease

G6PD, Glucose-6-phosphate dehydrogenase.

*Most often cause of anemia is iron deficiency, not bleeding per se.

- *Mean cell volume*: the average volume of a red cell expressed in femtoliters (fL)
- *Mean cell hemoglobin*: the average content (mass) of hemoglobin per red cell, expressed in picograms
- *Mean cell hemoglobin concentration*: the average concentration of hemoglobin in a given volume of packed red cells, expressed in grams per deciliter
- *Red cell distribution width*: the coefficient of variation of red cell volume

Adult reference ranges for red cell indices are shown in Table 14-2.

Whatever its cause, when sufficiently severe anemia leads to certain clinical findings. Patients appear pale. Weakness, malaise, and easy fatigability are common complaints. The lowered oxygen content of the circulating blood leads to dyspnea on mild exertion. Hypoxia can cause fatty change in the liver, myocardium, and kidney. If fatty changes in the myocardium are sufficiently severe, cardiac failure can develop and compound the tissue hypoxia caused by the deficiency of O₂ in the blood. On occasion, the myocardial hypoxia manifests as angina pectoris, particularly when complicated by pre-existing coronary artery disease. With acute blood loss and shock,

Table 14-2 Adult Reference Ranges for Red Cells*

Measurement (units)	Men	Women
Hemoglobin (gm/dL)	13.6-17.2	12.0-15.0
Hematocrit (%)	39-49	33-43
Red cell count ($\times 10^6/\mu\text{L}$)	4.3-5.9	3.5-5.0
Reticulocyte count (%)	0.5-1.5	
Mean cell volume (fL)	82-96	
Mean cell hemoglobin (pg)	27-33	
Mean cell hemoglobin concentration (gm/dL)	33-37	
Red cell distribution width	11.5-14.5	

*Reference ranges vary among laboratories. The reference ranges for the laboratory providing the result should always be used in interpreting test results.

oliguria and anuria can develop as a result of renal hypoperfusion. Central nervous system hypoxia can cause headache, dimness of vision, and faintness.

Anemias of Blood Loss

Acute Blood Loss

The effects of acute blood loss are mainly due to the loss of intravascular volume, which if massive can lead to cardiovascular collapse, shock, and death. The clinical features depend on the rate of hemorrhage and whether the bleeding is external or internal. If the patient survives, the blood volume is rapidly restored by the intravascular shift of water from the interstitial fluid compartment. This fluid shift results in hemodilution and a lowering of the hematocrit. The reduction in oxygenation triggers increased secretion of erythropoietin from the kidney, which stimulates the proliferation of committed erythroid progenitors (CFU-E) in the marrow (see Fig. 13-1). It takes about 5 days for the progeny of these CFU-Es to mature and appear as newly released red cells (reticulocytes) in the peripheral blood. The iron in hemoglobin is recaptured if red cells extravasate into tissues, whereas bleeding into the gut or out of the body leads to iron loss and possible iron deficiency, which can hamper the restoration of normal red cell counts.

Significant bleeding results in predictable changes in the blood involving not only red cells, but also white cells and platelets. If the bleeding is sufficiently massive to cause a decrease in blood pressure, the compensatory release of adrenergic hormones mobilizes granulocytes from the intravascular marginal pool and results in leukocytosis (see Fig. 13-2). Initially, red cells appear normal in size and color (normocytic, normochromic). However, as marrow production increases there is a striking increase in the reticulocyte count (*reticulocytosis*), which reaches 10% to 15% after 7 days. Reticulocytes are larger in size than normal red cells (macrocytes) and have a blue-red polychromatophilic cytoplasm. Early recovery from blood loss is also often accompanied by *thrombocytosis*, which results from an increase in platelet production.

Chronic Blood Loss

Chronic blood loss induces anemia only when the rate of loss exceeds the regenerative capacity of the marrow or when iron reserves are depleted and iron deficiency anemia appears (see later).

Hemolytic Anemias

Hemolytic anemias share the following features:

- A shortened red cell life span below the normal 120 days
- Elevated erythropoietin levels and a compensatory increase in erythropoiesis
- Accumulation of hemoglobin degradation products that are created as part of the process of red cell hemolysis

The physiologic destruction of senescent red cells takes place within macrophages, which are abundant in the spleen, liver, and bone marrow. This process appears to be triggered by age-dependent changes in red cell surface proteins, which lead to their recognition and phagocytosis. In the great majority of hemolytic anemias the premature destruction of red cells also occurs within phagocytes, an event that is referred to as *extravascular hemolysis*. If persistent, extravascular hemolysis leads to a hyperplasia of phagocytes manifested by varying degrees of *splenomegaly*.

Extravascular hemolysis is generally caused by alterations that render the red cell less deformable. Extreme changes in shape are required for red cells to navigate the splenic sinusoids successfully. Reduced deformability makes this passage difficult, leading to red cell sequestration and phagocytosis by macrophages located within the splenic cords. Regardless of the cause, the principal clinical features of extravascular hemolysis are *anemia*, *splenomegaly*, and *jaundice*. Some hemoglobin inevitably escapes from phagocytes, which leads to variable decreases in plasma *haptoglobin*, an α_2 -globulin that binds free hemoglobin and prevents its excretion in the urine. Because much of the pathologic destruction of red cells occurs in the spleen, individuals with extravascular hemolysis often benefit from splenectomy.

Less commonly, *intravascular hemolysis* predominates. Intravascular hemolysis of red cells may be caused by mechanical injury, complement fixation, intracellular parasites (e.g., *falciparum malaria*, Chapter 8), or exogenous toxic factors. Causes of mechanical injury include trauma caused by cardiac valves, thrombotic narrowing of the microcirculation, or repetitive physical trauma (e.g., marathon running and bongo drum beating). Complement fixation occurs in a variety of situations in which antibodies recognize and bind red cell antigens. Toxic injury is exemplified by clostridial sepsis, which results in the release of enzymes that digest the red cell membrane.

Whatever the mechanism, intravascular hemolysis is manifested by *anemia*, *hemoglobinemia*, *hemoglobinuria*, *hemosiderinuria*, and *jaundice*. The large amounts of free hemoglobin released from lysed red cells are promptly bound by haptoglobin, producing a complex that is rapidly cleared by mononuclear phagocytes. As serum haptoglobin is depleted, free hemoglobin oxidizes to *methemoglobin*, which is brown in color. The renal proximal tubular cells reabsorb and catabolize much of the filtered hemoglobin and methemoglobin, but some passes out in the urine, imparting a red-brown color. Iron released from hemoglobin can accumulate within tubular cells, giving rise to *renal hemosiderosis*. Concomitantly, heme groups derived from hemoglobin-haptoglobin complexes are catabolized to bilirubin within mononuclear phagocytes, leading to jaundice. Unlike in extravascular hemolysis, splenomegaly is not seen.

In all types of uncomplicated hemolytic anemias, the excess serum bilirubin is unconjugated. The level of hyperbilirubinemia depends on the functional capacity of the liver and the rate of hemolysis. When the liver is normal, jaundice is rarely severe. Excessive bilirubin excreted by the liver into the gastrointestinal tract leads to increased formation and fecal excretion of urobilin (Chapter 18), and often leads to the formation of gallstones derived from heme pigments.

MORPHOLOGY

Certain changes are seen in hemolytic anemias regardless of cause or type. Anemia and lowered tissue oxygen tension trigger the production of erythropoietin, which stimulates erythroid differentiation and leads to the appearance of **increased numbers of erythroid precursors (normoblasts)** in the marrow (Fig. 14-1). Compensatory increases in erythropoiesis result in a **prominent reticulocytosis** in the peripheral blood. The phagocytosis of red cells leads to the accumulation of the iron containing pigment **hemosiderin**, particularly in the spleen, liver, and bone marrow. Such iron accumulation is referred to as **hemosiderosis**. If the anemia is severe, **extramedullary hematopoiesis** can appear in the liver, spleen, and lymph nodes. With chronic hemolysis, elevated biliary excretion of bilirubin promotes the formation of **pigment gallstones** (cholelithiasis).

The hemolytic anemias can be classified in a variety of ways; here, we rely on the underlying mechanisms (Table 14-1). We begin by discussing the major inherited forms of hemolytic anemia, and then move on to the acquired forms that are most common or of particular pathophysiologic interest.

Hereditary Spherocytosis

Hereditary spherocytosis (HS) is an inherited disorder caused by intrinsic defects in the red cell membrane skeleton that render red cells spheroid, less deformable, and vulnerable to splenic sequestration and destruction. The prevalence of HS is highest in northern Europe, where rates of 1 in 5000 are reported. An autosomal dominant

Figure 14-1 Marrow smear from a patient with hemolytic anemia. The marrow reveals increased numbers of maturing erythroid progenitors (normoblasts). (Courtesy Dr. Steven Kroft, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas.)

inheritance pattern is seen in about 75% of cases. The remaining patients have a more severe form of the disease that is usually caused by the inheritance of two different defects (a state known as compound heterozygosity).

Pathogenesis. The remarkable deformability and durability of the normal red cell are attributable to the physicochemical properties of its specialized membrane skeleton (Fig. 14-2), which lies closely apposed to the internal surface of the plasma membrane. Its chief protein component, spectrin, consists of two polypeptide chains, α and β , which form intertwined (helical) flexible heterodimers. The “head” regions of spectrin dimers self-associate to form tetramers, while the “tails” associate with actin oligomers. Each actin oligomer can bind multiple spectrin tetramers, thus creating a two-dimensional spectrin-actin skeleton that is connected to the cell membrane by two distinct interactions. The first, involving the proteins ankyrin and band 4.2, binds spectrin to the transmembrane ion transporter, band 3. The second, involving protein 4.1, binds the “tail” of spectrin to another transmembrane protein, glycoporphin A.

Figure 14-2 Role of the red cell membrane skeleton in hereditary spherocytosis. The left panel shows the normal organization of the major red cell membrane skeletal proteins. Various mutations involving α -spectrin, β -spectrin, ankyrin, band 4.2, or band 3 that weaken the interactions between these proteins cause red cells to lose membrane fragments. To accommodate the resultant change in the ratio of surface area to volume these cells adopt a spherical shape. Spherocytic cells are less deformable than normal ones and therefore become trapped in the splenic cords, where they are phagocytosed by macrophages. GP, Glycophorin.

HS is caused by diverse mutations that lead to an insufficiency of membrane skeletal components. As a result of these alterations, the life span of the affected red cells is decreased on average to 10 to 20 days from the normal 120 days. The pathogenic mutations most commonly affect ankyrin, band 3, spectrin, or band 4.2, the proteins involved in one of the two tethering interactions, presumably because this complex is particularly important in stabilizing the lipid bilayer. Most mutations cause frameshifts or introduce premature stop codons, such that the mutated allele fails to produce any protein. The resulting deficiency of the affected protein reduces the assembly of the skeleton as a whole, destabilizing the overlying plasma membrane. Young HS red cells are normal in shape, but the destabilized lipid bilayer sheds membrane fragments as red cells age in the circulation. The loss of membrane relative to cytoplasm “forces” the cells to assume the smallest possible diameter for a given volume, namely, a sphere. Compound heterozygosity for two defective alleles understandably results in a more severe membrane skeleton deficiency.

The invariably beneficial effects of splenectomy prove that the spleen has a cardinal role in the premature demise of spherocytes. The travails of spherocytic red cells are fairly well defined. In the life of the portly inflexible spherocyte, the spleen is the villain. Normal red cells must undergo extreme deformation to leave the cords of Billroth and enter the sinusoids. Because of their spheroidal shape and reduced deformability, the hapless spherocytes are trapped in the splenic cords, where they are easy prey for macrophages. The splenic environment also somehow exacerbates the tendency of HS red cells to lose membrane along with K^+ ions and H_2O ; prolonged splenic exposure (erythroptosis), depletion of red cell glucose, and diminished red cell pH have all been suggested to contribute to these abnormalities (Fig. 14-3). After splenectomy the spherocytes persist, but the anemia is corrected.

MORPHOLOGY

The most specific morphologic finding is **spherocytosis**, apparent on smears as small, dark-staining (hyperchromic) red cells lacking the central zone of pallor (Fig. 14-4). Spherocytosis is distinctive but not pathognomonic, as spherocytes are also seen in other disorders associated with membrane loss, such as in autoimmune hemolytic anemia. Other features are common to all hemolytic anemias. These include reticulocytosis, marrow erythroid hyperplasia, hemosiderosis, and mild jaundice. **Cholelithiasis** (pigment stones) occurs in 40% to 50% of affected adults. Moderate **splenomegaly** is characteristic (500-1000 gm); in few other hemolytic anemias is the spleen enlarged as much or as consistently. Splenomegaly results from congestion of the cords of Billroth and increased numbers of phagocytes.

Clinical Features. The diagnosis is based on family history, hematologic findings, and laboratory evidence. In two thirds of the patients the red cells are abnormally sensitive to *osmotic lysis* when incubated in hypotonic salt solutions, which causes the influx of water into spherocytes with little margin for expansion. HS red cells also have an *increased mean cell hemoglobin concentration*, due to dehydration caused by the loss of K^+ and H_2O .

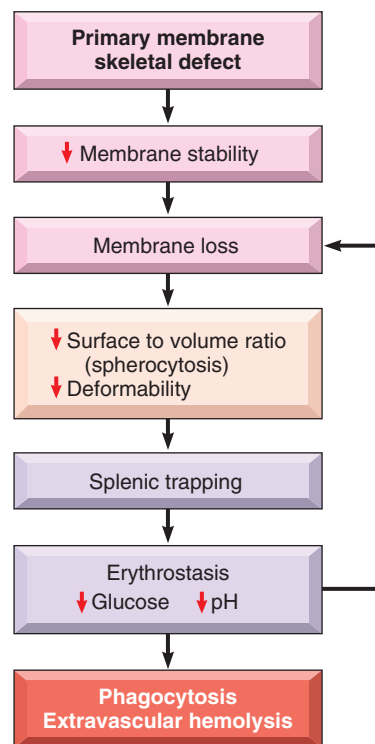

Figure 14-3 Pathophysiology of hereditary spherocytosis.

The characteristic clinical features are *anemia*, *splenomegaly*, and *jaundice*. The severity varies greatly. In a small minority (mainly compound heterozygotes) HS presents at birth with marked jaundice and requires exchange transfusions. In 20% to 30% of patients the disease is so mild as to be virtually asymptomatic; here the decreased red cell survival is readily compensated for by increased erythropoiesis. In most, however, the compensatory changes are outpaced, producing a chronic hemolytic anemia of mild to moderate severity.

The generally stable clinical course is sometimes punctuated by *aplastic crises*, usually triggered by an acute parvovirus infection. Parvovirus infects and kills red cell

Figure 14-4 Hereditary spherocytosis (peripheral smear). Note the anisocytosis and several dark-appearing spherocytes with no central pallor. Howell-Jolly bodies (small dark nuclear remnants) are also present in red cells of this asplenic patient. (Courtesy Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas.)

progenitors, effectively causing red cell production to cease until an immune response commences, generally in 1 to 2 weeks. Because of the reduced life span of HS red cells, cessation of erythropoiesis for even short time periods leads to sudden worsening of the anemia. Transfusions may be necessary to support the patient until the immune response clears the infection. *Hemolytic crises* are produced by intercurrent events leading to increased splenic destruction of red cells (e.g., infectious mononucleosis); these are clinically less significant than aplastic crises. Gallstones, found in many patients, can also produce symptoms. Splenectomy treats the anemia and its complications, but brings with it an increased risk of sepsis, since the spleen acts as an important filter for blood borne bacteria.

Hemolytic Disease Due to Red Cell Enzyme Defects: *Glucose-6-Phosphate Dehydrogenase Deficiency*

Abnormalities in the hexose monophosphate shunt or glutathione metabolism resulting from deficient or impaired enzyme function reduce the ability of red cells to protect themselves against oxidative injuries and lead to hemolysis. The most important of these enzyme derangements is the hereditary deficiency of glucose-6-phosphate dehydrogenase (G6PD) activity. G6PD reduces nicotinamide adenine dinucleotide phosphate (NADP) to NADPH while oxidizing glucose-6-phosphate (Fig. 14-5). NADPH then provides reducing equivalents needed for conversion of oxidized glutathione to reduced glutathione, which protects against oxidant injury by participating as a cofactor in reactions that neutralize compounds such as H_2O_2 (Fig. 14-5).

G6PD deficiency is a recessive X-linked trait, placing males at higher risk for symptomatic disease. Several hundred G6PD genetic variants are known, but most

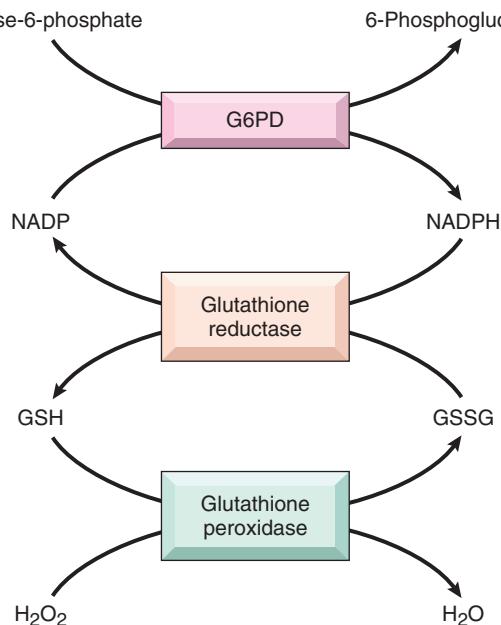

Figure 14-5 Role of glucose-6-phosphate dehydrogenase (G6PD) in defense against oxidant injury. The disposal of H_2O_2 , a potential oxidant, is dependent on the adequacy of reduced glutathione (GSH), which is generated by the action of the reduced form of nicotinamide adenine dinucleotide (NADPH). The synthesis of NADPH is dependent on the activity of G6PD. GSSG, Oxidized glutathione.

are harmless. Two variants, designated G6PD⁻ and G6PD Mediterranean, cause most of the clinically significant hemolytic anemias. G6PD⁻ is present in about 10% of American blacks; G6PD Mediterranean, as the name implies, is prevalent in the Middle East. The high frequency of these variants in each population is believed to stem from a protective effect against *Plasmodium falciparum* malaria (discussed later). G6PD variants associated with hemolysis result in misfolding of the protein, making it more susceptible to proteolytic degradation. Compared with the most common normal variant, G6PD B, the half-life of G6PD⁻ is moderately reduced, whereas that of G6PD Mediterranean is more markedly abnormal. Because mature red cells do not synthesize new proteins, G6PD⁻ or G6PD Mediterranean enzyme activities fall quickly to levels inadequate to protect against oxidant stress as red cells age. Thus, older red cells are much more prone to hemolysis than younger ones.

The episodic hemolysis that is characteristic of G6PD deficiency is caused by exposures that generate oxidant stress. The most common triggers are *infections*, in which oxygen-derived free radicals are produced by activated leukocytes. Many infections can trigger hemolysis; viral hepatitis, pneumonia, and typhoid fever are among those most likely to do so. The other important initiators are *drugs* and certain *foods*. The oxidant drugs implicated are numerous, including antimalarials (e.g., primaquine and chloroquine), sulfonamides, nitrofurantoin, and others. Some drugs cause hemolysis only in individuals with the more severe Mediterranean variant. The most frequently cited food is the *fava bean*, which generates oxidants when metabolized. "Favism" is endemic in the Mediterranean, Middle East, and parts of Africa where consumption is prevalent. Uncommonly, G6PD deficiency presents as neonatal jaundice or a chronic low-grade hemolytic anemia in the absence of infection or known environmental triggers.

Oxidants cause both *intravascular and extravascular hemolysis* in G6PD-deficient individuals. Exposure of G6PD-deficient red cells to high levels of oxidants causes the cross-linking of reactive sulfhydryl groups on globin chains, which become denatured and form membrane-bound precipitates known as *Heinz bodies*. These are seen as dark inclusions within red cells stained with crystal violet (Fig. 14-6). Heinz bodies can damage the membrane sufficiently to cause intravascular hemolysis. Less severe membrane damage results in decreased red cell deformability. As inclusion-bearing red cells pass through the splenic cords, macrophages pluck out the Heinz bodies. As a result of membrane damage, some of these partially devoured cells retain an abnormal shape, appearing to have a bite taken out of them (Fig. 14-6). Other less severely damaged cells become spherocytes due to loss of membrane surface area. Both bite cells and spherocytes are trapped in splenic cords and removed rapidly by phagocytes.

Acute intravascular hemolysis, marked by anemia, hemoglobinemia, and hemoglobinuria, usually begins 2 to 3 days following exposure of G6PD-deficient individuals to oxidants. The hemolysis is greater in individuals with the highly unstable G6PD Mediterranean variant. Because only older red cells are at risk for lysis, the episode is self-limited, as hemolysis ceases when only younger G6PD-replete red cells remain (even if the patient

Figure 14-6 Glucose-6-phosphate dehydrogenase deficiency: effects of oxidant drug exposure (peripheral blood smear). *Inset*, Red cells with precipitates of denatured globin (Heinz bodies) revealed by supravital staining. As the splenic macrophages pluck out these inclusions, “bite cells” like the one in this smear are produced. (Courtesy Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas.)

continues to take the offending drug). The recovery phase is heralded by reticulocytosis. Because hemolytic episodes related to G6PD deficiency occur intermittently, features related to chronic hemolysis (e.g., splenomegaly, cholelithiasis) are absent.

Sickle Cell Disease

Sickle cell disease is a common hereditary hemoglobinopathy caused by a point mutation in β -globin that promotes the polymerization of deoxygenated hemoglobin, leading to red cell distortion, hemolytic anemia, microvascular obstruction, and ischemic tissue damage. Several hundred different hemoglobinopathies caused by mutations in globin genes are known, but only those associated with sickle cell disease are prevalent enough in the United States to merit discussion. Hemoglobin is a tetrameric protein composed of two pairs of globin chains, each with its own heme group. Normal adult red cells contain mainly HbA ($\alpha_2\beta_2$), along with small amounts of HbA₂ ($\alpha_2\delta_2$) and fetal hemoglobin (HbF; $\alpha_2\gamma_2$). Sickle cell disease is caused by a point mutation in the sixth codon of β -globin that leads to the replacement of a glutamate residue with a valine residue. The abnormal physiochemical properties of the resulting sickle hemoglobin (HbS) are responsible for the disease.

About 8% to 10% of African Americans, or roughly 2 million individuals, are heterozygous for HbS, a largely asymptomatic condition known as sickle cell trait. The offspring of two heterozygotes has a 1 in 4 chance of being homozygous for the sickle mutation, a state that produces symptomatic sickle cell disease. In such individuals, almost all the hemoglobin in the red cell is HbS ($\alpha_2\beta^S_2$). There are about 70,000 individuals with sickle cell disease in the United States. In certain populations in Africa the prevalence of heterozygosity is as high as 30%.

This high frequency stems from protection afforded by HbS against falciparum malaria. Population studies have shown that the sickle hemoglobin mutation has arisen independently at least six times in areas in which falciparum

malaria is endemic, providing clear evidence of strong Darwinian selection for this trait. Parasite densities are lower in infected AS children than in AA children, and AS children are significantly less likely to have severe disease or to die from malaria. While mechanistic details are lacking two scenarios to explain these observations are favored:

- Metabolically active intracellular parasites consume O₂ and decrease intracellular pH, both of which promote hemoglobin sickling in AS red cells. These distorted and stiffened cells may be cleared more rapidly by phagocytes in the spleen and liver, helping to keep parasite loads down.
- Another effect of sickling is that it impairs the formation of membrane knobs containing a protein made by the parasite called PfEMP-1. These membrane knobs are implicated in adhesion of infected red cells to endothelium, which is believed to have an important pathogenic role in the most severe form of the disease, cerebral malaria.

It has been suggested that G6PD deficiency and thalassemias also protect against malaria by increasing the clearance and decreasing the adherence of infected red cells, possibly by raised levels of oxidant stress and causing membrane damage in the parasite-bearing cells.

Pathogenesis. The major pathologic manifestations—chronic hemolysis, microvascular occlusions, and tissue damage—all stem from the tendency of HbS molecules to stack into polymers when deoxygenated. Initially, this process converts the red cell cytosol from a freely flowing liquid into a viscous gel. With continued deoxygenation HbS molecules assemble into long needle-like fibers within red cells, producing a distorted sickle or holly-leaf shape.

Several variables affect the rate and degree of sickling:

- *Interaction of HbS with the other types of hemoglobin in the cell.* In heterozygotes with sickle cell trait, about 40% of the hemoglobin is HbS and the rest is HbA, which interferes with HbS polymerization. As a result, red cells in heterozygous individuals do not sickle except under conditions of profound hypoxia. HbF inhibits the polymerization of HbS even more than HbA; hence, infants do not become symptomatic until they reach 5 or 6 months of age, when the level of HbF normally falls. However, in some individuals HbF expression remains at relatively high levels, a condition known as hereditary persistence of HbF; in these individuals, sickle cell disease is much less severe. Another variant hemoglobin is HbC, in which lysine is substituted for glutamate in the sixth amino acid residue of β -globin. HbC is also common in regions where HbS is found; overall, about 2% to 3% of American blacks are HbC heterozygotes and about 1 in 1250 are compound HbS/HbC heterozygotes. In HbSC red cells the percentage of HbS is 50%, as compared with only 40% in HbAS cells. Moreover, HbSC cells tend to lose salt and water and become dehydrated, which increases the intracellular concentration of HbS. Both of these factors increase the tendency for HbS to polymerize. As a result, individuals who are compound heterozygotes for HbS and HbC have a symptomatic sickling disorder (termed *HbSC disease*), but it is milder than sickle cell disease.

- **Mean cell hemoglobin concentration (MCHC).** Higher HbS concentrations increase the probability that aggregation and polymerization will occur during any given period of deoxygenation. Thus, intracellular dehydration, which increases the MCHC, facilitates sickling. Conversely, conditions that decrease the MCHC reduce the disease severity. This occurs when the individual is homozygous for HbS but also has coexistent α -thalassemia, which reduces Hb synthesis and leads to milder disease.
- **Intracellular pH.** A decrease in pH reduces the oxygen affinity of hemoglobin, thereby increasing the fraction of deoxygenated HbS at any given oxygen tension and augmenting the tendency for sickling.
- **Transit time of red cells through microvascular beds.** As will be discussed, much of the pathology of sickle cell disease is related to vascular occlusion caused by sickling within microvascular beds. Transit times in most normal microvascular beds are too short for significant aggregation of deoxygenated HbS to occur, and as a result sickling is confined to microvascular beds with slow transit times. Blood flow is sluggish in the normal spleen and bone marrow, which are prominently affected in sickle cell disease, and also in vascular beds that are inflamed. The movement of blood through inflamed tissues is slowed because of the adhesion of leukocytes to activated endothelial cells and the transudation of fluid through leaky vessels. As a result, inflamed vascular beds are prone to sickling and occlusion.

Sickling causes cumulative damage to red cells through several mechanisms. As HbS polymers grow, they herniate through the membrane skeleton and project from the cell ensheathed by only the lipid bilayer. This severe derangement in membrane structure causes the influx of Ca^{2+} ions, which induce the cross-linking of membrane proteins and activate an ion channel that permits the efflux of K^+ and H_2O . With repeated episodes of sickling, red cells become increasingly dehydrated, dense, and rigid (Fig. 14-7). Eventually, the most severely damaged cells are converted to end-stage, nondeformable, irreversibly sickled cells, which retain a sickle shape even when fully oxygenated. The severity of the hemolysis correlates with the percentage of irreversibly sickled cells, which are rapidly sequestered and removed by mononuclear phagocytes (extravascular hemolysis). Sickled red cells are also mechanically fragile, leading to some intravascular hemolysis as well.

The pathogenesis of the *microvascular occlusions*, which are responsible for the most serious clinical features, is far less certain. Microvascular occlusions are not related to the number of irreversibly sickled cells in the blood, but instead may be dependent upon more subtle red cell membrane damage and local factors, such as inflammation or vasoconstriction, that tend to slow or arrest the movement of red cells through microvascular beds (Fig. 14-7). As mentioned above, sickle red cells express higher than normal levels of adhesion molecules and are sticky. Mediators released from granulocytes during inflammatory reactions up-regulate the expression of adhesion molecules on endothelial cells (Chapter 3) and further enhance the tendency for sickle red cells to get arrested during transit through the microvasculature. The stagnation of red cells within

Figure 14-7 Pathophysiology of sickle cell disease.

inflamed vascular beds results in extended exposure to low oxygen tension, sickling, and vascular obstruction. Once started, it is easy to envision how a vicious cycle of sickling, obstruction, hypoxia, and more sickling ensues. Depletion of nitric oxide (NO) may also play a part in the vascular occlusions. Free hemoglobin released from lysed sickle red cells can bind and inactivate NO, which is a potent vasodilator and inhibitor of platelet aggregation. The reduction in active NO leads to increased vascular tone (narrowing vessels) and enhances platelet aggregation, both of which may contribute to red cell stasis, sickling, and (in some instances) thrombosis.

MORPHOLOGY

In sickle cell anemia, the peripheral blood demonstrates variable numbers of **irreversibly sickled cells**, reticulocytosis, and target cells, which result from red cell dehydration (Fig. 14-8). **Howell-Jolly bodies** (small nuclear remnants) are also present in some red cells due to the asplenia (see later). The bone marrow is hyperplastic as a result of a compensatory erythroid hyperplasia. Expansion of the marrow leads to bone resorption and secondary new bone formation, resulting in prominent cheekbones and changes in the skull that resemble a “crewcut” on x-ray studies. Extramedullary hematopoiesis can also appear. The increased breakdown of hemoglobin can cause pigment gallstones and hyperbilirubinemia.

In early childhood, the spleen is enlarged up to 500 gm by red pulp congestion, which is caused by the trapping of sickled red cells in the cords and sinuses (Fig. 14-9). With time, however, the chronic erythrostatics leads to splenic infarction,

Figure 14-8 Sickle cell disease (peripheral blood smear). **A**, Low magnification shows sickle cells, anisocytosis, and poikilocytosis. **B**, Higher magnification shows an irreversibly sickled cell in the center. (Courtesy Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas.)

fibrosis, and progressive shrinkage, so that by adolescence or early adulthood only a small nubbin of fibrous splenic tissue is left; this process is called **autosplenectomy** (Fig. 14-10). Infarctions caused by vascular occlusions can occur in many other tissues as well, including the bones, brain, kidney, liver, retina, and pulmonary vessels, the latter sometimes producing cor pulmonale. In adult patients, vascular stagnation in subcutaneous tissues often leads to leg ulcers; this complication is rare in children.

Clinical Features

Sickle cell disease causes a moderately severe hemolytic anemia (hematocrit 18% to 30%) that is associated with reticulocytosis, hyperbilirubinemia, and the presence of irreversibly sickled cells. Its course is punctuated by a variety of “crises.” *Vaso-occlusive crises*, also called *pain crises*, are episodes of hypoxic injury and infarction that cause severe pain in the affected region. Although infection, dehydration, and acidosis (all of which favor sickling) can act as triggers, in most instances no predisposing cause is identified. The most commonly involved sites are the bones, lungs, liver, brain, spleen, and penis. In children, painful bone crises are extremely common and often difficult to distinguish from acute osteomyelitis. These

Figure 14-9 **A**, Spleen in sickle cell disease (low power). Red pulp cords and sinusoids are markedly congested; between the congested areas, pale areas of fibrosis resulting from ischemic damage are evident. **B**, Under high power, splenic sinusoids are dilated and filled with sickled red cells. (Courtesy Dr. Darren Wirthwein, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas.)

frequently manifest as the *hand-foot syndrome* or dactylitis of the bones of the hands or feet, or both. *Acute chest syndrome* is a particularly dangerous type of vaso-occlusive crisis involving the lungs, which typically presents with fever, cough, chest pain, and pulmonary infiltrates. Pulmonary inflammation (such as may be induced by a

Figure 14-10 “Autoinfarcted” splenic remnant in sickle cell disease. (Courtesy Drs. Dennis Burns and Darren Wirthwein, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas.)

simple infection) may cause blood flow to become sluggish and “spleenlike,” leading to sickling and vaso-occlusion. This compromises pulmonary function, creating a potentially fatal cycle of worsening pulmonary and systemic hypoxemia, sickling, and vaso-occlusion. *Priapism* affects up to 45% of males after puberty and may lead to hypoxic damage and erectile dysfunction. Other disorders related to vascular obstruction, particularly *stroke* and retinopathy leading to *loss of visual acuity* and even blindness, can take a devastating toll. Factors proposed to contribute to stroke include the adhesion of sickle red cells to arterial vascular endothelium and vasoconstriction caused by the depletion of NO by free hemoglobin.

Although occlusive crises are the most common cause of patient morbidity and mortality, several other acute events complicate the course. *Sequestration crises* occur in children with intact spleens. Massive entrapment of sickle red cells leads to rapid splenic enlargement, hypovolemia, and sometimes shock. Both sequestration crises and the acute chest syndrome may be fatal and sometimes require prompt treatment with exchange transfusions. *Aplastic crises* stem from the infection of red cell progenitors by parvovirus B19, which causes a transient cessation of erythropoiesis and a sudden worsening of the anemia.

In addition to these dramatic crises, chronic tissue hypoxia takes a subtle but important toll. Chronic hypoxia is responsible for a generalized impairment of growth and development, as well as organ damage affecting the spleen, heart, kidneys, and lungs. Sickling provoked by hypertonicity in the renal medulla causes damage that eventually leads to hyposthenuria (the inability to concentrate urine), which increases the propensity for dehydration and its attendant risks.

Increased susceptibility to infection with encapsulated organisms is another threat. This is due in large part to altered splenic function, which is severely impaired in children by congestion and poor blood flow, and completely absent in adults because of splenic infarction. Defects of uncertain etiology in the alternative complement pathway also impair the opsonization of bacteria. *Pneumococcus pneumoniae* and *Haemophilus influenzae* septicemia and meningitis are common, particularly in children, but can be reduced by vaccination and prophylactic antibiotics.

It must be emphasized that there is great variation in the clinical manifestations of sickle cell disease. Some individuals are crippled by repeated vaso-occlusive crises, whereas others have only mild symptoms. The basis for this wide range in disease expression is not understood; both modifying genes and environmental factors are suspected.

The diagnosis is suggested by the clinical findings and the presence of irreversibly sickled red cells and is confirmed by various tests for sickle hemoglobin. In general, these involve mixing a blood sample with an oxygen-consuming reagent, such as metabisulfite, which induces sickling of red cells if HbS is present. Hemoglobin electrophoresis is also used to demonstrate the presence of HbS and exclude other sickle syndromes, such as HbSC disease. Prenatal diagnosis is possible by analysis of fetal DNA obtained by amniocentesis or chorionic biopsy.

The outlook for patients with sickle cell disease has improved considerably over the past 10 to 20 years. About 90% of patients survive to age 20, and close to 50% survive

beyond the fifth decade. A mainstay of treatment is an inhibitor of DNA synthesis, hydroxyurea, which has several beneficial effects. These include (1) an increase in red cell HbF levels, which occurs by unknown mechanisms; and (2) an antiinflammatory effect, which stems from an inhibition of leukocyte production. These activities (and possibly others) are believed to act in concert to decrease crises related to vascular occlusions in both children and adults. Hematopoietic stem cell transplantation offers a chance at cure and is increasingly being explored as a therapeutic option.

Thalassemia Syndromes

The thalassemia syndromes are a heterogeneous group of disorders caused by inherited mutations that decrease the synthesis of either the α -globin or β -globin chains that compose adult hemoglobin, HbA ($\alpha_2\beta_2$), leading to anemia, tissue hypoxia, and red cell hemolysis related to the imbalance in globin chain synthesis. The two α chains in HbA are encoded by an identical pair of α -globin genes on chromosome 16, while the two β chains are encoded by a single β -globin gene on chromosome 11. β -thalassemia is caused by deficient synthesis of β chains, whereas α -thalassemia is caused by deficient synthesis of α chains. The hematologic consequences of diminished synthesis of one globin chain stem not only from hemoglobin deficiency but also from a relative excess of the other globin chain, particularly in β -thalassemia (described below).

Thalassemia syndromes are endemic in the Mediterranean basin (indeed, *thalassa* means “sea” in Greek), as well as the Middle East, tropical Africa, the Indian subcontinent, and Asia, and in aggregate are among the most common inherited disorders of humans. As with sickle cell disease and other common inherited red cell disorders, their prevalence seems to be explained by the protection they afford heterozygous carriers against malaria. Although we discuss the thalassemia syndromes with other inherited forms of anemia associated with hemolysis, it is important to recognize that the defects in globin synthesis that underlie these disorders cause anemia through two mechanisms: decreased red cell production, and decreased red cell lifespan.

β -Thalassemsias

The β -thalassemias are caused by mutations that diminish the synthesis of β -globin chains. The clinical severity varies widely due to heterogeneity in the causative mutations. We will begin our discussion with the molecular lesions in β -thalassemia and then relate the clinical variants to specific underlying molecular defects.

Molecular Pathogenesis. The causative mutations fall into two categories: (1) β^0 mutations, associated with absent β -globin synthesis, and (2) β^+ mutations, characterized by reduced (but detectable) β -globin synthesis. Sequencing of β -thalassemia genes has revealed more than 100 different causative mutations, mostly consisting of point mutations. Details of these mutations and their effects are found in specialized texts. [Figure 14-11](#) gives a few illustrative examples.

- *Splicing mutations.* These are the most common cause of β^+ -thalassemia. Most of these mutations lie within

Figure 14-11 Distribution of β -globin gene mutations associated with β -thalassemia. Arrows denote sites where point mutations giving rise to β^0 or β^+ thalassemia have been identified.

introns, while a few are located within exons. Some of these mutations destroy the normal RNA splice junctions and completely prevent the production of normal β -globin mRNA, resulting in β^0 -thalassemia. Others create an “ectopic” splice site within an intron. Because the flanking normal splice sites remain, both normal and abnormal splicing occurs and some normal β -globin mRNA is made, resulting in β^+ -thalassemia.

- **Promoter region mutations.** These mutations reduce transcription by 75% to 80%. Some normal β -globin is synthesized; thus, these mutations are associated with β^+ -thalassemia.
- **Chain terminator mutations.** These are the most common cause of β^0 -thalassemia. Two subtypes of mutations fall into this category. The most common type creates a new stop codon within an exon; the other introduces small insertions or deletions that shift the mRNA reading frames (frameshift mutations; see [Chapter 5](#)). Both block translation and prevent the synthesis of any functional β -globin.

Impaired β -globin synthesis results in anemia by two mechanisms (Fig. 14-12). The deficit in HbA synthesis produces “underhemoglobinized” hypochromic, microcytic red cells with subnormal oxygen transport capacity. Even more important is the diminished survival of red cells and their precursors, which results from the imbalance in α - and β -globin synthesis. Unpaired α chains precipitate within red cell precursors, forming insoluble inclusions. These inclusions cause a variety of untoward effects, but membrane damage is the proximal cause of most red cell pathology. Many red cell precursors succumb to membrane damage and undergo apoptosis. In severe β -thalassemia, it is estimated that 70% to 85% of red cell precursors suffer this fate, which leads to *ineffective erythropoiesis*. Those red cells that are released from the marrow also contain inclusions and have membrane damage, leaving them prone to splenic sequestration and *extravascular hemolysis*.

In severe β -thalassemia, ineffective erythropoiesis creates several additional problems. Erythropoietic drive in the setting of severe uncompensated anemia leads to massive erythroid hyperplasia in the marrow and extensive extramedullary hematopoiesis. The expanding mass of red cell precursors erodes the bony cortex, impairs bone growth, and produces skeletal abnormalities (described later). Extramedullary hematopoiesis involves the liver,

spleen, and lymph nodes, and in extreme cases produces extraosseous masses in the thorax, abdomen, and pelvis. The metabolically active erythroid progenitors steal nutrients from other tissues that are already oxygen-starved, causing severe cachexia in untreated patients.

Another serious complication of ineffective erythropoiesis is excessive absorption of dietary iron. Ineffective erythropoiesis suppresses hepcidin, a critical negative regulator of iron absorption (see [Iron Deficiency Anemia](#)). Increased absorption of iron from the gut due to low hepcidin levels and the iron load of repeated blood transfusions inevitably lead to severe iron accumulation unless preventive steps are taken. Secondary injury to parenchymal organs, particularly the liver, often follows and sometimes induces *secondary hemochromatosis* ([Chapter 18](#)).

Clinical Syndromes. The relationships of clinical phenotypes to underlying genotypes are summarized in [Table 14-3](#). Clinical classification of β -thalassemia is based on the severity of the anemia, which in turn depends on the genetic defect (β^+ or β^0) and the gene dosage (homozygous or heterozygous). In general, individuals with two β -thalassemia alleles (β^+/β^+ , β^+/β^0 , or β^0/β^0) have a severe, transfusion-dependent anemia called *β -thalassemia major*. Heterozygotes with one β -thalassemia gene and one normal gene (β^+/β or β^0/β) usually have a mild asymptomatic microcytic anemia. This condition is referred to as *β -thalassemia minor* or *β -thalassemia trait*. A third genetically heterogeneous variant of moderate severity is called *β -thalassemia intermedia*. This category includes milder variants of β^+/β^+ or β^+/β^0 -thalassemia and unusual forms of heterozygous β -thalassemia. Some patients with β -thalassemia intermedia have two defective β -globin genes and an α -thalassemia gene defect, which improves the effectiveness of erythropoiesis and red cell survival by lessening the imbalance in α - and β -chain synthesis. In other rare but informative cases, individuals have a single β -globin defect and one or two extra copies of normal α -globin genes (stemming from a gene duplication event), which worsens the chain imbalance. These unusual forms of the disease serve to emphasize the cardinal role of unpaired α -globin chains in the pathology. The clinical and morphologic features of β -thalassemia intermedia are not described separately but can be surmised from the following discussions of β -thalassemia major and β -thalassemia minor.

Figure 14-12 Pathogenesis of β -thalassemia major. Note that the aggregates of unpaired α -globin chains, a hallmark of the disease, are not visible in routinely stained blood smears. Blood transfusions are a double-edged sword, diminishing the anemia and its attendant complications, but also adding to the systemic iron overload.

β -Thalassemia Major. β -Thalassemia major is most common in Mediterranean countries, parts of Africa, and Southeast Asia. In the United States the incidence is highest in immigrants from these areas. The anemia manifests 6 to 9 months after birth as hemoglobin synthesis switches from HbF to HbA. In untransfused patients, hemoglobin levels are 3 to 6 gm/dL. The red cells may completely lack HbA (β^0/β^0 genotype) or contain small amounts (β^+/β^+ or β^0/β^+ genotypes). The major red cell hemoglobin is HbF, which is markedly elevated. HbA₂ levels are sometimes high but more often are normal or low.

MORPHOLOGY

Blood smears show severe red cell abnormalities, including marked variation in size (**anisocytosis**) and shape (**poikilocytosis**), **microcytosis**, and **hypochromia**. Target cells (so called because hemoglobin collects in the center of the cell), basophilic stippling, and fragmented red cells are also common. Inclusions of aggregated α chains are efficiently removed by the spleen and

not easily seen. The reticulocyte count is elevated, but it is lower than expected for the severity of anemia because of the ineffective erythropoiesis. Variable numbers of poorly hemoglobinized nucleated red cell precursors (normoblasts) are seen in the peripheral blood as a result of “stress” erythropoiesis and abnormal release from sites of extramedullary hematopoiesis.

Other major alterations involve the bone marrow and spleen. In the untransfused patient there is a striking expansion of hematopoietically active marrow. In the bones of the face and skull the burgeoning marrow erodes existing cortical bone and induces new bone formation, giving rise to a “crewcut” appearance on x-ray studies (Fig. 14-13). Both phagocyte hyperplasia and extramedullary hematopoiesis contribute to enlargement of the spleen, which can weigh as much as 1500 gm. The liver and the lymph nodes can also be enlarged by extramedullary hematopoiesis.

Hemosiderosis and secondary hemochromatosis, the two manifestations of iron overload (Chapter 18), occur in almost all patients. The deposited iron often damages organs, most notably the heart, liver, and pancreas.

Figure 14-13 Thalassemia. X-ray film of the skull showing new bone formation on the outer table, producing perpendicular radiations resembling a crewcut. (Courtesy Dr. Jack Reynolds, Department of Radiology, University of Texas Southwestern Medical School, Dallas, Texas.)

The clinical course of β -thalassemia major is brief unless blood transfusions are given. Untreated children suffer from growth retardation and die at an early age from the effects of anemia. In those who survive long enough, the cheekbones and other bony prominences are enlarged and distorted. Hepatosplenomegaly due to extramedullary hematopoiesis is usually present. Although blood transfusions improve the anemia and suppress complications related to excessive erythropoiesis, they lead to complications of their own. Cardiac disease resulting from progressive iron overload and secondary hemochromatosis (Chapter 18) is an important cause of death, particularly in heavily transfused patients, who must be treated with iron chelators to prevent or reduce this complication. With transfusions and iron chelation, survival into the third decade is possible, but the overall outlook remains guarded. Hematopoietic stem cell transplantation is the only therapy offering a cure and is being used increasingly. Prenatal diagnosis is possible by molecular analysis of DNA.

β -Thalassemia Minor. β -Thalassemia minor is much more common than β -thalassemia major and understandably affects the same ethnic groups. Most patients are heterozygous carriers of a β^+ or β^0 allele. These patients are usually asymptomatic. Anemia, if present, is mild. The peripheral blood smear typically shows some red cell abnormalities, including hypochromia, microcytosis, basophilic stippling, and target cells. Mild erythroid hyperplasia is seen in the bone marrow. Hemoglobin electrophoresis usually reveals an increase in HbA₂ ($\alpha_2\delta_2$) to 4% to 8% of the total hemoglobin (normal, $2.5\% \pm 0.3\%$), which is a reflection of an elevated ratio of δ -chain to β -chain synthesis. HbF levels are generally normal or occasionally slightly increased.

Recognition of β -thalassemia trait is important for two reasons: (1) it superficially resembles the hypochromic microcytic anemia of iron deficiency, and (2) it has implications for genetic counseling. Iron deficiency can usually be excluded through measurement of serum iron, total

iron-binding capacity, and serum ferritin (see [Iron Deficiency Anemia](#)). The increase in HbA₂ is diagnostically useful, particularly in individuals (such as women of child-bearing age) who are at risk for both β -thalassemia trait and iron deficiency.

α -Thalassemias

The α -thalassemias are caused by inherited deletions that result in reduced or absent synthesis of α -globin chains.

Normally, there are four α -globin genes, and the severity of α -thalassemia depends on how many α -globin genes are affected. As in β -thalassemias, the anemia stems both from a lack of adequate hemoglobin and the presence of excess unpaired globin chains (β , γ , and δ), which vary in type at different ages. In newborns with α -thalassemia, excess unpaired γ -globin chains form γ_4 tetramers known as *hemoglobin Barts*, whereas in older children and adults excess β -globin chains form β_4 tetramers known as *HbH*. Because free β and γ chains are more soluble than free α chains and form fairly stable homotetramers, hemolysis and ineffective erythropoiesis are less severe than in β -thalassemias. A variety of molecular lesions give rise to α -thalassemia, but gene deletion is the most common cause of reduced α -chain synthesis.

Clinical Syndromes. The clinical syndromes are determined and classified by the number of α -globin genes that are deleted. Each of the four α -globin genes normally contributes 25% of the total α -globin chains. α -Thalassemia syndromes stem from combinations of deletions that remove one to four α -globin genes. Not surprisingly, the severity of the clinical syndrome is proportional to the number of α -globin genes that are deleted. The different types of α -thalassemia and their salient clinical features are listed in [Table 14-3](#).

Silent Carrier State. Silent carrier state is associated with the deletion of a single α -globin gene, which causes a barely detectable reduction in α -globin chain synthesis. These individuals are completely asymptomatic but have slight microcytosis.

α -Thalassemia Trait. α -Thalassemia trait is caused by the deletion of two α -globin genes from a single chromosome ($\alpha/\alpha -/-$) or the deletion of one α -globin gene from each of the two chromosomes ($\alpha/- \alpha/-$) ([Table 14-3](#)). The former genotype is more common in Asian populations, the latter in regions of Africa. Both genotypes produce similar quantitative deficiencies of α -globin and are clinically identical, but have different implications for the children of affected individuals, who are at risk of clinically significant α -thalassemia (HbH disease or hydrops fetalis) only when at least one parent has the $-/-$ haplotype. As a result, symptomatic α -thalassemia is relatively common in Asian populations and rare in black African populations. The clinical picture in α -thalassemia trait is identical to that described for β -thalassemia minor, that is, small red cells (microcytosis), minimal or no anemia, and no abnormal physical signs. HbA₂ levels are normal or low.

Hemoglobin H Disease. HbH disease is caused by deletion of three α -globin genes. As discussed, HbH disease is most common in Asian populations. With only one normal

Table 14-3 Clinical and Genetic Classification of Thalassemias

Clinical Syndromes	Genotype	Clinical Features	Molecular Genetics
β-Thalassemias			
β -Thalassemia major	Homozygous β -thalassemia (β^0/β^0 , β^+/ β^+ , β^0/β^+)	Severe; requires blood transfusions	Mainly point mutations that lead to defects in the transcription, splicing, or translation of β -globin mRNA
β -Thalassemia intermedia	Variable (β^0/β^+ , β^+/ β^+ , β^0/β , β^+/β)	Severe but does not require regular blood transfusions	
β -Thalassemia minor	Heterozygous β -thalassemia (β^0/β , β^+/β)	Asymptomatic with mild or absent anemia; red cell abnormalities seen	
α-Thalassemias			
Silent carrier	$-/\alpha \alpha/\alpha$	Asymptomatic; no red cell abnormality	Mainly gene deletions
α -Thalassemia trait	$-/- \alpha/\alpha$ (Asian) $-/\alpha -/\alpha$ (black African, Asian)	Asymptomatic, like β -thalassemia minor	
HbH disease	$-/- -/\alpha$	Severe; resembles β -thalassemia intermedia	
Hydrops fetalis	$-/- -/-$	Lethal in utero without transfusions	

α -globin gene, the synthesis of α chains is markedly reduced, and tetramers of β -globin, called HbH, form. HbH has an extremely high affinity for oxygen and therefore is not useful for oxygen delivery, leading to tissue hypoxia disproportionate to the level of hemoglobin. Additionally, HbH is prone to oxidation, which causes it to precipitate and form intracellular inclusions that promote red cell sequestration and phagocytosis in the spleen. The result is a moderately severe anemia resembling β -thalassemia intermedia.

Hydrops Fetalis. Hydrops fetalis is the most severe form of α -thalassemia and is caused by deletion of all four α -globin genes. In the fetus, excess γ -globin chains form tetramers (hemoglobin Barts) that have such a high affinity for oxygen that they deliver little to tissues. Survival in early development is due to the expression of ζ chains, an embryonic globin that pairs with γ chains to form a functional $\zeta_2\gamma_2$ Hb tetramer. Signs of fetal distress usually become evident by the third trimester of pregnancy. In the past, severe tissue anoxia led to death in utero or shortly after birth; with intrauterine transfusion many such infants are now saved. The fetus shows severe pallor, generalized edema, and massive hepatosplenomegaly similar to that seen in hemolytic disease of the newborn (Chapter 10). There is a lifelong dependence on blood transfusions for survival, with the associated risk of iron overload. Hematopoietic stem cell transplantation can be curative.

Paroxysmal Nocturnal Hemoglobinuria

Paroxysmal nocturnal hemoglobinuria (PNH) is a disease that results from acquired mutations in the phosphatidylinositol glycan complementation group A gene (PIGA), an enzyme that is essential for the synthesis of certain membrane-associated complement regulatory proteins. PNH has an incidence of 2 to 5 per million in the United States. Despite its rarity, it has fascinated hematologists because it is the only hemolytic anemia caused by an acquired genetic defect. Recall that proteins are anchored into the lipid bilayer in two ways. Most have a hydrophobic region that spans the cell membrane; these are called transmembrane proteins. The others are attached to the cell membrane through a covalent linkage to a specialized

phospholipid called glycosylphosphatidylinositol (GPI). In PNH, these GPI-linked proteins are deficient because of somatic mutations that inactivate PIGA. PIGA is X-linked and subject to lyonization (random inactivation of one X chromosome in cells of females; Chapter 5). As a result, a single acquired mutation in the active PIGA gene of any given cell is sufficient to produce a deficiency state. Because the causative mutations occur in a hematopoietic stem cell, all of its clonal progeny (red cells, white cells, and platelets) are deficient in GPI-linked proteins. Typically the mutant clone coexists with the progeny of normal stem cells that are not PIGA deficient.

Remarkably, most normal individuals harbor small numbers of bone marrow cells with PIGA mutations identical to those that cause PNH. It is hypothesized that these cells increase in numbers (thus producing clinically evident PNH) only in rare instances where they have a selective advantage, such as in the setting of autoimmune reactions against GPI-linked antigens. Such a scenario might explain the frequent association of PNH and aplastic anemia, a marrow failure syndrome (discussed later) that has an autoimmune basis in many individuals.

PNH blood cells are deficient in three GPI-linked proteins that regulate complement activity: (1) decay-accelerating factor, or CD55; (2) membrane inhibitor of reactive lysis, or CD59; and (3) C8 binding protein. Of these factors, the most important is CD59, a potent inhibitor of C3 convertase that prevents the spontaneous activation of the alternative complement pathway.

Red cells deficient in these GPI-linked factors are abnormally susceptible to lysis or injury by complement. This manifests as *intravascular hemolysis*, which is caused by the C5b-C9 membrane attack complex. The hemolysis is paroxysmal and nocturnal in only 25% of cases; chronic hemolysis without dramatic hemoglobinuria is more typical. The tendency for red cells to lyse at night is explained by a slight decrease in blood pH during sleep, which increases the activity of complement. The anemia is variable but usually mild to moderate in severity. The loss of heme iron in the urine (hemosiderinuria) eventually leads to iron deficiency, which can exacerbate the anemia if untreated.

Thrombosis is the leading cause of disease-related death in individuals with PNH. About 40% of patients suffer

Figure 14-14 Paroxysmal nocturnal hemoglobinuria (PNH). **A**, Flow cytogram of blood from a normal individual shows that the red cells express two phosphatidylinositol glycan (PIG)-linked membrane proteins, CD55 and CD59, on their surfaces. **B**, Flow cytogram of blood from a patient with PNH shows a population of red cells that is deficient in both CD55 and CD59. As is typical of PNH, a second population of CD55+/CD59+ red cells that is derived from residual normal hematopoietic stem cells is also present. (Courtesy Dr. Scott Rodig, Department of Pathology, Brigham and Women's Hospital, Boston, Mass.)

from venous thrombosis, often involving the hepatic, portal, or cerebral veins. About 5% to 10% of patients eventually develop acute myeloid leukemia or a myelodysplastic syndrome, possibly because hematopoietic stem cells have suffered some type of genetic damage.

PNH is diagnosed by flow cytometry, which provides a sensitive means for detecting red cells that are deficient in GPI-linked proteins such as CD59 (Fig. 14-14). The cardinal role of complement activation in PNH pathogenesis has been proven by therapeutic use of a monoclonal antibody called Eculizumab that prevents the conversion of C5 to C5a. This inhibitor not only reduces the hemolysis and attendant transfusion requirements, but also lowers the risk of thrombosis by up to 90%. How complement activation leads to thrombosis in patients with PNH is not clear; the absorption of NO by free hemoglobin (discussed under sickle cell disease) may be one contributing factor. The drawbacks to C5 inhibitor therapy are its high cost and an increased risk of serious or fatal meningococcal infections (as is true in individuals with inherited complement defects). Immunosuppressive drugs are sometimes beneficial for those with evidence of marrow aplasia. The only cure is hematopoietic stem cell transplantation.

Immuno-hemolytic Anemias

Hemolytic anemias in this category are caused by antibodies that bind to red cells, leading to their premature destruction. Although these disorders are commonly referred to as *autoimmune hemolytic anemias*, the designation immuno-hemolytic anemia is preferred because in some instances the immune reaction is initiated by an ingested drug. Immuno-hemolytic anemia can be classified based on the characteristics of the responsible antibody (Table 14-4).

The diagnosis of immuno-hemolytic anemia requires the detection of antibodies and/or complement on red cells from the patient. This is done using the *direct Coombs antiglobulin test*, in which the patient's red cells are mixed with sera containing antibodies that are specific for human immunoglobulin or complement. If either immunoglobulin or complement is present on the surface of the red cells, the antibodies cause agglutination, which is easily appreciated visually as clumping. In the *indirect Coombs antiglobulin test*, the patient's serum is tested for its ability to agglutinate commercially available red cells bearing

Table 14-4 Classification of Immuno-hemolytic Anemias

Warm Antibody Type (IgG Antibodies Active at 37°C)
Primary (idiopathic)
Secondary
Autoimmune disorders (particularly systemic lupus erythematosus)
Drugs
Lymphoid neoplasms
Cold Agglutinin Type (IgM Antibodies Active Below 37°C)
Acute (mycoplasma infection, infectious mononucleosis)
Chronic
Idiopathic
Lymphoid neoplasms
Cold Hemolysin Type (IgG Antibodies Active Below 37°C)
Rare; occurs mainly in children following viral infections

particular defined antigens. This test is used to characterize the antigen target and temperature dependence of the responsible antibody. Quantitative immunologic tests to measure such antibodies directly are also available.

Warm Antibody Type. Warm antibody type is the most common form of immuno-hemolytic anemia. About 50% of cases are idiopathic (primary); the others are related to a predisposing condition (Table 14-4) or exposure to a drug. Most causative antibodies are of the IgG class; less commonly, IgA antibodies are the culprits. The red cell hemolysis is mostly extravascular. IgG-coated red cells bind to Fc receptors on phagocytes, which remove red cell membrane during "partial" phagocytosis. As in hereditary spherocytosis, the loss of membrane converts the red cells to spherocytes, which are sequestered and destroyed in the spleen. Moderate splenomegaly due to hyperplasia of splenic phagocytes is usually seen.

As with other autoimmune disorders, the cause of primary immuno-hemolytic anemia is unknown. In many cases, the antibodies are directed against the Rh blood group antigens. The mechanisms of drug-induced immuno-hemolytic anemia are better understood. Two different mechanisms have been described.

- **Antigenic drugs.** In this setting hemolysis usually follows large, intravenous doses of the offending drug and occurs 1 to 2 weeks after therapy is initiated. These drugs, exemplified by penicillin and cephalosporins, bind to the red cell membrane and are recognized by antidrug antibodies. Sometimes the antibodies bind only to the drug, as in penicillin-induced hemolysis. In other cases, such as in quinidine-induced hemolysis, the antibodies recognize a complex of the drug and a membrane protein. The responsible antibodies sometimes fix complement and cause intravascular hemolysis, but more often they act as opsonins that promote extravascular hemolysis within phagocytes.
- **Tolerance-breaking drugs.** These drugs, of which the anti-hypertensive agent α -methyl-dopa is the prototype, induce in some unknown manner the production of antibodies against red cell antigens, particularly the Rh blood group antigens. About 10% of patients taking α -methyl-dopa develop autoantibodies, as assessed by the direct Coombs test, and roughly 1% develop clinically significant hemolysis.

Cold Agglutinin Type. Cold agglutinin type of immunohemolytic anemia is caused by IgM antibodies that bind red cells avidly at low temperatures (0°C to 4°C). It is less common than warm antibody immunohemolytic anemia, accounting for 15% to 30% of cases. Cold agglutinin antibodies sometimes appear transiently following certain infections, such as with *Mycoplasma pneumoniae*, Epstein-Barr virus, cytomegalovirus, influenza virus, and human immunodeficiency virus (HIV). In these settings the disorder is self-limited and the antibodies rarely induce clinically important hemolysis. Chronic cold agglutinin immunohemolytic anemia occurs in association with certain B-cell neoplasms or as an idiopathic condition.

Clinical symptoms result from binding of IgM to red cells in vascular beds where the temperature may fall below 30°C, such as in exposed fingers, toes, and ears. IgM binding agglutinates red cells and fixes complement rapidly. As the blood recirculates and warms, IgM is released, usually before complement-mediated hemolysis can occur. However, the transient interaction with IgM is sufficient to deposit sublytic quantities of C3b, an excellent opsonin, which leads to the removal of affected red cells by phagocytes in the spleen, liver, and bone marrow. The hemolysis is of variable severity. Vascular obstruction caused by agglutinated red cells results in pallor, cyanosis, and Raynaud phenomenon (Chapter 11) in body parts exposed to cold temperature.

Cold Hemolysin Type. Cold hemolysins are autoantibodies responsible for an unusual entity known as *paroxysmal cold hemoglobinuria*. This rare disorder causes substantial, sometimes fatal, intravascular hemolysis and hemoglobinuria. The autoantibodies are IgGs that bind to the P blood group antigen on the red cell surface in cool, peripheral regions of the body. Complement-mediated lysis occurs when the cells recirculate to warm central regions, because the complement cascade functions more efficiently at 37°C. Most cases are seen in children following viral infections; in this setting the disorder is transient, and most of those affected recover within 1 month.

Treatment of warm antibody immunohemolytic anemia centers on the removal of initiating factors (i.e., drugs); when this is not feasible, immunosuppressive drugs and splenectomy are the mainstays. Chronic cold agglutinin immunohemolytic anemia caused by IgM antibodies is more difficult to treat.

Hemolytic Anemia Resulting from Trauma to Red Cells

The most significant hemolysis caused by trauma to red cells is seen in individuals with cardiac valve prostheses and microangiopathic disorders. Artificial mechanical cardiac valves are more frequently implicated than are bio-prosthetic porcine or bovine valves. The hemolysis stems from shear forces produced by turbulent blood flow and pressure gradients across damaged valves. *Microangiopathic hemolytic anemia* is most commonly seen with disseminated intravascular coagulation, but it also occurs in thrombotic thrombocytopenic purpura (TTP), hemolytic-uremic syndrome (HUS), malignant hypertension, systemic lupus erythematosus, and disseminated cancer. The common pathogenic feature in these disorders is a microvascular lesion that results in luminal narrowing, often due to the deposition of fibrin and platelets. These vascular changes

Figure 14-15 Microangiopathic hemolytic anemia. A peripheral blood smear from a person with hemolytic-uremic syndrome shows several fragmented red cells. (Courtesy Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas.)

produce shear stresses that mechanically injure passing red cells. Regardless of the cause, traumatic damage leads to the appearance of red cell fragments (*schistocytes*), “burr cells,” “helmet cells,” and “triangle cells” in blood smears (Fig. 14-15).

KEY CONCEPTS

Hereditary Spherocytosis

- Autosomal dominant disorder caused by mutations that affect the red cell membrane skeleton, leading to loss of membrane and eventual conversion of red cells to spherocytes, which are phagocytosed and removed in the spleen
- Manifested by anemia, splenomegaly

Thalassemias

- Autosomal codominant disorders caused by mutations in α - or β -globin that reduce hemoglobin synthesis, resulting in a microcytic, hypochromic anemia.
- In β -thalassemia, unpaired α -globin chains form aggregates that damage red cell precursors and further impair erythropoiesis.

Sickle Cell Anemia

- Autosomal recessive disorder resulting from a mutation in β -globin that causes deoxygenated hemoglobin to self-associate into long polymers that distort (sickle) the red cell
- Blockage of vessels by sickled cells causes pain crises and tissue infarction, particularly of the marrow and spleen
- Red cell membrane damage caused by repeated bouts of sickling results in a moderate to severe hemolytic anemia

Glucose-6-Phosphate Dehydrogenase Deficiency

- X-linked disorder caused by mutations that destabilize G6PD, making red cells susceptible to oxidant damage

Immunoheolytic Anemias

- Caused by antibodies against either normal red cell constituents or antigens modified by haptens (e.g., drugs)
- Antibody binding results in either red cell opsonization and extravascular hemolysis or (uncommonly) complement fixation and intravascular hemolysis

Anemias of Diminished Erythropoiesis

Although the anemias that stem from the inadequate production of red cells are heterogeneous, they can be classified into several major categories based on pathophysiology (Table 14-1). The most common and important anemias associated with red cell underproduction are those caused by nutritional deficiencies, followed by those that arise secondary to renal failure and chronic inflammation. Also included are less common disorders that lead to generalized bone marrow failure, such as aplastic anemia, primary hematopoietic neoplasms (Chapter 13), and infiltrative disorders that lead to marrow replacement (e.g., metastatic cancer and disseminated granulomatous disease). We first discuss the extrinsic causes of diminished erythropoiesis, which are more common and clinically important, and then nonneoplastic intrinsic causes.

Megaloblastic Anemias

The common theme among the various causes of megaloblastic anemia is an impairment of DNA synthesis that leads to ineffective hematopoiesis and distinctive morphologic changes, including abnormally large erythroid precursors and red cells. The causes of megaloblastic anemias are given in Table 14-5. The following discussion first describes the common features and then turns to the two principal types: pernicious anemia (the major form

of vitamin B₁₂ deficiency anemia) and folate deficiency anemia.

Some of the metabolic roles of vitamin B₁₂ and folate are considered later. For now it suffices that vitamin B₁₂ and folic acid are coenzymes required for the synthesis of thymidine, one of the four bases found in DNA. A deficiency of these vitamins or impairment in their metabolism results in defective nuclear maturation due to deranged or inadequate DNA synthesis, with an attendant delay or block in cell division.

MORPHOLOGY

Certain peripheral blood findings are shared by all megaloblastic anemias. The presence of red cells that are macrocytic and oval (**macro-ovalocytes**) is highly characteristic. Because they are larger than normal and contain ample hemoglobin, most macrocytes lack the central pallor of normal red cells and even appear “hyperchromic,” but the MCHC is not elevated. There is marked variation in the size (anisocytosis) and shape (poikilocytosis) of red cells. The reticulocyte count is low. Nucleated red cell progenitors occasionally appear in the circulating blood when anemia is severe. Neutrophils are also larger than normal (macropolymorphonuclear) and show **nuclear hypersegmentation**, having five or more nuclear lobules instead of the normal three to four (Fig. 14-16).

The marrow is usually markedly hypercellular as a result of increased hematopoietic precursors, which often completely replace the fatty marrow. **Megaloblastic changes** are detected at all stages of erythroid development. The most primitive cells (promegaloblasts) are large, with a deeply basophilic cytoplasm, prominent nucleoli, and a distinctive, fine nuclear chromatin pattern (Fig. 14-17). As these cells differentiate and begin to accumulate hemoglobin, the nucleus retains its finely distributed chromatin and fails to develop the clumped pyknotic chromatin typical of normoblasts. While nuclear maturation is delayed, cytoplasmic maturation and hemoglobin accumulation proceed at a normal pace, leading to nuclear-to-cytoplasmic asynchrony. Because DNA synthesis is impaired in all proliferating cells, granulocytic precursors also display dysmaturation in the form of **giant metamyelocytes and band forms**. Megakaryocytes, too, can be abnormally large and have bizarre, multilobate nuclei.

The marrow hyperplasia is a response to increased levels of growth factors, such as erythropoietin. However, the derangement in DNA synthesis causes most precursors to undergo apoptosis in the marrow (an example of ineffective hematopoiesis) and leads to pancytopenia. The anemia is further exacerbated by a mild degree of red cell hemolysis of uncertain etiology.

Table 14-5 Causes of Megaloblastic Anemia

Vitamin B₁₂ Deficiency
Decreased Intake
Inadequate diet, vegetarianism
Impaired Absorption
Intrinsic factor deficiency
Pernicious anemia
Gastrectomy
Malabsorption states
Diffuse intestinal disease (e.g., lymphoma, systemic sclerosis)
Ileal resection, ileitis
Competitive parasitic uptake
Fish tapeworm infestation
Bacterial overgrowth in blind loops and diverticula of bowel
Folic Acid Deficiency
Decreased Intake
Inadequate diet, alcoholism, infancy
Impaired Absorption
Malabsorption states
Intrinsic intestinal disease
Anticonvulsants, oral contraceptives
Increased Loss
Hemodialysis
Increased Requirement
Pregnancy, infancy, disseminated cancer, markedly increased hematopoiesis
Impaired Utilization
Folic acid antagonists
Unresponsive to Vitamin B₁₂ or Folic Acid Therapy
Metabolic Inhibitors of DNA Synthesis and/or Folate Metabolism (e.g., Methotrexate)

Modified from Beck WS: Megaloblastic anemias. In Wyngaarden JB, Smith LH (eds): Cecil Textbook of Medicine, 18th ed. Philadelphia, WB Saunders, 1988, p. 900.

Anemias of Vitamin B₁₂ Deficiency: Pernicious Anemia
Pernicious anemia is a specific form of megaloblastic anemia caused by an autoimmune gastritis that impairs the production of intrinsic factor, which is required for vitamin B₁₂ uptake from the gut.

Normal Vitamin B₁₂ Metabolism. Vitamin B₁₂ is a complex organometallic compound also known as cobalamin. Under normal circumstances humans are totally dependent on dietary vitamin B₁₂. Microorganisms are the source of cobalamin in the food chain. Plants and vegetables contain little cobalamin, save that contributed by microbial

Figure 14-16 Megaloblastic anemia. A peripheral blood smear shows a hypersegmented neutrophil with a six-lobed nucleus. (Courtesy Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas.)

contamination, and strictly vegetarian or macrobiotic diets do not provide adequate amounts of this essential nutrient. The daily requirement is 2 to 3 μg . A diet that includes animal products contains significantly larger amounts and normally results in the accumulation of intrahepatic stores of vitamin B₁₂ that are sufficient to last for several years.

Absorption of vitamin B₁₂ requires intrinsic factor, which is secreted by the parietal cells of the fundic mucosa (Fig. 14-18). Vitamin B₁₂ is freed from binding proteins in food through the action of pepsin in the stomach and binds to a salivary protein called *haptocorrin*. In the duodenum, bound vitamin B₁₂ is released from haptocorrin by the action of pancreatic proteases and it associates with intrinsic factor. This complex is transported to the ileum, where it is endocytosed by ileal enterocytes that express a receptor for intrinsic factor called *cubilin* on their surfaces. Within ileal cells, vitamin B₁₂ associates with a major carrier

Figure 14-17 Megaloblastic anemia (bone marrow aspirate). **A** to **C**, Megaloblasts in various stages of differentiation. Note that the orthochromatic megaloblast (**B**) is hemoglobinized (as revealed by cytoplasmic color), but in contrast to normal orthochromatic normoblasts, the nucleus is not pyknotic. The early erythroid precursors (**A** and **C**) and the granulocytic precursors are also large and have abnormally immature chromatin. Figure 14-19 Relationship of N^5 -methyl FH_4 , methionine synthase, and thymidylate synthetase. In cobalamin (Cbl) deficiency, folate is sequestered as N^5 -methyl FH_4 . This ultimately deprives thymidylate synthetase of its folate coenzyme ($N^{5,10}$ -methylene FH_4), thereby impairing DNA synthesis. FH_4 , Tetrahydrofolic acid.

protein, transcobalamin II, and is secreted into the plasma. Transcobalamin II delivers vitamin B_{12} to the liver and other cells of the body, including rapidly proliferating cells in the bone marrow and the gastrointestinal tract. In addition to this major pathway, there is also a poorly understood alternative uptake mechanism that is not dependent on intrinsic factor or an intact terminal ileum. Up to 1% of a large oral dose can be absorbed by this pathway, making it feasible to treat pernicious anemia with high doses of oral vitamin B_{12} .

Biochemical Functions of Vitamin B_{12} . Only two reactions in humans are known to require vitamin B_{12} . In one, methylcobalamin serves as an essential cofactor in the conversion of homocysteine to methionine by methionine synthase (Fig. 14-19). In the process, methylcobalamin yields a methyl group that is recovered from N^5 -methyltetrahydrofolic acid (N^5 -methyl FH_4), the principal form of folate in plasma. In the same reaction, N^5 -methyl FH_4 is converted to tetrahydrofolic acid (FH_4). FH_4 is crucial, because it is required (through its derivative $N^{5,10}$ -methylene FH_4) for the conversion of deoxyuridine monophosphate (dUMP) to deoxythymidine monophosphate (dTMP), a building block for DNA. It is postulated that the fundamental cause of the impaired DNA synthesis in vitamin B_{12} deficiency is the reduced availability of FH_4 , most of which is “trapped” as N^5 -methyl FH_4 . The FH_4 deficit may be further exacerbated by an “internal” folate deficiency caused by a failure to synthesize metabolically active polyglutamylated forms. This stems from the requirement for vitamin B_{12} in the synthesis of methionine, which contributes a carbon group needed in the metabolic reactions that create folate polyglutamates (Fig. 14-20). Whatever the mechanism, lack of folate is the proximate cause of anemia in vitamin B_{12} deficiency, because the anemia improves with administration of folic acid.

The neurologic complications associated with vitamin B_{12} deficiency are more enigmatic, because they are not improved (and may actually be worsened) by folate administration. The other known reaction that depends on vitamin B_{12} is the isomerization of methylmalonyl coenzyme A to succinyl coenzyme A, which requires

adenosylcobalamin as a prosthetic group on the enzyme methylmalonyl-coenzyme A mutase. A deficiency of vitamin B_{12} thus leads to increased plasma and urine levels of methylmalonic acid. Interruption of this reaction and the consequent buildup of methylmalonate and propionate (a precursor) could lead to the formation and incorporation of abnormal fatty acids into neuronal lipids. It has been suggested that this biochemical abnormality predisposes to myelin breakdown and thereby produces the neurologic complications of vitamin B_{12} deficiency (Chapter 28). However, rare individuals with hereditary deficiencies of methylmalonyl-coenzyme A mutase do not suffer from the neurologic abnormalities seen in vitamin B_{12} deficiency, casting doubt on this explanation.

Pernicious Anemia

Incidence. Although somewhat more prevalent in Scandinavian and other Caucasian populations, pernicious anemia occurs in all racial groups, including blacks and Hispanics. It is a disease of older adults; the median age at diagnosis is 60 years, and it is rare in people younger than 30. A genetic predisposition is strongly suspected, but no definable genetic pattern of transmission has been discerned. As described later, many affected individuals have a tendency to form antibodies against multiple self-antigens.

Pathogenesis. Pernicious anemia is believed to result from an autoimmune attack on the gastric mucosa. Histologically, there is a *chronic atrophic gastritis* marked by a loss of parietal cells, a prominent infiltrate of lymphocytes and plasma cells, and megaloblastic changes in mucosal cells similar to those found in erythroid precursors. Three types of auto-antibodies are present in many, but not all, patients. About 75% of patients have a *type I antibody* that blocks the binding of vitamin B_{12} to intrinsic factor. Type I antibodies are found in both plasma and gastric juice. *Type II antibodies* prevent binding of the intrinsic factor-vitamin B_{12} complex to its ileal receptor. These antibodies are also found in a large proportion of patients with pernicious anemia. *Type III antibodies* are present in 85% to 90% of patients and recognize the α and β subunits of the gastric proton pump, which is normally localized to the microvilli of the canalicular system of the gastric parietal cell. Type III

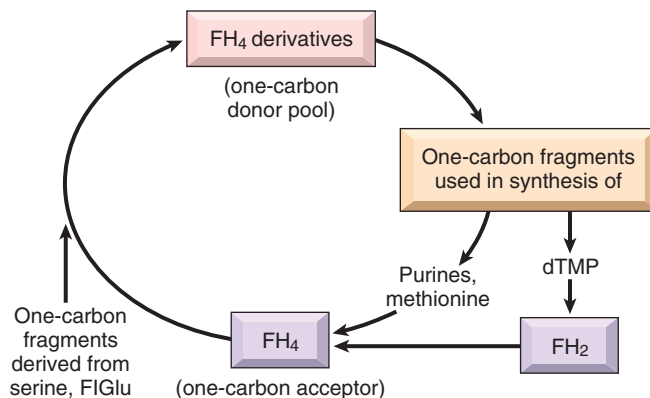

Figure 14-20 Role of folate derivatives in the transfer of one-carbon fragments for synthesis of biologic macromolecules. FH_4 , Tetrahydrofolic acid; FH_2 , dihydrofolic acid; FIGlu, formiminoglutamate; dTMP, deoxythymidine monophosphate.

antibodies are not specific, in that they are found in as many as 50% of older adults with idiopathic chronic gastritis not associated with pernicious anemia.

Autoantibodies are of diagnostic utility, but they are not thought to be the primary cause of the gastric pathology; rather, it seems that an autoreactive T-cell response initiates gastric mucosal injury and triggers the formation of autoantibodies. When the mass of intrinsic factor-secreting cells falls below a threshold (and reserves of stored vitamin B₁₂ are depleted), anemia develops. The common association of pernicious anemia with other autoimmune disorders, particularly autoimmune thyroiditis and adrenalitis, is also consistent with an underlying immune basis. The tendency to develop pernicious anemia (as well as other autoimmune disorders) is linked to genetic variants involving the inflammasome, suggesting that altered innate immunity may also play some role.

Vitamin B₁₂ deficiency is associated with disorders other than pernicious anemia. Most of these impair absorption of the vitamin at one of the steps outlined earlier (Table 14-5). With achlorhydria and loss of pepsin secretion (which occurs in some older adults), vitamin B₁₂ is not readily released from proteins in food. With gastrectomy, intrinsic factor is not available for uptake in the ileum. With loss of exocrine pancreatic function, vitamin B₁₂ cannot be released from haptocorrin-vitamin B₁₂ complexes. Ileal resection or diffuse ileal disease can remove or damage the site of intrinsic factor-vitamin B₁₂ complex absorption. Certain tapeworms (particularly those acquired by eating raw fish) compete with the host for B₁₂ and can induce a deficiency state. In some settings, such as pregnancy, hyperthyroidism, disseminated cancer, and chronic infection, an increased demand for vitamin B₁₂ can produce a relative deficiency, even with normal absorption.

MORPHOLOGY

The findings in the bone marrow and blood in pernicious anemia are similar to those described earlier for all megaloblastic anemias. The stomach typically shows diffuse chronic gastritis (Chapter 17). The most characteristic alteration is **fundic gland atrophy**, affecting both chief cells and parietal cells, the latter being virtually absent. The glandular epithelium is replaced by mucus-secreting goblet cells that resemble those lining the large intestine, a form of metaplasia referred to as **intestinalization**. Some of the cells as well as their nuclei may increase to double the normal size, a “megaloblastic” change analogous to that seen in the marrow. With time, the tongue may become shiny, glazed, and “beefy” (**atrophic glossitis**). The gastric atrophy and metaplastic changes are due to autoimmunity and not vitamin B₁₂ deficiency; hence, parenteral administration of vitamin B₁₂ corrects the megaloblastic changes in the marrow and the epithelial cells of the alimentary tract, but gastric atrophy and achlorhydria persist.

Central nervous system lesions are found in about three fourths of all cases of florid pernicious anemia but can also be seen in the absence of overt hematologic findings. The principal alterations involve the cord, where there is **demyelination of the dorsal and lateral spinal tracts**, sometimes followed by loss of axons. These changes give rise to spastic paraparesis, sensory ataxia, and severe paresthesias in the lower limbs. Less frequently, degenerative changes occur in the ganglia of the posterior roots and in peripheral nerves (Chapter 28).

Clinical Features

Pernicious anemia is insidious in onset, and the anemia is often quite severe by the time it comes to medical attention. The course is progressive unless halted by therapy.

The diagnosis is based on (1) a moderate to severe megaloblastic anemia, (2) leukopenia with hypersegmented granulocytes, (3) low serum vitamin B₁₂, and (4) elevated serum levels of homocysteine and methylmalonic acid. The diagnosis is confirmed by an outpouring of reticulocytes and a rise in hematocrit levels beginning about 5 days after parenteral administration of vitamin B₁₂. Serum antibodies to intrinsic factor are highly specific for pernicious anemia. Their presence attests to the cause rather than the presence or absence of vitamin B₁₂ deficiency.

Persons with atrophy and metaplasia of the gastric mucosa associated with pernicious anemia have an increased risk of gastric carcinoma (Chapter 17). Elevated homocysteine levels are a risk factor for atherosclerosis and thrombosis, and it is suspected that vitamin B₁₂ deficiency may increase the incidence of vascular disease on this basis. With parenteral or high-dose oral vitamin B₁₂, the anemia is cured and the progression of the peripheral neurologic disease can be reversed or at least halted, but the changes in the gastric mucosa and the risk of carcinoma are unaffected.

Anemia of Folate Deficiency

A deficiency of folic acid (more properly, pteroylmonoglutamic acid) results in a megaloblastic anemia having the same pathologic features as that caused by vitamin B₁₂ deficiency. FH₄ derivatives act as intermediates in the transfer of one-carbon units such as formyl and methyl groups to various compounds (Fig. 14-20). FH₄ serves as an acceptor of one-carbon fragments from compounds such as serine and formiminoglutamic acid. The FH₄ derivatives so generated in turn donate the acquired one-carbon fragments in reactions synthesizing various metabolites. FH₄, then, can be viewed as the biologic “middleman” in a series of swaps involving one-carbon moieties. The most important metabolic processes depending on such transfers are (1) purine synthesis; (2) the conversion of homocysteine to methionine, a reaction also requiring vitamin B₁₂; and (3) deoxythymidylate monophosphate (dTMP) synthesis. In the first two reactions, tetrahydrofolate (FH₄) is regenerated from its one-carbon carrier derivatives and is available to accept another one-carbon moiety and reenter the donor pool. In the synthesis of dTMP, a dihydrofolate (FH₂) is produced that must be reduced by dihydrofolate reductase for reentry into the FH₄ pool. The reductase step is significant, because this enzyme is susceptible to inhibition by various drugs. Among the molecules whose synthesis is dependent on folates, dTMP is perhaps the most important biologically, because it is required for DNA synthesis. It should be apparent from this discussion that **suppressed synthesis of DNA, the common denominator of folic acid and vitamin B₁₂ deficiency, is the immediate cause of megaloblastosis.**

Etiology. The three major causes of folic acid deficiency are (1) decreased intake, (2) increased requirements, and (3) impaired utilization (Table 14-5). Humans are entirely dependent on dietary sources for their folic acid

requirement, which is 50 to 200 µg daily. Most normal diets contain ample amounts. The richest sources are green vegetables such as lettuce, spinach, asparagus, and broccoli. Certain fruits (e.g., lemons, bananas, melons) and animal sources (e.g., liver) contain lesser amounts. The folic acid in these foods is largely in the form of polyglutamates. Despite their abundance in raw foods, polyglutamates are sensitive to heat; boiling, steaming, or frying of foods for 5 to 10 minutes destroys up to 95% of the folate content. Intestinal conjugases split the polyglutamates into monoglutamates that are readily absorbed in the proximal jejunum. During intestinal absorption they are modified to 5-methyltetrahydrofolate, the normal transport form of folate. The body's reserves of folate are relatively modest, and a deficiency can arise within weeks to months if intake is inadequate.

Decreased intake can result from either a nutritionally inadequate diet or impairment of intestinal absorption. A normal diet contains folate in excess of the minimal daily adult requirement. Inadequate dietary intakes are almost invariably associated with grossly deficient diets. Such dietary inadequacies are most frequently encountered in chronic alcoholics, the indigent, and the very old. In alcoholics with cirrhosis, other mechanisms of folate deficiency such as trapping of folate within the liver, excessive urinary loss, and disordered folate metabolism have also been implicated. Under these circumstances, the megaloblastic anemia is often accompanied by general malnutrition and manifestations of other avitaminoses, including cheilosis, glossitis, and dermatitis. Malabsorption syndromes, such as sprue, can lead to inadequate absorption of this nutrient, as can diffuse infiltrative diseases of the small intestine (e.g., lymphoma). In addition, certain drugs, particularly the anticonvulsant phenytoin and oral contraceptives, interfere with absorption.

Despite normal intake of folic acid, a *relative deficiency* can be encountered when requirements are increased. Conditions in which this is seen include pregnancy, infancy, derangements associated with hyperactive hematopoiesis (hemolytic anemias), and disseminated cancer. In all these circumstances the demands of increased DNA synthesis render normal intake inadequate.

Folic acid antagonists, such as methotrexate, inhibit dihydrofolate reductase and lead to a deficiency of FH₄. With inhibition of folate metabolism, all rapidly growing cells are affected, but particularly the cells of the bone marrow and the gastrointestinal tract. Many chemotherapeutic drugs used in the treatment of cancer damage DNA or inhibit DNA synthesis through other mechanisms; these can also cause megaloblastic changes in rapidly dividing cells.

As mentioned at the outset, the megaloblastic anemia that results from a deficiency of folic acid is identical to that encountered in vitamin B₁₂ deficiency. Thus, the diagnosis of folate deficiency can be made only by demonstration of decreased folate levels in the serum or red cells. As in vitamin B₁₂ deficiency, serum homocysteine levels are increased, but methylmalonate concentrations are normal. Importantly, neurologic changes do not occur.

Although prompt hematologic response heralded by reticulocytosis follows the administration of folic acid, it should be remembered that the hematologic symptoms of vitamin B₁₂ deficiency anemia also respond to folate

therapy. As already mentioned, folate does not prevent (and may even exacerbate) the neurologic deficits seen in vitamin B₁₂ deficiency states. It is thus essential to exclude vitamin B₁₂ deficiency in megaloblastic anemia before initiating therapy with folate.

Iron Deficiency Anemia

Deficiency of iron is the most common nutritional disorder in the world and results in a clinical signs and symptoms that are mostly related to inadequate hemoglobin synthesis. Although the prevalence of iron deficiency anemia is higher in developing countries, this form of anemia is common in the United States, particularly in toddlers, adolescent girls, and women of childbearing age. The factors underlying the iron deficiency differ somewhat in various population groups and can be best considered in the context of normal iron metabolism.

Iron Metabolism. The normal daily Western diet contains about 10 to 20 mg of iron, most in the form of heme contained in animal products, with the remainder being inorganic iron in vegetables. About 20% of heme iron (in contrast to 1% to 2% of nonheme iron) is absorbable, so the average Western diet contains sufficient iron to balance fixed daily losses. The total body iron content is normally about 2.5 gm in women and as high as 6 gm in men, and can be divided into functional and storage compartments (Table 14-6). About 80% of the functional iron is found in hemoglobin; myoglobin and iron-containing enzymes such as catalase and the cytochromes contain the rest. The storage pool represented by hemosiderin and ferritin contains about 15% to 20% of total body iron. The major sites of iron storage are the liver and mononuclear phagocytes. Healthy young females have smaller stores of iron than do males, primarily because of blood loss during menstruation, and often develop iron deficiency due to excessive losses or increased demands associated with menstruation and pregnancy, respectively.

Iron in the body is recycled between the functional and storage pools (Fig. 14-21). It is transported in plasma by an iron-binding glycoprotein called *transferrin*, which is synthesized in the liver. In normal individuals, transferrin is about one third saturated with iron, yielding serum iron levels that average 120 µg/dL in men and 100 µg/dL in women. The major function of plasma transferrin is to deliver iron to cells, including erythroid precursors, which require iron to synthesize hemoglobin. Erythroid precursors possess high-affinity receptors for transferrin that mediate iron import through receptor-mediated endocytosis.

Table 14-6 Iron Distribution in Healthy Young Adults (mg)

Pool	Men	Women
Total	3450	2450
Functional	2100	1750
Hemoglobin	300	250
Myoglobin	50	50
Enzymes		
Storage	1000	400
Ferritin, hemosiderin		

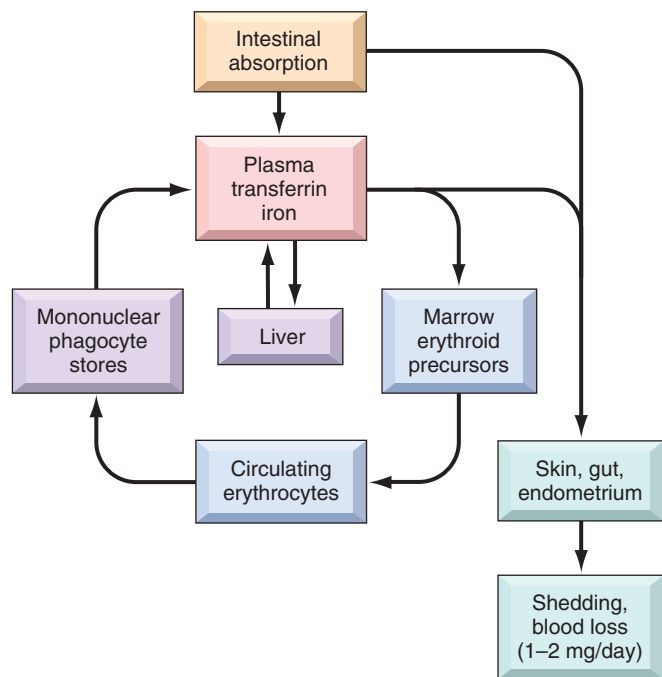

Figure 14-21 Iron metabolism. Iron absorbed from the gut is bound to plasma transferrin and transported to the marrow, where it is delivered to developing red cells and incorporated into hemoglobin. Mature red cells are released into the circulation and, after 120 days, are ingested by macrophages, primarily in the spleen, liver, and bone marrow. Here iron is extracted from hemoglobin and recycled to plasma transferrin. At equilibrium, iron absorbed from the gut is balanced by losses in shed keratinocytes, enterocytes, and (in women) endometrium.

Free iron is highly toxic (Chapter 18), and it is therefore important that storage iron be sequestered. This is achieved by binding of iron in the storage pool to either ferritin or hemosiderin. *Ferritin* is a ubiquitous protein-iron complex that is found at highest levels in the liver, spleen, bone marrow, and skeletal muscles. In the liver, most ferritin is stored within the parenchymal cells; in other tissues, such as the spleen and the bone marrow, it is found mainly in macrophages. Hepatocyte iron is derived from plasma transferrin, whereas storage iron in macrophages is derived from the breakdown of red cells. Intracellular ferritin is located in the cytosol and in lysosomes, in which partially degraded protein shells of ferritin aggregate into *hemosiderin* granules. Iron in hemosiderin is chemically reactive and turns blue-black when exposed to potassium ferrocyanide, which is the basis for the *Prussian blue stain*. With normal iron stores, only trace amounts of hemosiderin are found in the body, principally in macrophages in the bone marrow, spleen, and liver, most being stored as ferritin. In iron-overloaded cells, most iron is stored in hemosiderin.

Because plasma ferritin is derived largely from the storage pool of body iron, its levels correlate well with body iron stores. In iron deficiency, serum ferritin is below 12 $\mu\text{g/L}$, whereas in iron overload values approaching 5000 $\mu\text{g/L}$ may be seen. Of physiologic importance, the storage iron pool can be readily mobilized if iron requirements increase, as may occur after loss of blood.

Iron is both essential for cellular metabolism and highly toxic in excess, and total body iron stores must therefore be regulated meticulously. Iron balance is maintained by

regulating the absorption of dietary iron in the proximal duodenum. There is no regulated pathway for iron excretion, which is limited to the 1 to 2 mg lost each day through the shedding of mucosal and skin epithelial cells. In contrast, as body iron stores increase, absorption falls, and vice versa.

The pathways responsible for the absorption of iron are now understood in reasonable detail (Fig. 14-22), and differ partially for nonheme and heme iron. Luminal nonheme iron is mostly in the Fe^{3+} (ferric) state and must first be reduced to Fe^{2+} (ferrous) iron by ferrireductases, such as b cytochromes and STEAP3. Fe^{2+} iron is then transported across the apical membrane by divalent metal transporter 1 (DMT1). The absorption of nonheme iron is variable and often inefficient, being inhibited by substances in the diet that bind and stabilize Fe^{3+} iron and enhanced by substances that stabilize Fe^{2+} iron (described later). Frequently, less than 5% of dietary nonheme iron is absorbed. In contrast, about 25% of the heme iron derived from hemoglobin, myoglobin, and other animal proteins is absorbed. Heme iron is moved across the apical membrane into the cytoplasm through transporters that are incompletely characterized. Here, it is metabolized to release Fe^{2+} iron, which enters a common pool with nonheme Fe^{2+} iron.

Iron that enters the duodenal cells can follow one of two pathways: transport to the blood or storage as mucosal iron. This distribution is influenced by body iron stores. Fe^{2+} iron destined for the circulation is transported from the cytoplasm across the basolateral enterocyte membrane by ferroportin. This process is coupled to the oxidation of Fe^{2+} iron to Fe^{3+} iron, which is carried out by the iron oxidases hephaestin and ceruloplasmin. Newly absorbed Fe^{3+} iron binds rapidly to the plasma protein transferrin, which delivers iron to red cell progenitors in the marrow (Fig. 14-21). Both DMT1 and ferroportin are widely distributed in the body and are involved in iron transport in other tissues as well. For example, DMT1 also mediates the uptake of “functional” iron (derived from endocytosed transferrin) across lysosomal membranes into the cytosol of red cell precursors in the bone marrow, and ferroportin plays an important role in the release of storage iron from macrophages.

Iron absorption is regulated by hepcidin, a small circulating peptide that is synthesized and released from the liver in response to increases in intrahepatic iron levels. Hepcidin inhibits iron transfer from the enterocyte to plasma by binding to ferroportin and causing it to be endocytosed and degraded. As a result, as hepcidin levels rise, iron becomes trapped within duodenal cells in the form of mucosal ferritin and is lost as these cells are sloughed. Thus, when the body is replete with iron, high hepcidin levels inhibit its absorption into the blood. Conversely, with low body stores of iron, hepcidin synthesis falls and this in turn facilitates iron absorption. By inhibiting ferroportin, hepcidin not only reduces iron uptake from enterocytes but also suppresses iron release from macrophages, which are an important source of the iron that is used by erythroid precursors to make hemoglobin. This, as we shall see, is important in the pathogenesis of anemia of chronic diseases.

Alterations in hepcidin have a central role in diseases involving disturbances of iron metabolism. This is illustrated by the following examples.

Figure 14-22 Regulation of iron absorption. Duodenal epithelial cell uptake of heme and nonheme iron is depicted. When the storage sites of the body are replete with iron and erythropoietic activity is normal, plasma hepcidin levels are high. This leads to down-regulation of ferroportin and trapping of most of the absorbed iron, which is lost when duodenal epithelial cells are shed into the gut. Conversely, when body iron stores decrease or when erythropoiesis is stimulated, hepcidin levels fall and ferroportin activity increases, allowing a greater fraction of the absorbed iron to be transferred to plasma transferrin. *DMT1*, Divalent metal transporter 1.

- As will be described subsequently, the *anemia of chronic disease* (perhaps more accurately referred to as the anemia of chronic inflammation) is caused in part by inflammatory mediators that increase hepatic hepcidin production.
- A rare form of microcytic anemia is caused by mutations that disable *TMPRSS6*, a hepatic transmembrane serine protease that normally suppresses hepcidin production when iron stores are low. Affected patients have high hepcidin levels, resulting in reduced iron absorption and failure to respond to iron therapy.
- Conversely, hepcidin activity is inappropriately low in both primary and secondary *hemochromatosis*, a syndrome caused by systemic iron overload.
- Secondary hemochromatosis can occur in diseases associated with *ineffective erythropoiesis*, such as β -thalassemia major and myelodysplastic syndromes (Chapter 13). Through incompletely understood mechanisms, ineffective erythropoiesis suppresses hepatic hepcidin production, even when iron stores are high. As discussed in Chapter 18, the various inherited forms of primary hemochromatosis are associated with mutations in hepcidin or the genes that regulate hepcidin expression.

Etiology. Iron deficiency can result from (1) dietary lack, (2) impaired absorption, (3) increased requirement, or (4) chronic blood loss. To maintain a normal iron balance, about 1 mg of iron must be absorbed from the diet every day. Because only 10% to 15% of ingested iron is absorbed, the daily iron requirement is 7 to 10 mg for adult men and 7 to 20 mg for adult women. Because the average daily dietary intake of iron in the Western world is about 15 to 20 mg, most men ingest more than adequate iron, whereas many women consume marginally adequate amounts of iron. The bioavailability of dietary iron is as important as the overall content. Heme iron is much more absorbable than inorganic iron, the absorption of which is influenced by other dietary contents. Absorption of inorganic iron is

enhanced by ascorbic acid, citric acid, amino acids, and sugars in the diet, and inhibited by tannates (found in tea), carbonates, oxalates, and phosphates.

Dietary lack is rare in developed countries, where on average about two thirds of the dietary iron is in the readily absorbed heme form provided by meat. The situation is different in developing countries, where food is less abundant and most iron in the diet is found in plants in the poorly absorbable inorganic form. Dietary iron inadequacy occurs in even privileged societies in the following groups:

- *Infants*, who are at high risk due to the very small amounts of iron in milk. Human breast milk provides only about 0.3 mg/L of iron. Cow's milk contains about twice as much iron, but its bioavailability is poor.
- *The impoverished*, who can have suboptimal diets for socioeconomic reasons at any age
- *Older adults*, who often have restricted diets with little meat because of limited income or poor dentition
- *Teenagers* who subsist on "junk" food

Impaired absorption is found in sprue, other causes of fat malabsorption (steatorrhea), and chronic diarrhea. Gastrectomy impairs iron absorption by decreasing the acidity of the proximal duodenum (which enhances uptake), and also by increasing the speed with which gut contents pass through the duodenum. Specific items in the diet, as is evident from the preceding discussion, can also affect absorption.

Increased requirement is an important cause of iron deficiency in growing infants, children, and adolescents, as well as premenopausal women, particularly during pregnancy. Economically deprived women having multiple, closely spaced pregnancies are at exceptionally high risk.

Chronic blood loss is the most common cause of iron deficiency in the Western world. External hemorrhage or bleeding into the gastrointestinal, urinary, or genital tracts depletes iron reserves. Iron deficiency in adult men and postmenopausal women in the Western world must be

attributed to gastrointestinal blood loss until proven otherwise. To prematurely ascribe iron deficiency in such individuals to any other cause is to run the risk of missing an occult gastrointestinal cancer or other bleeding lesion. An alert clinician investigating unexplained iron deficiency anemia occasionally discovers an occult bleeding source such as a cancer and thereby saves a life.

Pathogenesis. Whatever its basis, iron deficiency produces a *hypochromic microcytic anemia*. At the outset of chronic blood loss or other states of negative iron balance, reserves in the form of ferritin and hemosiderin may be adequate to maintain normal hemoglobin and hematocrit levels as well as normal serum iron and transferrin saturation. Progressive depletion of these reserves first lowers serum iron and transferrin saturation levels without producing anemia. In this early stage there is increased erythroid activity in the bone marrow. Anemia appears only when iron stores are completely depleted and is accompanied by lower than normal serum iron, ferritin, and transferrin saturation levels.

MORPHOLOGY

The bone marrow reveals a mild to moderate increase in erythroid progenitors. A diagnostically significant finding is the **disappearance of stainable iron from macrophages in the bone marrow**, which is best assessed by performing Prussian blue stains on smears of aspirated marrow. In peripheral blood smears, the red cells are small (**microcytic**) and pale (**hypochromic**). Normal red cells with sufficient hemoglobin have a zone of central pallor measuring about one third of the cell diameter. In established iron deficiency the zone of pallor is enlarged; hemoglobin may be seen only in a narrow peripheral rim (Fig. 14-23). Poikilocytosis in the form of small, elongated red cells (pencil cells) is also characteristically seen.

Clinical Features

The clinical manifestations of the anemia are nonspecific and were detailed earlier. The dominating signs and symptoms frequently relate to the underlying cause of the anemia, for example, gastrointestinal or gynecologic disease, malnutrition, pregnancy, and malabsorption. In severe and long-standing iron deficiency, depletion of

Figure 14-23 Hypochromic microcytic anemia of iron deficiency (peripheral blood smear). Note the small red cells containing a narrow rim of peripheral hemoglobin. Scattered fully hemoglobinized cells, present due to recent blood transfusion, stand in contrast. (Courtesy Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas.)

iron-containing enzymes in cells throughout the body also causes other changes, including koilonychia, alopecia, atrophic changes in the tongue and gastric mucosa, and intestinal malabsorption. Depletion of iron from the central nervous system may lead to the appearance of pica, in which affected individuals consume non-foodstuffs such as clay or food ingredients such as flour, and periodically move their limbs during sleep. Esophageal webs appear together with microcytic hypochromic anemia and atrophic glossitis to complete the triad of major findings in the rare *Plummer-Vinson syndrome* (Chapter 17).

The diagnosis of iron deficiency anemia ultimately rests on laboratory studies. Both the hemoglobin and hematocrit are depressed, usually to a moderate degree, in association with hypochromia, microcytosis, and modest poikilocytosis. The serum iron and ferritin are low, and the total plasma iron-binding capacity (reflecting elevated transferrin levels) is high. Low serum iron with increased iron-binding capacity results in a reduction of transferrin saturation to below 15%. Reduced iron stores inhibit hepcidin synthesis, and its serum levels fall. In uncomplicated iron deficiency, oral iron supplementation produces an increase in reticulocytes in about 5 to 7 days that is followed by a steady increase in blood counts and the normalization of red cell indices.

Anemia of Chronic Disease

Impaired red cell production associated with chronic diseases that produce systemic inflammation is perhaps the most common cause of anemia among hospitalized patients in the United States. This form of anemia stems from a reduction in the proliferation of erythroid progenitors and impaired iron utilization. The chronic illnesses associated with this form of anemia can be grouped into three categories:

1. Chronic microbial infections, such as osteomyelitis, bacterial endocarditis, and lung abscess
2. Chronic immune disorders, such as rheumatoid arthritis and regional enteritis
3. Neoplasms, such as carcinomas of the lung and breast, and Hodgkin lymphoma

The anemia of chronic disease occurs in the setting of persistent systemic inflammation and is associated with low serum iron, reduced total iron-binding capacity, and abundant stored iron in tissue macrophages. Several effects of inflammation contribute to the observed abnormalities. Most notably, certain inflammatory mediators, particularly interleukin-6 (IL-6), stimulate an increase in the hepatic production of hepcidin. As was discussed under the anemia of iron deficiency, hepcidin inhibits ferroportin function in macrophages and reduces the transfer of iron from the storage pool to developing erythroid precursors in the bone marrow. As a result, the erythroid precursors are starved for iron in the midst of plenty. In addition, these progenitors do not proliferate adequately because erythropoietin levels are inappropriately low for the degree of anemia. The precise mechanism underlying this reduction in erythropoietin is uncertain, but transgenic mice expressing high levels of hepcidin develop a microcytic anemia associated with low erythropoietin levels, suggesting that hepcidin directly or indirectly suppresses erythropoietin production.

What might be the reason for iron sequestration in the setting of inflammation? The best guess is that it enhances the body's ability to fend off certain types of infection, particularly those caused by bacteria (e.g., *H. influenzae*) that require iron for pathogenicity. In this regard it is interesting to consider that hepcidin is structurally related to defensins, a family of peptides that have intrinsic antibacterial activity. This connection further highlights the poorly understood but intriguing relationship between inflammation, innate immunity, and iron metabolism.

The anemia is usually mild, and the dominant symptoms are those of the underlying disease. The red cells can be normocytic and normochromic, or hypochromic and microcytic, as in anemia of iron deficiency. The presence of increased storage iron in marrow macrophages, a high serum ferritin level, and a reduced total iron-binding capacity readily rule out iron deficiency as the cause of anemia. Only successful treatment of the underlying condition reliably corrects the anemia. However, some patients, particularly those with cancer, benefit from administration of erythropoietin.

Aplastic Anemia

Aplastic anemia refers to a syndrome of chronic primary hematopoietic failure and attendant pancytopenia (anemia, neutropenia, and thrombocytopenia). In the majority of patients autoimmune mechanisms are suspected, but inherited or acquired abnormalities of hematopoietic stem cells also seem to contribute in at least a subset of patients.

Etiology. The most common circumstances associated with aplastic anemia are listed in Table 14-7. Most cases of "known" etiology follow exposure to chemicals and drugs. Certain drugs and agents (including many cancer chemotherapy drugs and the organic solvent benzene) cause marrow suppression that is dose related and reversible. In other instances, aplastic anemia arises in an unpredictable, idiosyncratic fashion following exposure to drugs that normally cause little or no marrow suppression. The implicated drugs include chloramphenicol and gold salts.

Persistent marrow aplasia can also appear after a variety of *viral infections*, most commonly viral hepatitis of the non-A, non-B, non-C, non-G type, which is associated with 5% to 10% of cases. Why aplastic anemia develops in certain individuals is not understood.

Whole-body *irradiation* can destroy hematopoietic stem cells in a dose-dependent fashion. Persons who receive therapeutic irradiation or are exposed to radiation in nuclear accidents (e.g., Chernobyl) are at risk for marrow aplasia.

Specific abnormalities underlie some cases of aplastic aplasia.

- *Fanconi anemia* is a rare autosomal recessive disorder caused by defects in a multiprotein complex that is required for DNA repair (Chapter 7). Marrow hypofunction becomes evident early in life and is often accompanied by multiple congenital anomalies, such as hypoplasia of the kidney and spleen and bone anomalies, which most commonly involve the thumbs or radii.
- Inherited defects in *telomerase* are found in 5% to 10% of adult-onset aplastic anemia. Telomerase is required for

cellular immortality and limitless replication (Chapters 1 and 7). It might be anticipated, therefore, that partial deficits in telomerase activity could result in premature hematopoietic stem cell exhaustion and marrow aplasia.

- Even more common than telomerase mutations are abnormally short telomeres, which are found in the marrow cells of as many as half of those affected with aplastic anemia. It is unknown whether this shortening is due to other unappreciated telomerase defects or is a consequence of excessive stem cell replication.

In most instances, however, no initiating factor can be identified; about 65% of cases fall into this *idiopathic* category.

Pathogenesis. The pathogenesis of aplastic anemia is not fully understood. Indeed, it is unlikely that a single mechanism underlies all cases. However, **two major etiologies have been invoked: an extrinsic, immune-mediated suppression of marrow progenitors, and an intrinsic abnormality of stem cells** (Fig. 14-24).

Experimental studies have focused on a model in which activated T cells suppress hematopoietic stem cells. Stem cells may first be antigenically altered by exposure to drugs, infectious agents, or other unidentified environmental insults. This provokes a cellular immune response, during which activated T_H1 cells produce cytokines such as interferon- γ (IFN- γ) and TNF that suppress and kill hematopoietic progenitors. This scenario is supported by several observations.

- Analysis of the few remaining marrow stem cells from aplastic anemia marrows has revealed that genes

Figure 14-24 Pathophysiology of aplastic anemia. Damaged stem cells can produce progeny expressing neoantigens that evoke an autoimmune reaction, or give rise to a clonal population with reduced proliferative capacity. Either pathway could lead to marrow aplasia. See text for abbreviations.

involved in apoptosis and death pathways are up-regulated; of note, the same genes are up-regulated in normal stem cells exposed to interferon- γ .

- Even more compelling (and clinically relevant) evidence comes from experience with immunosuppressive therapy. Antithymocyte globulin and other immunosuppressive drugs such as cyclosporine produce responses in 60% to 70% of patients. It is proposed that these therapies work by suppressing or killing autoreactive T-cell clones. The antigens recognized by the autoreactive T cells are not well defined. In some instances GPI-linked proteins may be the targets, possibly explaining the previously noted association of aplastic anemia and PNH.

Alternatively, the notion that aplastic anemia results from a fundamental stem cell abnormality is supported by the presence of karyotypic aberrations in many cases; the occasional transformation of aplasias into myeloid neoplasms, typically myelodysplasia or acute myeloid leukemia; and the association with abnormally short telomeres. Some marrow insult (or a predisposition to DNA damage) presumably results in sufficient injury to limit the proliferative and differentiation capacity of stem cells. If the damage is extensive enough, aplastic anemia results. These two mechanisms are not mutually exclusive, because genetically altered stem cells might also express “neoantigens” that could serve as targets for a T-cell attack.

MORPHOLOGY

The markedly hypocellular bone marrow is largely devoid of hematopoietic cells; often only fat cells, fibrous stroma, and scattered lymphocytes and plasma cells remain. Marrow aspirates often yield little material (a “dry tap”); hence, aplasia is best appreciated in marrow biopsies (Fig. 14-25). Other nonspecific pathologic changes are related to granulocytopenia and thrombocytopenia, such as mucocutaneous bacterial infections and abnormal bleeding, respectively. If the anemia necessitates multiple transfusions, systemic hemosiderosis can appear.

Clinical Features

Aplastic anemia can occur at any age and in either sex. The onset is usually insidious. Initial manifestations vary somewhat, depending on which cell line is predominantly affected, but pancytopenia ultimately appears, with the expected consequences. Anemia can cause progressive weakness, pallor, and dyspnea; thrombocytopenia is heralded by petechiae and ecchymoses; and neutropenia manifests as frequent and persistent minor infections or the sudden onset of chills, fever, and prostration. Splenomegaly is characteristically absent; if it is present, the diagnosis of aplastic anemia should be seriously questioned. The red cells are usually slightly macrocytic and normochromic. Reticulocytopenia is the rule.

The diagnosis rests on examination of a bone marrow biopsy. It is important to distinguish aplastic anemia from other causes of pancytopenia, such as “aleukemic”

Figure 14-25 Aplastic anemia (bone marrow biopsy). Markedly hypocellular marrow contains mainly fat cells. **A**, Low power. **B**, High power. (Courtesy Dr. Steven Kroft, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas.)

leukemia and myelodysplastic syndromes (Chapter 13), which can have identical clinical manifestations. In aplastic anemia, the marrow is hypocellular (and usually markedly so), whereas myeloid neoplasms are associated with hypercellular marrows filled with neoplastic progenitors.

The prognosis is variable. Bone marrow transplantation is the treatment of choice in those with a suitable donor and provides a 5-year survival of more than 75%. Older patients or those without suitable donors often respond well to immunosuppressive therapy.

Pure Red Cell Aplasia

Pure red cell aplasia is a primary marrow disorder in which only erythroid progenitors are suppressed. In severe cases, red cell progenitors are completely absent from the marrow. It may occur in association with neoplasms, particularly thymoma and large granular lymphocytic leukemia (Chapter 13), drug exposures, autoimmune disorders, and parvovirus infection (see later). With the exception of those with parvovirus infection, it is likely that most cases have an autoimmune basis. When a thymoma is present, resection leads to hematologic improvement in about half of the patients. In patients without thymoma, immunosuppressive therapy is often beneficial. Plasmapheresis may also be helpful in unusual patients with pathogenic autoantibodies, such as neutralizing antibodies to erythropoietin that appear de novo or following the administration of recombinant erythropoietin.

A special form of red cell aplasia occurs in individuals infected with parvovirus B19, which preferentially infects and destroys red cell progenitors. Normal individuals clear parvovirus infections within 1 to 2 weeks; as a result, the aplasia is transient and clinically unimportant. However, in persons with moderate to severe hemolytic anemias, even a brief cessation of erythropoiesis results in rapid worsening of the anemia, producing an aplastic crisis. In those who are severely immunosuppressed (e.g., persons with advanced HIV infection), an ineffective immune response sometimes permits the infection to persist, leading to chronic red cell aplasia and a moderate to severe anemia.

Other Forms of Marrow Failure

Myelophthistic anemia describes a form of marrow failure in which space-occupying lesions replace normal marrow elements. The commonest cause is metastatic cancer, most often carcinomas arising in the breast, lung, and prostate. However, any infiltrative process (e.g., granulomatous disease) involving the marrow can produce identical findings. Myelophthistic anemia is also a feature of the spent phase of myeloproliferative disorders (Chapter 13). All of the responsible diseases cause marrow distortion and fibrosis, which act to displace normal marrow elements and disturb mechanisms that regulate the egress of red cells and granulocytes from the marrow. The latter effect causes the abnormal release of nucleated erythroid precursors and immature granulocytic forms (*leukoerythroblastosis*) into peripheral smears, and the appearance of *teardrop-shaped red cells*, which are believed to be deformed during their tortuous escape from the fibrotic marrow.

Chronic renal failure, whatever its cause, is almost invariably associated with an anemia that tends to be roughly proportional to the severity of the uremia. The basis of anemia in renal failure is multifactorial, but the

dominant cause is the diminished synthesis of erythropoietin by the damaged kidneys, which leads to inadequate red cell production. Other contributors are an extracorporeal defect that reduces red cell life span, and iron deficiency due to platelet dysfunction and increased bleeding, which is often encountered in uremia. Administration of recombinant erythropoietin results in a significant improvement of the anemia, although an optimal response may require concomitant iron replacement therapy.

Hepatocellular liver disease, whether toxic, infectious, or cirrhotic, is associated with anemia attributed to decreased marrow function. Folate and iron deficiencies caused by poor nutrition and excessive bleeding often exacerbate anemia in this setting. Erythroid progenitors are preferentially affected; depression of the white cell count and platelets is less common but also occurs. The anemia is often slightly macrocytic due to lipid abnormalities associated with liver failure, which cause red cell membranes to acquire phospholipid and cholesterol as they circulate in the peripheral blood.

Endocrine disorders, particularly hypothyroidism, may also be associated with a mild normochromic, normocytic anemia.

KEY CONCEPTS

Megaloblastic Anemia

- Caused by deficiencies of folate or vitamin B₁₂ that lead to inadequate synthesis of thymidine and defective DNA replication
- Results in enlarged abnormal hematopoietic precursors (megaloblasts), ineffective hematopoiesis, macrocytic anemia, and (in most cases) pancytopenia
- B₁₂ deficiency also associated with neurologic damage, particularly in the posterior and lateral tracts of the spinal cord

Iron Deficiency Anemia

- Caused by chronic bleeding or inadequate iron intake; results in insufficient hemoglobin synthesis and hypochromic, microcytic red cells

Anemia of Chronic Disease

- Caused by inflammatory cytokines, which increase hepcidin levels and thereby sequester iron in macrophages, and also suppress erythropoietin production

Aplastic Anemia

- Caused by bone marrow failure (hypocellularity) due to diverse causes, including exposures to toxins and radiation, idiosyncratic reactions to drugs and viruses, and inherited defects in telomerase and DNA repair

Pure Red Cell Aplasia

- Acute: Parvovirus B19 infection (may persist in immunosuppressed patients)
- Chronic: Associated with thymoma, large granular lymphocytic leukemia, presence of neutralizing antibodies against erythropoietin, and other autoimmune phenomenon

Other Causes of Underproduction Anemias

- Marrow replacement (tumors, granulomatous disease; so-called myelophthistic anemias), renal failure, endocrine disorders, liver failure

Polycythemia

Polycythemia denotes an abnormally high red cell count, usually with a corresponding increase in the hemoglobin level. It may be relative when there is hemoconcentration due to decreased plasma volume, or absolute when there is an increase in the total red cell mass. *Relative polycythemia* results from dehydration, such as occurs with deprivation of water, prolonged vomiting or diarrhea, or excessive use of diuretics. It is also associated with an obscure condition of unknown etiology called stress polycythemia, or Gaisböck syndrome. Affected individuals are usually hypertensive, obese, and anxious (“stressed”). *Absolute polycythemia* is *primary* when it results from an intrinsic abnormality of hematopoietic precursors and *secondary* when the red cell progenitors are responding to increased levels of erythropoietin. A pathophysiologic classification of polycythemia divided along these lines is given in Table 14-8.

The most common cause of primary polycythemia is *polycythemia vera*, a myeloproliferative disorder associated with mutations that lead to erythropoietin-independent growth of red cell progenitors (Chapter 13). Much less commonly, primary polycythemia results from familial mutations in the erythropoietin receptor that induce erythropoietin-independent receptor activation. One such individual won Olympic gold medals in cross-country skiing, having benefited from this natural form of blood doping! Secondary polycythemia may be caused by compensatory or pathologic increases in erythropoietin secretion. Causes of the latter include erythropoietin-secreting tumors and rare, but illustrative, inherited defects that lead to the stabilization of HIF-1 α , a hypoxia-induced factor that stimulates the transcription of the erythropoietin gene.

Bleeding Disorders: Hemorrhagic Diatheses

Excessive bleeding can result from (1) increased fragility of vessels, (2) platelet deficiency or dysfunction, and (3)

derangement of coagulation, alone or in combination. Before discussing specific bleeding disorders, it is helpful to review the common laboratory tests used in the evaluation of a bleeding diathesis. The normal hemostatic response involves the blood vessel wall, the platelets, and the clotting cascade (Chapter 4). Tests used to evaluate different aspects of hemostasis are the following:

- *Prothrombin time (PT)*. This test assesses the extrinsic and common coagulation pathways. The clotting of plasma after addition of an exogenous source of tissue thromboplastin (e.g., brain extract) and Ca²⁺ ions is measured in seconds. A prolonged PT can result from deficiency or dysfunction of factor V, factor VII, factor X, prothrombin, or fibrinogen.
- *Partial thromboplastin time (PTT)*. This test assesses the intrinsic and common clotting pathways. The clotting of plasma after addition of kaolin, cephalin, and Ca²⁺ ions is measured in seconds. Kaolin activates the contact-dependent factor XII, and cephalin substitutes for platelet phospholipids. Prolongation of the PTT can be due to deficiency or dysfunction of factors V, VIII, IX, X, XI, or XII, prothrombin, or fibrinogen, or to interfering antibodies to phospholipid (Chapter 4).
- *Platelet counts*. These are obtained on anticoagulated blood using an electronic particle counter. The reference range is 150 × 10³ to 300 × 10³ platelets/ μ L. Abnormal platelet counts are best confirmed by inspection of a peripheral blood smear, in that clumping of platelets can cause spurious “thrombocytopenia” during automated counting, and high counts may be indicative of a myeloproliferative disorder, such as essential thrombocythemia (Chapter 13).
- *Tests of platelet function*. At present, no single test provides an adequate assessment of the complex functions of platelets. Specialized tests that can be useful in particular clinical settings include tests of platelet aggregation, which measure the ability of platelets to aggregate in response to agonists like thrombin; and quantitative and qualitative tests of von Willebrand factor, which plays an important role in platelet adhesion to the extracellular matrix (Chapter 4). An older test, the bleeding time, has some value but is time-consuming and difficult to standardize and is therefore performed infrequently. Newer instrument-based assays that provide quantitative measures of platelet function show promise but remain imperfect at predicting bleeding risk, presumably because of difficulties in simulating in vivo clotting in the laboratory.

More specialized tests are available to measure the levels of specific clotting factors, fibrinogen, fibrin split products, and the presence of circulating anticoagulants.

Bleeding Disorders Caused by Vessel Wall Abnormalities

Disorders within this category are relatively common, but do not usually cause serious bleeding problems. Most often, they present with small hemorrhages (petechiae and purpura) in the skin or mucous membranes, particularly the gingivae. On occasion, however, more significant hemorrhages occur into joints, muscles, and subperiosteal

locations, or take the form of menorrhagia, nosebleeds, gastrointestinal bleeding, or hematuria. The platelet count and tests of coagulation (PT, PTT) are usually normal, pointing by exclusion to the underlying problem.

The varied clinical conditions in which abnormalities in the vessel wall cause bleeding include the following:

- *Infections* often induce petechial and purpuric hemorrhages, particularly meningococemia, other forms of septicemia, infective endocarditis, and several of the rickettsioses. The involved mechanisms include microbial damage to the microvasculature (vasculitis) and disseminated intravascular coagulation. Failure to recognize meningococemia as a cause of petechiae and purpura can be catastrophic for the patient.
- *Drug reactions* sometimes induce cutaneous petechiae and purpura without causing thrombocytopenia. In many instances the vascular injury is mediated by the deposition of drug-induced immune complexes in vessel walls, which leads to hypersensitivity (*leukocytoclastic*) vasculitis (Chapter 11).
- *Scurvy* and the *Ehlers-Danlos syndrome* are associated with microvascular bleeding that results from collagen defects that weaken vessel walls. The same mechanism may account for the spontaneous purpura that are commonly seen in older adults and the skin hemorrhages that are seen with *Cushing syndrome*, in which the protein-wasting effects of excessive corticosteroid production cause loss of perivascular supporting tissue.
- *Henoch-Schönlein purpura* is a systemic immune disorder of unknown cause that is characterized by a purpuric rash, colicky abdominal pain, polyarthralgia, and acute glomerulonephritis (Chapter 20). All these changes result from the deposition of circulating immune complexes within vessels throughout the body and within the glomerular mesangial regions.
- *Hereditary hemorrhagic telangiectasia* (also known as *Weber-Osler-Rendu syndrome*) is an autosomal dominant disorder that can be caused by mutations in at least five different genes, most of which modulate TGF- β signaling. It is characterized by dilated, tortuous blood vessels with thin walls that bleed readily. Bleeding can occur anywhere, but it is most common under the mucous membranes of the nose (epistaxis), tongue, mouth, and eyes, and throughout the gastrointestinal tract.
- *Perivascular amyloidosis* can weaken blood vessel walls and cause bleeding. This complication is most common with amyloid light-chain (AL) amyloidosis (Chapter 6) and often manifests as mucocutaneous petechiae.

Among these conditions, serious bleeding is most often associated with hereditary hemorrhagic telangiectasia. The bleeding in each is nonspecific, and the diagnosis of these entities is based on the recognition of other more specific associated findings.

Bleeding Related to Reduced Platelet Number: Thrombocytopenia

Reduction in platelet number (*thrombocytopenia*) constitutes an important cause of generalized bleeding. A count less

than 100,000 platelets/ μ L is generally considered to constitute thrombocytopenia. Platelet counts in the range of 20,000 to 50,000 platelets/ μ L can aggravate posttraumatic bleeding, while platelet counts less than 20,000 platelets/ μ L may be associated with spontaneous (nontraumatic) bleeding. Bleeding resulting from thrombocytopenia is associated with a normal PT and PTT.

Platelets are critical for hemostasis, in that they form temporary plugs that stop bleeding and promote key reactions in the coagulation cascade (Chapter 4). Spontaneous bleeding associated with thrombocytopenia most often involves small vessels. Common sites for such hemorrhages are the skin and the mucous membranes of the gastrointestinal and genitourinary tracts. Most feared, however, is *intracranial bleeding*, which is a threat to any patient with a markedly depressed platelet count.

The causes of thrombocytopenia fall into four major categories (Table 14-9).

- *Decreased platelet production.* This can result from conditions that depress marrow output generally (such as aplastic anemia and leukemia) or affect megakaryocytes somewhat selectively. Examples of the latter include certain drugs and alcohol, which may suppress platelet production through uncertain mechanisms when taken in large amounts; HIV, which may infect megakaryocytes and inhibit platelet production; and myelodysplastic syndromes (Chapter 13), which may occasionally present with isolated thrombocytopenia.

- **Decreased platelet survival.** This important mechanism of thrombocytopenia can have an immunological or non-immunological basis. In *immune thrombocytopenia*, destruction is caused by the deposition of antibodies or immune complexes on platelets. Antibodies to platelets can recognize self-antigens (autoantibodies) or non-self antigens (alloantibodies). Autoimmune thrombocytopenia is discussed in the following section. *Alloantibodies* can arise when platelets are transfused or cross the placenta from the fetus into the pregnant mother. In the latter case, IgG antibodies made in the mother can cause clinically significant thrombocytopenia in the fetus. This is reminiscent of hemolytic disease of the newborn, in which red cells are the target (Chapter 10). The most important nonimmunologic causes are *disseminated intravascular coagulation* and the *thrombotic microangiopathies*, in which unbridled, often systemic, platelet activation reduces platelet life span. Nonimmunologic destruction of platelets may also be caused by *mechanical injury*, such as in individuals with prosthetic heart valves.
- **Sequestration.** The spleen normally sequesters 30% to 35% of the body's platelets, but this can rise to 80% to 90% when the spleen is enlarged, producing moderate degrees of thrombocytopenia.
- **Dilution.** Massive transfusions can produce a dilutional thrombocytopenia. With prolonged blood storage the number of viable platelets decreases; thus, plasma volume and red cell mass are reconstituted by transfusion, but the number of circulating platelets is relatively reduced.

Chronic Immune Thrombocytopenic Purpura (ITP)

Chronic ITP is caused by autoantibody mediated destruction of platelets. It can occur in the setting of a variety of predisposing conditions and exposures (secondary) or in the absence of any known risk factors (primary or idiopathic). The contexts in which chronic ITP occurs secondarily are numerous and include individuals with systemic lupus erythematosus (Chapter 6), HIV infection, and B-cell neoplasms such as chronic lymphocytic leukemia (Chapter 13). The diagnosis of primary chronic ITP is made only after secondary causes are excluded.

Pathogenesis. The autoantibodies, most often directed against platelet membrane glycoproteins IIb-IIIa or Ib-IX, can be demonstrated in the plasma and bound to the platelet surface in about 80% of patients. In the overwhelming majority of cases, the antiplatelet antibodies are of the IgG class.

As in autoimmune hemolytic anemias, antiplatelet antibodies act as opsonins that are recognized by IgG Fc receptors expressed on phagocytes (Chapter 6), leading to increased platelet destruction. The thrombocytopenia is usually markedly improved by splenectomy, indicating that the spleen is the major site of removal of opsonized platelets. The splenic red pulp is also rich in plasma cells, and part of the benefit of splenectomy (a frequent treatment for chronic ITP) may stem from the removal of a source of autoantibodies. In some instances the autoantibodies may also bind to and damage megakaryocytes, leading to decreases in platelet production that further exacerbate the thrombocytopenia.

MORPHOLOGY

The principal changes of thrombocytopenic purpura are found in the spleen, bone marrow, and blood, but they are not specific. Secondary changes related to the bleeding diathesis may be found in any tissue or structure in the body.

The spleen is of normal size. Typically, there is congestion of the sinusoids and enlargement of the splenic follicles, often associated with prominent reactive germinal centers. In many instances scattered megakaryocytes are found within the sinuses, possibly representing a mild form of extramedullary hematopoiesis driven by elevated levels of thrombopoietin. **The marrow reveals a modestly increased number of megakaryocytes.** Some are apparently immature, with large, non-lobulated, single nuclei. These findings are not specific but merely reflect accelerated thrombopoiesis, being found in most forms of thrombocytopenia resulting from increased platelet destruction. The importance of bone marrow examination is to rule out thrombocytopenias resulting from bone marrow failure or other primary bone marrow disorders. The secondary changes relate to the hemorrhages that are dispersed throughout the body. **The peripheral blood often reveals abnormally large platelets** (megathrombocytes), which are a sign of accelerated thrombopoiesis.

Clinical Features

Chronic ITP occurs most commonly in adult women younger than 40 years of age. The female-to-male ratio is 3:1. It is often insidious in onset and is characterized by bleeding into the skin and mucosal surfaces. Cutaneous bleeding is seen in the form of pinpoint hemorrhages (*petechiae*), which are especially prominent in the dependent areas where the capillary pressure is higher. Petechiae can become confluent, giving rise to *ecchymoses*. Often there is a history of easy bruising, nosebleeds, bleeding from the gums, and hemorrhages into soft tissues from relatively minor trauma. The disease may manifest first with melena, hematuria, or excessive menstrual flow. Subarachnoid hemorrhage and intracerebral hemorrhage are serious and sometimes fatal complications, but fortunately they are rare in treated patients. Splenomegaly and lymphadenopathy are uncommon in primary disease, and their presence should lead one to consider other diagnoses, such as ITP secondary to a B-cell neoplasm.

The clinical signs and symptoms are not specific but rather reflective of the thrombocytopenia. The findings of a low platelet count, normal or increased megakaryocytes in the bone marrow, and large platelets in the peripheral blood are taken as presumptive evidence of accelerated platelet destruction. The PT and PTT are normal. Tests for platelet autoantibodies are not widely available. Therefore, the diagnosis is one of exclusion and can be made only after other causes of thrombocytopenia (such as those listed in Table 14-9) have been ruled out.

Almost all patients respond to glucocorticoids (which inhibit phagocyte function), but many eventually relapse. Those with moderately severe thrombocytopenia (platelet counts > 30,000/mL) can be followed carefully, and some of these individuals may have spontaneous remissions over a period of a year or more. In individuals with severe thrombocytopenia, splenectomy normalizes the platelet

count in about two thirds of patients, but with the attendant increased risk of bacterial sepsis. Immunomodulatory agents such as intravenous immunoglobulin or anti-CD20 antibody (rituximab) are often effective in patients who relapse after splenectomy or for whom splenectomy is contraindicated. Peptides that mimic the effects of thrombopoietin (so-called *TPO-mimetics*) are also effective in stimulating platelet production and improving platelet counts.

Acute Immune Thrombocytopenic Purpura

Like chronic ITP, this condition is caused by autoantibodies to platelets, but its clinical features and course are distinct. Acute ITP is mainly a disease of childhood occurring with equal frequency in both sexes. Symptoms appear abruptly, often 1 to 2 weeks after a self-limited viral illness, which appears to trigger the development of autoantibodies through uncertain mechanisms. Unlike chronic ITP, acute ITP is self-limited, usually resolving spontaneously within 6 months. Glucocorticoids are given only if the thrombocytopenia is severe. In about 20% of children, usually those without a viral prodrome, thrombocytopenia persists; these less fortunate children have a childhood form of chronic ITP that follows a course similar to the adult disease.

Drug-Induced Thrombocytopenia

Drugs can induce thrombocytopenia through direct effects on platelets and secondary to immunologically mediated platelet destruction. The drugs most commonly implicated are quinine, quinidine, and vancomycin, all of which bind platelet glycoproteins and in one way or another create antigenic determinants that are recognized by antibodies. Much more rarely, drugs induce true autoantibodies through unknown mechanisms. Thrombocytopenia, which may be severe, is also a common consequence of platelet inhibitory drugs that bind glycoprotein IIb/IIIa; it is hypothesized that these drugs induce conformational changes in glycoprotein IIb/IIIa and create an immunogenic epitope.

Heparin-induced thrombocytopenia (HIT) has a distinctive pathogenesis and is of particular importance because of its potential for severe clinical consequences. Thrombocytopenia occurs in about 5% of persons receiving heparin and is of two types:

- Type I thrombocytopenia occurs rapidly after the onset of therapy and is of little clinical importance, sometimes resolving despite the continuation of therapy. It most likely results from a direct platelet-aggregating effect of heparin.
- Type II thrombocytopenia is less common but of much greater clinical significance. It occurs 5 to 14 days after therapy begins (or sooner if the person has been sensitized to heparin) and, paradoxically, often leads to life-threatening venous and arterial thrombosis. This severe form of HIT is caused by antibodies that recognize complexes of heparin and platelet factor 4, which is a normal component of platelet granules. Binding of antibody to these complexes activates platelets and promotes thrombosis, even in the setting of thrombocytopenia. Unless therapy is immediately discontinued and an alternative nonheparin anticoagulant instituted, clots within large

arteries may lead to vascular insufficiency and limb loss, and emboli from deep venous thrombosis can cause fatal pulmonary thromboembolism. The risk of severe HIT is lowered, but not completely eliminated, by the use of low-molecular-weight heparin preparations. Unfortunately, once severe HIT develops even low-molecular-weight heparins exacerbate the thrombotic tendency and must be avoided.

HIV-Associated Thrombocytopenia

Thrombocytopenia is one of the most common hematologic manifestations of HIV infection. Both impaired platelet production and increased destruction contribute. CD4 and CXCR4, the receptor and coreceptor, respectively, for HIV, are found on megakaryocytes, allowing these cells to be infected. HIV-infected megakaryocytes are prone to apoptosis and their ability to produce platelets is impaired. HIV infection also causes B-cell hyperplasia and dysregulation, which predisposes to the development of autoantibodies. In some instances the antibodies are directed against platelet membrane glycoprotein IIb-III complexes. As in other immune cytopenias, the autoantibodies opsonize platelets, promoting their destruction by mononuclear phagocytes in the spleen and elsewhere. The deposition of immune complexes on platelets may also contribute to the accelerated loss of platelets in some patients who are HIV infected.

Thrombotic Microangiopathies: Thrombotic Thrombocytopenic Purpura (TTP) and Hemolytic-Uremic Syndrome (HUS)

The term *thrombotic microangiopathy* encompasses a spectrum of clinical syndromes that includes TTP and HUS. They are caused by insults that lead to excessive activation of platelets, which deposit as thrombi in small blood vessels.

According to its original description, TTP was defined as the pentad of fever, thrombocytopenia, microangiopathic hemolytic anemia, transient neurologic deficits, and renal failure. HUS is also associated with microangiopathic hemolytic anemia and thrombocytopenia but is distinguished by the absence of neurologic symptoms, the prominence of acute renal failure, and its frequent occurrence in children. With time, experience, and increased mechanistic insight, however, these distinctions have blurred. Many adult patients with "TTP" lack one or more of the five criteria, and some patients with "HUS" have fever and neurologic dysfunction.

In both conditions, intravascular thrombi cause a *microangiopathic hemolytic anemia* and widespread *organ dysfunction*, and the attendant consumption of platelets leads to thrombocytopenia. It is believed that the varied clinical manifestations of TTP and HUS are related to differing proclivities for thrombus formation in tissues. While disseminated intravascular coagulation (discussed later) and thrombotic microangiopathies share features such as microvascular occlusion and microangiopathic hemolytic anemia, they are pathogenically distinct. In TTP and HUS (unlike in disseminated intravascular coagulation), activation of the coagulation cascade is not of primary importance, and hence laboratory tests of coagulation, such as the PT and PTT, are usually normal.

Table 14-10 Thrombotic Microangiopathies: Causes and Associations

Thrombotic Thrombocytopenic Purpura
Deficiency of ADAMTS13
Inherited
Acquired (autoantibodies)
Hemolytic Uremic Syndrome
Typical: <i>Escherichia coli</i> strain O157:H7 infection
Endothelial damage by Shiga-like toxin
Atypical: alternative complement pathway inhibitor deficiencies
(complement factor H, membrane cofactor protein (CD46), or factor I)
Inherited
Acquired (autoantibodies)
Miscellaneous associations
Drugs (cyclosporine, chemotherapeutic agents)
Radiation, bone marrow transplantation
Other infections (HIV, pneumococcal sepsis)
Conditions associated with autoimmunity (systemic lupus erythematosus, HIV infection, lymphoid neoplasms)
<small>HIV, Human immunodeficiency virus.</small>

Although certain features of the various thrombotic microangiopathies overlap, the triggers for the pathogenic platelet activation are distinctive and provide a more satisfying and clinically relevant way of thinking about these disorders; these are summarized in [Table 14-10](#). **TTP is usually associated with a deficiency in a plasma enzyme called ADAMTS13**, also designated “vWF metalloprotease.” ADAMTS13 normally degrades very high-molecular-weight multimers of von Willebrand factor (vWF). In its absence, these multimers accumulate in plasma and tend to promote platelet activation and aggregation. Superimposition of endothelial cell injury (caused by some other condition) may further promote the formation of platelet microaggregates, thus initiating or exacerbating clinically evident TTP.

The deficiency of ADAMTS13 can be inherited or acquired. In the acquired form, an autoantibody that inhibits the metalloprotease activity of ADAMTS13 is present. Less commonly, patients inherit an inactivating mutation in ADAMTS13. In those with hereditary ADAMTS13 deficiency, the onset is often delayed until adolescence and the symptoms are episodic. Thus, factors other than ADAMTS13 (e.g., some superimposed vascular injury or prothrombotic state) must be involved in triggering full-blown TTP.

TTP is an important diagnosis to consider in any patient presenting with thrombocytopenia and microangiopathic hemolytic anemia, because delays in diagnosis can be fatal. With plasma exchange, which removes autoantibodies and provides functional ADAMTS13, TTP (which once was uniformly fatal) can be treated successfully in more than 80% of patients.

In contrast, HUS is associated with normal levels of ADAMTS13 and is initiated by several other distinct defects. “Typical” HUS is strongly associated with infectious gastroenteritis caused by *Escherichia coli* strain O157:H7, which elaborates a Shiga-like toxin. This toxin is absorbed from the inflamed gastrointestinal mucosa into the circulation, where it alters endothelial cell function in some manner that results in platelet activation and aggregation. Children and older adults are at highest risk. Those affected present with bloody diarrhea, and a few days later

HUS makes its appearance. With appropriate supportive care complete recovery is possible, but irreversible renal damage and death can occur in more severe cases.

“Atypical” HUS is often associated with defects in complement factor H, membrane cofactor protein (CD46), or factor I, three proteins that normally act to prevent excessive activation of the alternative complement pathway. Deficiencies of these proteins can be caused by inherited defects or acquired inhibitory autoantibodies and are associated with a remitting, relapsing course. Unlike TTP, the basis for the platelet activation in typical and atypical HUS is unclear. Therapeutic antibodies that inhibit the activation of the complement factor C5 are effective in preventing thrombosis in patients with inherited deficiencies of complement regulatory proteins, proving that excessive complement activation underlies the pathogenesis of this form of HUS. Similarly, immunosuppression can be beneficial to patients with inhibitory antibodies against complement regulatory factors. Typical HUS is treated supportively. Patients who survive the acute insult usually recover, but some have permanent renal damage and eventually require dialysis or renal transplantation. The impact of HUS and TTP on the kidneys is discussed further in Chapter 20.

Thrombotic microangiopathies resembling HUS can also be seen following exposures to other agents that damage endothelial cells (e.g., certain drugs and radiation therapy). The prognosis in these settings is guarded, because the HUS is often complicated by chronic, life-threatening conditions.

Bleeding Disorders Related to Defective Platelet Functions

Qualitative defects of platelet function can be inherited or acquired. Several inherited disorders characterized by abnormal platelet function and normal platelet count have been described. A brief discussion of these rare diseases is warranted because they provide excellent models for investigating the molecular mechanisms of platelet function.

Inherited disorders of platelet function can be classified into three pathogenically distinct groups: (1) defects of adhesion, (2) defects of aggregation, and (3) disorders of platelet secretion (release reaction).

- *Bernard-Soulier syndrome* illustrates the consequences of defective adhesion of platelets to subendothelial matrix. Bernard-Soulier syndrome is caused by an inherited deficiency of the platelet membrane glycoprotein complex Ib-IX. This glycoprotein is a receptor for vWF and is essential for normal platelet adhesion to the subendothelial extracellular matrix ([Chapter 4](#)). Affected patients have a variable, often severe, bleeding tendency.
- Bleeding due to *defective platelet aggregation* is exemplified by *Glanzmann thrombasthenia*, which is also transmitted as an autosomal recessive trait. Thrombasthenic platelets fail to aggregate in response to adenosine diphosphate (ADP), collagen, epinephrine, or thrombin because of deficiency or dysfunction of glycoprotein IIb-IIIa, an integrin that participates in “bridge formation” between platelets by binding fibrinogen. The associated bleeding tendency is often severe.

- *Disorders of platelet secretion* are characterized by the defective release of certain mediators of platelet activation, such as thromboxanes and granule-bound ADP. The biochemical defects underlying these so-called *storage pool disorders* are varied, complex, and beyond the scope of our discussion.

Among the *acquired defects* of platelet function, two are clinically significant. The first is caused by ingestion of *aspirin and other nonsteroidal anti-inflammatory drugs*. Aspirin is a potent, irreversible inhibitor of the enzyme cyclooxygenase, which is required for the synthesis of thromboxane A₂ and prostaglandins (Chapter 3). These mediators play important roles in platelet aggregation and subsequent release reactions (Chapter 4). The antiplatelet effects of aspirin form the basis for its use in the prophylaxis of coronary thrombosis (Chapter 12). *Uremia* (Chapter 20) is the second condition exemplifying an acquired defect in platelet function. The pathogenesis of platelet dysfunction in uremia is complex and involves defects in adhesion, granule secretion, and aggregation.

Hemorrhagic Diatheses Related to Abnormalities in Clotting Factors

Inherited or acquired deficiencies of virtually every coagulation factor have been reported as causes of bleeding diatheses. Bleeding due to isolated coagulation factor deficiencies most commonly manifests as large posttraumatic ecchymoses or hematomas, or prolonged bleeding after a laceration or any form of surgical procedure. Unlike bleeding seen with thrombocytopenia, bleeding due to coagulation factor deficiencies often occurs into the gastrointestinal and urinary tracts and into weight-bearing joints (hemarthrosis). Typical stories include the patient

who oozes blood for days after a tooth extraction or who develops a hemarthrosis after minor stress on a knee joint.

Hereditary deficiencies typically affect a single clotting factor. The most common and important inherited deficiencies of coagulation factors affect factor VIII (hemophilia A), and factor IX (hemophilia B). Deficiencies of vWF (von Willebrand disease) are also discussed here, as this factor influences both coagulation and platelet function. Rare inherited deficiencies of each of the other coagulation factors have also been described.

Acquired deficiencies usually involve multiple coagulation factors and can be based on decreased protein synthesis or a shortened half-life. Vitamin K deficiency (Chapter 9) results in the impaired synthesis of factors II, VII, IX, X and protein C. Many of these factors are made in the liver and are therefore deficient in severe parenchymal liver disease. Alternatively, in disseminated intravascular coagulation, multiple coagulation factors are consumed and are therefore deficient. Acquired deficiencies of single factors occur, but they are rare. These are usually caused by inhibitory autoantibodies.

The Factor VIII-vWF Complex

The two most common inherited disorders of bleeding, hemophilia A and von Willebrand disease, are caused by qualitative or quantitative defects involving factor VIII and vWF, respectively. Before we discuss these disorders it will be helpful to review the structure and function of these two proteins, which exist together in the plasma as part of a single large complex.

Factor VIII and vWF are encoded by separate genes and are synthesized in different cells. Factor VIII is an essential cofactor of factor IX, which converts factor X to factor Xa (Fig. 14-26; Chapter 4). It is made in several tissues; sinusoidal endothelial cells and Kupffer cells in the liver seem to be major sources. Once factor VIII reaches the

Figure 14-26 Structure and function of factor VIII-von Willebrand factor (vWF) complex. Factor VIII is synthesized in the liver and kidney, and vWF is made in endothelial cells and megakaryocytes. The two associate to form a complex in the circulation. vWF is also present in the subendothelial matrix of normal blood vessels and the α -granules of platelets. Following endothelial injury, exposure of subendothelial vWF causes adhesion of platelets, primarily via the glycoprotein IIb (GpIIb) platelet receptor. Circulating vWF and vWF released from the α -granules of activated platelets can bind exposed subendothelial matrix, further contributing to platelet adhesion and activation. Activated platelets form hemostatic aggregates; fibrinogen participates in aggregation through bridging interactions with the glycoprotein IIb/IIIa (GpIIb/IIIa) platelet receptor. Factor VIII takes part in the coagulation cascade as a cofactor in the activation of factor X on the surface of activated platelets.

circulation, it binds to vWF, which is produced by endothelial cells and, to a lesser degree, by megakaryocytes, which are the source of the vWF that is found in platelet α -granules. vWF stabilizes factor VIII, which has a half-life of about 2.4 hours when free and 12 hours when bound to vWF in the circulation.

Circulating vWF exists as multimers containing as many as 100 subunits that can exceed 20×10^6 daltons in molecular mass. In addition to factor VIII, these multimers interact with several other proteins involved in hemostasis, including collagen, heparin, and possibly platelet membrane glycoproteins. The most important function of vWF is to promote the adhesion of platelets to the subendothelial matrix. This occurs through bridging interactions between platelet glycoprotein Ib-IX, vWF, and matrix components such as collagen. Some vWF is secreted from endothelial cells directly into the subendothelial matrix, where it lies ready to promote platelet adhesion if the endothelial lining is disrupted (Fig. 14-26). Endothelial cells and platelets also release vWF into the circulation. Upon vascular injury, this second pool of vWF binds collagen in the subendothelial matrix to further augment platelet adhesion. vWF multimers may also promote platelet aggregation by binding to activated GpIIb/IIIa integrins; this activity may be of particular importance under conditions of high shear stress (such as occurs in small vessels).

Factor VIII and vWF protein levels are measured by immunological techniques. Factor VIII function is measured specifically by performing coagulation assays with mixtures of patient plasma and factor VIII-deficient plasma. vWF function is assessed using the ristocetin agglutination test. This assay is performed by mixing the patient's plasma with formalin-fixed platelets and ristocetin, a small molecule that binds and "activates" vWF. Ristocetin induces multivalent vWF multimers to bind platelet glycoprotein Ib-IX and form interplatelet "bridges." The resulting clumping (agglutination) of platelets is measured in a device called an aggregometer. Thus, the degree to which patient plasma promotes ristocetin-dependent platelet agglutination reflects the vWF activity of the sample.

Von Willebrand Disease

Von Willebrand disease is the most common inherited bleeding disorder of humans, affecting about 1% of adults in the United States. The bleeding tendency is usually mild and often goes unnoticed until some hemostatic stress, such as surgery or a dental procedure, reveals its presence. The most common presenting symptoms are spontaneous bleeding from mucous membranes (e.g., epistaxis), excessive bleeding from wounds, or menorrhagia. It is usually transmitted as an autosomal dominant disorder, but rare autosomal recessive variants also exist.

Von Willebrand disease is clinically and molecularly heterogeneous; several hundred vWF variants have been described, few of which have been formally proven to be disease-causing. Three broad categories of von Willebrand disease are recognized, each with a range of phenotypes:

- **Type 1 and type 3 von Willebrand disease are associated with quantitative defects in vWF. Type 1, an autosomal dominant disorder characterized by a mild to moderate vWF deficiency,** accounts for about 70% of all cases. Incomplete penetrance and variable expressivity are commonly observed, but it generally is associated

with mild disease. **Type 3 (an autosomal recessive disorder) is associated with very low levels of vWF and correspondingly severe clinical manifestations.**

Because a severe deficiency of vWF has a marked effect on the stability of factor VIII, some of the bleeding characteristics resemble those seen in hemophilia. Type 1 disease is associated with a spectrum of mutations, including point substitutions that interfere with maturation of the vWF protein or that result in rapid clearance from the plasma. Type 3 disease is usually caused by deletions or frameshift mutations involving both alleles.

- **Type 2 von Willebrand disease is characterized by qualitative defects in vWF;** there are several subtypes, of which type 2A is the most common. It is inherited as an autosomal dominant disorder. vWF is expressed in normal amounts, but missense mutations are present that lead to defective multimer assembly. Large and intermediate multimers, representing the most active forms of vWF, are missing from plasma. Type 2 von Willebrand disease accounts for 25% of all cases and is associated with mild to moderate bleeding.

Patients with von Willebrand disease have defects in platelet function despite a normal platelet count. The plasma level of active vWF, measured as the ristocetin cofactor activity, is reduced. Because vWF stabilizes factor VIII, a deficiency of vWF gives rise to a secondary decrease in factor VIII levels. This may be reflected by a prolongation of the PTT in von Willebrand disease types 1 and 3. However, except in rare type 3 patients, adverse complications typical of severe factor VIII deficiency, such as bleeding into the joints, are not seen.

Even within families in which a single defective vWF allele is segregating, wide variability in clinical expression is common. This is due in part to modifying genes that influence circulating levels of vWF, which show a wide range in normal populations. Persons with von Willebrand disease facing hemostatic challenges (dental work, surgery) can be treated with desmopressin, which stimulates vWF release, or with infusions of plasma concentrates containing factor VIII and vWF.

Hemophilia A (Factor VIII Deficiency)

Hemophilia A, the most common hereditary disease associated with life-threatening bleeding, is caused by mutations in factor VIII, an essential cofactor for factor IX in the coagulation cascade. Hemophilia A is inherited as an X-linked recessive trait and thus affects mainly males and homozygous females. Rarely, excessive bleeding occurs in heterozygous females, presumably as a result of inactivation of the X chromosome bearing the normal factor VIII allele by chance in most cells (unfavorable lyonization). About 30% of patients have no family history; their disease is caused by new mutations.

Hemophilia A exhibits a wide range of clinical severity that correlates well with the level of factor VIII activity. Those with less than 1% of normal levels have severe disease; those with 2% to 5% of normal levels have moderately severe disease; and those with 6% to 50% of normal levels have mild disease. The varying degrees of factor VIII deficiency are largely explained by heterogeneity in the causative mutations. As with β -thalassemia, the genetic lesions include deletions, nonsense mutations that create stop codons, and mutations that cause errors in mRNA

splicing. The most severe deficiencies result from an inversion involving the X chromosome that completely abolishes the synthesis of factor VIII. Less commonly, severe hemophilia A is associated with point mutations in factor VIII that impair the function of the protein. In such cases factor VIII protein levels may be normal by immunoassay. Mutations permitting some active factor VIII to be synthesized are associated with mild to moderate disease. The disease in such patients may be modified by other genetic factors that influence factor VIII expression levels, which vary widely in normal individuals.

In all symptomatic cases there is a tendency toward easy bruising and massive hemorrhage after trauma or operative procedures. In addition, “spontaneous” hemorrhages frequently occur in regions of the body that are susceptible to trauma, particularly the joints, where they are known as *hemarthroses*. Recurrent bleeding into the joints leads to progressive deformities that can be crippling. Petechiae are characteristically absent.

Patients with hemophilia A have a prolonged PTT and a normal PT, results that point to an abnormality of the intrinsic coagulation pathway. Factor VIII-specific assays are required for diagnosis. As explained in Chapter 4, the bleeding diathesis reflects the pre-eminent role of the factor VIIIa/factor IXa complex in activation of factor X in vivo. The precise explanation for the tendency of hemophiliacs to bleed at particular sites (joints, muscles, and the central nervous system) remains uncertain.

Hemophilia A is treated with infusions of recombinant factor VIII. About 15% of patients with severe hemophilia A develop antibodies that bind and inhibit factor VIII, probably because the protein is perceived as foreign, having never been “seen” by the immune system. These antibody inhibitors can be a very difficult therapeutic challenge. Before the development of recombinant factor VIII therapy, thousands of hemophiliacs received plasma-derived factor VIII concentrates containing HIV, and many developed AIDS (Chapter 6). The risk of HIV transmission has been eliminated but tragically too late for an entire generation of hemophiliacs. Efforts to develop somatic gene therapy for hemophilia are ongoing.

Hemophilia B (Christmas Disease, Factor IX Deficiency)

Severe factor IX deficiency produces a disorder clinically indistinguishable from factor VIII deficiency (hemophilia A). This should not be surprising, given that factors VIII and IX function together to activate factor X. A wide spectrum of mutations involving the gene that encodes factor IX is found in hemophilia B. Like hemophilia A, it is inherited as an X-linked recessive trait and shows variable clinical severity. In about 15% of these patients, factor IX protein is present but is nonfunctional. As with hemophilia A, the PTT is prolonged and the PT is normal. Diagnosis of Christmas disease (named after the first patient identified with this condition, and not the holiday) is possible only by assay of the factor levels. The disease is treated with infusions of recombinant factor IX.

Disseminated Intravascular Coagulation (DIC)

DIC is an acute, subacute, or chronic thrombohemorrhagic disorder characterized by the excessive activation of coagulation and the formation of thrombi in the microvasculature of the body. It occurs as a secondary

complication of many different disorders. Sometimes the coagulopathy is localized to a specific organ or tissue. As a consequence of the thrombotic diathesis there is consumption of platelets, fibrin, and coagulation factors and, secondarily, activation of fibrinolysis. DIC can present with signs and symptoms relating to the tissue hypoxia and infarction caused by the myriad microthrombi; with hemorrhage caused by the depletion of factors required for hemostasis and the activation of fibrinolytic mechanisms; or both.

Etiology and Pathogenesis. At the outset, it must be emphasized that DIC is not a primary disease. It is a coagulopathy that occurs in the course of a variety of clinical conditions. In discussing the general mechanisms underlying DIC, it is useful to briefly review the normal process of blood coagulation and clot removal (Chapter 4).

Clotting in vivo is thought to be initiated by exposure of tissue factor, which combines with factor VII to activate both factor X directly and to activate factor IX. Activation of factor X leads to the generation of *thrombin*, the central player in clotting. At sites where the endothelium is disrupted, thrombin converts fibrinogen to fibrin, feeds back to activate factors IX, VIII, and V, stimulates fibrin cross-linking, inhibits fibrinolysis, and activates platelets, all of which augment the formation of a stable clot. To prevent runaway clotting, this process must be sharply limited to the site of tissue injury. Remarkably, as thrombin is swept away in the bloodstream and encounters uninjured vessels, it is converted to an anticoagulant through binding to *thrombomodulin*, a protein found on the surface of endothelial cells. The thrombin-thrombomodulin complex activates protein C, which is an important inhibitor of factor V and factor VIII. Other activated coagulation factors are removed from the circulation by the liver, and as you will recall, the blood also contains several potent fibrinolytic factors, such as plasmin. These and additional checks and balances normally ensure that just enough clotting occurs at the right place and time.

From this brief review it should be clear that DIC could result from pathologic activation of coagulation or the impairment of clot-inhibiting mechanisms. Because the latter rarely constitute primary mechanisms of DIC, we will focus on the abnormal initiation of clotting.

Two major mechanisms trigger DIC: (1) release of tissue factor or other, poorly characterized procoagulants, into the circulation, and (2) widespread injury to the endothelial cells. Procoagulants such as tissue factor can be derived from a variety of sources, such as the placenta in obstetric complications or tissues injured by trauma or burns. Mucus released from certain adenocarcinomas may also act as procoagulants by directly activate factor X.

Endothelial injury can initiate DIC in several ways. Injuries that cause endothelial cell necrosis expose the subendothelial matrix, leading to the activation of platelets and the coagulation pathway. However, even subtle endothelial injuries can unleash procoagulant activity. One mediator of endothelial injury is TNF, which is implicated in DIC occurring with sepsis. TNF induces endothelial cells to express tissue factor on their cell surfaces and to decrease the expression of thrombomodulin, shifting the checks and balances that govern hemostasis towards coagulation. In addition, TNF up-regulates the expression of adhesion

molecules on endothelial cells, thereby promoting the adhesion of leukocytes, which can damage endothelial cells by releasing reactive oxygen species and preformed proteases. Widespread endothelial injury may also be produced by deposition of antigen-antibody complexes (e.g., systemic lupus erythematosus), temperature extremes (e.g., heat stroke, burns), or microorganisms (e.g., meningococci, rickettsiae). Even subtle endothelial injury can unleash procoagulant activity by enhancing membrane expression of tissue factor.

DIC is most likely to be associated with obstetric complications, malignant neoplasms, sepsis, and major trauma. The triggers in these conditions are often multiple and interrelated. For example, in bacterial infections *endotoxins* can inhibit the endothelial expression of thrombomodulin directly or indirectly by stimulating immune cells to make TNF, and can also activate factor XII. *Antigen-antibody complexes* formed in response to the infection can activate the classical complement pathway, giving rise to complement fragments that secondarily activate both platelets and granulocytes. In *massive trauma, extensive surgery, and severe burns*, the major trigger is the release of procoagulants such as tissue factor. In *obstetric conditions*, procoagulants derived from the placenta, dead retained fetus, or amniotic fluid may enter the circulation. *Hypoxia, acidosis, and shock*, which often coexist in very ill patients, can also cause widespread endothelial injury, and supervening infections can complicate the problems further. Among *cancers, acute promyelocytic leukemia and adenocarcinomas* of the lung, pancreas, colon, and stomach are most frequently associated with DIC.

The possible consequences of DIC are twofold (Fig. 14-27).

- *Widespread deposition of fibrin within the microcirculation*. This leads to *ischemia* of the more severely affected or more vulnerable organs and a *microangiopathic*

hemolytic anemia, which results from the fragmentation of red cells as they squeeze through the narrowed microvasculature.

- Consumption of platelets and clotting factors and the activation of plasminogen, leading to a *hemorrhagic diathesis*. Plasmin not only cleaves fibrin, but it also digests factors V and VIII, thereby reducing their concentration further. In addition, fibrin degradation products resulting from fibrinolysis inhibit platelet aggregation, fibrin polymerization, and thrombin.

MORPHOLOGY

Thrombi are most often found in the brain, heart, lungs, kidneys, adrenals, spleen, and liver, in decreasing order of frequency, but any tissue can be affected. Affected kidneys may have small thrombi in the glomeruli that evoke only reactive swelling of endothelial cells or, in severe cases, microinfarcts or even **bilateral renal cortical necrosis**. Numerous fibrin thrombi may be found in alveolar capillaries, sometimes associated with pulmonary edema and fibrin exudation, creating "hyaline membranes" reminiscent of acute respiratory distress syndrome (Chapter 15). In the central nervous system, fibrin thrombi can cause microinfarcts, occasionally complicated by simultaneous hemorrhage, which can sometimes lead to variable neurologic signs and symptoms. The manifestations in the endocrine glands are of considerable interest. In meningococemia, fibrin thrombi within the microcirculation of the adrenal cortex are the probable basis for the massive adrenal hemorrhages seen in **Waterhouse-Friderichsen syndrome** (Chapter 24). An unusual form of DIC occurs in association with giant hemangiomas (**Kasabach-Merritt syndrome**), in which thrombi form within the neoplasm because of stasis and recurrent trauma to fragile blood vessels.

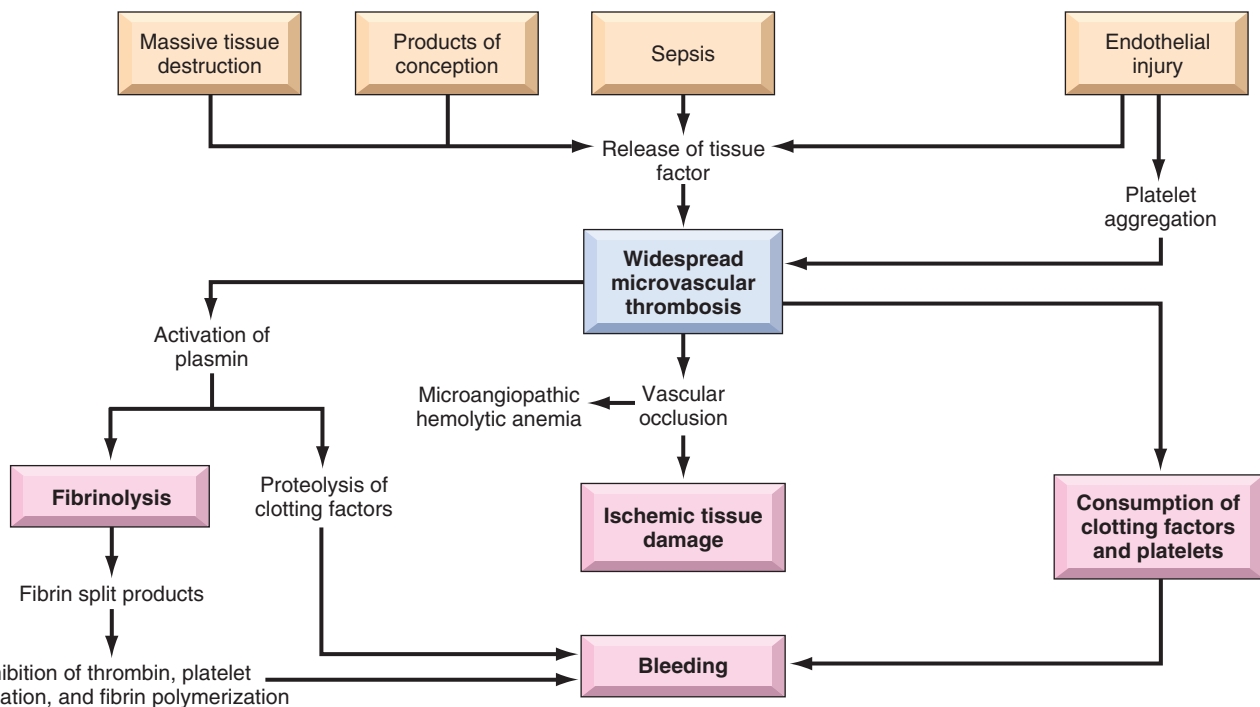

Figure 14-27 Pathophysiology of disseminated intravascular coagulation.

Clinical Features. The onset can be fulminant, as in endotoxic shock or amniotic fluid embolism, or insidious and chronic, as in cases of carcinomatosis or retention of a dead fetus. Overall, about 50% of the affected are obstetric patients having complications of pregnancy. In this setting the disorder tends to be reversible with delivery of the fetus. About 33% of the affected patients have carcinomatosis. The remaining cases are associated with the various entities previously listed.

It is almost impossible to detail all the potential clinical presentations, but a few common patterns are worthy of description. These include *microangiopathic hemolytic anemia*; dyspnea, cyanosis, and respiratory failure; convulsions and coma; oliguria and acute renal failure; and sudden or progressive circulatory failure and shock. In general, acute DIC, associated with obstetric complications or major trauma, for example, is dominated by a bleeding diathesis, whereas chronic DIC, such as occurs in cancer patients, tends to present with thrombotic complications. The diagnosis is based on clinical observation and laboratory studies, including measurement of fibrinogen levels, platelets, the PT and PTT, and fibrin degradation products.

The prognosis is highly variable and largely depends on the underlying disorder. The only definitive treatment is to remove or treat the inciting cause. The management requires meticulous maneuvering between the Scylla of thrombosis and the Charybdis of bleeding diathesis. Administration of anticoagulants or procoagulants has been advocated in specific settings, but not without controversy.

KEY CONCEPTS

Immune Thrombocytopenic Purpura

- Caused by autoantibodies against platelet antigens
- May be triggered by drugs, infections, or lymphomas, or may be idiopathic

Thrombotic Thrombocytopenic Purpura and Hemolytic Uremic Syndrome

- Both manifest with thrombocytopenia, microangiopathic hemolytic anemia, and renal failure; fever and CNS involvement are more typical of TTP.
- *TTP*: Caused by acquired or inherited deficiencies of ADAMTS 13, a plasma metalloprotease that cleaves very-high-molecular-weight multimers of von Willebrand factor (vWF). Deficiency of ADAMTS 13 results in abnormally large vWF multimers that activate platelets.
- *Hemolytic uremic syndrome*: caused by deficiencies of complement regulatory proteins or agents that damage endothelial cells, such as a Shiga-like toxin elaborated by *E. coli* strain O157:H7. The abnormalities initiate platelet activation, platelet aggregation, and microvascular thrombosis.

Von Willebrand Disease

- Autosomal dominant disorder caused by mutations in vWF, a large protein that promotes the adhesion of platelets to subendothelial collagen
- Typically causes a mild to moderate bleeding disorder resembling that associated with thrombocytopenia

Hemophilia

- *Hemophilia A*: X-linked disorder caused by mutations in factor VIII. Affected males typically present with severe bleeding into soft tissues and joints and have a PTT.
- *Hemophilia B*: X-linked disorder caused by mutations in coagulation factor IX. It is clinically identical to hemophilia A.

Disseminated Intravascular Coagulation

- Syndrome in which systemic activation of the coagulation leads to consumption of coagulation factors and platelets
- Can produce bleeding, vascular occlusion and tissue hypoxemia, or both
- Common triggers: sepsis, major trauma, certain cancers, obstetric complications

Complications of Transfusion

Blood products are often rightly called the gift of life, permitting people to survive traumatic injuries and procedures such as hematopoietic stem cell transplantation and complex surgical procedures that would otherwise prove fatal. Over 5 million red cell transfusions are given in US hospitals each year. Thanks to improved screening of donors, blood products (packed red blood cells, platelets, and fresh-frozen plasma) are safer than ever before.

Nevertheless, complications still occur. Most are minor and transient. The most common is referred to as a *febrile nonhemolytic reaction*, which takes the form of fever and chills, sometimes with mild dyspnea, within 6 hours of a transfusion of red cells or platelets. These reactions are thought to be caused by inflammatory mediators derived from donor leukocytes. The frequency of these reactions increases with the storage age of the product and is decreased by measures that limit donor leukocyte contamination. Symptoms respond to antipyretics and are short-lived.

Other transfusion reactions are uncommon or rare, but can have severe and sometimes fatal consequences, and therefore merit discussion.

Allergic Reactions

Severe, potentially fatal allergic reactions may occur when blood products containing certain antigens are given to previously sensitized recipients. These are most likely to occur in patients with IgA deficiency, which has a frequency of 1:300 to 1:500 people. In this instance, the reaction is triggered by IgG antibodies that recognize IgA in the infused blood product. Fortunately, most patients with IgA deficiency do not develop such antibodies, and these severe reactions are rare, occurring in 1 in 20,000 to 1 in 50,000 transfusions. *Urticarial allergic reactions* may be triggered by the presence of an allergen in the donated blood product that is recognized by IgE antibodies in the recipient. These are considerably more common, occurring in 1% to 3% of transfusions, but are generally mild. In most instances symptoms respond to antihistamines and do not require discontinuation of the transfusion.

Hemolytic Reactions

Acute hemolytic reactions are usually caused by preformed IgM antibodies against donor red cells that fix

complement. They most commonly stem from an error in patient identification or tube labeling that allows a patient to receive an ABO incompatible unit of blood. Pre-existing high affinity “natural” IgM antibodies, usually against polysaccharide blood group antigens A or B, bind to red cells and rapidly induce complement mediated lysis, intravascular hemolysis, and hemoglobinuria. Fever, shaking chills, and flank pain appear rapidly. The direct Coombs test is typically positive, unless all of the donor red cells have lysed. The signs and symptoms are due to complement activation rather than intravascular hemolysis *per se*, as osmotic lysis of red cells (e.g., by mistakenly infusing red cells and 5% dextrose in water simultaneously) produces hemoglobinuria without any of the other symptoms of a hemolytic reaction. In severe cases the process may rapidly progress to DIC, shock, acute renal failure, and occasionally death.

Delayed hemolytic reactions are caused by antibodies that recognize red cell antigens that the recipient was sensitized to previously, for example, through a prior blood transfusion. These are typically caused by IgG antibodies to foreign protein antigens and are associated with a positive direct Coombs test and laboratory features of hemolysis (e.g., low haptoglobin and elevated LDH). Antibodies to antigens such as Rh, Kell, and Kidd often induce sufficient complement activation to cause severe and potentially fatal reactions identical to those resulting from ABO mismatches. Other antibodies that do not fix complement typically result in red cell opsonization, extravascular hemolysis, and spherocytosis, and are associated with relatively minor signs and symptoms.

Transfusion-Related Acute Lung Injury

TRALI is a severe, frequently fatal complication in which factors in a transfused blood product trigger the activation of neutrophils in the lung microvasculature. The incidence of TRALI is low, probably less than 1 per 10,000 transfusions, but it may occur more frequently in patients with preexisting lung disease. Though its pathogenesis is incompletely understood, current models favor a “two hit” hypothesis. The first is a priming event that leads to increased sequestration and sensitization of neutrophils in the microvasculature of the lung. It is postulated that this event may involve endothelial activation, for example by inflammatory mediators. The primed neutrophils are then activated by a factor present in the transfused blood product, which constitutes the second hit.

A variety of factors have been implicated as “second hits”, but the leading candidates are antibodies in the transfused blood product that recognize antigens expressed on neutrophils. By far the most common antibodies associated with TRALI are those that bind major histocompatibility complex (MHC) antigens, particularly MHC class I antigens. These antibodies are often found in multiparous women, who generate such antibodies in response to foreign MHC antigens expressed by the fetus. Rarely, donor antibodies to neutrophil-specific antigens trigger TRALI. Although TRALI has been associated with virtually all plasma-containing blood products, it is more likely to occur following transfusion of products containing high levels of donor antibodies, such as fresh frozen plasma and platelets. The presentation is dramatic, sudden onset respiratory failure, during or soon after a transfusion. Diffuse

bilateral pulmonary infiltrates that do not respond to diuretics are seen on chest imaging. Other associated findings include fever, hypotension and hypoxemia. The treatment is largely supportive and the outcome is guarded; mortality is 5% in uncomplicated cases and up to 67% in those who were severely ill. TRALI is important to recognize, because donor products that induce the complication in one patient are much more likely to do so in a second. Indeed, recent measures to exclude multiparous women from plasma donation have resulted in the incidence of TRALI being cut in half.

Infectious Complications

Virtually any infectious agent can be transmitted through blood products, but bacterial and viral infections are most likely to be so. Most *bacterial infections* are caused by skin flora, indicating that the contamination occurred at the time that the product is taken from the donor. Significant bacterial contamination (sufficient to produce symptoms) is much more common in platelet preparations than red cell preparations, due in large part to the fact that platelets (unlike red cells) must be stored at room temperature, conditions that are favorable for bacterial growth. Rates of bacterial infection secondary to platelet transfusion can be as high as 1 in 5000, with infections secondary to red cell transfusions being several orders of magnitude less frequent. Many of the symptoms (fever, chills, hypotension) resemble those of hemolytic and non-hemolytic transfusion reactions, and it may be necessary to start broad-spectrum antibiotics prospectively in symptomatic patients while awaiting laboratory results.

Advances in donor selection, donor screening, and infectious disease testing have dramatically decreased the incidence of viral transmission by blood products. However on rare occasions when the donor is acutely infected but the virus is not yet detectable with current nucleic acid testing technology, there can be transfusion-related transmission of viruses such as HIV, hepatitis C, and hepatitis B. Rates of transmission of HIV, hepatitis C, and hepatitis B are estimated to be 1 in 2 million, 1 in 1 million, and 1 in 500,000, respectively. There also remains a low risk of “exotic” infectious agents such as West Nile virus, trypanosomiasis, and babesiosis.

The lungs are ingeniously constructed to carry out their cardinal function, the exchange of gases between inspired air and blood. Developmentally, the respiratory system is an outgrowth from the ventral wall of the foregut. The midline trachea develops two lateral outpocketings, the lung buds. The lung buds eventually divide into branches called lobar bronchi, three on the right and two on the left, thus giving rise to three lobes on the right and two on the left.

The lobar bronchi allow passage of air from the outside into the lung. They have firm cartilaginous walls that provide mechanical support, and are lined with columnar ciliated epithelium with abundant subepithelial glands that produce mucus, which impedes the entry of microbes. The mainstem bronchus is more vertical and directly in line with the trachea. Consequently, aspirated foreign materials, such as vomitus, blood, and foreign bodies, tend to enter the right lung more often than the left. The right and

left lobar bronchi branch dichotomously, giving rise to progressively smaller airways. Accompanying the branching airways is the double arterial supply to the lungs, derived from the pulmonary and bronchial arteries.

Progressive branching of the bronchi forms *bronchioles*, which are distinguished from bronchi by the lack of cartilage and submucosal glands within their walls. Further branching of bronchioles leads to the *terminal bronchioles*, which are less than 2 mm in diameter. The part of the lung distal to the terminal bronchiole is called the *acinus*; it is roughly spherical, with a diameter of about 7 mm. An acinus is composed of *respiratory bronchioles* (each of which gives off several alveoli from its sides), *alveolar ducts*, and *alveolar sacs*, the blind ends of the respiratory passages, whose walls are formed entirely of alveoli, which are the site of gas exchange (see Fig. 15-6). A cluster of three to five terminal bronchioles, each with its appended acinus, is referred to as the pulmonary *lobule*.

Except for the vocal cords, which are covered by stratified squamous epithelium, the entire respiratory tree, including the larynx, trachea, and bronchioles, is lined by pseudostratified, tall, columnar, ciliated epithelial cells. The bronchial mucosa also contains a population of neuroendocrine cells that have neurosecretory-type granules and can release a variety of factors, including serotonin, calcitonin, and gastrin-releasing peptide (bombesin). Numerous mucus-secreting goblet cells and submucosal glands are dispersed throughout the walls of the trachea and bronchi (but not the bronchioles).

The microscopic structure of the alveolar walls (or alveolar septa) consists of the following (Fig. 15-1):

- An intertwining network of *anastomosing capillaries* lined with endothelial cells
- *Basement membrane and surrounding interstitial tissue*, which separate the endothelial cells from the alveolar lining epithelial cells. In thin portions of the alveolar septum, the basement membranes of epithelium and endothelium are fused, whereas in thicker portions they are separated by an interstitial space (*pulmonary interstitium*) containing fine elastic fibers, small bundles

Figure 15-1 Microscopic structure of the alveolar wall. Note that the basement membrane (yellow) is thin on one side and widened where it is continuous with the interstitial space. Portions of interstitial cells are shown.

of collagen, a few fibroblast-like interstitial cells, smooth muscle cells, mast cells, and rare lymphocytes and monocytes.

- *Alveolar epithelium*, a continuous layer of two cell types: flattened, platelike *type I pneumocytes*, covering 95% of the alveolar surface, and rounded *type II pneumocytes*. Type II cells synthesize *surfactant* (which forms a very thin layer over the alveolar cell membranes) and are involved in the repair of alveolar epithelium through their ability to give rise to type I cells.
- *Alveolar macrophages*, loosely attached to the epithelial cells or lying free within the alveolar spaces

The alveolar walls are perforated by numerous *pores of Kohn*, which permit the passage of bacteria and exudate between adjacent alveoli (see Fig. 15-34B).

Congenital Anomalies

Developmental anomalies of the lung are rare; the more common of these include the following:

- *Pulmonary hypoplasia* is the defective development of both lungs (one may be more affected than the other) resulting in decreased weight, volume, and acini for body weight and gestational age. It is caused by abnormalities that compress the lung or impede normal lung expansion in utero, such as congenital diaphragmatic hernia and oligohydramnios. Severe hypoplasia is fatal in the early neonatal period.
- *Foregut cysts* arise from abnormal detachments of primitive foregut and are most often located in the hilum or middle mediastinum. Depending on the wall structure, these cysts are classified as bronchogenic (most common), esophageal, or enteric. A bronchogenic cyst is rarely connected to the tracheobronchial tree. Microscopically, the cyst is lined by ciliated pseudostratified columnar epithelium. The wall contains bronchial glands, cartilage, and smooth muscle. They usually present due to compression of nearby structures or are found incidentally.
- *Pulmonary sequestration* refers to a discrete area of lung tissue that (1) lacks any connection to the airway system and (2) has an abnormal blood supply arising from the aorta or its branches. *Extralobar sequestrations* are external to the lung and most commonly come to attention in infants as mass lesions. They may be associated with other congenital anomalies. *Intralobar sequestrations* occur within the lung. They usually present in older children, often due to recurrent localized infection or bronchiectasis.

Other less common congenital abnormalities include tracheal and bronchial anomalies (atresia, stenosis, tracheoesophageal fistula), vascular anomalies, congenital pulmonary airway malformation and congenital lobar overinflation (emphysema).

Atelectasis (Collapse)

Atelectasis refers either to incomplete expansion of the lungs (neonatal atelectasis) or to the collapse of previously

Figure 15-2 Various forms of acquired atelectasis. Dashed lines indicate normal lung volume.

inflated lung, producing areas of relatively airless pulmonary parenchyma. The main types of acquired atelectasis, which is encountered principally in adults, are the following (Fig. 15-2).

- **Resorption atelectasis** stems from complete obstruction of an airway. Over time, air is resorbed from the dependent alveoli, which collapse. Since lung volume is diminished, the mediastinum shifts *toward* the atelectatic lung. Airway obstruction is most often caused by excessive secretions (e.g., mucus plugs) or exudates within smaller bronchi, as may occur in bronchial asthma, chronic bronchitis, bronchiectasis, and postoperative states. Aspiration of foreign bodies and, rarely, fragments of bronchial tumors may also lead to airway obstruction and atelectasis.
- **Compression atelectasis** results whenever significant volumes of fluid (transudate, exudate or blood), tumor, or air (*pneumothorax*) accumulate within the pleural cavity. With compression atelectasis, the mediastinum shifts *away* from the affected lung.
- **Contraction atelectasis** occurs when focal or generalized pulmonary or pleural fibrosis prevents full lung expansion.

Significant atelectasis reduces oxygenation and predisposes to infection. Except in cases caused by contraction, atelectasis is a reversible disorder.

Pulmonary Edema

Pulmonary edema (leakage of excessive interstitial fluid which accumulates in alveolar spaces) can result from hemodynamic disturbances (hemodynamic or cardiogenic pulmonary edema) or from direct increases in capillary permeability, as a result of microvascular injury (Table 15-1). A general consideration of edema is given in Chapter 3, and pulmonary congestion and edema are described briefly in the context of congestive heart failure (Chapter 11). Whatever the clinical setting, pulmonary congestion and edema produce heavy, wet lungs. Therapy and outcome depend on the underlying etiology.

Hemodynamic Pulmonary Edema

Hemodynamic pulmonary edema is due to *increased hydrostatic pressure*, as occurs most commonly in **left-sided congestive heart failure**. Fluid accumulates initially in the basal regions of the lower lobes because hydrostatic pressure is greatest in these sites (dependent edema). Histologically, the alveolar capillaries are engorged, and an intra-alveolar transudate appears as finely granular pale pink material. Alveolar microhemorrhages and *hemosiderin-laden macrophages* (“heart failure” cells) may be present. In long-standing pulmonary congestion (e.g., as seen in mitral stenosis), hemosiderin-laden macrophages are abundant, and fibrosis and thickening of the alveolar walls cause the soggy lungs to become firm and brown (*brown induration*). These changes not only impair normal respiratory function but also predispose to infection.

Table 15-1 Classification and Causes of Pulmonary Edema

Hemodynamic Edema
Increased hydrostatic pressure (increased pulmonary venous pressure)
Left-sided heart failure (common)
Volume overload
Pulmonary vein obstruction
Decreased oncotic pressure (less common)
Hypoalbuminemia
Nephrotic syndrome
Liver disease
Protein-losing enteropathies
Lymphatic obstruction (rare)
Edema Due to Alveolar Wall Injury (Microvascular or Epithelial Injury)
Direct Injury
Infections: bacterial pneumonia
Inhaled gases: high concentration oxygen, smoke
Liquid aspiration: gastric contents, near-drowning
Radiation
Indirect Injury
Septicemia
Blood transfusion related
Burns
Drugs and chemicals: chemotherapeutic agents (bleomycin), other medications (methadone, amphotericin B), heroin, cocaine, kerosene, paraquat
Shock, trauma
Edema of Undetermined Origin
High altitude
Neurogenic (central nervous system trauma)

Edema Caused by Microvascular (Alveolar) Injury

Noncardiogenic pulmonary edema is due to injury to the alveolar septa. Primary injury to the vascular endothelium or damage to alveolar epithelial cells (with secondary microvascular injury) produces an inflammatory exudate that leaks into the interstitial space and, in more severe cases, into the alveoli. In most forms of pneumonia the edema remains localized and is overshadowed by the manifestations of infection. When diffuse, however, alveolar edema is an important contributor to a serious and often fatal condition, *acute respiratory distress syndrome* (discussed below).

Acute Lung Injury and Acute Respiratory Distress Syndrome (Diffuse Alveolar Damage)

Acute lung injury (ALI) (also called noncardiogenic pulmonary edema) is characterized by the abrupt onset of significant hypoxemia and bilateral pulmonary infiltrates in the absence of cardiac failure. Acute respiratory distress syndrome (ARDS) is a manifestation of severe ALI. Both ARDS and ALI are associated with inflammation-associated increases in pulmonary vascular permeability, edema and epithelial cell death. The histologic manifestation of these diseases is *diffuse alveolar damage* (DAD).

ALI is a well-recognized complication of diverse conditions, including both direct injuries to the lungs and systemic disorders (Table 15-2). In many cases, a combination of predisposing conditions is responsible (e.g., shock, oxygen therapy, and sepsis). Nonpulmonary organ dysfunction may also be present in severe cases.

Pathogenesis. ALI/ARDS is initiated by injury of pneumocytes and pulmonary endothelium, setting in motion a viscous cycle of increasing inflammation and pulmonary damage (Fig. 15-3).

- **Endothelial activation** is an important early event. In some instances, endothelial activation is secondary to pneumocyte injury, which is sensed by resident alveolar macrophages. In response, these immune sentinels secrete mediators such as TNF that act on the neighboring endothelium. Alternatively, circulating inflammatory mediators may activate pulmonary endothelium directly in the setting of severe tissue injury or sepsis. Some of these mediators injure endothelial cells, while others (notably cytokines) activate endothelial cells to express increased levels of adhesion molecules, procoagulant proteins and chemokines.
- **Adhesion and extravasation of neutrophils.** Neutrophils adhere to the activated endothelium and migrate into the interstitium and the alveoli, where they degranulate and release inflammatory mediators, including proteases, reactive oxygen species, and cytokines. Macrophage migration inhibitory factor (MIF) released into the local milieu also helps to sustain the ongoing proinflammatory response. The result is increased recruitment and adhesion of leukocytes, causing more endothelial injury, and local thrombosis. This cycle of

*More than 50% of cases of acute respiratory distress syndrome are associated with these four conditions.

inflammation and endothelial damage lies at the heart of ALI/ARDS.

- **Accumulation of intraalveolar fluid and formation of hyaline membranes.** Endothelial activation and injury make pulmonary capillaries leaky, allowing interstitial and intraalveolar edema fluid to form. Damage and necrosis of type II alveolar pneumocytes leads to surfactant abnormalities, further compromising alveolar gas exchange. Ultimately, the inspissated protein-rich edema fluid and debris from dead alveolar epithelial cells organize into hyaline membranes, a characteristic feature of ALI/ARDS.
- **Resolution of injury** is impeded in ALI/ARDS due to epithelial necrosis and inflammatory damage that impairs the ability of remaining cells to assist with edema resorption. Eventually, however, if the inflammatory stimulus lessens, macrophages remove intraalveolar debris and release fibrogenic cytokines such as transforming growth factor β (TGF- β) and platelet-derived growth factor (PDGF). These factors stimulate fibroblast growth and collagen deposition, leading to fibrosis of alveolar walls. Bronchiolar stem cells proliferate to replace pneumocytes. Endothelial restoration occurs through proliferation of uninjured capillary endothelium.

Figure 15-3 The normal alveolus (left side) compared with the injured alveolus in the early phase of acute lung injury and acute respiratory distress syndrome. (Modified with permission from Matthay MA, Ware LB, Zimmerman GA: The acute respiratory distress syndrome. *J Clin Invest* 122:2731, 2012.) *IL-1*, interleukin-1; *MIF*, migration inhibitory factor; *PAF*, platelet activating factor; *TNF*, tumor necrosis factor.

Epidemiologic studies have shown that ALI/ARDS is more common and associated with a worse prognosis in chronic alcoholics and in smokers. Genetic studies have identified a number of genes that increase the risk of ARDS, including variants that map to genes linked to inflammation and coagulation.

Clinical Course. Individuals who develop ALI are usually hospitalized for one of the predisposing conditions listed earlier. Profound *dyspnea* and *tachypnea* herald ALI, followed by increasing *cyanosis* and *hypoxemia*, *respiratory failure*, and the appearance of *diffuse bilateral infiltrates* on radiographic examination. Hypoxemia may be refractory

MORPHOLOGY

In the acute stage, the lungs are heavy, firm, red, and boggy. They exhibit congestion, interstitial and intra-alveolar edema, inflammation, fibrin deposition, and **diffuse alveolar damage**. The alveolar walls become lined with waxy **hyaline membranes** (Fig. 15-4) that are morphologically similar to those seen in hyaline membrane disease of neonates (Chapter 10). Alveolar hyaline membranes consist of fibrin-rich edema fluid mixed with the cytoplasmic and lipid remnants of necrotic epithelial cells. In the organizing stage, type II pneumocytes proliferate, and granulation tissue forms in the alveolar walls and spaces. In most cases the granulation tissue resolves, leaving minimal functional impairment. Sometimes, however, fibrotic thickening (scarring) of the alveolar septa ensues. Fatal cases often have superimposed bronchopneumonia.

Figure 15-4 Diffuse alveolar damage (acute respiratory distress syndrome). Some of the alveoli are collapsed, while others are distended. Many are lined by hyaline membranes (arrows).

to oxygen therapy due to ventilation perfusion mismatching (described below), and respiratory acidosis can develop. Early in the course, the lungs become stiff due to loss of functional surfactant.

The functional abnormalities in ALI are not evenly distributed throughout the lungs. The lungs have areas that are infiltrated, consolidated, or collapsed (and thus poorly aerated and poorly compliant) and regions that have nearly normal levels of compliance and ventilation. Poorly aerated regions continue to be perfused, producing *ventilation-perfusion mismatch* and hypoxemia.

There are no proven specific treatments; however, due to improvements in therapy for sepsis, mechanical ventilation, and supportive care, the mortality rate among the 200,000 ALI/ARDS cases seen yearly in the United States has decreased from 60% to about 40%, with the majority of deaths attributable to sepsis or multiorgan failure and, in some cases, direct lung injury. Most survivors recover pulmonary function but many have persistent impairment in physical and cognitive functions. In a minority of patients, the exudate and diffuse tissue destruction result in scarring, interstitial fibrosis, and chronic pulmonary disease.

KEY CONCEPTS

Acute Respiratory Distress Syndrome

- ARDS is a clinical syndrome of progressive respiratory insufficiency caused by diffuse alveolar damage in the setting of sepsis, severe trauma, or diffuse pulmonary infection.
- Damage to endothelial and alveolar epithelial cells, with inflammation, are the key initiating events and the basis of lung damage.
- The characteristic histologic picture is that of hyaline membranes lining alveolar walls. Edema, scattered neutrophils and macrophages, and epithelial necrosis are also present.

Acute Interstitial Pneumonia

Acute interstitial pneumonia is a term that is used to describe widespread ALI of unknown etiology associated with a rapidly progressive clinical course. It is sometimes referred to as idiopathic ALI-DAD. It is an uncommon disorder that occurs at a mean age of 59 years and has no sex predilection. Patients present with acute respiratory failure often following an illness of less than 3 weeks' duration that resembles an upper respiratory tract infection. The radiographic and pathologic features are identical to those of the organizing stage of ALI. The mortality rate

varies from 33% to 74%, with most deaths occurring within 1 to 2 months. Recurrences and chronic interstitial disease may occur in the survivors.

Obstructive and Restrictive Lung Diseases

Obstructive lung diseases (or airway diseases) are characterized by an increase in resistance to airflow due to partial or complete obstruction at any level from the trachea and larger bronchi to the terminal and respiratory bronchioles. These are contrasted with restrictive diseases, which are characterized by reduced expansion of lung parenchyma and decreased total lung capacity. The distinction between these chronic noninfectious diffuse pulmonary diseases is based primarily on pulmonary function tests. In individuals with diffuse obstructive disorders, pulmonary function tests show decreased maximal airflow rates during forced expiration, usually expressed as the forced expiratory volume at 1 second (FEV₁) over the forced ventilatory capacity (FVC). An FEV₁/FVC ratio of less than 0.7 generally indicates airway obstruction. Expiratory airflow obstruction may be caused by a variety of conditions (Table 15-3) that are ideally distinguished by distinct pathologic changes and different mechanisms of airflow obstruction. As discussed later, however, such neat distinctions are not always possible. In contrast, restrictive diseases are associated with proportionate decreases in both total lung capacity and FEV₁, leading to normal FEV₁/FVC ratio. Restrictive defects occur in two broad kinds of conditions: (1) *chest wall disorders* (e.g., severe obesity, pleural diseases, kyphoscoliosis, and neuromuscular diseases such as poliomyelitis) and (2) *chronic interstitial and infiltrative diseases*, such as pneumoconioses and interstitial fibrosis.

Obstructive Lung Diseases

Common obstructive lung diseases include emphysema, chronic bronchitis, asthma, and bronchiectasis, each of which has distinct pathologic features and clinical characteristics (Table 15-3). Emphysema and chronic bronchitis are often clinically grouped together and referred to as *chronic obstructive pulmonary disease* (COPD), since the majority of patients have features of both, almost certainly because they share a major trigger—cigarette

Table 15-3 Disorders Associated with Airflow Obstruction: The Spectrum of Chronic Obstructive Pulmonary Disease

Clinical Term	Anatomic Site	Major Pathologic Changes	Etiology	Signs/Symptoms
Chronic bronchitis	Bronchus	Mucous gland hyperplasia, hypersecretion	Tobacco smoke, air pollutants	Cough, sputum production
Bronchiectasis	Bronchus	Airway dilation and scarring	Persistent or severe infections	Cough, purulent sputum, fever
Asthma	Bronchus	Smooth muscle hyperplasia, excess mucus, inflammation	Immunologic or undefined causes	Episodic wheezing, cough, dyspnea
Emphysema	Acinus	Airspace enlargement; wall destruction	Tobacco smoke	Dyspnea
Small-airway disease, bronchiolitis*	Bronchiole	Inflammatory scarring/obliteration	Tobacco smoke, air pollutants, miscellaneous	Cough, dyspnea

*Can be seen with any form of obstructive lung disease or as an isolated finding.

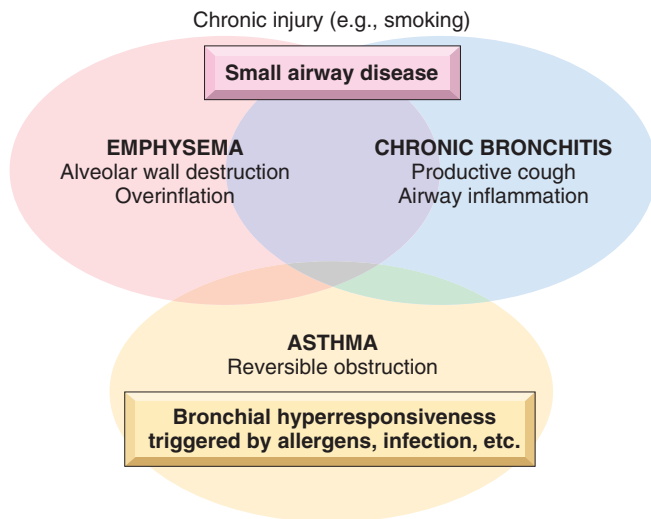

Figure 15-5 Schematic representation of overlap between chronic obstructive lung diseases.

smoking. In addition, small-airway disease, a variant of chronic bronchiolitis, is now known to contribute to obstruction both in emphysema and chronic bronchitis. While asthma is distinguished from chronic bronchitis and emphysema by the presence of reversible bronchospasm, some patients with otherwise typical asthma also develop an irreversible component (Fig. 15-5). Conversely, some patients with otherwise typical COPD have a reversible component. It is clinically common to label such patients as having COPD/asthma.

COPD is a major public health problem. It is the fourth leading cause of morbidity and mortality in the United States and is projected to rank fifth by 2020 as a worldwide burden of disease. There is a clear-cut association between heavy cigarette smoking and emphysema, and women and African Americans are more susceptible than other groups. About 35-50% of heavy smokers develop COPD; conversely 80% of COPD is due to smoking. Other risk factors include environmental and occupational pollutants, airway hyperresponsiveness and genetic polymorphisms.

Recognizing that there is overlap between various forms of COPD, it is still useful to discuss each individually in order to highlight the pathophysiologic basis of different causes of airflow obstruction.

Emphysema

Emphysema is characterized by irreversible enlargement of the airspaces distal to the terminal bronchiole, accompanied by destruction of their walls without obvious fibrosis. Small airway fibrosis (distinct from chronic bronchitis) has recently been shown to be present in patients with emphysema; it is a significant contributor to airflow obstruction. Emphysema is classified according to its anatomic distribution within the lobule. Recall that the lobule is a cluster of acini, the terminal respiratory units. Based on the segments of the respiratory units that are involved, emphysema is classified into four major types: (1) *centriacinar*, (2) *panacinar*, (3) *paraseptal*, and (4) *irregular*. Of these, only the first two cause clinically significant airflow obstruction (Fig. 15-6). Centriacinar emphysema is the

most common form, constituting more than 95% of clinically significant cases.

- **Centriacinar (centrilobular) emphysema.** In this type of emphysema the central or proximal parts of the acini, formed by respiratory bronchioles, are affected, whereas distal alveoli are spared (Figs. 15-6B and 15-7A). Thus, both emphysematous and normal airspaces exist within the same acinus and lobule. The lesions are more common and usually more severe in the upper lobes, particularly in the apical segments. Inflammation around bronchi and bronchioles is common. In severe centriacinar emphysema, the distal acinus may also be involved, making differentiation from panacinar emphysema difficult. Centriacinar emphysema occurs predominantly in heavy smokers, often in association with chronic bronchitis (COPD).
- **Panacinar (panlobular) emphysema.** In this type, the acini are uniformly enlarged from the level of the respiratory bronchiole to the terminal blind alveoli (Figs. 15-6C and 15-7B). The prefix “pan” refers to the entire acinus, not the entire lung. In contrast to centriacinar emphysema, panacinar emphysema tends to occur more commonly in the lower zones and in the anterior margins of the lung, and it is usually most severe at the bases. This type of emphysema is associated with α_1 -antitrypsin deficiency (Chapter 17).
- **Distal acinar (paraseptal) emphysema.** In this type, the proximal portion of the acinus is normal, and the distal part is predominantly involved. The emphysema is more striking adjacent to the pleura, along the lobular

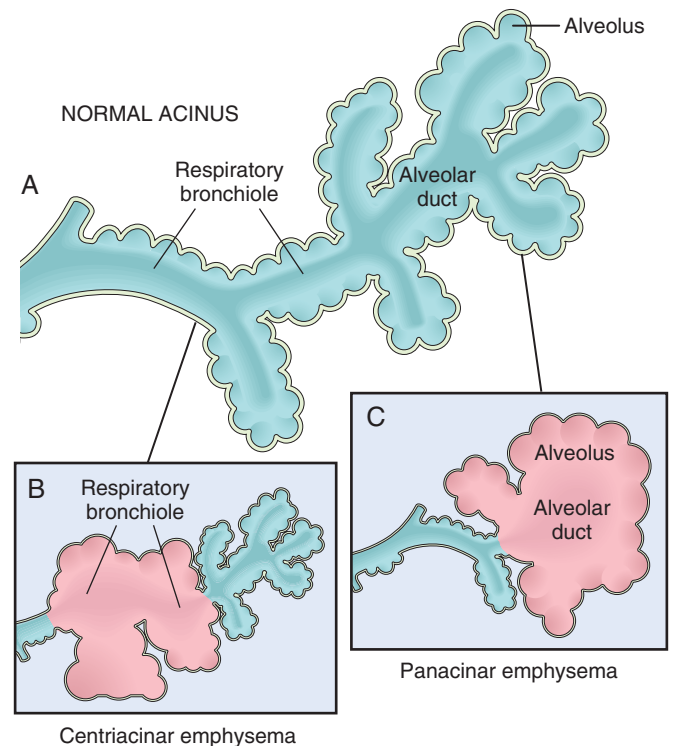

Figure 15-6 Clinically significant patterns of emphysema. **A**, Structure of the normal acinus. **B**, Centriacinar emphysema with dilation that initially affects the respiratory bronchioles. **C**, Panacinar emphysema with initial distention of the alveolus and alveolar duct.

Figure 15-7 **A**, Centriacinar emphysema. Central areas show marked emphysematous damage (E), surrounded by relatively spared alveolar spaces. **B**, Panacinar emphysema involving the entire pulmonary lobule.

connective tissue septa, and at the margins of the lobules. It occurs adjacent to areas of fibrosis, scarring, or atelectasis and is usually more severe in the upper half of the lungs. The characteristic findings are of multiple, continuous, enlarged airspaces from less than 0.5 cm to more than 2.0 cm in diameter, sometimes forming cystlike structures. This type of emphysema probably underlies many cases of spontaneous pneumothorax in young adults.

- **Airspace enlargement with fibrosis (irregular emphysema).** Irregular emphysema, so named because the acinus is irregularly involved, is almost invariably associated with scarring. In most instances it occurs in small foci and is clinically insignificant.

Pathogenesis. Inhaled cigarette smoke and other noxious particles cause lung damage and inflammation, which results in parenchymal destruction (emphysema) and airway disease (bronchiolitis and chronic bronchitis). Factors that influence the development of emphysema include the following (Fig. 15-8):

- **Inflammatory mediators and leukocytes.** A wide variety of mediators have been shown to be increased in the affected parts (including leukotriene B_4 , IL-8, TNF, and others) These mediators are released by resident epithelial cells and macrophages, and attract inflammatory

cells from the circulation (chemotactic factors), amplify the inflammatory process (proinflammatory cytokines) and induce structural changes (growth factors).

- **Protease-antiprotease imbalance.** Several proteases are released from the inflammatory cells and epithelial cells that break down connective tissue components. In patients who develop emphysema, there is a relative deficiency of protective antiproteases, which in some instances has a genetic basis (further discussed later).
- **Oxidative stress.** Substances in tobacco smoke, alveolar damage, and inflammatory cells all produce oxidants, which may beget more tissue damage and inflammation. The role of oxidants is supported by mouse models in which the *NRF2* gene is inactivated. *NRF2* encodes a transcription factor that serves as a sensor for oxidants in alveolar epithelial cells and many other cells types. Intracellular oxidants activate *NRF2*, which upregulates the expression of multiple genes that protect cells from oxidant damage. Mice without *NRF2* are significantly more sensitive to tobacco smoke than normal mice, and genetic variants in *NRF2*, *NRF2* regulators, and *NRF2* target genes are all associated with smoking-related lung disease in humans.
- **Infection.** Although infection is not thought to play a role in the initiation of tissue destruction, bacterial and/or viral infections may exacerbate the associated inflammation and chronic bronchitis.

The idea that proteases are important is based in part on the observation that patients with a genetic deficiency of the antiprotease α_1 -antitrypsin have a markedly enhanced tendency to develop pulmonary emphysema, which is compounded by smoking. About 1% of all patients with emphysema have this defect. α_1 -antitrypsin, normally present in serum, tissue fluids, and macrophages, is a major inhibitor of proteases (particularly elastase) secreted by neutrophils during inflammation. α_1 -antitrypsin is encoded by the proteinase inhibitor (*Pi*) locus on chromosome 14. The *Pi* locus is polymorphic, and approximately 0.012% of the US population is homozygous for the Z allele, a genotype that is associated with markedly decreased serum levels of α_1 -antitrypsin. More than 80% of these individuals develop symptomatic panacinar emphysema, which occurs at an earlier age and is of greater

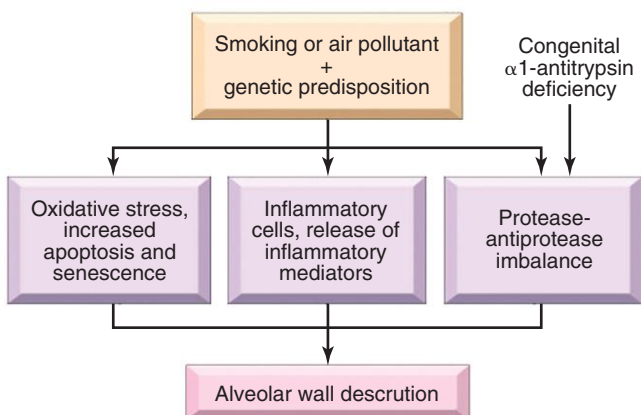

Figure 15-8 Pathogenesis of emphysema. See text for details.

severity if the individual smokes. It is postulated that any injury (e.g., that induced by smoking) that increases the activation and influx of neutrophils into the lung leads to local release of proteases, which in the absence of α_1 -antitrypsin activity result in excessive digestion of elastic tissue and emphysema.

Several other genetic variants have been linked to risk of emphysema. Among these are variants associated with the nicotinic acetylcholine receptor, which are hypothesized to influence the addictiveness of tobacco smoke and thus the behavior of smokers. Not surprisingly, the same variants are also linked to lung cancer risk, emphasizing the importance of smoking in both of these diseases.

A number of factors contribute to airway obstruction in emphysema. Small airways are normally held open by the elastic recoil of the lung parenchyma, and the loss of elastic tissue in the walls of alveoli that surround respiratory bronchioles reduces radial traction and thus causes the respiratory bronchioles to collapse during expiration. This leads to functional airflow obstruction despite the absence of mechanical obstruction. In addition, even young smokers often have small airway inflammation associated with the following changes:

- Goblet cell hyperplasia, with mucus plugging of the lumen
- Inflammatory infiltrates in bronchial walls consisting of neutrophils, macrophages, B cells (sometimes forming follicles), and T cells
- Thickening of the bronchiolar wall due to smooth muscle hypertrophy and peribronchial fibrosis

Together these changes narrow the bronchiolar lumen and contribute to airway obstruction.

MORPHOLOGY

Advanced emphysema produces voluminous lungs, often overlapping the heart and hiding it when the anterior chest wall is removed. Generally, the upper two thirds of the lungs are more severely affected. Large apical blebs or bullae are more characteristic of irregular emphysema secondary to scarring and of distal acinar emphysema. Large alveoli can easily be seen on the cut surface of fixed lungs (Fig. 15-7).

Microscopically, abnormally large alveoli are separated by thin septa with only focal centriacinar fibrosis. There is loss of attachments of the alveoli to the outer wall of small airways. The pores of Kohn are so large that septa appear to be floating or protrude blindly into alveolar spaces with a club-shaped end. Prolonged vasoconstriction leads to changes of pulmonary arterial hypertension. As alveolar walls are destroyed, there is a decrease in the capillary bed area. With advanced disease, there are even larger abnormal airspaces and possibly blebs or bullae, which often deform and compress the respiratory bronchioles and vasculature of the lung. Inflammatory changes in small airways were described earlier.

Clinical Course. Symptoms do not appear until at least one third of the functioning pulmonary parenchyma is damaged. *Dyspnea* usually appears first, beginning insidiously but progressing steadily. In some patients, cough or wheezing is the chief complaint, easily confused with asthma. Cough and expectoration are extremely variable and depend on the extent of the associated bronchitis.

Table 15-4 Emphysema and Chronic Bronchitis

	Predominant Bronchitis	Predominant Emphysema
Age (yr)	40-45	50-75
Dyspnea	Mild; late	Severe; early
Cough	Early; copious sputum	Late; scanty sputum
Infections	Common	Occasional
Respiratory insufficiency	Repeated	Terminal
Cor pulmonale	Common	Rare; terminal
Airway resistance	Increased	Normal or slightly increased
Elastic recoil	Normal	Low
Chest radiograph	Prominent vessels; large heart	Hyperinflation; small heart
Appearance	Blue bloater	Pink puffer

Weight loss is common and can be so severe as to suggest an occult cancer. Classically, the patient with severe emphysema is barrel-chested and dyspneic, with obviously prolonged expiration, sits forward in a hunched-over position, and breathes through pursed lips. *Impaired expiratory airflow*, best measured through spirometry, is the key to diagnosis.

In individuals with severe emphysema, cough is often slight, overdistention is severe, diffusion capacity is low, and blood gas values are relatively normal at rest. Such patients may overventilate and remain well oxygenated, and therefore are somewhat ingloriously designated *pink puffers* (Table 15-4). Development of cor pulmonale and eventually congestive heart failure, related to secondary pulmonary hypertension, is associated with a poor prognosis. Death in most patients with emphysema is due to (1) coronary artery disease, (2) respiratory failure, (3) right-sided heart failure, or (4) massive collapse of the lungs secondary to pneumothorax. Treatment options include smoking cessation, oxygen therapy, long-acting bronchodilators with inhaled corticosteroids, physical therapy, bullectomy, and, in selected patients, lung volume reduction surgery and lung transplantation. α_1 -AT replacement therapy is being evaluated.

KEY CONCEPTS

Emphysema

- Emphysema is a chronic obstructive airway disease characterized by permanent enlargement of air spaces distal to terminal bronchioles. It is a component of COPD (chronic obstructive pulmonary disease) along with chronic bronchitis.
- Subtypes include centriacinar (most common, smoking related), panacinar (seen in α_1 -antitrypsin deficiency), distal acinar and irregular.
- Smoking and inhaled pollutants cause ongoing accumulations of inflammatory cells, releasing elastases and oxidants, which destroy the alveolar walls.
- Most patients with emphysema also have some degree of chronic bronchitis, which is to be expected since cigarette smoking is an underlying risk factor for both.

Other Forms of Emphysema

The following are conditions to which the term emphysema is applied because they are associated with lung overinflation or focal emphysematous change

- **Compensatory hyperinflation.** This term is sometimes used to designate dilation of alveoli in response to loss of lung substance elsewhere. It is best exemplified by the hyperexpansion of residual lung parenchyma following surgical removal of a diseased lung or lobe.
- **Obstructive overinflation.** In this condition the lung expands because air is trapped within it. A common cause is subtotal obstruction of the airways by a tumor or foreign object. Another example is *congenital lobar overinflation* in infants, probably resulting from hypoplasia of bronchial cartilage and sometimes associated with other congenital cardiac and lung abnormalities. Overinflation in obstructive lesions occurs either (1) because the obstructive agent acts as ball valve, allowing air to enter on inspiration while preventing its exodus on expiration, or (2) because *collaterals* bring in air behind the obstruction. These collaterals consist of the *pores of Kohn* and other direct accessory bronchioalveolar connections (the *canals of Lambert*). Obstructive overinflation can be a life-threatening emergency, because the affected portion distends sufficiently to compress the remaining lung.
- **Bullous emphysema.** This is a descriptive term for large subpleural blebs or bullae (spaces greater than 1 cm in diameter in the distended state) that can occur in any form of emphysema (Fig. 15-9). These localized accentuations of emphysema occur near the apex, sometimes near old tuberculous scarring. On occasion, rupture of the bullae may give rise to pneumothorax.
- **Interstitial emphysema.** Entrance of air into the connective tissue stroma of the lung, mediastinum, or subcutaneous tissue produces *interstitial emphysema*. In most instances, alveolar tears in pulmonary emphysema

Figure 15-9 Bullous emphysema. Note the large subpleural bullae (upper left).

provide the avenue of entrance of air into the stroma of the lung, but rarely, chest wounds that allow entry of air or fractured ribs that puncture the lung substance underlie this disorder. Alveolar tears are usually caused by rapid increases in pressure within alveolar sacs, such as occurs when there is a combination of coughing and bronchiolar obstruction. Premature children on positive pressure ventilation adults who are being artificially ventilated are most at risk.

Chronic Bronchitis

Chronic bronchitis is defined clinically as persistent cough with sputum production for at least 3 months in at least 2 consecutive years, in the absence of any other identifiable cause. Common in habitual smokers and inhabitants of smog-laden cities, chronic bronchitis is one end of the spectrum of COPD, with emphysema being the other. Most patients lie somewhere in between, having features of both. When chronic bronchitis persists for years, it may accelerate decline in lung function, lead to cor pulmonale and heart failure, or cause atypical metaplasia and dysplasia of the respiratory epithelium, providing a rich soil for cancerous transformation.

Pathogenesis. The primary or initiating factor in the genesis of chronic bronchitis is exposure to noxious or irritating inhaled substances such as tobacco smoke (90% of patients are smokers) and dust from grain, cotton, and silica.

- **Mucus hypersecretion.** The earliest feature of chronic bronchitis is hypersecretion of mucus in the large airways, associated with hypertrophy of the submucosal glands in the trachea and bronchi. The basis for mucus hypersecretion is incompletely understood, but it appears to involve inflammatory mediators such as histamine and IL-13. With time, there is also a marked increase in goblet cells in small airways—small bronchi and bronchioles—leading to excessive mucus production that contributes to airway obstruction. It is thought that both the submucosal gland hypertrophy and the increase in goblet cells are protective reactions against tobacco smoke or other pollutants (e.g., sulfur dioxide and nitrogen dioxide).
- **Inflammation.** Inhalants that induce chronic bronchitis cause cellular damage, eliciting both acute and chronic inflammatory responses involving neutrophils, lymphocytes, and macrophages. Long-standing inflammation and accompanying fibrosis involving small airways (small bronchi and bronchioles, less than 2 to 3 mm in diameter) can also lead to chronic airway obstruction. This feature is similar to that described earlier in emphysema and is a common denominator in COPD.
- **Infection.** Infection does not initiate chronic bronchitis, but is probably significant in maintaining it and may be critical in producing acute exacerbations.

It should be recognized that cigarette smoke predisposes to chronic bronchitis in several ways. Not only does it damage airway lining cells, leading to chronic inflammation, but it also interferes with the ciliary action of the respiratory epithelium, preventing the clearance of mucus and increasing the risk of infection.

MORPHOLOGY

Grossly, there is hyperemia, swelling, and edema of the mucous membranes, frequently accompanied by excessive mucinous or mucopurulent secretions. Sometimes, heavy casts of secretions and pus fill the bronchi and bronchioles. The characteristic features are mild chronic inflammation of the airways (predominantly lymphocytes) and enlargement of the mucus-secreting glands of the trachea and bronchi. Although the numbers of goblet cells increase slightly, the **major change is in the size of mucous glands (hyperplasia)**. This increase can be assessed by the ratio of the thickness of the mucous gland layer to the thickness of the wall between the epithelium and the cartilage (**Reid index**). The Reid index (normally 0.4) is increased in chronic bronchitis, usually in proportion to the severity and duration of the disease. The bronchial epithelium may exhibit squamous metaplasia and dysplasia. There is marked narrowing of bronchioles caused by mucus plugging, inflammation, and fibrosis. In the most severe cases, there may be obliteration of lumen due to fibrosis (**bronchiolitis obliterans**).

Clinical Features. The cardinal symptom of chronic bronchitis is a persistent cough productive of sparse sputum. For many years no other respiratory functional impairment is present, but eventually dyspnea on exertion develops. With the passage of time, and usually with continued smoking, other elements of COPD may appear, including hypercapnia, hypoxemia, and mild cyanosis (“*blue bloaters*”). Differentiation of pure chronic bronchitis from that associated with emphysema can be made in the classic case (Table 15-4), but, as has been mentioned, many patients with COPD have both conditions. Long-standing severe chronic bronchitis commonly leads to cor pulmonale and cardiac failure. Death may also result from further impairment of respiratory function due to superimposed acute infections.

KEY CONCEPTS

Chronic Bronchitis

- Chronic bronchitis is defined as persistent productive cough for at least 3 consecutive months in at least 2 consecutive years.
- Cigarette smoking is the most important risk factor; air pollutants also contribute.
- The dominant pathologic features are mucus hypersecretion and persistent inflammation.
- Histologic examination demonstrates enlargement of mucous-secreting glands, goblet cell hyperplasia, chronic inflammation, and bronchiolar wall fibrosis.

Asthma

Asthma is a chronic disorder of the conducting airways, usually caused by an immunological reaction, which is marked by episodic bronchoconstriction due to increased airway sensitivity to a variety of stimuli; inflammation of the bronchial walls; and increased mucus secretion. The disease is manifested by recurrent episodes of wheezing, breathlessness, chest tightness, and cough, particularly at night and/or in the early morning.

These symptoms are usually associated with widespread but variable bronchoconstriction and airflow limitation that is at least partly reversible, either spontaneously or with treatment. Some of the stimuli that trigger attacks in patients would have little or no effect in subjects with normal airways. Rarely, a state of unremitting attacks, called acute severe asthma (formerly known as *status asthmaticus*), may prove fatal; usually, such patients have had a long history of asthma. Between the attacks, patients may be virtually asymptomatic. Of note, there has been a significant increase in the incidence of asthma in the Western world over the past 40 to 50 years, which may be reaching a plateau now. More recently, although treatment for asthma has improved substantially, the prevalence of asthma continues to increase in low and middle income countries and in some ethnic groups in which prevalence was previously low.

Asthma may be categorized as *atopic* (evidence of allergen sensitization and immune activation, often in a patient with allergic rhinitis or eczema) or *non-atopic* (no evidence of allergen sensitization). In either type, episodes of bronchospasm can have diverse triggers, such as respiratory infections (especially viral infections), exposure to irritants (e.g., smoke, fumes), cold air, stress, and exercise. There is some evidence that sub-classifying asthma according to its clinical features and underlying biology is clinically useful. One example is early-onset allergic asthma associated with T_H2 helper T cell inflammation, a feature seen in about half of the patients. This form of asthma responds well to corticosteroids. However, there is no current consensus as to definitions and diagnostic criteria. Asthma may also be classified according to the agents or events that trigger bronchoconstriction. These include seasonal, exercise-induced, drug-induced (e.g., aspirin), and occupational asthma, and asthmatic bronchitis in smokers.

Atopic Asthma. This most common type of asthma is a **classic example of IgE-mediated (type I) hypersensitivity reaction**, discussed in detail in Chapter 6. The disease usually begins in childhood and is triggered by environmental allergens, such as dusts, pollens, cockroach or animal dander, and foods, which most frequently act in synergy with other proinflammatory environmental cofactors, most notable respiratory viral infections. A positive family history of asthma is common, and a skin test with the offending antigen in these patients results in an immediate wheal-and-flare reaction. Atopic asthma may also be diagnosed based on high total serum IgE levels or evidence of allergen sensitization by serum radioallergosorbent tests (called RAST), which can detect the presence of IgE antibodies that are specific for individual allergens.

Non-Atopic Asthma. Individuals with non-atopic asthma do not have evidence of allergen sensitization and skin test results are usually negative. A positive family history of asthma is less common in these patients. Respiratory infections due to viruses (e.g., rhinovirus, parainfluenza virus and respiratory syncytial virus) are common triggers in non-atopic asthma. Inhaled air pollutants, such as smoking, sulfur dioxide, ozone, and nitrogen dioxide, may also contribute to the chronic airway inflammation and hyperreactivity in some cases. As already mentioned, in some instances attacks may be triggered by seemingly innocuous events, such as exposure to cold and even exercise.

Drug-Induced Asthma. Several pharmacologic agents provoke asthma. *Aspirin-sensitive asthma* is an uncommon type, occurring in individuals with recurrent rhinitis and nasal polyps. These individuals are exquisitely sensitive to small doses of aspirin as well as other nonsteroidal anti-inflammatory medications, and they experience not only asthmatic attacks but also urticaria. Aspirin (and other non-steroidal anti-inflammatory drugs) triggers asthma in these patients by inhibiting the cyclooxygenase pathway of arachidonic acid metabolism, leading to a rapid decrease in prostaglandin E_2 . Normally prostaglandin E_2 inhibits enzymes that generate proinflammatory mediators such as leukotrienes B_4 , C_4 , D_4 and E_4 , which are believed to have central roles in aspirin-induced asthma.

Occupational Asthma. This form of asthma may be triggered by fumes (epoxy resins, plastics), organic and chemical dusts (wood, cotton, platinum), gases (toluene), or other chemicals (formaldehyde, penicillin products). Only minute quantities of chemicals are required to induce the attack, which usually occurs after repeated exposure. The underlying mechanisms vary according to stimulus and include type I reactions, direct liberation of bronchoconstrictor substances, and hypersensitivity responses of unknown origin.

Pathogenesis. Atopic asthma is caused by a T_H2 and IgE response to environmental allergens in genetically predisposed individuals. Airway inflammation is central to disease pathophysiology and causes airway dysfunction partly through the release of potent inflammatory mediators and partly through remodeling of the airway wall. As the disease becomes more severe, there is increased local secretion of growth factors, which induce mucus gland hypertrophy, smooth muscle proliferation, angiogenesis, fibrosis and nerve proliferation. Varying combinations of these processes help explain the different asthma subtypes, their response to treatment and their natural history over a person's lifetime.

The contributions of the immune response, genetics and environment are discussed separately below, although they are closely intertwined.

T_H2 Responses, IgE and Inflammation. A fundamental abnormality in asthma is an exaggerated T_H2 response to normally harmless environmental antigens (Fig 15-10). T_H2 cells secrete cytokines that promote inflammation and stimulate B cells to produce IgE and other antibodies. These cytokines include IL-4, which stimulates the production of IgE; IL-5, which activates locally recruited eosinophils; and IL-13, which stimulates mucus secretion from bronchial submucosal glands and also promotes IgE production by B cells. The T cells and epithelial cells secrete chemokines that recruit more T cells and eosinophils, thus exacerbating the reaction. As in other allergic reactions (Chapter 6), IgE binds to the Fc receptors on submucosal mast cells, and repeat exposure to the allergen triggers the mast cells to release granule contents and produce cytokines and other mediators, which collectively induce the *early-phase (immediate hypersensitivity) reaction* and the *late-phase reaction*.

The early reaction is dominated by bronchoconstriction, increased mucus production, variable degrees of

vasodilation, and increased vascular permeability. Bronchoconstriction is triggered by direct stimulation of subepithelial vagal (parasympathetic) receptors through both central and local reflexes triggered by mediators produced by mast cells and other cells in the reaction. The late-phase reaction is dominated by recruitment of leukocytes, notably eosinophils, neutrophils, and more T cells. Although T_H2 cells are the dominant T cell type involved in the disease, other T cells that contribute to the inflammation include T_H17 (IL-17 producing) cells, which recruit neutrophils.

Many mediators produced by leukocytes and epithelial cells have been implicated in the asthmatic response. The long list of "suspects" in acute asthma can be ranked based on the clinical efficacy of pharmacologic intervention with antagonists of specific mediators.

- Mediators whose role in bronchospasm is clearly supported by efficacy of pharmacologic intervention are: (1) *leukotrienes* C_4 , D_4 , and E_4 , which cause prolonged bronchoconstriction as well as increased vascular permeability and increased mucus secretion, and (2) *acetylcholine*, released from intrapulmonary parasympathetic nerves, which can cause airway smooth muscle constriction by directly stimulating muscarinic receptors.
- A second group includes agents present at the "scene of the crime" but whose actual role in acute allergic asthma seems relatively minor on the basis of lack of efficacy of potent antagonists or synthesis inhibitors: (1) *histamine*, a potent bronchoconstrictor; (2) *prostaglandin* D_2 , which elicits bronchoconstriction and vasodilatation; and (3) *platelet-activating factor*, which causes aggregation of platelets and release of serotonin from their granules. These mediators might yet prove important in certain types of chronic or nonallergic asthma.
- Finally, a large third group comprises the "suspects" for whom specific antagonists or inhibitors are not available or have been insufficiently studied as yet. Several promising focused therapies for asthma that target the IL-13/IL-4 signal transduction pathways are in development, including anti-IL-13 monoclonal antibodies and IL-4 receptor antagonists. Other targets include IL-1, TNF, IL-6, chemokines (e.g., eotaxin, also known as CCL11), neuropeptides, nitric oxide, bradykinin, and endothelins.

It is thus clear that multiple mediators contribute to the acute asthmatic response. Moreover, the composition of this "mediator soup" might vary among individuals or different types of asthma. The appreciation of the importance of inflammatory cells and mediators in asthma has led to greater emphasis on anti-inflammatory drugs, such as corticosteroids, in its treatment.

Genetic Susceptibility. Susceptibility to atopic asthma is multigenic and often associated with increased incidence of other allergic disorders, such as allergic rhinitis (hay fever) and eczema. The genetic polymorphisms linked to asthma and other allergic disorders were described in Chapter 6. Suffice it to say here that many of these are likely to influence immune responses and the subsequent inflammatory reaction. Some of the stronger or more interesting associations include the following:

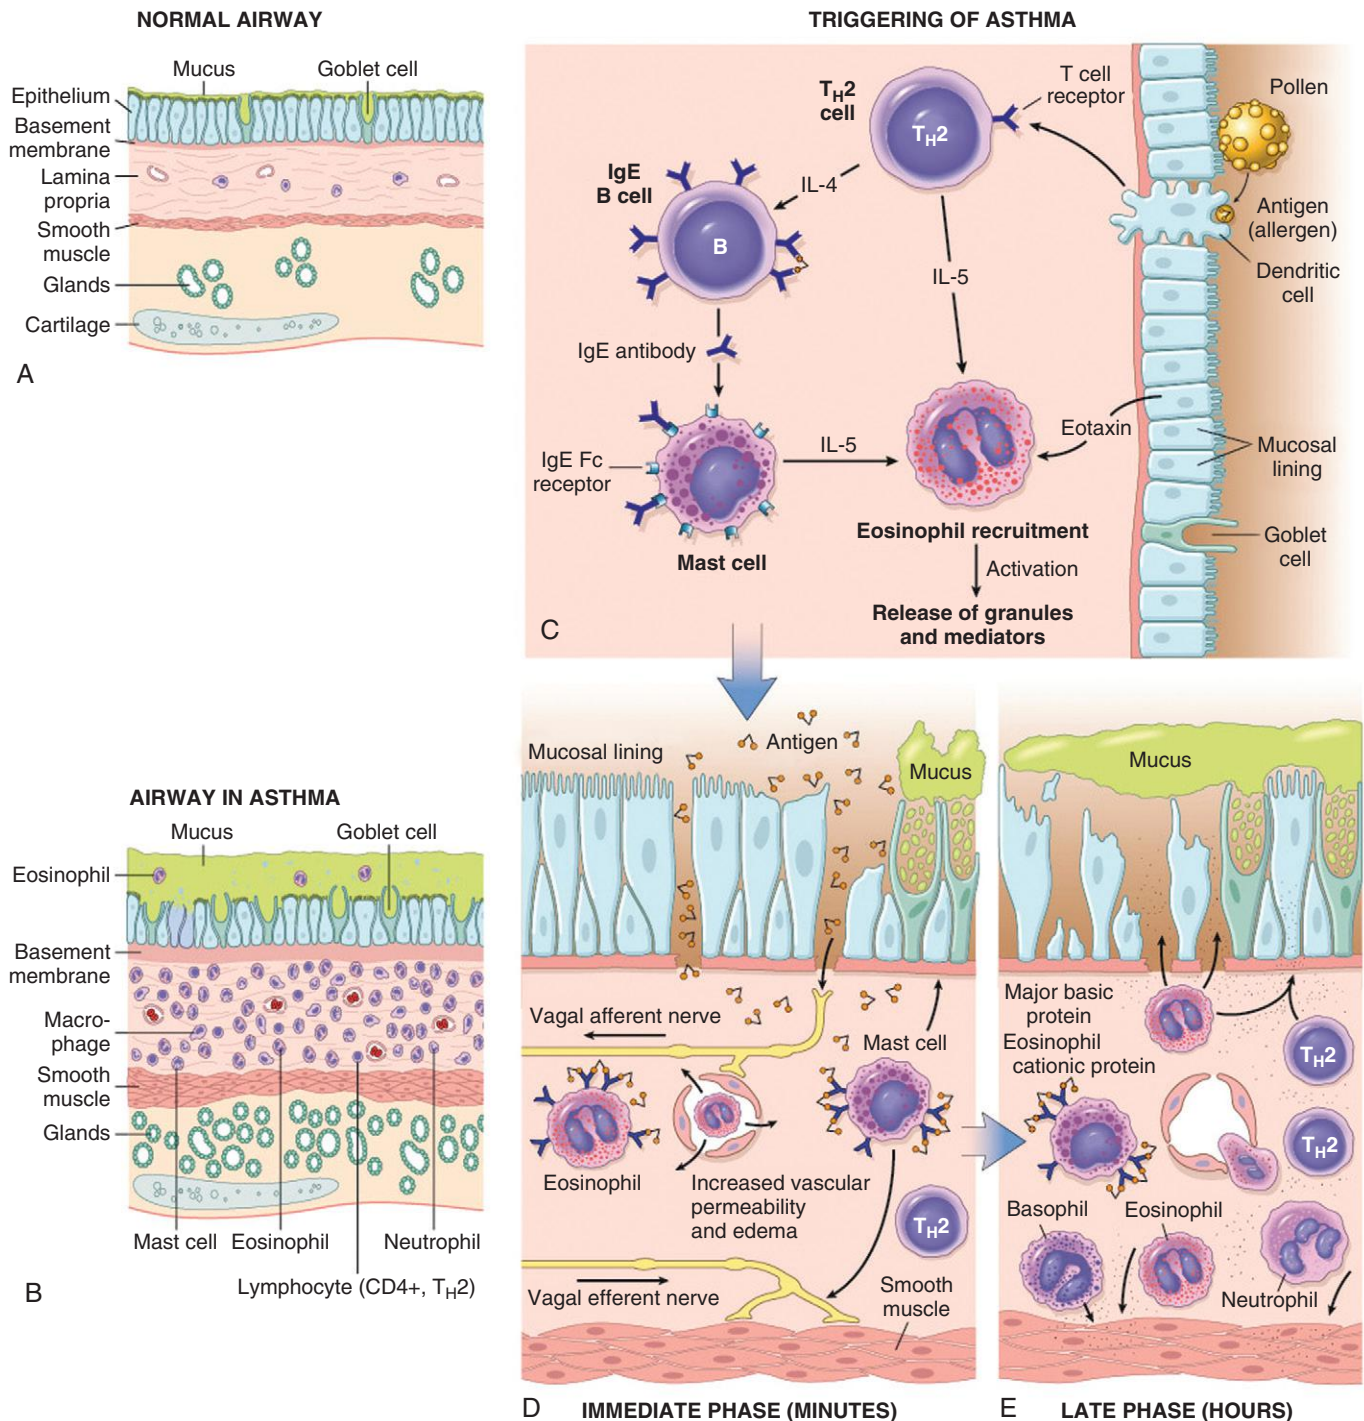

Figure 15-10 **A** and **B**, Comparison of a normal airway and an airway involved by asthma. The asthmatic airway is marked by accumulation of mucus in the bronchial lumen secondary to an increase in the number of mucus-secreting goblet cells in the mucosa and hypertrophy of submucosal glands; intense chronic inflammation due to recruitment of eosinophils, macrophages, and other inflammatory cells; thickened basement membrane; and hypertrophy and hyperplasia of smooth muscle cells. **C**, Inhaled allergens (antigen) elicit a T_H2-dominated response favoring IgE production and eosinophil recruitment. **D**, On re-exposure to antigen (Ag), the immediate reaction is triggered by Ag-induced cross-linking of IgE bound to Fc receptors on mast cells. These cells release preformed mediators that directly and via neuronal reflexes induce bronchospasm, increased vascular permeability, mucus production, and recruitment of leukocytes. **E**, Leukocytes recruited to the site of reaction (neutrophils, eosinophils, and basophils; lymphocytes and monocytes) release additional mediators that initiate the late phase of asthma. Several factors released from eosinophils (e.g., major basic protein, eosinophil cationic protein) also cause damage to the epithelium.

- One susceptibility locus for asthma is located on chromosome 5q, near the gene cluster encoding the cytokines IL-3, IL-4, IL-5, IL-9, and IL-13 and the IL-4 receptor. Among the genes in this cluster, polymorphisms in the *IL13* gene have the strongest and most consistent associations with asthma or allergic disease.
- Particular class II HLA alleles are linked to production of IgE antibodies against some antigens, such as ragweed pollen.
- Polymorphisms in the gene encoding ADAM33, a metalloproteinase, may be linked to increased proliferation of bronchial smooth muscle cells and fibroblasts, thus contributing to bronchial hyperreactivity and subepithelial fibrosis.
- β_2 -adrenergic receptor gene variants are associated with differential in vivo airway hyper-responsiveness and in vitro response to β -agonist stimulation.
- IL-4 receptor gene variants are associated with atopy, elevated total serum IgE, and asthma.
- Variants in several members of the mammalian family of chitinases, enzymes that cleave chitin, a polysaccharide contained in many human parasites and the cell walls of fungi, have been associated with asthma. Increased serum levels and lung expression of YKL-40 (a chitinase-like glycoprotein expressed and secreted by a variety of cells) are correlated with disease severity, airway remodeling, and decreased pulmonary function.

Environmental Factors. Asthma is a disease of industrialized societies where the majority of people live in cities. This likely has two main explanations. Firstly, industrialized environments contain many airborne pollutants that can serve as allergens to initiate the T_H2 response. Secondly, city life tends to limit the exposure of very young children to certain antigens, particularly microbial antigens, and exposure to such antigens seems to protect children from asthma and atopy. This protective effect is even more apparent if the microbial exposure occurred throughout the mother's pregnancy. The idea that microbial exposure during early development reduces the later incidence of allergic (and some autoimmune) diseases has been popularized as the *hygiene hypothesis*. Although the underlying mechanisms of this protective effect are unclear, it has spurred trials of probiotics and putative allergens given to children to decrease their risk of later developing allergies.

Infections themselves are not a cause or trigger for asthma, but young children with aeroallergen sensitization who develop lower respiratory tract viral infections (rhinovirus type C, respiratory syncytial virus) have a 10- to 30-fold increased risk of developing persistent and/or severe asthma. Both viral and bacterial infections (identified by cultures and non-culture tools) are associated with acute exacerbations of the disease.

Over time, repeated bouts of allergen exposure and immune reactions result in structural changes in the bronchial wall, referred to as "*airway remodeling*." These changes, described later in greater detail, include hypertrophy and hyperplasia of bronchial smooth muscle, epithelial injury, increased airway vascularity, increased subepithelial mucus gland hypertrophy, and deposition of subepithelial collagen.

MORPHOLOGY

In patients dying of acute severe asthma (status asthmaticus) the lungs are distended by overinflation and contain small areas of atelectasis. The most striking gross finding is occlusion of bronchi and bronchioles by thick, tenacious mucus plugs, which often contain shed epithelium. A characteristic finding in sputum or bronchoalveolar lavage specimens is **Curschmann spirals**, which may result from extrusion of mucus plugs from subepithelial mucous gland ducts or bronchioles. Also present are numerous eosinophils and **Charcot-Leyden crystals**; the latter are composed of an eosinophil protein called galectin-10. The other characteristic histologic findings of asthma, collectively called "**airway remodeling**" (Fig. 15-10B, and 15-11), include:

- Thickening of airway wall
- Subbasement membrane fibrosis (due to deposition of type I and III collagen)
- Increased vascularity
- An increase in the size of the submucosal glands and number of airway goblet cells
- Hypertrophy and/or hyperplasia of the bronchial wall muscle

While acute airflow obstruction is primarily attributed to muscular bronchoconstriction, acute edema, and mucus plugging, airway remodeling may also contribute to chronic irreversible airway obstruction as well.

Clinical Course. A classic acute asthmatic attack lasts up to several hours. In some patients, however, the cardinal symptoms of chest tightness, dyspnea, wheezing, and coughing (with or without sputum production) are present at a low level constantly. In its most severe form, *status asthmaticus*, the paroxysm persists for days and even weeks, sometimes causing airflow obstruction that is so extreme that marked cyanosis or even death ensues.

The diagnosis is based on demonstration of an increase in airflow obstruction (from baseline levels), difficulty with exhalation (prolonged expiration, wheeze), peripheral blood eosinophilia, and the finding of eosinophils, Curschmann spirals, and Charcot-Leyden crystals in the sputum (particularly in patients with atopic asthma). In the usual case with intervals of freedom from respiratory difficulty, the disease is more discouraging and disabling than lethal, and most individuals with asthma are able to maintain a productive life. Therapy is based on severity of the disease. Up to 50% of childhood asthma remits in adolescence only to return in adulthood in a significant number of patients. In other cases there is a variable decline in baseline lung function.

KEY CONCEPTS

Asthma

- Asthma is characterized by reversible bronchoconstriction caused by airway hyperresponsiveness to a variety of stimuli.
- Atopic asthma is caused by a T_H2 and IgE-mediated immunologic reaction to environmental allergens and is characterized by acute-phase (immediate) and late-phase

Figure 15-11 Bronchus from an asthmatic patient showing goblet cell hyperplasia (green arrowhead), subbasement membrane fibrosis (black arrowhead), eosinophilic inflammation (yellow arrowhead), and muscle hypertrophy (blue arrowhead).

reactions. The T_H2 cytokines IL-4, IL-5, and IL13 are important mediators. IL17 and IL9 are also being shown to be important in some asthmatics.

- Triggers for nonatopic asthma are less clear but include viral infections and inhaled air pollutants, which can also trigger atopic asthma.
- Eosinophils are key inflammatory cells found in almost all subtypes of asthma; other inflammatory cells include mast cells, neutrophils and T lymphocytes.
- Airway remodeling (sub-basement membrane fibrosis, hypertrophy of bronchial glands, and smooth muscle hyperplasia) adds an irreversible component to the obstructive disease.

Bronchiectasis

Bronchiectasis is a disorder in which destruction of smooth muscle and elastic tissue by chronic necrotizing infections leads to permanent dilation of bronchi and bronchioles. Because of better control of lung infections, bronchiectasis is now uncommon. It may still develop in association with a variety of conditions, including the following:

- *Congenital or hereditary conditions*, including cystic fibrosis, intralobar sequestration of the lung, immunodeficiency states, and primary ciliary dyskinesia and Kartagener syndromes
- *Infections*, including necrotizing pneumonia caused by bacteria, viruses, or fungi; this may be a single severe episode or recurrent infections
- *Bronchial obstruction*, due to tumor, foreign bodies, or mucus impaction; in each instance the bronchiectasis is localized to the obstructed lung segment
- *Other conditions*, including rheumatoid arthritis, systemic lupus erythematosus, inflammatory bowel disease, COPD, and posttransplantation (chronic lung rejection, and chronic graft-versus-host disease after bone marrow transplantation)

- One fourth to one half of cases are *idiopathic*, lacking the aforementioned associations.

Pathogenesis. Obstruction and infection are the major conditions associated with bronchiectasis, and it is likely that both are necessary for the development of full-fledged lesions. After bronchial obstruction, normal clearing mechanisms are impaired, resulting in pooling of secretions distal to the obstruction and secondary infection and inflammation. Conversely, severe infections of the bronchi lead to inflammation, often with necrosis, fibrosis, and eventually dilation of airways.

Both mechanisms are readily apparent in a severe form of bronchiectasis that is associated with cystic fibrosis (Chapter 10). In cystic fibrosis the primary defect in ion transport leads to defective mucociliary action and airway obstruction by thick viscous secretions. This sets the stage for chronic bacterial infections, which cause widespread damage to airway walls. With destruction of supporting smooth muscle and elastic tissue, the bronchi become markedly dilated, while smaller bronchioles are progressively obliterated as a result of fibrosis (bronchiolitis obliterans).

In *primary ciliary dyskinesia*, an autosomal recessive syndrome with a frequency of 1 in 15,000 to 40,000 births, ciliary dysfunction due to defects in ciliary motor proteins (e.g., mutations involving dynein) contributes to the retention of secretions and recurrent infections that in turn lead to bronchiectasis. Ciliary function is necessary during development to ensure proper rotation of the developing organs in the chest and abdomen; its absence, their location becomes a matter of chance. As a result, approximately half of the patients with primary ciliary dyskinesia have *Kartagener syndrome*, marked by situs inversus or a partial lateralizing abnormality associated with bronchiectasis and sinusitis. The lack of ciliary activity interferes with bacterial clearance, predisposes the sinuses and bronchi to infection, and affects cell motility during embryogenesis, resulting in the situs inversus. Males with this condition tend to be infertile, as a result of sperm dysmotility.

Allergic bronchopulmonary aspergillosis occurs in patients with asthma and cystic fibrosis who develop periods of exacerbation and remission that may lead to proximal bronchiectasis and fibrotic lung disease. It is a condition that results from a hypersensitivity reaction to the fungus *Aspergillus fumigatus*. Sensitization to *Aspergillus* in the allergic host leads to activation of T_H2 helper T cells, which play a key role in recruiting eosinophils and other leukocytes. Characteristically, there are high serum IgE levels, serum antibodies to *Aspergillus*, intense airway inflammation with eosinophils, and the formation of mucus plugs, which play a primary role in its pathogenesis.

MORPHOLOGY

Bronchiectasis usually affects the lower lobes bilaterally, particularly air passages that are vertical, and is most severe in the more distal bronchi and bronchioles. When tumors or aspiration of foreign bodies lead to bronchiectasis, the involvement may be localized to a single lung segment. **The airways are dilated, sometimes up to four times normal size.** Characteristically, the bronchi and bronchioles are so dilated that they can be

Figure 15-12 Bronchiectasis in a patient with cystic fibrosis, who underwent lung transplantation. Cut surface of lung shows markedly distended peripheral bronchi filled with mucopurulent secretions.

followed almost to the pleural surfaces. By contrast, in the normal lung, the bronchioles cannot be followed by eye beyond a point 2 to 3 cm from the pleural surfaces. On the cut surface of the lung, the dilated bronchi appear cystic and are filled with mucopurulent secretions (Fig. 15-12).

The histologic findings vary with the activity and chronicity of the disease. In the full-blown, active case there is an intense acute and chronic inflammatory exudation within the walls of the bronchi and bronchioles, associated with desquamation of the lining epithelium and extensive areas of ulceration. There may be pseudostratification of the columnar cells or squamous metaplasia of the remaining epithelium. In some instances necrosis destroys the bronchial or bronchiolar walls and forms a lung abscess. Fibrosis of the bronchial and bronchiolar walls and peribronchiolar fibrosis develop in the more chronic cases, leading to varying degrees of subtotal or total obliteration of bronchiolar lumens.

A large variety of bacteria can be found in the usual case of bronchiectasis. These include staphylococci, streptococci, pneumococci, enteric organisms, anaerobic and micro-aerophilic bacteria, and (particularly in children) *Haemophilus influenzae* and *Pseudomonas aeruginosa*. In allergic bronchopulmonary aspergillosis, a few fungal hyphae can be seen on special stains within the mucoinflammatory contents of the dilated segmental bronchi. In late stages the fungus may infiltrate the bronchial wall.

Clinical Course. Bronchiectasis causes severe, persistent cough; expectoration of foul smelling, sometimes bloody sputum; dyspnea and orthopnea in severe cases; and, on occasion, hemoptysis, which may be massive. Symptoms are often episodic and are precipitated by upper respiratory tract infections or the introduction of new pathogenic agents. Paroxysms of cough are particularly frequent when the patient rises in the morning, as the change in position causes collections of pus and secretions to drain into the bronchi. Obstructive respiratory insufficiency can lead to marked dyspnea and cyanosis. However, due to current treatment with better antibiotics and physical therapy, outcome has improved considerably and life expectancy has almost doubled. Hence cor pulmonale, brain abscesses, and amyloidosis are less frequent complications of bronchiectasis currently than in the past.

Chronic Diffuse Interstitial (Restrictive) Diseases

Restrictive lung disorders occur in two general conditions: (1) *chronic interstitial and infiltrative diseases*, such as pneumoconioses and interstitial fibrosis of unknown etiology; and (2) *chest wall disorders* (e.g., neuromuscular diseases such as poliomyelitis, severe obesity, pleural diseases, and kyphoscoliosis), which are not discussed here.

Chronic interstitial pulmonary diseases are a heterogeneous group of disorders characterized predominantly by inflammation and fibrosis of the pulmonary interstitium. Many of the entities are of unknown cause and pathogenesis, and some have an intra-alveolar as well as an interstitial component. There is frequent overlap in histologic features among the different conditions. These disorders account for about 15% of noninfectious diseases seen by pulmonary physicians.

In general, the clinical and pulmonary functional changes are those of *restrictive lung disease*. Patients have dyspnea, tachypnea, end-inspiratory crackles, and eventual cyanosis, without wheezing or other evidence of airway obstruction. The classic functional abnormalities are reductions in diffusion capacity, lung volume, and lung compliance. Chest radiographs show bilateral lesions that take the form of small nodules, irregular lines, or *ground-glass shadows*, all corresponding to areas of interstitial fibrosis. Eventually, secondary pulmonary hypertension and right-sided heart failure associated with cor pulmonale may result. Although the entities can often be distinguished in the early stages, the advanced forms are hard to differentiate because all result in scarring and gross destruction of the lung, often referred to as *end-stage lung* or *honeycomb lung*. Diffuse restrictive diseases are categorized based on histology and clinical features (Table 15-5).

Fibrosing Diseases

Idiopathic Pulmonary Fibrosis

Idiopathic pulmonary fibrosis (IPF) refers to a clinicopathologic syndrome marked by progressive interstitial pulmonary fibrosis and respiratory failure. In Europe the term *cryptogenic fibrosing alveolitis* is more popular. IPF has

Table 15-5 Major Categories of Chronic Interstitial Lung Disease

characteristic radiologic, pathologic, and clinical features. The histologic pattern of fibrosis is referred to as usual interstitial pneumonia (UIP), which can often be diagnosed based on its characteristic appearance in CT scans. The UIP pattern can also be seen in other diseases, notably connective tissue diseases, chronic hypersensitivity pneumonia, and asbestosis; these must be distinguished from IPF based on other clinical, laboratory, and histological features.

Pathogenesis. While the cause of IPF remains unknown, it appears that the fibrosis arises in genetically predisposed individuals who are prone to aberrant repair of recurrent alveolar epithelial cell injuries caused by environmental exposures (Fig. 15-13). The implicated factors are as follows:

- **Environmental factors.** Most important among these is cigarette smoking, which increases the risk of IPF several fold. IPF incidence is also increased in individuals who are exposed to metal fumes and wood dust, or who work in certain occupations, including farming, hair-dressing, and stone-polishing. It is hypothesized that exposure to environmental irritants or toxins in each of these contexts causes recurrent alveolar epithelial cell damage. Gastric reflux has also been recently implicated.
- **Genetic factors.** The vast majority of individuals who smoke or who have other environmental exposures linked to IPF do not develop the disorder, indicating that additional factors are required for its development. Chief among the suspects are inherited genetic variants. One group of genetic lesions of particular interest is germline loss-of-function mutations in the *TERT* and *TERC* genes, which encode components of telomerase. You will recall that telomerase is an enzyme that maintains the ends of chromosomes (the telomeres) and thereby prevents cellular senescence. Up to 15% of familial IPF is associated with telomerase gene defects, and up to 25% of sporadic IPF cases are associated with abnormal telomerase shortening in peripheral blood lymphocytes; the cause of this shortening is currently

unknown, and it is not yet known whether such individuals also have telomere shortening in their alveolar epithelial cells. Other, rare familial forms of IPF are associated with mutations in genes encoding components of surfactant; these mutations create folding defects in the affected proteins, leading to activation of the unfolded protein response in type II pneumocytes. This in turn appears to make pneumocytes more sensitive to environmental insults, enhancing the consequent cellular dysfunction and injury. Finally, roughly one-third of IPF cases are associated with a common genetic variant that greatly increases the secretion of MUC5B, a mucin that may make alveolar epithelial cells susceptible to injury or exaggerate downstream events that lead to fibrosis.

- **Age.** IPF is a disease of older individuals, rarely appearing before the age of 50 years. Whether this association stems from aging-related telomere shortening or from other acquired changes associated with aging is unknown.

It is easy to imagine how some of the factors cited herein might combine to exacerbate alveolar epithelial cell damage and senescence, which seems to be the initiating event

Figure 15-13 Proposed pathogenic mechanisms in idiopathic pulmonary fibrosis. Environmental factors that are potentially injurious to alveolar epithelium interact with genetic or aging-related factors that place epithelium at risk to create a persistent epithelial injury. Factors secreted from injured/activated epithelium, possibly augmented by factors released from innate and adaptive immune cells responding to “danger” signals produced by damaged epithelium, activate interstitial fibroblasts. There is some evidence that these activated fibroblasts exhibit signaling abnormalities that lead to increased signaling through the PI3K/AKT pathway. The activated fibroblasts synthesize and deposit collagen, leading to interstitial fibrosis and eventual respiratory failure.

in IPF, but it must be admitted that the pathogenesis of IPF is complex and poorly understood. For example, it is unknown precisely how alveolar epithelial cell damage translates into interstitial fibrosis. One model holds that the injured epithelial cells are the source of profibrogenic factors such as TGF- β , whereas a second, nonmutually exclusive model proposes that innate and adaptive immune cells produce such factors as part of the host response to epithelial cell damage. Other work has described abnormalities in the fibroblasts themselves that involve changes in intracellular signaling and features reminiscent of epithelial mesenchymal transition (Chapter 7), but a causal link to fibrosis has not been established.

MORPHOLOGY

Grossly, the pleural surfaces of the lung are cobblestoned as a result of the retraction of scars along the interlobular septa. The cut surface shows firm, rubbery white areas of fibrosis, which occurs preferentially in the lower lobes, the **subpleural regions**, and along the **interlobular septa**. Microscopically, the hallmark is **patchy interstitial fibrosis**, which varies in intensity (Fig. 15-14) and age. The earliest lesions contain exuberant fibroblastic proliferation (**fibroblastic foci**). With time these areas become more collagenous and less cellular. Quite typical is the coexistence of both early and late lesions (Fig. 15-15). The dense fibrosis causes the destruction of alveolar architecture and formation of cystic spaces lined by hyperplastic type II pneumocytes or bronchiolar epithelium (**honeycomb fibrosis**). With adequate sampling, these diagnostic histologic changes (i.e., areas of dense collagenous fibrosis with relatively normal lung and fibroblastic foci) can be identified even in advanced IPF. There is mild to moderate inflammation within the fibrotic areas, consisting of mostly lymphocytes admixed with a few plasma cells, neutrophils, eosinophils, and mast cells. Foci of squamous metaplasia and smooth muscle hyperplasia may be present, along with pulmonary arterial hypertensive changes (intimal fibrosis and medial thickening). In acute exacerbations diffuse alveolar damage may be superimposed on these chronic changes.

Figure 15-14 Usual interstitial pneumonia. The fibrosis is more pronounced in the subpleural region. (Courtesy Dr. Nicole Cipriani, Department of Pathology, University of Chicago, Chicago, Ill.)

Figure 15-15 Usual interstitial pneumonia. Fibroblastic focus with fibers running parallel to surface and bluish myxoid extracellular matrix. Honeycombing is present on the left.

Clinical Course. IPF begins insidiously with gradually increasing *dyspnea on exertion* and dry cough. Most patients are 55 to 75 years old at presentation. Hypoxemia, *cyanosis*, and clubbing occur late in the course. The progression in an individual patient is unpredictable. Usually there is a gradual deterioration in pulmonary status despite medical treatment with immunosuppressive drugs such as steroids, cyclophosphamide, or azathioprine. Other IPF patients have acute exacerbations of the underlying disease and follow a rapid downhill clinical course. The median survival is about 3 years after diagnosis. Lung transplantation is the only definitive therapy.

Nonspecific Interstitial Pneumonia

The concept of nonspecific interstitial pneumonia emerged when it was realized that there is a group of patients with diffuse interstitial lung disease whose lung biopsies lack the diagnostic features of any of the other well-characterized interstitial diseases. Despite its “nonspecific” name, this entity is important to recognize, since these patients have a much better prognosis than do those with usual interstitial pneumonia. Nonspecific interstitial pneumonia may be idiopathic or associated with connective tissue disease.

MORPHOLOGY

On the basis of its histology, nonspecific interstitial pneumonia is divided into cellular and fibrosing patterns. The cellular pattern consists primarily of mild to moderate chronic interstitial inflammation, containing lymphocytes and a few plasma cells, in a uniform or patchy distribution. The fibrosing pattern consists of diffuse or patchy interstitial fibrotic lesions of roughly the same stage of development, an important distinction from usual interstitial pneumonia. Fibroblastic foci, honeycombing, hyaline membranes and granulomas are absent.

Clinical Course. Patients present with dyspnea and cough of several months’ duration. They are more likely to be female nonsmokers in their sixth decade of life. Key features on high-resolution computed tomography are bilateral, symmetric, predominantly lower lobe reticular opacities. Those having the cellular pattern are somewhat younger than those with the fibrosing pattern and have a better prognosis.

Figure 15-16 Cryptogenic organizing pneumonia. Some alveolar spaces are filled with balls of fibroblasts (Masson bodies), while the alveolar walls are relatively normal. **A**, Low power. **B**, High power.

Cryptogenic Organizing Pneumonia

Cryptogenic organizing pneumonia is synonymous with the popular term *bronchiolitis obliterans organizing pneumonia*; however, the former is now preferred, since it conveys the essential features of a clinicopathologic syndrome of unknown etiology and avoids confusion with airway diseases such as bronchiolitis obliterans. Patients present with cough and dyspnea and have patchy subpleural or peribronchial areas of airspace consolidation radiographically. Histologically, cryptogenic organizing pneumonia is characterized by the presence of polypoid plugs of loose organizing connective tissue (Masson bodies) within alveolar ducts, alveoli, and often bronchioles (Fig. 15-16). The connective tissue is all of the same age, and the underlying lung architecture is normal. There is no interstitial fibrosis or honeycomb lung. Some patients recover spontaneously, but most need treatment with oral steroids for 6 months or longer for complete recovery.

It is important to recognize that organizing pneumonia with intra-alveolar fibrosis is most often seen as a response to infections or inflammatory injury of the lungs. These include viral and bacterial pneumonia, inhaled toxins, drugs, connective tissue disease, and graft-versus-host disease in bone marrow transplant recipients. The prognosis for these patients is dependent on the underlying disorder.

Pulmonary Involvement in Autoimmune Diseases

Many autoimmune diseases (also referred to a connective tissue diseases because of their frequent association with arthritis), most notably systemic lupus erythematosus, rheumatoid arthritis, progressive systemic sclerosis (scleroderma), and dermatomyositis-polymyositis, can involve the lung at some point in their course. Pulmonary involvement can take different histologic patterns; nonspecific interstitial pneumonia, usual interstitial pneumonia, vascular sclerosis, organizing pneumonia, and bronchiolitis are the most common.

- *Rheumatoid arthritis*: pulmonary involvement may occur in 30% to 40% of patients as (1) chronic pleuritis, with or without effusion; (2) diffuse interstitial pneumonitis and fibrosis; (3) intrapulmonary rheumatoid nodules; (4) follicular bronchiolitis; or (5) pulmonary hypertension

- *Systemic sclerosis (scleroderma)*: diffuse interstitial fibrosis (nonspecific interstitial pattern more common than usual interstitial pattern) and pleural involvement
- *Lupus erythematosus*: patchy, transient parenchymal infiltrates, or occasionally severe lupus pneumonitis, as well as pleurisy and pleural effusions.

Pulmonary involvement in these diseases has a variable prognosis that is determined by the extent and histologic pattern of involvement.

KEY CONCEPTS

Chronic Interstitial Lung Diseases

- Diffuse interstitial fibrosis of the lung gives rise to restrictive lung diseases characterized by reduced lung compliance and reduced forced vital capacity (FVC). The ratio of FEV₁ to FVC is normal.
- Idiopathic pulmonary fibrosis is prototypic of restrictive lung diseases. It is characterized by patchy interstitial fibrosis fibroblastic foci and formation of cystic spaces (honeycomb lung). This histologic pattern is known as usual interstitial pneumonia.
- The cause of idiopathic pulmonary fibrosis is unknown, but genetic analyses point to roles for senescence of alveolar epithelium (due to telomere shortening), cell stress related to protein misfolding, abnormal signaling in alveolar fibroblasts, and altered mucin production. The resulting injury to alveolar epithelial cells set in motion event that lead to increase local production of fibrogenic cytokines such as TGF- β
- The other diseases that cause diffuse interstitial fibrosis are heterogeneous poorly understood, but most have better prognoses than idiopathic pulmonary fibrosis.

Pneumoconioses

The term *pneumoconiosis*, originally coined to describe the nonneoplastic lung reaction to inhalation of mineral dusts encountered in the workplace, now also includes diseases induced by organic as well as inorganic particulates and chemical fumes and vapors. A simplified

Table 15-6 Lung Diseases Caused by Air Pollutants

Agent	Disease	Exposure
Mineral Dusts		
Coal dust	Anthracosis Macules Progressive massive fibrosis Caplan syndrome	Coal mining (particularly hard coal)
Silica	Silicosis Caplan syndrome	Metal casting work, sandblasting, hard rock mining, stone cutting, others
Asbestos	Asbestosis Pleural plaques Caplan syndrome Mesothelioma Carcinoma of the lung, larynx, stomach, colon	Mining, milling, manufacturing, and installation and removal of insulation
Beryllium	Acute berylliosis Beryllium granulomatosis Lung carcinoma (?)	Mining, manufacturing
Iron oxide	Siderosis	Welding

Chemical Fumes and Vapors		
Nitrous oxide, sulfur dioxide, ammonia, benzene, insecticides	Bronchitis, asthma Pulmonary edema ARDS Mucosal injury Fulminant poisoning	Occupational and accidental exposure

ARDS, Acute respiratory distress syndrome.

classification is presented in [Table 15-6](#). Where implemented, regulations limiting worker exposure have resulted in a marked decrease in dust-associated diseases.

Although the pneumoconioses result from well-defined occupational exposure to specific airborne agents, ambient air pollution also has deleterious effects on the general population, especially in urban areas ([Chapter 9](#)), and can have serious, sometimes fatal effects on those with COPD or heart disease. Pollution increases the risk of asthma, especially in children. Efforts to reduce air pollution have been effective in the west, but industrialization in other parts of the world, particularly China, has produced dangerous levels of air pollution. Even in the U.S. improvements are possible, as some data suggest that even low levels of air pollution can have deleterious effects on health.

Pathogenesis. The development of a pneumoconiosis depends on (1) the amount of dust retained in the lung and airways; (2) the size, shape, and buoyancy of the particles; (3) particle solubility and physiochemical reactivity; and (4) the possible additional effects of other irritants (e.g., concomitant tobacco smoking). In most cases, these particles stimulate resident innate immune cells in the lung, leading to the diseases discussed later. The following general principles apply to pneumoconioses:

- The amount of dust retained in the lungs is determined by the dust concentration in ambient air, the duration of exposure, and the effectiveness of clearance mechanisms. Any influence, such as cigarette smoking, that impairs mucociliary clearance significantly increases the accumulation of dust in the lungs.
- The most dangerous particles are from 1 to 5 μm in diameter, because particles of this size may reach the terminal small airways and air sacs and settle in their linings.
- The solubility and cytotoxicity of particles, which are influenced to a considerable extent by their size, modify the pulmonary response. In general, small particles composed of injurious substances of high solubility may produce rapid-onset lung damage. Such particles are more likely to cause acute lung injury. Larger particles are more likely to resist dissolution and may persist within the lung parenchyma for years. These tend to evoke fibrosing collagenous pneumoconioses, such as is characteristic of *silicosis*.
- Other particles may be taken up by epithelial cells or may cross the epithelial cell lining and interact directly with fibroblasts and interstitial macrophages. Some may reach the lymphatics by direct drainage or within

migrating macrophages and thereby initiate an immune response to components of the particulates or to self-proteins modified by the particles or both.

- Finally, certain types of particles activate the inflammatory (Chapter 3) when phagocytosed by macrophages. These innate and adaptive immune responses amplify the intensity and the duration of the local reaction.
- Tobacco smoking worsens the effects of all inhaled mineral dusts, but particularly those caused by asbestos. The effects of inhaled particles are not confined to the lung alone, since solutes from particles can enter the blood and lung inflammation invokes systemic responses.

In general, only a small percentage of exposed people develop occupational respiratory diseases, implying a genetic predisposition to their development. Many of the diseases listed in Table 15-6 are quite uncommon. Hence only a selected few that cause fibrosis of the lung are presented next.

Coal Workers' Pneumoconiosis

Coal workers' pneumoconiosis is lung disease caused by inhalation of coal particles and other admixed forms of dust. Dust reduction measures in coal mines around the globe have drastically reduced its incidence. The spectrum of lung findings in coal workers is wide, varying from asymptomatic anthracosis, to simple coal workers' pneumoconiosis with little to no pulmonary dysfunction, to complicated coal workers' pneumoconiosis, or *progressive massive fibrosis*, in which lung function is compromised. Contaminating silica in the coal dust can favor progressive disease. In most cases, carbon dust itself is the major culprit, and studies have shown that complicated lesions contain much more dust than simple lesions. Coal workers may also develop emphysema and chronic bronchitis independent of smoking.

MORPHOLOGY

Anthracosis is the most innocuous coal-induced pulmonary lesion in coal miners and is also seen to some degree in urban dwellers and tobacco smokers. Inhaled carbon pigment is engulfed by alveolar or interstitial macrophages, which then accumulate in the connective tissue along the lymphatics, including the pleural lymphatics, or in organized lymphoid tissue along the bronchi or in the lung hilus.

Simple coal workers' pneumoconiosis is characterized by **coal macules** (1 to 2 mm in diameter) and somewhat larger **coal nodules**. Coal macules consist of carbon-laden macrophages; nodules also contain a delicate network of collagen fibers. Although these lesions are scattered throughout the lung, the upper lobes and upper zones of the lower lobes are more heavily involved. They are located primarily adjacent to respiratory bronchioles, the site of initial dust accumulation. In due course dilation of adjacent alveoli occurs, sometimes giving rise to **centrilobular emphysema**.

Complicated coal workers' pneumoconiosis (progressive massive fibrosis) occurs on a background of simple disease and generally requires many years to develop. It is characterized by intensely blackened scars 1 cm or larger, sometimes up to

Figure 15-17 Progressive massive fibrosis superimposed on coal workers' pneumoconiosis. The large, blackened scars are located principally in the upper lobe. Note the extensions of scars into surrounding parenchyma and retraction of adjacent pleura. (Courtesy Drs. Werner Laquer and Jerome Kleinerman, the National Institute of Occupational Safety and Health, Morgantown, W.Va.)

10 cm in greatest diameter. They are usually multiple (Fig. 15-17). Microscopically the lesions consist of dense collagen and pigment. The center of the lesion is often necrotic, most likely due to local ischemia.

Clinical Course. Coal workers' pneumoconiosis is usually benign, causing little decrement in lung function. Even mild forms of complicated coal workers' pneumoconiosis do not to affect lung function significantly. In a minority of cases (fewer than 10%), progressive massive fibrosis develops, leading to increasing pulmonary dysfunction, pulmonary hypertension, and cor pulmonale. Once progressive massive fibrosis develops, it may continue to worsen even if further exposure to dust is prevented. Unlike silicosis (discussed below), there is no convincing evidence that coal dust increases susceptibility to tuberculosis. There is also no compelling evidence that coal workers' pneumoconiosis in the absence of smoking predisposes to cancer. Domestic indoor use of "smoky coal" (bituminous) for cooking and heating is, however,

associated with an increased risk of lung cancer death for both women and men.

Silicosis

Silicosis is a common lung disease caused by inhalation of proinflammatory crystalline silicon dioxide (silica) that usually presents after decades of exposure as slowly progressing, nodular, fibrosing pneumoconiosis. Currently, silicosis is the most prevalent chronic occupational disease in the world. Both dose and race are important in developing silicosis (African Americans are at higher risk than whites). As shown in Table 15-6, workers in a large number of occupations are at risk, including individuals involved with the repair, rehabilitation or demolition of concrete structures such as buildings and roads. Less commonly, the disease occurs in workers producing stressed denim by sandblasting, stone carvers, and jewelers using chalk molds. Occasionally, heavy exposure over months to a few years can result in acute silicosis, a disorder characterized by the accumulation of abundant lipoproteinaceous material within alveoli (identical morphologically to alveolar proteinosis, discussed later).

Pathogenesis. Silica occurs in both crystalline and amorphous forms, but crystalline forms (including quartz, cristobalite, and tridymite) are much more fibrogenic. Of these, quartz is most commonly implicated. After inhalation, the particles are phagocytosed by macrophages. The phagocytosed silica crystals activate the inflammasome, leading to the release of inflammatory mediators, particularly IL-1 and IL-18. The relatively benign response to silica in coal and hematite miners is thought to be due to coating of silica with other minerals, especially clay components, which render the silica less toxic. Although amorphous silicates are biologically less active than crystalline silica, heavy lung burdens of these minerals may also produce lesions.

MORPHOLOGY

Silicosis is characterized grossly in its early stages by tiny, barely palpable, discrete pale to blackened (if coal dust is also present) nodules in the hilar lymph nodes and upper zones of the lungs. As the disease progresses, these nodules coalesce into **hard, collagenous scars** (Fig. 15-18). Some nodules may undergo central softening and cavitation due to superimposed tuberculosis or to ischemia. Fibrotic lesions may also occur in the hilar lymph nodes and pleura. Sometimes, thin sheets of calcification occur in the lymph nodes and are seen radiographically as **eggshell calcification** (i.e., calcium surrounding a zone lacking calcification). If the disease continues to progress, expansion and coalescence of lesions may produce progressive massive fibrosis. Histologic examination reveals the hallmark lesion characterized by a central area of whorled collagen fibers with a more peripheral zone of dust-laden macrophages (Fig. 15-19). Examination of the nodules by polarized microscopy reveals the birefringent silicate particles (silica is weakly birefringent).

Clinical Course. Chest radiographs typically show a fine nodularity in the upper zones of the lung. Pulmonary functions are either normal or only moderately affected early in the course, and most patients do not develop shortness of breath until progressive massive fibrosis supervenes.

Figure 15-18 Advanced silicosis. Scarring has contracted the upper lobe into a small dark mass (arrow). Note the dense pleural thickening. (Courtesy Dr. John Godleski, Brigham and Women's Hospital, Boston, Mass.)

The disease may continue to worsen even if the patient is no longer exposed. Silicosis is slow to kill, but impaired pulmonary function may severely limit activity. It is associated with an increased susceptibility to *tuberculosis*. This may be because crystalline silica inhibits the ability of pulmonary macrophages to kill phagocytosed mycobacteria. The onset of silicosis may be slow and insidious (10 to 30 years after exposure; most common), accelerated (within 10 years of exposure) or rapid (in weeks or months after intense exposure to fine dust high in silica; rare). Patients with silicosis have double the risk for developing lung cancer.

Asbestos-Related Diseases

Asbestos is a family of proinflammatory crystalline hydrated silicates that are associated with pulmonary

Figure 15-19 Several coalescent collagenous silicotic nodules. (Courtesy Dr. John Godleski, Brigham and Women's Hospital, Boston, Mass.)

fibrosis, carcinoma, mesothelioma, and other cancers. Use of asbestos is tightly restricted in many developed countries; however, there is little, if any, control in less developed parts of the world. Asbestos-related diseases include:

- Localized fibrous plaques or, rarely, diffuse pleural fibrosis
- Pleural effusions, recurrent
- Parenchymal interstitial fibrosis (*asbestosis*)
- Lung carcinoma
- Mesotheliomas
- Laryngeal, ovarian and perhaps other extrapulmonary neoplasms, including colon carcinomas; increased risk for systemic autoimmune diseases and cardiovascular disease has been proposed

An increased incidence of asbestos-related cancer in family members of asbestos workers has alerted the general public to the potential hazards of even low-level exposure to asbestos. However, the necessity of expensive asbestos abatement programs for environments such as schools with low, but measurable, airborne asbestos fiber counts remains a matter of contention.

Pathogenesis. The disease-causing capabilities of the different forms of asbestos depend on concentration, size, shape, and solubility. Asbestos occurs in two distinct geometric forms, *serpentine* and *amphibole*. The serpentine chrysotile form accounts for 90% of the asbestos used in industry. Amphiboles, even though less prevalent, are more pathogenic than chrysotiles, particularly with respect to induction of mesothelioma, a malignant tumor derived from the lining cells of pleural surfaces.

The greater pathogenicity of amphiboles is apparently related to their aerodynamic properties and solubility. Chrysotiles, with their more flexible, curled structure, are likely to become impacted in the upper respiratory passages and removed by the mucociliary elevator. Furthermore, once trapped in the lungs, chrysotiles are gradually leached from the tissues because they are more soluble than amphiboles. In contrast, the straight, stiff amphiboles may align themselves in the airstream and thus be delivered deeper into the lungs, where they can penetrate epithelial cells and reach the interstitium. Both amphiboles and serpentines are fibrogenic, and increasing doses are associated with a higher incidence of asbestos-related diseases.

In contrast to other inorganic dusts, asbestos can also act as a tumor initiator and promoter. Some of its oncogenic effects are mediated by reactive free radicals generated by asbestos fibers, which preferentially localize in the distal lung, close to the mesothelial layers. Toxic chemicals adsorbed onto the asbestos fibers also likely contribute to the oncogenicity of the fibers. For example, the adsorption of carcinogens in tobacco smoke onto asbestos fibers may be the basis for the remarkable synergy between tobacco smoking and the development of lung carcinoma in asbestos workers. Smoking also enhances the effect of asbestos by interfering with the mucociliary clearance of fibers. One study of asbestos workers found a fivefold increase of lung carcinoma with asbestos exposure alone, while asbestos exposure and smoking together led to a 55-fold increase in the risk.

As with silica crystals, **once phagocytosed by macrophages asbestos fibers activate the inflammasome and**

Figure 15-20 High-power detail of an asbestos body, revealing the typical beading and knobbed ends (arrow).

stimulate the release of proinflammatory factors and fibrogenic mediators. The initial injury occurs at bifurcations of small airways and ducts, where asbestos fibers land, penetrate and are directly toxic to pulmonary parenchymal cells. Macrophages, both alveolar and interstitial, attempt to ingest and clear the fibers. Long-term deposition of fibers and persistent release of mediators (e.g., reactive oxygen species, proteases, cytokines, and growth factors) eventually lead to generalized interstitial pulmonary inflammation and interstitial fibrosis.

MORPHOLOGY

Asbestosis is marked by **diffuse pulmonary interstitial fibrosis**, which is indistinguishable from diffuse interstitial fibrosis resulting from other causes, except for the presence of multiple **asbestos bodies**. Asbestos bodies are **golden brown, fusiform or beaded rods with a translucent center and consist of asbestos fibers coated with an iron-containing proteinaceous material** (Fig. 15-20). They arise when macrophages phagocytose asbestos fibers; the iron is presumably derived from phagocyte ferritin. Other inorganic particulates may become coated with similar iron-protein complexes and are called **ferruginous bodies**. Rare single asbestos bodies can be found in the lungs of normal people.

Asbestosis begins as fibrosis around respiratory bronchioles and alveolar ducts and extends to involve adjacent alveolar sacs and alveoli. The fibrous tissue distorts the architecture, creating enlarged airspaces enclosed within thick fibrous walls; eventually the affected regions become honeycombed. The pattern of fibrosis is similar to that seen in usual interstitial fibrosis, with fibroblastic foci and varying degrees of fibrosis, the only difference being the presence of numerous asbestos bodies. In contrast to coal workers' pneumoconiosis and silicosis, asbestosis begins in the lower lobes and subpleurally. The middle and upper lobes of the lungs become affected as fibrosis progresses. The scarring may trap and narrow pulmonary arteries and arterioles, causing pulmonary hypertension and cor pulmonale.

Pleural plaques, the most common manifestation of asbestos exposure, are well-circumscribed plaques of dense collagen (Fig. 15-21) that are often calcified. They develop most frequently on the anterior and posterolateral aspects of the **parietal pleura** and over the domes of the diaphragm. The size

Figure 15-21 Asbestos-related pleural plaques. Large, discrete fibrocalcific plaques are seen on the pleural surface of the diaphragm. (Courtesy Dr. John Godleski, Brigham and Women's Hospital, Boston, Mass.)

and number of pleural plaques do not correlate with the level of exposure to asbestos or the time since exposure. They do not contain asbestos bodies; however, only rarely do they occur in individuals who have no history or evidence of asbestos exposure. Uncommonly, asbestos exposure induces pleural effusions, which are usually serous but may be bloody. Rarely, diffuse visceral pleural fibrosis may occur and, in advanced cases, bind the lung to the thoracic wall.

Both lung carcinomas and mesotheliomas (pleural and peritoneal) develop in workers exposed to asbestos (see sections on lung cancer and [pleural tumors](#)).

Clinical Course. The clinical findings in asbestosis are very similar to those caused by other diffuse interstitial lung diseases (discussed earlier). These rarely appear fewer than 10 years after first exposure and are more common after 20 to 30 years. Dyspnea is usually the first manifestation; at first, it is provoked by exertion, but later it is present even at rest. Cough associated with production of sputum, when present, is likely to be due to smoking rather than asbestosis. Chest x-ray studies reveal irregular linear densities, particularly in both lower lobes. With advancement of the pneumoconiosis, a honeycomb pattern develops. The disease may remain static or progress to respiratory failure, cor pulmonale, and death. Pleural plaques are usually asymptomatic and are detected on radiographs as circumscribed densities. Asbestosis complicated by lung or pleural cancer is associated with a particularly grim prognosis.

KEY CONCEPTS

Pneumoconioses

- Pneumoconioses encompass a group of chronic fibrosing diseases of the lung resulting from exposure to organic and inorganic particulates, most commonly mineral dust.
- Pulmonary alveolar macrophages play a central role in the pathogenesis of lung injury by promoting inflammation and producing reactive oxygen species and fibrogenic cytokines.
- Coal dust-induced disease varies from asymptomatic anthracosis to simple coal workers' pneumoconiosis (coal

macules or nodules, and centrilobular emphysema), to progressive massive fibrosis (PMF), manifested by increasing pulmonary dysfunction, pulmonary hypertension, and cor pulmonale.

- Silicosis is the most common pneumoconiosis in the world, and crystalline silica (e.g., quartz) is the usual culprit. The lung disease is progressive even after exposure stops.
- The manifestations of silicosis can range from asymptomatic silicotic nodules to large areas of dense fibrosis; persons with silicosis also have an increased susceptibility to tuberculosis. There is two-fold increased risk of lung cancer.
- Asbestos fibers come in two forms; the stiff amphiboles have a greater fibrogenic and carcinogenic potential than the serpentine chrysotiles.
- Asbestos exposure is linked with six disease processes: (1) parenchymal interstitial fibrosis (asbestosis); (2) localized pleural plaques (asymptomatic) or rarely diffuse pleural fibrosis; (3) recurrent pleural effusions; (4) lung cancer; (5) malignant pleural and peritoneal mesotheliomas; and (6) laryngeal cancer.
- Cigarette smoking increases the risk of lung cancer in the setting of asbestos exposure; even family members of workers exposed to asbestos are at increased risk for cancer and mesothelioma.

Complications of Therapies

Drug-Induced Lung Diseases. An increasing number of prescription drugs have been found to cause a variety of both acute and chronic alterations in lung structure and function, interstitial fibrosis, bronchiolitis obliterans, and eosinophilic pneumonia. For example, cytotoxic drugs used in cancer therapy (e.g., bleomycin) cause pulmonary damage and fibrosis as a result of direct toxicity and by stimulating the influx of inflammatory cells into the alveoli. Amiodarone, a drug used to treat cardiac arrhythmias, is preferentially concentrated in the lung and causes significant pneumonitis in 5% to 15% of patients receiving it. Cough induced by ace inhibitors is very common.

Illicit intravenous drug abuse most often causes lung infections. In addition, particulate matter is introduced into the lung microvasculature where granulomas and fibrosis occur.

Radiation-Induced Lung Diseases. Radiation pneumonitis is a well-known complication of therapeutic radiation of thoracic tumors (lung, esophageal, breast, mediastinal). It most often involves the lung within the radiation port and occurs in both acute and chronic forms. *Acute radiation pneumonitis* (lymphocytic alveolitis or hypersensitivity pneumonitis) occurs 1 to 6 months after irradiation in 3% to 44% of patients, depending on dose and age. It is manifest by fever, dyspnea out of proportion to the volume of lung irradiated, pleural effusion, and infiltrates that usually correspond to an area of previous irradiation. With steroid therapy, these symptoms may resolve completely in some patients, while in others there is progression to *chronic radiation pneumonitis* (pulmonary fibrosis). The latter is a consequence of the repair of injured endothelial and epithelial cells. It may also occur without antecedent pulmonary symptoms. Morphologic changes are those of

diffuse alveolar damage, including severe atypia of hyperplastic type II cells and fibroblasts. Epithelial cell atypia and foam cells within vessel walls are also characteristic of radiation damage.

Granulomatous Diseases

Sarcoidosis

Sarcoidosis is a systemic granulomatous disease of unknown cause that may involve many different tissues and organs. Sarcoidosis presents in many clinical patterns, but bilateral hilar lymphadenopathy or lung involvement is most common, occurring 90% of cases. Eye and skin lesions are next in frequency. Since other diseases, including mycobacterial and fungal infections and berylliosis, can also produce noncaseating granulomas, the diagnosis is one of exclusion.

Sarcoidosis usually occurs in adults younger than 40 years of age, but can affect any age group. The prevalence is higher in women but varies widely in different countries and populations. In the United States the rates are highest in the Southeast and are 10 times higher in blacks than in whites. In contrast, the disease is rare among Chinese and Southeast Asians. Patterns of organ involvement also vary with race.

Pathogenesis. Although the etiology of sarcoidosis remains unknown, several lines of evidence suggest that it is a disease of disordered immune regulation in genetically predisposed individuals. It is not clear whether exposure to any environmental or infectious agent has a role in its pathogenesis.

Immunologic Factors. There are several immunologic abnormalities in the local milieu of sarcoid granulomas that suggest the involvement of a cell-mediated immune response to an unidentified antigen. These abnormalities include:

- Intra-alveolar and interstitial accumulation of CD4+ T cells, resulting in CD4/CD8 T-cell ratios ranging from 5:1 to 15:1, suggesting pathogenic involvement of CD4+ helper T cells. There is oligoclonal expansion of T-cell subsets as determined by analysis of T-cell receptor rearrangement, consistent with an antigen-driven proliferation.
- Increased levels of T cell-derived T_H1 cytokines such as IL-2 and IFN- γ , which may be responsible for T-cell expansion and macrophage activation, respectively.
- Increased levels of several cytokines in the local environment (IL-8, TNF, macrophage inflammatory protein 1 α) that favor recruitment of additional T cells and monocytes and contribute to the formation of granulomas. TNF in particular is released at high levels by activated alveolar macrophages, and the TNF concentration in the bronchoalveolar fluid is a marker of disease activity.
- Impaired dendritic cell function.

Additionally, there are systemic immunologic abnormalities in individuals with sarcoidosis:

- Anergy to common skin test antigens such as *Candida* or tuberculosis purified protein derivative (PPD)

Figure 15-22 Bronchus with characteristic noncaseating sarcoid granulomas (asterisks), with many multinucleated giant cells (arrowheads). Note subepithelial location of granulomas.

- Polyclonal hypergammaglobulinemia, another manifestation of helper T-cell dysregulation

Genetic Factors. Evidence of genetic influences include familial and racial clustering of cases and the association with certain HLA genotypes (e.g., HLA-A1 and HLA-B8).

MORPHOLOGY

Virtually every organ in the body has been described as being affected by sarcoidosis, at least on rare occasions. Regardless of the tissue, involved tissues contain well-formed **nonnecrotizing granulomas** (Fig. 15-22) composed of aggregates of tightly clustered epithelioid macrophages, often with giant cells. Central necrosis is unusual. With chronicity the granulomas may become enclosed within fibrous rims or may eventually be replaced by hyaline fibrous scars. Laminated concretions composed of calcium and proteins known as **Schaumann bodies** and stellate inclusions known as **asteroid bodies** are found within giant cells in approximately 60% of the granulomas. Though characteristic, these microscopic features are not pathognomonic of sarcoidosis, because asteroid and Schaumann bodies may be encountered in other granulomatous diseases (e.g., tuberculosis).

The **lungs** are common sites of involvement. Macroscopically there is usually no demonstrable alteration, although in advanced cases the coalescence of granulomas produces small nodules that are palpable or visible as 1 to 2 cm, noncaseating, noncavitated consolidations. The lesions are distributed primarily along the lymphatics around bronchi and blood vessels, although alveolar lesions and pleural involvement are also seen. The relatively high frequency of granulomas in the bronchial submucosa accounts for the high diagnostic yield of bronchoscopic biopsies. There seems to be a strong tendency for lesions to heal in the lungs, so varying stages of fibrosis and hyalinization are often found. **Lymph nodes** are involved in almost all cases, particularly the hilar and mediastinal nodes, but any other node in the body may be involved. Nodes are

characteristically enlarged, discrete, and sometimes calcified. The tonsils are affected in about one fourth to one third of cases.

The **spleen** is affected in about three fourths of cases, but it is enlarged in only one fifth. On occasion, granulomas may coalesce to form small nodules that are visible macroscopically. The **liver** is affected slightly less often than the spleen. It may be moderately enlarged and typically contains scattered granulomas, more in portal triads than in the lobular parenchyma. Needle biopsy can be diagnostic.

The **bone marrow** is involved in about one fifth of cases. Radiologically visible bone lesions have a particular tendency to involve phalangeal bones of the hands and feet, creating small circumscribed areas of bone resorption within the marrow cavity and a diffuse reticulated pattern throughout the cavity, with widening of the bony shafts or new bone formation on the outer surfaces.

Skin lesions, encountered in one fourth of cases, assume a variety of appearances, including discrete subcutaneous nodules; focal, slightly elevated, erythematous plaques; or flat lesions that are slightly reddened and scaling, resembling those of systemic lupus erythematosus. Lesions may also appear on the mucous membranes of the oral cavity, larynx, and upper respiratory tract. **Ocular involvement**, seen in one fourth of cases, takes the form of iritis or iridocyclitis, either bilaterally or unilaterally. Consequently, corneal opacities, glaucoma, and total loss of vision may occur. These ocular lesions are frequently accompanied by inflammation of the lacrimal glands and suppression of lacrimation. Bilateral sarcoidosis of the parotid, submaxillary, and sublingual glands constitutes the combined uveoparotid involvement designated as Mikulicz syndrome (Chapter 16). **Muscle** involvement is underdiagnosed, since it may be asymptomatic. Muscle weakness, aches, tenderness, and fatigue should prompt consideration of occult sarcoid myositis, which can be diagnosed by muscle biopsy. Sarcoid granulomas occasionally occur in the heart, kidneys, central nervous system (neurosarcoidosis, seen in 5% to 15%), and endocrine glands, particularly in the pituitary, as well as in other body tissues.

Clinical Course. Because of its varying severity and inconstant tissue distribution, sarcoidosis may present with diverse features. It may be discovered unexpectedly on routine chest films as bilateral hilar adenopathy or may present with peripheral lymphadenopathy, cutaneous lesions, eye involvement, splenomegaly, or hepatomegaly. In the great majority of cases, however, individuals seek medical attention because of the insidious onset of respiratory abnormalities (shortness of breath, cough, chest pain, hemoptysis) or of constitutional signs and symptoms (fever, fatigue, weight loss, anorexia, night sweats).

Sarcoidosis follows an unpredictable course. It may be inexorably progressive, or marked by periods of activity interspersed with remissions, sometimes permanent, that may be spontaneous or induced by steroid therapy. Overall, 65% to 70% of affected patients recover with minimal or no residual manifestations. Twenty percent have permanent loss of some lung function or some permanent visual impairment. Of the remaining 10% to 15%, some die of cardiac or central nervous system damage, but most succumb to progressive pulmonary fibrosis and cor pulmonale.

KEY CONCEPTS

Sarcoidosis

- Sarcoidosis is a multisystem disease of unknown etiology; the diagnostic histopathologic feature is the presence of noncaseating granulomas in various tissues.
- Immunologic abnormalities include high levels of CD4+ T cells in the lung that secrete T_H1-dependent cytokines such as IFN- γ and IL-2 locally.
- Clinical manifestations include lymph node enlargement, eye involvement (sicca syndrome [dry eyes], iritis, or iridocyclitis), skin lesions (erythema nodosum, painless subcutaneous nodules), and visceral (liver, skin, marrow) involvement. Lung involvement occurs in 90% of cases, with formation of granulomas and interstitial fibrosis.

Hypersensitivity Pneumonitis

The term *hypersensitivity pneumonitis* describes a spectrum of immunologically mediated, predominantly interstitial, lung disorders caused by intense, often prolonged exposure to inhaled organic antigens. Affected individuals have an abnormal sensitivity or heightened reactivity to the causative antigen, which, in contrast to asthma, leads to pathologic changes that primarily involve the alveolar walls (thus the synonym “*extrinsic allergic alveolitis*”). It is important to recognize these diseases early in their course because progression to serious chronic fibrotic lung disease can be prevented by removal of the environmental agent.

Most commonly, hypersensitivity results from the inhalation of organic dust containing antigens made up of the spores of thermophilic bacteria, fungi, animal proteins, or bacterial products. Numerous syndromes are described, depending on the occupation or exposure of the individual. *Farmer’s lung* results from exposure to dusts generated from humid, warm, newly harvested hay that permits the rapid proliferation of the spores of thermophilic actinomycetes. *Pigeon breeder’s lung* (bird fancier’s disease) is provoked by proteins from serum, excreta, or feathers of birds. *Humidifier* or *air-conditioner lung* is caused by thermophilic bacteria in heated water reservoirs. Pet birds and moldy basements are easily missed unless asked about specifically.

Several lines of evidence suggest that hypersensitivity pneumonitis is an immunologically mediated disease:

- Bronchoalveolar lavage specimens from the acute phase show increased levels of proinflammatory chemokines such as macrophage inflammatory protein 1 α and IL-8.
- Bronchoalveolar lavage specimens also consistently demonstrate increased numbers of both CD4+ and CD8+ T lymphocytes.
- Most patients have specific antibodies against the causative antigen in their serum.
- Complement and immunoglobulins have been demonstrated within vessel walls by immunofluorescence.
- The presence of noncaseating granulomas in two thirds of the patients suggests that T-cell-mediated (type IV) hypersensitivity reactions against the implicated antigens are also common and have a pathogenic role.

Figure 15-23 Hypersensitivity pneumonitis. Loosely formed interstitial granulomas and chronic inflammation are characteristic.

MORPHOLOGY

Histologic changes are characteristically centered on bronchioles. They include (1) interstitial pneumonitis, consisting primarily of lymphocytes, plasma cells, and macrophages (eosinophils are rare); (2) noncaseating granulomas in two thirds of patients (Fig. 15-23); and (3) interstitial fibrosis with fibroblastic foci, honeycombing, and obliterative bronchiolitis (in late stages). In more than half of patients, there is also evidence of an intra-alveolar infiltrate.

Clinical Features. The clinical manifestations are varied. Acute attacks, which follow inhalation of antigenic dust in sensitized patients, consist of recurring episodes of fever, dyspnea, cough, and leukocytosis. Micronodular interstitial infiltrates may appear in the chest radiograph, and pulmonary function tests show an acute restrictive disorder. Symptoms usually appear 4 to 6 hours after exposure and may last for 12 hours to several days. They recur with reexposure. If exposure is continuous and protracted, a chronic form of the disease supervenes, leading to progressive respiratory failure, dyspnea, and cyanosis and a decrease in total lung capacity and compliance—a picture similar to other forms of chronic interstitial disease.

Pulmonary Eosinophilia

Although relatively rare, there are several clinical and pathologic pulmonary entities that are characterized by an infiltration of eosinophils, recruited in part by elevated alveolar levels of eosinophil attractants such as IL-5.

Pulmonary eosinophilia is divided into the following categories:

- *Acute eosinophilic pneumonia with respiratory failure.* This is an acute illness of unknown cause. It has a rapid onset with fever, dyspnea, and hypoxemic respiratory failure. The chest radiograph shows diffuse infiltrates, and bronchoalveolar lavage fluid contains more than 25% eosinophils. Histology shows diffuse alveolar damage and many eosinophils. There is a prompt response to corticosteroids.
- *Secondary eosinophilia,* which occurs in a number of parasitic, fungal, and bacterial infections; in hypersensitivity

pneumonitis; in drug allergies; and in association with asthma, allergic bronchopulmonary aspergillosis, or vasculitis (Churg-Strauss syndrome)

- *Idiopathic chronic eosinophilic pneumonia,* characterized by focal areas of cellular consolidation of the lung substance distributed chiefly in the periphery of the lung fields. Prominent in these lesions are heavy aggregates of lymphocytes and eosinophils within both the septal walls and the alveolar spaces. Interstitial fibrosis and organizing pneumonia are often present. These patients have cough, fever, night sweats, dyspnea, and weight loss, all of which respond to corticosteroid therapy. Chronic eosinophilic pneumonia is diagnosed when other causes of chronic pulmonary eosinophilia are excluded.

Smoking-Related Interstitial Diseases

Smoking-related diseases can be grouped into obstructive diseases (emphysema and chronic bronchitis, already discussed) and restrictive or interstitial diseases. A majority of individuals with idiopathic pulmonary fibrosis are smokers; however, the role of cigarette smoking in its pathogenesis has not been clarified yet. Desquamative interstitial pneumonia and respiratory bronchiolitis-associated interstitial lung disease are also smoking-associated interstitial lung diseases.

Desquamative Interstitial Pneumonia

Desquamative interstitial pneumonia is characterized by large collections of macrophages in the airspaces in a current or former smoker. The macrophages were originally thought to be desquamated pneumocytes, thus the misnomer “desquamative interstitial pneumonia.”

MORPHOLOGY

The most striking finding is the accumulation of a large number of macrophages with abundant cytoplasm containing dusty brown pigment (**smokers' macrophages**) in the airspaces (Fig. 15-24). Finely granular iron may be seen in the macrophage cytoplasm. Some of the macrophages contain lamellar

Figure 15-24 Desquamative interstitial pneumonia. Medium-power detail of lung demonstrates the accumulation of large numbers of macrophages within the alveolar spaces and only mild fibrous thickening of the alveolar walls.

bodies (composed of surfactant) within phagocytic vacuoles, presumably derived from necrotic type II pneumocytes. The alveolar septa are thickened by a sparse inflammatory infiltrate of lymphocytes, plasma cells, and occasional eosinophils. The septa are lined by plump, cuboidal pneumocytes. Interstitial fibrosis, when present, is mild. Emphysema is often present.

Desquamative interstitial pneumonia usually presents in the fourth or fifth decade of life, and is now equally common in men and women. Virtually all patients are cigarette smokers. Presenting symptoms include an insidious onset of dyspnea and dry cough over weeks or months, often associated with clubbing of digits. Pulmonary function tests usually show a mild restrictive abnormality with a moderate reduction of the diffusing capacity of carbon dioxide. Patients with desquamative interstitial pneumonia typically have an excellent response to steroid therapy and cessation of smoking but occasional patients may progress to interstitial fibrosis.

Respiratory Bronchiolitis-Associated Interstitial Lung Disease

Respiratory bronchiolitis-associated interstitial lung disease is marked by chronic inflammation and peribronchiolar fibrosis. It is a common histologic lesion in cigarette smokers. It is characterized by the presence of pigmented intraluminal macrophages within first- and second-order respiratory bronchioles. In its mildest form, it is most often an incidental finding in the lungs of smokers or ex-smokers. The term *respiratory bronchiolitis-associated interstitial lung disease* is used for patients who develop significant pulmonary symptoms, abnormal pulmonary function, and imaging abnormalities.

MORPHOLOGY

The changes are patchy at low magnification and have a bronchiolocentric distribution. Respiratory bronchioles, alveolar ducts, and peribronchiolar spaces contain aggregates of dusty brown macrophages (**smokers' macrophages**) similar to those seen in desquamative interstitial pneumonia. There is a patchy submucosal and peribronchiolar infiltrate of lymphocytes and histiocytes. Mild peribronchiolar fibrosis is also seen, which expands contiguous alveolar septa. Centrilobular emphysema is common but not severe. Desquamative interstitial pneumonia is often found in different parts of the same lung.

Symptoms are usually mild, consisting of gradual onset of dyspnea and cough in patients who are typically current smokers in the fourth or fifth decade of life with average exposures of over 30 pack-years of cigarette smoking. Cessation of smoking usually results in improvement.

Pulmonary Langerhans Cell Histiocytosis

Pulmonary Langerhans cell histiocytosis is a rare disease characterized by focal collections of Langerhans cells (often accompanied by eosinophils). As these lesions progress scarring occurs, leading to airway destruction and alveolar damage that result in the appearance of irregular cystic spaces. Imaging of the chest shows characteristic cystic and nodular abnormalities. Langerhans cells are immature

dendritic cells with grooved, indented nuclei and abundant cytoplasm. They are positive for S100, CD1a, and CD207 (langerin) and are negative for CD68.

More than 95% of affected patients are relatively young adult smokers who get better after smoking cessation, suggesting that in some cases the lesions are a reactive inflammatory process. However, in other cases the Langerhans cells have acquired activating mutations in the serine/threonine kinase BRAF, a feature consistent with a neoplastic process that is also commonly seen in Langerhans cell proliferations involving other tissues (Chapter 13). A neoplastic basis may explain why the disease progresses in some patients, sometimes even necessitating lung transplantation.

Pulmonary Alveolar Proteinosis

Pulmonary alveolar proteinosis (PAP) is a rare disease caused by defects related to granulocyte-macrophage colony-stimulating factor (GM-CSF) or pulmonary macrophage dysfunction that results in the accumulation of surfactant in the intra-alveolar and bronchiolar spaces. PAP is characterized radiologically by bilateral patchy asymmetric pulmonary opacifications. There are three distinct classes of disease—autoimmune (formerly called acquired), secondary, and congenital—each with a similar spectrum of histologic changes.

- *Autoimmune PAP* is caused by circulating neutralizing antibodies specific for GM-CSF. It occurs primarily in adults, represents 90% of all cases of PAP, and lacks any familial predisposition. Knockout of the GM-CSF gene in mice induces PAP, and these mice are “cured” by treatment with GM-CSF. Loss of GM-CSF signaling blocks the terminal differentiation of alveolar macrophages impairing their ability to catabolize surfactant.
- *Secondary PAP* is uncommon and is associated with diverse diseases, including hematopoietic disorders, malignancies, immunodeficiency disorders, lysinuric protein intolerance (an inborn error of amino acid metabolism), and acute silicosis and other inhalational syndromes. It is speculated that these diseases somehow impair macrophage maturation or function, again leading to inadequate clearance of surfactant from alveolar spaces.
- *Hereditary PAP* is extremely rare, occurs in neonates and is caused by mutations that disrupt genes involved in GM-CSF signaling (GM-CSF and GM-CSF receptor gene mutations).

MORPHOLOGY

The disease is characterized by a peculiar homogeneous, granular precipitate containing surfactant proteins within the alveoli, causing focal-to-confluent consolidation of large areas of the lungs with minimal inflammatory reaction (Fig. 15-25). As a consequence there is a marked increase in the size and weight of the lung. The alveolar precipitate is periodic acid-Schiff positive, and contains cholesterol clefts and surfactant proteins (which can be demonstrated by immunohistochemical stains). Ultrastructurally, the surfactant lamellae in type II pneumocytes are normal.

Figure 15-25 Pulmonary alveolar proteinosis. The alveoli are filled with a dense, amorphous, protein-lipid granular precipitate, while the alveolar walls are normal.

Adult patients, for the most part, present with cough and abundant sputum that often contains chunks of gelatinous material. Some have symptoms lasting for years, often with febrile illnesses. These patients are at risk for developing secondary infections with a variety of organisms. Progressive dyspnea, cyanosis, and respiratory insufficiency may occur, but other patients follow a benign course, with eventual resolution of the lesions. Whole-lung lavage is the standard of care and provides benefit regardless of the underlying defect. GM-CSF therapy is safe and effective in more than half of the patients with autoimmune PAP while therapy directed at the underlying disorder may be helpful in secondary PAP.

Surfactant Dysfunction Disorders

Surfactant dysfunction disorders are diseases caused by mutations in genes encoding proteins involved in surfactant trafficking or secretion. The mutated genes include the following:

- *ATP-binding cassette protein member 3 (ABCA3)* is the most frequently mutated gene in surfactant dysfunction disorders. It is an autosomal recessive disorder and usually presents in the first few months of life with rapidly progressive respiratory failure followed by death. Less commonly it comes to attention in older children and in adults with chronic interstitial lung disease.
- *Surfactant protein C* is the second most commonly mutated gene in surfactant dysfunction disorders. It is autosomal dominant with variable penetrance and severity in 45% and sporadic in 55%. It has a highly variable course.
- *Surfactant protein B* is the least commonly mutated gene and is associated with an autosomal recessive form of surfactant dysfunction disorder. Typically, the infant is full term and rapidly develops progressive respiratory distress shortly after birth. Death ensues between 3 and 6 months of age.

MORPHOLOGY

There is variable amount of intra-alveolar pink granular material, type II pneumocyte hyperplasia, interstitial fibrosis and alveolar simplification. Immunohistochemical stains show the lack of surfactant proteins C and B in their respective deficiencies. Ultrastructurally, abnormalities in lamellar bodies in type II pneumocytes can be seen in all three; small lamellar bodies with electron dense cores are diagnostic for *ABCA3* mutation (Fig 15-26).

Diseases of Vascular Origin

Pulmonary Embolism and Infarction

Pulmonary embolism is an important cause of morbidity and mortality, particularly in patients who are bedridden, but also in a wide range of conditions that are associated with hypercoagulability. Blood clots that occlude the large pulmonary arteries are almost always embolic in origin. The usual source—thrombi in the deep veins of the leg (>95% of cases)—and the magnitude of the clinical problem were discussed in [Chapter 4](#). Pulmonary embolism causes more than 50,000 deaths in the United States each year. Its incidence at autopsy has varied from 1% in the general population of hospital patients to 30% in patients dying after severe burns, trauma, or fractures. It is the sole or a major contributing cause of death in about 10% of adults who die acutely in hospitals. By contrast, large-vessel pulmonary thromboses are rare and develop only in the presence of pulmonary hypertension, pulmonary atherosclerosis, and heart failure.

Pathogenesis. Pulmonary embolism usually occurs in patients with a predisposing condition that produces an increased tendency to clot (thrombophilia). Patients often have cardiac disease or cancer, or have been immobilized for several days or weeks prior to the appearance of a

Figure 15-26 Pulmonary alveolar proteinosis associated with mutation of the *ABCA3* gene. An electron micrograph shows type 2 pneumocytes containing small surfactant lamellae with electron dense cores, an appearance that is characteristic of cases associated with *ABCA3* mutations.

symptomatic embolism. Those with hip fractures are at particularly high risk. Hypercoagulable states, either primary (e.g., factor V Leiden, prothrombin mutations, and antiphospholipid syndrome) or secondary (e.g., obesity, recent surgery, cancer, oral contraceptive use, pregnancy), are important risk factors. Indwelling central venous lines can be a nidus for formation of right atrial thrombi, which can embolize to the lungs. Rarely pulmonary embolism may consist of fat, air, or tumor. Small bone marrow emboli are often seen in patients who die after chest compressions performed during resuscitative efforts.

The pathophysiologic response and clinical significance of pulmonary embolism depend on the extent to which pulmonary artery blood flow is obstructed, the size of the occluded vessels, the number of emboli, and the cardiovascular health of the patient. Emboli have two deleterious pathophysiologic consequences: *respiratory compromise* due to the nonperfused, although ventilated, segment; and *hemodynamic compromise* due to increased resistance to pulmonary blood flow caused by the embolic obstruction. Sudden death often ensues, largely as a result of the blockage of blood flow through the lungs. Death may also be caused by acute right-sided heart failure (*acute cor pulmonale*).

MORPHOLOGY

Large emboli lodge in the main pulmonary artery or its major branches or at the bifurcation as a saddle embolus (Fig. 15-27). Smaller emboli travel out into the more peripheral vessels, where they may cause hemorrhage or infarction. In patients with adequate cardiovascular function, the bronchial arterial supply sustains the lung parenchyma; in this instance, hemorrhage may occur, but there is no infarction. In those in whom the cardiovascular function is already compromised, such as patients with heart or lung disease, infarction may occur. Overall, about 10% of emboli cause infarction. About three fourths of infarcts affect the lower lobes, and in more than half, multiple lesions occur. They vary in size from barely visible to massive lesions involving large parts of a lobe. Typically, they extend to the periphery of the lung as a wedge with the apex pointing toward the hilus of the lung. In many cases, an occluded vessel is identified near the apex of the infarct. Pulmonary embolus can be distinguished from a postmortem clot by the presence of the lines of Zahn in the thrombus (Chapter 4).

The pulmonary infarct is classically hemorrhagic and appears as a raised, red-blue area in the early stages (Fig. 15-28). Often, the apposed pleural surface is covered by a fibrinous exudate. The red cells begin to lyse within 48 hours, and the infarct becomes paler and eventually red-brown as hemosiderin is produced. With the passage of time, fibrous replacement begins at the margins as a gray-white peripheral zone and eventually converts the infarct into a contracted scar. Histologically, the hemorrhagic area shows ischemic necrosis of the alveolar walls, bronchioles, and vessels. If the infarct is caused by an infected embolus, the neutrophilic inflammatory reaction can be intense. Such lesions are referred to as **septic infarcts**, some which turn into abscesses.

Clinical Course. A large pulmonary embolus is one of the few causes of virtually instantaneous death. During

Figure 15-27 Large saddle embolus from the femoral vein lying astride the main left and right pulmonary arteries. (From the teaching collection of the Department of Pathology, University of Texas Southwestern Medical School, Dallas, Tex.)

cardiopulmonary resuscitation in such instances, the patient frequently is said to have *electromechanical dissociation*, in which the electrocardiogram has a rhythm but no pulses are palpated because no blood is entering the pulmonary arterial circulation. If the patient survives after a sizable pulmonary embolus, however, the clinical syndrome may mimic myocardial infarction, with severe chest pain, dyspnea, and shock. *Small emboli* are silent or induce only transient chest pain and cough. Pulmonary infarcts manifest as dyspnea, tachypnea, fever, chest pain, cough, and hemoptysis. An overlying fibrinous pleuritis may produce a pleural friction rub.

Findings on *chest radiograph* are variable and can be normal or disclose a pulmonary infarct, usually 12 to 36 hours after it has occurred, as a *wedge-shaped infiltrate*. The diagnosis of pulmonary embolism is usually made with spiral computed tomographic angiography. Rarely, other diagnostic methods, such as ventilation perfusion scanning or pulmonary angiography are required. Deep vein thrombosis can be diagnosed with duplex ultrasonography. After the initial acute insult, emboli often resolve via contraction and fibrinolysis, particularly in the relatively young. If unresolved, over the course of time multiple small emboli may lead to pulmonary hypertension and chronic cor

Figure 15-28 Acute hemorrhagic pulmonary infarct.

pulmonale. Perhaps most important is that a small embolus may presage a larger one. In the presence of an underlying predisposing condition, patients with a pulmonary embolus have a 30% chance of suffering a second embolus.

Prevention of pulmonary embolism is a major clinical challenge for which there is no easy solution. Prophylactic therapy includes early ambulation in postoperative and postpartum patients, elastic stockings and graduated compression stockings for bedridden patients, and anticoagulation in high-risk individuals. Treatment of pulmonary embolism includes anticoagulation and supportive measures; thrombolysis may have some benefit in those with severe complications (e.g., shock), but carries a high risk of bleeding. Those at risk of recurrent pulmonary embolism in whom anticoagulation is contraindicated may be fitted with an inferior vena cava filter (an “umbrella”) that catches clots before they reach the lungs.

KEY CONCEPTS

Pulmonary Embolism

- Almost all large pulmonary artery thrombi are embolic in origin, usually arising from the deep veins of the lower leg.
- Risk factors include prolonged bed rest, leg surgery, severe trauma, CHF, use of oral contraceptives (especially those with high estrogen content), disseminated cancer, and genetic diseases of hypercoagulability.
- The vast majority (60% to 80%) of emboli are clinically silent, a minority (5%) cause acute cor pulmonale, shock, or death (typically from large “saddle emboli”), and the remaining cause pulmonary infarction.
- Risk of recurrence is high.

Pulmonary Hypertension

Pulmonary hypertension is defined as a mean pulmonary artery pressure greater than or equal to 25 mm Hg at rest. Based on underlying mechanisms, the World Health Organization has classified pulmonary hypertension into five groups. These groups are: (1) pulmonary arterial hypertension, a diverse collection of disorders that all primarily impact small pulmonary muscular arteries; (2) pulmonary hypertension secondary to left-heart failure; (3) pulmonary hypertension stemming from lung parenchymal disease or hypoxemia; (4) chronic thromboembolic pulmonary hypertension; and (5) pulmonary hypertension of multifactorial basis.

Pathogenesis. As can be gathered from the classification above, pulmonary hypertension has diverse causes. It is most frequently associated with structural cardiopulmonary conditions that increase pulmonary blood flow, pulmonary vascular resistance, or left heart resistance to blood flow. Some of the more common causes are the following:

- *Antecedent congenital or acquired heart disease* (group 2). Mitral stenosis, for example, causes an increase in left atrial pressure and pulmonary venous pressure that is eventually transmitted to the arterial side of the pulmonary vasculature, leading to hypertension.
 - *Recurrent thromboemboli* (group 4). Recurrent pulmonary emboli may cause pulmonary hypertension by reducing the functional cross-sectional area of the pulmonary vascular bed, which in turn leads to an increase in pulmonary vascular resistance.
 - *Autoimmune diseases* (group 1). Several of these diseases (most notably systemic sclerosis) involve the pulmonary vasculature and/or the interstitium, leading to increased vascular resistance and pulmonary hypertension.
 - *Obstructive sleep apnea* (also group 3) is a common disorder that is associated with obesity and hypoxemia. It is now recognized to be a significant contributor to the development of pulmonary hypertension and cor pulmonale.
- Uncommonly, pulmonary hypertension is encountered in patients in whom all known causes are excluded; this is referred to as *idiopathic pulmonary arterial hypertension*. However, this is a bit of a misnomer, as up to 80% of “idiopathic” pulmonary hypertension (sometimes referred to as primary pulmonary hypertension) has a genetic basis, sometimes being inherited in families as an autosomal dominant trait. Within these families, there is incomplete penetrance, and only 10% to 20% of the family members actually develop overt disease.
- As is often the case, much has been learned about the pathogenesis of pulmonary hypertension by investigating the molecular basis of the uncommon familial form of the disease. The first mutation to be discovered in familial pulmonary arterial hypertension was in the bone morphogenetic protein receptor type 2 (BMPR2). Inactivating germline mutations in the BMPR2 gene are found in 75% of the familial cases of pulmonary hypertension, and 25% of sporadic cases. Subsequently other mutations have been discovered that also converge on the BMPR2 pathway and affect intracellular signaling. It has also been demonstrated that BMPR2 is down-regulated in lungs from some idiopathic pulmonary arterial hypertension patients without mutation in its gene.
- BMPR2 is a cell surface protein belonging to the TGF- β receptor superfamily, which binds a variety of cytokines, including TGF- β , bone morphogenetic protein (BMP), activin, and inhibin. Although originally described in the context of bone growth, BMP-BMPR2 signaling is now known to be important for embryogenesis, apoptosis, and cell proliferation and differentiation. Details remain to be worked out, but it appears that haploinsufficiency for BMPR2 leads to dysfunction and proliferation of endothelial cells and vascular smooth muscle cells. Because only 10% to 20% of individuals with BMPR2 mutations develop disease, it is likely that modifier genes and/or environmental triggers also contribute to the pathogenesis of the disorder. A two-hit model has been proposed whereby a genetically susceptible individual with a BMPR2 mutation requires additional genetic or environmental insults to develop the disease (Fig. 15-29).

- *Chronic obstructive or interstitial lung diseases* (group 3). These diseases obliterate alveolar capillaries, increasing pulmonary resistance to blood flow and, secondarily, pulmonary blood pressure.

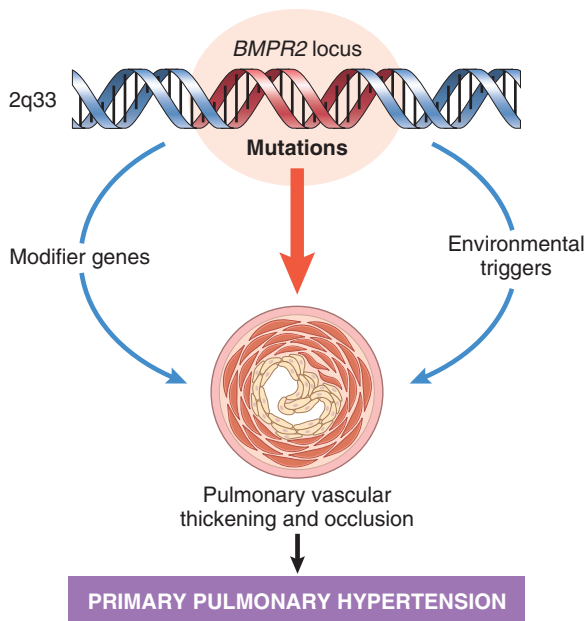

Figure 15-29 Pathogenesis of primary (idiopathic) pulmonary hypertension. See text for details.

MORPHOLOGY

Regardless of their etiology, all forms of pulmonary hypertension are associated with **medial hypertrophy of the pulmonary muscular and elastic arteries, pulmonary arterial atherosclerosis, and right ventricular hypertrophy**. The presence of many organizing or recanalized thrombi favors recurrent pulmonary emboli as the cause, and the coexistence of diffuse pulmonary fibrosis, or severe emphysema and chronic bronchitis, points to chronic hypoxia as the initiating event. The vessel changes can involve the entire arterial tree, from the main pulmonary arteries down to the arterioles (Fig. 15-30). In the most severe cases, atheromatous deposits form in the pulmonary artery and its major branches, resembling (but lesser in degree than) systemic atherosclerosis. The arterioles and small arteries (40 to 300 μm in diameter) are most prominently affected by striking medial hypertrophy and intimal fibrosis, sometimes narrowing the lumens to pinpoint channels. One extreme in the spectrum of pathologic changes is the plexiform lesion, so called because a tuft of capillary formations is present, producing a network, or web, that spans the lumens of dilated thin-walled, small arteries and may extend outside the vessel. Plexiform lesions are most prominent in idiopathic and familial pulmonary hypertension (group 1), unrepaired congenital heart disease with left-to-right shunts (group 2), and pulmonary hypertension associated with human immunodeficiency virus (HIV) infection and drugs (also group 1).

Clinical Course. Idiopathic pulmonary hypertension is most common in women who are 20 to 40 years of age and is also seen occasionally in young children. Clinical signs and symptoms in all forms of pulmonary hypertension become evident only in advanced disease. In cases of idiopathic disease, the presenting features are usually dyspnea and fatigue, but some patients have chest pain of the anginal type. Over time, severe respiratory distress,

cyanosis, and right ventricular hypertrophy occur, and death from decompensated cor pulmonale, often with superimposed thromboembolism and pneumonia, usually ensues within 2 to 5 years in 80% of patients.

Treatment choices depend on the underlying cause. For those with secondary disease, therapy is directed at the trigger (e.g., thromboembolic disease or hypoxemia). A variety of vasodilators have been used with varying success in those with group 1 or refractory disease belonging to other groups. Lung transplantation provides definitive treatment for selected patients.

Figure 15-30 Vascular changes in pulmonary arterial hypertension. **A**, Atheroma formation, a finding usually limited to large vessels. **B**, Marked medial hypertrophy. **C**, Plexiform lesion of small arteries that is characteristic of advanced pulmonary hypertension.

Figure 15-31 Diffuse pulmonary hemorrhage syndrome. There is acute intra-alveolar hemorrhage and hemosiderin-laden macrophages, reflecting previous hemorrhage (Prussian blue iron stain).

Diffuse Pulmonary Hemorrhage Syndromes

Pulmonary hemorrhage is a dramatic complication of some interstitial lung disorders. Among these so-called *pulmonary hemorrhage syndromes* (Fig. 15-31) are (1) Goodpasture syndrome, (2) idiopathic pulmonary hemosiderosis, and (3) vasculitis-associated hemorrhage, which is found in conditions such as hypersensitivity angiitis, Wegener granulomatosis, and systemic lupus erythematosus (Chapter 11).

Goodpasture Syndrome

Goodpasture syndrome is an uncommon autoimmune disease in which kidney and lung injury are caused by circulating autoantibodies against the noncollagenous domain of the $\alpha 3$ chain of collagen IV. When only renal disease is caused by this antibody, it is called anti-glomerular basement membrane disease. The term *Goodpasture syndrome* designates the 40% to 60% of patients who develop pulmonary hemorrhage in addition to renal disease. The antibodies initiate inflammatory destruction of the basement membrane in renal glomeruli and pulmonary alveoli, giving rise to *rapidly progressive glomerulonephritis* and a *necrotizing hemorrhagic interstitial pneumonitis*. Although any age can be affected, most cases occur in the teens or 20s, and in contrast to many other autoimmune diseases, there is a male preponderance. The majority of patients are active smokers.

Pathogenesis. The immunopathogenesis of the syndrome and the nature of the Goodpasture antigens are described in Chapter 20. The trigger that initiates the production of anti-basement membrane antibodies is still unknown. Because the epitopes that evoke anticollagen antibodies are normally hidden within the molecule, it is presumed that

some environmental insult such as viral infection, exposure to hydrocarbon solvents (used in the dry cleaning industry), or smoking is required to unmask the cryptic epitopes. As in other autoimmune disorders, a genetic predisposition is indicated by association with certain HLA subtypes (e.g., HLA-DRB1*1501 and *1502).

MORPHOLOGY

In the classic case, the lungs are heavy, with areas of red-brown consolidation. Histologically, there is focal necrosis of alveolar walls associated with intra-alveolar hemorrhages. Often the alveoli contain hemosiderin-laden macrophages (Fig. 15-31). In later stages there may be fibrous thickening of the septae, hypertrophy of type II pneumocytes, and organization of blood in alveolar spaces. In many cases immunofluorescence studies reveal linear deposits of immunoglobulins along the basement membranes of the septal walls. The kidneys have the characteristic findings of focal proliferative glomerulonephritis in early cases or crescentic glomerulonephritis in patients with rapidly progressive glomerulonephritis. Diagnostic linear deposits of immunoglobulins and complement are seen by immunofluorescence studies along the glomerular basement membranes even in the few patients without renal disease.

Clinical Features. Most cases begin clinically with respiratory symptoms, principally hemoptysis, and radiographic evidence of focal pulmonary consolidations. Soon, manifestations of glomerulonephritis appear, leading to rapidly progressive renal failure. The most common cause of death is uremia. The once dismal prognosis for this disease has been markedly improved by intensive *plasmapheresis*. This procedure is thought to be beneficial by removing circulating antibasement membrane antibodies as well as chemical mediators of immunologic injury. Simultaneous immunosuppressive therapy inhibits further antibody production, ameliorating both lung hemorrhage and glomerulonephritis.

Idiopathic Pulmonary Hemosiderosis

Idiopathic pulmonary hemosiderosis is a rare disorder characterized by intermittent, diffuse alveolar hemorrhage. Most cases occur in young children, although the disease has been reported in adults as well. It usually presents with an insidious onset of productive cough, hemoptysis, and anemia associated with diffuse pulmonary infiltrations similar to Goodpasture syndrome.

The cause and pathogenesis are unknown, and no anti-basement membrane antibodies are detectable in serum or tissues. However, favorable response to long-term immunosuppression with prednisone and/or azathioprine indicates that an immunologic mechanism could be involved in the pulmonary capillary damage underlying alveolar bleeding. In addition, long-term follow-up of patients shows that some of them develop other immune disorders.

Polyangiitis With Granulomatosis

Previously called Wegener granulomatosis, this autoimmune disease most often involves the upper respiratory tract and/or the lungs, with hemoptysis being the common presenting symptom. Its features are discussed in Chapter

11. Here, it is enough to emphasize that a transbronchial lung biopsy might provide the only tissue available for diagnosis. Since the amount of tissue is small, necrosis and granulomatous vasculitis might not be present. Rather, the diagnostically important features are capillaritis and scattered, poorly formed granulomas (unlike those of sarcoidosis, which are rounded and well-defined).

Pulmonary Infections

Respiratory tract infections are more frequent than infections of any other organ and account for the largest number of workdays lost in the general population. The vast majority are upper respiratory tract infections caused by viruses (common cold, pharyngitis), but bacterial, viral, mycoplasmal, and fungal infections of the lung (pneumonia) still account for an enormous amount of morbidity and are the eighth leading cause of death (responsible for 2.3% of all deaths) in the United States. Pneumonia can be very broadly defined as any infection of the lung parenchyma.

Pulmonary anti-microbial defense mechanisms are described in [Chapter 8](#). Pneumonia can result whenever these local defense mechanisms are impaired or the systemic resistance of the host is lowered. Factors that affect resistance in general include chronic diseases, immunologic deficiency, treatment with immunosuppressive agents, and leukopenia. The local defense mechanisms of the lung can be compromised by many factors, including:

- *Loss or suppression of the cough reflex* as a result of coma, anesthesia, neuromuscular disorders, drugs, or chest pain (may lead to *aspiration* of gastric contents)
- *Injury to the mucociliary apparatus* by either impairment of ciliary function or destruction of ciliated epithelium, due to cigarette smoke, inhalation of hot or corrosive gases, viral diseases, or genetic defects of ciliary function (e.g., the immotile cilia syndrome)
- *Accumulation of secretions* in conditions such as cystic fibrosis and bronchial obstruction
- *Interference with the phagocytic* or bactericidal action of alveolar macrophages by alcohol, tobacco smoke, anoxia, or oxygen intoxication
- *Pulmonary congestion and edema*

Defects in innate immunity (including neutrophil and complement defects) and humoral immunodeficiency typically lead to an increased incidence of infections with pyogenic bacteria. Germline mutations in MyD88 (an adaptor for several TLRs that is important for activation of the transcription factor NF κ B) are also associated with destructive bacterial (pneumococcal) pneumonias. On the other hand, cell-mediated immune defects (congenital and acquired) lead to increased infections with intracellular microbes such as mycobacteria and herpesviruses as well as with microorganisms of very low virulence, such as *Pneumocystis jiroveci*.

Several other points should be emphasized. First, to paraphrase the French physician Louis Cruveilhier in 1919 (during the Spanish flu epidemic), “flu condemns, and additional infection executes”. This is particularly true in debilitated patients. For example, the most common

cause of death in viral influenza epidemics is superimposed bacterial pneumonia. Second, although the portal of entry for most bacterial pneumonias is the respiratory tract, hematogenous seeding of the lungs from another organ may occur and may be difficult to distinguish from primary pneumonia. Finally, many patients with chronic diseases acquire terminal pneumonia while hospitalized (*nosocomial infection*). Bacteria common to the hospital environment may have acquired resistance to antibiotics; opportunities for spread are increased; invasive procedures, such as intubations and injections, are common; and bacteria may contaminate equipment used in respiratory care units.

Pneumonia is classified by the specific etiologic agent, which determines the treatment, or, if no pathogen can be isolated (which occurs in about 50% of cases), by the clinical setting in which the infection occurs. The latter considerably narrows the list of suspected pathogens, providing a guide for empirical antimicrobial therapy. As [Table 15-7](#) indicates, pneumonia can arise in seven distinct clinical settings (“pneumonia syndromes”), and the implicated pathogens are reasonably specific to each category.

Community-Acquired Bacterial Pneumonias

Community-acquired acute pneumonia refers to lung infection in otherwise healthy individuals that is acquired from the normal environment (in contrast to hospital acquired pneumonia). It may be bacterial or viral. Clinical and radiologic features are usually insensitive in differentiating between them. Several newer biomarkers have been developed to identify patients with bacterial infection and to define their prognosis. Of these, C-reactive protein and procalcitonin, both acute-phase reactants produced primarily in the liver, are significantly elevated in bacterial more than in viral infections.

Often, the bacterial infection follows an upper respiratory tract viral infection. Bacterial invasion of the lung parenchyma causes the alveoli to be filled with an inflammatory exudate, thus causing consolidation (“solidification”) of the pulmonary tissue. Many variables, such as the specific etiologic agent, the host reaction, and the extent of involvement, determine the precise form of pneumonia. Predisposing conditions include extremes of age, chronic diseases (congestive heart failure, COPD, and diabetes), congenital or acquired immune deficiencies, and decreased or absent splenic function (sickle cell disease or postsplenectomy, which puts the patient at risk for infection with encapsulated bacteria such as pneumococcus).

Streptococcus pneumoniae

***Streptococcus pneumoniae*, or *pneumococcus*, is the most common cause of community-acquired acute pneumonia.** Examination of Gram-stained sputum is an important step in the diagnosis of acute pneumonia. The presence of numerous neutrophils containing the typical gram-positive, lancet-shaped diplococci supports the diagnosis of pneumococcal pneumonia, but it must be remembered that *S. pneumoniae* is a part of the endogenous flora in 20% of adults, and therefore false-positive results may be obtained. Isolation of pneumococci from blood cultures is more specific but less sensitive (in the early phase of illness, only 20% to 30% of patients have positive blood cultures).

Table 15-7 Pneumonia Syndromes

Community-Acquired Acute Pneumonia
<i>Streptococcus pneumoniae</i> <i>Haemophilus influenzae</i> <i>Moraxella catarrhalis</i> <i>Staphylococcus aureus</i> <i>Legionella pneumophila</i> Enterobacteriaceae (<i>Klebsiella pneumoniae</i>) and <i>Pseudomonas</i> spp. <i>Mycoplasma pneumoniae</i> <i>Chlamydia</i> spp. (<i>C. pneumoniae</i> , <i>C. psittaci</i> , <i>C. trachomatis</i>) <i>Coxiella burnetii</i> (Q fever) Viruses: respiratory syncytial virus, parainfluenza virus and human metapneumovirus (children); influenza A and B (adults); adenovirus (military recruits);
Health Care-Associated Pneumonia
<i>Staphylococcus aureus</i> , methicillin-sensitive <i>Staphylococcus aureus</i> , methicillin-resistant <i>Pseudomonas aeruginosa</i> <i>Streptococcus pneumoniae</i>
Hospital-Acquired Pneumonia
Gram-negative rods, Enterobacteriaceae (<i>Klebsiella</i> spp., <i>Serratia marcescens</i> , <i>Escherichia coli</i>) and <i>Pseudomonas</i> spp. <i>Staphylococcus aureus</i> (usually methicillin-resistant)
Aspiration Pneumonia
Anaerobic oral flora (<i>Bacteroides</i> , <i>Prevotella</i> , <i>Fusobacterium</i> , <i>Peptostreptococcus</i>), admixed with aerobic bacteria (<i>Streptococcus pneumoniae</i> , <i>Staphylococcus aureus</i> , <i>Haemophilus influenzae</i> , <i>Pseudomonas aeruginosa</i>)
Chronic Pneumonia
<i>Nocardia</i> <i>Actinomyces</i> Granulomatous: <i>Mycobacterium tuberculosis</i> and atypical mycobacteria, <i>Histoplasma capsulatum</i> , <i>Coccidioides immitis</i> , <i>Blastomyces dermatitidis</i>
Necrotizing Pneumonia and Lung Abscess
Anaerobic bacteria (extremely common), with or without mixed aerobic infection <i>Staphylococcus aureus</i> , <i>Klebsiella pneumoniae</i> , <i>Streptococcus pyogenes</i> , and type 3 pneumococcus (uncommon)
Pneumonia in the Immunocompromised Host
Cytomegalovirus <i>Pneumocystis jiroveci</i> <i>Mycobacterium avium-intracellulare</i> Invasive aspergillosis Invasive candidiasis "Usual" bacterial, viral, and fungal organisms (listed herein)

Pneumococcal vaccines containing capsular polysaccharides from the common serotypes are used in individuals at high risk for pneumococcal sepsis.

Haemophilus influenzae

Haemophilus influenzae is a pleomorphic, gram-negative organism that occurs in encapsulated and nonencapsulated forms. There are six serotypes of the encapsulated form (types a to f), of which type b is the most virulent. Antibodies against the capsule protect the host from *H. influenzae* infection; hence the capsular polysaccharide b is incorporated in the widely used vaccine against *H. influenzae*. With routine use of *H. influenzae* conjugate vaccines, the incidence of disease caused by the b serotype has declined significantly. By contrast, infections with nonencapsulated forms, also called *nontypeable forms*, are

increasing. They are less virulent, spread along the surface of the upper respiratory tract, and produce otitis media (infection of the middle ear), sinusitis, and bronchopneumonia. Neonates and children with comorbidities such as prematurity, malignancy, and immunodeficiency are at high risk for development of invasive infection.

H. influenzae pneumonia, which may follow a viral respiratory infection, is a pediatric emergency and has a high mortality rate. Descending laryngotracheobronchitis results in airway obstruction as the smaller bronchi are plugged by dense, fibrin-rich exudates containing neutrophils, similar to that seen in pneumococcal pneumonias. Pulmonary consolidation is usually lobular and patchy but may be confluent and involve the entire lung lobe. Before a vaccine became widely available, *H. influenzae* was a common cause of suppurative meningitis in children up to 5 years of age. *H. influenzae* also causes an acute, purulent conjunctivitis (pink eye) in children and, in predisposed older patients, may cause septicemia, endocarditis, pyelonephritis, cholecystitis, and suppurative arthritis. *H. influenzae* is the most common bacterial cause of acute exacerbation of COPD.

Moraxella catarrhalis

Moraxella catarrhalis is being increasingly recognized as a cause of bacterial pneumonia, especially in the elderly. It is the second most common bacterial cause of acute exacerbation of COPD. Along with *S. pneumoniae* and *H. influenzae*, *M. catarrhalis* constitutes one of the three most common causes of otitis media in children.

Staphylococcus aureus

Staphylococcus aureus is an important cause of secondary bacterial pneumonia in children and healthy adults following viral respiratory illnesses (e.g., measles in children and influenza in both children and adults). Staphylococcal pneumonia is associated with a high incidence of complications, such as lung abscess and empyema. *Intravenous drug users* are at high risk for development of staphylococcal pneumonia in association with endocarditis. It is also an important cause of hospital-acquired pneumonia.

Klebsiella pneumoniae

Klebsiella pneumoniae is the most frequent cause of gram-negative bacterial pneumonia. It commonly afflicts debilitated and malnourished people, particularly *chronic alcoholics*. Thick, mucoid, (often blood-tinged) sputum is characteristic, because the organism produces an abundant viscid capsular polysaccharide, which the patient may have difficulty expectorating.

Pseudomonas aeruginosa

Although *Pseudomonas aeruginosa* most commonly causes hospital-acquired infections, it is mentioned here because of its occurrence in cystic fibrosis and immunocompromised patients. It is common in patients who are neutropenic and it has a propensity to invade blood vessels with consequent extrapulmonary spread. *Pseudomonas* septicemia is a very fulminant disease.

Legionella pneumophila

Legionella pneumophila is the agent of Legionnaires' disease, an eponym for the epidemic and sporadic forms

Figure 15-32 Comparison of bronchopneumonia and lobar pneumonia.

of pneumonia caused by this organism. It also causes Pontiac fever, a related self-limited upper respiratory tract infection. This organism flourishes in artificial aquatic environments, such as water-cooling towers and the tubing systems of domestic (potable) water supplies. The mode of transmission is either inhalation of aerosolized organisms or aspiration of contaminated drinking water. *Legionella* pneumonia is common in individuals with predisposing conditions such as cardiac, renal, immunologic, or hematologic disease. Organ transplant recipients are particularly susceptible. It can be quite severe, frequently requiring hospitalization, and immunosuppressed patients may have fatality rates of up to 50%. Rapid diagnosis is facilitated by demonstration of *Legionella* antigens in the urine or by a positive fluorescent antibody test on sputum samples; culture remains the diagnostic gold standard.

Figure 15-33 Bronchopneumonia. Section of lung showing patches of consolidation (arrows).

Mycoplasma pneumoniae

Mycoplasma infections are particularly common among children and young adults. They occur sporadically or as local epidemics in closed communities (schools, military camps, and prisons).

MORPHOLOGY

Bacterial pneumonia has two patterns of anatomic distribution: lobular bronchopneumonia and lobar pneumonia (Fig. 15-32). Patchy consolidation of the lung is the dominant characteristic of **bronchopneumonia** (Fig. 15-33), while consolidation of a large portion of a lobe or of an entire lobe defines **lobar pneumonia** (Fig. 15-34). These anatomic categorizations may be difficult to apply in individual cases because patterns overlap. The patchy involvement may become confluent, producing virtually total lobar consolidation; however, effective antibiotic therapy may limit involvement to a subtotal consolidation. Moreover, the same organisms may produce either pattern depending on patient susceptibility. **Most important from the clinical standpoint are identification of the causative agent and determination of the extent of disease.**

In **lobar pneumonia**, four stages of the inflammatory response have classically been described: congestion, red hepatization, gray hepatization, and resolution. In the first stage of **congestion** the lung is heavy, boggy, and red. It is characterized by vascular engorgement, intra-alveolar fluid with few neutrophils, and often the presence of numerous bacteria. The stage of **red hepatization** that follows is characterized by massive confluent exudation, as neutrophils, red cells, and fibrin fill the alveolar spaces (Fig. 15-35A). On gross examination, the lobe is red, firm, and airless, with a liver-like consistency, hence the term hepatization. The stage of **gray hepatization** that follows is marked by progressive disintegration of red cells and the persistence of a fibrinosuppurative exudate (Fig. 15-35B),

Figure 15-34 Lobar pneumonia—gray hepatization. The lower lobe is uniformly consolidated.

Figure 15-35 Stages of bacterial pneumonia. **A**, Acute pneumonia. The congested septal capillaries and numerous intra-alveolar neutrophils are characteristic of early red hepatization. Fibrin nets have not yet formed. **B**, Early organization of intra-alveolar exudate, seen focally to be streaming through the pores of Kohn (*arrow*). **C**, Advanced organizing pneumonia. The exudates have been converted to fibromyxoid masses rich in macrophages and fibroblasts.

resulting in a color change to grayish-brown. In the final stage of **resolution** the exudate within the alveolar spaces is broken down by enzymatic digestion to produce granular, semifluid debris that is resorbed, ingested by macrophages, expectorated, or organized by fibroblasts growing into it (*Fig. 15-35C*). Pleural fibrinous reaction to the underlying inflammation, often present in the early stages if the consolidation extends to the surface (**pleuritis**), may similarly resolve. More often it

undergoes organization, leaving fibrous thickening or permanent adhesions.

Foci of **bronchopneumonia** are consolidated areas of acute suppurative inflammation. The consolidation may be confined to one lobe but is more often multilobar and frequently bilateral and basal because of the tendency of secretions to gravitate to the lower lobes. Well-developed lesions are slightly elevated, dry, granular, gray-red to yellow, and poorly delimited at their margins (*Fig. 15-33*). Histologically, the reaction usually elicits a neutrophil-rich exudate that fills the bronchi, bronchioles, and adjacent alveolar spaces (*Fig. 15-35A*).

Complications of pneumonia include (1) tissue destruction and necrosis, causing **abscess formation** (particularly common with type 3 pneumococci or *Klebsiella* infections); (2) spread of infection to the pleural cavity, causing the intra-pleural fibrinosuppurative reaction known as **empyema**; and (3) **bacteremic dissemination** to the heart valves, pericardium, brain, kidneys, spleen, or joints, causing metastatic abscesses, endocarditis, meningitis, or suppurative arthritis.

Clinical Course. The major symptoms of community-acquired acute bacterial pneumonia are abrupt onset of high fever, shaking chills, and cough producing mucopurulent sputum; occasional patients may have hemoptysis. When pleuritis is present it is accompanied by pleuritic pain and pleural friction rub. The whole lobe is radiopaque in lobar pneumonia, whereas there are focal opacities in bronchopneumonia.

The clinical picture is markedly modified by the administration of antibiotics. Treated patients may be relatively afebrile with few clinical signs 48 to 72 hours after the initiation of antibiotics. The identification of the organism and the determination of its antibiotic sensitivity are the keystones to appropriate therapy. Fewer than 10% of patients with pneumonia severe enough to merit hospitalization now succumb, and in most such instances death results from a complication, such as empyema, meningitis, endocarditis, or pericarditis, or to some predisposing influence, such as debility or chronic alcoholism.

Community-Acquired Viral Pneumonia

Common viral infections include influenza virus types A and B, the respiratory syncytial viruses, human metapneumovirus, adenovirus, rhinoviruses, rubeola, and varicella viruses. Any of these agents can cause merely an upper respiratory tract infection, recognized as the common cold, or a more severe lower respiratory tract infection. Factors that favor such extension of the infection include extremes of age, malnutrition, alcoholism, and underlying debilitating illnesses.

Although the molecular details vary, all of the viruses that cause pneumonia produce disease through similar general mechanisms. These viruses have tropisms that allow them to attach to and enter respiratory lining cells. Viral replication and gene expression leads to cytopathic changes, inducing cell death and secondary inflammation. The resulting damage and impairment of local pulmonary defenses, such as mucociliary clearance, may predispose to bacterial superinfections, which are often more serious than the viral infection itself.

Influenza Infections

Influenza viruses of type A infect humans, pigs, horses, and birds and are the major cause of pandemic and epidemic influenza infections. The influenza genome encodes a number of proteins, but the most important from the vantage point of viral virulence are the hemagglutinin and neuraminidase proteins. Hemagglutinin has three major subtypes (H1-H3), while neuraminidase has two (N1, N2). Both proteins are components of the influenza virus envelope, which consists of a lipid bilayer. Hemagglutinin is particularly important, as it serves to attach the virus to its cellular target via sialic acid residues on surface polysaccharides. Following uptake of the virus into endosomal vesicles, acidification of the endosome triggers a conformation change in hemagglutinin that allows the viral envelope to fuse with the host cell membrane, releasing the viral genomic RNAs into the cytoplasm of the cell. Neuraminidase in turn facilitates the release of newly formed virions that are budding from infected cells by cleaving sialic acid residues. Neutralizing host antibodies against viral hemagglutinin and neuraminidase prevent and ameliorate, respectively, infection with the influenza virus by interfering with these functions.

The viral genome is composed of eight single-stranded RNAs, each encoding one or more proteins. The RNAs are packaged into helices by nucleoproteins that determine the influenza virus type (A, B, or C). A single subtype of influenza virus A predominates throughout the world at a given time. Epidemics of influenza are caused by spontaneous mutations that alter antigenic epitopes on the viral hemagglutinin and neuraminidase proteins. These antigenic changes (*antigenic drift*) result in new viral strains that are sufficiently different to elude, at least in part, anti-influenza antibodies produced in members of the population in response to prior exposures to other flu strains. Usually, however, these new strains bear sufficient resemblance to prior strains that some members of the population are at least partially resistant to infection. By contrast, pandemics, which are longer and more widespread than epidemics, occur when both the hemagglutinin and the neuraminidase genes are replaced through recombination with animal influenza viruses (*antigenic shift*). In this instance, essentially all individuals are susceptible to the new influenza virus. Viral assembly involves packaging of each of the 8 viral RNAs into single virions, and it is easy to see how infection of an animal by two different flu types could lead to swapping of genetic material within co-infected cells, creating a completely new viral strain. Thus, the unusual genome of influenza virus ensures that antigenic shifts leading to pandemics are inevitable.

If the host lacks protective antibodies, the virus infects pneumocytes and elicits several cytopathic changes. Shortly after entry into pneumocytes, the viral infection inhibits sodium channels, producing electrolyte and water shifts that lead to fluid accumulation in the alveolar lumen. This is followed by the death of the infected cells through several mechanisms, including inhibition of host cell mRNA translation and activation of caspases leading to apoptosis. The death of epithelial cells exacerbates the fluid accumulation and releases “danger signals” that activate resident macrophages. In addition, prior to their death, infected epithelial cells release a variety of inflammatory mediators, including several chemokines and cytokines,

adding fuel to the inflammatory fire. In addition, mediators released from epithelial cells and macrophages activate the nearby pulmonary endothelium, allowing neutrophils to attach and extravasate into the interstitium within the first day or two of infection. In some cases viral infection may cause sufficient lung injury to produce the acute respiratory distress syndrome, but more often severe and sometimes fatal pulmonary disease stems from a superimposed bacterial pneumonia. Of these, secondary pneumonias caused by *Staphylococcus aureus* are particularly common and often life-threatening.

Control of the infection relies on several host mechanisms. The presence of viral products induces innate immune responses in infected cells, such as the production of α - and β -interferon. These mediators upregulate the expression of the *MX1* gene, which encodes a GTPase that interferes with influenza gene transcription and viral replication. As with other viral infections, natural killer cells and cytotoxic T cells can recognize and kill infected host cells, limiting viral replication and viral spread to adjacent pneumocytes. The cellular immune response is eventually augmented by development of antibody responses to the viral hemagglutinin and neuraminidase proteins.

Insight into future pandemics has come from studying those past. DNA analysis of viral genomes retrieved from the lungs of a soldier who died in the great 1918 influenza pandemic that killed between 20 million and 40 million people worldwide identified swine influenza sequences, consistent with this virus having its origin in a “antigenic shift”. The first flu pandemic of this century, in 2009, was also caused by an antigenic shift involving a virus of swine origin. It caused particularly severe infections in young adults, apparently because older adults had antibodies against past influenza strains that conveyed at least partial protection. Comorbidities such as diabetes, heart disease, lung disease, and immunosuppression were also associated with a higher risk of severe infection.

What then might be the source of the next great pandemic? There is no certainty, but one concern is centered on avian influenza, which normally infects birds. One such strain, type H5N1, has spread throughout the world in wild and domestic birds. As of June 2011, a total of 562 H5N1 influenza virus infections and 325 deaths in humans (from 15 countries) have been reported to the World Health Organization (WHO). Nearly all cases have been acquired by close contact with domestic birds; most deaths resulted from pneumonia. Fortunately, the transmission of the current H5N1 avian virus is inefficient. However, if H5N1 influenza recombines with an influenza that is highly infectious for humans, a strain might result that is capable of sustained human-to-human transmission (and, thus, of causing the next great pandemic).

Human Metapneumovirus

Human metapneumovirus (MPV), a paramyxovirus discovered in 2001, is found worldwide and is associated with upper and lower respiratory tract infections. It can infect any age group but is most commonly seen in young children, elderly subjects, and immunocompromised patients. Human MPV can cause severe infections such as bronchiolitis and pneumonia and is responsible for 5% to 10% of hospitalizations and 12% to 20% of outpatient visits of children suffering from acute respiratory tract infections. Such infections are clinically indistinguishable from those

caused by human respiratory syncytial virus and are often mistaken for influenza. The first human MPV infection occurs during early childhood, but reinfections are common throughout life, especially in older subjects. Diagnostic methods include PCR tests for viral RNA and direct immunofluorescence. Ribavirin is the only antiviral treatment that is currently available for human MPV infections; it is used mostly in immunocompromised patients with severe disease. Although work is ongoing, a clinically effective and safe vaccine has yet to be developed.

Severe Acute Respiratory Syndrome

Severe acute respiratory syndrome (SARS) first appeared in November 2002 in the Guangdong Province of China and subsequently spread to Hong Kong, Taiwan, Singapore, Vietnam, and Toronto, where large outbreaks also occurred. The ease of travel between continents clearly contributed to this initial rapid spread. The epidemic went no further, however, perhaps in part because of public health measures, and the last cases of SARS were laboratory-associated infections reported in April 2004. The cause of SARS was a new coronavirus. Many upper respiratory infections are caused by coronaviruses, but the SARS virus differed from other coronaviruses in that it infected the lower respiratory tract and spread throughout the body. SARS is a cardinal example of sudden emergence of a new infectious agent (Chapter 8), but since 2004 the virus has completely disappeared as mysteriously as its original debut. It is unknown if or when it will appear again.

MORPHOLOGY

All viral infections produce similar morphologic changes. Upper respiratory infections are marked by mucosal hyperemia and swelling, lymphomonocytic and plasmacytic infiltration of the submucosa, and overproduction of mucus secretions. The swollen mucosa and viscous exudate may plug the nasal channels, sinuses or the Eustachian tubes, leading to suppurative secondary bacterial infection. Virus-induced tonsillitis causing hyperplasia of the lymphoid tissue within the Waldeyer ring is frequent in children.

In viral **laryngotracheobronchitis** and **bronchiolitis** there is vocal cord swelling and abundant mucus production. Impairment of bronchociliary function invites bacterial superinfection with more marked suppuration. Plugging of small airways may give rise to focal lung atelectasis. With more severe bronchiolar involvement, widespread plugging of secondary and terminal airways by cell debris, fibrin, and inflammatory exudate may, if prolonged, lead to organization and fibrosis, resulting in obliterative bronchiolitis and permanent lung damage.

Lung involvement may be quite patchy or may involve whole lobes bilaterally or unilaterally. The affected areas are red-blue and congested. Pleuritis or pleural effusions are infrequent. The histologic pattern depends on the severity of the disease.

Predominant is an interstitial inflammatory reaction involving the walls of the alveoli. The alveolar septa are widened and edematous and usually have a mononuclear inflammatory infiltrate of lymphocytes, macrophages, and occasionally plasma cells. In acute cases neutrophils may also be present. The alveoli may be free of exudate, but in many patients there is intra-alveolar proteinaceous material and a cellular exudate. When complicated by ARDS, pink hyaline membranes

line the alveolar walls (Fig. 15-4). Eradication of the infection is followed by reconstitution of the normal lung architecture.

Superimposed bacterial infection modifies this picture by causing ulcerative bronchitis, bronchiolitis, and bacterial pneumonia. Some viruses, such as herpes simplex, varicella, and adenovirus, may be associated with necrosis of bronchial and alveolar epithelium and acute inflammation. Characteristic viral cytopathic changes are described in Chapter 8.

Clinical Course. The clinical course of viral infections is extremely varied. Many cases masquerade as severe upper respiratory tract infections or as *chest colds*. Even individuals with well-developed atypical pneumonia have few localizing symptoms. Cough may be absent, and the major manifestations may consist only of fever, headache, muscle aches, and pains in the legs. The edema and exudation are both strategically located to cause mismatching of ventilation and blood flow and thus evoke symptoms out of proportion to the scanty physical findings.

Viral infections are usually mild and resolve spontaneously without any lasting sequelae. However, interstitial viral pneumonias may assume epidemic proportions, and in such instances even a low rate of complications can lead to significant morbidity and mortality, as is typically true of influenza epidemics.

Health Care-Associated Pneumonia

Health-care associated pneumonia was recently described as a distinct clinical entity associated with significant risk factors. These are: hospitalization of at least 2 days within the recent past; presentation from a nursing home or long-term care facility; attending a hospital or hemodialysis clinic; and recent intravenous antibiotic therapy, chemotherapy or wound care. The most common organisms isolated are methicillin-resistant *Staphylococcus aureus* and *P. aeruginosa*. These patients have a higher mortality than those with community-acquired pneumonia.

Hospital-Acquired Pneumonia

Hospital-acquired pneumonias are defined as pulmonary infections acquired in the course of a hospital stay. They are common in patients with severe underlying disease, immunosuppression, prolonged antibiotic therapy, or invasive access devices such as intravascular catheters. Patients on mechanical ventilation are at particularly high risk. Superimposed on an underlying disease (that caused hospitalization), hospital-acquired infections are serious and often life-threatening complications. Gram-positive cocci (mainly *S. aureus* and *S. pneumoniae*) and gram-negative rods (Enterobacteriaceae and *Pseudomonas* species) are the most common isolates. There are similar organisms isolated in ventilator associated pneumonia but gram-negative bacilli are more common.

KEY CONCEPTS

Acute Pneumonia

- *S. pneumoniae* (the pneumococcus) is the most common cause of community-acquired acute pneumonia; the distribution of inflammation is usually lobar.

- Lobar pneumonias evolve through four stages: congestion, red hepatization, gray hepatization, and resolution.
- Other common causes of acute pneumonias in the community include *H. influenzae* and *M. catarrhalis* (both associated with acute exacerbations of COPD), *S. aureus* (usually secondary to viral respiratory infections), *K. pneumoniae* (observed in patients who are chronic alcoholics), *P. aeruginosa* (seen in persons with cystic fibrosis, in burn victims, and in patients with neutropenia), and *L. pneumophila*, seen particularly in organ transplant recipients.
- The term *atypical organisms* is used for *Mycoplasma pneumoniae*, *Chlamydomphila pneumoniae*, *Coxiella burnetii*, and viruses (influenza viruses types A and B, human metapneumovirus) since they are not detectable on Gram stain nor do they grow on the standard bacteriologic culture media.
- Bacterial pneumonias are characterized by predominantly intra-alveolar neutrophilic inflammation while viral pneumonia shows interstitial lymphocytic inflammation. Characteristic viral inclusions may be seen.
- Lung abscess is often caused by anaerobic organisms or by mixed infections and frequently occur in debilitated individuals following aspiration of oral flora.

Aspiration Pneumonia

Aspiration pneumonia occurs in markedly debilitated patients or those who aspirate gastric contents either while unconscious (e.g., after a stroke) or during repeated vomiting. These patients have abnormal gag and swallowing reflexes that predispose to aspiration. The resultant pneumonia is partly chemical due to the irritating effects of gastric acid, and partly bacterial (from the oral flora). Typically, more than one organism is recovered on culture, aerobes being more common than anaerobes. This type of pneumonia is often necrotizing, pursues a fulminant clinical course, and is a frequent cause of death. In those who survive, lung abscess is a common complication.

Microaspiration, in contrast, occurs frequently in almost all people, especially those with gastroesophageal reflux disease. It usually results in small, poorly formed nonnecrotizing granulomas with multinucleated foreign body giant cell reaction. It is usually inconsequential, but may exacerbate other preexisting lung diseases such as asthma, interstitial fibrosis, and lung rejection.

Lung Abscess

The term *pulmonary abscess* describes a local suppurative process that produces necrosis of lung tissue. Oropharyngeal surgical or dental procedures, sinobronchial infections, and bronchiectasis play important roles in their development.

Etiology and Pathogenesis. Although under appropriate circumstances any pathogen can produce an abscess, the commonly isolated organisms include aerobic and anaerobic streptococci, *S. aureus*, and a host of gram-negative organisms. Mixed infections often occur because of the important causal role played by inhalation of foreign material. *Anaerobic organisms* normally found in the oral cavity,

including members of the *Bacteroides*, *Fusobacterium*, and *Peptococcus* species, are the exclusive isolates in about 60% of cases. The causative organisms are introduced by the following mechanisms:

- **Aspiration of infective material** (the most frequent cause). This is particularly common in acute alcoholism, coma, anesthesia, sinusitis, gingivodental sepsis, and debilitation in which the cough reflexes are depressed. Aspiration first causes pneumonia which progresses to tissue necrosis and formation of lung abscess.
- **Antecedent primary lung infection.** Postpneumonic abscess formations are usually associated with *S. aureus*, *K. pneumoniae*, and type 3 pneumococcus. Posttransplant or otherwise immunosuppressed individuals are at special risk.
- **Septic embolism.** Infected emboli from thrombophlebitis in any portion of the systemic venous circulation or from the vegetations of infective bacterial endocarditis on the right side of the heart are trapped in the lung.
- **Neoplasia.** Secondary infection is particularly common in the bronchopulmonary segment obstructed by a primary or secondary malignancy (*postobstructive pneumonia*).
- **Miscellaneous.** Direct traumatic penetrations of the lungs; spread of infections from a neighboring organ, such as suppuration in the esophagus, spine, subphrenic space, or pleural cavity; and hematogenous seeding of the lung by pyogenic organisms all may lead to lung abscess formation.

When all these causes are excluded, there are still cases in which no discernible basis for the abscess formation can be identified. These are referred to as *primary cryptogenic lung abscesses*.

MORPHOLOGY

Abscesses vary in diameter from a few millimeters to large cavities of 5 to 6 cm (Fig. 15-36). They may affect any part of the lung and may be single or multiple. Pulmonary abscesses due to aspiration are more common on the right (because of the

Figure 15-36 Cut surface of lung showing two abscesses. (Courtesy Dr. M. Kamran Mirza, University of Chicago, Chicago, Ill.)

more vertical right main bronchus) and are most often single. Abscesses that develop in the course of pneumonia or bronchiectasis are usually multiple, basal, and diffusely scattered. Septic emboli and pyemic abscesses are multiple and may affect any region of the lungs.

The **cardinal histologic change in all abscesses is suppurative destruction of the lung parenchyma within the central area of cavitation.** The abscess cavity may be filled with suppurative debris or, if there is communication with an air passage, may be partially drained to create an air-containing cavity. Superimposed saprophytic infections are prone to develop within the necrotic debris. Continued infection leads to large, poorly demarcated, fetid, green-black, multilocular cavities designated gangrene of the lung. In chronic cases considerable fibroblastic proliferation produces a fibrous wall.

Clinical Course. The manifestations of pulmonary abscesses are much like those of bronchiectasis and are characterized principally by cough, fever, and copious amounts of foul-smelling purulent or sanguineous sputum. Fever, chest pain, and weight loss are common. Clubbing of the fingers and toes may appear within a few weeks after the onset of an abscess. The diagnosis can be only suspected from the clinical findings and must be confirmed radiologically. Whenever an abscess is discovered in older individuals, it is important to rule out an underlying carcinoma, which is present in 10% to 15% of cases.

The course of abscesses is variable. With antimicrobial therapy, most resolve leaving behind a scar. Complications include extension of the infection into the pleural cavity, hemorrhage, the development of *brain abscesses* or *meningitis* from septic emboli, and (rarely) secondary amyloidosis (type AA).

Chronic Pneumonia

Chronic pneumonia is most often a localized lesion in the immunocompetent patient, with or without regional lymph node involvement. Typically, the inflammatory reaction is granulomatous, and is caused by bacteria (e.g., *M. tuberculosis*) or fungi (e.g., *Histoplasma capsulatum*). Tuberculosis of the lung and other organs was described in Chapter 8. Chronic pneumonias caused by fungi are discussed here.

Histoplasmosis

Histoplasma capsulatum infection is acquired by inhalation of dust particles from soil contaminated with bird or bat droppings that contain small spores (microconidia), the infectious form of the fungus. It is endemic along the Ohio and Mississippi rivers and the Caribbean. It is also found in Mexico, Central and South America, parts of eastern and southern Europe, Africa, eastern Asia and Australia. Like *M. tuberculosis*, *H. capsulatum* is an intracellular pathogen that is found mainly in phagocytes. The clinical presentations and morphologic lesions of histoplasmosis also strikingly resemble those of tuberculosis, including (1) a self-limited and often latent primary pulmonary involvement, which may result in coin lesions on chest radiography; (2) chronic, progressive, secondary

lung disease, which is localized to the lung apices and causes cough, fever, and night sweats; (3) spread to extrapulmonary sites, including mediastinum, adrenals, liver, or meninges; and (4) widely disseminated disease in immunocompromised patients. Histoplasmosis can occur in immunocompetent individuals but as expected it is more severe in those with depressed cell mediated immunity.

The pathogenesis of histoplasmosis is incompletely understood. It is known that macrophages are the major target of infection. *H. capsulatum* may be internalized into macrophages after opsonization with antibody. *Histoplasma* yeasts can multiply within the phagosome, and lyse the host cells. *Histoplasma* infections are controlled by helper T cells that recognize fungal cell wall antigens and heat-shock proteins and subsequently secrete IFN- γ , which activates macrophages to kill intracellular yeasts. In addition, *Histoplasma* induces macrophages to secrete TNF, which recruits and stimulates other macrophages to kill *Histoplasma*.

MORPHOLOGY

In the lungs of otherwise healthy adults, *Histoplasma* infections produce **granulomas**, which usually undergo caseation necrosis and coalesce to produce large areas of consolidation, but may also liquefy to form cavities (particularly in patients with COPD). With spontaneous resolution or effective treatment, these lesions undergo fibrosis and concentric calcification (tree-bark appearance) (Fig. 15-37A). Histologic differentiation from tuberculosis, sarcoidosis, and coccidioidomycosis requires identification of the 3- to 5- μ m thin-walled yeast forms, which may persist in tissues for years.

In **fulminant disseminated histoplasmosis**, which occurs in immunosuppressed individuals, granulomas do not form; instead, there are focal accumulations of mononuclear phagocytes filled with fungal yeasts throughout the body (Fig. 15-37B).

The diagnosis of histoplasmosis is established by culture or identification of the fungus in tissue lesions. In addition, serologic tests for antibodies and antigen are also available. Antigen detection in body fluids is most useful in the early stages, because antibodies are formed 2 to 6 weeks after infection.

Blastomycosis

Blastomyces dermatitidis is a soil-inhabiting dimorphic fungus. It causes disease in the central and southeastern United States; infection also occurs in Canada, Mexico, the Middle East, Africa, and India. There are three clinical forms: *pulmonary blastomycosis*, *disseminated blastomycosis*, and a rare *primary cutaneous form* that results from direct inoculation of organisms into the skin. Pulmonary blastomycosis most often presents as an abrupt illness with productive cough, headache, chest pain, weight loss, fever, abdominal pain, night sweats, chills, and anorexia. Chest radiographs reveal lobar consolidation, multilobar infiltrates, perihilar infiltrates, multiple nodules, or miliary infiltrates. The upper lobes are most frequently involved. The pneumonia most often resolves spontaneously, but it may persist, or progress to a chronic lesion.

Figure 15-37 Histoplasmosis. **A**, Laminated *Histoplasma* granuloma of the lung. **B**, *Histoplasma capsulatum* yeast forms fill phagocytes in the lung of a patient with disseminated histoplasmosis, inset shows high power of pear-shaped thin-based budding yeasts (silver stain).

MORPHOLOGY

In the normal host, the lung lesions of blastomycosis are suppurative granulomas. Macrophages have a limited ability to ingest and kill *B. dermatitidis*, and the persistence of the yeast cells leads to continued recruitment of neutrophils. In tissue, *B. dermatitidis* is a round, 5- to 15- μm yeast cell that divides by broad-based budding. It has a thick, double-contoured cell wall, and visible nuclei (Fig. 15-38). Involvement of the skin and larynx is associated with marked epithelial hyperplasia, which may be mistaken for squamous cell carcinoma.

Coccidioidomycosis

Almost everyone who inhales the spores of *Coccidioides immitis* becomes infected and develops a delayed-type hypersensitivity reaction to the fungus. Indeed, more than 80% of people in endemic areas of the southwestern and western United States and in Mexico have a positive skin test reaction. One reason for the infectivity of *C. immitis* is that infective arthroconidia, when ingested by alveolar macrophages, block fusion of the phagosome and lysosome and so resist intracellular killing. As is the case with *Histoplasma*, most primary infections with *C. immitis* are

asymptomatic, but 10% of infected people develop lung lesions, fever, cough, and pleuritic pains, accompanied by erythema nodosum or erythema multiforme (the San Joaquin Valley fever complex). Less than 1% of people develop disseminated *C. immitis* infection, which frequently involves the skin and meninges. Certain ethnic groups (e.g., Filipinos and African Americans) and the immunosuppressed are at particularly high risk for disseminated disease.

MORPHOLOGY

The primary and secondary lung lesions of *C. immitis* are similar to the granulomatous lesions of *Histoplasma*. Within macrophages or giant cells, *C. immitis* is present as thick-walled, nonbudding spherules 20 to 60 μm in diameter, often filled with small endospores. A pyogenic reaction is superimposed when the spherules rupture to release the endospores (Fig. 15-39). Rare progressive *C. immitis* disease involves the lungs, meninges, skin, bones, adrenals, lymph nodes, spleen, or liver. At all these sites, the inflammatory response may be purely granulomatous, pyogenic, or mixed. Purulent lesions dominate in patients with diminished resistance and with widespread dissemination.

Figure 15-38 Blastomycosis. **A**, Rounded budding yeasts, larger than neutrophils, are present. Note the characteristic thick wall and nuclei (not seen in other fungi). **B**, Silver stain.

Figure 15-39 Coccidioidomycosis. Intact and ruptured spherules are seen.

Pneumonia in the Immunocompromised Host

The appearance of a pulmonary infiltrate, with or without signs of infection (e.g., fever), is one of the most common and serious complications in patients whose immune defenses are suppressed by disease, immunosuppressive therapy for organ or hematopoietic stem cell transplants, chemotherapy for tumors, or irradiation. A wide variety of so-called opportunistic infectious agents, many of which rarely cause infection in normal hosts, can cause these pneumonias, and often more than one agent is involved. Mortality from these opportunistic infections is high. [Table 15-8](#) lists some of the opportunistic agents according to their prevalence and whether they cause local or diffuse pulmonary infiltrates. The differential diagnosis of such infiltrates includes drug reactions and involvement of the lung by tumor. The specific infections are discussed in [Chapter 8](#). Of these, the ones that commonly involve the lung can be classified according to the etiologic agent: (1) bacteria (*P. aeruginosa*, *Mycobacterium* species, *L. pneumophila*, and *Listeria monocytogenes*), (2) viruses (cytomegalovirus [CMV] and herpesvirus), and (3) fungi (*P. jiroveci*, *Candida* species, *Aspergillus* species, the Phycomyces, and *Cryptococcus neoformans*).

Table 15-8 Causes of Pulmonary Infiltrates in Immunocompromised Hosts

Diffuse Infiltrates	Focal Infiltrates
Common	
Cytomegalovirus <i>Pneumocystis jiroveci</i> Drug reaction	Gram-negative bacterial infections <i>Staphylococcus aureus</i> <i>Aspergillus</i> <i>Candida</i> Malignancy
Uncommon	
Bacterial pneumonia <i>Aspergillus</i> <i>Cryptococcus</i> Malignancy	<i>Cryptococcus</i> <i>Mucor</i> <i>Pneumocystis jiroveci</i> <i>Legionella pneumophila</i>

Pulmonary Disease in Human Immunodeficiency Virus Infection

Pulmonary disease accounts for 30% to 40% of hospitalizations in HIV-infected individuals. Although the use of potent antiretroviral agents and effective chemoprophylaxis has markedly altered the incidence and outcome of pulmonary disease in HIV-infected persons, the plethora of infectious agents and other pulmonary lesions make diagnosis and treatment a distinct challenge. Some of the individual microbial agents afflicting HIV-infected individuals have already been discussed; this section focuses only on the general principles of HIV-associated pulmonary disease.

- Despite the emphasis on opportunistic infections, it must be remembered that bacterial lower respiratory tract infections caused by the “usual” pathogens is one among the most serious pulmonary disorders in HIV infection. The implicated organisms include *S. pneumoniae*, *S. aureus*, *H. influenzae*, and gram-negative rods. Bacterial pneumonias in HIV-infected persons are more common, more severe, and more often associated with bacteremia than in those without HIV infection.
- Not all pulmonary infiltrates in HIV-infected individuals are infectious in etiology. A host of noninfectious diseases, including Kaposi sarcoma ([Chapters 6 and 11](#)), non-Hodgkin lymphoma ([Chapter 13](#)), and lung cancer, occur with increased frequency and must be excluded.
- The CD4+ T-cell count determines the risk of infection with specific organisms. As a rule of thumb, bacterial and tubercular infections are more likely at higher CD4+ counts (>200 cells/mm³). *Pneumocystis pneumonia* usually strikes at CD4+ counts less than 200 cells/mm³, while cytomegalovirus, fungal, and *Mycobacterium avium* complex infections are uncommon until the very late stages of immunosuppression (CD4+ counts less than 50 cells/mm³).

Finally, pulmonary disease in HIV-infected persons may result from more than one cause, and even common pathogens may present with atypical manifestations. Therefore, the diagnostic work-up of these patients may be more extensive (and expensive) than would be necessary in an immunocompetent individual.

Lung Transplantation

Indications for transplantation may include almost all non-neoplastic terminal lung diseases, provided that the patient does not have any other serious disease, which would preclude lifelong immunosuppressive therapy. The most common indications are end-stage emphysema, idiopathic pulmonary fibrosis, cystic fibrosis, and idiopathic/familial pulmonary arterial hypertension. While bilateral lung and heart-lung transplants are possible, in many cases a single-lung transplant is performed, offering sufficient improvement in pulmonary function for two recipients from a single (and all too scarce) donor. When bilateral chronic infection is present (e.g., cystic fibrosis, bronchiectasis),

both lungs of the recipient must be replaced to remove the reservoir of infection.

With improving surgical and organ preservation techniques, postoperative complications (e.g., anastomotic dehiscence, vascular thrombosis, primary graft dysfunction) are fortunately becoming rare. The transplanted lung is subject to two major complications: infection and rejection.

- **Pulmonary infections** in lung transplant patients are essentially those of any immunocompromised host, discussed earlier. In the early posttransplant period (the first few weeks), bacterial infections are most common. With ganciclovir prophylaxis and matching of donor-recipient CMV status, CMV pneumonia occurs less frequently and is less severe, although some resistant strains are emerging. Most infections occur in the third to twelfth month after transplantation. *Pneumocystis jiroveci* pneumonia is rare, since almost all patients receive adequate prophylaxis, usually with Bactrim (trimethoprim-sulfamethoxazole). Fungal infections are mostly due to *Aspergillus* and *Candida* species, and they involve the bronchial anastomotic site and/or the lung.
- **Acute rejection** of the lung occurs to some degree in all patients despite routine immunosuppression. It most often appears several weeks to months after surgery but also may present years later or whenever immunosuppression is decreased. Patients present with fever, dyspnea, cough, and radiologic infiltrates. Since these are similar to the picture of infections, diagnosis often relies on transbronchial biopsy.
- **Chronic rejection** is a significant problem in at least half of all patients by 3 to 5 years posttransplant. It is manifested by cough, dyspnea, and an irreversible decrease in lung function tests due to pulmonary fibrosis.

MORPHOLOGY

The morphologic features of acute rejection are primarily those of inflammatory infiltrates (lymphocytes, plasma cells, and few neutrophils and eosinophils), either around small vessels, in the submucosa of airways, or both. The major morphologic correlate of chronic rejection is **bronchiolitis obliterans**, the partial or complete occlusion of small airways by fibrosis, with or without active inflammation (Fig. 15-40). Bronchiolitis obliterans is patchy and therefore difficult to diagnose via transbronchial biopsy. Bronchiectasis and pulmonary fibrosis may develop in long-standing cases.

Acute cellular airway rejection (the presumed forerunner of later, fibrous obliteration of these airways) is generally responsive to therapy, but the treatment of established bronchiolitis obliterans has been disappointing. Its progress may be slowed or even halted for some time, but it cannot be reversed. Infrequent complications of lung transplantation include accelerated pulmonary arteriosclerosis in the graft and EBV-associated B cell lymphoma. With continuing improvement in surgical, immunosuppressive, and antimicrobial therapies, the short-term outcome of lung transplantation has improved considerably, although it is still not as good as that for renal or cardiac

Figure 15-40 Chronic rejection of lung allograft associated with bronchiolitis obliterans. An adjacent pulmonary artery is normal. (Courtesy of Dr. Thomas Krausz, Department of Pathology, The University of Chicago, Pritzker School of Medicine, Chicago, IL.)

transplantation. One-, five-, and ten-year survival rates are 79%, 53%, and 30%, respectively.

Tumors

A variety of benign and malignant tumors may arise in the lung, but 90% to 95% are carcinomas, about 5% are bronchial carcinoids, and 2% to 5% are mesenchymal and other miscellaneous neoplasms.

Carcinomas

Lung cancer is currently the most frequently diagnosed major cancer in the world (estimated 1.6 million new cases in 2008) and **the most common cause of cancer mortality worldwide** (1,380,000 deaths in 2008). This is largely due to the carcinogenic effects of cigarette smoke. Over the coming decades, changes in smoking habits will greatly influence lung cancer incidence and mortality as well as the prevalence of various histologic types of lung cancer.

The number of new cases of lung cancer occurring in 2012 in the United States was estimated to be 226,160 (note that in 1950 it was 18,000), accounting for about 14% of cancer diagnoses and 160,340 deaths, roughly 28% of all cancer-related deaths. As can be gathered from the sobering fact that the yearly mortality almost matches the yearly incidence, the overall outlook for affected patients remains bleak. Since the early 1990s, lung cancer incidence and mortality rates have been decreasing in men, due to the decreased smoking rates over the past 35 years. However, decreases in smoking patterns among women lag behind those of men. Since 1987 more women have died each year of lung cancer than of breast cancer, which for more than 40 years had been the major cause of cancer death in women. Cancer of the lung occurs most often between ages 40 and 70 years, with a peak incidence in the 50s or 60s. Only 2% of all cases appear before the age of 40.

Etiology and Pathogenesis. Most (but not all) lung cancers are associated with a well-known carcinogen—cigarette smoke. In addition there are other genetic and environmental factors which we will discuss after the role of

tobacco smoking. The molecular changes to vary among the histologic subtypes, which will be described later. Suffice it to say that lung cancers can be broadly classified into small cell and non-small cell types and the latter group is made up of squamous cell and adenocarcinomas.

Tobacco Smoking. About 80% of lung cancers occur in active smokers or those who stopped recently. There is a nearly linear correlation between the frequency of lung cancer and pack-years of cigarette smoking. The increased risk becomes 60 times greater among habitual heavy smokers (two packs a day for 20 years) compared with nonsmokers. However, since lung cancer develops in only 11% of heavy smokers, there are other factors that predispose individuals to this deadly disease. For reasons not entirely clear, women have a higher susceptibility to carcinogens in tobacco than men. Although cessation of smoking decreases the risk for lung cancer over time, it may never return to baseline levels. In fact, genetic changes that predate lung cancer can persist for many years in the bronchial epithelium of former smokers. Passive smoking (proximity to cigarette smokers) increases the risk for lung cancer development to approximately twice that of nonsmokers. The smoking of pipes and cigars also increases the risk, but only modestly.

Although the duration and intensity of smoking are well correlated with cancer risk, not all persons exposed to tobacco smoke develop cancer. Some of this may be a matter of chance, but it is also likely that the mutagenic effect of carcinogens in smoke is modified by genetic variants. Recall that many chemicals (procarcinogens) are converted into carcinogens via activation by the highly polymorphic P-450 monooxygenase enzyme system (Chapter 9). Specific P-450 polymorphisms have an increased capacity to activate procarcinogens in cigarette smoke, and smokers with these genetic variants appear to incur a greater risk of lung cancer. Similarly, individuals whose peripheral blood lymphocytes show more numerous chromosomal breakages after exposure to tobacco-related carcinogens (mutagen sensitivity genotype) have a greater than 10-fold higher risk of developing lung cancer as compared with controls, presumably because of genetic variation in genes involved in DNA repair.

The histologic changes that correlate with steps along the path to neoplastic transformation are best documented for squamous cell carcinomas and are described in more detail later. There is a linear correlation between the intensity of exposure to cigarette smoke and the appearance of ever more worrisome epithelial changes. These begin with rather innocuous-appearing basal cell hyperplasia and squamous metaplasia and progress to squamous dysplasia and carcinoma in situ, the last stage before progression to invasive cancer.

Unfortunately, the carcinogenic effects of tobacco smoke extend to those who live and work with smokers. *Secondhand smoke*, or environmental tobacco smoke, contains numerous human carcinogens for which there is no safe level of exposure. It is estimated that each year about 3000 nonsmoking adults die of lung cancer as a result of breathing secondhand smoke. Cigar and pipe smoking also increase risk, although much less than smoking cigarettes. Smokeless tobacco is not a safe substitute for smoking cigarettes or cigars, as these products spare the lung but cause oral cancers and can lead to nicotine addiction.

Industrial Hazards. Certain industrial exposures, such as asbestos, arsenic, chromium, uranium, nickel, vinyl chloride and mustard gas, increase the risk of developing lung cancer. High-dose ionizing radiation is carcinogenic. There was an increased incidence of lung cancer among survivors of the Hiroshima and Nagasaki atomic bomb blasts, as well as in workers heavily involved in clean-up after the Chernobyl disaster. Uranium is weakly radioactive, but lung cancer rates among nonsmoking uranium miners are four times higher than those in the general population, and among smoking miners they are about 10 times higher. Asbestos exposure also increases the risk for lung cancer development. The latent period before the development of lung cancer is 10 to 30 years. Lung cancer is the most frequent malignancy in individuals exposed to asbestos, particularly when coupled with smoking. Asbestos workers who do not smoke have a five-fold greater risk of developing lung cancer than do nonsmoking control subjects, and those who smoke have a 55-fold greater risk.

Air Pollution. It is uncertain whether air pollution, by itself, increases the risk of lung cancer, but it likely adds to the risk in those who smoke or are exposed to secondhand smoke. It may do so through several different mechanisms. Chronic exposure to air particulates in smog may cause lung irritation, inflammation and repair, and you will recall that chronic inflammation and repair increases the risk of a variety of cancers (Chapter 7). A specific form of air pollution that may contribute to an increased risk of lung cancer is radon gas. Radon is a ubiquitous radioactive gas that has been linked epidemiologically to increased lung cancer in uranium miners, particularly those who smoke. This has generated concern that low-level exposure (e.g., in well-insulated homes in areas with naturally high levels of radon in soil) may also increase the incidence of lung cancers, but this point remains unsettled.

Molecular Genetics. As with other cancers (Chapter 7), smoking-related carcinomas of the lung arise by a stepwise accumulation of oncogenic “driver” mutations that result in the neoplastic transformation of pulmonary epithelial cells. Some of the genetic changes associated with cancers can be found in the “benign” bronchial epithelium of smokers without lung cancers, suggesting that large areas of the respiratory mucosa are mutagenized by exposure to carcinogens in tobacco smoke (“field effect”). On this fertile soil, those few cells that accumulate a sufficient panoply of complementary driver mutations to acquire all of the hallmarks of cancer (Chapter 7) develop into invasive carcinomas.

Lung carcinomas fall into several major histologic subgroups (described later), each with distinctive molecular features, as follows:

- *Squamous cell carcinoma* is highly associated with exposure to tobacco smoke and harbors diverse genetic aberrations, many of which are chromosome deletions involving tumor suppressor loci. These losses, especially those involving 3p, 9p (site of the *CDKN2A* gene), and 17p (site of the *TP53* gene) are early events in tumor evolution, being detected at an appreciable frequency in the histologically normal respiratory mucosal cells of smokers. Squamous cell carcinomas show the highest

frequency of *TP53* mutations of all histologic types of lung carcinoma. p53 protein overexpression (as seen by immunohistochemical staining), a marker of *TP53* mutations, is also an early event, being reported in 10% to 50% of squamous dysplasias and 60% to 90% of squamous cell carcinoma in situ. Loss of expression of the retinoblastoma (RB) tumor suppressor is identified by immunohistochemistry in 15% of squamous cell carcinomas. The cyclin-dependent kinase inhibitor gene *CDKN2A* is inactivated and its protein product, p16, is lost in 65% of tumors. It has recently been recognized that many squamous cell carcinomas have amplification of *FGFR1*, a gene encoding the fibroblast growth factor receptor tyrosine kinase.

- *Small cell carcinoma* shows the strongest association with smoking and despite its divergent histologic features shares many molecular features with squamous cell carcinoma. This includes frequent loss-of-function aberrations involving *TP53* (75% to 90% of tumors), *RB* (close to 100% of tumors), and chromosome 3p deletions. Also common is amplification of genes of the *MYC* family.
- *Adenocarcinoma* is marked by oncogenic gain-of-function mutations involving components of growth factor receptor signaling pathways. All are found in a minority of tumors, but together they make up a substantial fraction of tumors as a whole. These include gain-of-function mutations in multiple genes encoding receptor tyrosine kinases, including *EGFR*, *ALK*, *ROS*, *MET*, and *RET*, which are all also mutated in other forms of cancer. Tumors without tyrosine kinase gene mutations often have mutations in the *KRAS* gene, which you will remember lies downstream of receptor tyrosine kinases in growth factor signaling pathways.

Lung Cancer in Never Smokers. The WHO estimates that 25% of lung cancer worldwide occurs in never smokers. This percentage is probably closer to 10% to 15% in Western countries. These cancers occur more commonly in women and most are adenocarcinomas. Cancers in nonsmokers are more likely to have *EGFR* mutations, and almost

Figure 15-41 Atypical adenomatous hyperplasia. The epithelium is cuboidal and there is mild interstitial fibrosis.

Table 15-9 Histologic Classification of Malignant Epithelial Lung Tumors

Tumor Classification
Squamous cell carcinoma
Papillary, clear cell, small cell, basaloid
Small-cell carcinoma
Combined small-cell carcinoma
Adenocarcinoma
Minimally invasive adenocarcinoma (nonmucinous, mucinous)
Lepidic, acinar; papillary, solid (according to predominant pattern)
Mucinous adenocarcinoma
Large-cell carcinoma
Large-cell neuroendocrine carcinoma
Adenosquamous carcinoma
Carcinomas with pleomorphic, sarcomatoid, or sarcomatous elements
Carcinoid tumor
Typical, atypical
Carcinomas of salivary gland type

never have *KRAS* mutations; *TP53* mutations are not uncommon, but occur less frequently than in smoking-related cancers.

Precursor (Preinvasive) Lesions. Four types of morphologic precursor epithelial lesions are recognized: (1) squamous dysplasia and carcinoma in situ, (2) atypical adenomatous hyperplasia, (3) adenocarcinoma in situ, and (4) diffuse idiopathic pulmonary neuroendocrine cell hyperplasia. It should be remembered that the term *precursor* does not imply that progression to cancer is inevitable. Currently it is not possible to distinguish between precursor lesions that progress and those that remain localized or regress.

Classification. Tumor classification is important for consistency in patient treatment and because it provides a basis for epidemiologic and biologic studies. The most recent classification is given in Table 15-9. Several histologic variants of each type of lung cancer are described; however, their clinical significance is still undetermined, except as mentioned herein. The relative proportions of the major categories are:

Figure 15-42 Adenocarcinoma in situ, mucinous subtype. Characteristic growth along pre-existing alveolar septa is evident, without invasion.

- Adenocarcinoma (38%)
- Squamous cell carcinoma (20%)
- Small cell carcinoma (14%)
- Large cell carcinoma (3%)
- Other (25%)

There may be mixtures of histologic patterns, even in the same cancer. Thus, combinations of squamous cell carcinoma and adenocarcinoma or small-cell and squamous cell carcinoma occur in about 10% of patients.

The incidence of adenocarcinoma has increased significantly in the last 2 decades. Adenocarcinoma is now the most common form of lung cancer in women and, in many studies, men as well. The basis for this change is unclear. A possible factor is the increase in women smokers, but this only highlights our lack of knowledge about why women tend to develop more adenocarcinomas. One possibility is that changes in cigarette type (filter tips, lower tar and nicotine) have caused smokers to inhale more deeply and thereby expose more peripheral airways and cells (with a predilection to adenocarcinoma) to carcinogens.

MORPHOLOGY

Lung carcinomas may arise in the peripheral lung (more often adenocarcinomas) or in the central/hilar region (more often squamous cell carcinomas), sometimes in association with recognizable precursor lesions.

Atypical adenomatous hyperplasia is a small lesion (≤ 5 mm) characterized by dysplastic pneumocytes lining alveolar walls that are mildly fibrotic (Fig. 15-41). It can be single or multiple and can be in the lung adjacent to invasive tumor or away from it.

Adenocarcinoma in situ (formerly called bronchioloalveolar carcinoma) is a lesion that is less than 3 cm and is composed entirely of dysplastic cells growing along preexisting alveolar septae. The cells have more dysplasia than atypical adenomatous hyperplasia and may or may not have intracellular mucin (mucinous and nonmucinous, respectively) (Fig. 15-42).

Adenocarcinoma is an invasive malignant epithelial tumor with glandular differentiation or mucin production by the tumor cells. Adenocarcinomas grow in various patterns, including acinar, lepidic, papillary, micropapillary, and solid with mucin formation. Compared with squamous cell cancers, the lesions are usually more peripherally located and tend to be smaller. They vary histologically from well-differentiated tumors with obvious glandular elements (Fig. 15-43A) to papillary lesions

Figure 15-43 Histologic variants of lung carcinoma. **A**, Gland-forming adenocarcinoma; *inset* shows thyroid transcription factor 1 (TTF-1) expression, as detected by immunohistochemistry. **B**, Well-differentiated squamous cell carcinoma showing keratinization (*arrow*). **C**, Small cell carcinoma. There are islands of small deeply basophilic cells and areas of necrosis. **D**, Large cell carcinoma. The tumor cells are pleomorphic and show no evidence of squamous or glandular differentiation.

Figure 15-44 Precursor lesions of squamous cell carcinomas. Some of the earliest (“mild”) changes in smoking-damaged respiratory epithelium include goblet cell hyperplasia (**A**), basal cell (or reserve cell) hyperplasia (**B**), and squamous metaplasia (**C**). More ominous changes include the appearance of squamous dysplasia (**D**), characterized by the presence of disordered squamous epithelium, with loss of nuclear polarity, nuclear hyperchromasia, pleomorphism, and mitotic figures. Squamous dysplasia may progress through the stages of mild, moderate, and severe dysplasia. Carcinoma-in-situ (CIS) (**E**), the stage immediately preceding invasive squamous carcinoma (**F**), by definition has not penetrated the basement membrane and has cytologic features similar to those in frank carcinoma. (**A-E**, Courtesy Dr. Adi Gazdar, Department of Pathology, University of Texas, Southwestern Medical School, Dallas. **F**, Reproduced with permission from Travis WD, et al [eds]: World Health Organization Histological Typing of Lung and Pleural Tumors. Heidelberg, Springer, 1999.)

resembling other papillary carcinomas to solid masses with only occasional mucin-producing glands and cells. The majority express thyroid transcription factor-1 (Fig 15-43A inset); first identified in the thyroid, this factor is required for normal lung development. At the periphery of the tumor there is often a lepidic pattern of spread, in which the tumor cells “crawl” along normal-appearing alveolar septae. Tumors (≤ 3 cm) with a small invasive component (≤ 5 mm) associated with scarring and a peripheral lepidic growth pattern are called **microinvasive adenocarcinoma**. These have a far better outcome than invasive carcinomas of the same size. **Mucinous adenocarcinomas** tend to spread aerogenously, forming satellite tumors. These may present as a solitary nodule or as multiple nodules, or an entire lobe may be consolidated by tumor, resembling lobar pneumonia and thus are less likely to be cured by surgery.

Squamous cell carcinoma is most commonly found in men and is strongly associated with smoking. Precursors lesions that give rise to invasive squamous cell carcinoma are well characterized. Squamous cell carcinomas are often antedated by **squamous metaplasia** or **dysplasia** in the bronchial epithelium, which then transforms to **carcinoma in situ**, a phase that may last for several years (Fig. 15-44). By this time, atypical cells may be identified in cytologic smears of sputum or in

bronchial lavage fluids or brushings (Fig. 15-45), although the lesion is asymptomatic and undetectable on radiographs. Eventually, an invasive squamous cell carcinoma appears. The tumor may then follow a variety of paths. It may grow exophytically into the bronchial lumen, producing an intraluminal mass. With further enlargement the bronchus becomes obstructed, leading to distal atelectasis and infection. The tumor may also penetrate the wall of the bronchus and infiltrate along the peribronchial tissue (Fig. 15-46) into the adjacent carina or mediastinum. In other instances, the tumor grows along a broad front to produce a cauliflower-like intraparenchymal mass that pushes lung substance ahead of it. As in almost all types of lung cancer, the neoplastic tissue is gray-white and firm to hard. Especially when the tumors are bulky, focal areas of hemorrhage or necrosis may appear to produce red or yellow-white mottling and softening. Sometimes these necrotic foci cavitate.

Histologically, squamous cell carcinoma is characterized by the presence of keratinization and/or intercellular bridges. Keratinization may take the form of squamous pearls or individual cells with markedly eosinophilic dense cytoplasm (Fig. 15-43B). These features are prominent in well-differentiated tumors, are easily seen but not extensive in moderately

Figure 15-45 Cytologic diagnosis of lung cancer. A sputum specimen shows an orange-staining, keratinized squamous carcinoma cell with a prominent hyperchromatic nucleus (*large arrow*). Note the size of the tumor cells compared with normal neutrophils (*small arrow*).

differentiated tumors, and are focally seen in poorly differentiated tumors. Mitotic activity is higher in poorly differentiated tumors. In the past, most squamous cell carcinomas were seen to arise centrally from the segmental or subsegmental bronchi. However, the incidence of squamous cell carcinoma of the peripheral lung is increasing. Squamous metaplasia, epithelial dysplasia, and foci of frank carcinoma in situ may be seen in bronchial epithelium adjacent to the tumor mass (Fig. 15-44).

Small cell carcinoma is a highly malignant tumor with a strong relationship to cigarette smoking; only about 1% occurs in nonsmokers. They may arise in major bronchi or in the periphery of the lung. There is no known preinvasive phase. They are the most aggressive of lung tumors, metastasizing widely and virtually always proving to be fatal.

Small cell carcinoma is comprised of relatively small cells with scant cytoplasm, ill-defined cell borders, finely granular nuclear chromatin (salt and pepper pattern), and absent or inconspicuous nucleoli (Fig. 15-43C). The cells are round, oval, or spindle-shaped, and nuclear molding is prominent. There is no absolute size for the tumor cells, but in general they are smaller than three

times the diameter of a small resting lymphocyte (a size of about 25 microns). The mitotic count is high. The cells grow in clusters that exhibit neither glandular nor squamous organization. Necrosis is common and often extensive. Basophilic staining of vascular walls due to encrustation by DNA from necrotic tumor cells (Azzopardi effect) is frequently present. All small cell carcinomas are high grade. Combined small cell carcinoma is a variant in which typical small cell carcinoma is mixed with non-small cell histologies, such as large cell neuroendocrine carcinoma and even spindled cell morphologies resembling sarcoma.

Electron microscopy shows dense-core neurosecretory granules, about 100 nm in diameter, in two thirds of cases. The occurrence of neurosecretory granules, the expression of neuroendocrine markers such as chromogranin, synaptophysin, and CD57, and the ability of some of these tumors to secrete hormones (e.g., parathormone-related protein, a cause of paraneoplastic hypercalcemia) suggest that this tumor originates from neuroendocrine progenitor cells, which are present in the lining bronchial epithelium. Among the various types of lung cancer, small cell carcinoma is the one that is most commonly associated with ectopic hormone production (discussed later). Immunohistochemistry demonstrates high levels of the anti-apoptotic protein BCL2 in 90% of tumors.

Large cell carcinoma is an undifferentiated malignant epithelial tumor that lacks the cytologic features of other forms of lung cancer. The cells typically have large nuclei, prominent nucleoli, and a moderate amount of cytoplasm (Fig. 15-43D). Large cell carcinoma is a diagnosis of exclusion since it expresses none of the markers associated with adenocarcinoma (TTF-1, napsin A) and squamous cell carcinoma (p63, p40) (Fig 15-43A inset). One histologic variant is large cell neuroendocrine carcinoma, which has molecular features similar to those that characterize small cell carcinoma, but is comprised of tumor cells of larger size.

Any type of lung carcinoma may extend on to the pleural surface and then within the pleural cavity or into the pericardium. Metastases to the bronchial, tracheal, and mediastinal nodes can be found in most cases. The frequency of nodal involvement varies slightly with the histologic pattern but averages greater than 50%.

Distant spread of lung carcinoma occurs through both lymphatic and hematogenous pathways. These tumors often spread early throughout the body except for squamous cell carcinoma, which metastasizes outside the thorax late. Metastasis may be the first manifestation of an underlying occult pulmonary lesion. No organ or tissue is spared in the spread of these lesions, but the adrenals, for obscure reasons, are involved in more than half the cases. The liver (30% to 50%), brain (20%), and bone (20%) are additional favored sites of metastases.

Combined Carcinoma. Approximately 10% of all lung carcinomas have a combined histology, including two or more of the aforementioned types.

Secondary Pathology. Lung carcinomas have local effects that may cause several pathologic changes in the lung distal to the point of bronchial involvement. Partial obstruction may cause marked **focal emphysema**; total obstruction may lead to **atelectasis**. The impaired drainage of the airways is a common cause for **severe suppurative or ulcerative bronchitis** or **bronchiectasis**. **Pulmonary abscesses** sometimes call attention to an otherwise silent carcinoma. Compression or invasion of the superior vena cava can cause venous

Figure 15-46 Lung carcinoma. The gray-white tumor infiltrates the lung parenchyma. Histologic sections identified this tumor as a squamous cell carcinoma.

congestion and edema of the head and arm, and, ultimately, circulatory compromise—the **superior vena cava syndrome**. Extension to the pericardial or pleural sacs may cause **pericarditis** (Chapter 11) or **pleuritis** with significant effusions.

Staging. A uniform TNM system for staging cancer according to its anatomic extent at the time of diagnosis is useful, particularly for comparing treatment results from different centers (Table 15-10).

Clinical Course. Lung cancer is one of the most insidious and aggressive neoplasms in the realm of oncology. In the usual case it is discovered in patients in their 50s or older whose symptoms are of several months' duration. The major presenting complaints are cough (75%), weight loss (40%), chest pain (40%), and dyspnea (20%). Some of the more common local manifestations of lung cancer and their pathologic bases are listed in Table 15-11. Not infrequently the tumor is discovered by its secondary spread during the course of investigation of an apparent primary or

Table 15-10 International Staging System for Lung Cancer

TNM Staging			
Tis	Carcinoma in Situ		
T1	Tumor ≤ 3 cm without pleural or mainstem bronchus involvement (T1a, <2 cm; T1b, 2-3 cm)		
T2	Tumor 3-7 cm or involvement of mainstem bronchus 2 cm from carina, visceral pleural involvement, or lobar atelectasis (T2a, 3-5 cm; T2b, 5-7 cm)		
T3	Tumor >7 cm or one with involvement of parietal pleura, chest wall (including superior sulcus tumors), diaphragm, phrenic nerve, mediastinal pleura, parietal pericardium, mainstem bronchus < 2 cm from carina but without involvement of carina, or entire lung atelectasis, or separate tumor nodules in the same lobe		
T4	Any tumor with invasion of mediastinum, heart, great vessels, trachea, recurrent laryngeal nerve, esophagus, vertebral body, or carina or separate tumor nodules in a different ipsilateral lobe		
N0	No metastasis to regional lymph nodes		
N1	Ipsilateral hilar or peribronchial nodal involvement		
N2	Metastasis to ipsilateral mediastinal or subcarinal lymph nodes		
N3	Metastasis to contralateral mediastinal or hilar lymph nodes, ipsilateral or contralateral scalene, or supraclavicular lymph nodes		
M0	No distant metastasis		
M1	Distant metastasis (M1a, separate tumor nodule in contralateral lobe or pleural nodules or malignant pleural effusion; M1b, distant metastasis)		
Stage Grouping			
Stage IA	T1a, T1b	N0	M0
Stage IB	T2a	N0	M0
Stage IIA	T2b	N0	M0
	T1a, T1b, T2a	N1	M0
Stage IIB	T2b	N1	M0
	T3	N0	M0
Stage IIIA	T1, T2	N2	M0
	T3	N1, N2	M0
	T4	N0, N1	M0
Stage IIIB	Any T	N3	M0
	T4	N2, N3	M0
Stage IV	Any T	Any N	M1a, M1b

Table 15-11 Local Effects of Lung Tumor Spread

Clinical Feature	Pathologic Basis
Cough (50%-75%)	Involvement of central airways
Hemoptysis (25%-50%)	Hemorrhage from tumor in airway
Chest pain (20%)	Extension of tumor into mediastinum, pleura or chest wall
Pneumonia, abscess, lobar collapse	Airway obstruction by tumor
Lipoid pneumonia	Tumor obstruction; accumulation of cellular lipid in foamy macrophages
Pleural effusion	Tumor spread into pleura
Hoarseness	Recurrent laryngeal nerve invasion
Dysphagia	Esophageal invasion
Diaphragm paralysis	Phrenic nerve invasion
Rib destruction	Chest wall invasion
SVC syndrome	SVC compression by tumor
Horner syndrome	Sympathetic ganglia invasion
Pericarditis, tamponade	Pericardial involvement
SVC, Superior vena cava.	

metastatic neoplasm elsewhere. Symptoms of metastases depend on the site, for example, back pain in bone metastases, headache, hemiparesis, cranial nerve damage, and seizures in brain metastases.

Despite some earlier studies that did not show any benefit, the first large-scale early detection trial produced a 20% reduction in lung cancer-related mortality by screening high-risk individuals with low-dose computed tomography. However, the outlook is still poor for most patients with lung carcinoma. Even with many incremental improvements in thoracic surgery, radiation therapy, and chemotherapy, the overall 5-year survival rate is only 16%. The 5-year survival rate is 52% for cases detected when the disease is still localized, 22% when there is regional metastasis and only 4% with distant metastases. In general, adenocarcinoma and squamous cell carcinoma tend to remain localized longer and have a slightly better prognosis than do the undifferentiated cancers, which are usually advanced by the time they are discovered.

Targeted treatment of patients with adenocarcinoma and activating mutations in EGFR (present in about 15% of all patients) or in other tyrosine kinases with specific inhibitors of the mutated kinases prolongs survival. Many tumors that recur carry new mutations that generate resistance to these inhibitors, proving that these drugs are “hitting” their target. In contrast, activating KRAS mutations (present in 30%) appear to be associated with a worse prognosis, regardless of treatment, in an already grim disease. New therapeutic targets are clearly needed.

Untreated, the survival time for patients with small-cell carcinoma is 6 to 17 weeks. This cancer is particularly sensitive to radiation therapy and chemotherapy, and cure rates of 15% to 25% for limited disease have been reported in some centers. However, most patients with small cell carcinoma have distant metastases at diagnosis. Thus, even with treatment, the mean survival after diagnosis is only about 1 year.

Paraneoplastic Syndromes. Lung carcinoma can be associated with several paraneoplastic syndromes (Chapter 7),

some of which may antedate the development of a detectable pulmonary lesion. The hormones or hormone-like factors elaborated include:

- *Antidiuretic hormone* (ADH), inducing hyponatremia due to inappropriate ADH secretion
- *Adrenocorticotropic hormone* (ACTH), producing Cushing syndrome
- *Parathormone, parathyroid hormone-related peptide, prostaglandin E, and some cytokines*, all implicated in the hypercalcemia often seen with lung cancer
- *Calcitonin*, causing hypocalcemia
- *Gonadotropins*, causing gynecomastia
- *Serotonin and bradykinin*, associated with the carcinoid syndrome

The incidence of clinically significant syndromes related to these factors in lung cancer patients ranges from 1% to 10%, although a much higher proportion of patients show elevated serum levels of these (and other) peptide hormones. Any histologic type of tumor may occasionally produce any one of the hormones, but tumors that produce ACTH and ADH are predominantly small cell carcinomas, whereas those that produce hypercalcemia are mostly squamous cell carcinomas.

Other systemic manifestations of lung carcinoma include the *Lambert-Eaton myasthenic syndrome* (Chapter 26), in which muscle weakness is caused by auto-antibodies (possibly elicited by tumor ionic channels) directed to the neuronal calcium channel; *peripheral neuropathy*, usually purely sensory; dermatologic abnormalities, including *acanthosis nigricans* (Chapter 25); hematologic abnormalities, such as *leukemoid reactions*, hypercoagulable states such as *Trousseau syndrome* (deep vein thrombosis and thromboembolism); and finally, a peculiar abnormality of connective tissue called *hypertrophic pulmonary osteoarthropathy*, associated with clubbing of the fingers.

Apical lung cancers in the superior pulmonary sulcus tend to invade the neural structures around the trachea, including the cervical sympathetic plexus, and produce a group of clinical findings that includes severe pain in the distribution of the ulnar nerve and *Horner syndrome* (enophthalmos, ptosis, miosis, and anhidrosis) on the same side as the lesion. Such tumors are also referred to as *Pancoast tumors*.

KEY CONCEPTS

Carcinomas of the Lung

- The four major histologic subtypes are adenocarcinomas (most common), squamous cell carcinoma, large cell carcinoma, and small cell carcinoma.
- Each of these is clinically and genetically distinct. Small cell lung carcinomas are best treated by chemotherapy, because almost all are metastatic at presentation. The other carcinomas may be curable by surgery if limited to the lung. Combination chemotherapy also is available along with tyrosine kinase inhibitors for those with EGFR, ALK, ROS, and c-MET mutations.
- Smoking is the most important risk factor for lung cancer; in women and nonsmokers, adenocarcinomas are the most common cancers.

- Precursor lesions include squamous dysplasia for squamous cancer and atypical adenomatous hyperplasia and adenocarcinoma in situ (formerly bronchioloalveolar carcinoma) for adenocarcinomas.
- Tumors 3 cm or less in diameter characterized by pure growth along preexisting structures (lepidic pattern) without stromal invasion are now called *adenocarcinoma in situ*.
- Lung cancers, particularly small cell lung carcinomas, can cause paraneoplastic syndromes.

Neuroendocrine Proliferations and Tumors

The normal lung contains neuroendocrine cells within the epithelium as single cells or as clusters, the neuroepithelial bodies. While virtually all pulmonary neuroendocrine cell hyperplasias are secondary to airway fibrosis and/or inflammation, a rare disorder called *diffuse idiopathic pulmonary neuroendocrine cell hyperplasia* seems to be a precursor to the development of multiple tumorlets and typical or atypical carcinoids.

Neoplasms of neuroendocrine cells in the lung include benign *tumorlets*, small, inconsequential, hyperplastic nests of neuroendocrine cells seen in areas of scarring or chronic inflammation; *carcinoids*; and the (already discussed) highly aggressive small cell carcinoma and large cell neuroendocrine carcinoma of the lung. Carcinoid tumors are classified separately, since they differ significantly from carcinomas with evidence of neuroendocrine differentiation in terms of incidence and clinical, epidemiologic, histologic, and molecular characteristics. For example, in contrast to small cell and large cell neuroendocrine carcinomas, carcinoids may occur in patients with multiple endocrine neoplasia type 1.

Carcinoid Tumors

Carcinoid tumors represent 1% to 5% of all lung tumors. Most patients with these tumors are younger than 40 years of age, and the incidence is equal for both sexes. Approximately 20% to 40% of patients are nonsmokers. Carcinoid tumors are low-grade malignant epithelial neoplasms that are subclassified into *typical* and *atypical carcinoids*.

MORPHOLOGY

Carcinoids may arise centrally or may be peripheral. On gross examination, the central tumors grow as fingerlike or spherical polypoid masses that commonly project into the lumen of the bronchus and are usually covered by an intact mucosa (Fig. 15-47A). They rarely exceed 3 to 4 cm in diameter. Most are confined to the mainstem bronchi. Others, however, penetrate the bronchial wall to fan out in the peribronchial tissue, producing the so-called **collar-button lesion**. Peripheral tumors are solid and nodular.

Histologically, the tumor is composed of organoid, trabecular, palisading, ribbon, or rosette-like arrangements of cells separated by a delicate fibrovascular stroma. In common with the lesions of the gastrointestinal tract, the individual cells are quite regular and have uniform round nuclei and a moderate

Figure 15-47 Bronchial carcinoid. **A**, Carcinoid growing as a spherical mass (arrow) protruding into the lumen of the bronchus. **B**, The tumor cells have small, rounded, uniform nuclei and moderate amounts of cytoplasm. (Courtesy Dr. Thomas Krausz, Department of Pathology, The University of Chicago, Pritzker School of Medicine, Chicago, Ill.)

amount of eosinophilic cytoplasm (Fig. 15-47B). Typical carcinoids have fewer than two mitoses per 10 high-power fields and lack necrosis, while atypical carcinoids have between two and 10 mitoses per 10 high-power fields and/or foci of necrosis. Atypical carcinoids also show increased pleomorphism, have more prominent nucleoli, and are more likely to grow in a disorganized fashion and invade lymphatics. On electron microscopy the cells exhibit the dense-core granules characteristic of other neuroendocrine tumors and, by immunohistochemistry, are found to contain serotonin, neuron-specific enolase, bombesin, calcitonin, or other peptides.

Clinical Features. The clinical manifestations of bronchial carcinoids emanate from their intraluminal growth, their capacity to metastasize, and the ability of some of the lesions to elaborate vasoactive amines. Persistent cough, hemoptysis, impairment of drainage of respiratory passages with secondary infections, bronchiectasis, emphysema, and atelectasis are all by-products of the intraluminal growth of these lesions.

Most interesting are functioning lesions capable of producing the classic *carcinoid syndrome*, characterized by intermittent attacks of diarrhea, flushing, and cyanosis. Approximately, 10 % of bronchial carcinoids give rise to this syndrome. Overall, most bronchial carcinoids do not have secretory activity and do not metastasize to distant sites but follow a relatively benign course for long periods and are therefore amenable to resection. The reported 5-year survival rates are 95% for typical carcinoids, 70% for atypical carcinoids, 30% for large cell neuroendocrine carcinoma, and 5% for small cell carcinoma, respectively.

Miscellaneous Tumors

Lesions of the complex category of benign and malignant mesenchymal tumors, such as inflammatory myofibroblastic tumor, fibroma, fibrosarcoma, lymphangioliomyomatosis, leiomyoma, leiomyosarcoma, lipoma, hemangioma, and chondroma, may occur but are rare. Benign and malignant hematopoietic tumors, similar to those described in other organs, may also affect the lung, either as isolated lesions or, more commonly, as part of a generalized

disorder. These include Langerhans cell histiocytosis, non-Hodgkin and Hodgkin lymphomas, lymphomatoid granulomatosis, an unusual EBV-positive B cell lymphoma, and low-grade extranodal marginal zone B-cell lymphoma (Chapter 13).

A lung *hamartoma* is a relatively common lesion that is usually discovered as an incidental, rounded radio-opacity (*coin lesion*) on a routine chest film. Most are, solitary, less than 3 to 4 cm in diameter, and well circumscribed. Pulmonary hamartoma consists of nodules of connective tissue intersected by epithelial clefts. Cartilage is the most common connective tissue, but there may also be cellular fibrous tissue and fat. The epithelial clefts are lined by ciliated columnar epithelium or nonciliated epithelium and probably represent entrapment of respiratory epithelium (Fig. 15-48). The traditional term *hamartoma* is retained for this lesion, but it is in fact a clonal neoplasm associated with chromosomal aberrations involving either 6p21 or 12q14-q15.

Lymphangioliomyomatosis is a pulmonary disorder that primarily affects young woman of childbearing age. It is

Figure 15-48 Pulmonary hamartoma. There are islands of cartilage, fat, smooth muscle, and entrapped respiratory epithelium.

characterized by a proliferation of perivascular epithelioid cells that express markers of both melanocytes and smooth muscle cells. The proliferation distorts the involved lung, leading to cystic, emphysema-like dilation of terminal airspaces, thickening of the interstitium, and obstruction of lymphatic vessels. The lesional epithelioid cells appear to frequently harbor loss of function mutations in the tumor suppressor *TSC2*, one of the loci linked to tuberous sclerosis (Chapter 28). You will recall that the protein encoded by *TSC2*, tuberin, is a negative regulator of mTOR, a key regulator of cellular metabolism. While *TSC2* mutations points to increased mTOR activity as a contributing factor, the disorder remains poorly understood. The strong tendency to affect young women suggests that estrogen contributes to the proliferation of perivascular epithelioid cells, which often express estrogen receptors. Patients most commonly present with dyspnea or spontaneous pneumothorax, the latter related to the emphysematous changes. The disease tends to be slowly progressive over a period of several decades. mTOR inhibitors are being tested in clinical trials, but lung transplantation is the only definitive treatment available currently.

Inflammatory myofibroblastic tumor, though rare, is more common in children, with an equal male-to-female ratio. Presenting symptoms include fever, cough, chest pain, and hemoptysis. It may also be asymptomatic. Imaging studies show a single (rarely multiple) round, well-defined, usually peripheral mass with calcium deposits in about a quarter of cases. Grossly, the lesion is firm, 3 to 10 cm in diameter, and grayish white. Microscopically, there is proliferation of spindle-shaped fibroblasts and myofibroblasts, lymphocytes, plasma cells, and peripheral fibrosis. Some of these tumors have activating rearrangements of the anaplastic lymphoma kinase (*ALK*) gene, located on 2p23, and treatment with *ALK* kinase inhibitors have produced sustained responses in such cases.

Tumors in the mediastinum either may arise in mediastinal structures or may be metastatic from the lung or other organs. They may also invade or compress the lungs. Table 15-12 lists the most common tumors in the various compartments of the mediastinum. Specific tumor types are discussed in appropriate sections of this book.

Table 15-12 Mediastinal Tumors and Other Masses

Anterior Mediastinum
Thymoma
Teratoma
Lymphoma
Thyroid lesions
Parathyroid tumors
Metastatic carcinoma
Posterior Mediastinum
Neurogenic tumors (schwannoma, neurofibroma)
Lymphoma

Pericardial cyst
Lymphoma

Figure 15-49 Numerous metastases to lung from a renal cell carcinoma. (Courtesy Dr. Michelle Mantel, Brigham and Women's Hospital, Boston, Mass.)

Metastatic Tumors

The lung is the most common site of metastatic neoplasms. Both carcinomas and sarcomas arising anywhere in the body may spread to the lungs via the blood or lymphatics or by direct continuity. Growth of contiguous tumors into the lungs occurs most often with esophageal carcinomas and mediastinal lymphomas.

MORPHOLOGY

The pattern of metastatic growth within the lungs is quite variable. In the usual case, multiple discrete nodules (cannonball lesions) are scattered throughout all lobes, more being at the periphery (Fig. 15-49). Other patterns include solitary nodule, endobronchial, pleural, pneumonic consolidation, and combinations of these. Foci of lepidic growth similar to adenocarcinoma in situ are seen occasionally with metastatic carcinomas and may be associated with any of the listed patterns.

Pleura

Pathologic involvement of the pleura is, most often, a secondary complication of some underlying disease. Secondary infections and pleural adhesions are particularly common findings at autopsy. Important primary disorders include (1) primary intrapleural bacterial infections that imply seeding of this space as an isolated focus in the course of a transient bacteremia and (2) a primary neoplasm of the pleura: mesothelioma (discussed later).

Pleural Effusion

Pleural effusion is a common manifestation of both primary and secondary pleural diseases, which may be inflammatory or noninflammatory. Normally, no more than 15 mL of serous, relatively acellular, clear fluid lubricates the pleural surface. Accumulation of pleural fluid occurs in the following settings:

- Increased hydrostatic pressure, as in congestive heart failure
- Increased vascular permeability, as in pneumonia
- Decreased osmotic pressure, as in nephrotic syndrome
- Increased intrapleural negative pressure, as in atelectasis
- Decreased lymphatic drainage, as in mediastinal carcinomatosis

Inflammatory Pleural Effusions

Serous, serofibrinous, and fibrinous pleuritis all have an inflammatory basis, differing only in the intensity and duration of the process. The most common causes of pleuritis are disorders associated with inflammation of the underlying lung, such as tuberculosis, pneumonia, lung infarcts, lung abscess, and bronchiectasis. Rheumatoid arthritis, systemic lupus erythematosus, uremia, diffuse systemic infections, other systemic disorders, and metastatic involvement of the pleura can also cause serous or serofibrinous pleuritis. Radiation used in therapy for tumors in the lung or mediastinum often causes a serofibrinous pleuritis. In most of these disorders, the serofibrinous reaction is only minimal, and the fluid exudate is resorbed with either resolution or organization of the fibrinous component. However, large amounts of fluid sometimes accumulate and compress the lung, causing respiratory distress.

A purulent pleural exudate (*empyema*) usually results from bacterial or mycotic seeding of the pleural space. Most commonly, this seeding occurs by contiguous spread of organisms from intrapulmonary infection, but occasionally, it occurs through lymphatic or hematogenous dissemination from a more distant source. Rarely, infections below the diaphragm, such as the subdiaphragmatic or liver abscess, may extend by continuity through the diaphragm into the pleural spaces, more often on the right side.

Empyema is characterized by loculated, yellow-green, creamy pus composed of masses of neutrophils admixed with other leukocytes. Although empyema may accumulate in large volumes (up to 500 to 1000 mL), usually the volume is small, and the pus becomes localized. Empyema may resolve, but more often the exudate organizes into dense, tough fibrous adhesions that frequently obliterate the pleural space or envelop the lungs; either can seriously restrict pulmonary expansion.

Hemorrhagic pleuritis manifested by sanguineous inflammatory exudates is infrequent and is found in hemorrhagic diatheses, rickettsial diseases, and neoplastic involvement of the pleural cavity. The sanguineous exudate must be differentiated from hemothorax (discussed later). When hemorrhagic pleuritis is encountered, careful search should be made for the presence of exfoliated tumor cells.

Noninflammatory Pleural Effusions

Noninflammatory collections of serous fluid within the pleural cavities are called *hydrothorax*. The fluid is clear and straw colored. Hydrothorax may be unilateral or bilateral, depending on the underlying cause. The most common cause of hydrothorax is cardiac failure, and for this reason it is usually accompanied by pulmonary congestion and edema. Transudates may also collect in any other systemic

disease associated with generalized edema and are therefore found in renal failure and cirrhosis of the liver.

The escape of blood into the pleural cavity is known as *hemothorax*. It is almost invariably a fatal complication of a ruptured aortic aneurysm or vascular trauma or it may occur postoperatively.

Chylothorax is an accumulation of milky fluid, usually of lymphatic origin, in the pleural cavity. Chyle is milky white because it contains finely emulsified fats. Chylothorax is most often caused by thoracic duct trauma or obstruction that secondarily causes rupture of major lymphatic ducts. This disorder is typically caused by malignancies that obstruct the major lymphatic ducts. Usually such cancers arise within the thoracic cavity and invade the lymphatics locally, but occasionally more distant cancers metastasize via the lymphatics and grow within the right lymphatic or thoracic duct, producing obstruction.

Pneumothorax

Pneumothorax refers to air or gas in the pleural cavities and is most commonly associated with emphysema, asthma, and tuberculosis. It may be spontaneous, traumatic, or therapeutic. Spontaneous pneumothorax may complicate any form of pulmonary disease that causes rupture of an alveolus. An abscess cavity that communicates either directly with the pleural space or with the lung interstitial tissue may also lead to the escape of air. In the latter circumstance the air may dissect through the lung substance or back through the mediastinum (interstitial emphysema), eventually entering the pleural cavity. Traumatic pneumothorax is usually caused by some perforating injury to the chest wall, but sometimes the trauma pierces the lung and thus provides two avenues for the accumulation of air within the pleural spaces. Resorption of the air in the pleural space occurs in spontaneous and traumatic pneumothorax, provided that the original communication seals itself.

Of the various forms of pneumothorax, the one that attracts greatest clinical attention is so-called *spontaneous idiopathic pneumothorax*. This entity is encountered in relatively young people, seems to be due to rupture of small, peripheral, usually apical subpleural blebs, and usually subsides spontaneously as the air is resorbed. Recurrent attacks are common and can be quite disabling.

Pneumothorax may have as much clinical significance as a fluid collection in the lungs because it also causes compression, collapse, and atelectasis of the lung and may be responsible for marked respiratory distress. When the defect acts as a flap valve and permits the entrance of air during inspiration but fails to permit its escape during expiration, it effectively acts as a pump that creates the progressively increasing pressures of *tension pneumothorax*, which may be sufficient to compress vital mediastinal structures and the contralateral lung.

Pleural Tumors

The pleura may be involved by primary or secondary tumors. Secondary metastatic involvement is far more common than are primary tumors. The most frequent metastatic malignancies arise from primary neoplasms of the lung and breast. In addition to these cancers, malignancy

Figure 15-50 Solitary fibrous tumor. Cut surface is solid with a whorled appearance. (Courtesy Dr. Justine A. Barletta, Department of Pathology, Brigham and Women's Hospital, Boston, Mass.)

from any organ of the body may spread to the pleural spaces. Ovarian carcinomas, for example, tend to cause widespread implants in both the abdominal and thoracic cavities. In most metastatic involvements, a serous or serosanguineous effusion follows that often contains neoplastic cells. For this reason, careful cytologic examination of the sediment is of considerable diagnostic value.

Solitary Fibrous Tumor

Solitary fibrous tumor is a soft-tissue tumor with a propensity to occur in the pleura and, less commonly, in the lung, as well as other sites. The tumor is often attached to the pleural surface by a pedicle. It may be small (1 to 2 cm in diameter) or may reach an enormous size, but it tends to remain confined to the surface of the lung (Fig. 15-50).

MORPHOLOGY

Grossly, solitary fibrous tumor consists of dense fibrous tissue with occasional cysts filled with viscid fluid; microscopically, the tumor shows whorls of reticulin and collagen fibers among which are interspersed spindle cells resembling fibroblasts. Rarely, this tumor may be malignant, with pleomorphism, mitotic activity, necrosis, and large size (>10 cm). The tumor cells are CD34+ and keratin-negative by immunostaining, features that are helpful in distinguishing these lesions from malignant mesotheliomas (which show the opposite phenotype). The solitary fibrous tumor has no relationship to asbestos exposure.

It has recently been shown to be highly associated with a cryptic inversion of chromosome 12 involving the genes *NAB2* and *STAT6*. This rearrangement creates a *NAB2-STAT6* fusion gene that appears to be virtually unique to solitary fibrous tumor. It encodes a chimeric transcription factor that is hypothesized to be a key driver of tumor development.

Malignant Mesothelioma

Malignant mesotheliomas, although rare, have assumed great importance in the past few decades because of their increased incidence among people with heavy exposure to asbestos (see [Pneumoconioses](#)). Thoracic mesothelioma

arises from either the visceral or the parietal pleura. In coastal areas with shipping industries in the United States and Great Britain, and in Canadian, Australian, and South African mining areas, as many as 90% of mesotheliomas are asbestos-related. The lifetime risk of developing mesothelioma in heavily exposed individuals is as high as 7% to 10%. There is a long latent period of 25 to 45 years for the development of asbestos-related mesothelioma, and there seems to be no increased risk of mesothelioma in asbestos workers who smoke. This is in contrast to the risk of asbestos-related lung carcinoma, already high, which is markedly magnified by smoking. Thus, for asbestos workers (particularly those who are also smokers), the risk of dying of lung carcinoma far exceeds that of developing mesothelioma.

Asbestos bodies (see Fig. 15-20) are found in increased numbers in the lungs of patients with mesothelioma. Another marker of asbestos exposure, the *asbestos plaque*, has been previously discussed (see Fig. 15-21).

Although several cytogenetic abnormalities have been detected, the most common is homozygous deletion of the tumor suppressor gene *CDKN2A/INK4a*, which occurs in about 80% of mesotheliomas. Demonstration of this deletion (usually by FISH) involving chromosome 9p can be very helpful in distinguishing mesothelioma from reactive mesothelial proliferations. Deep sequencing of mesothelioma genomes is ongoing and may produce new insights.

MORPHOLOGY

Malignant mesothelioma is a diffuse lesion arising either from the visceral or parietal pleura, that spreads widely in the pleural space and is usually associated with extensive pleural effusion and direct invasion of thoracic structures. The affected lung becomes ensheathed by a thick layer of soft, gelatinous, grayish pink tumor tissue (Fig. 15-51).

Microscopically, malignant mesotheliomas may be epithelioid (60%), sarcomatoid (20%), or mixed (20%). This is in keeping

Figure 15-51 Malignant mesothelioma. Note the thick, firm, white pleural tumor tissue that ensheathes the lung.

Figure 15-52 Histologic variants of malignant mesothelioma. **A**, Epithelioid type. **B**, Mixed type, stained for calretinin (immunoperoxidase method). The epithelial component is strongly positive (dark brown), while the sarcomatoid component is less so. (Courtesy Dr. Thomas Krausz, Department of Pathology, The University of Chicago, Pritzker School of Medicine, Chicago, Ill.)

with the fact that mesothelial cells have the potential to develop as epithelium-like cells or mesenchymal stromal cells.

The **epithelioid type** of mesothelioma consists of cuboidal, columnar, or flattened cells forming tubular or papillary structures resembling adenocarcinoma (Fig. 15-52A). Immunohistochemical stains are very helpful in differentiating it from pulmonary adenocarcinoma. Most mesotheliomas show strong positivity for keratin proteins, calretinin (Fig. 15-52B), Wilms tumor 1 (WT-1), cytokeratin 5/6, and D2-40. This panel of antibodies is diagnostic in a majority of cases when interpreted in the context of morphology and clinical presentation. The mesenchymal type of mesothelioma (**sarcomatoid type**) appears as a spindle cell sarcoma, resembling fibrosarcoma. Sarcomatoid mesotheliomas tend to have lower expression of many of the markers described previously and some may be positive only for keratin. The **mixed (biphasic) type** of mesothelioma contains both epithelioid and sarcomatoid patterns (Fig. 15-52B).

Clinical Course. The presenting complaints are chest pain, dyspnea, and, as noted, recurrent pleural effusions. Concurrent pulmonary asbestosis (fibrosis) is present in only 20% of individuals with pleural mesothelioma. The lung is invaded directly, and there is often metastatic spread to the hilar lymph nodes and, eventually, to the

liver and other distant organs. Fifty percent of patients die within 12 months of diagnosis, and few survive longer than 2 years. Aggressive therapy (extrapleural pneumonectomy, chemotherapy, radiation therapy) seems to improve this poor prognosis in some patients.

Mesotheliomas also arise in the peritoneum, pericardium, tunica vaginalis, and genital tract (benign adenomatoid tumor; see Chapter 21). *Peritoneal mesotheliomas* are related to heavy asbestos exposure in 60% of male patients (the number is much lower in females). Although in about half cases the disease remains confined to the abdominal cavity, intestinal involvement frequently leads to death from intestinal obstruction or inanition.

 - Other Salivary Gland Tumors 746

Diseases of the head and neck range from the common cold to uncommon neoplasms of the ear and nose. Those selected for discussion are assigned, sometimes arbitrarily,

to one of the following anatomic sites: (1) oral cavity; (2) upper airways, including the nose, pharynx, larynx, and nasal sinuses; (3) ears; (4) neck; and (5) salivary glands.

ORAL CAVITY

Diseases of Teeth and Supporting Structures

Caries (Tooth Decay)

Dental caries is caused by focal demineralization of tooth structure (enamel and dentin) by acidic metabolites of fermenting sugars that are produced by bacteria. Caries is one of the most common diseases worldwide and is the main cause of tooth loss before age 35. Traditionally, the prevalence of caries has been higher in industrialized countries, where there is ready access to processed and refined foods containing large amounts of carbohydrates. However, global trends have changed the demographics. First, the rate of caries has markedly dropped in countries such as the United States, where improved oral hygiene

has improved and fluoridation of the drinking water is widespread. Fluoride is incorporated into the crystalline structure of enamel, forming fluoroapatite, which contributes to the resistance to degradation by bacterial acids. Second, with the globalization of the world's economy, processed foods are being increasingly consumed in developing nations. With these trends, one can expect the rate of caries to increase dramatically in these regions of the world.

Gingivitis

Gingivitis is inflammation of the oral mucosa surrounding the teeth. It is the result of a poor oral hygiene and leads to the accumulation of dental plaque and calculus.

Dental plaque is a sticky, colorless, biofilm that collects between and on the surface of the teeth. It contains a mixture of bacteria, salivary proteins, and desquamated epithelial cells. If plaque is not removed, it becomes mineralized to form *calculus* (tartar). Plaque build-up beneath the gumline can lead to gingivitis, which is characterized by gingival erythema, edema, bleeding, changes in contour, and loss of soft tissue adaptation to the teeth. Gingivitis occurs at any age but is most prevalent and severe in adolescence (ranging from 40% to 60%). In addition, the bacteria in the plaque release acids from sugar-rich foods, thereby eroding the enamel surface and contributing to the development of caries. Gingivitis is a reversible disease; therapy is primarily aimed at reducing the accumulation of plaque and calculus via regular brushing, flossing, and dental visits.

Periodontitis

Periodontitis is an inflammatory process that affects the supporting structures of the teeth (periodontal ligaments) alveolar bone, and cementum. Periodontitis can lead to serious sequelae, including complete destruction of the periodontal ligament, which is responsible for the attachment of the teeth to the alveolar bone, leading to loosening and eventual loss of teeth. Periodontal disease is associated with a marked shift in the types and proportions of bacteria along the gingiva. Poor oral hygiene, with resultant change in oral flora, are believed to be important in the pathogenesis of periodontitis. For the most part, facultative gram-positive organisms colonize healthy gingival sites, while plaque within areas of active periodontitis contains anaerobic and microaerophilic gram-negative flora. Although 300 types of bacteria reside in the oral cavity, adult periodontitis is associated primarily with *Aggregatibacter (Actinobacillus) actinomycetemcomitans*, *Porphyromonas gingivalis*, and *Prevotella intermedia*.

While it typically presents without any associated disorders, periodontal disease can be a component of systemic disease, including acquired immunodeficiency syndrome (AIDS), leukemia, Crohn disease, diabetes mellitus, Down syndrome, sarcoidosis, and syndromes associated with defects in neutrophils (Chédiak-Higashi syndrome, agranulocytosis, and cyclic neutropenia). In addition, periodontal infections can be the origin of important systemic diseases, including infective endocarditis, and pulmonary and brain abscesses.

Inflammatory/Reactive Lesions

Aphthous Ulcers (Canker Sores)

Aphthous ulcers are common, often recurrent, exceedingly painful, superficial oral mucosal ulcerations of unknown etiology. They affect up to 40% of the population, and are most common in the first 2 decades of life. Aphthous ulcers tend to be prevalent within certain families and may also be associated with immunologic disorders including celiac disease, inflammatory bowel disease, and Behçet disease. The lesions appear as single or multiple, shallow, hyperemic ulcerations covered by a thin

Figure 16-1 Aphthous ulcer. Single ulceration with an erythematous halo surrounding a yellowish fibrinopurulent membrane.

exudate and rimmed by a narrow zone of erythema (Fig. 16-1). The underlying inflammatory infiltrate is at first largely mononuclear, but secondary bacterial infection may result in a neutrophilic infiltrate. The lesions typically resolve spontaneously in 7 to 10 days, but may sometimes persist stubbornly for weeks, particularly in immunocompromised patients.

Fibrous Proliferative Lesions

The *irritation fibroma*, also called traumatic fibroma and focal fibrous hyperplasia, is a submucosal nodular mass of fibrous connective tissue stroma that occurs primarily on the buccal mucosa along the bite line or the gingiva (Fig. 16-2). It is believed to be a reactive proliferation caused by repetitive trauma. Treatment is complete surgical excision.

The *pyogenic granuloma* (Fig. 16-3) is an inflammatory lesion typically found on the gingiva of children, young adults, and pregnant women (pregnancy tumor). The surface of the lesion is often ulcerated and red to purple in color. In some cases, growth is alarmingly rapid, raising the fear of malignancy. Histologically these lesions demonstrate a highly vascular proliferation of organizing granulation tissue. Pyogenic granulomas can regress, mature into dense fibrous masses, or develop into a peripheral

Figure 16-2 Fibroma. Smooth pink exophytic nodule on the buccal mucosa.

Figure 16-3 Pyogenic granuloma. Erythematous, hemorrhagic, and exophytic mass arising from the gingival mucosa.

ossifying fibroma. Complete surgical excision is the definitive treatment for these lesions.

The *peripheral ossifying fibroma* is a common gingival growth that is most likely reactive in nature rather than neoplastic. As mentioned, some may arise from a longstanding pyogenic granuloma, while others develop *de novo* from cells of the periodontal ligament. Peripheral ossifying fibromas appear as red, ulcerated, and nodular lesions of the gingiva. The peak incidence is in young and teenage females. Since the lesions have a recurrence rate of 15% to 20%, complete surgical excision down to the periosteum is the treatment of choice.

The *peripheral giant cell granuloma* is an uncommon lesion of the oral cavity, particularly the gingiva. Like the peripheral ossifying fibroma, peripheral giant cell granuloma most likely represents a reactive/inflammatory, rather than neoplastic, process. It is generally covered by intact gingival mucosa, but it may be ulcerated. Histologically, these lesions contain a striking aggregation of multinucleate, foreign body-like giant cells separated by a fibroangiomatic stroma. Although not encapsulated, these lesions are usually well delimited and easily excised. They should be differentiated from central giant-cell tumors found within the jaws and from the histologically similar but frequently multiple “brown tumors” seen in hyperparathyroidism (Chapter 24).

Infections

Herpes Simplex Virus Infections

Most orofacial herpetic infections are caused by herpes simplex virus type 1 (HSV-1) but oral HSV-2 (genital herpes) infections do occur. Primary infections typically occur in children between 2 and 4 years of age, are often asymptomatic, and do not cause significant morbidity. However, in 10% to 20% of cases, primary infections can present as *acute herpetic gingivostomatitis*, with abrupt onset of vesicles and ulcerations of the oral mucosa, particularly the gingiva. These lesions are also accompanied by lymphadenopathy, fever, anorexia, and irritability.

MORPHOLOGY

The vesicles range from lesions of a few millimeters to large bullae and are at first filled with a clear, serous fluid, but rapidly rupture to yield painful, red-rimmed, shallow ulcerations. On microscopic examination, there is intracellular and intercellular edema (acantholysis), creating clefts that may become transformed into macroscopic vesicles. Individual epidermal cells in the margins of the vesicle or lying free within the fluid sometimes develop eosinophilic **intranuclear viral inclusions**, or several cells may fuse to produce giant cells (**multinucleate polykaryons**), changes that are demonstrated by the diagnostic **Tzanck test**, based on microscopic examination of the vesicle fluid. The vesicles and shallow ulcers usually spontaneously clear within 3 to 4 weeks, but the virus treks along the regional nerves and eventually becomes dormant in the local ganglia (e.g., the trigeminal ganglion).

Infection is common and most adults harbor latent HSV-1. In some individuals, viral reactivation (recurrent herpetic stomatitis) occurs. The mechanisms of reactivation are poorly understood. It has been associated with trauma, allergies, exposure to ultraviolet light, upper respiratory tract infection, pregnancy, menstruation, immunosuppression, and exposure to temperature extremes. *Recurrent herpetic stomatitis* (in contrast to acute herpetic gingivostomatitis) occurs at the site of primary inoculation or in adjacent mucosa associated with the same ganglion. The lesions appear as groups of small (1 to 3 mm) vesicles on the lips (*Herpes labialis*), nasal orifices, buccal mucosa, gingiva, and hard palate. Although these lesions typically resolve in 7 to 10 days, they can persist in immunocompromised patients and may require systemic antiviral therapy.

Other viral infections that can involve the oral cavity as well as the head and neck region include herpes zoster, Epstein-Barr virus (EBV; mononucleosis, nasopharyngeal carcinoma, lymphoma), cytomegalovirus, enterovirus (herpangina, hand-foot-and-mouth disease, acute lymphonodular pharyngitis), and rubeola (measles).

Oral Candidiasis (Thrush)

Candida albicans is a normal component of the oral flora in approximately 50% of the population and is the most common fungal infection of the oral cavity. Several factors seem to influence the likelihood of a clinical infection. These include the immune status of the individual, the strain of *C. albicans* present, and the composition of an individual's oral flora. There are three major clinical forms of oral candidiasis: *pseudomembranous*, *erythematous*, and *hyperplastic*. The pseudomembranous form is the most common and is also known as *thrush*. It is characterized by a superficial, gray to white inflammatory membrane composed of matted organisms enmeshed in a fibrinosuppurative exudate that can be readily scraped off to reveal an underlying erythematous inflammatory base. The infection typically remains superficial except in the setting of immunosuppression, such as in individuals with organ or bone marrow transplants, neutropenia, chemotherapy-induced immunosuppression, AIDS, and diabetes mellitus. In addition, broad-spectrum

Table 16-1 Oral Manifestations of Some Systemic Diseases

Systemic Disease	Associated Oral Changes
Infectious Diseases	
Scarlet fever	Fiery red tongue with prominent papillae (raspberry tongue); white-coated tongue through which hyperemic papillae project (strawberry tongue)
Measles	Spotty enanthema in the oral cavity often precedes the skin rash; ulcerations on the buccal mucosa about Stensen duct produce Koplik spots
Infectious mononucleosis	Acute pharyngitis and tonsillitis that may cause coating with a gray-white exudative membrane; enlargement of lymph nodes in the neck, palatal petechiae
Diphtheria	Characteristic dirty white, fibrinosuppurative, tough, inflammatory membrane over the tonsils and retropharynx
Human immunodeficiency virus	Predisposition to opportunistic oral infections, particularly herpes virus, <i>Candida</i> , and other fungi; oral lesions of Kaposi sarcoma and hairy leukoplakia (described in text)
Dermatologic Conditions*	
Lichen planus	Reticulate, lacelike, white keratotic lesions that sometimes ulcerate and rarely form bullae; seen in more than 50% of patients with cutaneous lichen planus; rarely, is the sole manifestation
Pemphigus	Vesicles and bullae prone to rupture, leaving hyperemic erosions covered with exudates
Bullous pemphigoid	Oral lesions (mucus membrane pemphigoid) resemble those of pemphigus but can be differentiated histologically
Erythema multiforme	Maculopapular, vesiculobullous eruption that sometimes follows an infection elsewhere, ingestion of drugs, development of cancer, or a collagen vascular disease; when there is widespread mucosal and skin involvement, it is referred to as <i>Stevens-Johnson syndrome</i>
Hematologic Disorders	
Pancytopenia (agranulocytosis, aplastic anemia)	Severe oral infections in the form of gingivitis, pharyngitis, tonsillitis; may extend to produce cellulitis of the neck (<i>Ludwig angina</i>)
Leukemia	With depletion of functioning neutrophils, oral lesions may appear like those in pancytopenia
Monocytic leukemia	Leukemic infiltration and enlargement of the gingivae, often with accompanying periodontitis
Miscellaneous	
Melanotic pigmentation	May appear in Addison disease, hemochromatosis, fibrous dysplasia of bone (Albright syndrome), and Peutz-Jeghers syndrome (gastrointestinal polyposis)
Phenytoin (Dilantin) ingestion	Striking fibrous enlargement of the gingivae
Pregnancy	A friable, red, pyogenic granuloma protruding from the gingiva ("pregnancy tumor")
Rendu-Osler-Weber syndrome	Autosomal dominant disorder with multiple congenital aneurysmal telangiectasias beneath mucosal surfaces of the oral cavity and lips

*See Chapter 25.

antibiotics that eliminate or alter the normal bacterial flora of the mouth can result in the development of oral candidiasis.

Deep Fungal Infections

In addition to their usual sites of infection, certain deep fungal infections have a predilection for the oral cavity and the head and neck region. Such fungi include histoplasmosis, blastomycosis, coccidioidomycosis, cryptococcosis, zygomycosis, and aspergillosis. With an increasing number of patients who are immunocompromised due to diseases such as AIDS or therapies for cancer and organ transplantation, the prevalence of fungal infections of the oral cavity has increased in recent years.

Oral Manifestations of Systemic Disease

The mouth is not merely a gateway for delicacies; it is also the site of oral lesions in many systemic diseases. In fact, *it is not uncommon for oral lesions to be the first sign of some underlying systemic condition.* Some of the more common disease associations and their oral changes are cited in

Table 16-1. Only hairy leukoplakia is characterized in more detail here.

Hairy Leukoplakia

Hairy leukoplakia is a distinctive oral lesion on the lateral border of the tongue that is usually seen in immunocompromised patients and is caused by Epstein-Barr virus (EBV). It can be observed in patients infected with the human immunodeficiency virus (HIV) and may portend the development of AIDS. However, the lesions can also be found in patients who are immunocompromised for other reasons including cancer therapy, transplant associated immunosuppression, and advancing age. Hairy leukoplakia takes the form of *white, confluent patches of fluffy ("hairy"), hyperkeratotic thickenings, almost always situated on the lateral border of the tongue.* Unlike thrush, the lesion cannot be scraped off. The distinctive microscopic appearance consists of *hyperparakeratosis and acanthosis with "balloon cells" in the upper spinous layer.* Special stains can be used to demonstrate the presence of EBV RNA transcripts and proteins within the lesional cells. Sometimes there is superimposed candidal infection on the surface of the lesions, adding to the "hairiness."

Precancerous and Cancerous Lesions

Many epithelial and connective tissue tumors of the head and neck region (e.g., papillomas, hemangiomas, lymphomas) occur elsewhere in the body and are described adequately in other chapters. This discussion considers only squamous cell carcinoma and its associated precancerous lesions.

Leukoplakia and Erythroplakia

Leukoplakia is defined by the World Health Organization as “a white patch or plaque that cannot be scraped off and cannot be characterized clinically or pathologically as any other disease.” This clinical term is reserved for lesions that are present in the oral cavity for no apparent reason. As such, white patches caused by obvious irritation or entities such as lichen planus and candidiasis are not considered to be leukoplakias. Approximately 3% of the world’s population have leukoplakic lesions; 5% to 25% of these lesions are premalignant. **Thus, until proven otherwise by means of histologic evaluation, all leukoplakias must be considered precancerous.**

Related to leukoplakia, but much less common and much more ominous, is *erythroplakia*, which is a red, velvety, possibly eroded area within the oral cavity that usually remains level with or may be slightly depressed in relation to the surrounding mucosa (Fig. 16-4). The epithelium in such lesions tends to be markedly atypical, and the risk of malignant transformation is much higher than is leukoplakia. Intermediate forms are occasionally encountered that have the characteristics of both leukoplakia and erythroplakia, termed *speckled leukoerythroplakia*.

Both leukoplakia and erythroplakia may be seen in adults at any age, but they are usually found in persons aged 40 to 70, with a 2:1 male preponderance. Although these lesions have multifactorial origins, the use of tobacco (cigarettes, pipes, cigars, and certain forms of smokeless tobacco) is a common antecedent.

MORPHOLOGY

Leukoplakias may occur anywhere in the oral cavity (favored locations are buccal mucosa, floor of the mouth, ventral surface of the tongue, palate, and gingiva). They appear as solitary or multiple white patches or plaques, often with sharply demarcated borders. They may be slightly thickened and smooth or wrinkled and fissured, or they may appear as raised, sometimes corrugated, verrucous plaques (Fig. 16-5A). On histologic examination they present a spectrum of epithelial changes ranging from hyperkeratosis overlying a thickened, acanthotic but orderly mucosal epithelium to lesions with markedly dysplastic changes sometimes merging into carcinoma in situ (Fig. 16-5B).

The histologic changes in **erythroplakia** only rarely demonstrate orderly epidermal maturation; virtually all (approximately 90%) disclose severe dysplasia, carcinoma in situ, or minimally invasive carcinoma. Often, an intense subepithelial inflammatory reaction with vascular dilation is seen that likely contributes to the reddish clinical appearance.

Figure 16-4 Erythroplakia. A, Lesion of the maxillary gingiva. B, Red lesion of the mandibular alveolar ridge. Biopsy of both lesions revealed carcinoma in situ.

Squamous Cell Carcinoma

Approximately 95% of cancers of the head and neck are squamous cell carcinomas (SCCs), with the remainder largely consisting of adenocarcinomas of salivary gland origin. Head and neck squamous cell carcinoma is the sixth most common neoplasm in the world. At current rates, approximately 45,000 cases in the United States and more than 650,000 cases worldwide will be diagnosed each year.

The pathogenesis of squamous cell carcinoma is multifactorial.

- Within North America and Europe, oral cavity SCC has classically been a disease of middle-aged individuals who have been chronic abusers of *smoked tobacco* and *alcohol*.
- In India and Asia, the chewing of betel quid and paan is a major regional predisposing influence. This concoction, considered a delicacy by some, contains ingredients such as areca nut, slaked lime, and tobacco, wrapped in a betel leaf; many of the ingredients of paan could give rise to potential carcinogens.
- *Actinic radiation* (sunlight) and, particularly, pipe smoking are known predisposing influences for cancer of the lower lip.
- The incidence of oral cavity SCC (particularly the tongue) in individuals younger than age 40, who have no known risk factors, has been on the rise.

Figure 16-5 Leukoplakia. **A**, Clinical appearance of leukoplakias is highly variable. In this example, the lesion is relatively smooth and thin with well-demarcated borders. **B**, The histologic appearance of a leukoplakia showing severe dysplasia that is characterized by nuclear and cellular pleomorphism, numerous mitotic figures, and a loss of normal maturation.

The pathogenesis in this group of patients, who are nonsmokers and not infected with human papillomavirus (HPV), is unknown.

In the oropharynx, as many as 70% of SCCs, particularly those involving the tonsils, the base of the tongue, and the pharynx, harbor oncogenic variants of HPV, particularly HPV-16. HPV-associated SCC of the oropharynx has increased more than 2-fold over the last 2 decades. It is predicted that by the year 2020, the incidence of HPV-associated head and neck SCC will surpass that of cervical cancer, in part because the anatomic sites of origin (tonsillar crypts, base of tongue, and oropharynx) are not readily accessible or amenable to cytologic screening (unlike the cervix) for premalignant lesions. Conversely, it should be noted that, unlike the oropharynx, HPV-associated SCC of the oral cavity is relatively uncommon.

Survival is dependent on a number of factors including the specific etiology of SCC. The 5-year survival rate of “classic” (smoking and alcohol related) early-stage SCC is approximately 80%, while survival drops to 20% for late-stage disease. Patients with HPV-positive SCC have greater long-term survival than those with HPV-negative tumors. The dismal outlook for the classic SCC is due to several factors, including the fact that the tumors are often diagnosed when the disease has already reached an advanced stage. Furthermore, the frequent development of multiple primary tumors markedly decreases survival. The rate of second primary tumors in these patients has been reported to be 3% to 7% per year, which is higher than for any other malignancy. This observation has led to the concept of “field cancerization,” which postulates that multiple individual primary tumors develop independently in the upper aerodigestive tract as a result of years of chronic exposure of the mucosa to carcinogens. Because of such field cancerization, an individual who is fortunate to live 5 years after the detection of the initial primary tumor has an almost 35% chance of developing at least one new primary tumor within that period of time. An alternative hypotheses to explain multiple “primary” tumors is that they are actually intraepithelial metastases. The occurrence of new tumors can be particularly devastating for individuals whose initial lesions were small. The 5-year

survival rate for the first primary tumor is considerably better than 50%, but in such individuals, second primary tumors are the most common cause of death. Therefore, the early detection of all premalignant lesions is critical for the long-term survival of these patients. Finally, the HPV vaccine, which is protective against cervical cancer, offers hope to stem the tide of HPV-associated head and neck SCC. Although clinical trials are ongoing, the vaccine has not yet been approved for this use.

Molecular Biology of Squamous Cell Carcinoma. As with other cancers, the development of SCC is driven by the accumulation of mutations and epigenetic changes that alter the expression and function of oncogenes and tumor suppressor genes, leading to acquisition of cancer hallmarks (Chapter 7), such as resistance to cell death, increased proliferation, induction of angiogenesis, and the ability to invade and metastasize. Deep sequencing of the classic SCC subset has revealed a large number of genetic alterations that bear a molecular signature consistent with tobacco carcinogen induced cancers (Fig. 16-6). These mutations frequently involve the p53 pathway as well as proteins responsible for the regulation of squamous differentiation, such as p63 and NOTCH 1. Conversely, HPV-associated SCCs contain far fewer and different genetic alterations and typically overexpress p16, a cyclin-dependent kinase inhibitor. In addition, owing to the expression of the HPV oncoproteins E6 and E7, there is inactivation of the p53 and RB pathways in much the same way as has been observed in cervical cancer (Chapter 22).

While the model outlined in Figure 16-6 is an acceptable working draft of the clinical, histologic, and molecular changes involved in development of carcinogen-induced SCC, it does not reflect the natural history of the disease for all lesions. Data regarding the incidence and timing of these changes in oral premalignancy are limited. Furthermore, it is not clear whether any of the genotypic changes, used individually or in a panel, can consistently predict which dysplastic lesions will progress to oral SCC. To complicate the matter further, SCC progression does not always occur in a linear fashion over a uniform period of time. Rather, there are subsets of lesions with histologic evidence of dysplasia that may or may not progress to

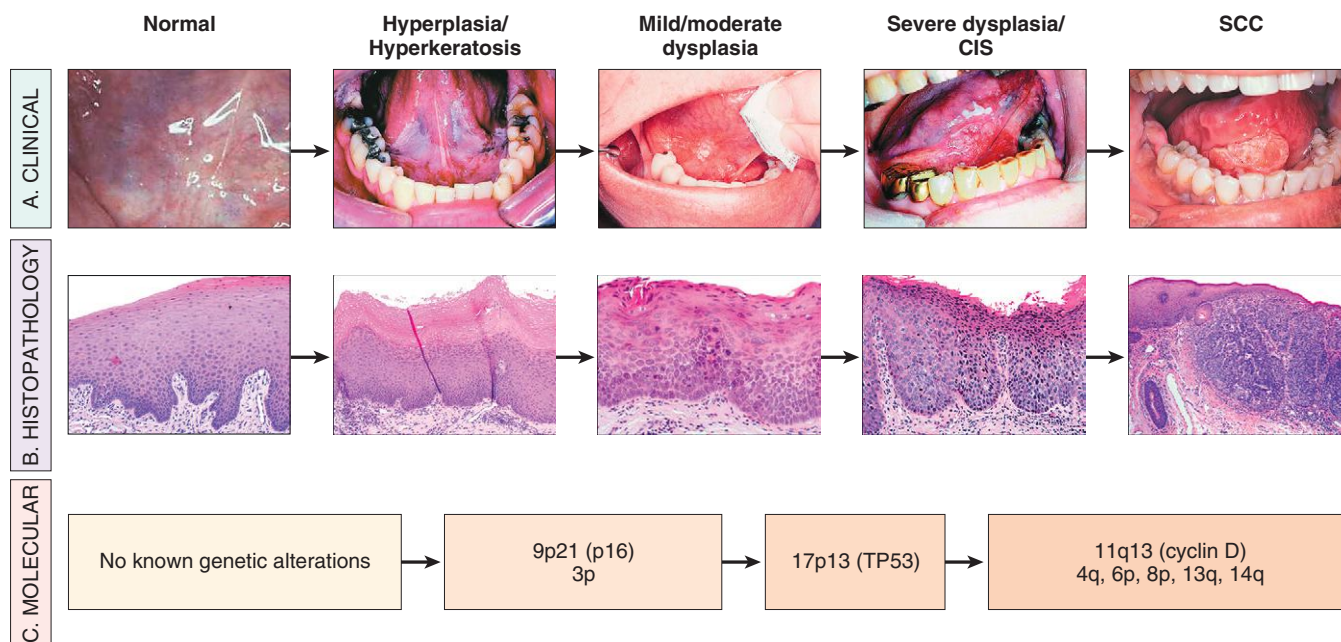

Figure 16-6 Clinical, histologic, and molecular progression of oral cancer. **A**, An idealized representation of the clinical progression of oral cancer. **B**, The histologic progression of squamous epithelium from normal, to hyperkeratosis, to mild/moderate dysplasia, to severe dysplasia, to cancer. **C**, The sites of the most common genetic alterations identified as important for cancer development. CIS, Carcinoma in situ; SCC, squamous cell carcinoma. (Clinical photographs courtesy of Sol Silverman, MD, from Silverman S: Oral Cancer. Hamilton, Ontario, Canada, BD Dekker, 2003.)

SCC. Similarly, histologically “normal” appearing mucosal lesions may truly be benign or they may represent molecularly premalignant lesions that have not yet developed morphologic changes consistent with dysplasia. Therefore, conventional histologic findings can only indicate that a given lesion may have malignant potential.

MORPHOLOGY

Squamous cell carcinoma may arise anywhere in the head and neck region that is lined by stratified squamous epithelium. For the “classic” oral cavity SCC, the favored locations are the ventral surface of the tongue, floor of the mouth, lower lip, soft palate, and gingiva (Fig. 16-7A). The “classic” malignancies are typically preceded by the presence of premalignant lesions that can be very heterogeneous in presentation (see earlier).

In the early stages, cancers of the oral cavity appear either as raised, firm, pearly plaques or as irregular, roughened, or verrucous areas of mucosal thickening, possibly mistaken for leukoplakia. Either pattern may be superimposed on a background of apparent leukoplakia or erythroplakia. As these lesions enlarge, they typically create ulcerated and protruding masses that have irregular and indurated (rolled) borders.

On histologic examination, these cancers begin as dysplastic lesions, which may or may not progress to full-thickness dysplasia (carcinoma in situ) before invading the underlying connective tissue stroma (Fig. 16-7B). This difference in progression should be contrasted with cervical cancer (Chapter 22), in which, typically, full-thickness dysplasia, representing carcinoma in situ, develops before invasion. Squamous cell carcinomas range from well-differentiated keratinizing neoplasms to anaplastic, sometimes sarcomatoid, tumors, and

Figure 16-7 Squamous cell carcinoma. **A**, Clinical appearance demonstrating ulceration and induration of the oral mucosa. **B**, Histologic appearance demonstrating numerous nests and islands of malignant keratinocytes invading the underlying connective tissue stroma and skeletal muscle.

from slowly to rapidly growing lesions. However, the degree of histologic differentiation, as determined by the relative degree of keratinization, is not correlated with behavior. As a group these tumors tend to infiltrate locally before they metastasize to other sites. The routes of extension depend on the primary site. The favored sites of local metastasis are the cervical lymph nodes, while the most common sites of distant metastasis are mediastinal lymph nodes, lungs, liver, and bones. Unfortunately, such distant metastases are often already present at the time of discovery of the primary lesion.

Odontogenic Cysts and Tumors

The overwhelming majority of odontogenic cysts are derived from remnants of odontogenic epithelium present within the jaws. In contrast to the rest of the skeleton, epithelial-lined cysts are quite common in the jaws. In general, these cysts are subclassified as either inflammatory or developmental (Table 16-2). Only the most common of these lesions are described later.

The *dentigerous cyst* is defined as a cyst that originates around the crown of an unerupted tooth and is thought to be the result of fluid accumulation between the developing tooth and the dental follicle. Radiographically, these are unilocular lesions most often associated with impacted third molar (wisdom) teeth. Histologically, they are lined by a thin layer of stratified squamous epithelium. Often, there is a dense chronic inflammatory cell infiltrate in the connective tissue stroma. Complete removal of the lesion is curative.

The *odontogenic keratocyst (OKC)*, now called *keratocystic odontogenic tumor*, is an important lesion that must be differentiated from other odontogenic cysts because of its aggressive behavior. OKCs can be seen at any age but are most often diagnosed in patients between ages 10 and 40. They occur most commonly in males within the posterior mandible. Radiographically, OKCs present as well-defined unilocular or multilocular radiolucencies. Histologically, the cyst lining consists of a thin layer of keratinized stratified squamous epithelium with a prominent basal cell layer and a corrugated epithelial surface. Treatment requires complete removal of the lesion, because OKCs are locally aggressive and recurrence rates for inadequately removed lesions can reach 60%. About 80% of the lesions are solitary, but multiple OKCs occur in roughly 20% of patients,

who should be evaluated for nevoid basal cell carcinoma syndrome (Gorlin syndrome), which is associated with mutations in the tumor suppressor gene *PTCH* (Patched) located on chromosome 9q22 (Chapter 25).

The *periapical cyst*, in contrast to the developmental cysts described earlier, is inflammatory in origin. These are common lesions found at the apex of teeth. They develop as a result of long-standing inflammation of the tooth (pulpitis), which may be caused by advanced carious lesions or by trauma to the tooth in question. The inflammatory process may result in necrosis of the pulpal tissue, which can traverse the length of the root and exit at the apex of the tooth into the surrounding alveolar bone. Over time, like any chronic inflammatory process, a lesion with granulation tissue may develop, and subsequent epithelialization may lead to the formation of a radicular cyst. While the term *periapical granuloma* is not the most appropriate terminology (the lesion does not show true granulomatous inflammation), this older name is still used. Periapical inflammatory lesions persist as a result of the continued presence of bacteria or other irritating agents in the area. Successful treatment, therefore, necessitates the complete removal of offending material and appropriate restoration of the tooth or extraction.

Odontogenic tumors are a group of lesions with diverse histologic appearances and clinical behavior. Some are true neoplasms (both benign and malignant), while others are more likely hamartomas. Odontogenic tumors are derived from odontogenic epithelium, ectomesenchyme, or both (Table 16-3). The two most common and clinically significant tumors are the following:

- *Ameloblastoma* arises from odontogenic epithelium and shows *no* ectomesenchymal differentiation. It is commonly cystic, slow growing, and locally invasive but has an indolent course in most cases. Treatment typically requires wide surgical resection to prevent recurrences.
- *Odontoma*, the most common type of odontogenic tumor, arises from epithelium but shows extensive depositions of enamel and dentin. Odontomas are probably hamartomas rather than true neoplasms and are cured by local excision.

KEY CONCEPTS

Oral Cavity

- **Caries** is the most common cause of tooth loss in persons younger than age 35 years. The primary cause is destruction of tooth structure by acid end-products of bacterial sugar fermentation.

- **Gingivitis** is a common and reversible inflammation of the mucosa surrounding the teeth.
- **Periodontitis** is a chronic inflammatory condition that results in the destruction of the supporting structures of the teeth with eventual loss of teeth. It is associated with poor oral hygiene and altered oral microbiota.
- **Aphthous ulcers** are painful superficial ulcers of unknown etiology.
- **Fibromas** and **pyogenic granulomas** are common reactive lesions of the oral mucosa.
- **Leukoplakias** and **erythroplakias** are oral mucosal lesions that may undergo malignant transformation.
- The majority of oral cavity and oropharyngeal cancers are **squamous cell carcinomas**. Oral cavity squamous cell carcinomas are classically linked to tobacco and alcohol use, but the incidence of HPV-associated lesions has risen dramatically in the oropharynx and base of the tongue.

UPPER AIRWAYS

The term *upper airways* is used here to include the nose, pharynx, and larynx and their related parts. Disorders of these structures are among the most common afflictions of humans, but fortunately the overwhelming majority of these disorders are more nuisance than threat.

Nose

Inflammatory diseases, mostly in the form of the common cold, are the most common disorders of the nose and accessory air sinuses. Most of these inflammatory conditions are viral in origin, but can be complicated by superimposed bacterial infections. Much less common are a few destructive inflammatory nasal diseases and primary tumors of the nasal cavity or maxillary sinus.

Inflammations

Infectious Rhinitis. Infectious rhinitis, commonly referred to as “common cold,” is in most instances caused by one or more viruses. Major offenders are adenoviruses, echoviruses, and rhinoviruses. They evoke a profuse catarrhal discharge that is familiar to all and the bane of the kindergarten teacher. During the initial acute stages, the nasal mucosa is thickened, edematous, and red; the nasal cavities are narrowed; and the turbinates are enlarged. These changes may extend, to produce pharyngotonsillitis. Secondary bacterial infection enhances the inflammatory reaction and produces a mucopurulent or sometimes frankly suppurative exudate. But as all have learned from experience, these infections soon clear up—as the saying goes, in a week if treated but in 7 days if ignored.

Allergic Rhinitis. Allergic rhinitis (hay fever) is initiated by hypersensitivity reactions to one of a large group of allergens, most commonly the plant pollens, fungi, animal allergens, and dust mites. It affects 20% of the U.S. population. As is the case with asthma, allergic rhinitis is an

IgE-mediated immune reaction with an early- and late-phase response (see “Immediate [Type I] Hypersensitivity” in Chapter 6). The allergic reaction is characterized by marked mucosal edema, redness, and mucus secretion, accompanied by a leukocytic infiltration in which eosinophils are prominent.

Nasal Polyps. Recurrent attacks of rhinitis may eventually lead to focal protrusions of the mucosa, producing so-called *nasal polyps*, which may reach 3 to 4 cm in length. On histologic examination these polyps consist of edematous mucosa having a loose stroma, often harboring hyperplastic or cystic mucous glands, infiltrated with a variety of inflammatory cells, including neutrophils, eosinophils, and plasma cells with occasional clusters of lymphocytes (Fig. 16-8). In the absence of bacterial infection, the mucosal covering of these polyps is intact, but with chronicity it may become ulcerated or infected. When multiple or large, the polyps may encroach on the airway and impair sinus drainage. Although the features of nasal polyps point to an allergic etiology, most people with nasal polyps are not atopic, and only 0.5% of atopic patients develop polyps.

Chronic Rhinitis. Chronic rhinitis is a sequel to repeated attacks of acute rhinitis, either microbial or allergic in origin, with the eventual development of superimposed bacterial infection. A deviated nasal septum or nasal polyps with impaired drainage of secretions contribute to the likelihood of microbial invasion. Frequently, there is superficial desquamation or ulceration of the mucosal epithelium and a variable inflammatory infiltrate of neutrophils, lymphocytes, and plasma cells subjacent to the epithelium. These suppurative infections sometimes extend into the air sinuses.

Sinusitis. Acute sinusitis is most commonly preceded by acute or chronic rhinitis, but maxillary sinusitis occasionally arises by extension of a periapical infection through the bony floor of the sinus. The offending agents are usually

Figure 16-8 A, Nasal polyps. Low-power magnification showing edematous masses lined by epithelium. **B**, High-power view showing edema and eosinophil-rich inflammatory infiltrate.

inhabitants of the oral cavity, and the inflammatory reaction is entirely nonspecific. Impairment of drainage of the sinus by inflammatory edema of the mucosa is an important contributor to the process and, when complete, may impound the suppurative exudate, producing *empyema* of the sinus. Obstruction of the outflow, most often from the frontal and less commonly from the anterior ethmoid sinuses, occasionally leads to an accumulation of mucous secretions, producing a so-called *mucocele*.

Acute sinusitis may, in time, give rise to *chronic sinusitis*, particularly when there is interference with drainage. There is usually a mixed microbial flora, largely of normal inhabitants of the oral cavity. Particularly severe forms of chronic sinusitis are caused by fungi (e.g., mucormycosis), especially in patients with diabetes. Uncommonly, sinusitis is a component of *Kartagener syndrome*, which also includes bronchiectasis and situs inversus (Chapter 15). All these features are secondary to defective ciliary action. Although most instances of chronic sinusitis are more uncomfortable than disabling or serious, the infections have the potential of spreading into the orbit or of penetrating into the surrounding bone to give rise to osteomyelitis or spreading into the cranial vault, causing septic thrombophlebitis of a dural venous sinus.

Necrotizing Lesions of the Nose and Upper Airways

Necrotizing ulcerating lesions of the nose and upper respiratory tract may be produced by the following:

- Acute fungal infections (including mucormycosis; Chapter 8), particularly in patients with diabetes and immunosuppressed patients
- Granulomatosis with polyangiitis, previously called Wegener granulomatosis (Chapter 11)
- Extranodal NK/T-cell lymphoma, nasal type, is a lymphoma in which the tumor cells harbor EBV (Chapter 13). These neoplasms are typically seen in males who are in the fifth or sixth decade of life and most commonly occur in individuals of Asian and Latin American descent. Ulceration and superimposed bacterial infection frequently complicate the process. At one time these lesions were almost always rapidly fatal as a result

of uncontrolled spread of the lymphoma and penetration into the cranial vault, or secondary bacterial infection and blood-borne dissemination of the infection. Currently, localized cases can often be controlled with radiotherapy, but relapse and recurrences remain common and are associated with poor outcomes.

Nasopharynx

Although the nasopharyngeal mucosa, related lymphoid structures, and glands may be involved in a wide variety of specific infections (e.g., diphtheria, infectious mononucleosis) and by neoplasms, the only disorders we describe here are nonspecific inflammations; tumors are discussed separately.

Inflammations

Pharyngitis and *tonsillitis* are frequent features of viral upper respiratory infections. Most commonly implicated are the rhinoviruses, echoviruses, and adenoviruses, and, less frequently, respiratory syncytial viruses and the various strains of influenza virus. In the usual case, there is reddening and edema of the nasopharyngeal mucosa, with reactive enlargement of nearby tonsils and lymph nodes. Bacterial infections may be superimposed on these viral infections, or may be primary invaders. The most common offenders are the β -hemolytic streptococci, but sometimes *Staphylococcus aureus* or other pathogens may be implicated. The inflamed nasopharyngeal mucosa may be covered by an exudative membrane (pseudomembrane), and the nasopalatine and palatine tonsils may be enlarged and covered by exudate. A typical appearance is of enlarged, reddened tonsils (due to reactive lymphoid hyperplasia) dotted by pinpoint spots of exudate emanating from the tonsillar crypts, so-called *follicular tonsillitis*.

The major importance of streptococcal “sore throats” lies in the possible development of late sequelae, such as rheumatic fever (Chapter 12) and glomerulonephritis (Chapter 20). Whether recurrent episodes of acute tonsillitis favor the development of chronic tonsillar enlargement is open to debate, but regardless of cause the enlargement of the lymphoid tissue invites the tender mercies of the ENT surgeon.

Tumors of the Nose, Sinuses, and Nasopharynx

Tumors in the nose, sinuses, and nasopharynx are infrequent but include the wide spectrum of mesenchymal and epithelial neoplasms. Distinctive types are described here.

Nasopharyngeal Angiofibroma. Nasopharyngeal angiofibroma is a benign, highly vascular tumor that occurs almost exclusively in adolescent males who are often fair-skinned and red headed. There is also an association with familial adenomatous polypos. It is believed to arise within the fibrovascular stroma of the posterolateral wall of the roof of the nasal cavity. Surgical removal is the treatment of choice. However, because of its locally aggressive nature and intracranial extension, recurrence rates can be as high as 20%. In about 9% of cases it is fatal, with death being caused by hemorrhage and intracranial extension.

Sinonasal (Schneiderian) Papilloma. Sinonasal papilloma is a benign neoplasm arising from the respiratory or schneiderian mucosa lining the nasal cavity and paranasal sinuses. These lesions occur in three forms: *exophytic* (most common), *endophytic (inverted; most important biologically)*, and *cylindrical*. HPV DNA, often types 6 and 11, has been identified in the exophytic and endophytic lesions, but not the cylindrical type. Sinonasal papillomas are observed most commonly in adult males between the ages of 30 and 60. Because of its uniquely aggressive biologic behavior, only the endophytic form is discussed here. Endophytic sinonasal papillomas are benign but locally aggressive neoplasms occurring in both the nose and the paranasal sinuses. As the name implies, the papillomatous proliferation of squamous epithelium, instead of producing an exophytic growth, invaginates into the underlying stroma (Fig. 16-9). It has a high rate of recurrence if not adequately excised, with the potentially serious complication of invasion of the orbit or cranial vault. Furthermore, malignant transformation is observed in approximately 10% of cases.

Olfactory Neuroblastoma (Esthesioneuroblastoma). Olfactory neuroblastomas arise from the neuroectodermal olfactory cells present within the mucosa, particularly in the superior aspect of the nasal cavity. There is a bimodal age distribution with peaks at 15 and 50 years of age. The patients typically present with nasal obstruction and/or epistaxis. Histologically, olfactory neuroblastomas are one of the small, blue, round cell neoplasms that include lymphoma, small cell carcinoma, Ewing sarcoma/peripheral neuroectodermal tumor, rhabdomyosarcoma, melanoma, and sinonasal undifferentiated carcinoma. Typically, olfactory neuroblastomas are composed of nests and lobules of well-circumscribed cells that are separated by a fibrovascular stroma. Many of the tumors also contain a fibrillary matrix that ultrastructurally corresponds to tangles of neuronal cell processes. Because these neoplasms are of neuroendocrine origin, the tumor cells contain membrane-bound secretory granules on electron microscopy and express neuron-specific enolase, synaptophysin, CD56, and chromogranin by immunohistochemistry. Depending on the stage and grade of a particular

Figure 16-9 Inverted papilloma. The masses of squamous epithelium are growing inward; hence, the term *inverted*.

neoplasm, combinations of surgery, radiation therapy, and chemotherapy yield 5-year survival rates of 40% to 90%.

NUT Midline Carcinoma. This is an uncommon tumor that may occur in the nasopharynx, the salivary gland, or in other midline structures in the thorax or abdomen. It can occur at any age, from infancy to late adulthood. Its true incidence is not known, as it easily mistaken for squamous cell carcinoma, which it resembles morphologically. It is extremely aggressive and resistant to conventional therapy; as a result, most patients survive for less than a year following diagnosis.

Although rare, NUT midline carcinoma is pathogenically interesting. It is uniformly associated with translocations that create fusion genes encoding chimeric proteins comprised of most of NUT, a chromatin regulator, and a portion of a “chromatin reader” protein, usually BRD4. Drugs that displace BRD4-NUT from chromatin induce NUT midline carcinoma cells to terminally differentiate, a mechanism of oncogenesis that is common in acute leukemias but unusual for epithelial cancers. Targeted therapy with BRD4-NUT inhibitors is now being tested in the clinic and offers hope for those with this lethal form of cancer.

Nasopharyngeal Carcinoma. Nasopharyngeal carcinoma is characterized by a distinctive geographic distribution, a close anatomic relationship to lymphoid tissue, and an association with EBV infection. The nomenclature for nasopharyngeal carcinomas is in constant flux. However, at present the disease is thought to take one of three patterns: (1) keratinizing squamous cell carcinomas, (2) nonkeratinizing squamous cell carcinomas, and (3) undifferentiated/basaloid carcinomas that have an abundant non-neoplastic, lymphocytic infiltrate. The last pattern has often been called *lymphoepithelioma*. While widely used in clinical practice, this descriptive term should be avoided.

Three factors influence the origins of these neoplasms: (1) heredity, (2) age, and (3) infection with EBV. Nasopharyngeal carcinomas are particularly common in some parts of Africa, where they are the most frequent childhood cancer. In contrast, in southern China, they are very common in adults but rarely occur in children. In the United States they are rare in both adults and children. In addition to EBV infection, diets high in nitrosamines, such as fermented foods and salted fish, as well as other environmental insults such as smoking and chemical fumes, have been linked to the disease. In the nonkeratinizing form, most patients have anti-EBV antibodies against early antigens or viral capsid antigens.

MORPHOLOGY

On histologic examination, the keratinizing and nonkeratinizing squamous cell lesions resemble usual well-differentiated and poorly differentiated squamous cell carcinomas arising in other locations. The undifferentiated/basaloid variant is composed of large epithelial cells with oval or round vesicular nuclei, prominent nucleoli, and indistinct cell borders disposed in a syncytium-like array (Fig. 16-10B). Admixed with the epithelial cells are abundant, mature, normal-appearing lymphocytes, which are predominantly T cells. In addition, EBV genomes can be detected in the serum by PCR, or EBV encoded RNAs such as EBER-1 or proteins such as LMP-1 can be identified in the malignant epithelial cells by in situ hybridization (Fig. 16-10C) or immunohistochemistry, respectively.

Primary nasopharyngeal carcinomas are often clinically occult for long periods, and present with nasal obstruction, epistaxis, and often metastases to the cervical lymph nodes in as many as 70% of the patients. Radiotherapy is the standard treatment. For all types, there is an overall 5-year survival of approximately 60%. Depending on stage, the 5-year survival for the nonkeratinizing type is 70% to 98%, while the 5-year survival for the keratinizing form is approximately 20%. These differences in survival have been attributed to the fact that the undifferentiated carcinoma is the most radiosensitive, while the keratinizing squamous cell carcinoma is the least radiosensitive.

Larynx

The most common disorders of the larynx are inflammatory. Tumors are uncommon but are amenable to resection, though often at the price of loss of natural voice.

Inflammations

Laryngitis may occur as the sole manifestation of allergic, viral, bacterial, or chemical insult, but it is more commonly part of a generalized upper respiratory tract infection or the result of heavy exposure to environmental toxins such as tobacco smoke. It may also occur in association with gastroesophageal reflux due to the irritating effect of gastric contents. The larynx may also be affected in systemic infections, such as tuberculosis and diphtheria. Although most infections are self-limited, they may at times be serious, especially in infancy or childhood, when mucosal congestion, exudation, or edema may cause

Figure 16-10 Nasopharyngeal carcinoma, undifferentiated type. **A**, Computed tomography study demonstrating thickening of the nasopharyngeal region (arrow) and an enlarged cervical lymph node (double arrow). **B**, The syncytium-like clusters of epithelium are surrounded by lymphocytes. **C**, In situ hybridization for EBER-1, a small nuclear RNA encoded by EBV.

laryngeal obstruction. In particular, in infants and young children with their small airways, laryngoepiglottitis, caused by respiratory syncytial virus, *Haemophilus influenzae*, or β -hemolytic streptococci may induce such sudden swelling of the epiglottis and vocal cords as to constitute a medical emergency. This form of disease is uncommon

Figure 16-11 Diagrammatic comparison of a singer's nodule, a benign papilloma and an exophytic carcinoma of the larynx to highlight the difference in their clinical appearance.

in adults because of the larger size of the larynx and the stronger accessory muscles of respiration. *Croup* is the name given to laryngotracheobronchitis in children, in which the inflammatory narrowing of the airway produces the inspiratory stridor so frightening to parents. The most common form of laryngitis, encountered in heavy smokers, predisposes to squamous epithelial metaplasia and sometimes overt carcinoma.

Reactive Nodules (Vocal Cord Nodules and Polyps)

Reactive nodules, also called polyps, sometimes develop on the vocal cords, most often in heavy smokers or in individuals who impose great strain on their vocal cords (singer's nodules) (Fig. 16-11). By convention, singers' nodules are bilateral lesions and polyps are unilateral. Adults are most often affected. These nodules are smooth, rounded, sessile or pedunculated excrescences, generally only a few millimeters in the greatest dimension, located usually on the true vocal cords. They are typically covered by squamous epithelium that may become keratotic, hyperplastic, or even slightly dysplastic. The core of the nodule is a loose myxoid connective tissue that may be variably fibrotic or punctuated by numerous vascular channels. When nodules on opposing vocal cords impinge on each other, the mucosa may undergo ulceration. Because of their strategic location and accompanying inflammation, they characteristically change the character of the voice and often cause progressive hoarseness. They virtually never give rise to cancers.

Squamous Papilloma and Papillomatosis

Laryngeal squamous papillomas are benign neoplasms, usually located on the true vocal cords, that form soft, raspberry-like proliferations rarely more than 1 cm in diameter (Fig. 16-11). On histologic examination, the papillomas are made up of multiple slender, finger-like projections supported by central fibrovascular cores and covered by an orderly stratified squamous epithelium. When the papillomas are on the free edge of the vocal cord, trauma

may lead to ulceration that can be accompanied by hemoptysis.

Papillomas are usually single in adults but are often multiple in children, in whom they are referred to as *juvenile laryngeal papillomatosis*. However, multiple recurring papillomas also occur in adults. *The lesions are caused by HPV types 6 and 11.* They do not become malignant, but frequently recur. They often spontaneously regress at puberty, but some affected patients endure numerous surgeries before this occurs.

Carcinoma of the Larynx

Carcinoma of the larynx is typically a squamous cell carcinoma seen in male chronic smokers.

Sequence of Hyperplasia-Dysplasia-Carcinoma. A spectrum of epithelial alterations is seen in the larynx. They range from *hyperplasia, atypical hyperplasia, dysplasia, and carcinoma in situ to invasive carcinoma*. Grossly, the epithelial changes vary from smooth, white or reddened focal thickenings, sometimes roughened by keratosis, to irregular verrucous or ulcerated white-pink lesions (Fig. 16-12).

There are all gradations of epithelial hyperplasia of the true vocal cords, and the likelihood of the development of an overt carcinoma is directly proportional to the grade of dysplasia when the lesion is first seen. Orderly hyperplasias have almost no potential for malignant transformation, but the risk rises to 1% to 2% during the span of 5 to 10 years with mild dysplasia and 5% to 10% with severe dysplasia. Only histologic evaluation can determine the gravity of the changes.

The epithelial alterations described above are most often related to tobacco smoke, the risk being proportional to the level of exposure. Indeed, up to the point of cancer, the changes often regress after cessation of smoking. Together

Figure 16-12 Laryngeal carcinoma. Note the large, ulcerated, fungating lesion involving the vocal cord and pyriform sinus.

smoking and alcohol increase the risk substantially. Other factors that may contribute to increased risk include nutritional factors, exposure to asbestos, irradiation, and infection with HPV.

MORPHOLOGY

About 95% of laryngeal carcinomas are typical squamous cell tumors. The tumor usually develops on the vocal cords, but it may also arise above or below the cords, on the epiglottis or aryepiglottic folds, or in the pyriform sinuses. Those confined within the larynx proper are termed **intrinsic**, whereas those that arise or extend outside the larynx are called **extrinsic**. Squamous cell carcinomas of the larynx follow the growth pattern of other squamous cell carcinomas. They begin as in situ lesions that later appear as pearly gray, wrinkled plaques on the mucosal surface, ultimately ulcerating and fungating (Fig. 16-12). The degree of anaplasia of the laryngeal tumors is highly variable. Sometimes massive tumor giant cells and multiple bizarre mitotic figures are seen. As expected with lesions arising from recurrent exposure to environmental carcinogens, adjacent mucosa may demonstrate squamous cell hyperplasia with foci of dysplasia or even carcinoma in situ.

Carcinoma of the larynx is most commonly seen in men in the sixth decade of life and often manifests clinically as

persistent hoarseness, dysphagia, and dysphonia. Prognosis is highly dependent on clinical staging. Organ preservation techniques (laser surgery, microsurgery, and radiation therapy) are being used with greater frequency, particularly with early disease. Combined chemotherapy and radiation therapy, with or without salvage laryngectomy, may be required for more advanced or recurrent disease.

KEY CONCEPTS

Upper Airways

- **Rhinitis** can be infectious or allergic in nature. When recurrent it can lead to chronic rhinitis, sinusitis, and the development of nasal polyps.
- **Pharyngitis** and **tonsillitis** are common upper respiratory tract viral infections typically caused by rhinoviruses, echoviruses, and adenoviruses.
- **Nasopharyngeal carcinoma** is most often caused by the EBV and is common among children in Africa and Asian adults.
- **Laryngitis** can be caused by a host of etiologies, including allergic, viral, bacterial, and chemical insults.
- **Vocal cord nodules** and **polyps** are reactive lesions seen in smokers or individuals who strain their vocal cords.
- **Laryngeal squamous cell carcinoma** is a disease of older males, related to smoking and alcohol use.

EARS

Although disorders of the ear rarely shorten life, many impair its quality. The most common aural disorders, in descending order of frequency, are (1) acute and chronic otitis (most often involving the middle ear and mastoid), sometimes leading to a cholesteatoma; (2) symptomatic otosclerosis; (3) aural polyps; (4) labyrinthitis; (5) carcinomas, largely of the external ear; and (6) paragangliomas, found mostly in the middle ear. Only those conditions that have distinctive morphologic features (save for labyrinthitis) are described. Paragangliomas are discussed later.

Inflammatory Lesions

Inflammations of the ear—*otitis media, acute or chronic*—occur mostly in infants and children. These lesions are typically viral in nature and produce a serous exudate but may become suppurative with superimposed bacterial infection. The most common bacteria in the acute infection are *Streptococcus pneumoniae*, non-typeable *H. influenzae*, and *Moraxella catarrhalis*.

Repeated bouts of acute otitis media with failure of resolution lead to chronic disease. The causative agents of chronic disease are usually *Pseudomonas aeruginosa*, *Staphylococcus aureus*, or a fungus; sometimes a mixed flora is the cause. Chronic infection has the potential to perforate the eardrum, encroach on the ossicles or labyrinth, spread into the mastoid spaces, and even penetrate into the cranial vault to produce a temporal cerebritis or abscess. Otitis media in the diabetic person, when caused by *P. aeruginosa*, is especially aggressive and spreads widely, causing destructive necrotizing otitis media.

Cholesteatomas, associated with chronic otitis media, are non-neoplastic, cystic lesions 1 to 4 cm in diameter, lined by keratinizing squamous epithelium or metaplastic mucus-secreting epithelium, and filled with amorphous debris (derived largely from desquamated epithelium). Sometimes they contain spicules of cholesterol. Their pathogenesis is not clear, but it is proposed that chronic inflammation and perforation of the eardrum with ingrowth of the squamous epithelium or metaplasia of the secretory epithelial lining of the middle ear are responsible for the formation of a squamous cell nest that becomes cystic. A chronic inflammatory reaction surrounds the keratinous cyst. Sometimes, the cyst ruptures, increasing the inflammatory reaction and inducing the formation of giant cells that enclose partially necrotic squames and other particulate debris. These lesions, by progressive enlargement, can erode into the ossicles, the labyrinth, the adjacent bone, or the surrounding soft tissue and sometimes produce visible neck masses.

Otosclerosis

As the name implies, **otosclerosis refers to abnormal bone deposition in the middle ear about the rim of the oval window into which the footplate of the stapes fits**. Both ears are usually affected. At first there is fibrous ankylosis of the footplate, followed in time by bony overgrowth anchoring it into the oval window. The degree of immobilization governs the severity of the hearing loss. This condition usually begins in the early decades of life; minimal degrees of this derangement are exceedingly common

in the United States in young to middle-aged adults, but fortunately more severe symptomatic otosclerosis is relatively uncommon. In most instances it is familial, following an autosomal dominant transmission with variable penetrance. The basis for the osseous overgrowth is completely obscure, but it appears to represent uncoupling of normal bone resorption and bone formation. Thus, it begins with bone resorption, followed by fibrosis and vascularization of the temporal bone in the immediate vicinity of the oval window, in time replaced by dense new bone anchoring the footplate of the stapes. In most instances the process is slowly progressive over the span of decades, leading eventually to marked hearing loss.

Tumors

Epithelial and mesenchymal tumors that arise in the ear—external, middle, internal—all are rare save for basal cell or squamous cell carcinomas of the pinna (external ear). These carcinomas tend to occur in elderly men and are associated with sun exposure. By contrast, squamous cell

carcinomas of the canal occur most often in middle-aged to elderly women and are not associated with sun exposure. Wherever they arise they morphologically resemble their counterparts in other skin locations, beginning as papules that extend and eventually erode and invade locally. Basal cell and squamous cell lesions of the pinna are locally invasive but they rarely spread. Squamous cell carcinomas arising in the external canal may invade the cranial cavity or metastasize to regional nodes, accounting for a 5-year mortality of about 50%.

KEY CONCEPTS

Ears

- **Infections** of the ear are common in children and typically viral in etiology. Chronic infections can be complicated by bacterial infections, which can lead to secondary complications including perforated eardrum as well as spreading to the ossicles or mastoid spaces.
- **Otosclerosis**, with its associated hearing loss, is caused by the abnormal deposition of bone in the middle ear.

NECK

Most of the conditions that involve the neck are described elsewhere (e.g., squamous cell and basal cell carcinomas of the skin, melanomas, lymphomas), or they are a component of a systemic disorder (e.g., generalized rashes, the lymphadenopathy of infectious mononucleosis or tonsillitis). What remains to be considered here are a few uncommon lesions unique to the neck.

Branchial Cyst (Cervical Lymphoepithelial Cyst)

The vast majority of these cysts are thought to arise from remnants of the second branchial arch and are most commonly observed in young adults between the ages of 20 and 40. These benign cysts usually appear on the upper lateral aspect of the neck along the sternocleidomastoid muscle. Clinically, the cysts are well circumscribed, 2 to 5 cm in diameter, with fibrous walls usually lined by stratified squamous or pseudostratified columnar epithelium. The cyst wall typically contains lymphoid tissue with prominent germinal centers. The contents of the cysts may be clear and watery or mucinous and may contain desquamated, granular cellular debris. The cysts enlarge slowly, are rarely the site of malignant transformation, and generally are readily excised. Similar lesions sometimes appear in the parotid gland or in the oral cavity beneath the tongue.

Thyroglossal Duct Cyst

Embryologically, the thyroid anlage begins in the region of the foramen cecum at the base of the tongue; as the gland develops it descends to its definitive midline location in the anterior neck. Remnants of this developmental tract may persist, producing cysts, 1 to 4 cm in diameter, which

may be lined by stratified squamous epithelium, when located near the base of the tongue, or by pseudostratified columnar epithelium in lower locations. Transitional patterns are also encountered. The connective tissue wall of the cyst may harbor lymphoid aggregates or remnants of recognizable thyroid tissue. The treatment is excision. Malignant transformation within the lining epithelium has been reported but is rare.

Paraganglioma (Carotid Body Tumor)

Paraganglia are clusters of neuroendocrine cells associated with the sympathetic and parasympathetic nervous systems. As a result, these neoplasms can be seen in various regions of the body. While the most common location of these tumors is within the adrenal medulla, where they give rise to pheochromocytomas (Chapter 24), approximately 70% of extra-adrenal paragangliomas occur in the head and neck region. The pathogenesis of paragangliomas is not fully understood. However, loss of function mutations in genes encoding succinate dehydrogenase subunits or cofactors, proteins that participate in mitochondrial oxidative phosphorylation, occur frequently in both hereditary and spontaneous paragangliomas. How these mutations contribute to tumor development is not yet clear, but it is suspected that they do so by altering cellular metabolism, which you will recall is one of the hallmarks of neoplasia (Chapter 7). Interestingly, the incidence of these tumors is greater in people living at high altitudes.

Paragangliomas typically develop in two locations:

- Paravertebral paraganglia (e.g., organs of Zuckerkandl and, rarely, bladder). Such tumors have sympathetic connections and are chromaffin-positive, a stain that detects catecholamines.

- Paraganglia related to the great vessels of the head and neck, the so-called aorticopulmonary chain, including the *carotid bodies* (most common); aortic bodies; jugulo-tympanic ganglia; ganglion nodosum of the vagus nerve; and clusters located about the oral cavity, nose, nasopharynx, larynx, and orbit. These are innervated by the parasympathetic nervous system and infrequently release catecholamines.

MORPHOLOGY

The **carotid body tumor** is a prototype of a parasympathetic paraganglioma. It rarely exceeds 6 cm in diameter and arises close to or envelops the bifurcation of the common carotid artery. The tumor tissue is red-pink to brown. The microscopic features of all paragangliomas, wherever they arise, are remarkably uniform. They are chiefly composed of nests (**zellballen**) of round to oval chief cells (neuroectodermal in origin) that are surrounded by delicate vascular septae (Fig. 16-13). The tumor cells contain abundant, clear or granular, eosinophilic cytoplasm and uniform, round to ovoid, sometimes vesicular, nuclei. In most tumors there is little cellular pleomorphism, and mitoses are scant. The chief cells stain strongly for neuroendocrine markers such as chromogranin, synaptophysin, neuron-specific enolase, CD56, and CD57. In addition, there is a supporting network of spindle-shaped stromal cells, collectively called sustentacular cells, which are positive for S-100 protein. Electron microscopy often discloses well-demarcated neuroendocrine granules in paravertebral tumors, but their number can be highly variable and they tend to be scant in nonfunctioning tumors.

Carotid body tumors (and paragangliomas in general) are rare. They are slow-growing and painless masses that usually arise in the fifth and sixth decades of life. They commonly occur singly and sporadically but may be familial, with autosomal dominant transmission in the multiple endocrine neoplasia 2 syndrome (Chapter 24); in this setting they are often multiple and sometimes bilateral. Carotid body tumors frequently recur after incomplete resection and, despite their benign appearance, may metastasize to regional lymph nodes and distant sites. About 50% ultimately prove fatal, largely because of infiltrative growth. Unfortunately, it is almost impossible to predict the clinical course of a carotid body tumor—mitoses, pleomorphism, and even vascular invasion are not reliable indicators.

Figure 16-13 Carotid body tumor. **A**, Low-power view showing tumor clusters separated by septa (Zellballen). The septae are marked by bright red capillaries. **B**, Immunohistochemistry demonstrating positivity for chromogranin in the tumor cells.

KEY CONCEPTS

Neck

- **Branchial cysts** arise from the region of the second branchial pouch and are typically seen in young adults.
- **Thyroglossal duct cysts** arise as a result of incomplete descent of the thyroid analog from the foramen cecum in the base of the tongue.
- Seventy percent of **paragangliomas** are observed in the head and neck region that often develop in the fifth decade of life. While often sporadic in appearance, they may be associated with multiple endocrine neoplasia 2 syndrome.

SALIVARY GLANDS

There are three major salivary glands—parotid, submandibular, and sublingual—as well as innumerable minor salivary glands distributed throughout the mucosa of the oral cavity. Inflammatory or neoplastic disease may develop within any of these.

Xerostomia

Xerostomia is defined as a *dry mouth* resulting from a decrease in the production of saliva. Its incidence among

various populations has been reported to be as high as 20% in individuals over the age of 70. It is a major feature of the autoimmune disorder Sjögren syndrome (Chapter 6), in which it is usually accompanied by dry eyes. A lack of salivary secretions is also a major complication of radiation therapy. However, xerostomia is most frequently a side-effect of many commonly prescribed classes of medications, including anticholinergic, antidepressant/antipsychotic, diuretic, antihypertensive, sedative, muscle relaxant, analgesic, and antihistamine drugs. Xerostomia may present as dry mucosa and/or atrophy of the papillae

of the tongue, with fissuring and ulcerations. In conditions such as Sjögren syndrome, concomitant inflammatory enlargement of the salivary glands may also be observed. Complications of xerostomia include increased rates of dental caries, candidiasis, as well as difficulty in swallowing and speaking.

Inflammation (Sialadenitis)

Sialadenitis may be induced by trauma, viral or bacterial infection, or autoimmune disease. Mucoceles are the most common type of inflammatory salivary gland lesion. The most common form of viral sialadenitis is mumps, in which the major salivary glands, particularly the parotids, are affected (Chapter 8). Other glands (e.g., the pancreas and testes) may also be involved. As already discussed, autoimmunity underlies Sjögren syndrome, in which widespread inflammation of the salivary glands and the mucus-secreting glands of the mucosa induces xerostomia. Concomitant involvement of the lacrimal glands in Sjögren syndrome may also produce dry eyes—*keratoconjunctivitis sicca*.

Mucocele. This is the most common lesion of the salivary glands. It results from either blockage or rupture of a salivary gland duct, with consequent leakage of saliva into the surrounding connective tissue stroma. Mucoceles are most often found on the lower lip and are the result of trauma (Fig. 16-14A). They occur at all ages but are most common in toddlers, young adults, and the elderly, who are more prone to falling. Clinically, they present as fluctuant swellings of the lower lip that have a blue translucent hue. Patients may report a history of changes in the size of the lesion, particularly in association with meals. Histologically, mucoceles are pseudocysts with cyst-like spaces lined by inflammatory granulation tissue or by fibrous connective tissue. The cystic spaces are filled with mucin and inflammatory cells, particularly macrophages (Fig. 16-14B). Complete excision of the cyst and its accompanying minor salivary gland

lobule is required, as incomplete excision may lead to recurrence.

Ranula is a term reserved for epithelial-lined cysts that arise when the duct of the sublingual gland has been damaged. A ranula may become so large that it develops into a “plunging ranula”, a colorful description of a cyst that has dissected through the connective tissue stroma connecting the two bellies of the mylohyoid muscle.

Sialolithiasis and Nonspecific Sialadenitis. Nonspecific bacterial sialadenitis, most often involving the major salivary glands, particularly the submandibular glands, is a common condition, usually secondary to ductal obstruction produced by stones (*sialolithiasis*). The common offenders are *S. aureus* and *Streptococcus viridans*. The stone formation is sometimes related to obstruction of the orifices of the salivary glands by impacted food debris or by edema about the orifice after some injury. Frequently, no underlying cause can be detected. Decreased secretory function may also predispose to secondary bacterial invasion, as sometimes occurs in patients receiving long-term phenothiazines that suppress salivary secretion. Decreased salivary secretions caused by dehydration may lead to the development of bacterial suppurative parotitis in elderly patients with a recent history of major thoracic or abdominal surgery.

Whatever the origin, the obstructive process and bacterial invasion lead to a nonspecific inflammation of the affected glands that may be largely interstitial or, when induced by staphylococcal or other pyogens, may be associated with overt suppurative necrosis and abscess formation. Unilateral involvement of a single gland is the rule. The inflammatory involvement causes painful enlargement and sometimes a purulent ductal discharge.

Neoplasms

Despite their relatively simple morphology, the salivary glands give rise to no fewer than 30 histologically distinct tumors. A classification and the relative incidence of

Figure 16-14 Mucocele. **A**, Fluctuant fluid-filled lesion on the lower lip subsequent to trauma. **B**, Cystlike cavity filled with mucinous material and lined by organizing granulation tissue.

Table 16-4 Histologic Classification and Incidence of the Most Common Benign and Malignant Tumors of the Salivary Glands

Benign	Malignant
Pleomorphic adenoma (50%) (mixed tumor)	Mucoepidermoid carcinoma (15%)
Warthin tumor (5%-10%)	Adenocarcinoma (NOS) (10%)
Oncocytoma (1%)	Acinic cell carcinoma (5%)
Other adenomas (5%-10%)	Adenoid cystic carcinoma (5%)
Basal cell adenoma	Malignant mixed tumor (3%-5%)
Canalicular adenoma	Squamous cell carcinoma (1%)
Ductal papillomas	Other carcinomas (2%)

NOS, Not otherwise specified.

Data from Ellis GL, Auclair PL: Tumors of the Salivary Glands. Atlas of Tumor Pathology, Fourth Series. Washington, DC, Armed Forces Institute of Pathology, 2008.

benign and malignant tumors is listed in Table 16-4; not included are the rare benign and malignant mesenchymal neoplasms.

As indicated in Table 16-4, a small number of neoplasms makes up more than 90% of salivary gland tumors, and so our discussion is restricted to these. Overall, these neoplasms are relatively uncommon and represent less than 2% of all tumors in humans. About 65% to 80% arise within the parotid, 10% in the submandibular gland, and the remainder in the minor salivary glands, including the sublingual glands. Approximately 15% to 30% of tumors in the parotid glands are malignant. In contrast, approximately 40% of submandibular, 50% of minor salivary gland, and 70% to 90% of sublingual tumors are cancerous. Thus, **the likelihood of a salivary gland tumor being malignant is more or less inversely proportional to the size of the gland.**

These tumors usually occur in adults, with a slight female predominance, but about 5% occur in children younger than age 16 years. Warthin tumors occur much more often in males than in females, perhaps reflecting the historically higher prevalence of smoking, a predisposing factor, among men. The benign tumors most often appear in the fifth to seventh decades of life. The malignant ones tend to appear somewhat later. Whatever the histologic pattern, neoplasms in the parotid glands produce distinctive swellings in front of and below the ear. In general, when they are first diagnosed, both benign and malignant lesions range from 4 to 6 cm in diameter and are mobile on palpation except in the case of neglected malignant tumors. Although benign tumors are known to have been present usually for many months to several years before coming to clinical attention, cancers are generally detected more quickly because of their rapid growth. Ultimately, however, there are no reliable clinical criteria to differentiate benign from malignant lesions.

Pleomorphic Adenoma

Pleomorphic adenomas are benign tumors that consist of a mixture of ductal (epithelial) and myoepithelial cells, and therefore they show both epithelial and mesenchymal differentiation. Because of their remarkable histologic diversity, these neoplasms have also been called *mixed tumors*. They represent about 60% of tumors in the parotid, are less common in the submandibular glands, and are relatively rare in the minor salivary glands. They reveal

epithelial elements dispersed throughout the matrix along with varying degrees of myxoid, hyaline, chondroid (cartilaginous), and even osseous tissue. In some tumors the epithelial elements predominate; in others they are present only in widely dispersed foci.

Little is known about the origins of these neoplasms, except that radiation exposure increases the risk. Equally uncertain is the histogenesis of the various components. A currently popular view is that all neoplastic elements, including those that appear mesenchymal, are of either myoepithelial or ductal reserve cell origin (hence the designation *pleomorphic adenoma*). A high fraction of cases are associated with chromosomal rearrangements involving *PLAG1*, a gene encoding a transcription factor that is overexpressed as a result of these rearrangements. *PLAG1* overexpression appears to upregulate expression of a number of genes that increase cell growth, such as components of growth factor receptor signaling pathways.

MORPHOLOGY

Most pleomorphic adenomas present as rounded, well-demarcated masses rarely exceeding 6 cm in the greatest dimension (Fig. 16-15). Although they are encapsulated, in some locations (particularly the palate) the capsule is not fully developed, and expansile growth produces protrusions into the surrounding gland, which may lead to recurrences if the tumor is merely enucleated. The cut surface is gray-white with myxoid and blue translucent areas of chondroid (cartilage-like).

The dominant histologic feature is the great heterogeneity mentioned. The epithelial elements resembling ductal cells or myoepithelial cells are arranged in duct formations, acini, irregular tubules, strands, or sheets of cells. These elements are typically dispersed within a mesenchyme-like background of loose myxoid tissue containing islands of cartilage and, rarely, foci of bone (Fig. 16-16). Sometimes the epithelial cells form well-developed ducts lined by cuboidal to columnar cells with an underlying layer of deeply chromatic, small myoepithelial cells. In other instances there may be strands or sheets of myoepithelial cells. Islands of well-differentiated squamous epithelium may also be present. In most cases there is no epithelial dysplasia or evident mitotic activity. There is no difference in biologic behavior between the tumors composed largely of epithelial elements and those composed largely of seemingly mesenchymal elements.

Clinical Features. These tumors present as painless, slow-growing, mobile, discrete masses within the parotid or submandibular areas or in the buccal cavity. The recurrence rate (perhaps months to years later) with parotidectomy is about 4% but, with simple enucleation approaches 25%.

A carcinoma arising in a pleomorphic adenoma is referred to variously as a *carcinoma ex pleomorphic adenoma* or a *malignant mixed tumor*. The incidence of malignant transformation increases with time, being about 2% for tumors present less than 5 years and almost 10% for those present for more than 15 years. The cancer usually takes the form of an adenocarcinoma or undifferentiated carcinoma. Like cancers elsewhere, these malignancies are highly infiltrative and tend to completely overrun and replace the preexisting pleomorphic adenoma. This may make it difficult to substantiate the diagnosis of carcinoma

Figure 16-15 Pleomorphic adenoma. **A**, Slowly enlarging neoplasm in the parotid gland of many years duration. **B**, The bisected, sharply circumscribed, yellow-white tumor can be seen surrounded by normal salivary gland tissue.

ex pleomorphic adenoma, which requires that recognizable traces of pleomorphic adenoma be found. Regrettably, these cancers, when they appear, are among the most aggressive of all salivary gland malignant neoplasms, producing mortality rates of 30% to 50% at 5 years.

Warthin Tumor (Papillary Cystadenoma Lymphomatosum)

This curious benign neoplasm with its intimidating histologic name is the second most common salivary gland neoplasm. It arises almost *exclusively in the parotid gland* (the only tumor virtually restricted to the parotid) and occurs more commonly in males than in females, usually in the fifth to seventh decades of life. About 10% are multifocal and 10% bilateral. Smokers have eight times the risk of nonsmokers for developing these tumors.

Figure 16-16 Pleomorphic adenoma. **A**, Low-power view showing a well-demarcated tumor with adjacent normal salivary gland parenchyma. **B**, High-power view showing epithelial cells and myoepithelial cells within a chondroid matrix material.

MORPHOLOGY

Most Warthin tumors are round to oval encapsulated masses, 2 to 5 cm in diameter, usually arising in the superficial parotid gland, where they are readily palpable. Transection reveals a pale gray surface punctuated by narrow cystic or cleftlike spaces filled with mucinous or serous secretions. On microscopic examination these spaces are lined by a double layer of neoplastic epithelial cells resting on a dense lymphoid stroma sometimes bearing germinal centers (Fig. 16-17). The spaces are frequently narrowed by polypoid projections of the lymphoepithelial elements. The double layer of lining cells is distinctive; the upper layer consists of palisading columnar cells with abundant, finely granular, eosinophilic cytoplasm, while the lower layer is comprised of cuboidal to polygonal cells. The granular appearance of the cytoplasm of the upper layer of cells is due to the presence of numerous mitochondria, a feature referred to as “oncocytic”. Secretory cells are dispersed in the columnar cell layer, accounting for the secretions within the dilated lumens. On occasion, there are foci of squamous metaplasia.

The histogenesis of these tumors has long been debated. The epithelial component of the tumor appears to be neoplastic, and presumably these cells make factors that serve as attractants for the lymphoid cells, which are believed to be reactive. Rarely, Warthin tumors have arisen within cervical lymph nodes, a finding that should not be mistaken for metastases. These neoplasms are benign, with recurrence rates of only 2% after resection.

Mucoepidermoid Carcinoma

These neoplasms are composed of variable mixtures of squamous cells, mucus-secreting cells, and intermediate

Figure 16-17 Warthin tumor. **A**, Low-power view showing epithelial and lymphoid elements. Note the follicular germinal center beneath the epithelium. **B**, Cystic spaces separate lobules of neoplastic epithelium consisting of a double layer of eosinophilic epithelial cells based on a reactive lymphoid stroma.

cells. They represent about 15% of all salivary gland tumors, and while they occur mainly (60% to 70%) in the parotids, they account for a large fraction of salivary gland neoplasms in the other glands, particularly the minor salivary glands. In more than half the cases, this tumor is associated with a balanced (11;19) (q21;p13) chromosomal translocation that creates a fusion gene composed of portions of the *MECT1* and *MAML2* genes. The *MECT1-MAML2* fusion gene is believed to play a key role in the genesis of this tumor, possibly by perturbing the Notch and cAMP-dependent signaling pathways. Overall, they are the most common form of primary malignant tumor of the salivary glands.

MORPHOLOGY

Mucoepidermoid carcinomas can grow as large as 8 cm in diameter and although they are apparently circumscribed, they lack well-defined capsules and are often infiltrative at the margins. Pale and gray-white on transection, they frequently contain small, mucin-containing cysts. The basic histologic pattern is that of cords, sheets, or cystic configurations of squamous, mucous, or intermediate cells (Fig. 16-18A). The hybrid cell types often have squamous features, with small to large mucus-filled vacuoles, best seen when highlighted with mucin stains (Fig. 16-18B). The tumor cells may be regular and benign appearing or, alternatively, highly anaplastic and unmistakably malignant. Accordingly, mucoepidermoid carcinomas are subclassified into low, intermediate, or high grade types.

The clinical course and prognosis depend on the grade of the neoplasm. Low-grade tumors may invade locally and recur in about 15% of cases, but only rarely do they metastasize and so yield a 5-year survival rate of more than 90%. By contrast, high-grade neoplasms and, to a lesser extent, intermediate-grade tumors are invasive and difficult to excise and so recur in about 25% to 30% of cases and, in 30% of cases, metastasize to distant sites. The 5-year survival rate in patients with these tumors is only 50%.

Other Salivary Gland Tumors

Two less common neoplasms merit brief description: adenoid cystic carcinoma and acinic cell carcinoma.

Adenoid cystic carcinoma is a relatively uncommon tumor, which in approximately 50% of cases is found in the minor salivary glands (in particular the palatine glands). Among the major salivary glands, the parotid and submandibular glands are the most common locations. Similar neoplasms

Figure 16-18 **A**, Mucoepidermoid carcinoma growing in nests composed of squamous cells as well as clear vacuolated cells containing mucin. **B**, Mucicarmine stains the mucin reddish pink.

have been reported in the nose, sinuses, upper airways, breast, and elsewhere.

MORPHOLOGY

In gross appearance, they are generally small, poorly encapsulated, infiltrative, gray-pink lesions. On histologic evaluation, they are composed of small cells having dark, compact nuclei and scant cytoplasm. These cells tend to be disposed in tubular, solid, or cribriform patterns reminiscent of cylindromas arising in the adnexa of the skin (Chapter 25). The spaces between the tumor cells are often filled with a hyaline material thought to represent excess basement membrane (Fig. 16-19A). Other less common histologic patterns have been designated as tubular and solid variants.

Although slow growing, adenoid cystic carcinomas are unpredictable tumors with a tendency to invade perineural spaces (Fig. 16-19B), and they are stubbornly recurrent. Eventually, 50% or more disseminate widely to distant sites such as bone, liver, and brain, sometimes decades after attempted removal. Thus, although the 5-year survival rate is about 60% to 70%, it drops to about 30% at 10 years and 15% at 15 years. Neoplasms arising in the minor salivary glands have, on average, a poorer prognosis than those that arise in the parotid glands.

Acinic cell carcinoma is composed of cells resembling the normal serous acinar cells of salivary glands. It is relatively uncommon, representing only 2% to 3% of salivary gland tumors. Most arise in the parotids; the remainder arise in the submandibular glands. It rarely involves the minor glands, which normally have only a scant number of serous cells. Like Warthin tumor, it is sometimes bilateral or multicentric. The tumors are generally small, discrete lesions that may appear encapsulated. On histologic examination, they reveal a variable architecture and cell morphology. Most characteristically, the cells have clear cytoplasm but the cells are sometimes solid and at other times vacuolated. The tumor cells are disposed in sheets or microcystic, glandular, follicular, or papillary patterns. There is usually little anaplasia and few mitoses, but some tumors are occasionally slightly more pleomorphic.

The clinical course of these neoplasms is somewhat dependent on the level of pleomorphism. Overall, recurrence after resection is uncommon, but about 10% to 15% of these neoplasms metastasize to lymph nodes. The survival rate is in the range of 90% at 5 years and 60% at 20 years.

KEY CONCEPTS

Diseases of Salivary Glands

- **Sialadenitis** (inflammation of the salivary glands) can be caused by trauma, infection, or an autoimmune reaction.
- **Mucoceles** are caused by trauma to or blockage of a salivary gland duct, with consequent leakage of saliva into the surrounding connective tissue stroma.
- **Pleomorphic adenoma** is a benign, slow-growing neoplasm composed of a heterogeneous mixture of epithelial and mesenchymal cells.
- **Mucoepidermoid carcinoma** is a malignant neoplasm of variable biological aggressiveness that is composed of a mixture of squamous and mucous cells.

The gastrointestinal (GI) tract is a hollow tube extending from the oral cavity to the anus that consists of anatomically distinct segments, including the esophagus, stomach, small intestine, colon, rectum, and anus. Each of these segments has unique, complementary, and highly integrated functions, which together serve to regulate the intake, processing, and absorption of ingested nutrients and the disposal of waste products. The regional

variations in structure and function are reflected in diseases of the GI tract, which often affect one or another segment preferentially. Accordingly, following consideration of several important congenital abnormalities, the discussion is organized anatomically. Disorders affecting more than one segment of the GI tract, such as Crohn disease, are discussed with the region that is involved most frequently.

CONGENITAL ABNORMALITIES

Depending on both the nature and timing of the insult during gestation, a variety of developmental anomalies can affect the GI tract. Importantly, because many organs develop simultaneously during embryogenesis, the presence of congenital GI disorders should prompt evaluation of other organs. Some defects are commonly associated with GI lesions.

Atresia, Fistulae, and Duplications

Atresia, fistulae, and duplications may occur in any part of the GI tract. When present within the esophagus they are discovered shortly after birth, usually due to regurgitation during feeding. Without prompt surgical repair, these lesions are incompatible with life. Absence, or *agenesis*, of the esophagus is extremely rare, but *atresia*, in which development is incomplete, is more common. In esophageal atresia a thin, noncanalized cord replaces a segment of esophagus, causing a mechanical obstruction (Fig. 17-1A). Atresia occurs most commonly at or near the tracheal bifurcation and is usually associated with a *fistula* connecting the upper or lower esophageal pouches to a bronchus or the trachea (17-1B). In other cases, a fistula can be present without atresia (Fig. 17-1B, C). Either form of fistula can lead to aspiration, suffocation, pneumonia, and severe fluid and electrolyte imbalances. Developmental

abnormalities of the esophagus are associated with congenital heart defects, genitourinary malformations, and neurologic disease. Intestinal atresia is less common than esophageal atresia but frequently involves the duodenum. *Imperforate anus*, the most common form of congenital intestinal atresia, is due to a failure of the cloacal diaphragm to involute.

Stenosis is an incomplete form of atresia in which the lumen is markedly reduced in caliber as a result of fibrous thickening of the wall. This results in either partial or complete obstruction. In addition to congenital forms, stenosis can be acquired as a consequence of inflammatory scarring, such as that caused by chronic gastroesophageal reflux, irradiation, systemic sclerosis, or caustic injury. Stenosis can involve any part of the GI tract, but the esophagus and small intestine are affected most often.

Diaphragmatic Hernia, Omphalocele, and Gastroschisis

Diaphragmatic hernia occurs when incomplete formation of the diaphragm allows the abdominal viscera to herniate into the thoracic cavity. When severe, the space-filling effect of the displaced viscera can cause pulmonary hypoplasia that is incompatible with life. *Omphalocele* occurs when closure of the abdominal musculature is incomplete and the abdominal viscera herniate into a ventral membranous sac. This may be repaired surgically, but as many as 40% of infants with an omphalocele have other birth defects. *Gastroschisis* is similar to omphalocele except that it involves all of the layers of the abdominal wall, from the peritoneum to the skin.

Ectopia

Ectopic tissues (developmental rests) are common in the GI tract. The most frequent site of *ectopic gastric mucosa* is the upper third of the esophagus, where it is referred to as an *inlet patch*. While generally asymptomatic, acid released by gastric mucosa within the esophagus can result in dysphagia, esophagitis, Barrett esophagus, or, rarely, adenocarcinoma. *Ectopic pancreatic tissue* occurs less frequently and can be found in the esophagus or stomach. Like inlet patches, these nodules are most often asymptomatic but they produce damage and local inflammation in some cases. When ectopic pancreatic tissue is

Figure 17-1 Esophageal atresia and tracheoesophageal fistula. **A**, Blind upper and lower esophagus with thin cord of connective tissue linking the two segments. **B**, Blind upper segment with fistula between lower segment and trachea. **C**, Fistula (without atresia) between patent esophagus and trachea. The developmental anomaly shown in **B** is the most common. (Adapted from Morson BC, Dawson IMP, eds: *Gastrointestinal Pathology*. Oxford, Blackwell Scientific Publications, 1972, p 8.)

present in the pylorus, inflammation and scarring may lead to obstruction. Because the rests may be present within any layer of the gastric wall, they can mimic invasive cancer. *Gastric heterotopia*, small patches of ectopic gastric mucosa in the small bowel or colon, may present with occult blood loss due to peptic ulceration of adjacent mucosa.

Meckel Diverticulum

A true diverticulum is a blind outpouching of the alimentary tract that communicates with the lumen and includes all three layers of the bowel wall. *The most common true diverticulum is the Meckel diverticulum, which occurs in the ileum.*

Meckel diverticulum occurs as a result of failed involution of the vitelline duct, which connects the lumen of the developing gut to the yolk sac. This solitary diverticulum extends from the antimesenteric side of the bowel (Fig. 17-2). The “rule of 2s” is often used to help remember characteristics of Meckel diverticula, which

- Occur in approximately 2% of the population
- Are generally present within 2 feet (60 cm) of the ileocecal valve
- Are approximately 2 inches (5 cm) long
- Are twice as common in males
- Are most often symptomatic by age 2 (only approximately 4% are ever symptomatic).

The mucosal lining of Meckel diverticula may resemble that of normal small intestine, but ectopic pancreatic or gastric tissue may also be present. The latter may secrete acid, cause peptic ulceration of adjacent small intestinal mucosa, and present with occult bleeding or abdominal pain resembling acute appendicitis or obstruction.

Less commonly, congenital diverticula occur in other parts of the small intestine and ascending colon. Virtually all other diverticula are acquired and either lack muscularis entirely or have an attenuated muscularis propria. The most common site of acquired diverticula is the sigmoid colon (discussed later).

Figure 17-2 Meckel diverticulum. The blind pouch is located on the antimesenteric side of the small bowel.

Pyloric Stenosis

Congenital hypertrophic pyloric stenosis is three to five times more common in males and occurs once in 300 to 900 live births. Monozygotic twins have a high rate of concordance, with a 200-fold increased risk if one twin is affected. Incidence of congenital hypertrophic pyloric stenosis is also increased in dizygotic twins and siblings of affected individuals, although here the risk is only increased by 20-fold, reflecting a complex multifactorial pattern of inheritance. Consistent with a genetic basis, Turner syndrome and trisomy 18 also confer an increased risk of congenital hypertrophic pyloric stenosis. While the underlying mechanisms are not understood, erythromycin or azithromycin exposure, either orally or via mother’s milk, in the first 2 weeks of life has been linked to increased disease incidence.

Congenital hypertrophic pyloric stenosis generally presents between the third and sixth weeks of life as new-onset regurgitation, projectile, nonbilious vomiting after feeding, and frequent demands for re-feeding. Physical examination reveals a firm, ovoid, 1 to 2 cm abdominal mass. In some cases abnormal left to right hyperperistalsis is evident during feeding and immediately before vomiting. This constellation of findings stems from hyperplasia of the pyloric muscularis propria, which obstructs the gastric outflow tract. Edema and inflammatory changes in the mucosa and submucosa may aggravate the narrowing. Surgical splitting of the muscularis (myotomy) is curative. Acquired pyloric stenosis occurs in adults as a consequence of antral gastritis or peptic ulcers close to the pylorus. Carcinomas of the distal stomach and pancreas may also narrow the pyloric channel due to fibrosis or malignant infiltration.

Hirschsprung Disease

Hirschsprung disease occurs in approximately 1 of 5000 live births. It may be isolated or occur in combination with other developmental abnormalities; 10% of all cases occur in children with Down syndrome and serious neurologic abnormalities are present in another 5%.

Pathogenesis. The enteric neuronal plexus develops from neural crest cells that migrate into the bowel wall during embryogenesis. Hirschsprung disease, also known as congenital aganglionic megacolon, results when the normal migration of neural crest cells from cecum to rectum is arrested prematurely or when the ganglion cells undergo premature death. This produces a distal intestinal segment that lacks both the Meissner submucosal and the Auerbach myenteric plexus (“aganglionosis”). Coordinated peristaltic contractions are absent and functional obstruction occurs, resulting in dilation proximal to the affected segment.

The mechanisms underlying defective neural crest cell migration in Hirschsprung disease are unknown, but a genetic component is present in nearly all cases, and 4% of patients’ siblings are affected. Heterozygous loss-of-function mutations in the receptor tyrosine kinase *RET* account for the majority of familial cases and

approximately 15% of sporadic cases. Mutations in at least seven other genes encoding proteins involved in enteric neurodevelopment, including the RET ligand glial-derived neurotrophic factor, endothelin, and the endothelin receptor, have also been described. However, these account for fewer than 30% of patients, suggesting that many other defects remain to be discovered. Because penetrance is incomplete, modifying genes or environmental factors must also be important. In addition, it is clear that sex-linked factors exist, since the disease is more common in males, but, when present in females, tends to involve longer aganglionic segments.

MORPHOLOGY

Diagnosis of Hirschsprung disease requires documenting the absence of ganglion cells within the affected segment. In addition to their characteristic morphology in hematoxylin and eosin-stained sections, ganglion cells can be identified using immunohistochemical stains for acetylcholinesterase.

The rectum is always affected, but the length of the additional involved segments varies widely, from the rectum and sigmoid colon in most cases to the entire colon in severe cases. The aganglionic region may have a grossly normal or contracted appearance. In contrast, the normally innervated proximal colon may undergo progressive dilation (Fig. 17-3) and, in time become massively distended (**megacolon**), reaching diameters of as much as 20 cm. This may stretch and thin the colonic wall to the point of rupture, which occurs most frequently near the cecum. Mucosal inflammation or shallow ulcers may also be present in normally innervated segments, making gross identification of the extent of aganglionosis difficult. Hence, intraoperative frozen-section analysis is commonly used to confirm the presence of ganglion cells at the anastomotic margin.

Figure 17-3 Hirschsprung disease. **A**, Preoperative barium enema study showing constricted rectum (bottom of the image) and dilated sigmoid colon. **B**, Corresponding intraoperative photograph showing constricted rectum and dilation of the sigmoid colon. (Courtesy Dr. Aliya Husain, The University of Chicago, Chicago, Ill.)

Clinical Features. Hirschsprung disease typically presents with a failure to pass meconium in the immediate postnatal period. Obstruction or constipation follows, often with visible, ineffective peristalsis, and may progress to abdominal distention and bilious vomiting. When only a few centimeters of rectum are involved occasional passage of stool may occur and obscure the diagnosis. The major threats to life are enterocolitis, fluid and electrolyte disturbances, perforation, and peritonitis. The primary mode of treatment is surgical resection of the aganglionic segment followed by anastomosis of the normal proximal colon to the rectum. Even after successful surgery, it may take years to attain normal bowel function and continence.

In contrast to the congenital megacolon of Hirschsprung disease, acquired megacolon may occur at any age as a result of Chagas disease, obstruction by a neoplasm or inflammatory stricture, toxic megacolon complicating ulcerative colitis, visceral myopathy, or in association with functional psychosomatic disorders. Of these, only Chagas disease (discussed later) is associated with loss of ganglion cells.

KEY CONCEPTS

Congenital malformations of the GI tract

- The GI tract is a common site of developmental abnormalities. In these cases, defects of other organs that develop in the same embryonic period should be sought.
- **Atresia, and fistulae**, are structural developmental anomalies that disrupt normal gastrointestinal transit and typically present early in life. **Imperforate anus** is the most common form of congenital intestinal atresia, while the esophagus is the most common site of fistulization.
- **Stenosis** may be developmental or acquired. Both forms are characterized by a thickened wall and partial or complete luminal obstruction. Acquired forms are often due to inflammatory scarring.
- **Diaphragmatic hernia** is characterized by incomplete diaphragm development and herniation of abdominal organs into the thorax. This often results in pulmonary hypoplasia. **Omphalocele** and **gastroschisis** refer to ventral herniation of abdominal organs.
- **Ectopia** refers to the presence of normally formed tissues in an abnormal site. This is common in the gastrointestinal tract, with **ectopic gastric mucosa** in the upper third of the esophagus being the most common form.
- The **Meckel diverticulum** is a true diverticulum, defined by the presence of all three layers of the bowel wall, that reflects failed involution of the vitelline duct. It is common and is a frequent site of gastric ectopia, which may result in occult bleeding.
- **Congenital hypertrophic pyloric stenosis** is a form of obstruction that presents between the third and sixth weeks of life. There is an ill-defined genetic component to this disease, which is most common in males.
- **Hirschsprung disease** is caused by the absence of neural crest derived ganglion cells within the colon. It causes functional obstruction of the affected bowel and proximal dilation. The defect always begins at the rectum, but extends proximally for variable lengths.

ESOPHAGUS

The esophagus develops from the cranial portion of the foregut and is recognizable by the third week of gestation. It is a hollow, highly distensible muscular tube that extends from the epiglottis in the pharynx to the gastroesophageal junction. Acquired diseases of the esophagus run the gamut from highly lethal cancers to the persistent “heartburn” of gastroesophageal reflux that may be chronic and incapacitating or merely an occasional annoyance.

Esophageal Obstruction

The esophagus is, essentially, a tube that delivers ingested solid food and fluids to the stomach. This can be impeded by structural, i.e. (mechanical) obstruction or functional obstruction. The latter results from disruption of the coordinated waves of peristaltic contractions that follow swallowing. Esophageal manometry allows separation of esophageal dysmotility into three principal forms, termed nutcracker esophagus, diffuse esophageal spasm, and hypertensive lower esophageal sphincter.

- *Nutcracker esophagus* describes patients with high-amplitude contractions of the distal esophagus that are, in part, due to loss of the normal coordination of inner circular layer and outer longitudinal layer smooth muscle contractions.
- *Diffuse esophageal spasm* is characterized by repetitive, simultaneous contractions of the distal esophageal smooth muscle.
- Lower esophageal sphincter dysfunction, such as high resting pressure or incomplete relaxation, are present in many patients with nutcracker esophagus or diffuse esophageal spasm. In the absence altered patterns of esophageal contraction, these sphincter abnormalities are termed *hypertensive lower esophageal sphincter*. As discussed below, these can be distinguished from achalasia in that the latter includes reduced esophageal peristaltic contractions.

Because wall stress is increased, esophageal dysmotility may result in development of small diverticulae, primarily the epiphrenic diverticulum located immediately above the lower esophageal sphincter. Similarly, impaired relaxation and spasm of the cricopharyngeus muscle after swallowing can result in increased pressure within the distal pharynx and development of a Zenker diverticulum (pharyngoesophageal diverticulum), which is located immediately above the upper esophageal sphincter. Zenker diverticulae are uncommon, but typically develop after age 50 and may reach several centimeters in size. When small they may be asymptomatic, but larger Zenker diverticulae may accumulate significant amounts of food, producing a mass and symptoms that include regurgitation and halitosis.

In contrast to functional obstruction, mechanical obstruction, which can be caused by strictures or cancer, presents as progressive dysphagia that begins with inability to swallow solids. With progression ingestion of liquids is also affected. Because obstruction develops slowly, patients may subconsciously modify their diet to favor soft

foods and liquids and be unaware of their condition until the obstruction is nearly complete.

Benign *esophageal stenosis*, or narrowing of the lumen, is generally caused by fibrous thickening of the submucosa and is associated with atrophy of the muscularis propria as well as secondary epithelial damage. Although occasionally congenital, stenosis is most often due to inflammation and scarring that may be caused by chronic gastroesophageal reflux, irradiation, or caustic injury. In general, patients with functional obstruction or benign strictures maintain their appetite and weight, while, as discussed later, malignant strictures are often associated with weight loss.

Esophageal mucosal webs are idiopathic ledge-like protrusions of mucosa that may cause obstruction. These uncommon lesions typically occur in women older than age 40 and can be associated with gastroesophageal reflux, chronic graft-versus-host disease, or blistering skin diseases. In the upper esophagus, webs may be accompanied by iron-deficiency anemia, glossitis, and cheilosis as part of the *Paterson-Brown-Kelly* or *Plummer-Vinson syndrome*. In general, esophageal webs are semi-circumferential lesions that protrude less than 5 mm, have a thickness of 2 to 4 mm, and are composed of a fibrovascular connective tissue and overlying epithelium. The main symptom of webs is nonprogressive dysphagia associated with incompletely chewed food.

Esophageal rings, or *Schatzki rings*, are similar to webs, but are circumferential, thicker, and include mucosa, submucosa, and, occasionally, hypertrophic muscularis propria. When present in the distal esophagus, above the gastroesophageal junction, they are termed *A rings* and are covered by squamous mucosa; in contrast, those located at the squamocolumnar junction of the lower esophagus are designated *B rings* and may have gastric cardia-type mucosa on their undersurface.

Achalasia

Increased tone of the lower esophageal sphincter (LES), as a result of impaired smooth muscle relaxation, is an important cause of esophageal obstruction. Normally, release of nitric oxide and vasoactive intestinal polypeptide from inhibitory neurons, along with interruption of normal cholinergic signaling, allows the LES to relax during swallowing. *Achalasia is characterized by the triad of incomplete LES relaxation, increased LES tone, and aperistalsis of the esophagus*. Symptoms include dysphagia for solids and liquids, difficulty in belching, and chest pain. Although there is some increased risk for esophageal cancer, it is not considered great enough to warrant surveillance endoscopy.

Primary achalasia is the result of distal esophageal inhibitory neuronal, that is, ganglion cell, degeneration. This leads to increased tone, an inability to relax of the lower esophageal sphincter, and esophageal aperistalsis. Degenerative changes in the extraesophageal vagus nerve or the dorsal motor nucleus of the vagus may also occur. The cause is unknown; rare familial cases have been described.

Secondary achalasia may arise in Chagas disease, in which Trypanosoma cruzi infection causes destruction of the myenteric plexus, failure of peristalsis, and esophageal dilatation. Duodenal, colonic, and ureteric myenteric plexuses can also be affected in Chagas disease. Achalasia-like disease may be caused by diabetic autonomic neuropathy; infiltrative disorders such as malignancy, amyloidosis, or sarcoidosis; lesions of dorsal motor nuclei, particularly polio or surgical ablation; in association with Down syndrome; or as part of Allgrove (triple A) syndrome, an autosomal recessive disorder characterized by achalasia, alacrima, and adrenocorticotropic hormone-resistant adrenal insufficiency. The association of some achalasia cases with remote herpes simplex virus 1 (HSV1) infection, linkage of immunoregulatory gene polymorphisms to achalasia, and occasional coexistence of Sjögren syndrome or autoimmune thyroid disease suggest that achalasia may also be driven by immune-mediated destruction of inhibitory esophageal neurons. Treatment modalities for both primary and secondary achalasia aim to overcome the mechanical obstruction, and include laparoscopic myotomy and pneumatic balloon dilatation. Botulinum neurotoxin (Botox) injection, to inhibit LES cholinergic neurons, can also be effective.

Esophagitis

Lacerations

Longitudinal mucosal tears near the gastroesophageal junction are termed *Mallory-Weiss tears*, and are most often associated with severe retching or vomiting secondary to acute alcohol intoxication. Normally, a reflex relaxation of the gastroesophageal musculature precedes the antiperistaltic contractile wave associated with vomiting. It is speculated that this relaxation fails during prolonged vomiting, with the result that refluxing gastric contents overwhelm the gastric inlet and cause the esophageal wall to stretch and tear. The roughly linear lacerations of Mallory-Weiss syndrome are longitudinally oriented and range in length from millimeters to several centimeters. These tears usually cross the gastroesophageal junction and may also be located in the proximal gastric mucosa. Up to 10% of upper GI bleeding, which often presents as hematemesis (Table 17-1), is due to superficial esophageal lacerations such as

Table 17-1 Esophageal Causes of Hematemesis

Lacerations (Mallory-Weiss syndrome)
Esophageal perforation (cancer or Boerhaave syndrome)
Varices (cirrhosis)
Esophageal-aortic fistula (usually with cancer)
Chemical and pill esophagitis
Infectious esophagitis (<i>Candida</i> , herpes)
Benign strictures
Vasculitis (autoimmune, cytomegalovirus)
Reflux esophagitis (erosive)
Eosinophilic esophagitis
Esophageal ulcers (many etiologies)
Barrett esophagus
Adenocarcinoma
Squamous cell carcinoma
Hiatal hernia

those associated with Mallory-Weiss syndrome. These do not generally require surgical intervention, and healing tends to be rapid and complete. In contrast, Boerhaave syndrome is a much less common but more serious disorder characterized by transmural tearing and rupture of the distal esophagus. This catastrophic event produces severe mediastinitis and generally requires surgical intervention. Because patients can present with severe chest pain, tachypnea, and shock, the initial differential diagnosis can include myocardial infarction.

Chemical and Infectious Esophagitis

The stratified squamous mucosa of the esophagus may be damaged by a variety of irritants including alcohol, corrosive acids or alkalis, excessively hot fluids, and heavy smoking. Symptoms range from self-limited pain, particularly on swallowing, that is, *odynophagia*, to hemorrhage, stricture, or perforation in severe cases.

In children esophageal chemical injury is often secondary to accidental ingestion of household cleaning products; severe damage may follow attempted suicide in adults. Less severe chemical injury to the esophageal mucosa can occur when medicinal pills lodge and dissolve in the esophagus rather than passing into the stomach intact, a condition termed *pill-induced esophagitis*. Iatrogenic esophageal injury may be caused by cytotoxic chemotherapy, radiation therapy, or graft-versus-host disease. The esophagus may also be involved by the desquamative skin diseases bullous pemphigoid, epidermolysis bullosa and, rarely, Crohn disease.

Esophageal infections in otherwise healthy individuals are uncommon and most often due to herpes simplex virus. Infections in patients who are debilitated or immunosuppressed, as a result of disease or therapy, is more common and can be caused by herpes simplex virus, cytomegalovirus (CMV), or fungal organisms. Among fungi, candidiasis is most common, although mucormycosis and aspergillosis are also seen.

MORPHOLOGY

The morphology of chemical and infectious esophagitis varies with etiology. Dense infiltrates of neutrophils are present in most cases but may be absent following injury induced by chemicals (lye, acids, or detergent), which can lead to outright necrosis of the esophageal wall. Pill-induced esophagitis frequently occurs at the site of strictures that impede passage of luminal contents. When present, ulceration is accompanied by superficial necrosis with granulation tissue and eventual fibrosis.

Esophageal irradiation causes damage similar to that seen in other tissues and includes intimal proliferation and luminal narrowing of submucosal and mural blood vessels. The mucosal damage is, in part, secondary to this radiation-induced vascular injury as discussed in Chapter 9.

Infection by fungi or bacteria can either cause injury or complicate a preexisting ulcer. Nonpathogenic oral bacteria are frequently found in ulcer beds, while pathogenic organisms, which account for about 10% of infectious esophagitis, may invade the lamina propria and cause necrosis of overlying mucosa. Candidiasis, in its most advanced form, is characterized by adherent, gray-white **pseudomembranes** composed

Figure 17-4 Viral esophagitis. **A**, Postmortem specimen with multiple, overlapping herpetic ulcers in the distal esophagus. **B**, Multinucleate squamous cells containing herpesvirus nuclear inclusions. **C**, Cytomegalovirus-infected endothelial cells with nuclear and cytoplasmic inclusions.

of densely matted fungal hyphae and inflammatory cells covering the esophageal mucosa.

The endoscopic appearance often provides a clue as to the infectious agent in viral esophagitis. Herpes viruses typically cause punched-out ulcers (Fig. 17-4A). Biopsy specimens demonstrate nuclear viral inclusions within a rim of degenerating epithelial cells at the margin of the ulcer (Fig. 17-4B). In contrast, CMV causes shallower ulcerations and characteristic nuclear and cytoplasmic inclusions within capillary endothelium and stromal cells (Fig. 17-4C). Although the histologic appearance is characteristic, immunohistochemical stains for virus-specific antigens are sensitive and specific ancillary diagnostic tools.

Histologic features of esophageal **graft-versus-host disease** are similar to those in the skin and include basal epithelial cell apoptosis, mucosal atrophy, and submucosal fibrosis without significant acute inflammatory infiltrates. The microscopic appearances of esophageal involvement in bullous pemphigoid, epidermolysis bullosa, and Crohn disease are also similar to those in the skin (Chapter 25).

Reflux Esophagitis

The stratified squamous epithelium of the esophagus is resistant to abrasion from foods but is sensitive to acid. Submucosal glands, which are most abundant in the proximal and distal esophagus, contribute to mucosal protection by secreting mucin and bicarbonate. More importantly, the tone of the lower esophageal sphincter prevents reflux of acidic gastric contents, which are under positive pressure and would otherwise enter the esophagus. Reflux of gastric contents into the lower esophagus is the most frequent cause of esophagitis and the most common outpatient GI

diagnosis in the United States. The associated clinical condition is termed *gastroesophageal reflux disease (GERD)*.

Pathogenesis. The most common cause of gastroesophageal reflux is transient lower esophageal sphincter relaxation. This is thought to be mediated via vagal pathways, and can be triggered by gastric distention, by gas or food, mild pharyngeal stimulation that does not trigger swallowing, and stress. Gastroesophageal reflux can also occur following swallow-induced lower esophageal sphincter relaxations or due to forceful opening of a relatively hypotensive lower esophageal sphincter by an abrupt increase in intraabdominal pressure, such as that due to coughing, straining, or bending. Other conditions that decrease lower esophageal sphincter tone or increase abdominal pressure and contribute to GERD include alcohol and tobacco use, obesity, central nervous system depressants, pregnancy, hiatal hernia (discussed later), delayed gastric emptying, and increased gastric volume. In many cases, no definitive cause is identified. Reflux of gastric juices is central to the development of mucosal injury in GERD. In severe cases, reflux of bile from the duodenum may exacerbate the damage.

MORPHOLOGY

Simple hyperemia, evident to the endoscopist as redness, may be the only alteration. In mild GERD the mucosal histology is often unremarkable. With more significant disease, eosinophils are recruited into the squamous mucosa followed by neutrophils, which are usually associated with more severe injury (Fig. 17-5A). Basal zone hyperplasia exceeding 20% of the total epithelial thickness and elongation of lamina propria papillae, such that they extend into the upper third of the epithelium, may also be present.

Clinical Features. GERD is most common in individuals older than age 40 but also occurs in infants and children. The most frequent clinical symptoms are heartburn, dysphagia, and regurgitation of sour-tasting gastric contents.

Figure 17-5 Esophagitis. **A**, Reflux esophagitis with scattered intraepithelial eosinophils and mild basal zone expansion. **B**, Eosinophilic esophagitis is characterized by numerous intraepithelial eosinophils. Abnormal squamous maturation is also apparent.

Rarely, chronic GERD is punctuated by attacks of severe chest pain that may be mistaken for heart disease. Treatment with proton pump inhibitors, which have replaced H₂ histamine receptor antagonists, to reduce gastric acidity typically provides symptomatic relief. While the severity of symptoms is not closely related to the degree of histologic damage, the latter tends to increase with disease duration. Complications of reflux esophagitis include ulceration, hematemesis, melena, stricture development, and Barrett esophagus.

Hiatal hernia can give rise to symptoms, such as heartburn and regurgitation of gastric juices, that are similar to those of GERD. It is characterized by separation of the diaphragmatic crura and protrusion of the stomach into the thorax through the resulting gap. Congenital hiatal hernias are recognized in infants and children, but many are acquired in later life. Hiatal hernia is symptomatic in fewer than 10% of adults, but can be a cause of lower esophageal sphincter incompetence.

Eosinophilic Esophagitis

The incidence of eosinophilic esophagitis is increasing markedly. Symptoms include food impaction and dysphagia in adults and feeding intolerance or GERD-like symptoms in children. The cardinal histologic feature is large numbers of intraepithelial eosinophils, particularly superficially (Fig. 17-5B). Their abundance can help to differentiate eosinophilic esophagitis from GERD, Crohn disease, and other causes of esophagitis. In addition, unlike patients with GERD, acid reflux is not prominent and high doses of proton pump inhibitors usually do not provide relief. *The majority of individuals with eosinophilic esophagitis are atopic and many have atopic dermatitis, allergic rhinitis, asthma, or modest peripheral eosinophilia.* Treatments include dietary restrictions to prevent exposure to food allergens, such as cow's milk and soy products, and topical or systemic corticosteroids.

Esophageal Varices

Venous blood from the GI tract passes through the liver, via the portal vein, before returning to the heart. This circulatory pattern is responsible for the first-pass effect in which drugs and other materials absorbed in the intestines are processed by the liver before entering the systemic circulation. Diseases that impede this flow cause portal hypertension and can lead to the development of esophageal varices, an important cause of esophageal bleeding.

Pathogenesis. Portal hypertension results in the development of collateral channels at sites where the portal and caval systems communicate. These collateral veins allow some drainage to occur, but at the same time they lead to development of congested subepithelial and submucosal venous plexi within the distal esophagus and proximal stomach. These vessels, termed *varices*, develop in the vast majority of cirrhotic patients, most commonly in association with alcoholic liver disease. Worldwide, hepatic schistosomiasis is the second most common cause of varices. A more detailed consideration of portal hypertension is given in Chapter 18.

Figure 17-6 Esophageal varices. **A**, Although no longer used as a diagnostic approach, this angiogram demonstrates several tortuous esophageal varices. **B**, Collapsed varices are present in this postmortem specimen corresponding to the angiogram in **A**. The polyoid areas represent previous sites of variceal hemorrhage that have been ligated with bands. **C**, Dilated varices beneath intact squamous mucosa.

MORPHOLOGY

Varices are tortuous dilated veins lying primarily within the submucosa of the distal esophagus and proximal stomach (Fig. 17-6A). Venous channels directly beneath the esophageal epithelium may also become massively dilated. Varices may not be grossly obvious in surgical or postmortem specimens, because they collapse in the absence of blood flow (Fig. 17-6B) and are obscured by the overlying mucosa (Fig. 17-6C). Variceal rupture results in hemorrhage into the lumen or the esophageal wall, in which case the overlying mucosa appears ulcerated and necrotic. If rupture has occurred in the past, venous thrombosis, inflammation, and evidence of prior therapy may also be present.

Clinical Features. Gastroesophageal varices are present in nearly half of the patients with cirrhosis, and 25-40% of patients with cirrhosis develop variceal bleeding. Approximately 12% of previously asymptomatic varices bleed each year. Variceal hemorrhage is an emergency that can be treated medically by inducing splanchnic vasoconstriction or endoscopically by sclerotherapy (injection of thrombotic agents), balloon tamponade, or variceal

ligation. Despite these interventions, 30% or more of patients with variceal hemorrhage die as a direct consequence of hemorrhage such as hypovolemic shock, hepatic coma, or other complications. Furthermore, more than 50% of patients who survive a first variceal bleed have recurrent hemorrhage within 1 year, and this carries a mortality rate similar to that of the first episode. Thus, patients with risk factors for hemorrhage, including large varices, elevated hepatic venous pressure gradient, previous bleeding, and advanced liver disease may be treated prophylactically with beta-blockers to reduce portal blood flow and with endoscopic variceal ligation. Despite the frequency and risks of variceal hemorrhage, it is important to recognize that cirrhosis patients with small varices that have never bled are at relatively low risk for bleeding and death, and that, even when varices are present, they are only one of several causes of hematemesis.

Barrett Esophagus

Barrett esophagus is a complication of chronic GERD that is characterized by intestinal metaplasia within the esophageal squamous mucosa. The incidence of Barrett esophagus is rising, and it is estimated to occur in as many as 10% of individuals with symptomatic GERD. Barrett esophagus is most common in white males and typically presents between 40 and 60 years of age. *The greatest concern in Barrett esophagus is that it confers an increased risk of esophageal adenocarcinoma.* Genomic sequencing of biopsies involved by Barrett esophagus has revealed the presence of mutations that are shared with esophageal adenocarcinoma, in keeping with the idea that Barrett esophagus is a precursor lesion to cancer. Potentially oncogenic mutations are more numerous when biopsies demonstrate dysplasia, which is detected in 0.2% to 2% of persons with Barrett esophagus each year. The presence of dysplasia, a preinvasive change, is associated with prolonged symptoms, longer segment length, increased patient age, and Caucasian race. Although the vast majority of esophageal adenocarcinomas are associated with Barrett esophagus, it is important to remember that most individuals with Barrett esophagus do not develop esophageal tumors.

MORPHOLOGY

Barrett esophagus can be recognized as one or several tongues or patches of red, velvety mucosa extending upward from the gastroesophageal junction. This metaplastic mucosa alternates with residual smooth, pale squamous (esophageal) mucosa and interfaces with light-brown columnar (gastric) mucosa distally (Fig. 17-7A, B). High-resolution endoscopes have increased the sensitivity of Barrett esophagus detection. This has led to subclassification of Barrett esophagus as long segment, which involves 3 cm or more, or short segment, in which less than 3 cm is involved. Available data suggest that the risk of dysplasia correlates with length of esophagus affected.

Diagnosis of Barrett esophagus requires endoscopic evidence of metaplastic columnar mucosa above the gastroesophageal junction. Microscopically, intestinal-type metaplasia is seen as replacement of the squamous esophageal epithelium with goblet cells. These are diagnostic of Barrett esophagus, and have distinct mucous vacuoles that stain pale blue by

Figure 17-7 Barrett esophagus. **A**, Normal gastroesophageal junction. **B**, Barrett esophagus. Note the small islands of residual pale squamous mucosa within the Barrett mucosa. **C**, Histologic appearance of the gastroesophageal junction in Barrett esophagus. Note the transition between esophageal squamous mucosa (left) and Barrett metaplasia, with abundant metaplastic goblet cells (right).

hematoxylin and eosin and impart the shape of a wine goblet to the remaining cytoplasm (Fig. 17-7C). Non-goblet columnar cells, such as gastric type foveolar cells, may also be present. However, whether the latter are sufficient for diagnosis is controversial.

When **dysplasia** is present, it is classified as low grade or high grade. Atypical mitoses, nuclear hyperchromasia, irregularly clumped chromatin, increased nuclear-to-cytoplasmic ratio, and a failure of epithelial cells to mature as they migrate to the esophageal surface are present in both grades of dysplasia (Fig. 17-8A). Gland architecture is frequently abnormal and is characterized by budding, irregular shapes, and cellular crowding. High-grade dysplasia (Fig. 17-8B) exhibits more severe cytologic and architectural changes. With progression, epithelial cells may invade the lamina propria, a feature that defines intramucosal carcinoma.

Clinical Features. Barrett esophagus can only be identified through endoscopy and biopsy, which are usually prompted by GERD symptoms. Once diagnosed, the best course of management is a matter of debate. Many support periodic endoscopy with biopsy, for dysplasia surveillance. However, randomized trials have failed to demonstrate that surveillance improves patient survival. Furthermore, uncertainties regarding the potential of dysplasia, particularly low grade, to regress spontaneously and limited information on the risk of progression complicate clinical decisions.

Figure 17-8 Dysplasia in Barrett esophagus. **A**, Abrupt transition from Barrett metaplasia to low-grade dysplasia (arrow). Note the nuclear stratification and hyperchromasia. **B**, Architectural irregularities, including gland-within-gland, or cribriform, profiles in high-grade dysplasia.

Intramucosal or invasive carcinoma requires therapeutic intervention. Treatment options include surgical resection, or esophagectomy, as well as newer modalities such as photodynamic therapy, laser ablation, and endoscopic mucosectomy. Multifocal high-grade dysplasia, which carries a significant risk of progression to intramucosal or invasive carcinoma, is treated as intramucosal carcinoma. Many physicians follow low-grade dysplasia or a single focus of high-grade dysplasia with endoscopy and biopsy at frequent intervals. However, management of esophageal dysplasia is evolving, and it is hoped that improved molecular understanding of neoplastic progression may allow development of chemopreventive approaches that reduce the incidence of esophageal adenocarcinoma.

Esophageal Tumors

The vast majority of esophageal cancers fall into one of two types, adenocarcinoma and squamous cell carcinoma. Squamous cell carcinoma is more common worldwide, but adenocarcinoma is on the rise in the United States and other Western countries. Other malignancies of the esophagus are far less common and include unusual forms of adenocarcinoma, undifferentiated carcinoma, carcinoid tumor, melanoma, lymphoma, and sarcoma; these are not discussed here. Benign tumors of the esophagus are generally mesenchymal, and arise within the esophageal wall, with leiomyomas being most common. Fibromas, lipomas, hemangiomas, neurofibromas, and lymphangiomas also occur.

Adenocarcinoma

Most esophageal adenocarcinomas arise from Barrett esophagus. Thus, increased rates of esophageal adenocarcinoma may be partly due to the increased incidence of obesity-related gastroesophageal reflux and Barrett esophagus. Additional risk factors include tobacco use and exposure to radiation. Conversely, risk is reduced by diets rich in fresh fruits and vegetables. Some serotypes of *Helicobacter pylori* are associated with decreased risk of esophageal

adenocarcinoma, because they cause gastric atrophy, which in turn leads to reduced acid secretion and reflux, and reduced incidence of Barrett esophagus. Thus, reduced rates of *Helicobacter pylori* infection may also be a factor in the increasing incidence of esophageal adenocarcinoma.

Esophageal adenocarcinoma occurs most frequently in Caucasians and shows a strong gender bias, being sevenfold more common in men. However, the incidence varies widely worldwide, with rates being highest in countries that include the United States, the United Kingdom, Canada, Australia, the Netherlands, and Brazil, and lowest in Korea, Thailand, Japan, and Ecuador. In countries where esophageal adenocarcinoma is more common, the incidence has increased markedly since 1970, more rapidly than almost any other cancer. For unknown reasons, these increases have been restricted to white and Hispanic men and white women in the United States. As a result, esophageal adenocarcinoma, which represented less than 5% of esophageal cancers before 1970, now accounts for more than half of all esophageal cancers in the United States.

Pathogenesis. Molecular studies suggest that the progression of Barrett esophagus to adenocarcinoma occurs over an extended period through the stepwise acquisition of genetic and epigenetic changes. This model is supported by the observation that epithelial clones identified in nondysplastic Barrett metaplasia persist and accumulate mutations during progression to dysplasia and invasive carcinoma. Chromosomal abnormalities, mutation of *TP53*, and downregulation of the cyclin-dependent kinase inhibitor *CDKN2A*, also known as *p16/INK4a*, are detected at early stages. In the case of *CDKN2A*, both allelic loss and hypermethylation-induced epigenetic silencing have been described. Later during progression there is amplification of *EGFR*, *ERBB2*, *MET*, *cyclin D1*, and *cyclin E* genes.

MORPHOLOGY

Esophageal adenocarcinoma usually occurs in the distal third of the esophagus and may invade the adjacent gastric cardia (Fig. 17-9A). Initially appearing as flat or raised patches in otherwise intact mucosa, large masses of 5 cm or more in diameter may develop. Alternatively, tumors may infiltrate diffusely or ulcerate and invade deeply. Microscopically, Barrett esophagus is frequently present adjacent to the tumor. Tumors most commonly produce mucin and form glands (Fig. 17-10A), often with intestinal-type morphology; less frequently tumors are composed of diffusely infiltrative signet-ring cells (similar to those seen in diffuse gastric cancers) or, in rare cases, small poorly differentiated cells (similar to small-cell carcinoma of the lung).

Clinical Features. Although esophageal adenocarcinomas are occasionally discovered in evaluation of GERD or surveillance of Barrett esophagus, they more commonly present with pain or difficulty in swallowing, progressive weight loss, hematemesis, chest pain, or vomiting. By the time symptoms appear, the tumor has usually spread to submucosal lymphatic vessels. As a result of the advanced stage at diagnosis, overall 5-year survival is less than 25%. In contrast, 5-year survival approximates 80% in the few patients with adenocarcinoma limited to the mucosa or submucosa.

Figure 17-9 Esophageal cancer. **A**, Adenocarcinoma usually occurs distally and, as in this case, often involves the gastric cardia. **B**, Squamous cell carcinoma is most frequently found in the mid-esophagus, where it commonly causes strictures.

Squamous Cell Carcinoma

In the United States, esophageal squamous cell carcinoma occurs in adults older than age 45 and affects males four times more frequently than females. Risk factors include alcohol and tobacco use, poverty, caustic esophageal injury, achalasia, tylosis, Plummer-Vinson syndrome, diets that are deficient in fruits or vegetables, and frequent consumption of very hot beverages. Previous radiation to the mediastinum also predisposes individuals to esophageal carcinoma, with most cases occurring 5 to 10 or more years after exposure. Esophageal squamous cell carcinoma is nearly eight-fold more common in African Americans than Caucasians, a striking risk disparity that reflects differences in rates of alcohol and tobacco use as well as other poorly understood factors.

Esophageal squamous cell carcinoma incidence varies up to 180-fold between and within countries, being more common in rural and underdeveloped areas. The regions with highest incidence are Iran, central China, Hong Kong, Brazil, and South Africa. A pocket of extremely high esophageal squamous cell carcinoma incidence in western Kenya includes patients younger than 30 years of age and has been linked to consumption of a traditional fermented milk, termed *mursik*, which contains the carcinogen acetaldehyde (Chapter 9).

Pathogenesis. The majority of esophageal squamous cell carcinomas in Europe and the United States are linked to the use of alcohol and tobacco, which synergize to increase the risk. However, esophageal squamous cell carcinoma is also common in some regions where alcohol and tobacco use is uncommon. Thus, nutritional deficiencies, as well as polycyclic hydrocarbons, nitrosamines, and other

mutagenic compounds, such as those found in fungus-contaminated foods, must also be considered. Human papillomavirus (HPV) infection has also been implicated in esophageal squamous cell carcinoma in high-risk areas but not in low-risk regions. The molecular pathogenesis of esophageal squamous cell carcinoma remains incompletely defined, but recurrent abnormalities include amplification of the transcription factor gene *SOX2* (believed to be involved in cancer stem cell self-renewal and survival); overexpression of the cell cycle regulator cyclin D1; and loss-of-function mutations in the tumor suppressors *TP53*, *E-cadherin*, and *NOTCH1*.

MORPHOLOGY

In contrast to adenocarcinoma, half of squamous cell carcinomas occur in the middle third of the esophagus (Fig. 17-9B). Squamous cell carcinoma begins as an in situ lesion termed **squamous dysplasia** (this lesion is referred to as intraepithelial neoplasia or carcinoma in situ at other sites). Early lesions appear as small, gray-white, plaque-like thickenings. Over months to years they grow into tumor masses that may be

Figure 17-10 Esophageal cancer. **A**, Esophageal adenocarcinoma organized into back-to-back glands. **B**, Squamous cell carcinoma composed of nests of malignant cells that partially recapitulate the organization of squamous epithelium.

polypoid, or exophytic, and protrude into and obstruct the lumen. Other tumors are either ulcerated or diffusely infiltrative lesions that spread within the esophageal wall and cause thickening, rigidity, and luminal narrowing. They may invade surrounding structures including the respiratory tree, causing pneumonia; the aorta, causing catastrophic exsanguination; or the mediastinum and pericardium.

Most squamous cell carcinomas are moderately to well-differentiated (Fig. 17-10B). Less common histologic variants include verrucous squamous cell carcinoma, spindle cell carcinoma, and basaloid squamous cell carcinoma. Regardless of histology, symptomatic tumors are generally very large at diagnosis and have already invaded the esophageal wall. The rich lymphatic network promotes circumferential and longitudinal spread, and intramural tumor nodules may be present several centimeters away from the principal mass. The sites of lymph node metastases vary with tumor location: cancers in the upper third of the esophagus favor cervical lymph nodes; those in the middle third favor mediastinal, paratracheal, and tracheobronchial nodes; and those in the lower third spread to gastric and celiac nodes.

Clinical Features. The onset of esophageal squamous cell carcinoma is insidious and it most commonly presents with dysphagia, odynophagia (pain on swallowing), or obstruction. Patients subconsciously adjust to the progressively increasing obstruction by altering their diet from solid to liquid foods. Prominent weight loss and debilitation result from both impaired nutrition and effects of the tumor itself. Hemorrhage and sepsis may accompany tumor ulceration, and symptoms of iron deficiency are often present. Occasionally, the first symptoms are caused by aspiration of food via a tracheoesophageal fistula.

Increased prevalence of endoscopic screening has led to earlier detection of esophageal squamous cell carcinoma. This is critical, because 5-year survival rates are 75% in individuals with superficial esophageal squamous cell carcinoma but much lower in patients with more advanced tumors. Lymph node metastases, which are common, are

associated with poor prognosis. The overall 5-year survival rate in the United States remains less than 20%, and varies by tumor stage and patient age, race, and gender.

KEY CONCEPTS

Esophageal Diseases

- Abnormalities of esophageal motility include **nutcracker esophagus** and **diffuse esophageal spasm**.
- **Achalasia**, characterized by incomplete lower esophageal sphincter (LES) relaxation, increased LES tone, and esophageal aperistalsis, is a common form of functional esophageal obstruction. It can be primary or secondary, with the latter form most commonly due to *Trypanosoma cruzi* infection.
- **Mallory-Weiss tears** of mucosa at the gastroesophageal junction develop as a result of severe retching or vomiting.
- **Esophagitis** can result from chemical or infectious mucosal injury. Infection is most common in immunocompromised individuals.
- The most prevalent cause of esophagitis is **gastroesophageal reflux disease (GERD)**.
- **Eosinophilic esophagitis** is strongly associated with food allergy, allergic rhinitis, asthma, or modest peripheral eosinophilia. It is a common cause of GERD-like symptoms in children living in developed countries.
- **Gastroesophageal varices** are a consequence of portal hypertension and are present in nearly half of cirrhosis patients.
- **Barrett esophagus** develops in patients with chronic GERD and represents columnar metaplasia of the esophageal squamous mucosa.
- Barrett esophagus is a risk factor for development of **esophageal adenocarcinoma**.
- **Esophageal squamous cell carcinoma** is associated with alcohol and tobacco use, poverty, caustic esophageal injury, achalasia, tylosis, and Plummer-Vinson syndrome.

STOMACH

Disorders of the stomach are a frequent cause of clinical disease, with inflammatory and neoplastic lesions being particularly common. In the United States, diseases related to the stomach account for nearly one third of all health care spending on GI disease. In addition, despite decreasing incidence in certain locales such as the United States, gastric cancer remains a leading cause of death worldwide.

The stomach is divided into four major anatomic regions: the cardia, fundus, body, and antrum. The cardia and antrum are lined mainly with mucin-secreting foveolar cells that form small glands. The antral glands are similar but also contain endocrine cells, such as G cells, that release gastrin to stimulate luminal acid secretion by parietal cells within the gastric fundus and body. The well-developed glands of the body and fundus also contain chief cells that produce and secrete digestive enzymes such as pepsin.

Gastropathy and Acute Gastritis

Gastritis is a mucosal inflammatory process. When neutrophils are present, the lesion is referred to as acute gastritis. When inflammatory cells are rare or absent, the term gastropathy is applied; it includes a diverse set of disorders marked by gastric injury or dysfunction. Agents that cause gastropathy include NSAIDs, alcohol, bile, and stress induced injury. Acute mucosal erosion or hemorrhage, such as Curling ulcers or lesions following disruption of gastric blood flow, for example, in portal hypertension, can also cause gastropathy that typically progress to gastritis. The term *hypertrophic gastropathy* is applied to a specific group of diseases exemplified by Ménétrier disease and Zollinger-Ellison Syndrome (discussed later).

Figure 17-11 Mechanisms of gastric injury and protection. This diagram illustrates the progression from more mild forms of injury to ulceration that may occur with acute or chronic gastritis. Ulcers include layers of necrosis (N), inflammation (I), and granulation tissue (G), but a fibrotic scar (S), which takes time to develop, is only present in chronic lesions.

Both gastropathy and acute gastritis may be asymptomatic or cause variable degrees of epigastric pain, nausea, and vomiting. In more severe cases there may be mucosal erosion, ulceration, hemorrhage, hematemesis, melena, or, rarely, massive blood loss.

Pathogenesis. The gastric lumen has a pH of close to 1, more than a million times more acidic than the blood. This harsh environment contributes to digestion but also has the potential to damage the gastric mucosa. Multiple mechanisms have evolved to protect the gastric mucosa (Fig. 17-11). Mucin secreted by surface foveolar cells forms a thin layer of mucus and phospholipids that prevents large food particles from directly touching the epithelium. The mucus covering also promotes formation of an “unstirred” layer of fluid over the epithelium that protects the mucosa and has a neutral pH as a result of bicarbonate ion secretion by surface epithelial cells. Beneath the mucus, a continuous layer of gastric epithelial cells forms a physical barrier that limits back diffusion of acid and leakage of other luminal materials, including pepsin, into the lamina propria. Complete replacement of the surface foveolar cells every 3 to 7 days is essential for both the maintenance of the epithelial layer and the secretion of mucus and bicarbonate from these cells. In acid-secreting parts of the stomach, a capillary “alkaline tide” is generated as parietal cells secrete hydrochloric acid into the gastric lumen and bicarbonate into the vessels. In addition to delivering bicarbonate, the rich mucosal vasculature delivers oxygen and nutrients while washing away acid that has back-diffused into the lamina propria.

Gastropathy, acute gastritis, and chronic gastritis can occur following disruption of any of these protective mechanisms.

- Nonsteroidal antiinflammatory drugs (NSAIDs) inhibit cyclooxygenase- (COX) dependent synthesis of prostaglandins E_2 and I_2 , which stimulate nearly all of the above defense mechanisms including mucus, bicarbonate, and phospholipid secretion, mucosal blood flow, and epithelial restitution while reducing acid secretion. Although COX-1 plays a larger role than COX-2, both isoenzymes contribute to mucosal protection. Thus, while the risk of NSAID-induced gastric injury is greatest with non-selective inhibitors, for example, aspirin, ibuprofen, and naproxen, selective COX-2 inhibition, for example, by celecoxib, can also result in gastropathy or gastritis.
- The gastric injury that occurs in uremic patients and those infected with urease-secreting *H. pylori* may be due to inhibition of gastric bicarbonate transporters by ammonium ions.
- Reduced mucin and bicarbonate secretion have been suggested as factors that explain the increased susceptibility of older adults to gastritis.
- Decreased oxygen delivery may account for an increased incidence of acute gastritis at high altitudes.

Ingestion of harsh chemicals, particularly acids or bases, either accidentally or as a suicide attempt, also results in severe gastric injury, predominantly as a result of direct injury to mucosal epithelial and stromal cells. Direct cellular damage also contributes to gastritis induced by excessive alcohol consumption, NSAIDs, radiation therapy, and

chemotherapy. Agents that inhibit DNA synthesis or the mitotic apparatus, including those used in cancer chemotherapy, may cause generalized mucosal damage due to insufficient epithelial renewal.

MORPHOLOGY

Histologically, gastropathy and mild acute gastritis may be difficult to recognize, since the lamina propria shows only moderate edema and slight vascular congestion. The surface epithelium is intact, but foveolar cell hyperplasia, with characteristic corkscrew profiles and epithelial proliferation are typically present. Neutrophils are not abundant, but a few may be found among the epithelial cells or within mucosal glands in gastritis. There are few lymphocytes and plasma cells.

The presence of neutrophils above the basement membrane in direct contact with epithelial cells is abnormal in all parts of the GI tract and signifies active inflammation, or, in this case, gastritis (rather than gastropathy). The term active inflammation is preferred over acute inflammation, since active inflammation may be present in both acute and chronic disease states. With more severe mucosal damage, erosions and hemorrhage develop. Erosion denotes loss of the epithelium, resulting in a superficial mucosal defect. It is accompanied by a pronounced mucosal neutrophilic infiltrate and a fibrin-containing purulent exudate in the lumen. Hemorrhage may occur and cause dark punctae in hyperemic mucosa. Concurrent erosion and hemorrhage is termed **acute erosive hemorrhagic gastritis**. Large areas of the gastric surface may be denuded, although the involvement is typically superficial. When erosions extend deeply, they may progress to ulcers, as described later.

Clinical Features. The presentation of gastropathy and acute gastritis varies according to etiology, and the two cannot be distinguished on clinical grounds. Patients with NSAID-induced gastropathy may be asymptomatic or have persistent epigastric pain that responds to antacids or proton pump inhibitors. In contrast, pain associated with bile reflux is typically refractory to such therapies and may be accompanied by occasional bilious vomiting.

Stress-Related Mucosal Disease

Stress-related mucosal disease occurs in patients with severe trauma, extensive burns, intracranial disease, major surgery, serious medical disease, and other forms of severe physiologic stress. More than 75% of critically ill patients develop endoscopically visible gastric lesions during the first 3 days of their illness. In some cases, the associated ulcers are given specific names based on location and clinical associations. For example:

- *Stress ulcers* are most common in individuals with shock, sepsis, or severe trauma.
- Ulcers occurring in the proximal duodenum and associated with severe burns or trauma are called *Curling ulcers*.
- Gastric, duodenal, and esophageal ulcers arising in persons with intracranial disease are termed *Cushing ulcers* and carry a high incidence of perforation.

Pathogenesis. The pathogenesis of stress-related gastric mucosal injury is most often related to local ischemia. This

may be due to systemic hypotension or reduced blood flow caused by stress-induced splanchnic vasoconstriction. Upregulation of inducible NO synthase and increased release of the vasoconstrictor endothelin-1 also contribute to ischemic gastric mucosal injury, while increased COX-2 expression appears to be protective.

Lesions associated with intracranial injury are thought to be caused by direct stimulation of vagal nuclei, which causes hypersecretion of gastric acid. Systemic acidosis, a frequent finding in these settings, may also contribute to mucosal injury by lowering the intracellular pH of mucosal cells.

MORPHOLOGY

Stress-related gastric mucosal injury ranges from shallow erosions caused by superficial epithelial damage to deeper lesions that penetrate the depth of the mucosa. Acute ulcers are rounded and less than 1 cm in diameter. The ulcer base is frequently stained brown to black by acid digestion of extravasated blood and may be associated with transmural inflammation and local serositis. Unlike peptic ulcers, which arise in the setting of chronic injury, acute stress ulcers are found anywhere in the stomach and are most often multiple. Microscopically, acute stress ulcers are sharply demarcated, with essentially normal adjacent mucosa. There may be a suffusion of blood into the mucosa and submucosa and an associated inflammatory reaction. Conspicuously absent are the scarring and blood vessel thickenings that characterize chronic peptic ulcers. Healing with complete re-epithelialization occurs within days to several weeks after removal of the injurious factors.

Clinical Features. Most critically ill patients admitted to hospital intensive care units have histologic evidence of gastric mucosal damage. Bleeding from superficial gastric erosions or ulcers that may require transfusion develops in 1% to 4% of these patients. Other complications, including perforation, can also occur. Prophylactic proton pump inhibitors may blunt the impact of stress ulceration, but the most important determinant of clinical outcome is the ability to correct the underlying condition. The gastric mucosa can recover completely if the patient does not succumb to the primary disease.

Other, non-stress-related causes of gastric bleeding include the *Dieulafoy lesion* and *gastric antral vascular ectasia* (GAVE).

- Dieulafoy lesion is caused by a submucosal artery that does not branch properly within the wall of the stomach. This results in a mucosal artery with a diameter of up to 3 mm, or 10 times the size of mucosal capillaries. Dieulafoy lesions are most commonly found along the lesser curvature, near the gastroesophageal junction. Erosion of the overlying epithelium can cause gastric bleeding that, while usually self-limited, can be copious. Bleeding is often associated with NSAID use and may be recurrent.
- GAVE is responsible for 4% of non-variceal upper gastrointestinal bleeding. It can be recognized endoscopically as longitudinal stripes of edematous erythematous mucosa that alternate with less severely injured, paler mucosa, and is sometimes referred to as watermelon

stomach. The erythematous stripes are created by ectatic mucosal vessels. Histologically, the antral mucosa shows reactive gastropathy with dilated capillaries containing fibrin thrombi. While most often idiopathic, GAVE can also be associated with cirrhosis and systemic sclerosis. Patients may present with occult fecal blood or iron deficiency anemia.

Chronic Gastritis

The most common cause of chronic gastritis is infection with the bacillus *H. pylori*. Autoimmune gastritis, the most common cause of diffuse atrophic gastritis, represents less than 10% of cases of chronic gastritis, but is the most common form of chronic gastritis in patients without *H. pylori* infection. However, it is important to recognize that longstanding *H. pylori* infection can also result in atrophic gastritis, typically in a multifocal rather than diffuse pattern. Less common causes of chronic gastritis include radiation injury, chronic bile reflux, mechanical injury (e.g. an indwelling nasogastric tube), and involvement by systemic diseases, such as Crohn disease, amyloidosis, or graft-versus-host disease.

In contrast to acute gastritis, the symptoms associated with chronic gastritis are typically less severe but more persistent. Nausea and upper abdominal pain are typical, sometimes with vomiting, but hematemesis is uncommon.

Helicobacter pylori Gastritis

H. pylori are spiral-shaped or curved bacilli present in gastric biopsy specimens of almost all patients with duodenal ulcers as well as most individuals with gastric ulcers or chronic gastritis. Acute *H. pylori* infection does not produce sufficient symptoms to come to medical attention in most cases; it is the chronic gastritis that ultimately causes the individual to seek treatment. *H. pylori* organisms are present in 90% of individuals with chronic gastritis affecting the antrum.

Epidemiology. In the United States, *H. pylori* infection is associated with poverty, household crowding, limited education, African American or Mexican American ethnicity, residence in rural areas, and birth outside of the United States. Humans are the primary carriers, suggesting that transmission is primarily by the fecal-oral route. Infection is typically acquired in childhood and persists for life without treatment. Improved sanitation in the United States likely explains the marked reduction in *H. pylori* infection rates among younger people that has resulted in a cohort effect. For example, the prevalence of *H. pylori* infection in those younger than 12 years old is less than 15% relative to the 50% to 60% prevalence in those older than 60 years of age. Accordingly, colonization rates vary from less than 10% to more than 80% worldwide, as a function of age and geography.

Pathogenesis. *H. pylori* infection most often presents as a predominantly antral gastritis with normal or increased acid production. Local gastrin production may be increased, but hypergastrinemia (increased serum gastrin) is uncommon. When inflammation remains limited to the

antrum, increased acid production results in greater risk of duodenal peptic ulcer (see later). In other patients gastritis may progress to involve the gastric body and fundus. This *multifocal atrophic gastritis* is associated with patchy mucosal atrophy, reduced parietal cell mass and acid secretion, intestinal metaplasia, and increased risk of gastric adenocarcinoma. Thus, there is an inverse relationship between duodenal ulcer and gastric adenocarcinoma that correlates with the pattern of gastritis. The bacterial and host factors that determine which pattern develops in an individual patient are discussed later.

H. pylori organisms have adapted to the ecologic niche provided by gastric mucus. Its virulence is linked to the following factors:

- *Flagella*, which allow the bacteria to be motile in viscous mucus
- *Urease*, which generates ammonia from endogenous urea and thereby elevates local gastric pH and enhances bacterial survival
- *Adhesins* that enhance bacterial adherence to surface foveolar cells
- *Toxins*, such as cytotoxin-associated gene A (*CagA*), that may be involved in disease progression

Variation in these and other bacterial factors are strongly linked to outcome. For example, *CagA* gene and the associated 20 gene pathogenicity islands are present in 50% of *H. pylori* isolates overall but in 90% of *H. pylori* isolates found in populations with elevated gastric cancer risk. This may, in part, be because *CagA* expressing strains can effectively colonize the gastric body and cause multifocal atrophic gastritis.

Host factors also play an important role in the outcome of *H. pylori* infection. Genetic polymorphisms that lead to increased expression of the proinflammatory cytokines tumor necrosis factor (TNF) and interleukin-1 β (IL-1 β) or decreased expression of the antiinflammatory cytokine interleukin-10 (IL-10) are associated with development of pangastritis, atrophy, and gastric cancer. Iron deficiency may also be a risk factor for *H. pylori*-associated gastric cancer. The course of *H. pylori* gastritis is, therefore, the result of interplay between gastroduodenal mucosal defenses, inflammatory responses, and bacterial virulence factors.

MORPHOLOGY

Gastric biopsy specimens generally demonstrate *H. pylori* in infected individuals. The organism is concentrated within the superficial mucus overlying epithelial cells in the surface and neck regions. The distribution can be irregular, with areas of heavy colonization adjacent to those with few organisms. In extreme cases, the organisms carpet the luminal surfaces of foveolar and mucous neck cells, and can even extend into the gastric pits. Organisms are most easily demonstrated with special stains (Fig. 17-12A). *H. pylori* display tropism for gastric epithelia and are generally not found in association with intestinal metaplasia or duodenal epithelium.

Within the stomach, *H. pylori* are most often found in the antrum (Table 17-2). Although there is often concordance between colonization of the antrum and cardia, infection of the

Figure 17-12 *Helicobacter pylori* gastritis. **A**, Spiral-shaped *H. pylori* are highlighted in this Warthin-Starry silver stain. Organisms are abundant within surface mucus. **B**, Intraepithelial and lamina propria neutrophils are prominent. **C**, Lymphoid aggregates with germinal centers and abundant subepithelial plasma cells within the superficial lamina propria are characteristic of *H. pylori* gastritis.

cardia occurs at somewhat lower rates. *H. pylori* are less common in oxyntic (acid-producing) mucosa of the fundus and body. Thus, an antral biopsy is preferred for evaluation of *H. pylori* gastritis. When viewed endoscopically, *H. pylori*-infected antral mucosa is usually erythematous and has a coarse or even nodular appearance. The inflammatory infiltrate generally includes variable numbers of neutrophils within the lamina propria, including some that cross the basement membrane to assume an intraepithelial location (Fig. 17-12B) and accumulate in the lumen of gastric pits to create pit abscesses. In addition, the superficial lamina propria contains large numbers of plasma cells, often in clusters or sheets, and increased numbers of lymphocytes and macrophages. Intraepithelial neutrophils and subepithelial plasma cells are characteristic of *H. pylori* gastritis. When intense, inflammatory infiltrates may create thickened rugal folds, mimicking the appearance of early cancers. Lymphoid aggregates, some with germinal centers, are frequently present (Fig. 17-12C) and represent an induced form of mucosa-associated lymphoid tissue, or MALT, that has the potential to transform into lymphoma.

Long-standing *H. pylori* gastritis may extend to involve the body and fundus, and the mucosa can become atrophic, with loss of parietal and chief cells. As a result, the oxyntic mucosa can take on the appearance of antral mucosa. In contrast to

autoimmune gastritis, this is typically a patchy process, and biopsies of the gastric body can show intact oxyntic glands adjacent to antral-type glands. The development of atrophy is typically associated with the presence of intestinal metaplasia and increased risk of gastric adenocarcinoma.

Clinical Features. In addition to histologic identification of the organism, several diagnostic tests have been developed including a noninvasive serologic test for antibodies to *H. pylori*, fecal bacterial detection, and the urea breath test based on the generation of ammonia by the bacterial urease. Gastric biopsy specimens can also be analyzed by the rapid urease test, bacterial culture, or bacterial DNA detection by PCR.

Effective treatments for *H. pylori* infection include combinations of antibiotics and proton pump inhibitors. Individuals with *H. pylori* gastritis usually improve after treatment, although relapses can occur after incomplete eradication or reinfection, which is common in regions with high endemic colonization rates. Prophylactic and therapeutic vaccines are still at an early stage of development.

Autoimmune Gastritis

Autoimmune gastritis accounts for less than 10% of cases of chronic gastritis. In contrast to *H. pylori*-associated gastritis, autoimmune gastritis typically spares the antrum and is associated with hypergastrinemia (Table 17-2). Autoimmune gastritis is characterized by:

- Antibodies to parietal cells and intrinsic factor that can be detected in serum and gastric secretions
- Reduced serum pepsinogen I concentration
- Endocrine cell hyperplasia
- Vitamin B₁₂ deficiency
- Defective gastric acid secretion (achlorhydria)

Table 17-2 Characteristics of *Helicobacter pylori*-Associated and Autoimmune Gastritis

	<i>H. pylori</i> -Associated	Autoimmune
Location	Antrum	Body
Inflammatory infiltrate	Neutrophils, subepithelial plasma cells	Lymphocytes, macrophages
Acid production	Increased to slightly decreased	Decreased
Gastrin	Normal to decreased	Increased
Other lesions	Hyperplastic/inflammatory polyps	Neuroendocrine hyperplasia
Serology	Antibodies to <i>H. pylori</i>	Antibodies to parietal cells (H ⁺ ,K ⁺ -ATPase, intrinsic factor)
Sequelae	Peptic ulcer, adenocarcinoma, MALToma	Atrophy, pernicious anemia, adenocarcinoma, carcinoid tumor
Associations	Low socioeconomic status, poverty, residence in rural areas	Autoimmune disease; thyroiditis, diabetes mellitus, Graves disease

Pathogenesis. Autoimmune gastritis is associated with loss of parietal cells, which are responsible for secretion of gastric acid and intrinsic factor. The absence of acid production stimulates gastrin release, resulting in hypergastrinemia and hyperplasia of antral gastrin-producing G cells. Lack of intrinsic factor disables ileal vitamin B₁₂ absorption, which ultimately leads to vitamin B₁₂ deficiency and a slow-onset megaloblastic anemia (*pernicious anemia*). Reduced serum pepsinogen I concentration results from chief cell destruction. Although *H. pylori* infection can cause gastric atrophy and hypochlorhydria, it is not associated with achlorhydria or pernicious anemia. This is because, in contrast to the diffuse atrophy of autoimmune gastritis, the damage in *H. pylori* gastritis is multifocal and leaves patches of residual parietal and chief cells.

CD4+ T cells directed against parietal cell components, including the H⁺,K⁺-ATPase, are considered to be the principal agents of injury in autoimmune gastritis. This is supported by the observation that transfer of H⁺,K⁺-ATPase-reactive CD4+ T cells into naïve mice results in gastritis and production of H⁺,K⁺-ATPase autoantibodies. There is no evidence of an autoimmune reaction to chief cells, suggesting that these may be lost through gastric gland destruction during autoimmune attack on parietal cells. If autoimmune destruction is controlled by immunosuppression, the glands can repopulate, demonstrating that gastric stem cells survive and are able to differentiate into parietal and chief cells.

Autoantibodies to parietal cell components, most prominently the H⁺,K⁺-ATPase, or proton pump, and intrinsic factor are present in up to 80% of patients with autoimmune gastritis. However, these antibodies are not thought to be pathogenic because neither secreted intrinsic factor nor the lumenally oriented proton pump are accessible to circulating antibodies, and passive transfer of these antibodies does not produce gastritis in experimental animals. Nevertheless, the presence of these autoantibodies is a useful diagnostic tool.

MORPHOLOGY

Autoimmune gastritis is characterized by diffuse mucosal damage of the oxyntic (acid-producing) mucosa within the body and fundus. Damage to the antrum and cardia is typically absent or mild. With diffuse atrophy, the oxyntic mucosa of the body and fundus appears markedly thinned, and rugal folds are lost. If vitamin B₁₂ deficiency is severe, nuclear enlargement (megaloblastic change) occurs within epithelial cells. Neutrophils may be present, but the inflammatory infiltrate is typically composed of lymphocytes, macrophages, and plasma cells, often in association with lymphoid aggregates and follicles. The superficial lamina propria plasma cells typical of *H. pylori* gastritis are absent, and the inflammatory reaction is deeper and centered on the gastric glands (Fig. 17-13A). Loss of parietal and chief cells can be extensive. When atrophy is incomplete, residual islands of oxyntic mucosa may give the appearance of multiple small polyps or nodules. In other areas, small surface elevations may represent sites of intestinal metaplasia, characterized by the presence of goblet cells and columnar absorptive cells (Fig. 17-13B). Although present in most patients, endocrine cell hyperplasia can be difficult to appreciate on hematoxylin and eosin-stained sections. This

Figure 17-13 Autoimmune gastritis. **A**, Low-magnification image of gastric body demonstrating deep inflammatory infiltrates, primarily composed of lymphocytes, and glandular atrophy. **B**, Intestinal metaplasia, recognizable as the presence of goblet cells admixed with gastric foveolar epithelium.

hyperplasia, which can be clearly demonstrated with immunostains for proteins such as chromogranin A, parallels the degree of mucosal atrophy and is a physiologic response to decreased acid production. Over time, hypergastrinemia can stimulate endocrine cell hyperplasia in the fundus and body. Rarely, this may progress to form small, multicentric, low-grade neuroendocrine (carcinoid) tumors.

Clinical Features. Antibodies to parietal cells and to intrinsic factor are present early in the disease course. Progression to gastric atrophy probably occurs over 2 to 3 decades, and anemia is seen in only a few patients. Because of the slow onset and variable progression, patients are generally diagnosed only after being affected for many years; the median age at diagnosis is 60. Slightly more women than men are affected. Pernicious anemia and autoimmune gastritis are often associated with other autoimmune diseases including Hashimoto thyroiditis, insulin-dependent (type I) diabetes mellitus, Addison disease, primary ovarian failure, primary hypoparathyroidism, Graves disease, vitiligo, myasthenia gravis, and Lambert-Eaton syndrome. These associations, along with concordance in some monozygotic twins and clustering of disease in families, support a genetic predisposition. In general, about 20% of relatives of individuals with pernicious anemia also have autoimmune gastritis, although they may be asymptomatic. Despite this strong genetic influence, autoimmune gastritis stands apart from many other autoimmune diseases in that there is little evidence of linkage to specific HLA alleles.

Clinical presentation may be linked to symptoms of anemia (Chapter 14). Vitamin B₁₂ deficiency may also cause atrophic glossitis, in which the tongue becomes smooth and beefy red, epithelial megaloblastosis, malabsorptive

diarrhea, peripheral neuropathy, spinal cord lesions, and cerebral dysfunction. Neuropathic changes include demyelination, axonal degeneration, and neuronal death. The most frequent manifestations of peripheral neuropathy are paresthesias and numbness. The spinal lesions result from demyelination of the dorsal and lateral spinal tracts, giving rise to a clinical picture that is often referred to as *subacute combined degeneration of the cord*. It is associated with a mixture of loss of vibration and position sense, sensory ataxia with positive Romberg sign, limb weakness, spasticity, and extensor plantar responses. Cerebral manifestations range from mild personality changes and memory loss to psychosis. In contrast to anemia, neurologic changes are not reversed by vitamin B₁₂ replacement therapy.

Uncommon Forms of Gastritis

Eosinophilic Gastritis. This form of gastritis is characterized by tissue damage associated with dense infiltrates of eosinophils in the mucosa and muscularis, usually in the antral or pyloric region. The lesion may also be present at other sites within the GI tract and is associated with peripheral eosinophilia and increased serum IgE levels. Allergic reactions are one cause of eosinophilic gastritis, with cow's milk and soy protein being the most common allergens in children. Eosinophilic gastritis can also occur in association with immune disorders such as systemic sclerosis and polymyositis, parasitic infections, and even *H. pylori* infection.

Lymphocytic Gastritis. This disease preferentially affects women and produces nonspecific abdominal symptoms. It is idiopathic, but approximately 40% of cases are associated with celiac disease, suggesting an immune-mediated pathogenesis. Lymphocytic gastritis typically affects the entire stomach and is often referred to as *varioliform gastritis* based on the distinctive endoscopic appearance (thickened folds covered by small nodules with central aphthous ulceration). Histologically there is a marked increase in the number of intraepithelial T lymphocytes.

Granulomatous Gastritis. This descriptive term is applied to any gastritis that contains well-formed granulomas or aggregates of epithelioid macrophages. It encompasses a diverse group of diseases with widely varying clinical and pathologic features. Many cases are idiopathic. In Western populations, gastric involvement by Crohn disease is the most common specific cause of granulomatous gastritis, followed by sarcoidosis and infections (including mycobacteria, fungi, CMV, and *H. pylori*). In addition to the presence of histologically evident granulomas, narrowing and rigidity of the gastric antrum may occur secondary to transmural granulomatous inflammation.

Complications of Chronic Gastritis

Peptic Ulcer Disease

Peptic ulcer disease (PUD) refers to chronic mucosal ulceration affecting the duodenum or stomach. Nearly all peptic ulcers are associated with *H. pylori* infection,

Table 17-3 Risk factors for Peptic Ulcer Disease

<ul style="list-style-type: none"> • <i>H. pylori</i> infection • Cigarette use (synergizes with <i>H. pylori</i> for gastric PUD) • Chronic obstructive pulmonary disease • Illicit drugs, e.g. cocaine, that reduce mucosal blood flow • NSAIDs (potentiated by corticosteroids) • Alcoholic cirrhosis (primarily duodenal PUD) • Psychological stress (can increase gastric acid secretion) • Endocrine cell hyperplasia (can stimulate parietal cell growth and gastric acid secretion) • Zollinger-Ellison Syndrome (PUD of stomach, duodenum, and jejunum) • Viral infection (CMV, herpes simplex virus)
--

NSAIDs, or cigarette smoking. The most common form of peptic ulcer disease (PUD) occurs within the gastric antrum or duodenum as a result of chronic, *H. pylori*-induced antral gastritis, which is associated with increased gastric acid secretion, and decreased duodenal bicarbonate secretion. In contrast, PUD within the gastric fundus or body is usually accompanied by lesser acid secretion as a result of mucosal atrophy (associated with some cases of *H. pylori*-induced or autoimmune chronic gastritis, as discussed earlier). While these patients still secrete more acid than normal individuals, they are incapable of secreting the much larger amounts needed to overcome the defense mechanisms that “protect” the antral and duodenal mucosa. Thus, individuals with gastric mucosal atrophy are generally protected from antral and duodenal ulcers. PUD may also be caused by acid secreted by ectopic gastric mucosa within the duodenum or an ileal Meckel diverticulum. PUD may also occur in the esophagus as a result of GERD or acid secretion by esophageal ectopic gastric mucosa (an inlet patch).

Epidemiology. The incidence of PUD is falling in developed countries along with reduced prevalence of *H. pylori* infection. However, a new group of duodenal PUD patients older than 60 years of age has emerged as a result of increased NSAID use. This is particularly true when low-dose aspirin (for cardiovascular benefits) is combined with other NSAIDs. This is facilitated if concurrent *H. pylori* infection is also present. PUD has been associated with cigarette use and cardiovascular disease, likely due to reduced mucosal blood flow, oxygenation, and healing. Other risk factors for PUD are listed in [Table 17-3](#).

Pathogenesis. PUD results from imbalances between mucosal defense mechanisms and damaging factors that cause chronic gastritis (discussed earlier). Thus, PUD generally develops on a background of chronic gastritis. The reasons why some people develop only chronic gastritis while others develop PUD are poorly understood. However, as with *H. pylori* gastritis, it is likely that host factors as well as variation between bacterial strains are involved.

MORPHOLOGY

Peptic ulcers occur in the context of chronic gastritis, but are most common in the proximal duodenum, where they occur within a few centimeters of the pyloric valve and involve the anterior duodenal wall. Gastric peptic ulcers are predominantly located along the lesser curvature near the interface of the body and antrum.

Figure 17-14 Acute gastric perforation in a patient presenting with free air under the diaphragm. **A**, Mucosal defect with clean edges. **B**, The necrotic ulcer base is composed of granulation tissue.

Peptic ulcers are solitary in more than 80% of patients. Lesions less than 0.3 cm in diameter tend to be shallow while those greater than 0.6 cm are likely to be deeper. The classic peptic ulcer is a round to oval, **sharply punched-out defect** (Fig. 17-14A). The mucosal margin may overhang the base slightly, particularly on the upstream side, but is usually level with the surrounding mucosa. In contrast, **heaped-up margins are more characteristic of cancers**. The depth of ulcers may be limited by the thick gastric muscularis propria or by adherent pancreas, omental fat, or the liver. Hemorrhage and fibrin deposition are often present on the gastric serosa. **Perforation** into the peritoneal cavity is a surgical emergency that may be identified by detection of free air under the diaphragm on upright radiographs of the abdomen.

The base of peptic ulcers is smooth and clean as a result of peptic digestion of exudate. Active ulcers may be lined by a thin layer of fibrinoid debris underlaid by a predominantly neutrophilic inflammatory infiltrate. Beneath this, granulation tissue infiltrated with mononuclear leukocytes and a fibrous or collagenous scar forms the ulcer base (Fig. 17-14B). Vessel walls within the scarred area are typically thickened and are occasionally thrombosed. Bleeding from damaged vessels within the

ulcer base may cause life-threatening **hemorrhage**. Scarring may involve the entire thickness of the wall and pucker the surrounding mucosa into folds that radiate outward.

Size and location do not differentiate between benign and malignant ulcers. However, the gross appearance of chronic peptic ulcers is virtually diagnostic. **Malignant transformation of peptic ulcers occurs rarely**, if ever, and reports of transformation probably represent cases in which a lesion thought to be a chronic peptic ulcer was actually an ulcerated carcinoma from the start.

Clinical Features. Peptic ulcers can be chronic, recurring lesions with significant morbidity. The majority of peptic ulcers come to clinical attention because of *epigastric burning or aching pain*, although a significant fraction present with complications such as *iron deficiency anemia, hemorrhage, or perforation* (Table 17-4). The pain tends to occur 1 to 3 hours after meals during the day, is worse at night (usually between 11 PM and 2 AM), and is relieved by alkali or food. Nausea, vomiting, bloating, belching, and significant weight loss are additional manifestations. With penetrating ulcers the pain is occasionally referred to the back, the left upper quadrant, or the chest, where it may be misinterpreted as cardiac in origin.

Current therapies for PUD are aimed at *H. pylori* eradication and neutralization of gastric acid, primarily with proton pump inhibitors. It is also important to withdraw other offending agents, such as NSAIDs, including selective COX-2 inhibitors, that may interfere with mucosal healing. While peptic ulcers were previously notorious for their recurrence, the recurrence rate is now less than 20% following successful clearance of *H. pylori*.

A variety of surgical approaches were formerly used to treat PUD, including antrectomy to remove gastrin-producing cells and vagotomy to prevent the acid-stimulatory effects mediated by the vagus nerve. However, the success of proton pump inhibitors and *H. pylori* eradication has relegated surgical intervention to treatment of bleeding or perforated peptic ulcers.

Table 17-4 Complications of Peptic Ulcer Disease

Bleeding
Occurs in 15% to 20% of patients
Most frequent complication
May be life-threatening
Accounts for 25% of ulcer deaths
May be the first indication of an ulcer
Perforation
Occurs in up to 5% of patients
Accounts for two thirds of ulcer deaths
Is rarely first indication of an ulcer
Obstruction
Mostly in chronic ulcers
Secondary to edema or scarring
Occurs in about 2% of patients
Most often associated with pyloric channel ulcers
May occur with duodenal ulcers
Causes incapacitating, crampy abdominal pain
Can rarely cause total obstruction and intractable vomiting

KEY CONCEPTS

Gastritis

- **Gastritis** is a mucosal inflammatory process. When inflammatory cells are absent or rare, the term **gastropathy** can be applied.
- The spectrum of **acute gastritis** ranges from asymptomatic disease to mild epigastric pain, nausea, and vomiting. Causative factors include any agent or disease that interferes with gastric mucosal protective mechanisms.
- Severe acute gastritis can result in **acute gastric ulceration**.
- The most common cause of chronic gastritis is ***H. pylori* infection**. Other agents include NSAIDs and alcohol.
- ***H. pylori* gastritis** typically affects the antrum and is associated with increased gastric acid production. In later disease, the body can be involved and the resulting glandular atrophy can lead to mildly reduced acid production. Host immune responses and bacterial characteristics determine whether the infection remains antral or progresses to **pangastritis**.
- ***H. pylori* gastritis induces mucosa-associated lymphoid tissue (MALT)** that can give rise to B cell lymphomas (MALTomas).
- **Autoimmune gastritis** is the most frequent etiology of noninfectious chronic gastritis. It results in atrophy of the gastric body oxyntic glands, which leads to decreased gastric acid production, antral G cell hyperplasia, achlorhydria, and vitamin B₁₂ deficiency. Anti-parietal cell and anti-intrinsic factor antibodies are typically present.
- **Intestinal metaplasia** develops in both forms of chronic gastritis and is a risk factor for gastric adenocarcinoma.
- **Peptic ulcer disease** is usually secondary to *H. pylori* chronic gastritis and the resulting hyperchlorhydria. Ulcers can develop in the stomach or duodenum, and usually heal after suppression of gastric acid production and eradication of *H. pylori*.

Mucosal Atrophy and Intestinal Metaplasia

Long-standing chronic gastritis that involves the body and fundus may ultimately lead to significant loss of parietal cell mass. This oxyntic atrophy may be associated with intestinal metaplasia, recognized by the presence of goblet cells, and is strongly associated with increased risk of gastric adenocarcinoma. The risk of adenocarcinoma is greatest in autoimmune gastritis. This may be because achlorhydria of gastric mucosal atrophy permits overgrowth of bacteria that produce carcinogenic nitrosamines. Intestinal metaplasia also occurs in chronic *H. pylori* gastritis and may regress after clearance of the organism.

Dysplasia

Chronic gastritis exposes the epithelium to inflammation-related free radical damage and proliferative stimuli. Over time this combination of stressors can lead to the accumulation of genetic alterations that result in carcinoma. Preinvasive in situ lesions can be recognized histologically as dysplasia. The morphologic hallmarks of dysplasia are variations in epithelial size, shape, and orientation along

with coarse chromatin texture, hyperchromasia, and nuclear enlargement. The distinction between dysplasia and regenerative epithelial changes induced by active inflammation can be a challenge for the pathologist, since increased epithelial proliferation and mitotic figures may be prominent in both. However, reactive epithelial cells mature as they reach the mucosal surface, while dysplastic lesions remain cytologically immature.

Gastritis Cystica

Gastritis cystica is an exuberant reactive epithelial proliferation associated with entrapment of epithelial-lined cysts. These may be found within the submucosa (gastritis cystica polyposa) or deeper layers of the gastric wall (gastritis cystica profunda). Because of the association with chronic gastritis and partial gastrectomy, it is presumed that gastritis cystica is trauma-induced, but the reasons for the development of epithelial cysts within deeper portions of the gastric wall are not clear. Regenerative epithelial changes can be prominent in the entrapped epithelium, and gastritis cystica can therefore mimic invasive adenocarcinoma.

Hypertrophic Gastropathies

Hypertrophic gastropathies are uncommon diseases characterized by giant “cerebriform” enlargement of the rugal folds due to epithelial hyperplasia without inflammation. As might be expected, the hypertrophic gastropathies are linked to excessive growth factor release. Two well-defined examples are Ménétrier disease and Zollinger-Ellison syndrome, the morphologic features of which are compared with other gastric proliferations in [Table 17-5](#).

Ménétrier Disease

Ménétrier disease is a rare disorder associated with excessive secretion of transforming growth factor α (TGF- α). It is characterized by diffuse hyperplasia of the foveolar epithelium of the body and fundus and hypoproteinemia due to protein-losing enteropathy. Secondary symptoms, such as weight loss, diarrhea, and peripheral edema, are commonly present. Symptoms and pathologic features of Ménétrier disease in children are similar to those in adults, but pediatric disease is usually self-limited and often follows a respiratory infection. Risk of gastric adenocarcinoma is increased in adults with Ménétrier disease.

MORPHOLOGY

Ménétrier disease is characterized by irregular enlargement of the gastric rugae. Some areas may appear polypoid. Enlarged rugae are present in the body and fundus ([Fig. 17-15A](#)), but the antrum is generally spared. Histologically, the most characteristic feature is hyperplasia of foveolar mucous cells. The glands are elongated with a corkscrew-like appearance and cystic dilation is common ([Fig. 17-15B](#)). Inflammation is usually modest, although some cases show marked intraepithelial lymphocytosis. Diffuse or patchy glandular atrophy, evident as hypoplasia of parietal and chief cells, is typical.

Table 17-5 Hypertrophic Gastropathies and Gastric Polyps

Parameter	Ménétrier Disease (adult)	Zollinger-Ellison Syndrome	Inflammatory and Hyperplastic Polyps	Gastritis Cystica	Fundic Gland Polyps	Gastric Adenomas
Mean patient age (yr)	30-60	50	50-60	Variable	50	50-60
Location	Body and fundus	Fundus	Antrum > body	Body	Body and fundus	Antrum > body
Predominant cell type	Mucous	Parietal > mucous, endocrine	Mucous	Mucous, cyst-lining	Parietal and chief	Dysplastic, intestinal
Inflammatory infiltrate	Limited, lymphocytes	Neutrophils	Neutrophils and lymphocytes	Neutrophils and lymphocytes	None	Variable
Symptoms	Hypoproteinemia, weight loss, diarrhea	Peptic ulcers	Similar to chronic gastritis	Similar to chronic gastritis	None, nausea	Similar to chronic gastritis
Risk factors	None	Multiple endocrine neoplasia	Chronic gastritis, <i>H. pylori</i>	Trauma, prior surgery	PPIs, FAP	Chronic gastritis, atrophy, intestinal metaplasia
Association with adenocarcinoma	Yes	No	Occasional	No	Syndromic (FAP) only	Frequent

FAP, Familial adenomatous polyposis; PPIs, proton pump inhibitors.

Treatment of Ménétrier disease is supportive, with intravenous albumin and parenteral nutritional supplementation. In severe cases gastrectomy may be needed. More recently, agents that block TGF- α -mediated activation of the epidermal growth factor receptor have shown promise.

Figure 17-15 Ménétrier disease. **A**, Marked hypertrophy of rugal folds. **B**, Foveolar hyperplasia with elongated and focally dilated glands. (Courtesy Dr. M. Kay Washington, Vanderbilt University, Nashville, Tenn.)

Zollinger-Ellison Syndrome

Zollinger-Ellison syndrome is caused by gastrin-secreting tumors. These gastrinomas are most commonly found in the small intestine or pancreas. Patients often present with duodenal ulcers or chronic diarrhea. Within the stomach, the most remarkable feature is a doubling of oxyntic mucosal thickness due to a five-fold increase in the number of parietal cells. Gastrin also induces hyperplasia of mucous neck cells, mucin hyperproduction, and proliferation of endocrine cells within oxyntic mucosa. In some cases these endocrine cells can form small dysplastic nodules or, rarely, true carcinoid tumors.

Treatment of individuals with Zollinger-Ellison syndrome includes blockade of acid hypersecretion. This can be accomplished in almost all patients with proton pump inhibitors. Acid suppression allows peptic ulcers to heal and prevents gastric perforation, allowing treatment to focus on the gastrinoma, which becomes the main determinant of long-term survival.

Although they grow slowly, 60% to 90% of gastrinomas are malignant. Tumors are sporadic in 75% of patients. These tend to be solitary and can be surgically resected. The remaining 25% of patients with gastrinomas have multiple endocrine neoplasia type I (MEN I). These individuals often have multiple tumors or metastatic disease and may benefit from treatment with somatostatin analogues. Detection of tumors may be enhanced by using somatostatin receptor scintigraphy or endoscopic ultrasonography.

Gastric Polyps and Tumors

Polyps, nodules or masses that project above the level of the surrounding mucosa, are identified in up to 5% of upper GI endoscopies. Polyps may develop as a result of epithelial or stromal cell hyperplasia, inflammation, ectopia, or neoplasia. Only the most common types of polyps will be discussed here (Peutz-Jeghers and juvenile polyps are discussed with intestinal polyps). This is followed by a presentation of gastric tumors, including adenocarcinomas, lymphomas, carcinoid tumors, and stromal tumors.

Figure 17-16 Gastric polyps. **A**, Hyperplastic polyp containing corkscrew-shaped foveolar glands. **B**, Hyperplastic polyp with ulceration (*arrow*). **C**, Fundic gland polyp composed of cystically dilated glands lined by parietal, chief, and foveolar cells. **D**, Gastric adenoma recognized by the presence of epithelial dysplasia.

Inflammatory and Hyperplastic Polyps

Up to 75% of all gastric polyps are inflammatory or hyperplastic polyps. Since chronic inflammation drives the development of such polyps, the incidence depends partly on the regional prevalence of *H. pylori* infection. These polyps are most common in individuals between 50 and 60 years of age, and usually develop in association with chronic gastritis, which initiates the injury that leads to reactive hyperplasia and polyp growth. Among individuals with *H. pylori* gastritis, polyps may regress after bacterial eradication. Because the risk of dysplasia correlates with size, polyps larger than 1.5 cm should be resected and examined histologically.

MORPHOLOGY

The majority of inflammatory or hyperplastic polyps are smaller than 1 cm in diameter and are frequently multiple, particularly in individuals with atrophic gastritis. These polyps are ovoid in shape and have a smooth surface, though superficial erosions are common. Microscopically, polyps have irregular, cystically dilated, and elongated foveolar glands (Fig. 17-16A). The lamina propria is typically edematous with variable degrees of acute and chronic inflammation, and surface ulceration may be present (Fig. 17-16B).

Fundic Gland Polyps

Fundic gland polyps occur sporadically and in individuals with familial adenomatous polyposis (FAP). The prevalence of fundic gland polyps has increased markedly in recent years as a result of increasing use of proton pump inhibitor therapy. These drugs inhibit acid production, which leads to increased gastrin secretion and, in turn, oxyntic gland growth. Fundic gland polyps may be asymptomatic or associated with nausea, vomiting, or epigastric pain.

MORPHOLOGY

Fundic gland polyps occur in the gastric body and fundus and are well-circumscribed lesions with a smooth surface. They may be single or multiple and are composed of cystically dilated, irregular glands lined by flattened parietal and chief cells. Inflammation is typically absent or minimal (Fig. 17-16C). Dysplasia and even cancer may occur in FAP-associated fundic gland polyps, but sporadic fundic gland polyps carry no cancer risk.

Gastric Adenoma

Gastric adenomas represent up to 10% of all gastric polyps (Table 17-5). Their frequency increases progressively with age, and there is a marked variation in prevalence among different populations that parallels the incidence of gastric adenocarcinoma. Patients are usually between 50 and 60 years of age, and males are affected three times more often than females. Like fundic gland polyps, the incidence of adenomas is increased in individuals with FAP. *Similar to other forms of gastric dysplasia, adenomas almost always occur on a background of chronic gastritis with atrophy and intestinal metaplasia.* The risk of adenocarcinoma in gastric adenomas is related to the size of the lesion and is particularly increased in lesions greater than 2 cm in diameter. Overall, carcinoma may be present in up to 30% of gastric adenomas.

MORPHOLOGY

Gastric adenomas are usually solitary lesions less than 2 cm in diameter, most commonly located in the antrum. The majority of adenomas are composed of intestinal-type columnar epithelium that exhibits varying degrees of dysplasia (Fig. 17-16D). Dysplasia can be classified as low or high grade, and both grades may include enlargement, elongation, pseudostratification, and hyperchromasia of epithelial cell nuclei, and epithelial

crowding. High-grade dysplasia is characterized by more severe cytologic atypia and irregular architecture, including glandular budding and gland-within-gland, or cribriform, structures. Like intestinal adenomas, gastric adenomas are premalignant neoplastic lesions. However, the risk of transformation to invasive cancer is much higher in gastric adenomas.

Gastric Adenocarcinoma

Adenocarcinoma is the most common malignancy of the stomach, comprising more than 90% of all gastric cancers.

As discussed in more detail later, gastric adenocarcinoma is often separated morphologically into intestinal type, which tends to form bulky masses, and a diffuse type, which infiltrates the wall diffusely, thickens it, and is typically composed of signet ring cells. Early symptoms of both types of gastric adenocarcinoma resemble those of chronic gastritis and peptic ulcer disease, including dyspepsia, dysphagia, and nausea. As a result, these tumors are often discovered at advanced stages, when symptoms such as weight loss, anorexia, early satiety (primarily in diffuse cancers), anemia, and hemorrhage trigger further diagnostic evaluation.

Epidemiology. Gastric cancer incidence varies markedly with geography. In Japan, Chile, Costa Rica, and Eastern Europe, the incidence is up to 20-fold higher than in North America, northern Europe, Africa, and Southeast Asia. Mass endoscopic screening programs have been successful in regions where the incidence is high, such as Japan, where 35% of newly detected cases are early gastric cancers, limited to the mucosa and submucosa. Unfortunately, mass screening programs are not cost-effective in regions where the incidence is low, and fewer than 20% of cases are detected at an early stage in North America and northern Europe. Metastases are often detected at time of diagnosis. Sites most commonly involved include the supraclavicular sentinel lymph node (Virchow node), periumbilical lymph nodes (Sister Mary Joseph nodule), the left axillary lymph node (Irish node), the ovary (Krukenberg tumor), or the pouch of Douglas (Blumer shelf).

Gastric cancer is more common in lower socioeconomic groups and in individuals with multifocal mucosal atrophy and intestinal metaplasia. *Gastric dysplasia and adenomas are recognizable precursor lesions associated with gastric adenocarcinoma.* PUD does not impart an increased risk of gastric cancer, but patients who have had partial gastrectomies for PUD have a slightly higher risk of developing cancer in the residual gastric stump, possibly due to hypochlorhydria, bile reflux, and chronic gastritis.

In the United States, gastric cancer rates dropped by more than 85% during the twentieth century. Adenocarcinoma of the stomach was the most common cause of cancer death in the United States in 1930 and remains a leading cause of cancer death worldwide, but now accounts for fewer than 2.5% of cancer deaths in the United States. Similar declines have been reported in many other Western countries, suggesting that environmental and dietary factors contribute to the development of gastric cancers. Consistent with this conclusion, studies of migrants from high-risk to low-risk

regions have shown that gastric cancer rates in second-generation immigrants are similar to those in their new country of residence.

The cause of the overall reduction in gastric cancer is most closely linked to decreases in H. pylori prevalence. Another possible contributor is the decreased consumption of dietary carcinogens, such as N-nitroso compounds and benzo[a]pyrene, because of the reduced use of salt and smoking for food preservation and the widespread availability of food refrigeration.

Although overall incidence of gastric adenocarcinoma is falling, cancer of the gastric cardia is on the rise. This is probably related to Barrett esophagus and may reflect the increasing incidence of chronic GERD and obesity. Consistent with this presumed common pathogenesis, distal esophageal adenocarcinomas and gastric cardia adenocarcinomas are similar in morphology, clinical behavior, and therapeutic response.

Pathogenesis. While the majority of gastric cancers are not hereditary, the mutations identified in familial gastric cancer have provided important insights into mechanisms of carcinogenesis in sporadic cases. Familial gastric cancer is strongly associated with germline loss-of-function mutations in the tumor suppressor gene *CDH1*, which encodes the cell adhesion protein E-cadherin (discussed in [Chapter 7](#)). Loss-of-function mutations in *CDH1* are also present in about 50% of sporadic diffuse gastric tumors, while E-cadherin expression is drastically decreased in the rest, often by hyper methylation and silencing of the *CDH1* promoter. *Thus, the loss of E-cadherin is a key step in the development of diffuse gastric cancer.* *CDH1* mutations are also common in sporadic and familial lobular carcinoma of the breast, which, like diffuse gastric cancer (see later), tends to infiltrate as single cells, and individuals with *BRCA2* mutations are at increased risk of developing diffuse gastric cancer. Mutation of *TP53* is also found in the majority of sporadic gastric cancers of both diffuse and intestinal types.

In contrast to diffuse gastric cancers, sporadic intestinal-type gastric cancers are strongly associated with mutations that result in increased signaling via the Wnt pathway. These include loss-of-function mutations in the adenomatous polyposis coli (*APC*) tumor suppressor gene and gain-of-function mutations in the gene encoding β -catenin. Loss-of-function mutations or silencing of a number of other tumor suppressor genes have also been identified, including those involved in TGF β signaling (TGF β R2), regulation of apoptosis (BAX), and cell cycle control (*CDKN2A*), all of which are discussed in more detail in [Chapter 7](#). As expected, FAP patients, who carry germline *APC* mutations, have an increased risk of intestinal-type gastric cancer. This is particularly true in Japan and other high-risk areas, as compared to individuals with FAP residing in areas of low gastric cancer incidence. Thus, both host genetic background and environmental factors affect risk. As discussed in the context of *H. pylori* gastritis, genetic variants of proinflammatory and immune response genes, including those that encode IL-1 β , TNF, IL-10, IL-8, and Toll-like receptor 4 (TLR4), are associated with elevated risk of gastric cancer when accompanied by *H. pylori* infection. Thus, it is clear that chronic inflammation promotes gastric neoplasia. Other associations between chronic inflammation and cancer are discussed in [Chapter 7](#).

MORPHOLOGY

Gastric adenocarcinomas are classified according to their location and gross and histologic morphology. Most gastric adenocarcinomas involve the gastric antrum; the lesser curvature is involved more often than the greater curvature. **Gastric tumors with an intestinal morphology**, which tend to form bulky tumors (Fig. 17-17A), are composed of glandular structures (Fig. 17-18A), while cancers with a **diffuse infiltrative growth pattern** (Fig. 17-17B) are more often composed of signet-ring cells (Fig. 17-18B). Although intestinal-type adenocarcinomas may penetrate the gastric wall, they more frequently grow along broad cohesive fronts to form either an exophytic mass or an ulcerated tumor. The neoplastic cells often contain apical mucin vacuoles, and abundant mucin may be present in gland lumina. In contrast, diffuse gastric cancer is generally composed of discohesive cells, likely as a result of E-cadherin loss. These cells do not form glands but instead have large mucin vacuoles that expand the cytoplasm and push the nucleus to the periphery, creating a signet-ring cell morphology. They permeate the mucosa and stomach wall individually or in small clusters, and may be mistaken for inflammatory cells, such as macrophages, at low magnification. Release of extracellular mucin in either type of gastric cancer can result in formation of large mucin lakes that dissect tissue planes.

Figure 17-17 Gastric adenocarcinoma. **A**, Intestinal-type adenocarcinoma consisting of an elevated mass with heaped-up borders and central ulceration. Compare to the peptic ulcer in Figure 17-14A. **B**, Linitis plastica. The gastric wall is markedly thickened and rugal folds are partially lost.

Figure 17-18 Gastric adenocarcinoma. **A**, Intestinal-type adenocarcinoma composed of columnar, gland-forming cells infiltrating through desmoplastic stroma. **B**, Signet-ring cells can be recognized by their large cytoplasmic mucin vacuoles and peripherally displaced, crescent-shaped nuclei.

A mass may be difficult to appreciate in diffuse gastric cancer, but these infiltrative tumors often evoke a **desmoplastic** reaction that stiffens the gastric wall and may provide a valuable diagnostic clue. When there are large areas of infiltration, diffuse rugal flattening and a rigid, thickened wall may impart a **leather bottle** appearance termed **linitis plastica** (Fig. 17-17B).

Clinical Features. Intestinal-type gastric cancer predominates in high-risk areas and develops from precursor lesions, including flat dysplasia and adenomas. The mean age of presentation is 55 years, and the male-to-female ratio is 2:1. In contrast, the incidence of diffuse gastric cancer is relatively uniform across countries, there are no identified precursor lesions, and the disease occurs at similar frequencies in males and females. Notably, the remarkable decrease in gastric cancer incidence applies only to the intestinal type, which is most closely associated with

atrophic gastritis and intestinal metaplasia. As a result, the incidence of diffuse type gastric cancer, which was previously low, is now similar to intestinal type gastric cancer.

The depth of invasion and the extent of nodal and distant metastases at the time of diagnosis remain the most powerful prognostic indicators in gastric cancer. Local invasion into the duodenum, pancreas, and retroperitoneum is common. In such cases efforts are usually focused on chemotherapy or radiation therapy and palliative care. However, when possible, surgical resection remains the preferred treatment for gastric adenocarcinoma. With surgical resection, the 5-year survival rate of early gastric cancer can exceed 90%, even if lymph node metastases are present. In contrast, the 5-year survival rate for advanced gastric cancer remains less than 20%. Because of the advanced stage at which most gastric cancers are discovered in the United States, the overall 5-year survival is less than 30%.

Lymphoma

Although extranodal lymphomas can arise in virtually any tissue, they do so most commonly in the GI tract, particularly the stomach. In allogeneic hematopoietic stem cell and organ transplant recipients, the bowel is also the most frequent site for Epstein-Barr virus-positive B-cell lymphoproliferations. This preferential location is most likely because the deficits in T-cell function caused by oral immunosuppressive agents (e.g., cyclosporine) are greatest at intestinal sites of drug absorption. Nearly 5% of all gastric malignancies are primary lymphomas, the most common of which are indolent extranodal marginal zone B-cell lymphomas. *In the gut these tumors are often referred to as lymphomas of mucosa-associated lymphoid tissue (MALT), or MALTomas.* This and other lymphomas of the gut are discussed in [Chapter 13](#).

Pathogenesis. Extranodal marginal zone B-cell lymphomas usually arise at sites of chronic inflammation. They can originate in the GI tract at sites of preexisting MALT, such as the Peyer patches of the small intestine, but more commonly arise within tissues that are normally devoid of organized lymphoid tissue. *In the stomach, MALT is induced, typically as a result of chronic gastritis. H. pylori infection is the most common inducer in the stomach and, therefore, is found in association with most cases of gastric MALToma.* Remarkably, *H. pylori* eradication results in durable remissions with low rates of recurrence in most MALToma patients.

Three translocations are associated with gastric MALToma, the t(11;18)(q21;q21) and the less common t(1;14)(p22;q32) and t(14;18)(q32;q21). The t(11;18)(q21;q21) translocation brings together the apoptosis inhibitor 2 (API2) gene on chromosome 11 with the “mutated in MALT lymphoma,” or *MLT*, gene on chromosome 18. This creates a chimeric *API2-MLT* fusion gene that encodes an API2-MLT fusion protein. The t(14;18)(q32;q21) and t(1;14)(p22;q32) translocations cause increased expression of intact MALT1 and BCL-10 proteins, respectively.

Each of the three translocations has the same net effect, the constitutive activation of NF- κ B, a transcription factor that promotes B-cell growth and survival. Antigen-dependent activation of NF- κ B in normal B and T cells

requires both BCL-10 and MLT, which work together in a pathway downstream of the B- and T-cell antigen receptors. Thus, *H. pylori*-induced inflammation may trigger NF- κ B activation through the MLT/BCL-10 pathway in MALTomas that lack these translocations. Removal of this stimulus may explain why these tumors tend to respond to *H. pylori* eradication. In contrast, NF- κ B is constitutively active in tumors bearing translocations involving *MLT* or *BCL10*, and *H. pylori* treatment is ineffective. Other tumor characteristics, including invasion to the muscularis propria or beyond and lymph node involvement, also correlate with failure of *H. pylori* eradication to induce remission.

As with other low-grade lymphomas, MALTomas can transform into more aggressive tumors that are histologically identical to diffuse large B-cell lymphomas. This is often associated with additional genetic changes, such as inactivation of the tumor suppressor genes that encode p53 and p16. As one might guess, MALTomas that have undergone such transformation are not responsive to *H. pylori* eradication.

MORPHOLOGY

Histologically, gastric MALToma takes the form of a dense lymphocytic infiltrate in the lamina propria ([Fig. 17-19A](#)). Characteristically, the neoplastic lymphocytes infiltrate the gastric glands focally to create **diagnostic lymphoepithelial lesions** ([Fig. 17-19A](#), inset). Reactive-appearing B-cell follicles may be present, and, in about 40% of tumors, plasmacytic differentiation is observed. At other sites GI lymphomas may disseminate as discrete small nodules ([Fig. 17-19B](#)) or infiltrate the wall diffusely ([Fig. 17-19C](#)).

Like other tumors of mature B cells, MALTomas express the B-cell markers CD19 and CD20. They do not express CD5 or CD10, but are positive for CD43 in about 25% of cases, an unusual feature that can be diagnostically helpful. In cases lacking lymphoepithelial lesions, monoclonality may be demonstrated by restricted expression of either κ or λ immunoglobulin light chains or by molecular detection of clonal IgH rearrangements. Molecular analysis is being used increasingly to identify tumors with translocations that predict resistance to therapy.

Clinical Features. The most common presenting symptoms are dyspepsia and epigastric pain. Hematemesis, melena, and constitutional symptoms such as weight loss can also be present. Because gastric MALTomas and *H. pylori* gastritis often coexist and have overlapping clinical symptoms and endoscopic appearances, diagnostic difficulties may arise, particularly in small biopsy specimens.

Carcinoid Tumor

Carcinoid tumors arise from the diffuse components of the endocrine system and are now properly referred to as *well-differentiated neuroendocrine tumors*. The term carcinoid, or “carcinoma-like,” was applied because these tumors tend to have a more indolent clinical course than GI carcinomas. Most are found in the GI tract, and more than 40% occur in the small intestine ([Table 17-6](#)). The tracheobronchial tree and lungs are the next most

Figure 17-19 Lymphoma. **A**, Gastric MALT lymphoma replacing much of the gastric epithelium. Inset shows lymphoepithelial lesions with neoplastic lymphocytes surrounding and infiltrating gastric glands. **B**, Disseminated lymphoma within the small intestine with numerous small serosal nodules. **C**, Large B-cell lymphoma infiltrating the small intestinal wall and producing diffuse thickening.

commonly involved sites. Gastric carcinoid tumors may be associated with endocrine cell hyperplasia, autoimmune chronic atrophic gastritis, MEN-I, and Zollinger-Ellison syndrome. In addition to autoimmune chronic atrophic gastritis, as already discussed, gastric endocrine cell hyperplasia has been linked to proton pump inhibitor therapy, but the risk of progression to a neuroendocrine neoplasm in this circumstance is extremely low.

MORPHOLOGY

Grossly, carcinoids are intramural or submucosal masses that create small polypoid lesions (Fig. 17-20A). In the stomach they typically arise within oxyntic mucosa. At all GI sites, the overlying mucosa may be intact or ulcerated, and in the intestines the tumors may invade deeply to involve the mesentery. Carcinoids tend to be yellow or tan in color and are very firm as a consequence of an intense desmoplastic reaction, which may cause kinking and obstruction of the bowel. Histologically, carcinoids are composed of islands, trabeculae, strands, glands, or sheets of uniform cells with scant, pink granular cytoplasm and a round to oval stippled nucleus (Fig. 17-20). In most tumors there is minimal pleomorphism, but anaplasia, mitotic activity, and necrosis may be present in rare cases. Immunohistochemical stains are typically positive for endocrine granule markers, such as synaptophysin and chromogranin A.

Clinical Features. The peak incidence of carcinoid tumors is in the sixth decade, but they may appear at any age. Symptoms are determined by the hormones produced. For example, tumors that produce gastrin may cause Zollinger-Ellison syndrome, while ileal tumors may cause carcinoid syndrome, which is characterized by cutaneous flushing, sweating, bronchospasm, colicky abdominal pain, diarrhea, and right-sided cardiac valvular fibrosis. Carcinoid syndrome occurs in fewer than 10% of patients and is caused by vasoactive substances secreted by the tumor into the systemic circulation. When tumors are confined to the

Table 17-6 Features of Gastrointestinal Carcinoid Tumors

Feature	Esophagus	Stomach	Proximal Duodenum	Jejunum and Ileum	Appendix	Colorectum

Figure 17-20 GI carcinoid tumor (neuroendocrine carcinoma). **A**, Gross cross-section of a submucosal tumor nodule. **B**, Microscopically the nodule is composed of tumor cells embedded in dense fibrous tissue. **C**, In other areas, the tumor has spread extensively within mucosal lymphatic channels. **D**, High magnification shows the bland cytology of carcinoid tumors. The chromatin texture, with fine and coarse clumps, is frequently described as a “salt and pepper” pattern. Despite their innocuous appearance, carcinoids can be clinically aggressive. **E**, Electron microscopy reveals cytoplasmic dense core neurosecretory granules.

intestine, the vasoactive substances released are metabolized to inactive forms by the liver, a “first-pass” effect similar to that exerted on oral drugs. This can be overcome by a large tumor burden or, more commonly, when tumors secrete hormones into a nonportal venous circulation. The carcinoid syndrome is therefore strongly associated with metastatic disease in the liver since the bioactive products can be released directly into systemic circulation.

The most important prognostic factor for GI carcinoid tumors is location.

- *Foregut carcinoid tumors*, those found within the stomach, duodenum proximal to the ligament of Treitz, and esophagus, rarely metastasize and are generally cured by resection. This is particularly true for gastric carcinoid tumors that arise in association with atrophic gastritis, while gastric carcinoid tumors without predisposing factors are often more aggressive.
- *Midgut carcinoid tumors* that arise in the jejunum and ileum are often multiple and tend to be aggressive. In these tumors, greater depth of local invasion, increased size, and the presence of necrosis and mitoses are associated with a worse outcome.
- *Hindgut carcinoids* arising in the appendix and colorectum are typically discovered incidentally. Those in the appendix occur at any age and are generally located at the tip. These tumors are rarely more than 2 cm in diameter and are almost always benign. Rectal carcinoid tumors tend to produce polypeptide hormones and, when symptomatic, present with abdominal pain and weight loss. Because they are usually discovered when small, metastasis of rectal carcinoid tumors is uncommon.

Gastrointestinal Stromal Tumor

A wide variety of mesenchymal neoplasms may arise in the stomach. Many are named according to the cell type they most resemble; for example, smooth muscle tumors are called *leiomyomas* or *leiomyosarcomas*, nerve sheath tumors are termed *schwannomas*, and those resembling glomus bodies in the nail beds and at other sites are termed

glomus tumors. These are all rare and are discussed in greater detail in [Chapter 26](#). **GI stromal tumor (GIST) is the most common mesenchymal tumor of the abdomen**, with annual incidences between 11 and 20 per million people. More than half of these tumors occur in the stomach. The term stromal reflects historical confusion about the origin of this tumor, which is now recognized to arise from the interstitial cells of Cajal, or pacemaker cells, of the gastrointestinal muscularis propria.

Epidemiology. Clinically silent, microscopic proliferations that may represent precursors to GIST are present in 10% to 30% of resected stomachs. These have a low mitotic index and lack pleomorphism and other features suggesting malignancy. The risk of of these benign proliferations becoming a GIST is estimated to be 1 in 2000.

The peak age at which clinically evident GISTs are recognized is approximately 60 years, with fewer than 10% occurring in individuals younger than 40 years of age. Of the uncommon GISTs in children, some are related to the *Carney triad*, a nonhereditary syndrome of unknown etiology seen primarily in young females that includes gastric GIST, paraganglioma, and pulmonary chondroma. There is also an increased incidence of GIST in individuals with neurofibromatosis type 1.

Pathogenesis. Approximately 75% to 80% of all GISTs have oncogenic, gain-of-function mutations in the receptor tyrosine kinase *KIT*. Approximately 8% of GISTs have mutations that activate a closely related receptor tyrosine kinase, platelet-derived growth factor receptor α (*PDGFRA*). For unknown reasons, GISTs bearing *PDGFRA* mutations are overrepresented in the stomach. *KIT* and *PDGFRA* gene mutations are mutually exclusive, reflecting their activities within the same signal transduction pathway. Germline mutations in these same genes are present in rare familial GISTs, in which patients develop multiple GISTs and may also have diffuse hyperplasia of Cajal cells. Both sporadic and germline mutations result in constitutively active *KIT* or *PDGFRA* receptor tyrosine kinases and produce intracellular signals that promote tumor cell proliferation and survival ([Chapter 7](#)). Some GISTs without mutated *KIT* or *PDGFRA* have mutations in

other genes that function in these pathways (*NF1*, *BRAF*, *HRAS*, or *NRAS*). However, more common are mutations in genes encoding components of the mitochondrial succinate dehydrogenase complex (*SDHA*, *SDHB*, *SDHC*, *SDHD*). These mutations, which cause loss of SDH function, are often inherited in the germline and confer an increased risk for GIST and paraganglioma (*Carney-Stratakis syndrome*, not to be confused with Carney triad); with the second copy of the affected gene being either mutated or lost in the tumor. The mechanisms by which SDH mutations lead to GIST are unclear; one hypothesis is that the accumulation of succinate leads to dysregulation of hypoxia inducible factor-1 α (HIF-1 α), which results in increased transcription of the vascular endothelial growth factor (*VEGF*) and insulin-like growth factor-1 (*IGF1R*) genes.

Mutation of KIT or PDGFRA is an early event in sporadic GISTs and is detectable in lesions as small as 3 mm. Therefore, *KIT* or *PDGFRA* mutations alone are insufficient for tumorigenesis. Changes associated with progression to overt GIST are not well-defined, but loss or partial deletion of chromosomes 14 and 22 is common and losses and gains at other chromosomes also occur. In particular, deletion of 9p results in loss of the cell cycle regulator *CDKN2A*, a tumor suppressor that is involved in many cancers. In addition to potentially being related to progression, increased numbers of chromosomal alterations correlate with poor prognosis.

MORPHOLOGY

Primary gastric GISTs can be quite large, as much as 30 cm in diameter. They usually form a solitary, well-circumscribed, fleshy mass (Fig. 17-21A) covered by ulcerated or intact mucosa (Fig. 17-21B), but can also project outward toward the serosa. The cut surface shows a whorled appearance. Metastases may take the form of multiple serosal nodules throughout the peritoneal cavity or as one or more nodules in the liver; spread outside of the abdomen is uncommon, but can occur. GISTs composed of thin elongated cells are classified as **spindle cell type** (Fig. 17-21C), whereas tumors dominated by epithelial-appearing cells are termed **epithelioid type**; mixtures of the two patterns also occur. The most useful diagnostic marker is *KIT*, which is detectable in Cajal cells and 95% of gastric GISTs by immunohistochemical stains.

Clinical Features. Symptoms of GISTs at presentation may be related to mass effects. Mucosal ulceration can cause blood loss, and approximately half of individuals with GIST present with anemia or related symptoms. GISTs may also be discovered as an incidental finding during radiologic imaging, endoscopy, or abdominal surgery performed for other reasons. Complete surgical resection is the primary treatment for localized gastric GIST. The prognosis correlates with tumor size, mitotic index, and location, with gastric GISTs being less aggressive than those arising in the small intestine. Recurrence or metastasis is rare for gastric GISTs smaller than 5 cm but common for mitotically active tumors larger than 10 cm. Many tumors fall into an intermediate category where the malignant potential of the lesion cannot be predicted with certainty on the basis of histology alone.

Figure 17-21 GI stromal tumor. **A**, On cross-section a whorled texture is evident within the white, fleshy tumor. **B**, The mass is covered by intact mucosa. **C**, Histologically the tumor is primarily composed of bundles, or fascicles, of spindle-shaped tumor cells. (Courtesy Dr. Christopher Weber, The University of Chicago, Chicago, Ill.)

The molecular phenotype is an important consideration in the treatment of patients with unresectable, recurrent, or metastatic GISTs. Those with mutations in *KIT* or *PDGFRA* often respond to the tyrosine kinase inhibitor imatinib. In contrast, tumors without these mutations are generally resistant. Further, specific *KIT* or *PDGFRA* mutations are associated with different drug sensitivities. In treated patients, development of imatinib-resistance is common.

This is due to secondary *KIT* or *PDGFRA* mutations. Tumors with secondary mutations may respond to other tyrosine kinase inhibitors as well as experimental therapies that target other pathways.

KEY CONCEPTS

Neoplastic and Non neoplastic proliferations of the stomach

- **Ménétrier disease** is a rare disorder caused by excessive secretion of transforming growth factor α (TGF- α) and characterized by diffuse foveolar hyperplasia and protein-losing enteropathy.
- **Zollinger-Ellison syndrome** is caused by gastrin-secreting tumors that cause parietal cell hyperplasia and acid hypersecretion; 60% to 90% of gastrinomas are malignant.
- The majority of gastric polyps are **inflammatory or hyperplastic polyps**, reactive lesions that are associated with chronic gastritis.
- **Fundic gland polyps** occur sporadically, most often as a consequence of proton pump inhibitor therapy, and in familial adenomatous polyposis (FAP) patients.
- **Gastric adenomas** develop in a background of chronic gastritis and are particularly associated with intestinal metaplasia and mucosal (glandular) atrophy. Adenocarcinoma is frequent in gastric adenomas, which

therefore require more aggressive therapy than adenomas of the colon.

- **Gastric adenocarcinoma** incidence varies markedly with geography. Individual tumors are classified according to location, gross, and histologic morphology. Gastric tumors with an **intestinal histology tend to form bulky tumors** and may be ulcerated, while those composed of **signet-ring cells typically display a diffuse infiltrative growth pattern** that may thicken the gastric wall without forming a discrete mass. Gastric adenocarcinomas are linked to *H. pylori* induced chronic gastritis.
- **Primary gastric lymphomas** are most often derived from mucosa-associated lymphoid tissue (MALT), whose development is induced by chronic gastritis that is most often induced by *H. pylori*.
- **Carcinoid tumors** (well-differentiated neuroendocrine tumors) arise from diffuse components of the endocrine system and are most common in the GI tract, particularly the small intestine. Prognosis is based on location; tumors of the small intestine tend to be most aggressive, while those of the appendix are typically benign.
- **Gastrointestinal stromal tumor (GIST)** is the most common mesenchymal tumor of the abdomen, occurs most often in the stomach, and is related to benign pacemaker cells, or interstitial cells of Cajal. Tumors generally have activating mutations in either *KIT* or *PDGFRA* tyrosine kinases and respond to specific kinase inhibitors.

SMALL INTESTINE AND COLON

The small intestine and colon make up the majority of the GI tract and are the sites of a broad array of diseases. Some of these relate to nutrient and water transport. Perturbation of these processes can cause malabsorption and diarrhea. The intestines are also the principal site where the immune system interfaces with a diverse array of antigens present in food and gut microbes. Indeed, intestinal bacteria outnumber eukaryotic cells in our bodies by tenfold. Thus, it is not surprising that the small intestine and colon are frequently affected by infectious and inflammatory disorders. Finally, the colon is the most common site of GI neoplasia in Western populations.

Intestinal Obstruction

Obstruction of the GI tract may occur at any level, but the small intestine is most often involved because of its relatively narrow lumen. Collectively, *hernias*, *intestinal adhesions*, *intussusception*, and *volvulus* account for 80% of mechanical obstructions (Fig. 17-22), while tumors, infarction, and other causes of strictures, for example, Crohn disease, account for an additional 10% to 15%. **The clinical manifestations of intestinal obstruction include abdominal pain and distention, vomiting, and constipation.** Surgical intervention is usually required in cases where the obstruction has a mechanical basis or is associated with bowel infarction.

Hernias

Any weakness or defect in the abdominal wall may permit protrusion of a serosa-lined pouch of peritoneum called a hernia sac. Acquired hernias typically occur anteriorly, via the inguinal and femoral canals, umbilicus, or at sites of surgical scars, and are common, occurring in up to 5% of the population. *Hernias are the most frequent cause of intestinal obstruction worldwide* and the third most common cause of obstruction in the U.S. Obstruction usually occurs because of visceral protrusion (external herniation) and is most frequently associated with inguinal hernias, which tend to have narrow orifices and large sacs. Small bowel loops are typically involved, but omentum or large bowel may also protrude, and any of these may become entrapped. Pressure at the neck of the pouch may impair venous drainage of the entrapped viscus. The resultant stasis and edema increase the bulk of the herniated loop, leading to permanent entrapment (incarceration) and, over time, arterial and venous compromise (strangulation), and infarction (Fig. 17-23A).

Adhesions

Surgical procedures, infection, or other causes of peritoneal inflammation, such as endometriosis, may result in development of adhesions between bowel segments, the abdominal wall, or operative sites. These fibrous bridges can

Figure 17-22 Intestinal obstruction. The four major causes of intestinal obstruction are (1) herniation of a segment in the umbilical or inguinal regions, (2) adhesion between loops of intestine, (3) volvulus, and (4) intussusception.

create closed loops through which other viscera may slide and become entrapped, resulting in internal herniation. Sequelae, including obstruction and strangulation, are much the same as with external hernias; *adhesions are the most common cause of intestinal obstruction in the United States*. Fibrous adhesions are most often acquired, but can be congenital in rare cases. Therefore, internal herniation must be considered even in the absence of a history of peritonitis or surgery.

Volvulus

Twisting of a loop of bowel about its mesenteric point of attachment is termed volvulus; it results in both luminal and vascular compromise. Thus, volvulus presents with features of both obstruction and infarction. It occurs most often in large redundant loops of sigmoid colon, followed in frequency by the cecum, small bowel, stomach, or, rarely, transverse colon. Because it is rare, volvulus can be overlooked clinically.

Intussusception

Intussusception occurs when a segment of the intestine, constricted by a wave of peristalsis, telescopes into the immediately distal segment. Once trapped, the invaginated segment is propelled by peristalsis and pulls the mesentery along. Untreated intussusception may progress to intestinal obstruction, compression of mesenteric vessels, and infarction.

Intussusception is the most common cause of intestinal obstruction in children younger than 2 years of age. In these

idiopathic cases there is usually no underlying anatomic defect and the patient is otherwise healthy. Other cases have been associated with viral infection and rotavirus vaccines, perhaps due to reactive hyperplasia of Peyer patches and other mucosa-associated lymphoid tissue which can act as the leading edge of the intussusception. Intussusception is rare in older children and adults, and is generally caused by an intraluminal mass or tumor that serves as the initiating point of traction (**Fig. 17-23B**). Contrast enemas can be used both diagnostically and therapeutically for idiopathic intussusception in infants and young children, in whom air enemas may also effectively reduce the intussusception. However, surgical intervention is necessary when a mass is present, as is generally the case in older children and adults.

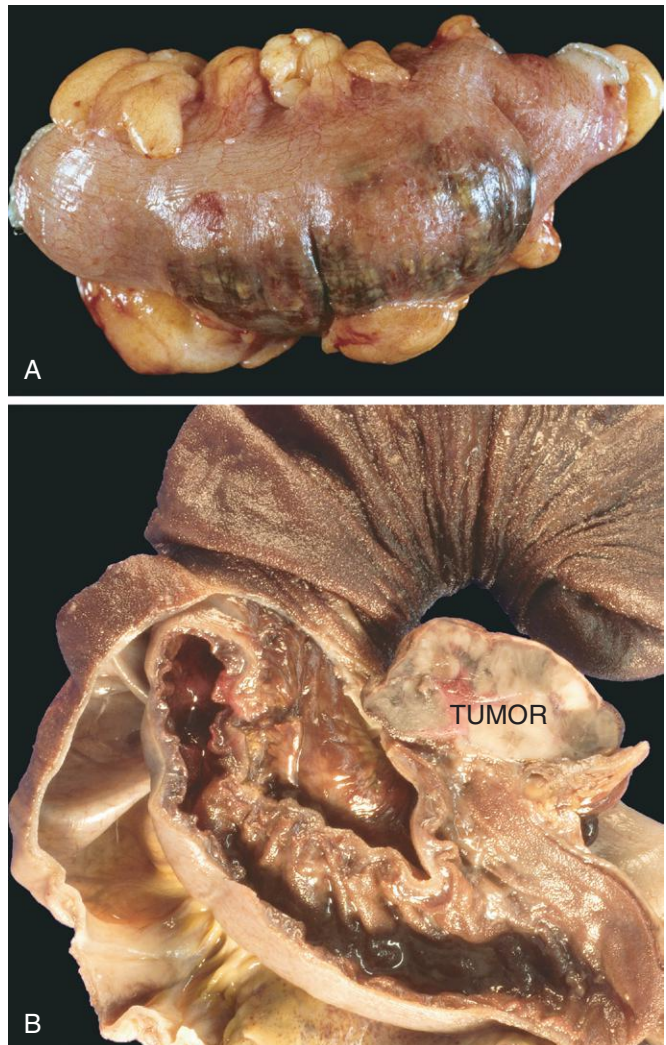

Figure 17-23 Intestinal obstruction. **A**, Portion of bowel incarcerated within an inguinal hernia. Note dusky serosa and hemorrhage that indicate ischemic damage. **B**, Intussusception caused by a tumor. The outermost layer of intestine with external serosa has been removed, leaving the mucosa of the second layer exposed. The serosa of the second layer is apposed to the serosa of the intussuscepted intestine. A tumor mass (right, labeled tumor) is present at the leading edge of the intussusception. Compare to **Figure 17-22**. (**B**, Courtesy Dr. Christopher Weber, The University of Chicago, Chicago, Ill.)

Ischemic Bowel Disease

The majority of the GI tract is supplied by the celiac, superior mesenteric, and inferior mesenteric arteries. As they approach the intestinal wall the superior and inferior mesenteric arteries ramify into the mesenteric arcades. Interconnections between arcades, as well as collateral supplies from the proximal celiac and distal pudendal and iliac circulations, make it possible for the small intestine and colon to tolerate slowly progressive loss of blood supply from one artery.

In contrast to chronic, progressive hypoperfusion, acute compromise of any major vessel can lead to infarction of several meters of intestine. Damage can range from mucosal infarction, extending no deeper than the muscularis mucosae; to mural infarction of mucosa and submucosa; to transmural infarction involving all three wall layers. While mucosal or mural infarctions can follow acute or chronic hypoperfusion, transmural infarction is typically caused by acute vascular obstruction. Important causes of acute arterial obstruction include severe atherosclerosis (which is often prominent at the origin of mesenteric vessels), aortic aneurysm, hypercoagulable states, oral contraceptive use, and embolization of cardiac vegetations or aortic atheromas. Intestinal hypoperfusion can be associated with cardiac failure, shock, dehydration, or use of vasoconstrictive drugs. Systemic vasculitides, such as polyarteritis nodosa, Henoch-Schönlein purpura, or granulomatosis with polyangiitis (Wegener granulomatosis), may also damage intestinal arteries. Mesenteric venous thrombosis, which can also lead to ischemic disease, is uncommon but can result from inherited or acquired hypercoagulable states, invasive neoplasms, cirrhosis, trauma, or abdominal masses that compress the portal drainage.

Pathogenesis. Intestinal responses to ischemia occur in two phases. The initial *hypoxic injury* occurs at the onset of vascular compromise. While some damage occurs during this phase, the epithelial cells lining the intestine are relatively resistant to transient hypoxia. The second phase, *reperfusion injury*, is initiated by restoration of the blood supply and it is at this time that the greatest damage occurs. In severe cases this may trigger multiorgan failure. While the underlying mechanisms of reperfusion injury are incompletely understood, they include leakage of gut lumen bacterial products, e.g. lipopolysaccharide, into the systemic circulation, free radical production, neutrophil infiltration, and release of additional inflammatory mediators (Chapter 2).

The severity of vascular compromise, the time frame during which it develops, and the vessels affected are the major variables in ischemic bowel disease. Two aspects of intestinal vascular anatomy also contribute to the distribution of ischemic damage and are worthy of note:

- Intestinal segments at the end of their respective arterial supplies are particularly susceptible to ischemia. These *watershed zones* include the splenic flexure, where the superior and inferior mesenteric arterial circulations terminate, and, to a lesser extent, the sigmoid colon and rectum where inferior mesenteric, pudendal, and iliac arterial circulations end. Generalized hypotension or

hypoxemia can therefore cause localized injury, and ischemic disease should be considered in the differential diagnosis of focal colitis of the splenic flexure or rectosigmoid colon.

- Intestinal capillaries run alongside the glands, from crypt to surface, before making a hairpin turn to empty into the post-capillary venules. This arrangement makes the surface epithelium particularly vulnerable to ischemic injury, relative to the crypts. Organization of the blood supply in this patterns has advantages, as it protects the epithelial stem cells, which are located within the crypts and are necessary for recovery from epithelial injury. This pattern of surface epithelial atrophy, or even necrosis and sloughing, with normal or hyperproliferative crypts is a morphologic signature of ischemic intestinal disease.

MORPHOLOGY

Although the colon is the most common site of gastrointestinal ischemia, mucosal and mural infarction may involve any level of the gut from stomach to anus. The lesions can be continuous but are most often segmental and patchy (Fig. 17-24A). The mucosa is hemorrhagic and may be ulcerated (Fig. 17-24B). The bowel wall is also thickened by edema that may involve the mucosa or extend into the submucosa and muscularis propria.

Substantial portions of the bowel are generally involved in **transmural infarction** due to acute arterial obstruction. The demarcation between normal and ischemic bowel is sharply defined and the infarcted bowel is initially intensely congested and dusky to purple-red. Later, blood-tinged mucus or frank blood accumulates in the lumen and the wall becomes edematous, thickened, and rubbery. There is coagulative necrosis of the muscularis propria within 1 to 4 days, and perforation may occur. Serositis, with purulent exudates and fibrin deposition, may be prominent.

In mesenteric venous thrombosis, arterial blood continues to flow for a time, resulting in a less abrupt transition from affected to normal bowel. However, propagation of the thrombus may lead to secondary involvement of the splanchnic bed. The ultimate result is similar to that produced by acute arterial obstruction because impaired venous drainage eventually prevents oxygenated arterial blood from entering the capillaries.

Microscopic examination of ischemic intestine demonstrates the characteristic atrophy or sloughing of surface epithelium (Fig. 17-24C). In contrast, crypts may be hyperproliferative. Inflammatory infiltrates are initially absent in acute ischemia, but neutrophils are recruited within hours of reperfusion. Chronic ischemia is accompanied by fibrous scarring of the lamina propria (Fig. 17-24D) and, uncommonly, stricture formation. In both acute and chronic ischemia, bacterial superinfection and enterotoxin release may induce **pseudomembrane formation** that resembles *Clostridium difficile*-associated pseudomembranous colitis (discussed later).

Clinical Features. Ischemic disease of the colon is most common in patients older than 70 years of age, and occurs slightly more often in women. While frequently associated with coexisting cardiac or vascular disease ischemia can also be precipitated by therapeutic vasoconstrictors, some illicit drugs, for example, cocaine, endothelial damage and small vessel occlusion after cytomegalovirus or *Escherichia*

Figure 17-24 Ischemic bowel disease. **A**, Jejunal resection with dusky serosa of acute ischemia (mesenteric thrombosis). **B**, Mucosa is stained with blood after hemorrhage. **C**, Characteristic attenuated villous epithelium in this case of acute mesenteric thrombosis. **D**, Chronic colonic ischemia with atrophic surface epithelium and fibrotic lamina propria.

coli O157:H7 infection, strangulated hernia, or vascular compromise due to prior surgery.

Acute colonic ischemia typically presents with sudden onset of cramping, left lower abdominal pain, a desire to defecate, and passage of blood or bloody diarrhea. The blood loss is usually insufficient to require transfusion, but patients may progress to shock and vascular collapse within hours in severe cases. Surgical intervention, which is necessary in approximately 10% of cases, should be considered if peristaltic sounds diminish or disappear, that is, paralytic ileus, or other features of infarction, such as guarding and rebound tenderness develop. Because these physical signs overlap with those of other abdominal emergencies, including acute appendicitis, perforated ulcer, and acute cholecystitis, the diagnosis of intestinal necrosis may be delayed or missed, with disastrous consequences.

With appropriate management, mortality in the first 30 days is approximately 10%. Mortality is doubled in patients with right sided colonic disease, who have a more severe course in general. This may be because the right side of the colon is supplied by the superior mesenteric artery, which also supplies much of the small intestine. Thus, right sided colonic ischemia may be the initial presentation of more severe disease, including that caused by acute occlusion of the superior mesenteric artery (Fig. 17-24). Other poor prognostic indicators include co-existing chronic obstructive pulmonary disease (COPD) and persistence of symptoms for more than 2 weeks. Happily, most patients recover fully and colonic ischemia does not recur in the majority of cases. Listed below are some additional forms of bowel ischemia, their antecedents and outcomes.

- *Mucosal and mural infarctions* by themselves may not be fatal. However, these often progress to more extensive infarction if the vascular supply is not restored by correction of the insult or, in chronic disease, by development of inadequate collateral supplies. The diagnosis of nonocclusive ischemic enteritis and colitis can be particularly difficult because there may be a confusing array of nonspecific abdominal symptoms, including intermittent bloody diarrhea and intestinal obstruction.
- *Chronic ischemia* may masquerade as inflammatory bowel disease, with episodes of bloody diarrhea interspersed with periods of healing.

- *CMV infection* causes ischemic GI disease due to viral tropism for endothelial cells. CMV infection, which can be a complication of immunosuppressive therapy, is discussed further in Chapter 8.
- *Radiation enterocolitis* occurs when the GI tract is irradiated. In addition to epithelial damage, radiation-induced vascular injury may be significant and produce changes that are similar to ischemic disease. Beyond clinical history, the presence of highly atypical “radiation fibroblasts” within the stroma may provide an important clue to the etiology. Acute radiation enteritis manifests as anorexia, abdominal cramps, and malabsorptive diarrhea, while chronic radiation enteritis or colitis is often more indolent and may present as an inflammatory enterocolitis.
- *Necrotizing enterocolitis (NEC)* is an acute disorder of the small and large intestines that can result in transmural necrosis. It is the most common acquired GI emergency of neonates, particularly those who are premature or of low birth weight, and frequently presents when oral feeding is initiated. NEC is discussed in more detail in Chapter 10, but is noted here because ischemic injury is thought to contribute to the pathogenesis.

Angiodysplasia

Angiodysplasia, a lesion characterized by malformed submucosal and mucosal blood vessels, occurs most often in the cecum or right colon and usually presents after the sixth decade of life. Although the prevalence of angiodysplasia is less than 1% in the adult population, it accounts for 20% of major episodes of lower intestinal bleeding; intestinal hemorrhage may be chronic and intermittent or acute and massive.

The pathogenesis of angiodysplasia remains undefined but has been attributed to mechanical and congenital factors. Normal distention and contraction may intermittently occlude the submucosal veins that penetrate through the muscularis propria and can lead to focal dilation and tortuosity of overlying submucosal and mucosal vessels. Because the cecum has the largest diameter of

any colonic segment, it develops the greatest wall tension. This may explain the preferential distribution of angiodysplastic lesions in the cecum and right colon. Finally, some data link angiodysplasia with Meckel diverticulum, suggesting the possibility of a developmental component.

Morphologically, angiodysplastic lesions are characterized by ectatic nests of tortuous veins, venules, and capillaries. The vascular channels may be separated from the intestinal lumen by only the vascular wall and a layer of attenuated epithelial cells; limited injury may therefore result in significant bleeding.

Malabsorption and Diarrhea

Malabsorption, which presents most commonly as chronic diarrhea, is characterized by defective absorption of fats, fat- and water-soluble vitamins, proteins, carbohydrates, electrolytes and minerals, and water. Chronic malabsorption can be accompanied by weight loss, anorexia, abdominal distention, borborygmi, and muscle wasting. A hallmark of malabsorption is *steatorrhea*, characterized by excessive fecal fat and bulky, frothy, greasy, yellow or clay-colored stools. The chronic malabsorptive disorders most commonly encountered in the United States are pancreatic insufficiency, celiac disease, and Crohn disease (Table 17-7). Intestinal graft-versus-host disease is an important cause of malabsorption and diarrhea after allogeneic hematopoietic stem cell transplantation.

Malabsorption results from disturbance in at least one of the four phases of nutrient absorption:

- *Intraluminal digestion*, in which proteins, carbohydrates, and fats are broken down into forms suitable for absorption;
- *Terminal digestion*, which involves the hydrolysis of carbohydrates and peptides by disaccharidases and peptidases in the brush border of the small intestinal mucosa;
- *Transepithelial transport*, in which nutrients, fluid, and electrolytes are transported across and processed within the small intestinal epithelium; and
- *Lymphatic transport of absorbed lipids*.

In many malabsorptive disorders a defect in one of these processes predominates, but more than one usually contributes. As a result, malabsorption syndromes resemble each other more than they differ. General symptoms include diarrhea (from nutrient malabsorption and excessive intestinal secretion), flatus, abdominal pain, and weight loss. Inadequate absorption of vitamins and minerals can result in anemia and mucositis due to pyridoxine, folate, or vitamin B₁₂ deficiency; bleeding, due to vitamin K deficiency; osteopenia and tetany due to calcium, magnesium, or vitamin D deficiencies; or peripheral neuropathy due to vitamin A or B₁₂ deficiencies. A variety of endocrine and skin disturbances may also occur.

Diarrhea is defined as an increase in stool mass, frequency, or fluidity, typically greater than 200 gm per day. In severe cases stool volume can exceed 14 L per day and, without fluid resuscitation, result in death. Painful, bloody, small-volume diarrhea is known as *dysentery*. Diarrhea can be classified into four major categories:

- *Secretory diarrhea* is characterized by isotonic stool and persists during fasting.
- *Osmotic diarrhea*, such as that which occurs with lactase deficiency, is due to the excessive osmotic forces exerted by unabsorbed luminal solutes. The diarrhea fluid is more than 50 mOsm more concentrated than plasma and abates with fasting.
- *Malabsorptive diarrhea* follows generalized failure of nutrient absorption, is associated with steatorrhea, and is relieved by fasting.
- *Exudative diarrhea* due to inflammatory disease is characterized by purulent, bloody stools that continue during fasting.

Table 17-7 Defects in Malabsorptive and Diarrheal Disease

Disease	Intraluminal Digestion	Terminal Digestion	Transepithelial Transport	Lymphatic Transport
Celiac disease		+	+	
Environmental enteropathy		+	+	
Chronic pancreatitis	+			
Cystic fibrosis	+			
Primary bile acid malabsorption	+		+	
Carcinoid syndrome			+	
Autoimmune enteropathy		+	+	
Disaccharidase deficiency		+		
Whipple disease				+
Abetalipoproteinemia			+	
Viral gastroenteritis		+	+	
Bacterial gastroenteritis		+	+	
Parasitic gastroenteritis		+	+	
Inflammatory bowel disease	+	+	+	

+ indicates that the process is abnormal in the disease indicated. Other processes are not affected.

Cystic Fibrosis

Cystic fibrosis affects many organ systems, primarily the lungs, and is discussed in greater detail elsewhere (Chapter 10). Only the malabsorption associated with cystic fibrosis is considered here. Due to the absence of the epithelial cystic fibrosis transmembrane conductance regulator (CFTR), individuals with cystic fibrosis have defects in chloride and, in certain tissues, bicarbonate ion secretion. This interferes with bicarbonate, sodium, and water secretion, ultimately resulting in defective luminal hydration. Reduced hydration can occasionally lead to intestinal obstruction, but commonly results in formation of pancreatic intraductal concretions. The latter can begin in utero, and result in duct obstruction, low-grade chronic autodigestion of the pancreas, and eventual exocrine pancreatic insufficiency in more than 80% of patients. The result is failure of the intraluminal phase of nutrient absorption, which can be effectively treated in most patients with oral enzyme supplementation.

Celiac Disease

Celiac disease is also known as celiac sprue or gluten-sensitive enteropathy. It is an immune-mediated enteropathy triggered by the ingestion of gluten-containing foods, such as wheat, rye, or barley, in genetically predisposed individuals. Celiac disease has an overall worldwide incidence of 0.6% to 1%, but its prevalence varies widely between countries and regions. Some of these differences correlate with variation in wheat consumption, but the reasons for other disparities are not defined. While previously uncommon, the incidence of celiac disease in developing countries is growing, possibly as a result of adoption of Western diets.

Pathogenesis. Celiac disease is triggered by ingestion of gluten, which is the major storage protein of wheat and similar grains. The alcohol-soluble fraction of gluten, *gliadin*, contains most of the disease-producing components. Gluten is digested by luminal and brush-border enzymes into amino acids and peptides, including a 33-amino acid α -gliadin peptide that is resistant to degradation by gastric, pancreatic, and small intestinal proteases (Fig. 17-25). Some gliadin peptides may induce epithelial cells to express IL-15, which in turn triggers activation and proliferation of CD8⁺ intraepithelial lymphocytes. These lymphocytes express NKG2D, a natural killer cell marker and receptor for MIC-A. Enterocytes that have been induced to express surface MIC-A, in response to stress, are then attacked by NKG2D-expressing intraepithelial lymphocytes. The resulting epithelial damage may enhance passage of other gliadin peptides into the lamina propria where they are deamidated by tissue transglutaminase. These gliadin peptides interact with HLA-DQ2 or HLA-DQ8 on antigen-presenting cells and, in turn, can stimulate CD4⁺ T cells to produce cytokines that contribute to tissue damage.

While nearly all people eat grain and are exposed to gluten and gliadin, most do not develop celiac disease. Thus, host factors determine whether disease develops. Among these, HLA proteins seem to be critical, since almost all people with celiac disease carry the class II HLA-DQ2 or HLA-DQ8 allele. However, the HLA locus accounts for less than half of the genetic component of celiac disease. Remaining genetic factors may include polymorphisms of genes involved in immune regulation and epithelial function. These genetic variables may also contribute to associations between celiac disease and other immune diseases, including type 1 diabetes, thyroiditis, and Sjögren syndrome, IgA nephropathy, as well as neu-

Figure 17-25 The left panel illustrates the morphologic alterations that may be present celiac disease, including villous atrophy, increased numbers of intraepithelial lymphocytes (IELs), and epithelial proliferation with crypt elongation (compare to Fig. 17-26). The right panel depicts a model for the pathogenesis of celiac disease. Note that both innate (CD8⁺ intraepithelial T cells, activated by IL-15) and adaptive (CD4⁺ T cells, and B cells sensitization to gliadin) immune mechanisms are involved in the tissue responses to gliadin.

rologic disorders, such as ataxia, autism, depression, epilepsy, Down syndrome, and Turner syndrome.

MORPHOLOGY

Biopsy specimens from the second portion of the duodenum or proximal jejunum, which are exposed to the highest concentrations of dietary gluten, are generally diagnostic in celiac disease. The histopathology is characterized by increased numbers of intraepithelial CD8+ T lymphocytes (intraepithelial lymphocytosis), crypt hyperplasia, and villous atrophy (Fig. 17-26). This loss of mucosal and brush-border surface area probably accounts for the malabsorption. In addition, increased rates of epithelial turnover, reflected in increased crypt mitotic activity, may limit the ability of absorptive enterocytes to fully differentiate and express proteins necessary for terminal digestion and transepithelial transport. Other features of fully developed celiac disease include increased numbers of plasma cells, mast cells, and eosinophils, especially within the upper part of the lamina propria. With increased frequency of serologic screening and early detection of disease-associated antibodies, it is now appreciated that an increase in the number of intraepithelial lymphocytes, particularly within the villus, is a sensitive marker of celiac disease, even in the absence of epithelial damage and villous atrophy. However, intraepithelial lymphocytosis and villous atrophy are not specific for celiac disease and can be present in other diseases, including viral enteritis. The combination of histology and serology, therefore, is most specific for diagnosis of celiac disease.

Adherence to a gluten-free diet typically results in resolution of symptoms, decreasing titers of anti-tissue transglutaminase or other celiac disease-associated antibodies, and restoration of normal or near normal mucosal histology within 6 to 24 months.

Clinical Features. In adults, celiac disease presents most commonly between the ages of 30 and 60. Many cases of celiac disease escape clinical attention for extended periods because of atypical presentations. Other patients may have silent celiac disease, defined as positive serology and

villous atrophy without symptoms, or latent celiac disease, in which positive serology is not accompanied by villous atrophy. Celiac disease may be associated with chronic diarrhea, bloating, or chronic fatigue, but is often asymptomatic. These cases may present with anemia due to chronic iron and vitamin malabsorption. In adults, celiac disease is detected twice as frequently in women, perhaps because monthly menstrual bleeding accentuates the effects of impaired absorption.

Pediatric celiac disease, which affects males and females equally, may present with malabsorption or atypical symptoms affecting almost any organ. In those with classic symptoms, disease typically begins after introduction of gluten to the diet, between ages of 6 and 24 months, and manifests as irritability, abdominal distention, anorexia, chronic diarrhea, failure to thrive, weight loss, or muscle wasting. Children with nonclassic symptoms tend to present at older ages with complaints of abdominal pain, nausea, vomiting, bloating, or constipation. Common extraintestinal complaints include arthritis or joint pain, aphthous stomatitis, iron deficiency anemia, delayed puberty, and short stature.

A characteristic itchy, blistering skin lesion, dermatitis herpetiformis (Chapter 25), can be present in as many as 10% of patients. Unfortunately, the only treatment currently available for celiac disease is a gluten-free diet. While adhering to this diet can be challenging, it does result in symptomatic improvement for most patients. A gluten-free diet may also reduce the risk of long-term complications including anemia, female infertility, osteoporosis, and cancer (discussed below).

Noninvasive serologic tests are generally performed prior to biopsy. The most sensitive tests are the measurement of IgA antibodies against tissue transglutaminase. IgA anti-endomysial antibodies can also be present. IgG anti-tissue transglutaminase antibodies may be detected in patients with IgA deficiency. The absence of HLA-DQ2 and HLA-DQ8 is useful for its high negative predictive value, but the presence of these alleles is not helpful in confirming the diagnosis.

Individuals with celiac disease have a higher than normal rate of malignancy. The most common celiac disease-associated cancer is enteropathy-associated T-cell lymphoma, an aggressive lymphoma of intraepithelial T lymphocytes. Small intestinal adenocarcinoma is also more frequent in individuals with celiac disease. Thus, when symptoms such as abdominal pain, diarrhea, and weight loss develop despite a strict gluten-free diet, cancer or refractory sprue, in which the response to a gluten-free diet is lost, must be considered.

Environmental Enteropathy

Environmental enteropathy, which has also been referred to as *tropical enteropathy* or *tropical sprue*, is a disorder prevalent in areas and populations with poor sanitation and hygiene, such as those in developing countries, including many parts of sub-Saharan Africa, such as Gambia; aboriginal populations within northern Australia; and some groups within South America and Asia, such as residents of impoverished communities within Brazil, Guatemala, India, and Pakistan. Affected individuals often suffer from malabsorption and malnutrition, stunted growth, and

Figure 17-26 Celiac disease. **A**, Advanced cases of celiac disease show complete loss of villi, or total villous atrophy. Note the dense plasma cell infiltrates in the lamina propria. **B**, Infiltration of the surface epithelium by T lymphocytes, which can be recognized by their densely stained nuclei (labelled **T**). Compare to elongated, pale-staining epithelial nuclei (labeled **E**).

defective intestinal mucosal immune function. The relatively high oral vaccine failure rates in regions where environmental enteropathy is endemic has been proposed to be due to defective mucosal immune function.

There are presently no accepted clinical, laboratory, or histopathologic criteria that allow diagnosis of environmental enteropathy. Intestinal biopsy specimens have been examined in a small number of cases, and reported histologic features are more similar to severe celiac disease than infectious enteritis.

The underlying causes of environmental enteropathy are unknown, but defective intestinal barrier function, chronic exposure to fecal pathogens and other microbial contaminants, and repeated bouts of diarrhea within the first 2 or 3 years of life are likely involved. Many pathogens are endemic in these communities, but no single infectious agent has been linked to environmental enteropathy. Neither oral antibiotics nor nutritional supplementation, with calorie-dense foods, vitamins, or minerals, are able to correct these deficits. Moreover, recent data suggest that irreversible losses in physical development may be accompanied by uncorrectable cognitive deficits. Thus, the global impact of environmental enteropathy, which is estimated to affect more than 150 million children worldwide and may contribute to a very large number of childhood deaths, is difficult to overstate.

Autoimmune Enteropathy

Autoimmune enteropathy is an X-linked disorder characterized by severe persistent diarrhea and autoimmune disease that occurs most often in young children. A particularly severe familial form, termed *IPEX*, an acronym denoting immune dysregulation, polyendocrinopathy, enteropathy, and X-linkage, is due to a germline mutation in the *FOXP3* gene, which is located on the X chromosome. *FOXP3* is a transcription factor expressed in CD4+ regulatory T cells, and individuals with *IPEX* and *FOXP3* mutations have defective function of these cells. Other defects in regulatory T cell function have also been linked to less severe forms of autoimmune enteropathy. Autoantibodies to enterocytes and goblet cells are common, and some patients may have antibodies to parietal or islet cells. Within the small intestine, intraepithelial lymphocytes may be increased, but not to the extent seen in celiac disease, and neutrophils are often present. Therapy includes immunosuppressive drugs such as cyclosporine and, in rare cases, hematopoietic stem cell transplantation.

Lactase (Disaccharidase) Deficiency

The disaccharidases, including lactase, are located in the apical brush-border membrane of the villus absorptive epithelial cells. Because the defect is biochemical, biopsy histology is generally unremarkable. Lactase deficiency is of two types:

- **Congenital lactase deficiency**, caused by a mutation in the gene encoding lactase, is an autosomal recessive disorder. The disease is rare and presents as explosive diarrhea with watery, frothy stools and abdominal distention upon milk ingestion. Symptoms abate when exposure to milk and milk products is terminated, thus removing the osmotically active but unabsorbable lactose from the lumen. As a result, congenital lactase deficiency was often fatal prior to the availability of soy-based infant formula.
- **Acquired lactase deficiency** is caused by down-regulation of lactase gene expression and is particularly common among Native American, African American, and Chinese populations. Acquired lactase deficiency can develop following enteric viral or bacterial infections and may resolve over time. Symptoms of acquired lactase deficiency, including abdominal fullness, diarrhea, and flatulence, due to fermentation of the unabsorbed sugars by colonic bacteria, are triggered by ingestion of lactose-containing dairy products.

Abetalipoproteinemia

Abetalipoproteinemia is a rare autosomal recessive disease characterized by an inability to secrete triglyceride-rich lipoproteins. It is caused by a mutation in the microsomal triglyceride transfer protein (MTP) that catalyzes transfer of lipids to specialized domains of the nascent apolipoprotein B polypeptide within the rough endoplasmic reticulum. MTP also promotes production of triglyceride droplets within the smooth endoplasmic reticulum. Without MTP, enterocytes cannot assemble or export lipoproteins. This results in intracellular lipid accumulation. The malabsorption of abetalipoproteinemia is therefore a failure of intraepithelial processing and transport. Because of the triglyceride accumulation, vacuolization of small intestinal epithelial cells is evident and can be highlighted by special stains, such as oil red-O, particularly after a fatty meal.

Abetalipoproteinemia presents in infancy and the clinical picture is dominated by failure to thrive, diarrhea, and steatorrhea. Patients also have a complete absence of all plasma lipoproteins containing apolipoprotein B, although the gene that encodes apolipoprotein B itself is not affected. Failure to absorb essential fatty acids leads to deficiencies of fat-soluble vitamins as well as lipid membrane defects that can be recognized by the presence of *acanthocytic red cells (burr cells)* in peripheral blood smears.

KEY CONCEPTS

Congenital and acquired (non infectious) disorders of the intestines

- **Abdominal hernias** may occur through any weakness or defect in the wall of the peritoneal cavity, including inguinal and femoral canals, the umbilicus, and sites of surgical scars.
- **Intussusception** occurs when a segment of intestine telescopes into the immediately distal segment. It is the most common cause of intestinal obstruction in children younger than 2 years of age.
- **Ischemic bowel disease** of the colon is most common at the splenic flexure, sigmoid colon, and rectum; these

are watershed zones where two arterial circulations terminate.

- **Angiodysplasia** is a malformation of submucosal and mucosal blood vessels and a common cause of lower intestinal bleeding in those older than 60 years of age.
- **Diarrhea** can be characterized as secretory, osmotic, malabsorptive, or exudative.
- The malabsorption associated with **cystic fibrosis** is the result of pancreatic insufficiency, leading to inadequate pancreatic digestive enzymes, and deficient luminal breakdown of nutrients.
- **Celiac disease** is an immune-mediated enteropathy triggered by the ingestion of gluten-containing grains. The malabsorptive diarrhea in celiac disease is due to loss of brush border surface area, including villous atrophy, and, possibly, deficient enterocyte maturation as a result of immune-mediated epithelial damage.
- **Environmental enteropathy** is prevalent in areas with poor sanitation. It is estimated to affect more than 150 million children worldwide and may contribute to a very large number of childhood deaths.
- **Lactase deficiency** causes an osmotic diarrhea due to the inability to break down or absorb lactose. The autosomal recessive form is rare and severe; the acquired form usually presents in adulthood and is common.
- **Autoimmune enteropathy** is an X-linked disorder characterized by severe persistent diarrhea and autoimmune disease that is caused by mutation in *FOXP3* gene, resulting in defective function of regulatory T cells.
- **Abetalipoproteinemia** is a rare autosomal recessive disease due to a mutation in microsomal triglyceride transfer protein that is required for enterocytes to process and secrete triglyceride-rich lipoproteins.

Infectious Enterocolitis

Enterocolitis can present with a broad range of symptoms including diarrhea, abdominal pain, urgency, perianal discomfort, incontinence, and hemorrhage (Table 17-8). This global problem is responsible for more than 2000 deaths each day among children in developing countries and greater than 10% of all deaths before age 5 worldwide. Bacterial infections, such as enterotoxigenic *Escherichia coli*, are frequently responsible, but the etiology varies with age, nutrition, and host immune status as well as environmental influences (Table 17-8). For example, epidemics of cholera are common in areas with poor sanitation, as a result of inadequate public health measures, natural disasters, such as floods and earthquakes, or war. Pediatric infectious diarrhea, which may result in severe dehydration and metabolic acidosis, is commonly caused by enteric viruses.

Cholera

***Vibrio cholerae* are comma-shaped, gram-negative bacteria that cause cholera, a disease that has been endemic in the Ganges Valley of India and Bangladesh** for almost all of recorded history. Since 1817, seven great pandemics have spread along trade routes to large parts of Europe, Australia, and the Americas, but, for unknown reasons

these pandemics resolved and cholera retreated back to the Ganges Valley. Cholera also persists within the Gulf of Mexico but causes only rare cases of seafood-associated disease; this occurs because shellfish and plankton can be reservoirs of *Vibrio* bacteria.

There is a marked seasonal variation in the incidence of cholera in most climates due to rapid growth of *Vibrio* bacteria at warm temperatures. While the bacteria can be present in food, the infection is primarily transmitted by contaminated drinking water. Thus, cholera can become rampant in areas devastated by natural or man-made disasters, such as earthquakes or war, that threaten sewage systems and drinking water supplies. For example, the January 2010 Haitian earthquake led to a cholera epidemic that began in October 2010. At the end of the first year, more than 5% of the population was affected. More than half of the cases required hospitalization and approximately 1% were fatal. In all, the cholera epidemic in Haiti accounted for more than half of worldwide cholera cases and deaths reported to the World Health Organization in 2010 and 2011.

Pathogenesis. Despite the severe diarrhea, *Vibrio* organisms are noninvasive and remain within the intestinal lumen. While cholera toxin, encoded by a virulence phage and released by the *Vibrio* organism, causes disease, the flagellar proteins, which are involved in motility and attachment, are necessary for efficient bacterial colonization. Hemagglutinin, a metalloproteinase, is important for bacterial detachment and shedding in the stool. The mechanism by which cholera toxin induces diarrhea is well understood (Fig. 17-27). Cholera toxin is composed of five B subunits and a single A subunit. The B subunit binds GM1 ganglioside on the surface of intestinal epithelial cells, and is carried by endocytosis to the endoplasmic reticulum, a process called retrograde transport. Here, the A subunit is reduced by protein disulfide isomerase, and a fragment of the A subunit is unfolded and released. This peptide fragment is then transported into the cytosol using host cell machinery that moves misfolded proteins from the endoplasmic reticulum to the cytosol. Such unfolded proteins are normally disposed of via the proteasome, but the A subunit refolds to avoid degradation. The refolded A subunit peptide then interacts with cytosolic ADP ribosylation factors (ARFs) to ribosylate and activate the stimulatory G protein $G_s\alpha$. This stimulates adenylate cyclase and the resulting increase in intracellular cAMP opens the cystic fibrosis transmembrane conductance regulator, CFTR, which releases chloride ions into the lumen. Chloride and sodium absorption are also inhibited by cAMP. The resulting accumulation of chloride, bicarbonate, and sodium within the intestinal lumen creates an osmotic driving force that draws water into the lumen and causes massive diarrhea. Remarkably, mucosal biopsies show only minimal histologic alterations.

Clinical Features. Most individuals exposed to *V. cholerae* are asymptomatic or develop only mild diarrhea. In those with severe disease there is an abrupt onset of watery diarrhea and vomiting following an incubation period of 1 to 5 days. The voluminous stools resemble rice water and are sometimes described as having a fishy odor. The rate of diarrhea may reach 1 liter per hour, leading to

Table 17-8 Features of Bacterial Enterocolitides

Infection Type	Geography	Reservoir	Transmission	Epidemiology	Affected GI Sites	Symptoms	Complications
Cholera	India, Africa	Shellfish	Fecal-oral, water	Sporadic, endemic, epidemic	Small intestine	Severe watery diarrhea	Dehydration, electrolyte imbalances
<i>Campylobacter</i> spp.	Developed countries	Chickens, sheep, pigs, cattle	Poultry, milk, other foods	Sporadic; children, travelers	Colon	Watery or bloody diarrhea	Arthritis, Guillain-Barré syndrome
Shigellosis	Worldwide, endemic in developing countries	Humans	Fecal-oral, food, water	Children, migrant workers, travelers, nursing homes	Left colon, ileum	Bloody diarrhea	Reactive arthritis, urethritis, conjunctivitis, hemolytic-uremic syndrome
Salmonellosis	Worldwide	Poultry, farm animals, reptiles	Meat, poultry, eggs, milk	Children, older adults	Colon and small intestine	Watery or bloody diarrhea	Sepsis, abscess
Enteric (typhoid) fever	India, Mexico, Philippines	Humans	Fecal-oral, water	Children, adolescents, travelers	Small intestine	Bloody diarrhea, fever	Chronic infection, carrier state, encephalopathy, myocarditis, intestinal perforation
<i>Yersinia</i> spp.	Northern and central Europe	Pigs, cows, puppies, cats	Pork, milk, water	Clustered cases	Ileum, appendix, right colon	Abdominal pain, fever, diarrhea	Reactive arthritis, erythema nodosum
<i>Escherichia coli</i>							
Enterotoxigenic (ETEC)	Developing countries	Unknown	Food or fecal-oral	Infants, adolescents, travelers	Small intestine	Severe watery diarrhea	Dehydration, electrolyte imbalances
Enteropathogenic (EPEC)	Worldwide	Humans	Fecal-oral	Infants	Small intestine	Watery diarrhea	Dehydration, electrolyte imbalances
Enterohemorrhagic (EHEC)	Worldwide	Widespread, includes cattle	Beef, milk, produce	Sporadic and epidemic	Colon	Bloody diarrhea	Hemolytic-uremic syndrome
Enteroinvasive (EIEC)	Developing countries	Unknown	Cheese, other foods, water	Young children	Colon	Bloody diarrhea	Unknown
Enterogastric (EAEC)	Worldwide	Unknown	Unknown	Children, adults, travelers	Colon	Nonbloody diarrhea, afebrile	Poorly defined
Pseudomembranous colitis (<i>C. difficile</i>)	Worldwide	Humans, hospitals	Antibiotics allow emergence	Immunosuppressed, antibiotic-treated	Colon	Watery diarrhea, fever	Relapse, toxic megacolon
Whipple disease	Rural > urban	Unknown	Unknown	Rare	Small intestine	Malabsorption	Arthritis, CNS disease
Mycobacterial infection	Worldwide	Unknown	Unknown	Immunosuppressed, endemic	Small intestine	Malabsorption	Pneumonia, infection at other sites

CNS, Central nervous system; GI, gastrointestinal.

dehydration, hypotension, muscular cramping, anuria, shock, loss of consciousness, and death. Most deaths occur within the first 24 hours after presentation. Although the mortality for severe cholera is about 50% without treatment, timely fluid replacement can save more than 99% of patients. Oral rehydration is often sufficient. Because of an improved understanding of the host and *Vibrio* proteins involved, new therapies are being developed, including CFTR inhibitors that block chloride secretion and prevent diarrhea. Prophylactic vaccination is a long-term goal, and data from trials of new cholera vaccines have prompted the WHO to recommend vaccination with other prevention and control strategies in endemic regions and during outbreaks. However, it should be noted that variant strains

that cause more severe clinical disease may be displacing earlier strains as the major cause of disease. Thus, vaccines may need to be modified to keep pace with changes in pathogenic cholera strains.

Campylobacter Enterocolitis

Campylobacter jejuni is the most common bacterial enteric pathogen in developed countries and is an important cause of traveler's diarrhea. Most infections are associated with ingestion of improperly cooked chicken, but outbreaks can also be caused by unpasteurized milk or contaminated water. It is an important bacterial cause of food poisoning.

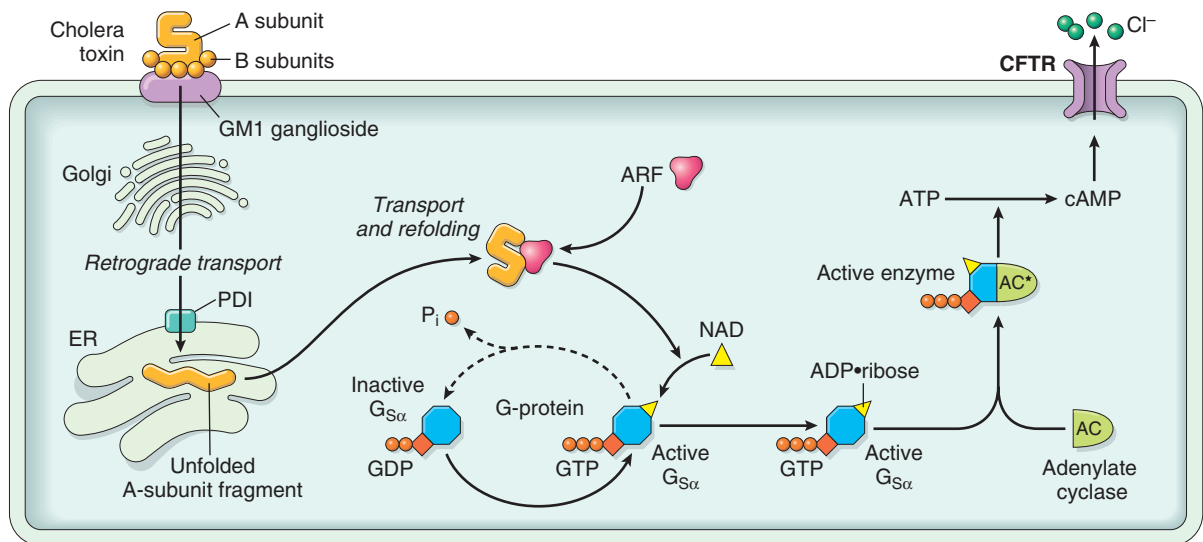

Figure 17-27 Cholera toxin transport and signaling. After retrograde toxin transport to the endoplasmic reticulum (ER), the A subunit is released by the action of protein disulfide isomerase (PDI) and is then able to access the epithelial cell cytoplasm. In concert with an ADP-ribosylation factor (ARF), the A subunit then ADP-ribosylates G_{sα}, which locks it in the active, GTP-bound state. This leads to adenylate cyclase (AC) activation, and the cAMP produced opens CFTR to drive chloride secretion and diarrhea.

Pathogenesis. The pathogenesis of *Campylobacter* infection remains poorly defined, but the four major properties that contribute to virulence are: motility, adherence, toxin production, and invasion. Flagella allow *Campylobacter* to be motile. This facilitates adherence and colonization, which are necessary for mucosal invasion. Cytotoxins that cause epithelial damage and a cholera toxin-like enterotoxin are also released by some *C. jejuni* isolates. Dysentery, i.e. bloody diarrhea, is generally associated with invasion and only occurs with a small minority of *Campylobacter* strains. Enteric fever occurs when bacteria proliferate within the lamina propria and mesenteric lymph nodes.

Campylobacter infection can result in reactive arthritis, primarily in patients with HLA-B27. Other extraintestinal complications, including erythema nodosum and Guillain-Barré syndrome, a flaccid paralysis caused by immunologically mediated inflammation of peripheral nerves, are not HLA-linked (Chapter 27). Molecular mimicry has been implicated in the pathogenesis of Guillain-Barré syndrome, as serum antibodies to *C. jejuni* lipopolysaccharide cross-react with peripheral and central nervous system gangliosides. Up to 40% of Guillain-Barré syndrome cases are associated with *Campylobacter* infection in the preceding 1 to 2 weeks and up to 50% have positive stool cultures or circulating antibodies to *Campylobacter*. Guillain-Barré syndrome develops in 0.1% or less of those infected with *Campylobacter*.

MORPHOLOGY

Campylobacter are comma-shaped, flagellated, gram-negative organisms. Diagnosis is primarily by stool culture, since biopsy findings are nonspecific, and reveal acute self-limited colitis with features common to many forms of infectious colitis. Mucosal and intraepithelial neutrophil infiltrates are prominent, particularly within the superficial mucosa (Fig. 17-28A); cryptitis (neu-

trophil infiltration of the crypts) and crypt abscesses (crypts with accumulations of luminal neutrophils) may also be present. Importantly, crypt architecture is preserved (Fig. 17-28D), although this can be difficult to assess in cases with severe mucosal damage.

Clinical Features. Ingestion of as few as 500 *C. jejuni* organisms can cause disease after an incubation period of up to 8 days. Watery diarrhea, either acute or following an influenza-like prodrome, is the primary symptom, but dysentery develops in 15% of adults and more than 50% of children. Patients may shed bacteria for 1 month or more after clinical resolution. Antibiotic therapy is generally not required.

Shigellosis

Shigella are gram-negative unencapsulated, nonmotile, facultative anaerobes that belong to the Enterobacteriaceae family and are closely related to enteroinvasive *E. coli*. Although humans are the only known reservoir, *Shigella* spp. remain one of the most common causes of bloody diarrhea. It is estimated that 165 million cases occur worldwide each year. Given the infective dose of fewer than several hundred organisms and the presence of as many as 10⁹ organisms in each gram of stool during acute disease, *Shigella* are highly transmissible by the fecal-oral route or via contaminated water and food.

In the United States and Europe, children in daycare centers, migrant workers, travelers to developing countries, and those in nursing homes are most commonly affected. Most *Shigella* infections and deaths occur in children younger than 5 years of age. In countries where *Shigella* is endemic it is responsible for approximately 10% of pediatric diarrheal disease and as many as 75% of diarrheal deaths.

Figure 17-28 Bacterial enterocolitis. **A**, *Campylobacter jejuni* infection produces acute, self-limited colitis. Neutrophils can be seen within the surface and crypt epithelia and a crypt abscess is present at the lower right. **B**, In *Yersinia* infection the surface epithelium can be eroded by neutrophils and the lamina propria is densely infiltrated by sheets of plasma cells admixed with lymphocytes and neutrophils. **C**, Enterohemorrhagic *E. coli* O157:H7 results in an ischemia-like morphology with surface atrophy and erosion. **D**, Enteroinvasive *E. coli* infection is similar to other acute, self-limited colitides such as those caused by *Campylobacter jejuni*. Note the maintenance of normal crypt architecture and spacing, despite abundant intraepithelial neutrophils.

Pathogenesis. *Shigella* are resistant to the harsh acidic environment of the stomach, thereby explaining the extremely low infective dose. Once in the intestine, organisms are taken up by M, or microfold cells. These are epithelial cells, which are specialized for sampling and presentation of luminal antigens. *Shigella* proliferate intracellularly, escape into the lamina propria, and are phagocytosed by macrophages, in which they induce apoptosis. The ensuing inflammatory response damages surface epithelia and allows *Shigella* within the intestinal lumen to gain access to the basolateral membranes of colonic epithelial cells, which is the preferred domain for invasion. All *Shigella* spp. carry virulence plasmids, some of which encode a type III secretion system capable of directly injecting bacterial proteins into the host cytoplasm. *S. dysenteriae* serotype 1 also release the Shiga toxin Stx, which inhibits eukaryotic protein synthesis, resulting in host cell damage and death.

MORPHOLOGY

Shigella infections are most prominent in the left colon, but the ileum may also be involved, perhaps reflecting the abundance of M cells in the dome epithelium over the Peyer patches. The mucosa is hemorrhagic and ulcerated, and pseudomembranes may be present. The histology of early cases is similar to other acute self-limited colitides, such as *Campylobacter* colitis, but because of the tropism for M cells, aphthous-appearing ulcers similar to those seen in Crohn disease may occur. The potential for confusion with chronic inflammatory bowel disease is significant, particularly if there is distortion of crypt architecture.

Clinical Features. After an incubation period of up to 1 week, *Shigella* causes self-limited disease characterized by about 1 week of diarrhea, fever, and abdominal pain. The initially watery diarrhea progresses to a dysenteric phase

in approximately 50% of patients, and constitutional symptoms can persist for as long as 1 month. The subacute presentation that develops in a minority of adults is characterized by several weeks of waxing and waning diarrhea that can mimic new-onset ulcerative colitis. While duration is typically shorter in children, severity is often much greater. Confirmation of *Shigella* infection requires stool culture.

Complications of *Shigella* infection are uncommon and include a triad of sterile reactive arthritis, urethritis, and conjunctivitis that preferentially affects HLA-B27-positive men between 20 and 40 years of age. Hemolytic-uremic syndrome, which is typically associated with enterohemorrhagic *E. coli* (EHEC), may also occur after infection with *S. dysenteriae* serotype 1 that secrete Shiga toxin (Chapter 20). Toxic megacolon and intestinal obstruction are uncommon complications. Antibiotic treatment shortens the clinical course and reduces the duration of organism shedding in stools, but antidiarrheal medications are contraindicated because they can prolong symptoms and delay *Shigella* clearance.

Salmonella

Salmonella, which are classified within the Enterobacteriaceae family of gram-negative bacilli, are divided into *Salmonella typhi*, the causative agent of typhoid fever (discussed in the next section) and nontyphoid *Salmonella*. The latter are the causative agent of salmonellosis, which is usually due to *S. enteritidis*; more than 1 million cases occur each year in the United States, and the prevalence is even greater in developing countries. Infection is most common in young children and older adults, with peak incidence in the summer and fall. *Salmonella* may also cause food poisoning by ingestion of contaminated food, particularly raw or undercooked meat, poultry, eggs, and milk. Centralized food processing can lead to large

outbreaks. Vaccines are available for both humans and farm animals, e.g. egg-laying hens.

Pathogenesis. Very few viable *Salmonella* are necessary to cause infection, and the absence of gastric acid, in individuals with atrophic gastritis or those on acid-suppressive therapy, further reduces the required inoculum. *Salmonella* possess virulence genes that encode a type III secretion system capable of transferring bacterial proteins into M cells and enterocytes. The transferred proteins activate host Rho GTPases, thereby triggering actin rearrangement and bacterial endocytosis which, in turn, allows bacterial growth within endosomes. In addition, flagellin, the core protein of bacterial flagellae, activates TLR5 on host cells and increases the local inflammatory response. Similarly, bacterial lipopolysaccharide activates TLR4, although some *Salmonella* strains express a virulence factor that prevents TLR4 activation. *Salmonella* also secrete a molecule that induces epithelial cell release of the eicosanoid hepoxilin A3, thereby drawing neutrophils into the intestinal lumen and potentiating mucosal damage. Both T_H1 and T_H17 immune responses limit infection and explain why those with genetic defects in T_H17 immunity are at risk for disseminated salmonellosis.

The gross and microscopic features of *Salmonella* enteritis are nonspecific and are similar to the acute self-limited colitis of *Campylobacter* and *Shigella*. Stool cultures are essential for diagnosis.

Clinical Features. *Salmonella* infections are clinically indistinguishable from those caused by other enteric pathogens, and symptoms range from loose stools to cholera-like profuse diarrhea to dysentery. Fever often resolves within 2 days, but diarrhea can persist for a week and organisms can be shed in the stool for several weeks after resolution. Antibiotic therapy is not recommended in uncomplicated cases because it can prolong the carrier state or even cause relapse and does not typically shorten the duration of diarrhea. Most *Salmonella* infections are self-limited, but deaths do occur. The risk of severe illness and complications is increased in patients with malignancies, immunosuppression, alcoholism, cardiovascular dysfunction, sickle cell disease, and hemolytic anemia.

Typhoid Fever

Typhoid fever, also referred to as enteric fever, affects up to 30 million individuals worldwide each year. The disease is caused by *Salmonella enterica*, and its two subtypes, *typhi* and *paratyphi*. The majority of cases in endemic countries are due to *S. typhi*, while infection by *S. paratyphi* is more common among travelers, perhaps because travelers tend to be vaccinated against *S. typhi*. In endemic areas, children and adolescents are affected most often, but there is no age preference in developed countries. Infection is strongly associated with travel to India, Mexico, the Philippines, Pakistan, El Salvador, and Haiti. Humans are the sole reservoir for *S. typhi* and *S. paratyphi* and transmission occurs from person to person or via food or contaminated water. Gallbladder colonization with *S. typhi* or *S. paratyphi* may be associated with gallstones and the chronic carrier state.

Pathogenesis. *S. typhi* are able to survive in gastric acid and, once in the small intestine, they are taken up by and invade M cells. Bacteria are then engulfed by mononuclear cells in the underlying lymphoid tissue. Unlike *S. enteritidis*, *S. typhi* can then disseminate via lymphatic and blood vessels. This causes reactive hyperplasia of phagocytes and lymphoid tissues throughout the body.

MORPHOLOGY

Infection causes **Peyer patches in the terminal ileum** to enlarge into sharply delineated, plateau-like elevations up to 8 cm in diameter. Draining mesenteric lymph nodes are also enlarged. Neutrophils accumulate within the superficial lamina propria, and macrophages containing bacteria, red cells, and nuclear debris mix with lymphocytes and plasma cells in the lamina propria. Mucosal damage creates oval ulcers, oriented along the axis of the ileum, that may perforate. The draining lymph nodes also harbor organisms and are enlarged due to phagocyte accumulation.

The spleen is enlarged and soft, with uniformly pale red pulp, obliterated follicular markings, and prominent phagocyte hyperplasia. The liver shows small, randomly scattered foci of parenchymal necrosis in which hepatocytes are replaced by macrophage aggregates, called **typhoid nodules**; such nodules may also develop in the bone marrow and lymph nodes.

Clinical Features. Patients experience anorexia, abdominal pain, bloating, nausea, vomiting, and bloody diarrhea followed by a short asymptomatic phase that gives way to bacteremia and fever with flulike symptoms. *Blood cultures are positive in more than 90% of affected individuals during the febrile phase. Antibiotic treatment can prevent further disease progression.* In patients who do not receive antibiotics, the initial febrile phase continues for up to 2 weeks; patients have sustained high fevers and abdominal tenderness that may mimic appendicitis. *Rose spots*, small erythematous maculopapular lesions, are seen on the chest and abdomen. Symptoms abate after several weeks in those who survive, although relapse can occur. Systemic dissemination may cause *extraintestinal complications* including encephalopathy, meningitis, seizures, endocarditis, myocarditis, pneumonia, and cholecystitis. Patients with sickle cell disease are particularly susceptible to *Salmonella* osteomyelitis.

Yersinia

Three *Yersinia* species are human pathogens. *Y. enterocolitica* and *Y. pseudotuberculosis* cause GI disease and are discussed here; *Y. pestis*, the agent of pulmonic and bubonic plague, is discussed in [Chapter 8](#). *Yersinia* infections of the GI system are more common in Europe than North America and are most frequently linked to ingestion of pork, raw milk, and contaminated water. *Y. enterocolitica* is far more common than *Y. pseudotuberculosis*, and infections tend to cluster in the winter, possibly related to inadequately cooked foods.

Pathogenesis. *Yersinia* invade M cells and use specialized bacterial proteins, called adhesins, to bind to host cell β_1

integrins. A pathogenicity island encodes an iron uptake system that mediates iron capture and transport; similar iron transport systems are also present in *E. coli*, *Klebsiella*, *Salmonella*, and enterobacteria. In *Yersinia*, iron enhances virulence and stimulates systemic dissemination, explaining why individuals with increased non-heme iron, such as those with certain chronic forms of anemia or hemochromatosis, are more likely to develop sepsis and are at greater risk for death.

MORPHOLOGY

Yersinia infections preferentially involve the ileum, appendix, and right colon (Fig. 17-28B). The organisms multiply extracellularly in lymphoid tissue, resulting in regional lymph node and Peyer patch hyperplasia as well as bowel wall thickening. The mucosa overlying lymphoid tissue may become hemorrhagic, and aphthous-like erosions and ulcers may develop, along with neutrophil infiltrates (Fig. 17-28B) and granulomas. This can result in diagnostic confusion with Crohn disease.

Clinical Features. People infected with *Yersinia* generally present with abdominal pain, but fever and diarrhea may also occur. Nausea, vomiting, and abdominal tenderness are common, and Peyer patch invasion with subsequent involvement of regional lymphatics can mimic acute appendicitis in teenagers and young adults. Enteritis and colitis predominate in younger children. *Extraintestinal symptoms of pharyngitis, arthralgia, and erythema nodosum occur frequently.* *Yersinia* can be detected by stool culture on *Yersinia*-selective agar. In cases with extraintestinal disease, cultures of lymph nodes or blood may also be positive. Postinfectious complications include reactive arthritis with urethritis and conjunctivitis, myocarditis, erythema nodosum, and kidney disease.

Escherichia coli

E. coli are gram-negative bacilli that colonize the healthy GI tract; most are nonpathogenic, but a subset cause human disease. The latter are classified according to morphology, mechanism of pathogenesis, and in vitro behavior. Subgroups with major clinical relevance include enterotoxigenic *E. coli* (ETEC), enteropathogenic *E. coli* (EPEC), enterohemorrhagic *E. coli* (EHEC), enteroinvasive *E. coli* (EIEC), and enteroaggregative *E. coli* (EAEC).

Enterotoxigenic *E. coli*. ETEC organisms are the principal cause of traveler's diarrhea and spread via contaminated food or water. In developing countries, children younger than 2 years of age are particularly susceptible. ETEC produce heat-labile toxin (LT) and heat-stable toxin (ST), both induce chloride and water secretion while inhibiting intestinal fluid absorption. The LT toxin is similar to cholera toxin and activates adenylate cyclase, resulting in increased intracellular cAMP. This stimulates chloride secretion and, simultaneously, inhibits absorption. ST toxins, which have homology to the mammalian regulatory protein guanylin, bind to guanylate cyclase and increase intracellular cGMP with resulting effects on transport that are similar to those produced by LT. Like cholera, the histopathology induced by ETEC infection is limited. The patients have secretory,

noninflammatory diarrhea, dehydration, and, in severe cases, shock.

Enteropathogenic *E. coli*. EPEC are prevalent in developed and developing countries, where they are an important cause of endemic diarrhea as well as diarrheal outbreaks particularly in children less than 2 years of age. EPEC are characterized by their ability to produce attaching and effacing (A/E) lesions in which bacteria attach tightly to the enterocyte apical membranes and cause local loss, i.e. effacement, of the microvilli. The proteins necessary for creating A/E lesions are all encoded by large genomic pathogenicity island, the locus of enterocyte effacement (LEE), which is also present in many EHEC strains. These proteins include Tir, which is inserted into the intestinal epithelial cell plasma membrane. Tir acts as a receptor for the bacterial outer membrane protein intimin, which is encoded by the *espE* gene and is used for molecular detection and diagnosis of EPEC infection. The locus of enterocyte effacement also encodes a type III secretion system, similar to that in *Shigella*, that injects bacterial effector proteins into the epithelial cell cytoplasm. All EPEC strains lack genes to produce Shiga toxin.

Enterohemorrhagic *E. coli*. EHEC are categorized as *E. coli* O157:H7 and non-O157:H7 serotypes. Because cows are a natural reservoir, it is not surprising that large outbreaks of *E. coli* O157:H7 infection in developed countries are often associated with the consumption of inadequately cooked ground beef. However, contaminated milk and vegetables are also vehicles for infection. Both O157:H7 and non-O157:H7 serotypes produce Shiga-like toxins, and therefore lesions (Fig. 17-28C) and clinical symptoms are similar to those resulting from *S. dysenteriae* infection. O157:H7 strains of EHEC are more likely than non-O157:H7 serotypes to cause large outbreaks, bloody diarrhea, hemolytic-uremic syndrome, and ischemic colitis. Importantly, antibiotics are not recommended for treatment because killing the bacteria can lead to increased release of Shiga-like toxins that enhance the risk of hemolytic uremic syndrome, especially in children.

Enteroinvasive *E. coli*. EIEC organisms are bacteriologically similar to *Shigella* and are transmitted via food, water, or by person-to-person contact. While EIEC do not produce toxins, they invade epithelial cells and cause non-specific features of acute self-limited colitis (Fig. 17-28D). EIEC infections are most common among young children in developing countries and are occasionally associated with outbreaks in developed countries.

Enteroaggregative *E. coli*. EAEC organisms were identified on the basis of their unique pattern of adherence to epithelial cells. These organisms are now recognized as a cause of diarrhea in children and adults in developed as well as developing countries. EAEC can also cause traveler's diarrhea. The organisms attach to enterocytes via adherence fimbriae and are aided by dispersin, a bacterial surface protein that neutralizes the negative surface charge of lipopolysaccharide. While the bacteria do produce enterotoxins related to *Shigella* enterotoxin and ETEC ST toxin, histologic damage is minimal and the characteristic adherence lesions are only visible by electron microscopy.

EAEC organisms cause nonbloody diarrhea that may be prolonged in individuals with the acquired immunodeficiency syndrome.

Pseudomembranous Colitis

Pseudomembranous colitis, generally caused by *C. difficile*, can also be referred to as antibiotic-associated colitis or antibiotic-associated diarrhea. While antibiotic-associated diarrhea may also be caused by other organisms such as *Salmonella*, *C. perfringens* type A, or *Staphylococcus aureus* only *C. difficile* causes pseudomembranous colitis.

Pathogenesis. It is likely that disruption of the normal colonic microbiota by antibiotics allows *C. difficile* overgrowth. Almost any antibiotic may be responsible; the most important determinants of the disease are frequency of use and the affect on colonic microbiota. Immunosuppression is also a predisposing factor for *C. difficile* colitis. Toxins released by *C. difficile* cause the ribosylation of small GTPases, such as Rho, and lead to disruption of the epithelial cytoskeleton, tight junction barrier loss, cytokine release, and apoptosis. The mechanisms by which these processes lead to pseudomembranous colitis are incompletely understood.

MORPHOLOGY

Fully developed *C. difficile*-associated colitis is accompanied by formation of **pseudomembranes** (Fig. 17-29A, B), made up of an adherent layer of inflammatory cells and debris at sites of colonic mucosal injury. While pseudomembranes are not specific and may occur with ischemia or necrotizing infections, the histopathology of *C. difficile*-associated colitis is pathognomonic. The surface epithelium is denuded, and the superficial lamina propria contains a dense infiltrate of neutrophils and occasional fibrin thrombi within capillaries. Superficially damaged crypts are distended by a mucopurulent exudate that forms an eruption reminiscent of a volcano (Fig. 17-29C). These exudates coalesce to form pseudomembranes.

Clinical Features. Risk factors for *C. difficile*-associated colitis include advanced age, hospitalization, and antibiotic treatment. The organism is particularly prevalent in hospitals; as many as 30% of hospitalized adults are colonized with *C. difficile* (a rate tenfold greater than the general population), but most colonized patients are free of disease. Individuals with *C. difficile*-associated colitis present with fever, leukocytosis, abdominal pain, cramps, watery diarrhea, and dehydration. Protein loss can give rise to hypoalbuminemia. Fecal leukocytes and occult blood may be present, but grossly bloody diarrhea is uncommon. Diagnosis of *C. difficile*-associated colitis is usually accomplished by detection of *C. difficile* toxin, rather than culture, and is supported by the characteristic histopathology. Metronidazole or vancomycin are generally effective therapies, but antibiotic-resistant and hypervirulent *C. difficile* strains are increasingly common. Another major challenge in *C. difficile*-associated colitis is recurrent infection, which occurs in up to 40% of patients. New antibiotics, monoclonal antibodies against toxins A

Figure 17-29 *Clostridium difficile* colitis. **A**, The colon is coated by tan pseudomembranes composed of neutrophils, dead epithelial cells, and inflammatory debris (endoscopic view). **B**, Pseudomembranes are easily appreciated on gross examination. **C**, Typical pattern of neutrophils emanating from a crypt is reminiscent of a volcanic eruption.

and B, and fecal microbial transplants can be effective therapies for recurrent *C. difficile* infection, but are not yet in widespread use.

Whipple Disease

Whipple disease is a rare, multivisceral chronic disease first described as intestinal lipodystrophy in 1907 by George Hoyt Whipple. A mere 27 years later the pathologist went on to win the Nobel Prize for his work on pernicious anemia. He was a contemporary, but not a relative, of Allen Oldfather Whipple, the surgeon who pioneered the pancreatoduodenectomy.

Pathogenesis. Whipple's original case report described an individual with malabsorption, lymphadenopathy, and arthritis of undefined origin. Postmortem examination demonstrated the presence of foamy macrophages and large numbers of argyrophilic rods in the lymph nodes, suggesting that the disease was caused by a microbe. The gram-positive actinomycete, named *Tropheryma whippelii*, which is responsible for Whipple disease, was identified by PCR in 1992 and finally cultured in 2000. Clinical symptoms occur because organism-laden macrophages accumulate within the small intestinal lamina propria and mesenteric lymph nodes, causing lymphatic obstruction. Thus, *the malabsorptive diarrhea of Whipple disease is due to impaired lymphatic transport.*

Figure 17-30 Whipple disease and mycobacterial infection. **A**, hematoxylin and eosin staining shows effacement of normal lamina propria by a sheet of swollen macrophages. **B**, PAS stain highlights macrophage lysosomes full of bacilli. Note the positive staining of mucous vacuoles in the overlying goblet cells. **C**, An electron micrograph of part of a macrophage shows bacilli within the cell (top arrow); also seen at higher magnification (inset). **D**, The morphology of mycobacterial infection can be similar to Whipple disease, particularly in the immunocompromised host. Compare with **A**. **E**, Mycobacteria are positive with stains for acid-fast bacteria. (**C**, Courtesy George Kasnic and Dr. William Clapp, University of Florida, Gainesville, Fla.)

MORPHOLOGY

The morphologic hallmark of Whipple disease is a **dense accumulation of distended, foamy macrophages in the small intestinal lamina propria** (Fig. 17-30A). The macrophages contain periodic acid–Schiff (PAS)-positive, diastase-resistant granules that represent lysosomes stuffed with partially digested bacteria (Fig. 17-30B). Intact rod-shaped bacilli can also be identified by electron microscopy (Fig. 17-30C). A similar infiltrate of foamy macrophages is present in intestinal tuberculosis (Fig. 17-30D), and the organisms are PAS-positive in both

diseases. The acid-fast stain can be helpful, since mycobacteria stain positively (Fig. 17-30E) while *T. whippelli* do not.

The **villous expansion** caused by the dense macrophage infiltrate imparts a shaggy gross appearance to the mucosal surface. Lymphatic dilatation and mucosal lipid deposition account for the common endoscopic detection of white to yellow mucosal plaques. In Whipple disease, bacteria-laden macrophages can accumulate within **mesenteric lymph nodes, synovial membranes of affected joints, cardiac valves, the brain**, and other sites.

Whipple disease is most common in Caucasian men, particularly farmers and others with occupational exposure to soil or animals. While there is no consistent familial clustering, the rarity of infection despite a large number of healthy carriers suggests that genetic risk factors may exist.

The clinical presentation of Whipple disease is usually a triad of diarrhea, weight loss, and arthralgia. Extraintestinal symptoms, which can exist for months or years before malabsorption, include arthritis, arthralgia, fever, lymphadenopathy, and neurologic, cardiac, or pulmonary disease.

Mycobacterial infections are considered in detail in Chapter 8.

Viral Gastroenteritis

Symptomatic human infection is caused by several distinct groups of viruses. The most common are discussed here.

Norovirus. This was previously known as Norwalk-like virus and is a common cause of nonbacterial gastroenteritis. These are small icosahedral viruses with a single-stranded RNA genome that forms a genus within the Caliciviridae family. **Norovirus causes approximately half of all gastroenteritis outbreaks worldwide and is a common cause of sporadic gastroenteritis in developed countries.** In the United States, noroviruses are the most common cause of acute gastroenteritis requiring medical attention and are second only to rotavirus as a cause of severe diarrhea in infants and young children. In developing countries, noroviruses cause more than 200,000 childhood deaths annually. Norovirus is expected to become the most common cause of diarrhea worldwide in all age groups as rotavirus vaccination becomes widespread.

Local norovirus outbreaks are usually related to contaminated food or water, but person-to-person transmission underlies most sporadic cases. Infections spread easily within schools, hospitals, nursing homes, and other large groups in close quarters, such as those on cruise ships. In these environments, vehicles of infection include airborne droplets, environmental surfaces and fomites.

Following a short incubation period, affected individuals develop nausea, vomiting, watery diarrhea, and abdominal pain. Biopsy morphology is nonspecific. When present, abnormalities are most evident in the small intestine and include mild villous shortening, epithelial vacuolization, loss of the microvillus brush border, crypt hypertrophy, and lamina propria infiltration by lymphocytes (Fig. 17-31A). The disease is self-limited in immunocompetent hosts.

Figure 17-31 Infectious enteritis. **A**, Histologic features of viral enteritis include increased numbers of intraepithelial and lamina propria lymphocytes and crypt hypertrophy. **B**, Diffuse eosinophilic infiltrates in parasitic infection. This case was caused by *Ascaris* (upper inset), but a similar tissue reaction could be caused by *Strongyloides* (lower inset). **C**, Schistosomiasis can induce an inflammatory reaction to eggs trapped within the lamina propria. **D**, *Entamoeba histolytica* in a colon biopsy specimen. Note some organisms ingesting red blood cells (arrow). **E**, *Giardia lamblia*, which are present in the luminal space over nearly normal-appearing villi, are easily overlooked. **F**, *Cryptosporidia* organisms are seen as small blue spheres that appear to lie on top of the brush border but are actually enveloped by a thin layer of host cell cytoplasm.

Norovirus infection in immunocompromised patients is a significant problem. Some data suggest that nearly 20% of patients on immunosuppression after renal transplantation or as treatment for graft-versus-host disease after hematopoietic stem cell transplantation are infected with norovirus and have intermittent diarrhea. Many of these patients fail to clear the infection, and diarrhea persists for an average of 9 months. The resulting malnutrition and dehydration can increase morbidity of the underlying disease.

Rotavirus. This encapsulated virus with a segmented, double-stranded RNA genome infects 140 million people and causes 1 million deaths each year, making rotavirus a common cause of severe childhood diarrhea and diarrheal mortality worldwide. Children between 6 and 24 months of age are most vulnerable. Protection in the first 6 months of life is probably due to the presence of antibodies in breast milk, while protection beyond 2 years is due to immunity that develops following the first or second infection. However, protection conferred by maternal antibodies seems to be less effective in India, Asia and Africa. Thus, in these locales infections are common in those younger than 6 months of age, hence early vaccination has been suggested. Because live, attenuated virus is

used, vaccination is contraindicated in patients with immunodeficiency. Vaccination has also been associated with intussusception, as discussed earlier.

Rotavirus outbreaks in hospitals and daycare centers are common, and infection spreads easily; the estimated minimal infective inoculum is only 10 viral particles. Rotavirus selectively infects and destroys mature enterocytes in the small intestine, and the villus surface is repopulated by immature secretory cells. Enterocyte damage may be mediated by a viral factor called non-structural protein 4 (NSP4), which can induce epithelial apoptosis. The loss of absorptive function and net secretion of water and electrolytes is compounded by an osmotic diarrhea caused by the incomplete absorption of nutrients. Like norovirus, rotavirus has a short incubation period followed by several days of vomiting and watery diarrhea.

Adenovirus. A common cause of pediatric diarrhea, adenovirus also affects immunocompromised patients. Small intestinal biopsy specimens can show epithelial degeneration but more often exhibit nonspecific villous atrophy and compensatory crypt hyperplasia. Viral nuclear inclusions are uncommon. Disease typically presents after an incubation period of 1 week with nonspecific symptoms that

include diarrhea, vomiting, and abdominal pain. Fever and weight loss may also be present. Symptoms generally resolve within 10 days.

Parasitic Enterocolitis

Although viruses and bacteria are the predominant enteric pathogens in the United States, parasitic disease and protozoal infections affect more than one half of the world's population on a chronic or recurrent basis. The small intestine can harbor as many as 20 species of parasites, including nematodes, such as the roundworms *Ascaris* and *Strongyloides*; hookworms and pinworms; cestodes, including flatworms and tapeworms; trematodes, or flukes; and protozoa. Parasitic infections are covered in [Chapter 8](#); those that are common in the intestinal tract are discussed briefly here.

Ascaris lumbricoides. This nematode infects more than a billion individuals worldwide as a result of human fecal-oral contamination. Ingested eggs hatch in the intestine and larvae penetrate the intestinal mucosa. Larvae then migrate from splanchnic to systemic circulation and, finally, enter the lungs to grow within the alveoli. Approximately 3 weeks later, the larvae are coughed up and swallowed. Upon return to the small intestine, the larvae mature into adult worms, which induce an eosinophil-rich inflammatory reaction ([Fig. 17-31B](#)) that can cause physical obstruction of the intestine or biliary tree. Larvae can also form hepatic abscesses and cause *Ascaris* pneumonitis. Diagnosis is usually made by detection of eggs in stool samples.

Strongyloides. The larvae of *Strongyloides* live in fecally contaminated ground soil and can penetrate unbroken skin. They migrate through the lungs, where they induce inflammatory infiltrates, and then reside in the intestine while maturing into adult worms. Unlike other intestinal worms, which require an ova or larval stage outside the human, the eggs of *Strongyloides* can hatch within the intestine and release larvae that penetrate the mucosa, causing autoinfection ([Fig. 17-31B](#)). Hence, *Strongyloides* infection can persist for life, and immunosuppressed individuals can develop overwhelming autoinfection. *Strongyloides* incite a strong tissue reaction and induce peripheral eosinophilia.

Necator duodenale and Ancylostoma duodenale. These hookworms infect 1 billion people worldwide and cause significant morbidity. Infection is initiated by larval penetration through the skin and, after further development in the lungs the larvae migrate up the trachea and are swallowed. Once in the duodenum the worms attach to the mucosa, suck blood, and reproduce. This causes multiple superficial erosions, focal hemorrhage, and inflammatory infiltrates and, in chronic infection, iron deficiency anemia. Diagnosis can be made by detection of the eggs in fecal smears.

Enterobius vermicularis. Also known as pinworms, these parasites infect people in industrialized and developing countries; in the United States as many as 40 million people have pinworms. Because they do not invade host tissue

and live their entire life within the intestinal lumen, they rarely cause serious illness. Infection by *E. vermicularis*, or enterobiasis, is primarily by the fecal-oral route. Adult worms living in the intestine migrate to the anal orifice at night, where the female deposits eggs on the perirectal mucosa. The eggs cause intense irritation. Rectal and perineal pruritus ensues. The intense itching leads to contamination of the fingers, which promotes human-to-human transmission. Both eggs and adult pinworms remain viable outside the body, and repeat infection is common. Diagnosis can be made by applying cellophane tape to the perianal skin and examining the tape for eggs under a microscope.

Trichuris trichiura. Whipworms primarily infect young children. Similar to *E. vermicularis*, *Trichuris trichiura* does not penetrate the intestinal mucosa and rarely cause serious disease. Heavy infections, however, may cause bloody diarrhea and rectal prolapse.

Schistosomiasis. This disease involving the intestines most commonly takes the form of adult worms residing within the mesenteric veins. Symptoms of intestinal schistosomiasis are caused by trapping of eggs within the mucosa and submucosa ([Fig. 17-31C](#)). The resulting immune reaction is often granulomatous and can cause bleeding and even obstruction. More details are presented in [Chapter 8](#).

Intestinal Cestodes. The three primary species of cestodes that affect humans are *Diphyllobothrium latum*, fish tapeworms; *Taenia solium*, pork tapeworms; and *Hymenolepis nana*, dwarf tapeworms. They reside exclusively within the intestinal lumen and are transmitted by ingestion of raw or undercooked fish, meat, or pork that contains encysted larvae. Release of the larvae allows attachment to the intestinal mucosa through its head, or scolex. The worm derives its nutrients from the food stream and enlarges by formation of egg-filled segments termed proglottids. Humans are usually infected by a single worm, and since the worm does not penetrate the intestinal mucosa, peripheral eosinophilia does not generally occur. Nevertheless, the parasite burden can be staggering, since adult worms can grow to many meters in length. Large numbers of proglottids and eggs are shed in the feces. Clinical symptoms include abdominal pain, diarrhea, and nausea, but the majority of cases are asymptomatic. Occasionally, *D. latum* causes B₁₂ deficiency and megaloblastic anemia because it competes with the host for dietary B₁₂. Identification of proglottids and eggs in stools is the most efficient method of diagnosis.

Entamoeba histolytica. This protozoan causes amebiasis and is spread by fecal-oral transmission. *E. histolytica* infects approximately 500 million people in countries such as India, Mexico, and Colombia, and causes 40 million cases of dysentery and liver abscess annually. *E. histolytica* cysts, which have a chitin wall and four nuclei, are resistant to gastric acid, a characteristic that allows them to pass through the stomach without harm. Cysts then colonize the epithelial surface of the colon and release trophozoites, ameboid forms that reproduce under anaerobic conditions.

While amebiasis affects the cecum and ascending colon, most often, the sigmoid colon, rectum, and appendix can also be involved. Dysentery develops when the amebae attach to the colonic epithelium, induce apoptosis, invade crypts, and burrow laterally into the lamina propria. This recruits neutrophils, causes tissue damage, and creates a flask-shaped ulcer with a narrow neck and broad base. Histologic diagnosis can be difficult, since amebae are similar to macrophages in size and general appearance (Fig. 17-31D). Parasites may penetrate splanchnic vessels and embolize to the liver to produce abscesses in about 40% of patients with amebic dysentery. Amebic liver abscesses, which can exceed 10 cm in diameter, have a scant inflammatory reaction at their margins and a shaggy fibrin lining. The abscesses persist after the acute intestinal illness has passed and may, rarely, reach the lung and the heart by direct extension. Amebae may also spread to the kidneys and brain via the bloodstream.

Individuals with amebiasis may present with abdominal pain, bloody diarrhea, or weight loss. Occasionally, acute necrotizing colitis and megacolon occur, and both are associated with significant mortality. The parasites lack mitochondria or Krebs cycle enzymes and are thus obligate fermenters of glucose. Metronidazole, which inhibits pyruvate oxidoreductase, an enzyme required for fermentation, is the most effective treatment for systemic disease.

Giardia lamblia. These organisms, also referred to as *G. duodenalis* or *G. intestinalis*, were initially described by van Leeuwenhoek, the inventor of the microscope, who discovered the pathogen in his own stool. *Giardia lamblia* are the most common parasitic pathogen in humans and are spread by fecally contaminated water or food. Infection may occur after ingestion of as few as 10 cysts. Because cysts are resistant to chlorine, *Giardia* are endemic in unfiltered public water supplies. They are commonly present in rural streams, explaining infection in campers who use these as a water source. Infection may also occur by the fecal-oral route and, because the cysts are stable, they may be accidentally swallowed while swimming in contaminated water.

Giardia are flagellated protozoans that cause decreased expression of brush-border enzymes, including lactase. In addition they cause microvillous damage and apoptosis of small intestinal epithelial cells. Secretory IgA and mucosal IL-6 responses are important for clearance of *Giardia* infections. Immunosuppressed, agammaglobulinemic, or malnourished individuals are often severely affected. *Giardia* can evade immune clearance through continuous modification of the major surface antigen, variant surface protein, and can persist for months or years while causing intermittent symptoms.

Giardia trophozoites can be identified in duodenal biopsies based on their characteristic pear shape and the presence of two equally sized nuclei. Despite large numbers of trophozoites, which are tightly bound to the brush border of villous enterocytes, there is no invasion and small intestinal morphology may be normal (Fig. 17-31E). However, villous blunting with increased numbers of intraepithelial lymphocytes and mixed lamina propria inflammatory infiltrates can develop in patients with heavy infections.

Giardiasis may be subclinical or accompanied by acute or chronic diarrhea, malabsorption, and weight loss.

Infection is usually documented by immunofluorescent detection of cysts in stool samples. Although oral antimicrobial therapy is effective, recurrence is common.

Cryptosporidium. Like *Giardia*, cryptosporidia are an important cause of diarrhea worldwide. Cryptosporidiosis was first discovered in the 1980s as an agent of chronic diarrhea in AIDS patients and is now recognized as a cause of acute, self-limited disease in immunologically normal hosts. Cryptosporidiosis also causes persistent diarrhea in residents of developing countries. The organisms are present worldwide, with the exception of Antarctica, perhaps because the oocysts are killed by freezing. The oocysts are resistant to chlorine and may, therefore, persist in treated, but unfiltered, water. Contaminated drinking water continues to be the most common means of transmission. The largest documented outbreak, a result of inadequate water purification, occurred in 1993 in Milwaukee, Wisconsin, and affected more than 400,000 people. Like giardiasis, cryptosporidiosis can be spread to water sport participants via contaminated water. Food-borne infection occurs less frequently.

Humans are infected by several different *Cryptosporidium* species, including *C. hominis* and *C. parvum*. All are able to go through an entire life cycle, with asexual and sexual reproductive phases, in a single host. The ingested encysted oocyte, of which 10 are sufficient to cause symptomatic infection, releases sporozoites following activation of proteases by gastric acid. The sporozoites are motile and have a specialized organelle that attaches to the brush border and causes changes in the enterocyte cytoskeleton. These changes induce the enterocyte to engulf the parasite, which takes up residence in an endocytic vacuole within the microvilli. The presence of the parasite leads to sodium malabsorption, chloride secretion, and increased tight junction permeability, which are responsible for the non-bloody, watery diarrhea that ensues.

Mucosal histology is often only minimally altered, but persistent cryptosporidiosis in children and heavy infection in immunosuppressed patients can result in villous atrophy, crypt hyperplasia, and inflammatory infiltrates. Although the sporozoite is intracellular, it appears, by light microscopy, to sit on top of the epithelial apical membrane (Fig. 17-31F). Organisms are typically most concentrated in the terminal ileum and proximal colon, but can be present throughout the gut, biliary tract, and even the respiratory tract of immunodeficient hosts. Diagnosis is based on finding oocysts in the stool.

KEY CONCEPTS

Infectious Enterocolitis

- *Vibrio cholerae* secrete a preformed toxin that causes massive chloride secretion. Water follows the resulting osmotic gradient, leading to secretory diarrhea.
- *Campylobacter jejuni* is the most common bacterial enteric pathogen in developed countries and also causes traveler's diarrhea. Most isolates are noninvasive.
- *Salmonella* and *Shigella* spp. are invasive and associated with and exudative bloody diarrhea (dysentery).
- *Salmonella* infection is a common cause of food poisoning.

- ***S. typhi*** can cause systemic disease (typhoid fever).
- **Pseudomembranous colitis** is often triggered by antibiotic therapy that allows colonization by ***Clostridium difficile***. The organism releases toxins that disrupt epithelial function. The associated inflammatory response includes characteristic volcano-like eruptions of neutrophils from colonic crypts that spread to form mucopurulent pseudomembranes.
- **Norovirus** is a very common cause of self limited diarrhea both in adults and children. It spreads from person to person in sporadic cases and by water in epidemic cases.
- **Rotavirus** is the most common cause of severe childhood diarrhea and diarrheal mortality worldwide. The diarrhea is caused by loss of mature enterocytes, resulting in malabsorption as well as secretion.
- **Parasitic and protozoal infections** affect more than one half of the world's population on a chronic or recurrent basis. Each parasite has a distinctive life cycle and tissue reaction. Most are associated with tissue and systemic eosinophilia.

Irritable Bowel Syndrome

Irritable bowel syndrome (IBS) is characterized by chronic, relapsing abdominal pain, bloating, and changes in bowel habits. Despite very real symptoms, the gross and microscopic evaluation is normal in most IBS patients. Thus, the diagnosis depends on clinical symptoms and functional testing. It should be recognized that IBS is a syndrome, and that multiple illnesses are represented under this global descriptor. IBS is currently divided into several subtypes, as defined by successive revisions of the Rome criteria.

Pathogenesis. The pathogenesis of IBS remains poorly defined, although there is clearly interplay between psychologic stressors, diet, perturbation of the gut microbiome, increased enteric sensory responses to gastrointestinal stimuli, and abnormal GI motility. For example, patients with *constipation-predominant* or *diarrhea-predominant* IBS tend to have decreased or increased colonic contractions and transit rates, respectively. Excess bile acid synthesis or bile acid malabsorption has been identified as one cause of diarrhea-predominant IBS, likely due to the effects of bile acids on intestinal motility.

Other data link disturbances in enteric nervous system function to IBS, suggesting a role for defective brain-gut axis signaling. Consistent with this, deep sequencing and genome wide association studies have linked several candidate genes to IBS, including serotonin reuptake transporters, cannabinoid receptors, and TNF-related inflammatory mediators. Further, 5-HT₃ receptor antagonists are effective in many cases of diarrhea-predominant IBS. Opioids and psychoactive drugs with anti-cholinergic effects are also commonly used to treat diarrhea-predominant IBS.

A separate group of IBS patients, relate onset to a bout of infectious gastroenteritis, suggesting that immune activation or, alternatively, a shift in the gut microbiome may

trigger some cases. While unproven, this could explain the efficacy of fecal transplantation in some IBS cases.

There may be some overlap in mechanisms underlying constipation-predominant and diarrhea-predominant IBS. For example, single nucleotide polymorphisms in immune mediators have been detected in both.

Clinical Features. The peak prevalence of IBS is between 20 and 40 years of age, and there is a significant female predominance. Variability in diagnostic criteria makes it difficult to establish the incidence, but most authors report prevalence in developed countries of between 5% and 10%. IBS is presently diagnosed using clinical criteria that require the occurrence of abdominal pain or discomfort at least 3 days per month over 3 months with improvement following defecation and a change in stool frequency or form. Other causes, such as enteric infection or inflammatory bowel disease, must be excluded.

IBS is not associated with serious long-term sequelae, but affected patients may undergo unnecessary abdominal surgery due to chronic pain and their ability to function socially may be compromised. The prognosis of IBS is most closely related to symptom duration, with longer duration correlating with reduced likelihood of improvement.

Inflammatory Bowel Disease

Inflammatory bowel disease (IBD) is a chronic condition resulting from inappropriate mucosal immune activation. The two disorders that comprise IBD are *ulcerative colitis* and *Crohn disease*. Descriptions of ulcerative colitis and Crohn disease date back to antiquity and at least the sixteenth century, respectively, but it took modern microbiologic techniques to exclude conventional infectious etiologies for these diseases. As will be discussed later, however, the luminal microbiota likely play a role in the pathogenesis of IBD.

The distinction between ulcerative colitis and Crohn disease is based, in large part, on the distribution of affected sites (Fig. 17-32) and the morphologic expression of disease (Table 17-9) at those sites. **Ulcerative colitis is limited to the colon and rectum and extends only into the mucosa and submucosa. In contrast, Crohn disease, which has also been referred to as regional enteritis (because of frequent ileal involvement) may involve any area of the GI tract and is typically transmural.**

Epidemiology. Ulcerative colitis and Crohn disease frequently present in the teens and early 20s, with the former being slightly more common in females. IBD is most common among Caucasians and, in the United States, occurs 3 to 5 times more often among eastern European (Ashkenazi) Jews than the general population. This is at least partly due to genetic factors, as discussed later. The geographic distribution of IBD is highly variable, but it is most common in North America, northern Europe, and Australia. However, IBD incidence worldwide is on the rise, and it is becoming more common in regions such as Africa, South America, and Asia where its prevalence was historically low. The hygiene hypothesis suggests that this increasing incidence is related to improved food storage conditions, decreased food contamination, and changes in

Figure 17-32 Distribution of lesions in inflammatory bowel disease. The distinction between Crohn disease and ulcerative colitis is primarily based on morphology.

gut microbiome composition. Apparently this results in inadequate development of regulatory processes that limit mucosal immune responses. This in turn allows some mucosa-associated microbial organisms to trigger persistent and chronic inflammation in susceptible hosts. Although many details to support this hypothesis are lacking, the observation that helminth infections, which are endemic in regions where IBD incidence is low, can prevent IBD development in animal models and even reduce disease in some patients, lends support to this idea.

Pathogenesis. Although precise causes are not yet defined most investigators believe that IBD results from the combined effects of alterations in host interactions with intestinal microbiota, intestinal epithelial dysfunction, aberrant mucosal immune responses, and altered composition of the gut microbiome. This view is supported by epidemiologic, genetic, and clinical studies as well as data from laboratory models of IBD (Fig. 17-33).

- **Genetics.** There is compelling evidence that genetic factors contribute to IBD. Risk of disease is increased when there is an affected family member and, in Crohn disease, the concordance rate for monozygotic twins approaches 50%. Genetic factors may also contribute to phenotypic expression of the disease, because twins affected by Crohn disease tend to present within a few years of each other and develop disease in similar regions of the GI tract. The concordance of monozygotic twins for ulcerative colitis is only about 15%, suggesting that genetic factors are less dominant than in Crohn disease. Concordance for dizygotic twins is less than 10% for both forms of IBD.

Population based genome wide association studies have identified over 160 IBD-associated genes. Most of these are shared between Crohn disease and ulcerative colitis, as well as other complex immune-mediated diseases. Interestingly, several IBD associated genes overlap with genes involved in responses to mycobacteria, including *Mycobacterium tuberculosis* and *Mycobacterium leprae*. This supports the idea that host-microbial interactions are critical to the pathogenesis of IBD and may explain some overlap in the histopathology of Crohn disease and mycobacterial infection. One of genes most strongly associated with Crohn disease is *NOD2* (nucleotide oligomerization binding domain 2), which encodes an intracellular protein that binds to bacterial peptidoglycans and activates signaling events, including the NF- κ B pathway. Despite the increase in risk attributable to *NOD2* polymorphisms, it should be remembered that fewer than 10% of individuals carrying risk associated *NOD2* variants develop disease. Thus, as is the case with all IBD-associated genes, any one gene confers only a small increase in the risk of developing these diseases.

In addition to *NOD2*, two Crohn disease-related genes of particular interest are *ATG16L1* (autophagy-related 16-like), and *IRGM* (immunity-related GTPase M). Both are part of the autophagy pathways that are critical for cellular responses to intracellular bacteria; *ATG16L1* may also regulate epithelial homeostasis.

NOD2, *ATG16L1*, and *IRGM* are expressed in multiple cell types, and their precise roles in the pathogenesis of Crohn disease have yet to be defined. However, all

Table 17-9 Features That Differ between Crohn Disease and Ulcerative Colitis

Feature	Crohn Disease	Ulcerative Colitis
Macroscopic		
Bowel region	Ileum \pm colon	Colon only
Distribution	Skip lesions	Diffuse
Stricture	Yes	Rare
Wall appearance	Thick	Thin
Microscopic		
Inflammation	Transmural	Limited to mucosa
Pseudopolyps	Moderate	Marked
Ulcers	Deep, knife-like	Superficial, broad-based
Lymphoid reaction	Marked	Moderate
Fibrosis	Marked	Mild to none
Serositis	Marked	Mild to none
Granulomas	Yes (~35%)	No
Fistulae/sinuses	Yes	No
Clinical		
Perianal fistula	Yes (in colonic disease)	No
Fat/vitamin malabsorption	Yes	No
Malignant potential	With colonic involvement	Yes
Recurrence after surgery	Common	No
Toxic megacolon	No	Yes

All features may not be present in a single case.

Figure 17-33 One model of IBD pathogenesis. Aspects of both Crohn disease and ulcerative colitis are shown. See text for details.

three are involved in recognition and response to intracellular pathogens, supporting the hypothesis that inappropriate immune reactions to luminal bacteria are an important component of IBD pathogenesis.

- **Mucosal immune responses.** Several observations support a role for mucosal immune responses in the pathogenesis of IBD. Some of these are:

- T helper cells are activated in Crohn disease and the response is polarized to the T_H1 type (see [Chapter 6](#))
- T_H17 T cells most likely contribute to disease pathogenesis. Consistent with this, certain polymorphisms of the IL-23 receptor, which is involved in the development and maintenance of T_H17 cells, confer marked reductions in the risk of both Crohn disease and ulcerative colitis.
- Many other pro-inflammatory cytokines, including TNF, interferon- γ and IL-13, as well as immunoregulatory molecules such as IL-10 and TGF- β , appear to play a role in the pathogenesis of IBD. The role of IL-10 is supported by the observations that autosomal recessive mutations of the IL-10 and IL-10 receptor genes are linked to severe, early onset IBD.

Overall, while details remain to be defined, it is clear that deranged mucosal immune activation and defective immunoregulation contribute to the development of ulcerative colitis and Crohn disease. Immunosuppressive agents remain the mainstay of treatment for these conditions.

- **Epithelial defects.** A variety of epithelial defects have been described in both Crohn disease and ulcerative colitis. Some examples follow:

- Defects in intestinal epithelial tight junction barrier function are present in Crohn disease patients and a subset of their healthy first-degree relatives. In

patients with Crohn disease and their relatives, this barrier dysfunction is associated with specific disease-associated *NOD2* polymorphisms; experimental models demonstrate that barrier dysfunction can activate innate and adaptive mucosal immunity and sensitize subjects to disease.

- Some polymorphisms, such as those involving *ECM1* (extracellular matrix protein 1), which inhibits matrix metalloproteinase 9, are linked to ulcerative colitis but not Crohn disease. In this context it is notable that inhibition of matrix metalloproteinase 9 reduces the severity of colitis in experimental models.
- Certain polymorphisms in the transcription factor *HNFA* are associated with ulcerative colitis but not Crohn disease. These *HNFA* polymorphisms are also strongly associated with maturity onset diabetes of the young (MODY), which like IBD, is associated with reduced intestinal barrier function.

Together these data suggest that, derangements in epithelial function is an important component are critical to IBD pathogenesis.

- **Microbiota.** The abundance of microbiota in the GI lumen is overwhelming, amounting to as much as 10^{12} organisms per milliliter in the colon and 50% of fecal mass. In total, these organisms greatly outnumber human cells in our bodies, a sober reminder that at a cellular level, we may be only about 10% human. A sampling of data that supports the notion that microbiota play a role in the evolution of IBD follows:

- As mentioned earlier, linkage to *NOD2*, points to the involvement of microbes in the causation of Crohn disease.
- The presence of antibodies against the bacterial protein flagellin are most common in Crohn disease patients who have disease associated *NOD2* variants, stricture formation, perforation, and small-bowel involvement. In contrast, anti-flagellin antibodies are uncommon in ulcerative colitis patients.
- Microbial transfer studies are able to induce or reduce disease in animal models of IBD, and clinical trials suggest that probiotic (or beneficial) bacteria or even fecal microbial transplants from healthy individuals may benefit IBD patients.

One model that unifies the roles of intestinal microbiota, epithelial function, and mucosal immunity suggests a cycle by which transepithelial flux of luminal bacterial components activates innate and adaptive immune responses. In a genetically susceptible host, the subsequent release of TNF and other immune-mediated signals direct epithelia to increase tight junction permeability, which causes further increases in the influx of luminal material. These events may establish a self-amplifying cycle that gives rise to maladaptive and injurious immune responses.

Crohn Disease

Crohn disease, an eponym based on the 1932 description by Crohn, Ginzburg, and Oppenheimer, has existed for centuries. Louis XIII of France (1601-1643) suffered relapsing bloody diarrhea, fever, rectal abscess, small intestinal and colonic ulcers, and fistulae beginning at age 20 years, most likely due to Crohn disease.

Figure 17-34 Gross pathology of Crohn disease. **A**, Small-intestinal stricture. **B**, Linear mucosal ulcers, which impart a cobblestone appearance to the mucosa, and thickened intestinal wall. **C**, Perforation and associated serositis. **D**, Creeping fat.

MORPHOLOGY

Crohn disease may occur in any area of the GI tract, but the most common sites involved at presentation are the terminal ileum, ileocecal valve, and cecum. Disease is limited to the small intestine alone in about 40% of cases; the small intestine and colon are both involved in 30% of patients; the remainder have only colonic involvement. The presence of multiple, separate, sharply delineated areas of disease, resulting in **skip lesions**, is characteristic of Crohn disease and may help in the differentiation from ulcerative colitis. Strictures are common in Crohn disease, but do not generally develop in ulcerative colitis (Fig. 17-34A).

The earliest lesion, the **aphthous ulcer**, may progress, and multiple lesions often coalesce into elongated, serpentine ulcers oriented along the axis of the bowel (Fig. 17-34B). Edema and loss of the normal mucosal texture are common. Sparing of interspersed mucosa, a result of the patchy distribution of Crohn disease, results in a coarsely textured, **cobblestone** appearance in which diseased tissue is depressed below the level of normal mucosa (Fig. 17-34B). **Fissures** frequently develop between mucosal folds and may extend deeply to become fistula tracts or sites of perforation (Fig. 17-34C). The intestinal wall is thickened and rubbery as a consequence of transmural edema, inflammation, submucosal fibrosis, and hypertrophy of the muscularis propria, all of which contribute to stricture formation (Fig. 17-34A). In cases with extensive transmural disease, mesenteric fat frequently extends around the serosal surface (**creeping fat**) (Fig. 17-34D).

The microscopic features of active Crohn disease include abundant neutrophils that infiltrate and damage crypt epithelium. Clusters of neutrophils within a crypt are referred to as **crypt abscesses** and are often associated with crypt destruction. Ulceration is common in Crohn disease, and there may be an abrupt transition between ulcerated and adjacent normal mucosa. Even in areas where gross examination suggests diffuse disease, microscopic pathology can appear patchy. Repeated cycles of crypt destruction and regeneration lead to **distortion of mucosal architecture**; the normally straight and parallel crypts take on bizarre branching shapes and unusual orientations to one another (Fig. 17-35A). Epithelial metaplasia, another consequence of chronic relapsing injury, often takes the form of gastric antral-appearing glands, and is called **pseudopyloric metaplasia**. **Paneth cell metaplasia** may also occur in the left colon, where Paneth cells are normally absent. These architectural and metaplastic changes may persist even when active inflammation has resolved. Mucosal atrophy, with loss of crypts, may occur after years of disease. **Noncaseating granulomas** (Fig. 17-35B), a hallmark of Crohn disease, are found in approximately 35% of cases and may occur in areas of active disease or uninvolved regions in any layer of the intestinal wall (Fig. 17-35C). Granulomas may also be present in mesenteric lymph nodes. Cutaneous granulomas form nodules that are referred to as **metastatic Crohn disease** (a misnomer since there is no cancer). The absence of granulomas does not preclude a diagnosis of Crohn disease.

Figure 17-35 Microscopic pathology of Crohn disease. **A**, Haphazard crypt organization results from repeated injury and regeneration. **B**, Noncaseating granuloma. **C**, Transmural Crohn disease with submucosal and serosal granulomas (arrows).

Clinical Features. The clinical manifestations of Crohn disease are extremely variable. In most patients disease begins with intermittent attacks of relatively mild diarrhea, fever, and abdominal pain. Approximately 20% of patients present acutely with right lower quadrant pain, fever, and bloody diarrhea that may mimic acute appendicitis or bowel perforation. Periods of active disease are typically interrupted by asymptomatic periods that last for weeks to many months. Disease re-activation can be associated with a variety of external triggers, including physical or emotional stress, specific dietary items, and cigarette smoking. The latter is a strong exogenous risk factor for development of Crohn disease and, in some cases, disease onset is associated with initiation of smoking. Unfortunately, smoking cessation does not result in disease remission.

Iron-deficiency anemia may develop in individuals with colonic disease, while extensive small bowel disease may result in serum protein loss and hypoalbuminemia, generalized nutrient malabsorption, or malabsorption of vitamin B₁₂ and bile salts. *Fibrosing strictures*, particularly of the terminal ileum, are common and require surgical resection. Disease often recurs at the site of anastomosis, and as many as 40% of patients require additional resections within 10 years. *Fistulae* develop between loops of bowel and may also involve the urinary bladder, vagina, and abdominal or perianal skin. *Perforations* and peritoneal abscesses are common. Anti-TNF antibodies have revolutionized treatment of Crohn disease, and other biologic therapies are becoming available.

Extraintestinal manifestations of Crohn disease include uveitis, migratory polyarthritis, sacroiliitis, ankylosing spondylitis, erythema nodosum, and clubbing of the fingertips, any of which may develop before intestinal disease is recognized. Pericholangitis and primary sclerosing cholangitis occur in Crohn disease with a higher frequency than in those without Crohn disease, but are even more common in those who have ulcerative colitis (see below and Chapter 18). As discussed later, risk of colonic adenocarcinoma is increased in patients with long-standing IBD affecting the colon.

Ulcerative Colitis

Ulcerative colitis is closely related to Crohn disease. However, the disease in ulcerative colitis is limited to the colon and rectum. Common extraintestinal manifestations of ulcerative colitis overlap with those of Crohn disease and include migratory polyarthritis, sacroiliitis, ankylosing spondylitis, uveitis, and skin lesions. Approximately 2.5% to 7.5% of individuals with ulcerative colitis also have primary sclerosing cholangitis (Chapter 18). The long-term outlook for ulcerative colitis patients depends on the severity of active disease and disease duration.

MORPHOLOGY

Grossly, ulcerative colitis always involves the rectum and extends proximally in a continuous fashion to involve part or all of the colon. Disease of the entire colon is termed pancolitis (Fig. 17-36A), while left-sided disease extends no farther than the transverse colon. Limited distal disease may be referred to descriptively as ulcerative proctitis or ulcerative

proctosigmoiditis. The small intestine is normal, although mild mucosal inflammation of the distal ileum, termed backwash ileitis, may be present in severe cases of pancolitis. Skip lesions are not seen (although focal appendiceal or cecal inflammation may occasionally be present in left-sided ulcerative colitis).

Grossly, involved colonic mucosa may be slightly red and granular or have extensive, **broad-based ulcers**. There can be an abrupt transition between diseased and uninvolved colon (Fig. 17-36B). Ulcers are aligned along the long axis of the colon but do not typically replicate the serpentine ulcers of Crohn disease. Isolated islands of regenerating mucosa often bulge into the lumen to create **pseudopolyps** (Fig. 17-36C), and the tips of these polyps may fuse to create **mucosal bridges** (Fig. 17-36D). Chronic disease may lead to **mucosal atrophy** with a flat and smooth mucosal surface that lacks normal folds. Unlike Crohn disease, **mural thickening is not present, the serosal surface is normal, and strictures do not occur**. However, inflammation and inflammatory mediators can damage the muscularis propria and disturb neuromuscular function leading to colonic dilation and **toxic megacolon**, which carries a significant risk of perforation.

Histologic features of mucosal disease in ulcerative colitis are similar to colonic Crohn disease and include inflammatory infiltrates, crypt abscesses (Fig. 17-37A), crypt distortion, and pseudopyloric epithelial metaplasia (Fig. 17-37B). However, **the inflammatory process is diffuse and generally limited to the mucosa and superficial submucosa** (Fig. 17-37C). In severe cases, extensive mucosal destruction may be accompanied by ulcers that extend more deeply into the submucosa, but the muscularis propria is rarely involved. Submucosal fibrosis, mucosal atrophy, and distorted mucosal architecture remain as residua of healed disease but histology may also revert to near normal after prolonged remission. **Granulomas are not present** in ulcerative colitis.

Clinical Features. Ulcerative colitis is a relapsing disorder characterized by attacks of bloody diarrhea with stringy, mucoid material, lower abdominal pain, and cramps that are temporarily relieved by defecation. These symptoms may persist for days, weeks, or months before they subside. The initial attack may, in some cases, be severe enough to constitute a medical or surgical emergency. More than half of patients have clinically mild disease, although almost all experience at least one relapse during a 10-year period, and up to 30% require colectomy within the first 3 years after presentation because of uncontrollable symptoms. Colectomy effectively cures intestinal disease in ulcerative colitis, but extraintestinal manifestations may persist.

The factors that trigger ulcerative colitis are not known, but infectious enteritis precedes disease onset in some cases. In other cases the first attack is preceded by psychologic stress, which may also be linked to relapse during remission. The initial onset of symptoms has also been reported to occur shortly after smoking cessation in some patients, and smoking may partially relieve symptoms. Unfortunately, studies of nicotine as a therapeutic agent have been disappointing.

Indeterminate Colitis

Because of the extensive pathologic and clinical overlap between ulcerative colitis and Crohn disease (Table 17-9),

Figure 17-36 Gross pathology of ulcerative colitis. **A**, Total colectomy with pancolitis showing active disease, with red, granular mucosa in the cecum (left) and smooth, atrophic mucosa distally (right). **B**, Sharp demarcation between active ulcerative colitis (right) and normal mucosa (left). **C**, Inflammatory polyps. **D**, Mucosal bridges.

definitive diagnosis is not possible in approximately 10% of IBD patients. These cases, termed indeterminate colitis, do not involve the small bowel and have colonic disease in a continuous pattern that would typically indicate ulcerative colitis. However, patchy histologic disease, fissures, a family history of Crohn disease, perianal lesions, onset after initiating use of cigarettes, or other features that are not typical of ulcerative colitis may prompt more detailed endoscopic, radiographic, and histologic examination. Serologic studies can be useful in these cases because perinuclear anti-neutrophil cytoplasmic antibodies are found in 75% of individuals with ulcerative colitis but only 11% with Crohn disease. In contrast, ulcerative colitis patients tend to lack antibodies to *Saccharomyces cerevisiae*, which are often present in those with Crohn disease. However, even the serologic results can be ambiguous in cases that are indeterminate on clinical grounds. Despite diagnostic uncertainty, extensive overlap in medical management of ulcerative colitis and Crohn disease allows patients carrying a diagnosis of indeterminate colitis to be treated effectively.

Colitis-Associated Neoplasia

One of the most feared long-term complications of ulcerative colitis and colonic Crohn disease is the development of neoplasia. The risk of dysplasia is related to several factors:

- *Duration of the disease.* Risk increases sharply 8 to 10 years after disease onset.
- *Extent of the disease.* Patients with pancolitis are at greater risk than those with only left-sided disease.
- *Nature of the inflammatory response.* Greater frequency and severity of active inflammation (characterized by the presence of neutrophils) confers increased risk.

To facilitate early detection of neoplasia, patients are typically enrolled in surveillance programs approximately 8 years after diagnosis of IBD. The major exception to this is patients with IBD and primary sclerosing cholangitis, who have an even greater risk of developing cancer and are generally enrolled for surveillance at the time of diagnosis. Surveillance requires regular and extensive mucosal biopsies, making it a costly practice. Research efforts are therefore focused on discovery of molecular markers of dysplasia.

The goal of surveillance biopsies is to identify dysplastic epithelium, which is a precursor to colitis-associated carcinoma. Dysplasia can develop in flat areas of mucosa that are not grossly recognized as abnormal. Thus, advanced endoscopic imaging techniques including chromoendoscopy and confocal endoscopy are beginning to be used to increase the sensitivity of detection. IBD-associated dysplasia is classified histologically as low grade or high grade (Fig. 17-38A, B) and may be multifocal. High-grade dysplasia may be associated with invasive carcinoma at the same site (Fig. 17-38C) or elsewhere in the colon and, therefore, often prompts colectomy. Low-grade dysplasia may be treated with colectomy or followed closely, depending on a variety of factors including patient age and the number of dysplastic foci present. Colonic

Figure 17-37 Microscopic pathology of ulcerative colitis. **A**, Crypt abscess. **B**, Pseudopyloric metaplasia (bottom). **C**, Disease is limited to the mucosa. Compare to [Figure 17-35C](#).

adenomas (discussed later) also occur in IBD patients, and in some cases these may be difficult to differentiate from a polypoid focus of IBD-associated dysplasia.

Other Causes of Chronic Colitis

Diversion Colitis

Surgical treatment of ulcerative colitis, Hirschsprung disease and other intestinal disorders sometimes require creation of a temporary or permanent ostomy and a blind distal segment of colon, from which the normal fecal flow is diverted. Colitis can develop within the diverted segment, particularly in ulcerative colitis patients. Besides mucosal erythema and friability, the most striking feature of diversion colitis is the development of numerous mucosal lymphoid follicles ([Fig. 17-39A](#)). Increased numbers of lamina propria lymphocytes, monocytes, macrophages, and plasma cells may also be present. In severe cases the histopathology may resemble IBD and include crypt abscesses, mucosal architectural distortion, or, rarely, granulomas. The mechanisms responsible for diversion colitis are not well understood, but changes in the luminal microbiota and diversion of the fecal stream that provides nutrients to colonic epithelial cells have been proposed. Consistent with this, enemas containing short-chain fatty acids, a product of bacterial digestion in

the colon and an important energy source for colonic epithelial cells, can promote mucosal recovery in some cases. The ultimate cure is reanastomosis of the diverted segment.

Microscopic Colitis

Microscopic colitis encompasses two entities, *collagenous colitis* and *lymphocytic colitis*. These idiopathic diseases both present with chronic, nonbloody, watery diarrhea without weight loss. Radiologic and endoscopic studies are typically normal. Collagenous colitis, which occurs primarily in middle-aged and older women, is characterized by the presence of a dense subepithelial collagen layer, increased numbers of intraepithelial lymphocytes, and a mixed inflammatory infiltrate within the lamina propria ([Fig. 17-39B](#)). Lymphocytic colitis is histologically similar, but the subepithelial collagen layer is of normal thickness and the increase in intraepithelial lymphocytes is greater, frequently exceeding one T lymphocyte per five colonocytes ([Fig. 17-39C](#)). Lymphocytic colitis shows a strong association with celiac disease and autoimmune diseases, including Graves disease, rheumatoid arthritis, and autoimmune or lymphocytic gastritis.

Graft-Versus-Host Disease

Graft-versus-host disease occurs following hematopoietic stem cell transplantation. The small bowel and colon are involved in most cases. Although graft-versus-host disease is secondary to donor T cells targeting antigens on the recipient's GI epithelial cells, the lamina propria lymphocytic infiltrate is typically sparse. Epithelial apoptosis,
